In the presence of limited resources and a range of goals, adaptation implies trade-offs between alternative policy goals *(high confidence)*. Economics offers insights into these trade-offs and into the wider consequences of adaptation. It also helps to explain the differences between the potential of adaptation and its achievement as a function of costs, barriers, behavioral biases, and resources available. [17.3.2, 17.3.3, 17.3.4] Economic analysis of adaptation is broadening from an emphasis on efficiency and market solutions to include consideration of inequities, non-market goods and services, behavioral biases, barriers and constraints, the consideration of ancillary benefits and costs, as well as decision-making processes including the notion of risk management. Impacts of climate change and of adaptation responses on the distribution of income and wealth, and on ecosystems and the goods and services that they provide, are increasingly recognized as important components of the overall picture that must be included in economic evaluations. [17.5.4, 17.3.6.3, 17.3.6.4]

Economics offers several types of insights into the following aspects of adaptation policy *(high confidence)*:

- The monetary dimension of costs and benefits [17.2.1]
- The assessment of non-market costs and benefits [17.2.1, 17.3.7.3]
- Estimation of the distributional consequences of adaptation and its impact on poverty [17.2.1, 17.2.7]
- The relationship between adaptation and development [17.2.7]
- The types of adaptation that will occur without centralized actions (autonomous or private adaptation) and those that require centralized support or direct public action (planned or public adaptation) [17.2.1]

- Approaches to the design of incentive systems that will encourage private adaptation [17.5]
- Situations where adaptation actions may totally or partially worsen climate change effects. [17.5.1]
- The impact of different value systems and ethical considerations on which adaptation options appear desirable [17.3.5]
- Although the theoretical basis for economic evaluation of adaptation options is clear, there is little experience of practical application of this approach to adaptation problems. There is however extensive experience of applying the concepts and methods underlying the economic framework in other contexts, which is useful for designing climate adaptation policies. [17.6.1].

Economics provides important inputs to the evaluation and ranking of adaptation options in the face of uncertainty (*high confidence)*. Approximate approaches are often necessary because of the lack of data or because of uncertainties about the nature of climate change or the efficacy of adaptation actions. A range of economic tools helps to address these uncertainties and helps design policies that are acceptable with a range of preferences and robust to existing uncertainties. There are methodologies that are able to capture non-monetary effects and distributional impacts, and to reflect ethical considerations. The resulting ranking depends on the "value system", i.e. on the weights attributed to different objectives. [17.2.6.1, 17.2.6.4, 17.3.5, 17.3.7]

Development and adaptation can be complementary or competitive and development can yield adaptation co-benefits, provided it takes into account climate change in its design. Adaptation actions can provide significant co benefits such as alleviating poverty and enhancing development especially in developing countries *(high confidence)*. Ancillary effects may be a source of market failure. Many aspects of economic development also facilitate adaptation to a changing climate, such as better education and health, and there are adaptation strategies that can yield welfare benefits even in the event of a constant climate, such as more efficient use of water and more robust crop varieties. Maximizing these synergies requires a close integration of adaptation actions with existing policies, referred to as "mainstreaming". [17.2.7, 17.4.4]

Existing incentives will lead to private adaptation actions. But public action to support adaptation is justified by the public goods nature of knowledge and much of the required infrastructure, by market failures, by the distributional impacts of climate change, and by behavioral biases. Economic instruments have high potential in fostering adaptation as they directly and indirectly provide incentives for anticipating and reducing impacts (*high confidence*). Instruments comprise risk sharing and transfer mechanisms (insurance), loans including public private finance partnerships, payment for environmental services, improved resource pricing (water markets), charges and subsidies including land taxes, direct investment, norms and regulations, behavioral approaches and institutional innovations. [17.4, 17.5]

Risk financing mechanisms at local, national, regional, and global scales contribute to increasing resilience to climate extremes (*medium confidence*). Applicable mechanisms comprise informal and traditional risk sharing, such as relying on kinship networks, as well as market-based instruments including microinsurance, insurance, reinsurance, and national, regional and global risk pools. With considerable disaster insurance market failure, public private partnerships are the norm rather than the exception with the public sector acting as regulator, provider or insurer of last resort (*high confidence*). Price signals associated with risk financing can provide incentives for reducing risk, yet the evidence of effectiveness is weak and the presence of many counteracting factors actually often leads to disincentives, which is also known as *moral hazard*. [17.3.4, 17.3.6, 17.4, 17.5.1]

Estimates of the global costs of adaptation continue to improve, but remain inconsistent in methods, sectoral coverage, purposes, and time frames. The most recent estimates suggest a range from $75 billion to $100 billion per year globally by 2050, but important omissions from these estimates suggest the high end of this range could be much higher, and important shortcomings in the data and methods available for costing adaptation suggest the low end of this range could be substantially lower (*low confidence*).

- Defining the benefits and cost of adaptation is difficult, limited by data, and depends on value judgments. Estimating adaptation costs poses methodological, practical and moral difficulties, with consequences for how adaptation can be funded. [17.3.6.3, 17.3.6.4, 17.3.10, 17.3.11, 17.6]
- The existing estimates of global adaptation cost could be higher if sectors such as ecosystems, tourism, and socially contingent effects are included, and if the adaptation deficits of developing countries are more fully

taken into account. The global figures are based on only a few lines of evidence [17.6], and cover a selected number of sectors.

- Some evidence suggests that incremental adaptation costs increase over time as climate change unfolds (*low confidence*), but consideration of current adaptation deficits suggests that costs could be high in the short-term as well, and inconsistencies in the effect of economic development on adaptation capacity also confound the reliability of estimates of the trend over time [17.6.3].

Adaptation costing studies suffer from the absence of a robust community of practice, with great inconsistencies in the purposes, methods, data quality, and sectoral coverage of these analyses, limiting attempts to aggregate the finer-scale study results across regions and time [17.6.3]. Among these regional and local-scale analyses desirable characteristics include: a broad representation of relevant climate stressors to ensure robust economic evaluation; consideration of multiple alternative and/or conditional groupings of adaptation options; rigorous economic analysis of costs and benefits across the broadest possible market and nonmarket scope; and a strong focus on support of practical decision-making that incorporates consideration of sources of uncertainty [17.6.3]. Few current studies manage to achieve all of these objectives.

17.1. Background

This chapter assesses the literature on the economics of climate change adaptation, building on the Fourth Assessment Report (AR4) and the increasing role that economic considerations are playing in adaptation decision-making and policy. AR4 provided a limited assessment of the costs and benefits of adaptation, based on narrow and fragmented sectoral and regional literature (Adger *et al*, 2007). Substantial advances have been made in the economics of climate change after AR4. A key economic message from this literature is that the benefits of early action are greater than the costs of inaction. The literature also addresses the economic problem of climate change as a global market failure that is characterized by risk and uncertainty.

Adaptation action and policy has also advanced since AR4, and the literature on the economics of adaptation has reflected this. This chapter builds on other chapters in this assessment, in particular Chapter 2, which sets the basis for decision-making, recognizing economics as a decision support tool for both public and private actors. The type of economic approach used depends on factors discussed in Chapter 2 among others, including the agent making the decision, the nature or type of decision, the information used to make the decision, who implements the decision, others affected by the outcomes and the values attached to those outcomes. While realizing the linkages between adaptation and mitigation, the starting point of this chapter is that adaptation is a given need.

17.2. Adaptation as an Economic Problem

There are many adaptation strategies, and when considering these we need to judge whether the benefits outweigh the costs, with benefits and costs broadly defined. We have to consider current and future benefits, costs and resource usages, as well as uncertainty. Non-economic goals (concerning equity or environmental targets) are also of importance, as are efforts to achieve goals at highest net benefit or lowest net cost.

17.2.1. Reasons for Public Provision of Adaptation

Adaptation actions can be autonomous or planned. Some planned adaptations are public goods, which need to be put in place by elements of broader society (governments, NGOs, international organizations etc.). Their role exemplifies the classical economic definition of a public good, which is generally provided by an agency acting on behalf of a group of people. Economic analysis shows that market forces will under-provide such goods (Samuelson, 1954). Other reasons for public provision of certain adaptation measures include the existence of:

- Divergence between the social and private discount rates (i.e. different valuations of the future)
- Differences in risk aversion and risk perception between society and private individuals
- The value that society places on resolving inequities caused by climate change
- Possibilities for maladaptation where actions on behalf of one party worsen another's adaptation status

- Barriers to adaptation arising from lack of resources (human, financial, technical, etc.)
- Land ownership or property rights patterns that preclude private adaptation efforts on affected lands
- A desire to facilitate adaptation in unmanaged but highly vulnerable areas.

17.2.1.1. Broad Categorization of Adaptation Strategies

There are many possible adaptation actions, as indicated in chapters 14 and 15. In economic terms these include:

- Direct capital investments, including in infrastructure (e.g. dams and water management)
- Technology development through research (e.g. crop varieties)
- Creation and dissemination of adaptation information (through extension or other communication vehicles)
- Human capital enhancement (investment in education)
- Redesign of or development of new adaptation institutions (e.g. forms of insurance)
- Changes in norms and regulations to facilitate autonomous actions (e.g. building codes)
- Changes in individual behavior
- Emergency response procedures and crisis management

Not all adaptation involves investment or is costly. Some adaptation measures involve modification of recurring expenditures as opposed to new investments (replacing depreciated equipment with more adapted items). Sometimes it involves changes in behaviors and lifestyles (e.g. due to increased frequency of heat waves).

17.2.1.2. Broad Definition of Benefits and Costs

The consequences of adaptation decisions cannot be expressed comprehensively only through the standard economic accounting of costs and revenues. Adaptation decisions can also affect:

- Income distribution and poverty (Jacoby et al, 2011)
- Macroeconomic performance (see, e.g., Fankhauser and Tol, 1995);
- Allocation of funds with a crowding out effect on other investments (Hallegatte et al., 2007) and future technical progress (Hallegatte and Dumas, 2008)
- Welfare of current and future generations through non-monetary effects
- Changes in regional distribution of economic activity, including employment
- Alterations in non-market factors such as water quality, ecosystem function, and human health.

17.2.2. Toward a Realistic Assessment of Strategy Attractiveness

Adaptation cannot reasonably overcome all climate change effects (Parry et al 2009). Some adaptation options will simply be too costly (from now the words cost and benefit will be broadly used as discussed in 17.2.1.2). Additionally social and political willingness to act and scarcity of resources will limit strategy adoption and preclude complete adaptation. A conceptual way of looking at this for a given adaptation endeavor is in Figure 17-1.

[INSERT FIGURE 17-1 HERE
Figure 17-1: The narrowing of adaptation from suggested adaptations to what will be done. Forces causing the narrowing are listed in black.]

Figure 17-1 shows factors that will make the use of all adaptation strategies and complete adaptation impossible in a reasonable time scale. First, the sheer magnitude of the earth system suggests one cannot cancel all impacts (e.g., it is impractical to restore outdoor comfort under high temperatures). Second, certain processes (species extinction, melting of an ice cap) may be irreversible in any practical time period. Third, resource and knowledge availability plus uncertainty limits adoption. Fourth, adaptation measures may not be consistent with other policy objectives and priorities (i.e. competition for resources). Fifth, implementation barriers, obstacles, financial constraints and other market failures may constrain adoption (see Section 17.3).

17.2.2.1. Adaptation as a Dynamic Issue

Adaptation is not aimed at going from one stable situation to another. The challenge is to continually adapt to a "perpetually changing" climate (Hallegatte, 2009). Fundamentally adaptation is a long-term transitional process.

Many adaptations have long lasting effects like construction of seawalls or discovery of drought resistant crop genes. The optimal levels of investments with upfront costs and persistent benefits increase when the benefits are more long lasting or when climate change damages accumulate slowly (Wang and McCarl,2012). However, dynamic maladaptation is also possible as protecting now can expand investment in vulnerable areas and worsen future vulnerability (Hallegatte, 2011).

17.2.2.2. Funding Project-Based Adaptation

Adaptation to climate change is generally thought to be most efficient if it is mainstreamed into existing activities and processes (needs a reference). However, adaptation actions financed by external sources (e.g., multilateral or bilateral adaptation funds, research and development funds) are usually organized in discrete fixed-term projects that allow funders to monitor progress and adjust conditions if necessary. This raises difficult issues related to eligibility and potential co-funding, particularly in developing countries with a large "adaptation deficit" (Burton, 2004), where there are close links between adaptation to climate change, adaptation to natural climate variability and broader issues of socio-economic development. These links raise two central questions for defining eligible adaptation measures:

1) Is eligible adaptation restricted to measures that reduce the risks of anthropogenic climate change or are measures to reduce the risks of natural climate variability also included?
2) Is eligible adaptation restricted to measures that are motivated primarily by climatic risks or does it also include measures where reduction of such risks is only one of several benefits?

Based on these two questions definitions of adaptation range from very strict (definition 1) to very broad (definition 4) (Table 17-1).

[INSERT TABLE 17-1 HERE
Table 17-1: Four definitions of eligible adaptation.]

A strict definition of eligible adaptation may make it politically easier to motivate the need for international adaptation funding but risks excluding many efficient projects if they are not primarily motivated by climate change. A broader definition makes it easier to find projects that reduce current as well as future climatic risks but it risks losing the focus on adaptation and the associated political momentum for international funding. When a broad definition of adaptation is applied, co-financing by recipient countries may appear justified under certain conditions. The level of co-financing would depend on the relative importance of climate change compared to other reasons for a particular measure and on the resources that a country can reasonably provide itself (Füssel *et al.*, 2012). However, coherent criteria for measuring the fraction of an "adaptation project" attributable to anthropogenic climate change or for determining the level of co-financing requested for projects that address climate change adaptation jointly with other policy goals have not been developed so far. If adaptation funding is restricted to additional adaptation costs and primary funding comes from another external source, close coordination between both funders is required for practical reasons (Agrawala, 2008).

17.2.2.3. International Burden Sharing

Climate change is characterized by a "double inequity" (Stern, 2007) because those countries that are most vulnerable to climate change have generally contributed least (on a per capita basis) to causing it (Panayotou *et al.*, 2002; Tol *et al.*, 2004; Mendelsohn *et al.*, 2006; Patz *et al.*, 2007; SEGCC, 2007; Srinivasan *et al.*, 2008; Füssel, 2010). This asymmetry between responsibility and capability on the one hand and vulnerability on the other is

considered unjust based on concepts of justice that include the "no harm" principle and the polluter pays principle. This injustice implies obligations for countries with high responsibility and/or capability, and rights for countries with high vulnerability. The distinctive justice issues raised by international adaptation policy have recently gained a more prominent role in the scientific literature (Adger *et al*., 2006; Paavola and Adger, 2006; Miller, 2007; Heyward, 2007; Comim, 2008; Jagers and Duus-Otterström, 2008; Mearns and Norton, 2009; Klinsky and Dowlatabadi, 2009; Grasso, 2010; Harris, 2010; Inthorn *et al*., 2010; Füssel, 2011; Füssel *et al*., 2012).

The United Nations Framework Convention on Climate Change (UNFCCC) contains various provisions for financial support from industrialized countries to vulnerable developing countries but adaptation became really important in the UNFCCC negotiations only in 2001, when the 7th Conference of the Parties (COP 7) to the UNFCCC established three funds to support adaptation in developing countries. However, the rights and obligations related to adaptation funding were not clearly defined in the UNFCCC, leaving significant room for legal and political debates (Verheyen, 2002, 2005; Klein and Persson, 2008; Dellink *et al*., 2009; Klein, 2009; Persson *et al*., 2009; Hof *et al*., 2010; Füssel *et al*., 2012).

Important questions that are the subject of controversy in international negotiations on global adaptation funding as well as in academic debates are (Füssel *et al*., 2012):

- Who pays and how much into the adaptation fund based on which criteria?
- Who is eligible for receiving payments from the fund, and which criteria are used for prioritising recipients and for allocating funds?
- Which adaptation measures are eligible for funding, and what are the conditions and modalities for payment?
- How and by whom are decisions made?

While there is broad agreement that substantial payments are required from industrialized countries to support adaptation in developing countries, none of the questions above can be answered unequivocally based on legal or ethical considerations. Furthermore, these questions are not independent of each other as insufficient availability of funds can give rise to additional conflicts. In particular, efficiency and equality goals can be in conflict with each other if effective adaptation in one country is much more costly through no fault of their own (e.g. due to unfavourable geographical conditions) than in another country and the adaptation fund has insufficient resources to fulfil all justified claims (Füssel, 2011; Füssel *et al*., 2012).

17.2.3. Adaptation and Mitigation as Competitive or Complementary Investments

Adaptation and mitigation funding may need coordination. AR4 WGII chapter 18 presents a discussion of trade-offs and synergies. Often these are rival choices where investments in one might preclude those in the other. They also compete with consumption and non-climate investments. For example some adaptation strategies require land-use change as do both mitigation strategies and food production. Nevertheless the judicious use of adaptation jointly with mitigation lowers the total cost of climate change and implies a portfolio approach (de Bruin et al, 2009; Wang and McCarl, 2012, Koetse and Rietveld, 2012). Also mitigation reduces the uncertainty and magnitude of future changes in climate, making adaptation cheaper and thus more efficient (Hallegatte et al., 2010).

17.2.4. Inter-Relationships between Adaptation Costs and Residual Damage

In the climate change context, residual damages are those damages of that remain after adaptation actions are taken. Some literature has attempted to define residual damages more precisely. The U.S. National Academy of Sciences (2010), for example, distinguishes potential impacts (defined as "All impacts that may occur given a projected change in climate, without considering adaptation") from residual damages (defined as "The impacts of climate change that would occur after adaptation") Others have simply identified residual damages as those that remain after adaptation is implemented (World Bank 2010).

As an illustration of the relationship between adaptation cost and residual damage, Hallegatte *et al* (2011) conducted a study of the consequence for Copenhagen of sea level rise and the costs of adaptation, projecting mean annual losses as a function of the protection provided (see Figure 17-2).

[INSERT FIGURE 17-2 HERE
Figure 17-2: Illustrative example assuming a homogenous protection at 180 cm above current mean sea level (in the 'No SLR' and '50 cm SLR' cases). The vertical arrow shows the cost of SLR in the absence of adaptation. The horizontal arrow shows the need for adaptation to maintain unchanged mean annual losses.]

De Bruin et al (2009) and Hof et al (2009) have examined how increasing efforts lowers residual damages and formulate a model where adaptation actions are taken to the point that their marginal costs just offset marginal residual damages. Parry et al 2009 introduces unavoidable damages and Wang and McCarl (2012) study them, showing that higher degrees of unavoidable damages merit more mitigation but less adaptation effort.

17.2.5 Defining What Constitutes The Cost of Adaptation

Some define the cost of adaptation as simply the additional investment needed to adapt to future climate change (UNFCCC, 2007). But a full cost accounting needs to consider capital, operating, and nonmonetary costs of adaptation, considering metrics beyond those in monetary units. An economic approach would commonly take one of two definitions: 1) Costs of adaptation are the full range of costs incurred to undertake all appropriate adaptation measures; or 2) Costs of adaptation are the full range of costs incurred to restore economic welfare to pre-climate change levels (World Bank 2010). This would include the costs of fully implementing a given set of adaptation strategies including the opportunity cost of the funds used.

Defining an "adaptation project" and its cost raises conceptual issues. Many actions have an influence on the impact of climate change without being adaptation projects per se (e.g., enhanced building norms). Many "adaptation actions" have consequences beyond a reduction in climate change impacts. Defining the adaptation component (and cost and benefit) of a project requires the definition of a baseline (what would be the impact of climate change in absence of the adaptation action? What alternative project would be implemented in the absence of climate change?), and evaluation of the "additionality" of the project. For instance, action to adapt existing infrastructure to climate change are pure adaptation projects, and their cost can be considered as adaptation costs. The building of new infrastructure may be more costly because of climate and in that case only a fraction of their cost can be attributed to climate change and be labeled adaptation cost (See Dessai and Hulme 2007).

17.2.6. Methodological Considerations

17.2.6.1. Data Quality and Quantity

There is very little discussion on data gaps related to assessing the benefits of adaptation. Callaway (2004) suggests that a major challenge is the low quality and limited nature of data, especially in many developing countries. He also notes many transactions are not reported because they occur in informal economies and social networks. In a more general setting Hughes et al (2010) note that historical weather data is not typically sufficiently detailed while others note sparse data on costs of adaptation actions. For example, Bjarnadottie et al. (2011) note incomplete and contradictory data on house retrofit costs for hurricane protection. Also there are simply missing non market data on such items as recreational fishing as affected by climate and possible adaptation.

17.2.6.2. Costs and Benefits are Location-Specific

Calculating localized impacts requires detailed geographical knowledge of climate change impacts, but these are a major source of uncertainty in climate models (see J. C. Refsgaard & K. Arnbjerg-Nielsen & M. Drews & K. Halsnæs & E. Jeppesen, H. Madsen & A. Markandya & J. E. Olesen & J. R. Porter & J. H. Christensen (2013), The

role of uncertainty in climate change adaptation strategies—A Danish water management example Mitig. Adapt. Strateg. Glob Change, 18, 3, 337/359.). Compared with developed countries, there is also a limited understanding of the potential market sector impacts of climate change in developing countries.

17.2.6.3. Costs and Benefits Depend on Socio-Economics

It is sometimes assumed that climate will change but society will not (Pielke, 2007; Hallegatte et al 2011; Mechler and Bouwer, 2013). Future development paths affect climate change impact estimate, and can alter estimates from positive to negative impacts or vice versa. Some studies show higher growth rates raise hurricane vulnerability (Bjarnadottir, 2011). On the other hand, higher incomes allow the funding of risk-reducing policies.

17.2.6.4. Discount Rates Matter

Because adaptation costs and consequences occur over time, discount rates are a core question. Opinions vary sharply on this question (Baum, 2009, Beltratti Chichilnisky and Heal XXXX). Hof et al (2010) notes that a low discount rate is needed for distant future climate change to matter. A low discount rate is the primary reason for the relatively high estimates of climate damage in the Stern Review.

For climate adaptation projects, the social discount rate is the relevant one (Heal 2009). The rates used fall between 0.1 and 2.5%, although without good arguments for specific values (see Heal 2009). Nordhaus (2007) chooses a value of 1.5% while Stern uses a much lower value of 0.1%. Nordhaus emphasizes consistency with the rate of return on investment as a driving rationale while Stern points to ethical issues. Allowing environmental services to enter consumption can change the social discount rate substantially and generate a low or even negative social discount rate (Heal (2009), Guesnerie (2004) and Sterner and Persson (2007)). The UK Treasury now mandates the use of declining discount rates for long-term projects, as suggested by behavioral studies and by theoretical analysis (Arrow et al. 2012).

Weitzman (2007) treats differences in discount rates as different independent estimates of a true but unknown discount rate and points out that we should average different discount factors rather than rates, providing a case for a declining discount rate. Heal (2012) suggests that differences in discount rates reflect different value judgments and suggests they be resolved by a social choice procedure, perhaps by choice of the median rate. Wen (in: Bjarnadottir et al (2011)) investigates adaptation sensitivity against multi-hazards under discount rates varying from 0% to 9%. He proposes using a discount rate that decreases over time, as also recommended for longer term appraisals in the Green Book of the UK Treasury (from Hof et al, 2010).

17.2.7. Adaptation, Poverty, Equity, and Development

There is a relationship between adaptation actions and economic development actions, particularly in lesser-developed countries (see chapter 20). Development goals can be consistent with adaption goals, but not always. Many development projects enhance both adaptation and future development. For example, road construction practices that accommodate higher temperatures and more intense rainfall (World Bank 2009); agricultural investments that enhance heat tolerance and drought resilience (Butt et al. 2005, Strzepek et al. 2010); and public health investments that increase climate-enhanced disease resistance (Samet 2009, Markandya and Chiabai 2009). Development in general can make more resources available for adaptation.

A relevant question concerns whether economic development is a form of adaptation. SREX (IPCC, 2012) shows extreme event damages are ten times as large in developing areas as in developed areas and also that sustainable development can be threatened by climate change. Development generally diminishes vulnerability and raises adaptation capability (Schelling 1992, Schelling 1997, Tol 2005). However, development can also lead to increased vulnerability, for instance through urbanization of flood-prone areas (Hanson et al 2011). Furthermore better protection creates increased vulnerability to extreme events or protection failure (Burby 2001. Hallegatte 2012).

17.3. Decisionmaking and Economic Context for Adaptation

This section focuses on aspects of adaptation decisions making, individual interactions, and limits and obstacles to adaptation.

17.3.1. What are the Objectives of Adaptation?

The specific objectives involved in an adaptation effort can be diverse. One may try to cancel all impacts (negative and positive), maintaining the status quo. Alternatively one can try to cancel adverse impacts and capture positive opportunities, so that the welfare gain (or loss) is maximized (or minimized) as in IPCC (2007). These general objectives can be translated into operational rules and indicators for success in many ways.

Part of the literature presents adaptation as a continuous, flexible process, based on learning and adjustments. This branch emphasizes the need to preserve welfare, and opposes the static view of maintaining a status quo (IPCC SREX, Ch 8). Adaptation projects informed by this approach emphasize the role of learning and experimenting, plus the value of using reversible and adjustable strategies (Berkhout *et al*., 2006; Pelling *et al*., 2007; Leary et al., 2008; McGray et al., 2007; Hallegatte, 2009; Hallegatte et al., 2011c). Adaptation can also be "transformative', when achieving existing goals becomes impossible or undesirable, and changing goals becomes necessary (Stafford-Smith et al., 2011). Hunt and Taylor (2009) outline methods that could be used to model changes in future preferences, and provide examples addressing health and cultural heritage. Beltratti, Chichilnisky and Heal (1998) consider option values that arise as a result of uncertainty about future preferences.

17.3.2. Information, Transaction Costs, and Market Barriers

Transaction costs include the costs of accessing markets and information, along with reaching an agreement (Coase, 1937 and 1960; Williamson, 1979) and enforcement costs. Because of transaction costs, a mutually beneficial exchange may be impossible, and some adaptation actions may be impeded.

Certain publicly beneficial adaptation measures may not be privately beneficial due to such costs. Homeowners may not insulate homes due to transaction costs, whereas the collective benefit would be considerable (Hallegatte et al., 2007). This is a "market barrier" that appears even in absence of market failure (Jaffe et al., 2004).

17.3.3. Market Failures and adjustment costs

Adaptation may also face market failures such as externalities and moral hazards. As a consequence, some socially desirable actions may not be privately profitable. For example, construction may proceed in flood-prone areas even though this raises future social costs. In many countries flood plain risks are partly assumed by social insurance, transferring risk to the community (Burby et al., 1991, Laffont 1995). There are also externalities, since one household or firm located in a risky location may create higher social damages, for instance through the impact on supply chain (Tierney, 1997, and Henriet et al., 2012), thus requiring public norms and standards, tax measures or institutions in order to avoid such effects.

Significant (non-marginal) economic shifts and transitions involve significant adjustment cost driven by coordination failures and by factor immobility. There would be no adjustment costs if workers were able to move freely, firms were able to mobilize their fixed capital and technologies, and all economic actors had perfect information on the future. But experience with trade liberalization shows significant adjustment costs. We observe that this creates and destroys jobs in different sectors, but causes only limited intersectoral labor flows. In Brazil workers displaced from de-protected industries were only absorbed by other sectors with a several year lag (Muendler 2010). The same effects will be observed in the process of adapting to climate change.

17.3.4. Behavioral Obstacles to Adaptation

Economic agents adapt continuously to climate conditions, though not always using the available information, especially long-term projections (Camerer and Kunreuther, 1989) and consequences (Thaler, 1999, Michel-Kerjan, 2008). It has been observed for energy efficiency investments that households act in a way consistent with a very high discount rate of 20 to 100% (Train, 1985).

Also, individuals defer choosing between ambiguous choices (Tversky and Shafir 1992; Trope and Lieberman, 2003), a common situation regarding climate change adaptation. They systematically favor the status quo and familiar choices (Johnson and Goldstein, 2003). Also, individuals value profits and losses differently (Tversky and Kahnman 1974). In-depth studies show that these behavioral issues partly explain suboptimal household decisions (Shogren and Taylor, 2008, Gillingham et al., 2009), and lead to patterns of adaptation that are suboptimal.

17.3.5. Ethics and Political Economy

A difficulty in allocating adaptation resources is that there is no obvious choice of performance indicator (Füssel, 2010). Outcomes are often measured using indicators like GDP or cost benefit tests. But their limits are well known, (e.g., CMEPSP, 2009; OECD, 2009, Heal 2012) and include the failure to take into account resource depletion, environmental change, and distributional issues.

Distributional issues justify public intervention. Climate change impacts vary greatly by social group, and many have suggested that the poor are particularly vulnerable (e.g., Stern, 2006; Füssel, 2012). Some individuals, firms, communities and even countries may be unable to afford adaptation, even if it is in their own interest. Consideration of justice and fairness will play a role in adaptation option design (Pelling and Dill, 2009; O'Brien et al., 2009; Dalby 2009; Brauch, 2009a, 2009b; O'Brien et al., 2010b). The implementation of adaptation options may thus require taking into account the political economy of reforms and the addition of complementary policies to compensate losers (World Bank 2012).

Consequently, we must compare measures considering their equity implications. The traditional economic approach suggests choosing the most cost-effective projects and then resorting to financial transfers to satisfy equity objectives (Brown and Heal 1979: Atkinson and Stiglitz, xxxx). However this embodies strong assumptions including the ability to realize perfect and costless financial transfers. In more realistic situations the choice is not so clear cut. And in practical terms transfers are difficult to organize and may not be politically acceptable (Kanbur 2010). For example international development aid is often politically controversial (Bulir and Hamann, 2008). In these cases we have to resort to rankings that reflect both the net benefits and the impacts on equity.

17.3.6. Economic Decisionmaking with Uncertainty

17.3.6.1. Climate Change and Uncertainty

Decisions about adaptation have to be made in the face of uncertainty on items ranging from demography and technology to economic futures. Climate change adds to this with sources of uncertainty including:

- Uncertainty about the extent of future climate change (AR5, WGI report).
- Uncertainty about how climate change will translate into local impacts (AR5, WGI report).
- Uncertainty about the reaction of ecosystems and societies to climate change. An example is the ability of coral reefs to cope with warming.

The combination of uncertainty coupled with the long lifespan of a number of options leads to possible maladaptation. A distinction must be made between two types of maladaptation. An "*avoidable*" maladaptation situation arises from a poor *ex ante choice*. An "*unavoidable*" *ex post* maladaptation can result from entirely

appropriate decisions based on the information that was available *at the time*. An example is agricultural irrigation, where current investments to cope with a drying climate deplete water resources, resources that could facilitate later adaptation (Pfeiffer and Lin, 2010).

17.3.6.2. Comparing Adaptation Measures under Uncertainty

Next we consider methods to compare adaptation strategies under uncertainty. The first method is cost-benefit analysis under uncertainty where subjective probabilities are assigned to different climate futures (e.g., Tebaldi et al., 2005; New and Hulme, 2006). The "best" average project then will be the one that maximizes the average net present value of costs and benefits considering the probabilities. Risk aversion can be taken into account by seeking to maximize average income minus a risk-aversion measure times the variation in costs and benefits (or via an expected utility approach). It is also possible to implement a robust decision making approach that focuses largely on the worst possible outcomes, the so-called "maxi-min" approach. The cost-benefit approach also allows attribution of a higher weight to the poorest (Harberger, 1984).

Application of cost-benefit analysis requires evaluations in monetary terms. In many cases this is straightforward although these prices may need to be corrected for policies, monopoly power or other external factors distorting market prices (Squire and van der Tak, 1975). In cases where there are non-market items, a range of non-market valuation approaches (section ***17.3.6.3)*** can be adopted, but results are dependent on local conditions plus ethical and political choices.

When conducting cost-benefit analyses under uncertainty, an important concept is that of decision delay or option value (Henry 1974, Arrow and Fisher 1974). Indeed, when knowledge improves over time, it is possible to delay a decision and wait for more information. A key issue concerns irreversible actions, such as the destruction of a unique environment (Heal and Kristrom (2003)).

All these methods require probabilities for each climate scenario. However, these are difficult to determine, especially for low-probability, high-impact cases (Weitzman 2009, Kunreuther et al. 2012). Climate problems are in the realm of ambiguity rather than risk, meaning that while there is some information about relative likelihoods, this does constitute a probability distribution (Gilboa 2010). There is little work that applies such ideas to climate policy (see Henry and Henry, 2002, Millner et al 2010 and Kunreuther et al 2012). One approach is to work with a variety of physical models and posit probabilities that these models are correct. These alternative models can be thought of as scenarios.

In practice, a set of model scenarios is often the only available information. In this case, a scenario-by-scenario decision approach can be used (Lempert and Schlesinger, 2000; Ranger et al, 2010; Hallegatte et al 2012), looking for policies that are acceptable within a maximum number of scenarios. The aim is not to maximize the benefits within a scenario (or the average scenario) but to remain above the acceptable level for as many scenarios as possible. The most rigorous version of this method is the "maxi-min approach", in which we optimize for the most pessimistic scenario. The disadvantage can be that the most pessimistic hypothesis is highly unlikely.

17.3.6.3. Valuation of Non-Market Costs and Benefits

Cost-benefit analysis (CBA) of adaptation options often requires the valuation of non-market costs and benefits, i.e. the valuation of effects for which no value can be directly observed in a market. This is the case for impacts on public health, cultural heritage, environmental quality and ecosystems. The impacts of climate change on ecosystem services clearly have consequences for human wellbeing, both directly and through their impacts on economic activities. There has been progress in valuation of regulating, provision and cultural ecosystem services , as elaborated in the Millennium Ecosystem Assessment (MEA, 2005), The Economics of Ecosystems and Biodiversity (TEEB 2010) and Bateman et al (2011). There are two main categories of approaches to valuing ecosystem services; revealed and stated preference methods. As time and resources are scares when doing a CBAs we often resort to value transfer techniques (Navrud and Ready 2007). Brander et al (2012) applies value transfer to climate change

impacts on wetlands, which would be the benefits side of adaptation measures. For an overview see National Research Council 2004.

17.3.6.4. Examples of Multi-Metrics Decisionmaking for Adaptation

Multi-criteria analysis (MCA) is applicable to non-market impacts when valuation is impossible for theoretical or practical reasons. This approach does not require criteria to be measured in a common metric, but they must be weighted to reflect relative importance. Decision makers can include a full range of social, environmental, technical, and economic criteria—mainly by quantifying and displaying trade-offs. MCA is also useful when there is insufficient data for cost-benefit or cost-effectiveness analysis.

MCA approaches have been applied to adaptation issues including urban flood risk (Grafakos 2011; Kubal et al. 2009), agricultural vulnerability (Julius and Scheraga 2000) and studies on choice of options in the Netherlands (De Bruin et al. 2009; Brouwer and van Ek 2004), Canada (Qin et al. 2008) and Africa (Smith and Lenhart 1996). The UNFCCC developed guidelines for the adaptation assessment process in developing countries in which it suggests the use of multi-criteria analysis (UNFCCC 2002).

17.4. Ancillary Economic Effects of Adaptation Measures and Policies

In addition to creating an economy that is more resilient to the effects of climate change, adaptation strategies often have unintended ancillary effects of substantial importance. Ancillary effects also arise when investment funds devoted to mitigation or non-climate related investments in addition increase climate adaptation.

17.4.1. Broad Economic Consideration of Adaptation

In some cases adaptation strategies may be justified without detailed consideration of climate-related benefits because of ancillary benefits (these are sometimes referred to as “no regrets” strategies). Examples include:

- Sea walls that protect against sea level rise and at the same time will protect against tsunamis. However they also have co-costs causing damages to adjacent regions, fisheries and mangroves (Frihy, 2001);
- Crop varieties that are adapted to droughts and heat – will also raise productivity in the absence of climate change (Birthal et al, 2011);
- Better building insulation – which protects against heat will also reduce heating and cooling energy consumption (Sartori and Hestnes, 2007) and mitigate greenhouse gas emissions;
- Public health measures targeted at insect-borne diseases whose range will expand in a warmer world – will also have health benefits at present (Egbendewe-Mondzozo et al, 2011);
- More efficient use of water –adaptation to a drier world- will also yield benefits under current conditions of water scarcity. Development of lower-cost desalination methods have the same merits (Khan et al, 2009);
- Locating infrastructure away from low-lying coastal areas provide adaption to sea level rise and will also protection against tsunamis and storm surges;
- Afforestation and reforestation may improve adaptation of land production and will also both mitigate by carbon sequestration and benefit society by securing soil and reducing water run-off (Pattanayak et al,2005);
- Reducing the need to use coal-fired power plants though energy conserving adaptation will also provide mitigation , improve air quality and reduce health impacts (Burtraw et al, 2003).

17.4.2. Economic Consideration of Ancillary Effects

Suppose that a country has a fixed sum of money to allocate between two competing adaptation projects, each showing diminishing returns. To maximize benefits the funds should be allocated so that the marginal returns to each activity are the same. If both strategies generate positive ancillary effects not captured by the actor undertaking

the adaptation, then the socially optimal allocation of adaptation investment will differ from the private optimum and will favor the activity with the larger ancillary effects. Elbakidze and McCarl (2007) argue that it may be best to disregard ancillary effects because of the complexity of a complete analysis and the fact that in the settings they examine ancillary effects are roughly of the same magnitude. Viguie and Hallegatte (2011), Kubal et al. (2009), De Bruin et al. (2009), Brouwer and van Ek (2004), Ebi and Burton (2008), Qin et al. (2008), among others argue the contrary.

Equally important, and more difficult, is determining how much should be spent in total on adaptation versus other investments – mitigation, other aspects of development. For the best possible outcome the marginal social returns to all forms of expenditure should be the same, if appropriate, allowing for distributional impacts by differentially weighting benefits and costs to different income groups (Brent, 1996; Musgrave and Musgrave, 1973). In practice governments try to achieve this by setting a target rate of return for all public expenditures: if the marginal returns in all areas are equal to this then the equality of marginal rates is assured (Atkinson and Stiglitz, 1980; Starret, 1998)

17.4.3. Adaptation and Development Pathways

Adaptation is often considered on a project by project basis. In this "stand-alone" framework, adaptation actions are additional policies, and they are not included in other policies, such as development or economic policy. This is for instance the approach followed by the "National Adaptation Programmes of Action" of the UNFCCC (2002). Another vision is considering adaptation as an additional objective of development, which influences development policies (Klein et al. 2005; Füssel, 2007; Kok and De Coninck, 2007; O'Brien et al., 2012). This broader approach is often referred to as a "mainstreaming" of adaptation in public policies, in which all public policies need to take into account climate change and adaptation objectives. It is consistent with other trends in environmental policies that integrate risk management policies within development policies (Kellenberg and Mobarak, 2008; UN-ISDR 2009; World Bank and UN 2011), and climate mitigation polices now approached more as a low-carbon development issue than as a purely environmental issue (Stern, 2006; World Bank 2010).

17.5. Economic and Related Instruments to Provide Incentives

With the exception of insurance-related instruments there is relatively little literature on the use of economic instruments for adaptation. One reason is that, apart from insurance, few adaptation instruments work directly via economic incentives and through the use of markets. The potential of economic instruments in an adaptation context is, however, recognized. Agrawala and Fankhauser (2010) distinguish the following incentive-providing instruments relevant for key sectors: (i) Insurance schemes (all sectors; extreme events), (ii) Price signals / markets (water; ecosystems), (iii) Financing schemes via public private partnerships (PPPs) or private finance (flood defence, coastal protection, water); (iv) Regulatory measures and incentives (building standards; zone planning); (v) Research and development incentives (agriculture, health).

17.5.1. Risk Sharing and Risk Transfer, including Insurance

Insurance-related mechanisms can directly lead to adaptation and provide incentives or disincentives, which may involve formal and informal mechanisms. Informal mechanisms include reliance on national or international aid or remittances, and while such mechanisms are common, they tend to break down for large, covariate events (Cohen and Sebstad, 2003). Another informal mechanism is the inclusion of climate change risk under corporate disclosure regulations (National Round Table on the Environment and the Economy, 2012). Formal mechanisms include insurance (including micro-insurance), reinsurance, and national, regional and global risk pooling arrangements. Insurance typically involves ongoing premium payments to an insurer / reinsurer or the financial markets in exchange for coverage and post event claim payments (UNISDR, 2009). Markets differ substantially according to how liability and responsibility is distributed (Botzen et al., 2009; Aakre et al., 2010), and in many instances governments play a key role as regulators, insurers, or reinsurers in developed and developing countries alike (Linnerooth-Bayer et al., 2005). Insurance penetration in developed countries is considerable, whereas it is low in

many developing regions (Linnerooth-Bayer et al., 2011). In 2010 globally about 30% of disaster losses and 20% of climate related losses were insured.

Insurance-related instruments may directly and indirectly lead to adaptation. Two direct channels can be distinguished: i) instruments provide claim payments after an event, and thus reduce follow-on risk and consequences; (ii) they alleviate certain pre-event risks and allow for improved decisions (Skees et al., 2008; Hess and Syroka, 2005; Hoeppe and Gurenko, 2006). As one interesting example, using crop micro insurance linked to loans, farmers exposed to severe drought in Malawi were able to grow higher-yield, yet higher-risk crops, which allowed them to increase incomes (Linnerooth-Bayer and Mechler, 2011).

Indirect effects also exist. Premiums for risk coverage can provide an incentive to reduce the premium by reducing the risk. For example, differential UK flood insurance premium pricing offered according to flood zones has been effective in deterring new construction in high risk areas (Kunreuther and Michel-Kerjan, 2009; Kunreuther) and the National Flood Insurance program (NFIP) in the US requires communities to reduce risks before homeowners can access insurance for their homes (Surminski, 2010)

Developing countries are beginning to pool risks and transfer portions to international reinsurance markets. The Caribbean Catastrophic Risk Insurance Facility (CCRIF) set the precedent by pooling risks basin wide, thus reducing insurance premiums against hurricane and earthquake risks (World Bank, 2007). Similar schemes are under development and planning in Europe, Africa and the Pacific (Linerooth-Beyer and Mechler 2011).

The incentive effect is typically rather weak since decisions regarding risk prevention and adaptation are often influenced by many diverse factors. Kunreuther et al. (2009) found that insurance decisions are not based solely on costs and premiums, but also desires to reduce anxiety, comply with mortgage requirements, and satisfy social norms. Further, purchasing insurance may reduce adaptation with insured agents reducing their risk-minimizing efforts after taking out coverage. This is termed moral hazard and has been found to be rational for agents given the financial security provided by the contract (Kunreuther, 1996). Ultimately, this may increase maladaptation over time (Rao and Hess, 2009). Under-insurance can also arise when agents expect that the public sector will provide disaster assistance. Some refer to this as the Samaritan's dilemma (IMF, 2008).

17.5.2. Incentive Design

Through regulations, subsidies and direct intervention, there are many opportunities for policy makers to encourage autonomous adaptive responses to climate change. However, these efforts need to be designed so that they lead to efficient, cost effective responses while avoiding perverse results that run counter to the policy maker's objectives. A basic principle of designing efficient policies is that they affect the behavior of those who have the most to gain. For this reason, economists tend to favor policies based on voluntary actions influenced by incentives, either positive or negative, over mandates or uniform policies. Examples of these include water markets and various Payments for Environmental Services (PES), which are discussed in 17.5.4. A second consideration is cost effectiveness, i.e. the extent to which governments make the best use of their resources. The measurement of the net effect of a policy is challenging because it is difficult to anticipate what would have occurred in the absence of the policy.

Finally, policies must be carefully designed to avoid perverse outcomes that actually run counter to the policy maker's objectives. A classic example of this is found in policies that encourage adoption of water-saving technology in arid regions. Pfeiffer and Lin (2010) review cases where subsidizing irrigation water conservation actually leads farmers to increase total water use as they respond to greater efficiency by increasing the acreage under irrigation, an example of what is often called the rebound effect (Roy, 2000) whereby increases in efficiency of resource use result in more being demanded. In general it is best addressed by increasing the price of the scarce resource when efficiency gains from technological developments increase demand without increasing the supply of the scarce resource.

17.5.3. Loans, Public Private Finance Partnerships

The private sector has long been involved in the provision of public goods through Public Private Partnerships (PPPs). The rationale for governments is to reduce their financial cost by leveraging private funding, as well as to reduce the financial and operational risks involved in carrying out projects. Key instruments comprise public contracts, service concessions, public loan guarantees and concessional loans (Bräuninger et al. 2011). PPPs have been widely used for large infrastructure projects, one relevant example being the Thames flood defence barrier which protects London and the Thames estuary from tidal surges and coastal flooding. Finance was generated entirely by taxpayers, yet design, building supervision and construction were outsourced to the private sector (Bräuninger et al. 2011).

17.5.4. Payments for Environmental Services

Environmental services (ES) can contribute to adaptation (Millennium Ecosystem Assessment (2005), Daily (1997) and Heal (2000)). Payments for environmental services (PES) are a popular market-based approach that has been applied increasingly to translate external, non-market environmental services into financial incentives for preservation (Wunder et al, 2008; Wünscher et al, 2008; Engel et al, 2008). Those who stand to lose from decisions resulting in ES loss could choose to provide incentives for decision makers to adopt practices that ensure the continuation of the ES (Engel et al., 2008).

PES approaches in developing countries have met with mixed success. Focusing on payments for watershed services, Porras et al (2008) identified 50 ongoing schemes, 8 advanced proposals and 37 preliminary proposals. However it has been found that structuring the schemes is difficult when the services are hard to define (such as biodiversity) and where the scheme is driven more by government objectives and less by local needs. In such cases payments often do not guarantee the environmental improvements in spite of large outlays.

There are ample cases of mitigation–focused PES schemes (e.g. Wunder and Borner (2011), Pagiola (2008), Wunder and Albán (2008)), and more recently emerging evidence of the use of PES adaptation approaches. (Butzengeiger_Geyer et al., 2011; Schultz, 2012). Potentially well designed PES schemes they offer a framework for adaptation. Chishakwe *et al* (2011) draw comparisons and find synergies between PES community based natural resources management approaches in Southern Africa and community-based adaptation.

17.5.5. Improved Resource Pricing (Water Markets)

Studies of water sector adaptation often begin by citing the prospect of future water shortages and the potential for conflict among sectors (and sometimes among nations). One technique frequently cited for resolving these conflicts is the establishment of water markets and pricing schemes (e.g., Alavian et al. 2009; Vorosmarty et al. 2000, Adler, 2009). Traditionally water markets facilitate transfer from lower to higher-valued uses (Olmstead, 2010). A few studies make the case that water markets and pricing lower the impacts of climate change (Medellin-Azuara et al. 2008). In the most extreme cases, the projected increase in climate-induced water demand (particularly in the agriculture sector), coupled with a projected decrease in water supply, suggests that water supply/demand adaptation can only be achieved by a choice between water rationing and water pricing.

Many countries have instituted structures for water pricing in the domestic and agricultural sectors. Nevertheless tariffs for water are unevenly applied, collection rates are low, metering is rarely implemented (at least for the agricultural sector, which is typically the largest water user) and pricing structures are often based on annual rather than usage-based fees (Saleth et al.,2012). In a number of countries, there remain a number of important institutional barriers to water markets and pricing. These include a lack of property rights, limits on transferability, legal and physical infrastructures, affordability issues, and institutional shortcomings (Saleth et al. 2012) coupled with issues involved with return flows, third part impacts, market design, transactions costs, and average versus marginal cost pricing, (Griffin, 2012).

17.5.6. Charges and Subsidies including Land Taxes

The environmental economics literature over the past 30 years has emphasized the importance of market-based instruments (MBIs) relative to command and control regulations. MBIs are shown to be generally more cost effective, providing stronger incentives for innovation and dynamic efficiency. Within the wide range of instruments that qualify as market based, there is a general preference in terms of overall efficiency for axes over subsidies (Sterner, 2002; Barbier and Markandya, 2012).
In many cases climate change exacerbates the effects of pricing resources at below their social costs. This is true for some forms of energy (e.g. hydro) as well as most of the ecosystem services like water, genetic materials, pollination, erosion control and soil retention. If these resources were better priced, the need for additional public sector adaptation measures would be lessened.

In addition to the instruments already identified, others that are potentially important include: raising the price of energy through a tax (Sterner, 2011), developing markets for genetic resources (Markandya and Nunes, 2012) and strengthening property rights so schemes such as PES can be more effective. While the case for such social cost pricing through the use of charges is strong, it also has its limitations. Higher prices for key commodities can hurt the poor and vulnerable.

17.5.7. Behavioral Approaches

Because individuals fail to take into account properly low-probability risks (Tversky and Shafir 1992), and because they do not weigh long term consequences consistently (Ainslie 1975), taking into account behavioral biases can increase the efficiency of policies. For instance, people differently react to abstract information on distant events, versus concrete, emotionally-charged information linked with real-world experience (Trope and Liberman, 2003). In practice, this limits the impact of “dry”, emotion-free, information such as information on flood return periods (Fischhoff et al., 1978; Slovic, 1997). It is well documented that individuals do not use available information on natural risks when they make their choices (Magat et al., 1987; Camerer and Kunreuther, 1989; and Hogarth and Kunreuther, 1995). In the case of disaster risk management and risk awareness, it is well established that communication is more efficient if it goes beyond informing on probabilities and risks and provides information on how to react, using specific examples and real-world stories. Moreover, people usually overreact in the aftermath of a rare event (Weber et al. 2004), leading to biased and under-optimal responses (Hallegatte, 2011).

17.5.8. Intellectual Property Rights

Technology transfer is increasingly seen as an important means of adaptation. Christensen et al. (2011) in a Technology Needs Assessments carried out in developing countries list about 165 technological needs. In many of these cases patents and other intellectual property protection constrain technology transfer. Patent buy-outs, patent pools, compulsory licenses and other open source approaches have been used to relax this constraint (Dutz and Sharma, 2012). Patent buy-outs involve third parties (e.g. international financial institutions or foundations) acquiring the marketing rights for a patented product in a developing country. Patent pools represent a group of patent holders who agree to license their individual patents to each other (closed pool) or to any party (open pool). Compulsory licenses are issued by governments and allow patent rights to be overridden in critical situations. It is suggested that limits to technology transfer are limiting climate change adaptation (Henry and Stiglitz, 2010).

Health is one of the areas where adaptation to climate change will be required, and where developments in vaccines and treatments for vector borne diseases could be important. Hence these mechanisms for addressing IPR issues are directly relevant here. A similar approach can be applied in other areas such as seeds in drought prone or saline environments, water management technologies, pest management techniques etc.

17.5.9. Innovation, R&D Subsidies

Subsidies may be employed to encourage adaptation investments as well as behavioural change (Bräuninger at al., 2011). Subsidies involve direct payments, tax reductions or price supports that enhance the rewards from the implementation of an activity (Gupta et al., 2007). There has been some criticism of the efficiency of subsidies in terms of rent seeking and adverse effects on competitiveness (Barbier and Markandya, 2012); yet they are popular with decision-makers and the wider public. Subsidies are today mostly used for reasons other than climate adaptation, and evidence regarding its use for adaptation as well as regarding the incentivizing of adaptation R&D specifically is missing.

17.6. Costing Adaptation

Interest in estimating the costs of adaptation has grown as the need for action has become clearer. The literature focuses on two levels of costing: 1. global scale estimates, largely to assess the overall need for adaptation finance funds; and regional and local-scale estimates, often limited to a particular vulnerable economic sector, which may be applied to inform budgeting or to support adaptation decision-making, or to allocate scarce resources among the best prospects for effective adaptation.

17.6.1. Review of Existing Global Estimates: Gaps and Limitations

There have been a limited number of global and regional adaptation cost assessments over the last few years (World Bank, 2006; Stern, 2006, Oxfam, 2007; UNDP, 2007, UNFCCC, 2007; 2008; World Bank, 2010). These estimates exhibit a large range and have been completed mostly for developing countries. The most recent global adaptation costs range from $75 to more than $100 billion annually by 2050 (Table 17-2).

[INSERT TABLE 17-2 HERE
Table 17-2: Estimates of global costs of adaptation.]

IPCC (2012) considers confidence in these numbers to be *low*. The World Bank (2006) estimates the cost of climate proofing foreign direct investments (FDI), gross domestic investments (GDI) and Official Development Assistance (ODA), as does the Stern Review (2006), Oxfam (2007) and UNDP (2007). UNFCCC (2007) calculated existing and planned investment and financial flows required for adaptation. The World Bank (2010a) followed the UNFCCC (2007) methodology but included more extensive modeling as opposed to developing unit cost estimates, constructing marginal cost curves and climate stressor-response functions for adaptation actions, and included maintenance and coastal port upgrading costs.

Given their common approaches these estimates are interlinked, which explains the seeming convergence of their estimates, as discussed by Parry et al (2009). However there are important differences in terms of sectoral estimates, as Figure 17-3 shows in comparing the UNFCCC (2007) and World Bank (2010) studies. Extreme events, a potential source of large adaptation costs, are not covered by UNFCCC (2007), but are partially covered in the World Bank (2010) study and take into account a limited set of adaptation options. Parry et al. (2009) consider the UNFCCC (2007) estimates a significant underestimation by at least a factor of two to three plus omitted costs in ecosystem services, energy, manufacturing, retailing and tourism. They argue these estimates are low, based mostly on low levels of investment due to an existing adaptation deficit in many regions. Thus the numbers have to be treated with caution. There are a number of gaps, challenges and omissions associated with those global estimates that merit further discussion.

[INSERT FIGURE 17-3 HERE
Figure 17-3: Comparison of sectoral results on the costs of adaptation in developing countries across the UNFCCC and World Bank studies. Note: Bars indicate estimates using ranges, crosses point estimates.]

The practical challenges of conducting global adaptation cost studies are apparent in the literature. The broad scope of these studies limits the analysis to few climate scenarios, and while the scenarios might be strategically chosen it is difficult to fully represent the range of future adaptation costs across all sectors. The broad scope also limits comprehensive consideration of adaptation options, non-market and co-benefits, equity issues, and adaptation decision-making (such limitations also apply to local and regional scale studies see Section 17.6.3). The global studies, designed to reflect the best available methods and data for the purpose of estimating the magnitude of the global economic adaptation challenge, achieve this limited goal but must be interpreted in light of these important limitations and uncertainties.

17.6.2. Consistency between Localized and Global Analysis

Adaptation costs and benefits are derived to inform specific investment decisions, generally at national and local levels, or to derive a "price tag" for overall funding needs for adaptation (generally at a global level). Given these different purposes it is difficult to compare "local", i.e, national and sectoral, with global numbers. The quantity/quality of local studies also varies by sector with more treatment of adaptation in coastal zones and agriculture. Less is known and many gaps remain for sectors such as water resources, energy, ecosystems, infrastructure, tourism and public health. Also assessments have predominantly been conducted in a developed country context (see Table 17-3 for examples of costs and benefits assessment).

[INSERT TABLE 17-3 HERE
Table 17-3: Coverage of adaptation costs and benefits.]

However, as Fankhauser (2010) notes, with the sole exception of coastal protection costs, adaptation costs have shown little convergence locally or in terms of sectoral to global costs. Fankhauser suggests that the global cost estimates using the I&FF methodology estimate the "true" costs of adaptation. The World Bank (2010) study uniquely takes a two-track approach doing parallel national (7 cases) and global adaptation estimates. For a number of country studies (Bangladesh, Samoa and Vietnam) a cross-country comparison of local and global adaptation costs was made, with the costs in terms of GDP found to be in reasonable agreement. Costs for strengthening infrastructure against windstorms, precipitation and flooding were about 10-20% higher compared to disaggregated global estimates, largely owing to the ability of country-level studies to consider at least some socially contingent impacts (World Bank 2010b, 2010c, 2010d). Further, there is evidence of under investment in adaptation with global estimates of the need for agricultural adaptation funds variously estimated in the range of $10-40 billion annually, but with actual expenditures in 2011 estimated at $244 million (Elbehri et al, 2011)

17.6.3. Selected Studies on Sectors or Regions

Now let us address studies that focus on costs and benefits of specific adaptation strategies. This section focuses on studies that illustrate the current state-of-the-art, with a particular focus on support of adaptation decision-making through economic analysis. Within that class of work, there are two broad categories of economic analyses of adaptation at the sectoral level: econometric and simulation approaches.

Econometric studies generally looks at past adaptations that have happened across climate regimes and relies on historical cross-sectional, time series, or panel data to infer the effects of adapting to climate across space or time. Within the econometric category, there are Ricardian studies (which relate to land values, or to profitability, e.g., Mendelsohn et al 1994, Deschenes and Greenstone (2007)) and more generic correlational approaches (e.g., Schlenker et al. (2005) linking temperature and precipitation to crop yields and in the livestock sector Seo and Mendelsohn (2008)). Both can be used to estimate the marginal effect of climate on impacts, incorporating adaptation, and in some cases they can infer types of adaptation strategies employed.

The simulation approach traces costs and benefits of adaptation strategies through mechanisms of interest, typically through a series of climate-biophysical-behavioral response–economic components. Within simulation modeling there are two main threads in the behavioral response/economic component of the simulation. The first involves

rational actors who consider the benefit and cost consequences of their choices and pursue economically efficient adaptation outcomes, and the second involves a decision-rule or reference based characterization of the response of actors to climate stressors (Dinar and Mendelsohn, 2011; Schlenker et al, 2005). As noted below, in many sectors the state-of-the-art begins with the simpler decision-rule based approach, and may progress to consider benefits and costs, and then perhaps to consider other factors, such as equity and nonmarket values.

The key advantages of an econometric approach are reliance on real-world data, "natural experiments" in some cases, and an ability to reflect the joint costs and benefits of multiple adaptation strategies to the extent they are employed together in real world. The econometric approach does not require the analyst to simulate all adaptation mechanisms, only to establish that there is a robust relationship is between a climate stressor and the outcome of interest. The data required to implement the approach, at its simplest level, are limited to seasonal climate and economic output and may be more generally consistent with current availability in many countries, so the approach also has the advantage that it can be applied broadly. The key disadvantages of the Ricardian approach are an inability to trace transmission mechanisms of specific adaptation measures or to isolate the marginal effect of these strategies or measures; the inability to transfer estimates out of context (e.g., an African study does not apply to Asia, where the climate, adaptation, and social context all differ and affect the marginal costs and benefits of adaptation measures); and that the statistical estimation can be challenging and sometimes subject to multiple interpretations (Schlenker et al (2005)). Finally, the econometric approach is limited in its ability to consider adaptive actions that are beyond the scope of current observations, particularly actions that might prove beneficial in responding to large increases in extremes or even changes in carbon dioxide concentrations that have not been experienced in the historical record.

Simulation modeling can be demanding – a key disadvantage – as it requires extensive data inputs and careful calibration. It is often not appropriate where data are sparse, and requires that models be available for the task. The payoff is that the modeling system can estimate the incremental change in crop output and water supply in response to changes in climatic conditions and agricultural and water resource management techniques. A further advantage of the simulation approach is that it provides an opportunity for stakeholder involvement at several stages of the analytic process: designing scope, adjusting parameters, selecting inputs, calibrating results, and incorporating adaptation measures of specific local interest (Dinar and Mendelsohn, 2011).

A separate issue from the benefit and cost estimation method is the perspective adopted with respect to the goals of adaptation. Some studies adopt the perspective that the goal of adaptation should be restoring pre-climate change (or current) level of service: these studies are typically for sectors where the analytic tools are in their infancy. Major drawbacks include implicit assumptions that current service can be restored without residual impacts, and the lack of attention to whether restoration is a cost-effective response. The alternative and typically more mature perspective involves an economic evaluation within the study that compares costs and benefits of adaptation options, and their distributional consequences. Such an approach implicitly acknowledges that planners have a choice along a broad continuum concerning whether to invest in adaptation or tolerate impacts and/or residual impacts. The decision-making framework can focus not only on whether to adopt an adaptation measure, but also the scale or extent of its implementation (e.g, how much sand to place on a beach to protect a dune from sea-level rise and storm surge). A potential drawback of this approach is the difficulty in knowing and estimating all costs and benefits of adaptive measures or suites of measures.

There are a wide range of studies available that attempt an economic evaluation of adaptation options. From these, several desirable characteristics can be identified. Namely such studies should contain:

- A broad representation of climate stressors, including both gradual change and extreme events, spanning multiple future outcomes((GCM) forecasts and greenhouse gas emissions scenarios). Consideration of multiple outcomes reflects forecasting uncertainty and can help to ensure the adaptation rankings that result are robust across a range of future outcomes (Lempert and Kalra 2009, also see Chapter 2).
- Representation of a wide variety of alternative adaptation responses (for example, in the agriculture sector, consideration of changes in crop varieties and farmer education to ensure the varieties are grown with the best available know-how). Depending on the context, single adaptation response with variation in dimension may be useful (for example, varying the height of a levee or the capacity of a dam spillway) (World Bank 2010, Fankhauser 2010, Fankhauser et al. 1999).

- Rigorous economic analysis of costs and benefits, which ideally includes consideration of market, nonmarket, and socially contingent implications; one-time and replacement capital and ongoing recurring costs; and costs of residual damages after an adaptation response is implemented (Watkiss 2011b).
- A strong focus on adaptation decision making, including a clear exposition of the form of adaptation decision-making that is implied in the study, and consideration of both climate and non-climate sources of uncertainty (Lempert et al. 2006, also see Chapter 2).

Table 17-4 highlights a select group of studies chosen to illustrate some of these characteristics. The studies include both simulation studies of the economic implications of adaptation options, and econometric ones which examine choices that producers make to adapt. These studies generally fall in the category of positive economics, where economic tools and analysis are used to examine the implications of alternative choices without imposing values of the author (see Friedman (1953)). A few studies incorporate a normative perspective, either explicitly or implicitly, reflecting value judgments of authors or study participants.

Frequently Asked Questions

FAQ 17.1: Given the significant uncertainty about the effects of adaptation measures, can economics contribute much to decision-making in this area?

Economic methods have been developed precisely to address decision-making in the face of uncertainty. Indeed some of these have already been applied to the evaluation of adaptation measures such as decisions on which coastal areas to protect and how much to protect them.

There are different methods that can be applied, varying with the underlying information and data. Where probabilities can be attached to different outcomes arising from an adaptation measure, economic tools such as risk and portfolio theory allow us to choose the measure that maximizes the expected net benefits allowing for the risks associated with different options. Such an approach compares not only the net benefits of each measure but also the risks associated with it (e.g. the possibility of a very poor outcome).

In some cases it is difficult to place values on some outcomes (e.g. disasters involving large scale loss of life). An alternative to the risk or portfolio theory approach can then be used, that looks for a least cost solution that keeps probable losses to an acceptable level.

In situations where probabilities cannot be defined the analyst can define scenarios that describe a possible set of outcomes for each adaptation measure. In such cases economic tools have been developed that search for solutions which meet some criteria of minimum acceptable benefits across a range of scenarios, allowing the decision-maker to explore different levels of acceptable benefits in a systematic way, providing "acceptability" can be defined. Applications in the literature can be found for sea level rise, river flooding and energy planning.

There are, however, still unanswered questions on how to apply these methods (particularly when the changes caused by climate change are non-marginal and when preferences change), and how to improve the quality of information on the possible impacts and benefits.

FAQ 17.2: Are economic approaches likely to bias adaptation policy and decisions against the interests of the poor, vulnerable and ecosystems?

An economic approach, which focuses on the costs and benefits of an action is an important component of the final decision on which action to take, given the limited resources available for addressing adaptation. A narrow economic approach can bias decisions against the poor, vulnerable and ecosystems whose value systems are often not captured, or are understated by market prices. For example, the market value of timber does not reflect the ecological and hydrological functions of trees as well as the value of non-marked non-timber forest products like medicines. But the final decision is not based on just this information. Account is also taken of who gains and who loses (the distributional effects of the action), and of the impacts of the measures on factors that are not reported in monetary terms. If one only relied on the narrow economic information, decisions could be biased against the vulnerable and against measures that are more protective of the environment and other impacts that are non-quantifiable in monetary terms. Economic data feeds into a broader decision-making framework as one of several

considerations. What is crucial is that the overall decision-framework is broad, with both economic and non-economic factors being taken into consideration.

A frequently used decision-making framework that provides for the inclusion of economic and non-economic indicators to measure the impacts of a policy or measure, including impacts on vulnerable groups and ecosystems is multi-criteria analysis (MCA). An issue that remains problematic with methods such as MCA is what weights (including equity weights) to attach to the different criteria.

Alternatively one can attach monetary values to non-market impacts, for example to changes in the services provided by ecosystems. The numbers are less certain than those attached to market impacts but they are still useful in extending the economic assessment and providing a way of comparing market and non-market impacts.

FAQ 17.3: In what ways can economic instruments be deployed to facilitate adaptation to climate change in developed and developing countries?

Economic instruments (EIs) are designed to make more efficient use of scarce resources and to ensure that risks are more effectively shared between agents in society. In the context of adaptation, EIs are useful in a number of ways. First they help to ensure that the starting point for any adaptation policy involves an efficient use of the resources that will be affected by climate change: water pricing is an example of an EI. If water is already priced properly, there will be less overuse that has to be corrected through adaptation measures when supplies become scarcer. Second, they can function as a flexible, low-cost tool for adaptation. With the same example, if climate impacts result in increasing water scarcity it is easier to adjust the water tariff and less costly than finding new ways of increasing supply.

Insurance is another economic instrument that serves as a flexible, low cost adaptation tool. Where risks can be well defined insurance markets can help reduce vulnerability and also generate funds for post disaster recovery.

Payments for environmental services (PES) schemes are evolving voluntary market based economic instruments used in countries such as Costa Rica to manage natural resources, and can be applied to adaptation. In developed countries, where markets function reasonably well, EIs can be directly deployed through market mechanisms. In many developing countries, this is not always the case and markets often need public action and support. The insurance markets for example, do not cover all risks and there are issues of affordability, which mean that public-private partnerships are often required. The public sector also has an important role in making voluntary market instruments work effectively through establishing the legal frameworks that define property rights over scarce resources such as land and water in areas where such rights are not well established. PES schemes, for example, can only function well when the public sector ensures that rights are defined and agreements honored.

Table 17-4: Studies illustrating economic evaluation of adaptation options.

Sector, Study, and Scope	Methodology	Key Points Illustrated
Agriculture, Forestry, and Livestock		
Seo and coinvestigators (e.g. Seo et al , 2008, 2009, 2011): Impacts to livestock producers in Africa	Econometric. Examines the economic choices that livestock owners make to maintain production in the face of climate Insights into adaption possibilities by examining the ways economic choices vary over locations and times with varying climate conditions.	Consideration of multiple options (implicit) Residual impacts reflected Applicable at multiple geographic scales Results provide a ready means to re-estimate results for multiple climate scenarios.
Butt and McCarl (2006): Crop sector in Mali	Simulation. Simulates the economic implications of potential adaptation possibilities. Examines the consequences of migration in cropping patterns, development of heat resistant cultivars, reduction in soil productivity loss, cropland expansion, and changes in trade patterns.	Broad consideration of options (explicit, allowing for ranking of measures) Residual impacts reflected Rigorous economic costing of adaptation options and consequences for yields, revenue, and food security.
Sutton et al (2013): Crop and livestock sector in four Eastern European and Central Asian countries	Simulation with benefit-cost analysis. Ranks options initially based on net economic benefits over 2010 to 2050 period. Considers non-market and socially contingent effects through stakeholder consultation process.	Broad consideration of options (explicit, measures ranked) Very broad representation of climate scenarios (56 GCM-SRES combinations) Rigorous economic costing of adaptation options Integrated analysis of agriculture and irrigation water sectors
Sea-level Rise and Coastal Systems		
Nichols and Tol (2006):Coastal regions at a global scale	Simulation of adaptation through construction of seawalls and levees, adoption of beach nourishment to maintain recreational value, and migration of coastal dwellers from vulnerable areas. The study, reflects an economic decision-rule for most categories and benefit-cost analysis for a few categories	Capable of broad representation of sea-level rise scenarios. Optimization of alternatives considering both the impact of adaptation and resulting residual impacts. Rigorous economic costing of adaptation options.
Neumann et al. (2010a): Risks of sea-level rise for a portion of the coastal United States	Simulation of adaptation decision-making including seawalls, bulkheads, elevation of structures, beach nourishment, and strategic retreat, primarily using a benefit-cost framework but with alternatives based on local land-use decision-making rules.`	Capable of broad representation of sea-level rise scenarios Flexibility to consider both benefit-cost and rule-based decision making Rigorous and dynamic economic costing of adaptation options
Purvis et al. (2008): Risks of coastal flooding in Somerset, England	What is adaptation strategy here Simulation using a probabilistic representation to characterize uncertainty in future sea-level rise and, potentially, other factors that could affect coastal land-use planning and development investment decisions	Considers the impact of both gradual climate change (sea-level rise) and extreme events (the 1 in 200 year recurrence interval coastal flooding event). Incorporates probabilistic uncertainty analysis
Energy		
Margulis (2011): Energy production in Brazil, particularly from hydropower	Simulation of multiple adaptation options, including energy source substitution and regional "wheeling" of power coupled with modeling of river flow and hydropower production under future climatic conditions. Uses an optimization model of overall energy production	Considers multiple GHG emissions scenarios and a "no-climate change" baseline Scalable to multiple spatial resolutions, with national and regional results reported Considers multiple adaptation strategies Rigorous economic costing of capital and recurring adaptation costs
Health		
Ebi (2008): Global adaptation costs of treatment of diarrhoeal diseases, malnutrition, and malaria	What is the adaptation considered The costs of three diseases estimated in 2030 for three climate scenarios using (1) the current numbers of cases; (2) the projected relative risks of these diseases in 2030; and (3) current treatment costs. The analysis assumed that the costs of treatment would remain constant. There was limited consideration of socioeconomic development.	Multiple climate scenarios Clear description of framework and key assumptions Rigorous economic costing of adaptation options using multiple assumptions to characterize uncertainty

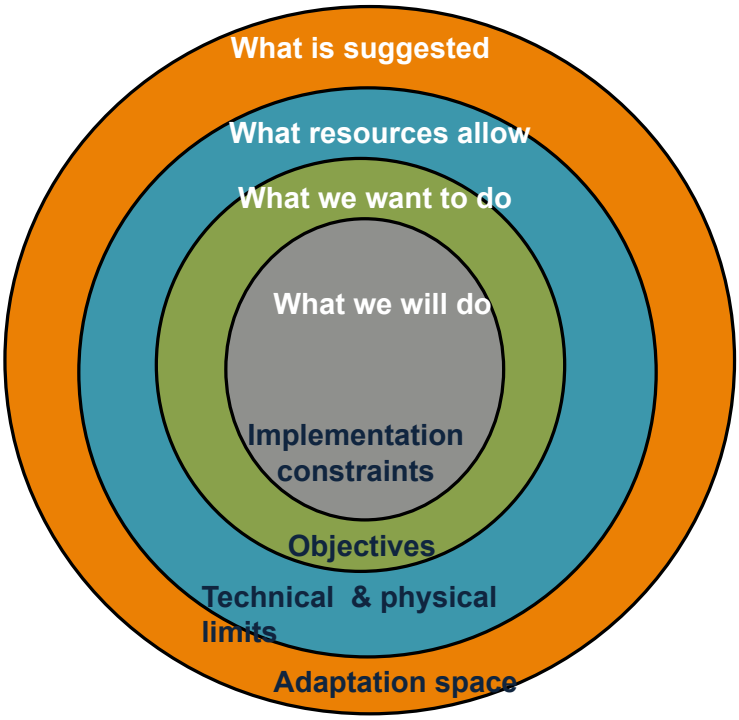

Figure 17-1: The narrowing of adaptation from suggested adaptations to what will be done. Forces causing the narrowing are listed in black.

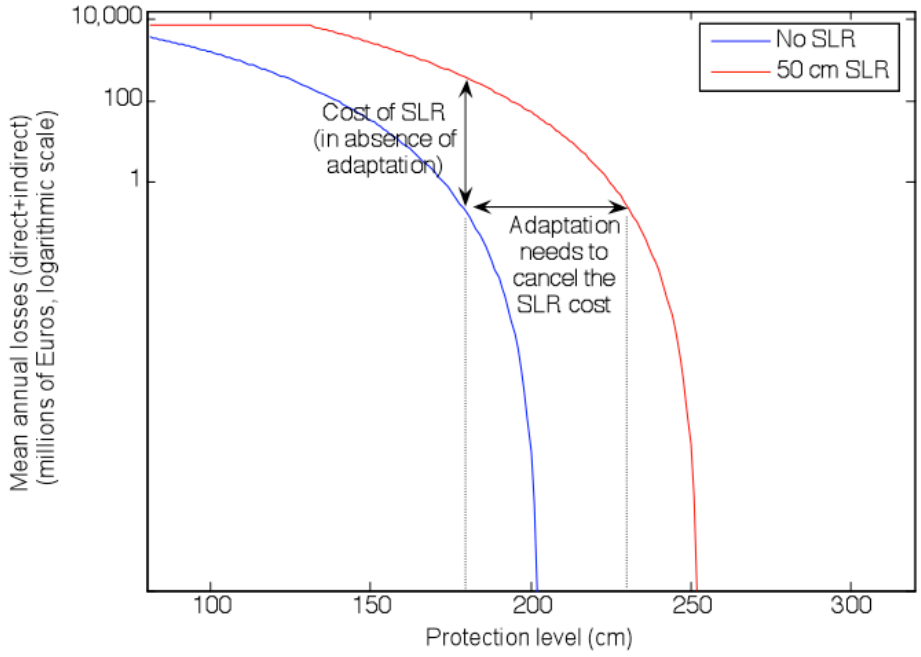

Figure 17-2. Illustrative example assuming a homogenous protection at 180 cm above current mean sea level (in the 'No SLR' and '50 cm SLR' cases). The vertical arrow shows the cost of SLR in the absence of adaptation. The horizontal arrow shows the need for adaptation to maintain unchanged mean annual losses.

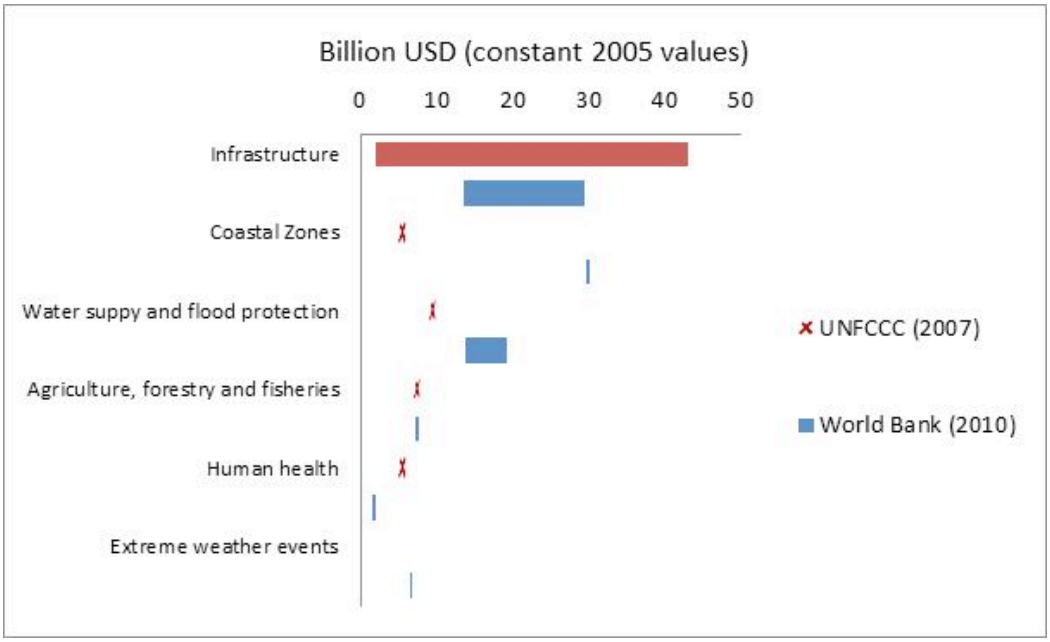

Figure 17-3: Comparison of sectoral results on the costs of adaptation in developing countries across the UNFCCC and World Bank studies. Note: Bars indicate estimates using ranges, crosses point estimates.

Executive Summary

Impacts of recent observed climate change on physical, biological, and human systems have been detected on all continents and in most oceans. This conclusion is strengthened by observations since the AR4 as well as through more extensive analyses of earlier observations. Most reported impacts of climate change are attributed to regional warming of the atmosphere and the ocean. The level of confidence in attribution of observed impacts to shifts in rainfall patterns is lower. There is emerging evidence of impacts of ocean acidification. [18.3-18.6]

For many natural systems, new or stronger evidence for substantial and wide-ranging impacts of climate change exists, including the cryosphere, water resources, coastal systems and ecosystems on land and in the ocean.

Cryosphere and water resources

Glaciers worldwide continue to shrink; new glacier lakes have formed and existing ones have changed; seasonal ice in many lakes and rivers forms later and breaks up earlier. A major part of these changes can be attributed with *high confidence* to climate change. [18.3.1.3, 18.5; Figure 18-3]

Widespread changes and degradation of permafrost of both high-latitude and high-elevation mountain regions have been observed over the past years and decade*s (high confidence)*. The permafrost boundary has been moving polewards and to higher elevations, and the active layer thickness has increased at many sites (*medium confidence* in attribution to climate change). [18.3.1.3, 18.5]

Hydrological systems have changed in many regions, due to changing rainfall or melting glaciers, affecting water resources, water quality, and sediment transport (*medium confidence*). In many river systems, the frequency of floods has been altered by climate change (*low to medium confidence*). The duration of droughts in some regions has been altered by climate change (*medium confidence*). [18.3.1.1, 18.5]

Terrestrial and freshwater ecosystems

Across all climate zones and continents, an increasing range of species and communities in terrestrial ecosystems have been impacted by recent climate change and increasing atmospheric CO_2. Many plants and animals show changes in phenology (*high confidence*), productivity and / or geographic range (*medium confidence*). Elevated rates of extinction cannot be attributed to climate change. [18.3.2, 18.5]

In freshwater ecosystems of most continents and climate zones, rising temperatures have been linked to shifts in animal community composition, especially in headwater streams. While confidence in detection of change is *high*, there is *low confidence* in attribution to climate change due to many confounding factors. [18.3.2.4, 18.5]

Several major terrestrial ecosystems are undergoing broad-scale changes that can be characterized as early warnings for coming regime shifts, in part due to climate change. For wide-spread shrub encroachment in the Arctic tundra there is *high confidence*, for boreal forest tree mortality there is *low confidence* of climate change as driver. The recession and degradation of the Amazon forest cannot be attributed to climate change. [18.3.2.4, 18.5.6, 18.5.7]

Oceans and coastal systems

The physical and chemical properties of the ocean have changed significantly over the past 60 years, due to anthropogenic climate change. **As a result, marine organisms have moved to higher latitudes,**

changed their depth distribution or their phenology (*high confidence*). Facilitated by changes in the distribution of sea ice and changes in ocean currents, organisms such as crustaceans, zooplankton and fish have migrated toward higher latitudes. These changes also affect coastal ecosystems including kelp forests and seagrass meadows [18.3.3, 18.3.4.1]

Climate change has influenced ocean primary productivity, with positive consequences for some fisheries and negative ones for others (*medium confidence*). Together with non-climate influences such as excess nutrient input from human activities, climate change has contributed to an increase in the frequency, geographical distribution, and severity of hypoxic areas in the ocean. [18.3.4.1, 18.3.4.2]

Due to the increased frequency of stress events arising from elevated sea temperatures, coral reefs have experienced increased mass bleaching and mortality (*very high confidence*). These events have contributed to the loss of reef building corals in many parts of the world since the early 1980s. [18.3.3, 18.3.4, Box 18-3, 18.5, Table 18-8, Box CC-CR]

Arctic sea ice has been shrinking in extent, thickness, composition, with observed impacts on marine biology and the livelihoods of indigenous people (*medium to high confidence*). [18.3.1.3, 18.3.4, 18.4.7, 18.5.7]

Despite the known sensitivity of coastal systems to sea-level rise, local perturbations from regional variability in the ocean and human activities preclude the confident detection of sea level-related impacts attributable to climate change outside of the Arctic. [18.3.3]

For managed ecosystems and human systems, the effects of changing social and economic factors often dominate over any direct impact of climate change. Despite this, numerous impacts of climate change have been detected.

Even accounting for changes in technology and other non-climate factors, agricultural crop yields have changed in many regions in response to climate. Yields have increased in some (mid to high latitude) regions, due to warming and higher CO_2 *(low confidence)*, and decreased in other (mainly low latitude) regions due to water shortages and higher temperatures *(medium confidence*). Despite the high sensitivity of crop yields to temperature extremes, observed trends in the agricultural markets cannot presently be attributed to climate change, due presence of other drivers. [18.4.1, Table 18-9]

The catch potential of fisheries has increased in some regions and decreased in others with consequences for the food and livelihood of involved human communities (*high confidence*). Fisheries at high latitudes are showing increased productivity due to sea ice retreats and increases in net primary productivity. In other regions, stratification of the water column driven by warming has reduced net primary productivity of the ocean. [18.3.4, 18.4.1.2, 18.5.7]

In some regions, increases in the prevalence of vector-borne diseases have been detected and attributed to warming. Dengue fever and malaria have increased in several regions of the world over the past few decades, but there is *very low confidence* in attribution of these trends to climate change. [18.4.5]

Climate impacts on Arctic indigenous groups have been detected and attributed to climate change. These include changes in seasonal migration and hunting patterns, health, and cultural identity (*medium confidence*). [18.4.7, Box 18-5, 18.5.7, Table 18-9]

Extreme climate events have impacted natural and physical livelihood assets, incomes, public health, and social institutions. Economic losses due to extreme weather events have increased globally, mostly due to increase in wealth and exposure, but with a documented contribution of climate change and variability in some cases. [18.4.4, 18.4.7]

Despite known vulnerabilities and increasing exposure to climatic stressors, impacts of climate change on human livelihoods have rarely been detected with confidence. Such detection is complicated by the effects of other economic and social factors. There is emerging literature on the impact of climate on poverty, working conditions, violent conflict, migration, and economic growth, but evidence for detection or attribution remains limited. [18.4.3, 18.4.6, 18.4.7]

Detection and attribution of observed impacts of climate change supports assessments of current conditions with respect to "Reasons for Concern" formulated by earlier IPCC assessments. The degree to which projected damages are now manifest, or the detection of stronger early warning signals for expected impacts, can contribute to a more comprehensive risk assessment for dangerous anthropogenic interference with the climate system.

Increases in "risks to unique and threatened systems" are now documented with higher confidence by the observed impacts on Arctic marine and terrestrial ecosystems and indigenous livelihoods (*medium to high confidence*), tropical coral reefs (*high confidence*) and glaciers in most mountain regions (*high confidence*). Observed impacts thus confirm this reason for concern. [18.6.2.1]

"Risks of extreme weather events" – extreme warming events continue to increase for warm water coral reefs (*high confidence*), confirming this reason for climate-related concern. Risks have also increased in some other systems, causing economic losses, however this is predominantly due to the increases in wealth and exposure. [18.6.2.2]

Impacts of climate change have now been documented globally, covering all continents and the ocean (*high confidence*). However, research coverage is still insufficient and too heterogeneous to effectively address spatial or social disparities concerning the "distribution of impacts" beyond local case studies. [18.6.2.3]

"Aggregate impacts" have been documented with measures of glacier volume and permafrost extent (*medium to high confidence*). There is limited evidence of a climate contribution to aggregate impacts on biospheric carbon fluxes, agricultural yields, fishery production and economic losses due to extreme weather, due to the presence of dominant non-climatic drivers. For the cryospheric impacts, observations clearly confirm the reason for concern. [18.6.2.4]

"Risks from large-scale singularities" relating to irreversible shifts with significant feedback potential in the Earth system have yet to be observed. However, there is now robust evidence of significant early warning signals in observed impacts of climate change that indicate large-scale regime shifts for the Arctic region and the tropical coral reef systems. This evidence confirms reasons for concern. [18.6.2.5]

Though evidence is improving, there is a persistent gap of knowledge regarding how large parts of the world are being affected by observed climate change. The number of attribution studies linking observed impacts to the anthropogenic component of climate change remains limited. Research to improve the timeliness and knowledge about the detection and attribution is needed in particular for the risk of extreme events. [18.7]

In most studies, the attribution of observed impacts and vulnerabilities is related to all changes in climate that represent deviations from historical means and / or historic variability. Only a smaller number of robust attribution studies link responses in physical and biological systems to *anthropogenic* climate change. [18.1]

Methods for rigorous assessment of observed impacts of climate change are evolving. Evidence for attribution comes from assessment of the relative contribution by all known drivers affecting the dynamics of a system to its behavior, using scientific methods, involving an assessment of confidence in both detection and attribution. Formal meta-analysis or aggregated assessments of many observations or studies can help to improve confidence. [18.2.1, Box 18-1]

18.1. Introduction

This chapter synthesizes the scientific literature on the detection and attribution of observed changes in physical, biological and human systems in response to the climate change that has occurred during the recent few decades. It assesses the degree to which detected changes in such systems can be attributed to observed climate change and where possible, separates out the relative importance of anthropogenic drivers of climate change. For most natural and essentially all human systems, climate is only one of many drivers that cause systems to change, which therefore requires a careful accounting of the importance of other confounding factors on the overall change in these systems.

18.1.1. Scope and Goals of the Chapter

Previous assessments, notably Rosenzweig *et al*. (2007), in the IPCC Fourth Assessment Report (AR4), and the increasing body of literature published since, indicated that numerous physical and biological systems are affected by recent climate change. Human systems have received comparatively little attention in this literature, with the exception of the food system, which is a coupled human/natural system. Rigorous formal assessment of the literature going beyond just detection of change across a variety of regions and sectors, to scientifically robust attribution to climate change and its anthropogenic drivers is critical for several purposes (Brander *et al*., 2011; Hoegh-Guldberg, 2011; Stocker *et al*., 2011). Only formal detection studies provide robust evidence of where climate change impacts already being observed and where they are not, supporting near-term planned adaptation if and where necessary.

For policy makers and the public, detection and attribution of observed impacts will be a key element to determine the necessity and degree of mitigation and adaptation efforts. Detection and attribution are vital parts of the evidence base requested of the IPCC by signatories to the United Nations Framework Convention on Climate change to judge policies aiming to stabilize “greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous atmospheric interference with the climate system”.

Full attribution of changes in these systems to anthropogenic climate is extremely hard to accomplish for many complex systems with diverse responses and multiple significant confounding drivers (Parmesan *et al*., 2011). There has, however, been a significant increase in studies attributing changes in some systems to local climate change without direct linkage to anthropogenic drivers. This chapter assesses the studies that exist for both full and partial attribution, and the methodologies that can be brought to bear on attribution and the uncertainties inherent in doing so.

18.1.2. Summary of Findings from the AR4

Rosenzweig *et al*. (2007) reported that “observational evidence from all continents and most oceans shows that many natural systems are being affected by regional climate changes, particularly temperature increases.” In particular, they highlighted several areas where this general conclusion could be supported by specific conclusions that were reported with *high confidence:*

- Changes in snow, ice and frozen ground had been seen to increase ground instability in mountain and other permafrost regions; these changes had led to changes in some Arctic and Antarctic ecosystems and produced increases in the number and size of glacial lakes.
- Some hydrological systems had been affected by increased runoff and earlier spring peak discharges; in particular many glacier- and snow-fed rivers and lakes had warmed, producing changes in their thermal structures and water quality.
- Spring events had appeared earlier in the year so that some terrestrial ecosystems had moved poleward and upward; these shifts in plant and animal ranges were attributed to recent warming.
- Shifts in ranges and changes in algal, plankton and fish abundance as well as changes in ice cover, salinity, oxygen levels and circulation had been associated with rising water temperatures in some marine and freshwater systems.

In terms of a global synthesis, this assessment noted "that it is likely that anthropogenic warming over the last three decades has had a discernible influence on many physical and biological systems" (Rosenzweig *et al*., 2007). Though it was based on analyses of a very large number of observational datasets, the assessment noted a lack of geographic balance in data and literature on observed changes, with marked scarcity in low and middle income countries.

Observed impacts to human systems were less obviously attributed to anthropogenic climate change. Rosenzweig *et al*. (2007) concluded with *medium confidence* only that, "other effects of regional climate change on natural and human environments are emerging, although many are difficult to discern due to adaptation and non-climatic drivers". They especially noted effects of temperature increases on:

- Some agricultural and forestry management practices in the higher latitudes of the Northern Hemisphere; these included earlier spring planting as well as changes in the disturbance regimes of fires and pests.
- Some aspects of human health, including heat-related mortality in Europe, changes in some vectors of infectious diseases across the world, and phenological changes in allergenic pollen in the mid to high latitudes of the Northern Hemisphere.
- Some human activities in the Arctic (such as hunting and travel) and in lower-elevation alpine areas (such as mountain sports).

18.2. Methodological Concepts for Detection and Attribution of Impacts of Climate Change

There are three substantial challenges to the detection and attribution of change in environmental systems to a changing climate. First, all systems are affected also by environmental factors other than climate; to detect a climate change impact, it is therefore necessary to control for the effects of such confounding factors. Second, the ability of many systems to adapt to change complicates the detection and attribution of any impacts; that is, adaptation can mask an impact. Detection (and attribution) of adaptation to climate change is in this chapter considered to be detection (and attribution) of a climate change impact (Box 18-1). Third, because systems are typically affected by local or regional climate change, attribution of a detected climate change impact to anthropogenic climate change can be difficult. To overcome these difficulties and to best account for all available knowledge on observed impacts, a range of methods is employed here. They are summarized in this section.

18.2.1 Concepts and Approaches

18.2.1.1. Detecting and Attributing Change in the Earth System

From an analysis perspective, the Earth system can be separated into three connected subsystems; we name them here as the climate system, the natural system, and the human system (Figure 18-1). Many external drivers may influence any system, including the changing climate and other confounding factors (Hegerl *et al*., 2010). Each climate, natural or human subsystem affects the other two directly or indirectly. For example, the human system may directly affect the natural system through deforestation, which in turn affects the climate system through changes in albedo; this can alter surface temperatures which in turn feed back on natural and human systems.

[INSERT FIGURE 18-1 HERE
Figure 18-1: Schematic of the subject covered in this chapter. The Earth system can be divided into three broad interacting systems. Direct drivers of the human system on the climate system are denoted with a red arrow; some of these drivers may also directly affect natural systems. These effects can in turn influence other systems (dashed red arrows). Further influences of each of the systems on each other (confounding factors) that do not involve climate drivers are represented by blue arrows. Examples of drivers and their impacts are given in the table. Adapted from Stone *et al*. (2013).]

If an observed change in the human system impacts the climate system, we call this an anthropogenic driver of climate change. In order to highlight potential reasons for concern (including the uncertainties in detection and

attribution), impacts of any observed climate change are covered in this chapter, irrespective of whether the particular aspect of climate change has been identified as anthropogenic.

18.2.1.2. Concepts of Detection and Attribution of Climate Change Impacts

Concepts and approaches to detection and attribution have been evolving throughout the work of the IPCC. In 2010, an IPCC Expert Meeting on Detection and Attribution was held to reconcile methods and terminology across IPCC working groups. The report from this meeting (Hegerl *et al*., 2010), along with the discussion of Stone *et al*. (2013), is an important conceptual basis for this chapter.

Detection *addresses the question of whether a system is changing beyond what might be considered normal behaviour in the absence of climate change*. While Hegerl *et al*. (2010) proposed a broad definition that could be used across IPCC Working Groups, this definition, used in this chapter and in other Working Group II chapters, is more specific in not just considering any observed changes (Stone *et al*., 2013). The appropriate reference normal behaviour may be stationary (e.g. glaciers) or non-stationary (e.g. economic activity), and the nature of that reference needs to be spelled out clearly. Typically, detection studies involve the initial assumption of climate being at least one of the drivers of that change, but other drivers (such as changes in land use) may be recognized to play a significant role too. For many systems, the role of these confounding factors may exceed that of climate change.

Attribution *addresses the question of whether climate change has contributed substantially to the detected change in a system*. In practice, attribution studies ask how much of the observed change is due to climate change. Attribution requires the evaluation of the contributions of all external drivers to the system change.

Failure to include relevant factors in an attribution study can lead to erroneous conclusions. This is referred to as the omitted variable problem (Greene, 2003). It is a particular problem in time series regressions when both climate and non-climate factors may vary roughly monotonically over time. It is also important not to equate empirical correlation with causality (Holland, 1986). This underscores the crucial role that system understanding must play in high-quality detection and attribution studies.

Detection and attribution studies rely on quantitative or qualitative analysis. Quantitative studies adhere to basic principles of statistical inference. One is that effects of formal or informal variable selection – in which a range of statistical models is screened to identify the best-fitting model – must be taken into account to avoid spurious attribution (Chatfield, 1995).

Qualitative attribution studies typically involve the identification of multiple, intersecting “impact chains” that recognize confounding variables acting alongside climate change. These studies usually do not specifically isolate certain social or environmental changes to climate change alone but rather, they aim to identify dynamic interactions among an assemblage of intersecting forces in human-environment systems.

Evidence for testing the hypothesis that some observed change can be attributed to climate change may come from different sources. The nature of the tools used for testing hypotheses varies depending on the details of the study (Stone *et al*., 2013). Mechanistic models can be used, for example representing a system through a chain of explicit functions based on understanding of the individual processes that together comprise the mechanics of the system. These mechanistic models can sometimes be formulated numerically. In other cases, empirical models may be useful, relating the response of a system to external drivers according to mathematical relationships estimated through observation, experimentation, or survey. In practice, though, many modeling setups will contain both mechanistic and empirical components.

Box 18-1. The Role of Climate Sensitivity and Adaptation for Impact Models in Human Systems

Impacts of climate change on a measurable attribute of a human system only occur if a) the attribute is sensitive to climate and b) a change in climate has occurred. A large literature has developed attempting to quantify both climate sensitivity of various systems and observed changes in climate.

The literature estimating the climate sensitivity of an outcome such as crop yields, heat related mortality or migration, has relied on observed climate variability either across space (e.g., Schlenker *et al*., 2005), time (e.g., Mann and Emanuel, 2012), or space and time (Hsiang *et al*., 2011; e.g., Dell *et al*., 2012). While there is a rich literature using climate variability across space, the long observational weather time series required for exploring climate variability across space and time have limited the opportunities for study. A number of studies have instead estimated the weather sensitivity of outcomes in order to project the future impacts of weather under climate change (Deschênes and Greenstone, 2007; Deschênes and Greenstone, 2011), or attribute impacts for the past (Auffhammer *et al*., 2006). The issue with impact studies using a weather based sensitivity measure is that they cannot provide estimates of impacts based on the climate sensitivity. For example, farmers may respond to an unusually hot summer, which is a weather event, by applying more irrigation water. However, in the long run farmers may respond to a warmer climate by switching crops, changing irrigation technology or abandoning farming altogether. The two sensitivities and resulting magnitudes of attributable impacts due to a change in weather versus a change in climate are therefore different.

In order to detect and attribute a change in a system to climate change, one needs to combine a measure of sensitivity of the outcome to climate with an observed measure of climate under climate change. This can be done via a multi-step approach (Hegerl *et al*., 2010), whereby one estimates the outcome of interest using measures of climate sensitivity combined with measures of observed climate and compares these to a simulated outcome using the same sensitivity but removing the climate change from the climate input.

18.2.1.3. Approaches to Attribution

There are many levels at which drivers and responses can be defined for observed impacts of climate change (Table 18-1). In practice, two different levels of external drivers are used:

- Attribution to climate change, where impacts are related to identified long-term trends in climate (including changes in variability patterns). Studies examining this relationship do not formally identify the role of anthropogenic emissions in the observed climate change or, by extension, in the observed impact, but they do indicate the degree to which the system is sensitive to long term climate change.
- Attribution to anthropogenic climate change, where impacts are related, via the climate, to anthropogenic emissions of greenhouse gases and other human activities that are affecting the climate. Because of the complexity of the causal chain, investigation of this relationship is extremely challenging (Parmesan *et al*., 2011) and only a limited number of these studies have been performed to date.

Attribution studies use two main approaches (see Figure 18-2). Single-step methods consider all relevant systems in a single setup. The assessment tool can comprise a single model or a sequence of models, provided the output of each model is directly employed as an input for the next model in a logical sequence. The attribution analysis is performed through a comparison of the change in the final output from the model(s) against the observed change in the system of interest.

[INSERT FIGURE 18-2 HERE
Figure 18-2: A schematic diagram comparing approaches to attribution for an ecological system. The multi-step approach differs from the single-step approach in having a discontinuity between the attributed climate change and the observed weather driving the ecological model. Adapted from Stone *et al*. (2013).]

Multi-step attribution approaches comprise multiple attribution analyses, with an overall conclusion deduced from the collection of analyses. A multi-step approach could include an analysis of the attribution of changes in a measure of interest to changing climatic conditions and a separate analysis of how external climate drivers affected relevant climatic conditions. Typically, the separation of these analyses creates gaps or inconsistencies between the outputs from one step and the inputs to the next. These gaps must be assessed themselves with respect to their impact on the confidence in the overall attribution.

In areas where extensive monitoring records are available, such as for phenological measures in ecological systems, studies may be combined into a formal quantitative synthesis assessment. For instance, Rosenzweig *et al.* (2008) noted that the spatial pattern of observed changes in a large number of natural systems around the globe matched the pattern expected based on the observed warming pattern, and argued that other global factors such as land use change could not account for this pattern (see also Box 18-2).

_____ START BOX 18-2 HERE _____

Box 18-2. Quantitative Synthesis Assessment of Detection and Attribution Studies

There are a number of powerful tools for quantitative synthesis assessment of detection and attribution across multiple studies. These tools include associative pattern analyses (e.g., Rosenzweig *et al.*, 2008) and regression analyses (Chen *et al.*, 2011) which compare expected changes due to anthropogenic climate change across multiple studies against observed changes.

Quantitative synthesis assessments have been particularly prominent in ecology, where measures of phenology (timing of seasonal events) and geographical range can be assembled across species into standardized indices (Parmesan and Yohe, 2003; Rosenzweig *et al.*, 2008; Chen *et al.*, 2011). Synthesizing across multiple species can increase our confidence in detection of general patterns of change in the biological indices. This confidence increases with the number of species / ecosystems observed, the number of independent studies, the geographical distribution of these observations, the temporal depth and resolution of the data, and the representativeness of species/ecosystems and locations studied.

Synthesis assessments examining climate change as the only driver can provide some insight into the attribution of biological responses to climate change because they can indicate whether plausible hypotheses are supported by data. However, increasing spatial coverage, numbers of species, etc. does not a priori increase confidence that climate change is a more credible explanation for biological change than alternative hypotheses. Additional data can contribute to confidence in causal relationships, i.e. attribution, in a synthesis assessment when it provides new evidence for explicit testing against a credible range of alternative hypotheses.

18.2.2. Challenges to Detection and Attribution

18.2.2.1. Types and Quality of Observations

The nature of indicators can take many forms, some of which are more amenable for precise long-term monitoring than others. Many changing phenomena can be measured directly, e.g., the temperature of the surface waters of a lake. Often, however, important indicators are less specific and thus difficult to pinpoint, for instance the excess mortality and increased human vulnerability associated with heat waves, or the percentage of species migrating polewards or upwards.

The quality of observations of these indicators varies in space and time. Monitoring of ecosystems, for example, is often not designed with the intention of measuring incremental long-term changes and are not optimized for the detection of climate-related changes (Midgley *et al.*, 2007). Consequently, the record length may be too short, too

heterogeneous or discontinuous to be useful, or measuring standards may have been improved through time resulting in measurement artifacts. This latter factor is most visible in the extensive and long-running networks designed to monitor human health, where the priority is an accurate timely assessment of current health status and risk rather than the determination of long-term trends (see also 18.4.5).

18.2.2.2. Spatial and Temporal Characteristics of Change

Detection studies require observational data spanning a time period longer than the typical time scale of natural variability in the system in the absence of external drivers. A particular challenge is that this required time scale is usually difficult to discern from available observational records and thus other sources of information must be used to determine them (Hegerl *et al.*, 2010). Lags between changes in external drivers and responses to those drivers vary among different impact systems and within them, from seconds or minutes to centuries or millennia, and thus need to be recognised (Stone *et al.*, 2013).

Non-linear system response to change is a fundamental issue for detection studies. Some systems may respond by step-wise changes, other systems may have tipping points, showing little or no change until a certain threshold where they suddenly start to respond vigorously and often in a chaotic way (e.g., De Young and Jarre, 2009; Wassmann and Lenton, 2012, 18.6.2.5).

Change in environmental and human systems occurs on multiple spatial scales from local to global. Attribution of change to climate change (e.g., over the last several decades) faces different challenges at different spatial scales. At the local scale, detection may be straightforward due to the availability of long-term observations, but attribution may be difficult because many local factors have been changing as well (e.g., Parmesan *et al.*, 2013). Furthermore, local climate may be affected by localised drivers such as land cover change (De Noblet-Ducoudré *et al.*, 2012), which complicates the evaluation of the role of global anthropogenic emissions.

18.2.2.3. Publication Bias

Conclusions about the effect of climate change on natural and human systems in this report are based on a synthesis of findings in the scientific literature. A potential problem with this approach is publication bias, specifically the preferential publication of papers reporting statistically significant findings (Parmesan and Yohe, 2003). The effect of publication bias could be a false impression of the strength of the evidence in favor of a hypothesized effect. Methods exist for detecting and correcting for publication bias in formal quantitative synthesis analysis (Rothstein *et al.*, 2005). For instance, the availability of a large sample of observations from an existing phenological monitoring network has permitted the assessment that publication bias has not been an important factor in conclusions about the role of climate change in studies of the timing of leafing, flowering, and fruiting in Europe (Menzel *et al.*, 2006), but the lack of such long-term monitoring networks preclude such a conclusion for measures related to vector-borne diseases (Kovats *et al.*, 2001).

18.3. Detection and Attribution of Observed Climate Change Impacts in Natural Systems

The IPCC AR4 provided extensive reporting on observed impacts of climate change (in Rosenzweig *et al.*, 2007, but also other chapters of the WGII report). The scientific literature on this topic is growing quickly. Rather than a full analysis of this literature, the following section provides a synthetic overview of the state of knowledge across major sectors of natural systems, based largely on the respective sectoral chapters (3, 4, 5, 6) and chapter 30 of this report, and a methodological framework with these chapters.

18.3.1 Freshwater Resources

The availability of freshwater resources, and essentially all aspects of the hydrological cycle, are affected by climate change on all continents and probably most islands, with different characteristics of change in different regions. Observed changes in each of the components of the water system are assessed by the IPCC WGI in their chapters 2 and 10, and WGII in their chapters 3, 4 and the regional chapters.

Figure 18-3 presents a synthesis of confidence in detection of changes in freshwater resources and related systems (notably erosion and slope stability), and their attribution to climate change. Frozen components of freshwater systems tend to show higher confidence in detection and attribution, while components that are strongly influenced by non-climatic drivers, such as groundwater or river flow, have lower confidence.

[INSERT FIGURE 18-3 HERE
Figure 18-3: Levels of confidence in detection and attribution of observed climate change impacts for freshwater systems over the past several decades, based on expert assessment contained in this section 18.3.1 and augmented by subsections of chapter 3 as indicated. Numbered symbols refer to: Freshwater systems (18.3.1.1): 1 groundwater depletion (Ch.3.2.4), 2 changing river flow (Ch. 3.2.3), 3 changing flood frequency or intensity (Ch. 3.2.3), 4 reduction in lake and river ice duration or thickness (Ch. 18.3.1.2); Cryosphere: 5 shrinking glaciers (Ch. 3.2.2; 18.3.1.2), 6 changes in glacier lakes (Ch. 18.3.1.1), 7 erosion and degradation of arctic coastal permafrost (Ch. 18.3.1.2), 8 degradation and thaw of lowland and mountain permafrost (Ch. 18.3.1.2), Soils and rock (18.3.1.3): 9 increasing erosion (Ch.3.2.6), 10 changes in shallow landslides (Ch.3.2.6), 11 increasing frequency of alpine rock failures.]

18.3.1.1. The Regional Water Balance

The regional water balance is the net result of gains (precipitation, ice and snow melt, river and groundwater inflow) and losses (evapotranspiration, water use and river and groundwater outflow). Impacts of climate change include reduced availability of freshwater for use (one of the variables defining drought) or excess water (floods). Evapotranspiration, being a function of surface temperature, vegetation cover, soil moisture and wind, is affected by the changing climate, but also by changing vegetation processes and land cover.

At the global scale, human influence has contributed to large scale changes in precipitation patterns over land and, since the mid 20th century, in extreme precipitation (medium confidence, WGI AR5 Chapter10, Min *et al.*, 2011). More locations worldwide have experienced an increase than a decrease in heavy rainfall events, yet with significant regional and seasonal variations (Seneviratne *et al.*, 2012). While runoff has not changed in the majority of rivers, year-to-year variability has increased (WGI AR5 Chapter 2). At the regional scale, however, human influence has affected streamflow and also evapotranspiration (WGI AR5 Chapter 10).

Change in river flow is a direct indicator of a changing regional water balance. Globally, one-third of the top 200 rivers (ranked by river flow) show statistically significant trends during 1948–2004, with the rivers having downward trends (45) outnumbering those with upward trends (19) (Dai *et al.*, 2009). In the western United States, observed changes in the hydrological cycle (river flow, snow pack) during the second half of the 20th century have been linked to recent climate change, and 60% thereof were due to anthropogenic influences (Barnett *et al.*, 2008). Likewise, the Uruguay River in South America experienced a positive trend in average streamflow from 1960 to 2000, due to increased rainfall, with shorter-term peaks in runoff caused by changes in land cover (Saurral *et al.*, 2008). In the Yellow River in China, however, long-term change in streamflow are mostly attributed to anthropogenically enhanced soil erosion rather than to climatic changes (Zhang *et al.*, 2007). Changes in rainfall seasonality in monsoon systems also affect river flows. In South America, for example, wet seasons have increased in duration from an average of 170 days before 1972, to 195 days after (Carvalho *et al.*, 2010), with significant impacts on the Amazon and the La Plata basins.

18.3.1.2. Floods and Droughts

Floods, defined as impacts caused by the overtopping of river banks and levées, have increased in magnitude and frequency over recent decades in many river systems. There are limited instrumental records for these, and the existing gauging stations do not necessarily report whether impact-relevant overtopping has occurred. In addition, the highest annual flood will not necessarily imply the same overtopping each year. Other confounding factors, such as human alteration of river channels and land use also play a role, hence there is only *low to medium confidence* in global detection of a change in floods.

In regions with detected increase in heavy rainfall events and supposable consequences for pluvial floods (North America, Central Europe), both increases and decreases in floods have been found (Petrow and Merz, 2009; Villarini *et al.*, 2009). An attribution study using a multi-step modeling framework of floods suggests that an anthropogenic signal is detectable for a 20% increase in flood risk for the autumn 2000 floods in England and Wales (Kay *et al.*, 2011; Pall *et al.*, 2011, see also 18.4.4.2).

In mountain areas, glacial lake outburst floods (GLOFs) are characterized by their low frequency and high magnitude with most devastating impacts on downstream areas. While there is no evidence for a change in frequency or magnitude of GLOFs anywhere in the world (Seneviratne *et al.*, 2012), changes in the number and area of glacial lakes have been observed, with varying degrees of increasing trends in several regions over the Hindu Kush Himalayan mountain arc in the past two decades (Gardelle *et al.*, 2011), and a similarly strong increase in lake numbers in the Andes of Peru in the second half of the 20th century (Carey, 2005), and in northern Patagonia from 1945 to 2011 (Loriaux and Casassa, 2013). The growing number of these lakes is of concern since it suggests an increased likelihood of GLOFs.

Since the 1950s some regions of the world have experienced more intense and longer droughts (*medium confidence*), although a global trend cannot currently be established (Seneviratne *et al.*, 2012). Drought conditions have increased (with *medium confidence*) in Southern Europe and the Mediterranean, West Africa, East Asia, Southern Australia and New Zealand, and decreased in most of North America and Northern Australia (the rest of the world had either no change or insufficient data).

Groundwater storage has been reduced in large parts of the world, and this has been primarily attributed to human activities, such as in northeastern India where groundwater depletion, as detected by satellite data for the 21st century, was largely attributed to groundwater withdrawal for irrigation and other human use (Rodell *et al.*, 2009). Attribution of groundwater change to climatic drivers is more rare (Taylor *et al.*, 2012). For Kashmir (India), Jeelani (2008) suggests that the observed decline in groundwater recharge between 1981 and 2005 can be attributed to decreasing precipitation and glacier retreat, while a modeling study for southeast Spain indicates an effect of temperature related changes in evapotranspiration on groundwater (Aguilera and Murillo, 2009).

Water quality in watersheds and lakes is expected to change with increasing temperature through an increase in eutrophication. It is difficult, however, to link observed changes in water quality to climate change due to the counfounding factors. Eutrophication is mostly driven by other causes, such as untreated sewage inflows in urban and industrial areas and surface runoff delivering residues of fertilizers used in agriculture, and vegetation decay and manure inputs in flooding events (Kundzewicz and Krysanova, 2010). There is emerging evidence for downstream impacts on water quality due to upstream climate impacts, such as high sulfide content in rivers of Peru's Cordillera Blanca due to sulfide-rich rocks that became exposed as glaciers retreated (Fortner *et al.*, 2011).

18.3.1.3. The Cryosphere

There is extensive evidence of significant recent changes in various componentes of the cryosphere, including glaciers, ice sheets and floating ice shelves, sea, lake and river ice, subsurface ice (permafrost) and snow (WGI AR5 Chapter 4). It is *likely* that there is an anthropogenic component in the changes observed in Arctic sea ice, Greenland surface melt, glaciers, permafrost and snow cover (WGI AR5 Chapter 10).

Changes in glaciers continue to provide a globally largely homogeneous but regionally variable signal of retreat. There is *high confidence* that glacier changes over the past 2-3 decades exceed internal variability, but only few studies are available that attribute these glacier changes to anthropogenic forcing (WGI AR5 Chapter 10). The absolute contribution of glaciers and ice caps to sea level rise has increased since the early 20th century and has been close to 1 mm yr^{-1} for the past two decades (WGI AR5 Chapter 4), around a third of total observed sea level rise. The decadal-scale mass loss of ice sheets and glaciers causes accelerated uplift of underlying land in the North Atlantic Region (Jiang *et al*., 2010). There is *medium confidence* regarding the effects of decadal ice loss on seismicity due to unloading of the lithosphere beneath ice sheets (Hampel *et al*., 2010) and Alaskan glaciers (Sauber and Ruppert, 2008), and on volcanic activity such as enhanced magma generation (Sigmundsson *et al*., 2010). The strong and rapid downwasting observed on alpine glaciers has prompted a number of impacts. Expanding or new lakes at the margin of many retreating glaciers in the Alps of Europe, Himalayas, Andes and other mountain regions have altered the risk of outburst floods. In the Swiss Alps and the Peruvian Andes, outburst floods from several lakes in the 21st century have caused damages, and required risk reduction measures on the order of tens of millions USD (Huggel *et al*., 2011; Carey *et al*., 2012b). New glacier lakes have also become a tourist attraction, led to additional infrastructure, and stimulated assessment of potential for hydropower generation (Terrier *et al*., 2011). There is also evidence of slope instabilities as a consequence of recent decadal scale glacier downwasting (Haeberli and Hohmann, 2008; Huggel *et al*., 2011).

Depending on local conditions, variations in runoff in high-mountain regions are often attributed to glacier and climate change (Casassa *et al*., 2009). Current understanding suggests that during the continuous shrinkage of glaciers a 'peak meltwater' exists, with increasing runoff trends before, and decreasing trend after this threshold (3.4.4). An increase in runoff from glacier areas has been documented for catchments in western and south-central China over the past several decades, and for western Canada and Europe (Zhang *et al*., 2008; Moore *et al*., 2009; Li *et al*., 2010; Stahl *et al*., 2010). In the Peruvian Andes there is evidence that 'peak meltwater' has recently been passed, based on runoff decrease during the dry season in seven out of nine glacier-fed catchments in the Cordillera Blanca (Baraer *et al*., 2012), also confirmed by qualitative observations made by local people (Bury *et al*., 2010; Carey *et al*., 2012a). In the Swiss Alps, positive variations in river runoff have occurred primarily in highly glaciated catchments during warm periods of the 20th century (1940's, 1990's), while for less glaciated catchments a runoff decrease was detected for the warm and dry 1990s (Collins, 2006; Pellicciotti *et al*., 2010). For large catchments (Po and Rhône catchments with <1% basin glacier cover), the contribution of glacier melt to total runoff in August was significantly lower for 2004-2008 than for the previous twenty years (Huss, 2011).

Earlier reported trends of Arctic sea ice decline in terms of extent and thickness have continued, with a significant increase of the rate of sea ice decline in the first decade of the 21st century (WGI AR5 Chapter 4). It is *likely* that at least some of the decline in Arctic sea ice extent can be attributed to anthropogenic climate forcing (WGI AR5 Chapter 10). Observations by Inuit people in the Canadian Arctic confirm with *high confidence* the instrumental observations on the various changes of sea ice (see Box 18-5). Antarctic sea ice has slightly increased over the past 30 years, yet with strong regional differences (WGI AR5 Chapter 4).

For lake and river ice, there is generally *high confidence* of later freeze-up and earlier break-up over the past 100+ years, yet with regional differences (WGI AR5 Chapter 4). Changes in lake and river ice can have effects on freshwater ecosystems, transport and traffic over frozen lakes and rivers, and ice induced floods during freeze-up and break-up events (Voigt *et al*., 2011). Some evidence exists in Europe that ice-jam floods were reduced during the last century due to reduced freshwater freezing (Svensson *et al*., 2006).

Combined in-situ and satellite observations indicate a decline in snow cover extent in most months of the period 1922-2010, with the largest decline in spring (8%) (WGI AR5 Chapter 4). Only few formal detection and attribution studies exist but they consistently indicate an anthropogenic influence on snow cover reduction (WGI AR5 Chapter 10), including an up to 60% contribution of anthropogenic climate forcing on changes in snow pack and runoff timing between 1950 and 1999 in the Western United States (Barnett *et al*., 2008). Impacts on winter tourism have been observed (18.4.3.3).

Widespread changes and degradation of permafrost of both, high-latitude/low-land and high-elevation mountain regions, have been observed over the past years and decades (WGI AR5 Chapter 4). Generally, the permafrost

boundary has been moving polewards and to higher elevations, and the active layer thickness has increased at many sites. While formal attribution studies are hardly available for any of the above mentioned permafrost attributes, several impacts have been related to permafrost changes, including an increase of flow speed of Alpine rock glaciers in particular in the 21st century, resulting in rock fall and debris flows (Kääb *et al.*, 2007; Delaloye *et al.*, 2010), expansion and deepening of thermokarst lakes, erosion at the Arctic coast, resulting in a doubling of the erosion rate at Alaska's northern coastline over the past 50 years (Karl *et al.*, 2009). Furthermore, expansion of channel networks (Toniolo *et al.*, 2009), increased river bank erosion (Costard *et al.*, 2007) and higher dynamics in shrinkage and expansion of lakes and ponds have been observed in the Arctic (Rowland *et al.*, 2010), as well as an increase in hillslope erosion and landsliding in Northern Alaska since the 1980's (Gooseff *et al.*, 2009). Complex feedbacks and interactions across surface systems, and spatial and temporal scales complicate detection of drivers and effects. For example, drying of land surface due to permafrost degradation may cause an increase in wildfires, in turn resulting in a loss of ground surface insulation and change in surface albedo that accelerates permafrost thawing (Rowland *et al.*, 2010; Forkel *et al.*, 2012).

18.3.1.4. Erosion, Landslides, and Avalanches

Erosion and landsliding typically increases during phases of deglaciation in mountain areas (Ballantyne, 2002; Korup *et al.*, 2012) and there is emerging evidence for this to occur during contemporary deglaciation (Schneider *et al.*, 2011; Uhlmann *et al.*, 2012). Erosion related to sediment flux changes from mountain areas has been observed in the Western Himalaya in relation with hydrologic extreme events (medium confidence, Wulf *et al.*, 2012), increasing over the past 60 years (Malik *et al.*, 2011), with important impacts on hydropower schemes. For southern China, there is robust evidence of decline in sediment load in some rivers since the 1980s and 1990s (Zhang *et al.*, 2008a). Dam construction is an important driver of the recent decline in sediment load, leaving only *low confidence* in attributing the change to any climate impacts for the Yangtze catchment in China (Xu *et al.*, 2008).

Changes in sediment yield, e.g. from rockfall or disintegration of rock glaciers, related or unrelated to climate impacts, can significantly influence frequency and magnitude of alpine shallow landslides and debris flows (Lugon and Stoffel, 2010), but no clear evidence exists so far for a change in frequency of shallow landslides and debris flows from recently deglaciated mountain areas in the European Alps (Jomelli *et al.*, 2004; Stoffel and Huggel, 2012).

Rock slope failures in mountain areas with permafrost occurrence have increased since the 1990s (*high confidence* in the Western European Alps, *medium confidence* for New Zealand Alps, and *low confidence* globally). There also is *high confidence* that glacier retreat and downwasting, permafrost degradation and high-temperature events have contributed to many high-mountain rock slope failures over the past 20 years (Allen *et al.*, 2010; Ravanel and Deline, 2011; Schneider *et al.*, 2011; Fischer *et al.*, 2012; Huggel *et al.*, 2012a). Damages and costs for risk reduction measures in Alpine areas have increased due to rock fall and debris flows, with climate change playing a major role in triggering complex downstream impact chains and feedback (*medium to high confidence* of influence of anthropogenic climate forcing), such as recently documented in the Swiss Alps with costs on the order of tens of millions USD (Huggel *et al.*, 2012b). Rock and ice avalanches, and other landslides from destabilized slopes have also impacted glacier lakes and caused downstream damage in several high-mountain regions (e.g., Xin *et al.*, 2008; Bajracharya and Mool, 2009; Künzler *et al.*, 2010; Carey *et al.*, 2012a; Huggel *et al.*, 2012b).

Other than for the above mentioned types of landslides, there is no clear evidence that their frequency or magnitude has changed over the past decades (Huggel *et al.*, 2012b). This is true for shallow landslides and also for regions with a relatively complete event record (e.g. Switzerland, see Hilker *et al.*, 2009). In general, detection of changes in the occurrence of landslides is complicated by incomplete inventories, both in time and space, and inconsistency in terminology. In line with loss from other extreme events (see 18.4.4) an increase in terms of casualties, or loss due to landslides has been documented in South, East and South-East Asia over the past years, but are largely attributed to changes in exposure, i.e. population growth (Petley, 2010).

No change in snow avalanche activity has been detected so far in Europe (Laternser and Schneebeli, 2002; Voigt *et al*., 2011). However, the detection of changes in snow avalanche impacts, such as fatalities and property loss, is difficult over the past decades due to changes in snow sport activities and avalanche defense measures.

18.3.2. Terrestrial and Inland Water Systems

As documented by previous IPCC reports (notably Rosenzweig *et al*., 2007), numerous changes in terrestrial and inland water systems have been attributed to recent climate change. Confidence in such detection of change is often *very high,* reflecting high agreement among many independent sources of evidence of change, and robust evidence that changes in ecosystems or species are outside of their natural variation. Confidence in attribution to climate change is also often *high*, due to process understanding of responses to climate change, or strong correlations with climate trends and where confounding factors are understood to have limited importance. The scientific literature in this field is growing quickly, precluding a full review in this chapter. Therefore, statements of confidence for detection and attribution are given without references, as detailed traceability is provided in chapter 4.

Organisms respond to changing climate in a multitude of ways, including through their phenology (the timing of key life history events such as flowering in plants or migration of birds), productivity (the assimilation of carbon and nutrients in biomass), spatial distribution, mortality / extinction, or by invading new territory. Noticeable changes may occur at the level of individual organisms, ecosystems, landscapes, or by modification of entire biomes. Organisms and ecosystems are adapted to a variable environment, and they are capable to adapt to gradual change to some degree – for the scope of this chapter, available knowledge will be reviewed concerning changes in terrestrial and freshwater ecosystems that occur beyond natural variability and which can be assumed to be due to recent climate change and/or increased in atmospheric CO_2. Confidence in the detection of such change involves therefore assumptions about natural variability in these ecosystems, and confidence in the attribution of detected change to climate drivers (or CO_2) implies the assessment of confounding drivers such as land use change.

18.3.2.1. Phenology

Since the AR4 there has been a further significant increase in observations of phenology of plants and animals, showing that many, but not all species have changed functioning to some degree over the last decades to centuries on all continents (*high confidence* due to robust evidence but only moderate agreement across all species). New satellite-based analyses confirm earlier trends, showing, for example, that the onset of the growing season in the northern hemisphere has advanced by 5.4 days from 1982 to 2008 and its end has been delayed by 6.6 days (Jeong *et al*., 2011). Significant changes have been detected, by direct observation, for many different species, for example, for amphibians, birds (breeding, migration), mammals, and plants; a number of meta-analyses have been carried out summarizing this literature (e.g., Cook *et al*., 2012). Attribution of these changes to climate change is supported by more refined analyses that consider also the regional changes in several variables such as temperature, growing season length, precipitation, snow cover duration and others, as well as experimental evidence. The *high confidence* in attributing many observed changes in phenology to changing climate is a result of these analyses, as well as of improved knowledge of confounding factors such as land use and land management (for more references and details see 4.3.2.1).

18.3.2.2. Productivity and Biomass

Many terrestrial ecosystems are now net sinks for carbon over much of the Northern hemisphere and also in parts of the Southern hemisphere (*high confidence*). This is shown, for example, by inference from atmospheric chemistry, but also by direct observations of increased tree growth in many regions including Europe, the United States, tropical Africa and the Amazon. During the decade 2000 to 2009, global land net primary productivity was approx. 5% above the preindustrial level, contributing to a net carbon sink on land of 2.6 ± 0.7 Pg C yr^{-1} (Raupach *et al*., 2008; Le Quéré *et al*., 2009, WGI AR5 Chapter 6), despite ongoing deforestation. These trends are in part due to nitrogen deposition, afforestation and altered land management which makes direct attribution of the increase to

climate change difficult (*low confidence* in attribution). The degree to which rising atmospheric CO_2 concentrations contribute to this trend remains a particularly important source of uncertainty (for more references and details, see 4.3.2.2 and 4.3.2.3).

18.3.2.3. Biodiversity

Each species responds differently to a changing environment, therefore the composition of species, genotypes, communities and even ecosystems varies in different ways from place to place, in response to climate change. The consequences are changing ranges of species, changing composition of the local species pool, invasions, mortality and ultimately extinctions. For different species and species groups, detected range shifts vary, and so do the confidence of detection and the degree of attribution to climate change. The number of species studied has considerably increased since the AR4. Overall, many terrestrial species have recently moved, on a global average, 17 km poleward and 11 m up in altitude per decade (e.g., Europe, North America, Chile, Malaysia), which corresponds to predicted range shifts due to warming (Chen *et al.*, 2011) and is 2 to 3 times faster than previous estimates (Parmesan and Yohe, 2003; Fischlin *et al.*, 2007), *high confidence* in detection. For example, over the last decades, arthropods have moved large and statistically significant distances towards the poles (many 10s of km). Species with short life cycles and high dispersal capacity – such as butterflies (*high confidence* in attribution) – are generally tracking climate more closely than longer-lived species or those with more limited dispersal such as trees (*medium confidence* in attribution). There are many less well-studied species for which detection of change and its attribution to climate change are more uncertain.

Across the world, species extinctions are at or above the highest rates of species extinction in the fossil record (*high confidence* in detection). However, only a small fraction of observed species extinctions have been attributed to climate change — most have been ascribed to non-climatic factors such as invasive species, overexploitation or habitat loss (*very low confidence* in attribution to climate change). For those species where climate change has been invoked as a causal factor in extinction (such as for the case of Central American amphibians), there is *low agreement* among investigators concerning the importance of climate variation in driving extinction and even less agreement that extinctions were caused by global warming. *Confidence* in the attribution of extinctions across all species to climate change is *very low*.

Species invasions have been increasing over the last several decades world-wide, notably in freshwater ecosystems (*very high confidence*), often causing biodiversity loss or other negative impacts. While there is a documented contribution of recent climate trends to establishment, growth, spread and survival of some invasive species populations, there is only *low confidence* that the species invasions have generally been assisted by recent climatic trends because of the overwhelming importance of human facilitated dispersal in mediating invasions (for more references and details see 4.3.2.5 and 4.3.2.6).

18.3.2.4. Impacts on Major Systems

The extent of recent change in major ecosystems such as the boreal forest, the Arctic tundra, or the Amazon forest has been characterized as a “regime shift” by some authors (e.g., Biggs *et al.*, 2009), implying significant and broad-scale changes in both distribution and functioning of the ecosystem.

Field and satellite measurements indicate a substantial increase in shrub growth (often linked to permafrost thawing) in many areas of the Arctic tundra (*high confidence* in detection). This change corresponds to expectations, based on experiments, models and paleoecological responses to past warming, of broad-scale boreal forest encroachment into tundra, a process which takes decades and which would have very large impacts on ecosystem structure and function. The particular strength of warming over the last 50 years for most of the Arctic further facilitates attribution (*high confidence*). The change affects a significant area of the tundra biome and can be considered an early warning for an upcoming regime shift.

For the boreal forest, increases in tree mortality are observed in many regions, including wide-spread dieback related to insect infestations in North America, but there is *low confidence* in detection of a global trend. Local and regional mortality has in some cases been linked to climate fluctuations, but there is *low confidence* in attributing any perceived overall dieback to climate change. At the Southern "trailing end" of the shifting boreal zone, there are indications of enhanced mortality of plant species (notably trees), but there is *low confidence* in overall detection due to a lack of temporal and spatial coverage of observations. There is consequently also *low confidence* in attribution of the changes to climatic change.

In the humid tropical forests of the Amazon basin, increases in tree turnover (increased mortality and growth) have been detected with *medium confidence* for recent decades. These changes have been explained by a number of factors, including the direct effect of rising CO_2 on lianas, recovery from past disturbance and changing climate. Overall, there is *very low confidence* in attribution of these observations to climate change.

In freshwater ecosystems of most continents and climate zones, rising temperatures have been linked to shifts in invertebrate and fish community composition, especially in headwater streams where species are more sensitive to warming (*high confidence* in detection, *low confidence* in attribution due to numerous confounding factors; 4.3.3.1, 4.3.3.3).

18.3.3. Coastal Systems and Low Lying Areas

In coastal waters, both average warming rate and changes in seasonal timing are larger than in the open oceans (see 5.3.3). Sea surface temperatures have warmed significantly during the past 30 years along more than 70% of the world's coastlines, albeit with large spatial and seasonal variation in the rates of change *(very high confidence)*. The frequency of extreme temperature events has changed in many areas (Lima and Wethey, 2012). Seawater pH also spans larger ranges and exhibits higher variability near coastlines, and anthropogenic ocean acidification can be enhanced or lessened by coastal geochemical processes (Borges and Gypens, 2010; Feely *et al*., 2010; Duarte *et al*., 2013, see also Box CC-OA), and extreme winds, changes in wave regime and sea level play important roles in coastal processes (seeTable 5-1).

While it is *extremely likely* that observed global sea level rise can at least in part be attributed to anthropogenic emissions (WGI AR5 Chapter 10.4.3), the evaluation of local sea level trends must consider important local confounding factors, such as regional variability in ocean and atmospheric circulation, subsidence, coastal erosion, and coastal modification (see also 5.3.2). Thus far, it has not been possible to isolate an anthropogenic climate signal in local sea level changes from the contributions of these confounding factors. A possible emerging exception is along the coasts of regions with melting glaciers and ice sheets, where local gravitational effects leading to a lowering of sea level may dominate other factors (Kopp *et al*., 2010; Tamisiea and Mitrovica, 2011). As a consequence, attribution of observed effects of relative sea level change to climate change is hardly possible (see Nicholls *et al*., 2007; Nicholls *et al*., 2009), despite attempts for very few locations, e.g. for flood damages in Venice (Carbognin *et al*., 2010).

18.3.3.1.Erosion, Shoreline Processes, and Coastal Aquifers

Throughout the world, beaches and dunes, as well as bluffs and cliffs, are eroding due to a variety of climate related processes, such as rising mean sea levels (Leatherman *et al*., 2000; Ranasinghe and Stive, 2009), more frequent extreme sea levels (Woodworth *et al*., 2011), changes in wave regimes (Tamura *et al*., 2010; Reguero *et al*., 2013), the loss of natural protective structures such as coral reefs (Grevelle and Mimura, 2008) or mangrove forests due to increased ocean temperatures or ocean acidification (Bongaerts *et al*., 2010), or permafrost degradation and sea ice retreat (Manson and Solomon, 2007). However, there are multiple non-climate related drivers involved in shoreline erosion, including dams capturing fluvial sands, subsidence due to resource extraction, mining and coastal engineering and development. Due to the fragmentary nature of the information available and to the multiple natural and anthropic stressors contributing to coastal erosion, confidence in attribution of shoreline changes to climate change is *very low*, with the exception of polar regions (Forbes, 2011, see also 18.5).

Coastal lagoons and estuaries, as well as deltas are highly susceptible to alterations of sediment input and accumulation (Syvitski *et al.*, 2005; Ravens *et al.*, 2009), processes that can be influenced by climate change via changes in sea level, storminess, and precipitation. However, the primary drivers of widespread observed changes in those systems are human drivers other than climate change (thereby *very low confidence* in attribution to climate change, see 5.4.2.6, 5.4.2.7).

Coastal aquifers are crucial for the water supply of densely populated coastal areas, in particular in Small Island environments. Aquifer recharge is sensitive to changes in temperature and precipitation; and rising sea levels and sea water overwash from storm surges can contribute to saline intrusion into groundwater (Post and Abarca, 2010; Terry and Falkland, 2010; White and Falkland, 2010, see also 29.3, Table 18-8). However, excessive groundwater extraction for coastal settlements and agriculture is the main cause for widely observed groundwater degradation in coastal aquifers (e.g., White *et al.*, 2007a; Barlow and Reichard, 2010). Attribution to climate change, in particular incremental sea level rise, is not supported in the literature (Rozell and Wong, 2010; White and Falkland, 2010).

18.3.3.2. Coastal Ecosystems

Coastal habitats and ecosystems experience cumulative impacts of land- and ocean-based anthropogenic stressors (Halpern *et al.*, 2008). Most coral reefs, seagrass beds, mangroves, rocky reefs and shelves have undergone substantial changes. Coral reefs have been degraded due to both local anthropogenic factors such as unsustainable fishing and pollution, and global change factors such as increased heat waves, ocean warming and acidification (see also Box CC_CR). Coral bleaching is being detected with *high confidence* on all coasts, and warming is a major contributor (*high confidence*, for further discussion see Box 18-3, and Box CC_OA). Overexploitation and habitat destruction have been responsible for a large fraction of historical changes observed in coastal ecosystems (Lotze *et al.*, 2006).

Hypoxia poses a serious threat to marine life, which is exacerbated when combined with elevated temperature (Vaquer-Sunyer and Duarte, 2011). Increased loads of nutrients from anthropogenic sources generate coastal eutrophication and constitute the primary cause of increasing hypoxia, while upwelling of low oxygen waters and ocean warming constitute secondary drivers (see Zhang *et al.*, 2010). Persisting hypoxia can result in so-called "dead zones", which have approximately doubled each decade since 1960 (Diaz and Rosenberg, 2008).

Changes in abundance and distribution of rocky shore species have been observed since the late 1940s in the North East Atlantic (Hawkins *et al.*, 2008), and the role of temperature has been demonstrated by experiments (e.g., Peck *et al.*, 2009; Somero, 2012, see also 5.4.2.2). Distinguishing the response to climatic stressors from changes due to hydrology, or natural temporal and spatial fluctuations, is nevertheless challenging.

Globally, the range limits of many intertidal species have shifted up to 50 km per decade, much faster than most recorded shifts of terrestrial species (Helmuth *et al.*, 2006, see also Box 18-4). However, the geographical distribution of some species did not change in the past decades. This may be due to weak local warming (Rivadeneira and Fernández, 2005), or overriding effects of variables such as timing of low tide, hydrographic features, lack of suitable bottom types, larval dispersal, food supply, predation and competition (Helmuth *et al.*, 2002; Helmuth *et al.*, 2006; Poloczanska *et al.*, 2011). Changes in current patterns and increased storminess can dislodge benthic invertebrates and affect the distribution of propagules and recruitment.

Changes in musselbeds in response to higher temperatures induced by climatic change have been observed along the West coasts of the United States (Smith *et al.*, 2006a; Menge *et al.*, 2008; Harley, 2011). On Tatoosh Island (Washington, USA), a shift in community structure from a mussel to an algal-barnacle-dominated community has been attributed to rapidly declining pH (Wootton *et al.*, 2008; Wootton and Pfister, 2012).

Ocean warming is also leading to range shifts in vegetated coastal habitats such as coastal wetlands, mangrove forests and seagrass meadows (*medium confidence*, see 5.4.2.3). Extreme temperature events can alter marine and

coastal communities, as shown for the European heatwave 2003 (Garrabou *et al*., 2009), and the early 2011 heat wave off the Australian West Coast (Wernberg *et al*., 2012).

Poleward expansion of mangrove forests, consistent with expected behavior under climate change, has been observed in the Gulf of Mexico (Perry and Mendelssohn, 2009; Comeaux *et al*., 2011; Raabe *et al*., 2012), and New Zealand (Stokes *et al*., 2010). High temperatures have impacted seagrass biomass in the Atlantic Ocean (Reusch *et al*., 2005; Díez *et al*., 2012; Lamela-Silvarrey *et al*., 2012), the Mediterranean Sea (Marbà and Duarte, 2010) and Australian waters (Rasheed and Unsworth, 2011). Extreme weather events contributed to the overall degradation of seagrass meadows in a Portuguese estuary (Cardoso *et al*., 2008).

Decline in kelp populations attributed to ocean warming has occurred off the North coast of Spain (Fernández, 2011), as well as in southern Australia, where the poleward range expansion of some herbivores have also contributed to observed kelp decline (Johnson *et al*., 2011; Wernberg *et al*., 2011; Wernberg *et al*., 2011). The spread of subtropical invasive macroalgal species (e.g., Lima *et al*., 2007) may be adding to the stresses temperate seagrass meadows experience from ocean warming.

Overall, there is *high confidence* in detection of range shifts and biodiversity changes in intertidal and other coastal species, as well as in a decline in kelp forests, and increased mortality of seagrasses, and *high confidence* that climate change has contributed to these effects (5.4.4, Figure 5-5). For the widespread decline observed in salt marshes and mangroves, there is *very low confidence* in a role of climate change due to overriding effects of other human drivers.

18.3.3.3. Coastal Settlements, Infrastructure, and Economic Activities

Recent global (e.g., Menéndez and Woodworth, 2010; Woodworth *et al*., 2011) and regional studies (e.g., Marcos *et al*., 2009; Haigh *et al*., 2010; Haigh *et al*., 2011) have found that observed trends in extreme sea levels are mainly consistent with mean sea level trends (Woodworth *et al*., 2011), indicating that the increasing frequency of extreme events affecting coastal infrastructures observed so far is related to rising mean sea level rather than to changes in the behaviour of severe storms. Increased damages from coastal flooding have been observed with *high confidence*, however, with exposure and subsidence constituting the major drivers, confidence in attribution to climate change is *very low* (Seneviratne *et al*., 2012, see also 5.4.3, 5.4.4).

Increases in saltwater intrusion and flooding have been observed in low-lying agricultural areas of deltaic regions and Small Islands, but the contribution of climate change to this is not clear (e.g., Rahman *et al*., 2011, see also 18.5.9). Both climate variability and change impact fishermen livelihoods (Badjeck *et al*., 2010) and physiological and ecological properties of fish (e.g., Barange and Perry, 2009, see also 18.3.4, 18.4.1.2); however local and regional observations of climate impacts on output of coastal fisheries are scarce.

While vulnerability of coastal settlements and infrastructure to future climate change, in particular sea level rise and coastal flooding, is widely accepted and well-documented (seeTable 5-5), there is a shortage of studies on the role of climate change in observed impacts on coastal systems.

_____ START BOX 18-3 HERE _____

Box 18-3. Detection and Attribution of Mass Coral Bleaching and Mortality to Climate Change

Declining water quality as well as increasing fishing pressure and coastal development have been implicated in the rapid decline in the abundance of corals and coral reefs over the past 50 years (Bryant *et al*., 1998; Gardner *et al*., 2003; Bruno and Selig, 2007; Sheppard *et al*., 2010; Burke *et al*., 2011; De'ath *et al*., 2012). Since 1980, mass coral bleaching and mortality events began to occur on reefs throughout the tropics and subtropics with no precedent in the scientific literature (Box CC-CR). While bleaching of individual coral colonies has been reported prior to 1980 (Yonge and Nichols, 1931), mass coral bleaching events involving hundreds and thousands of coral colonies across entire reef and coastal regions have not (Hoegh-Guldberg, 1999; Baker *et al*., 2008). These novel events are often

followed by the mass mortality of coral communities, especially if conditions remain anomalously warm for long periods (ibid). In the very warm year of 1998, for example, mass coral bleaching affected almost every part of the seas associated with the tropics and subtropics resulting in the loss of 16% of the world's reef-building coral (Wilkinson and Hodgson, 1999).

There is broad agreement that mass coral bleaching can be triggered by small increases in sea temperature (> 1°C) above the summer maxima for a region over several weeks (very high confidence, Hoegh-Guldberg, 1999; Baker *et al.*, 2008; Strong *et al.*, 2011). The impact of temperature is also exacerbated by strong solar irradiance (Hoegh-Guldberg, 1999). There is also broad agreement that thermal stress impacts the ability of *Symbiodinium* to capture and process light, leading to the production of damaging reactive oxygen species which precedes the loss of symbionts (Jones *et al.*, 1998). As the symbiosis breaks down, the brown dinoflagellates leave their host corals, turning their tissues white and depriving corals of an important source of energy (Muscatine, 1986; Hoegh-Guldberg and Smith, 1989).

There is little or no evidence that reef-building corals and their *Symbiodinium* have, or evolved substantially in terms of the thermal tolerance over yearly or decadal time frames, or can be expected to do so (Hoegh-Guldberg, 2012). The relationship between elevated sea temperatures and mass coral bleaching remains robust enough to be used within algorithms that reliably detect and project the incidence of mass coral bleaching from satellites (Strong *et al.*, 2004; Strong *et al.*, 2011). Depending on the size of the thermal anomaly and exposure time, communities of reef-building corals have either recovered, or have experienced large-scale mortalities such as those seen worldwide in 1998 (Hoegh-Guldberg, 1999; Wilkinson and Hodgson, 1999; Baker *et al.*, 2008) and 2005 in the Caribbean (Eakin *et al.*, 2010). The detection of mass coral bleaching has been improved using satellite algorithms such as Degree Heating Weeks (DHW) (ibid).

Of the many variables investigated, only elevated sea temperature co-occurs consistently with mass coral bleaching and mortality events, and has a well worked physiological model associated with it (Hoegh-Guldberg, 1999). Consequently, given the relationship between global climate change and increased ocean temperatures, and that between coral bleaching and elevated temperature, the detected increase in the frequency of mass coral bleaching and mortality events can be attributed to anthropogenic climate change as the dominant driver with *very high confidence*.

_____ END BOX 18-3 HERE _____

18.3.4. Oceans

Since 1970, ocean temperatures have increased by around 0.1°C decade^{-1} in the upper 75 m and approximately 0.02°C decade^{-1} in the upper 500m, due to anthropogenic warming.

The increased flux of CO_2 from the atmosphere to the ocean has reduced the average pH of seawater by 0.1 pH units over the past century, with the greatest reduction occurring at high latitudes (Box CC-OA). These changes have been attributed to increases in the atmospheric concentration of greenhouse gases as result of human activities (*high to very high confidence*, WGI AR5 Chapter 10.4.1-10.4.4). Changes in wind speed, upwelling, water column stratification, surface salinity, ocean currents, solar irradiance, cloud distribution, and oxygen depth profile have also occurred (WGI AR5 Chapter 3.2 – 3.8; Figure 30-5, 30-6, 30-7).

Changes in the physical and chemical nature of ocean environments are predicted to have impacts on marine organisms and ecosystems, with many already having been observed across most ocean regions (see 6.2, 6.3, 6.5, 30.4, 30.5). However, the detection and attribution of recent changes in ocean systems is complicated by the influence of long-term variability such as the Pacific Decadal Oscillation (PDO), El Niño-Southern Oscillation (ENSO), and the Atlantic Multidecadal Oscillation (AMO). The fragmentary nature of ocean observations and the influence of confounding factors such as fishing, habitat alteration, and pollution also represent significant challenges to detection and attribution (Hoegh-Guldberg *et al.*, 2011; Parmesan *et al.*, 2011).

18.3.4.1. Impacts on Ocean System Properties and Marine Organisms and Ecosystems

Greater thermal stratification in many regions has reduced ocean ventilation and mixing depth, thereby reducing the availability of inorganic nutrients and hence primary productivity in surface layers, with controversial trends depending on methodology (see 6.1.3, 6.2.3, 30.5.6). However, upwelling has increased in some regions bringing greater concentrations of nutrients to surface waters, boosting productivity (see 30.5.5) and enhancing fisheries output (see also 18.4.1.2 for fisheries). Increases in productivity also occurred with warming and sea ice loss at high latitude. At a global scale a small increase in net primary production has been detected (Table 18-1, *medium confidence*).

Poleward shifts in the distributions of zooplankton, fish, seabirds and benthic invertebrate have been observed, particularly from the well-studied NE Atlantic, with a clear attribution to warming (*high confidence*, 6.3.2, 30.5.1). In many regions, Temperature exerts the strongest influence on ecosystems and the responses of ecological systems to changing temperature are well-studied. However, it is often difficult to clearly identify the interaction of temperature with other factors (6.3.5). Some studies have found changes in the abundance of fish species that are consistent with regional warming, with differences in response between species, in line with differential specializations of coexisting species (6.2, 6.3.2, Pörtner, 2012). Anthropogenic influences modulate responses to climate, e.g., due to exploitation status (Tasker, 2008; Belkin, 2009; Overland *et al*., 2010; Schwing *et al*., 2010), with more heavily exploited species being more sensitive to environmental variability in general, including temperature trends and extremes (Hsieh *et al*., 2005; Stige *et al*., 2006; Hsieh *et al*., 2008).

Changes to water column mixing have combined with other factors such as nutrient loading to drive down oxygen concentrations and increase the number and extent of hypoxic zones. These zones are characterized by very low oxygen and high CO_2 levels and have been detected with *high confidence*, and attributed in part to enhanced stratification and microbial respiration caused by warming *(medium confidence,* see Table 18-1). In some cases, expanding or shifted hypoxia exerts strong local and regional effects on marine biota such as distribution shifts, habitat contraction or loss, and fish kills.

Laboratory experiments have shown that a broad range of marine organisms (e.g. corals, fish, pteropods coccolithophores, and macroalgae), physiological processes (e.g., skeleton formation, gas exchange, reproduction, growth and neural function), and ecosystems processes (e.g., productivity, reef building and erosion) are sensitive to changes in pH and carbonate chemistry of seawater (*high confidence*, 6.2.2-5, 6.3.4, Box CC-OA). However, few field studies have been able to detect and attribute specific changes in marine ecosystems to anthropogenic ocean acidification due to the inability to identify the effect of ocean acidification from ocean warming or local factors (Wootton *et al*., 2008; De Moel *et al*., 2009; Moy *et al*., 2009; Bednaršek *et al*., 2012, see also 6.3.4).

[INSERT TABLE 18-1 HERE
Table 18-1: Observed changes in ocean system properties and their effects, with confidence levels for detection and attribution to climate change, based on assessment in Chapter 6.2, 6.3, and summarized in 6.6.1 and Figure 6-16. Observed impacts related to temperature effects have been attributed to warming, although the relative contributions of regional climate variation and long-term global trends have not been quantified.]

There has been a substantial increase in the number of studies documenting significant changes in marine species and processes since the AR4 (Hoegh-Guldberg and Bruno, 2010). A new meta-analysis using a database of long-term observations from peer-reviewed studies of biological systems, with nearly half of the time series extending prior to 1960, shows that a high proportion (81%) of observed responses are consistent with regional climate change (see 30.4). Poloczanska *et al*. (2013) argue that the high consistency of marine species' responses across geographic regions (coastal to open ocean, polar to tropical), taxonomic groups (phytoplankton to top predators), and types of responses (distribution, phenology, abundance) reported in their analysis support the detection of a widespread impact of climate change on marine populations and ecosystems (see 30.4 and 30.5 for more detail).

The impacts of climate change on marine organisms such as fish, invertebrates and marine algae include changes in abundance, distribution, and community structure and shifts in phenology and migration patterns. Table 18-2 gives examples of the manifestation of climate change on marine species.

[INSERT TABLE 18-2 HERE
Table 18-2: Observed changes on marine species and ecosystems, with confidence levels for assessment of detection of changes and their attribution to climate change, based on assessment in Chapter 6.2, 6.3, summarized in 6.6.1 and Figure 6-16, and 30.4. Observed impacts related to temperature effects have been attributed to warming, although the relative contributions of regional climate variation and long-term global trends have not been quantified.]

18.3.4.2. Observed Climate Change Effects across Ocean Regions

While climate change is evident across the Ocean, its impacts vary between ocean regions (Table 30.2; Figures 30-2, 30.3 and 30.5; WGI AR5 Chapter 3). Considerable differences in system understanding, data availability, and the potential contribution of climate change in relation to other factors add to the heterogeneity of the assessment. Attribution of regional heat content changes are less certain than on a global level, but warming patterns have been detected in all basins (Table 30-2, Figure 30-2) and attributed to anthropogenic influence with *high confidence* (WGI AR5 Chapters 3, 10.3.1, and 10.4), with the important exception of Eastern Boundary Upwelling Ecosystems (EBUE), where two of the four major upwelling systems show no change in sea surface temperatures over the last 60 years (table 30-2). These differences may relate to geographical differences that contribute to different levels of change in wind stress and hence upwelling, which influences the amount of cooler water flooding the surface layers of the water column in these regions (see Box 30.8.2). Recent research shows deep penetration of warming in some regions, and declining oxygen levels *(low to medium confidence*, see Table 18-3). Regional estimates of CO_2 uptake are in line with global estimates, and ocean acidification has been detected and attributed with *high confidence* in most regions (WGI AR5 Chapter 3.8.1, 30.5, Box CC-CAO). Table 18-3 shows confidence in detection and attribution of observed climate change impacts across the world's major open ocean regions, with the exception of the Deep Sea.

[INSERT TABLE 18-3 HERE
Table 18-3: Confidence in detection and attribution of observed climate change effects across ocean regions, based on expert assessment in Chapter 30.5 (respective subsections are given below). Confidence levels assigned are for detection / attribution, respectively.]

The high latitude spring bloom systems of the Northern Hemisphere show strong warming and associated effects (see above). In the North Pacific, the Bering Sea is one of the productive sub-regions and has undergone major changes in recent decades as a result of climate variability, climate change and fishing impacts (Litzow *et al*., 2008; Mueter and Litzow, 2008; Jin *et al*., 2009; Hunt, 2010). Loss of sea ice has led to the retreat of the cold pool in the Bering Sea, and northward expansion of productivity.

Marginal seas such as the East China Sea are also warming rapidly. There is *high confidence* that this has contributed to declining primary productivity and fisheries yields as well as other ecological changes (30.5.4.1). However, other human pressures including over-fishing, habitat alteration, and nutrient loading are important contributing factors and it is difficult to disentangle these from the impacts of climate change.

Semi-enclosed seas like the Black and Baltic Seas and the Arabian / Persian Gulf have their own specific environmental conditions and responses (30.5.3.1). The Baltic and Black Seas show an expansion of hypoxic zones attributed in part to climate change (*medium confidence*). Coral reefs in the Arabian / Persian Gulf and Red Seas appear to have experienced widespread bleaching in 1996 and 1998 associated with elevated temperature. It is highly likely that these impacts are associated with long-term variability that has, combined with climate change, resulted in warmer than normal summer sea temperatures that now periodically exceed the thermal tolerance of reef-building corals (*high confidence*).

Warming of the Mediterranean has been associated with mass mortality events as well as with invasions and subsequent spread of new warm water species, which has resulted in the 'tropicalisation' of fauna (30.5.3.1.3). In many tropical regions and the subtropical gyres of the Pacific, Indian, and Atlantic, periodic heat stress combined with other local stresses has driven mass coral bleaching and mortality (see also Box CC-CR, 30.5).

In other regions, such as the California Current upwelling system, high-quality databases support *very high confidence* in the detection of ecological changes, but attribution of these to climate change can be made with *very low confidence* due to large-scale environmental variability associated with ENSO and the PDO.

In overall terms, attributing observed local and regional changes in marine species and ecosystems to climate change remains an important question for on-going research (Stock *et al*., 2010).

_____ START BOX 18-4 HERE _____

Box 18-4. Differences in Detection and Attribution of Ecosystem Change on Land and in the Ocean

Marine and terrestrial ecosystems differ in fundamental ways. Gradients in turbulence, light, pressure and nutrients uniquely drive fundamental characteristics of organisms and ecosystems in the ocean. While the critical factor for transporting nutrients to marine primary producers ocean mixing driven by wind, water is the primary mode for transporting nutrients to land plants. In addition to these characteristics, marine ecosystems are often more technically difficult and costly to explore than terrestrial equivalents, which explains the low number and shorter scientific studies of marine ecosystems (Hoegh-Guldberg and Bruno, 2010). The latter has restricted the extent to which we can accurately detect and attribute of changes within the Ocean.

Impacts of climate change in terrestrial and marine systems differ significantly for the same types of measures, e.g., species phenology and range shifts, leading to differences in expert's interpretations of the data and possibly divergent levels of confidence in detection and attribution. There are also fundamental differences in exposure of organisms to recent warming, their biological responses and our ability to detect change through observations. Changes in temperature of ocean systems have generally been less than those of terrestrial ecosystems over the last four decades (Burrows *et al*., 2011). Furthermore, despite higher variability the horizontal spatial gradient of temperature change (°C km^{-1}) is generally much higher in terrestrial ecosystems than in marine ecosystems. All else being equal, the net result is that species have generally needed to move much shorter distances in terrestrial ecosystems to stay within their preferred climates, also due to the influence of the topography such as mountain ranges (Burrows *et al*., 2011), although many marine species can potentially exploit strong vertical thermal gradients to attenuate the need for range shifts in response to warming.

Species and ecosystems may respond very differently to these climate signals in ways that influence the ability to detect change. For example, a comparison of ectotherm species (i.e., species that do not actively regulate their body temperatures such as reptiles and fish) indicates that marine species' ranges have tracked recent warming at both their poleward and equatorial range limits, while many other terrestrial species' ranges have only tracked warming at their poleward range limits (Sunday *et al*., 2012). Biological processes influencing phenological shifts may also differ substantially between systems. For example, the effect of climate on the timing of flowering of terrestrial plants at high latitudes is only moderately influenced by confounding effects, whereas the timing of phytoplankton blooms in high latitude marine systems is highly dependant on ocean temperature and associated stratification and changes in nutrient availability.

18.4. Detection and Attribution of Observed Climate Change Impacts in Human and Managed Systems

Observed impacts on human systems have received considerably less attention in previous IPCC reports and the scientific literature, compared to observed impacts on natural systems. Human systems' "normal state in the absence of climate change" is almost never stationary. Confounders other than climate change have been and continue to

drive the normal evolution of these systems with climate often playing a relatively minor role. It is therefore difficult to detect and attribute the signal of climate change in the majority of human systems. The food system is one noteworthy exception. There is emerging literature estimating the climate *sensitivity* of many sectors within the human system, yet climate impacts are often not detectable over the impacts from non-climate confounders.

For some human systems, the only observed situations where a climate signal had a detectable and sometimes attributable impact are during extreme weather events. Extreme events for a variety of sectors are therefore discussed in a single section below. Overall, the literature has made significant progress for certain sectors, such as food systems, since AR4. The following sections provide a synthesis of findings with regard to food systems, cities, economic systems, human health, human security and human livelihoods and poverty, which are documented in greater detail in chapters 7, 8, 9, 10, 11, 12 and 13. We have also incorporated evidence from regional chapters and further available literature, especially for the discussion of extreme events, human security, and observed changes in indigenous communities.

18.4.1. Food Production Systems

Over the past several decades food production systems across the globe have changed significantly. Factors other than atmospheric CO_2 or climate, such as cultivar improvement and increased use of synthetic fertilizers, herbicides, and irrigation were primarily responsible for these changes. In a number of settings the effects of past changes in weather or CO_2 have been regarded as noise that obscures other effects of interest (Bell and Fischer, 1994). Due to the large number and relative importance of non-climate drivers in food systems and food security, formal detection and attribution of impacts is extremely difficult for this sector. The majority of confounders, such as fertilizer application or adoption of modern crop varieties, are not well measured in terms of their distribution across space and time. Further, it is difficult to quantify the exact relationship between these confounders and outcomes of interest (e.g., crop yields). The identification of a unique fingerprint from greenhouse gas emissions in these systems is therefore impractical. There are no known studies simulating historical trends in food-related outcomes with and without changes in anthropogenic emissions of greenhouse gases. A possible exception is the study by Auffhammer et al. (2006) who compared predicted rice yields in India using climate model simulations of temperature in the late 20^{th} century with yields estimated from observed temperatures for 1930-1960, using the latter period as a surrogate for climate without recent changes in greenhouse gases. They find that rice yields in a world without greenhouse gas emissions would have been significantly higher, thus attributing negative impacts to emissions.

18.4.1.1. Agricultural Crops

In order to make attribution statements regarding crop changes to climate change, one needs to make assumptions about how farmers adapt. Some studies assume that farmers do not change their practices or technology as a response to changes in climate during the period of study. This may be a valid assumption in some cases (Schlenker and Roberts, 2009) yet there is evidence of significant adaptation to climate via technology for a variety of crops and locations (Zhang *et al*., 2008b; Liu *et al*., 2010).

A significant number of studies have provided impact estimates of observed changes in climate on cropping systems over the past few decades (see chapter 7.2). Based on this literature, there is *medium confidence* that over the past several decades observed climate trends have adversely affected wheat and maize production for many regions. There is *medium confidence* that observed climate trends since 1980 have had adverse impacts on global total production of these crops (Figure 7-2). There is *medium confidence* that climate change impacts on rice and soybean yields over this time period have been small in major production regions and globally (Figure 7-2). There is *high confidence* that in some cold regions warming has benefitted crop production in recent decades (Jaggard *et al*., 2007; Chen *et al*., 2011).

Many crop modeling studies focus on production for single sites or provinces and/or short time-series, rendering attribution of observed yields to climate change problematic. Some recent studies, however, examine outcomes at the continental or global scale (Lobell and Field, 2007; You *et al*., 2009; Lobell *et al*., 2011). At this scale, observed

trends in some climatic variables, including mean summer temperatures, can be attributed to anthropogenic activity (e.g., Jones *et al.*, 2008). These studies indicate that this observed warming has had significant negative impacts on trends in crop yields for certain crops. Figure 7-3 presents a summary of the detectability of changes in growing season climate and crop yield changes, as well as the ability to attribute changes to climate and CO_2 trends (in the case of yield changes) or anthropogenic emissions (in the case of growing season climate changes).

The recent literature has increasingly documented attibutable trends not only in the seasonal averages of climate variables, but also for extremes. Extreme rainfall events are widely recognized as important to cropping systems (Rosenzweig *et al.*, 2002). Changes in the patterns of rainfall extremes have been attributed to anthropogenic activity (Min *et al.*, 2011). A similar observation has been made for frost patterns in nearly every region of the world (Alexander *et al.*, 2006; Zwiers *et al.*, 2011), as well as for the occurrence of very hot nights (WGI AR5 Chapter 10.6.1). High nighttime temperatures are harmful to most crops, but this effect has been observed most frequently for rice yield (Peng *et al.*, 2004; Wassmann *et al.*, 2009; Welch *et al.*, 2010) and quality (Okada *et al.*, 2009). Daytime extreme heat is also damaging and sometimes lethal to crops (Porter and Gawith, 1999; Schlenker and Roberts, 2009). At the global scale, trends in annual maximum daytime temperatures have been attributed to greenhouse gas emissions (Zwiers *et al.*, 2011).

Further, changing atmospheric conditions are affecting crops both positively and negatively. It is *virtually certain* that the dramatic increase in atmospheric CO_2 conentrations since preindustrial times has improved water use efficiency and yields most notably in C_3 crops. It is important to note that these effeects are of relatively minor importance when explaining total yield trends (Amthor, 2001; Long *et al.*, 2006; McGrath and Lobell, 2011).

Emissions of CO_2 have been associated with ozone (O_3) precursors (Morgan *et al.*, 2006; Mills *et al.*, 2007). There is *high confidence* that elevated O_3 currently suppresses global output of major crops, with reductions estimated at roughly 10% for wheat and soy and 3-5% for maize and rice (Van Dingenen *et al.*, 2009). Detected impacts are most significant for India and China, but can also be found for soybean production in the United States in recent decades (Fishman *et al.*, 2010).

18.4.1.2. Fisheries

There is a large literature focusing on the relationship between the dynamics of marine fish stocks and climate variability, suggesting that climate change has impacts on these stocks and on the fisheries that exploit them (Hollowed *et al.*, 2001; Roessig *et al.*, 2004; Shriver *et al.*, 2006; Brander, 2007). Some fisheries and aquaculture do not show evidence of climate change impacts (e.g. aquaculture in the UK and Ireland, Callaway *et al.*, 2012), while many others do with both positive and negative changes (30.6.2.1; Figure 30-15B, see also 18.3.4).

There is *high confidence* in the detection and attribution of shifts in the spatial distributions of marine fishes (Perry *et al.*, 2005, 30.6.2.1) and in the timing of events like spawning and migration (Sydeman and Bograd, 2009, 30.4). The challenges produced by ocean warming and acidification vary from region to region, however, with decreases in many regions and increases (probably short-term) in some regions, especially at high latitudes (30.6.2.1; Figure 30-15B). The ability to attribute detected changes to climate change is confounded by the influence of other factors such as harvesting, habitat modification, technological development, pollution, and interannual to decadal climate variability (Brander, 2010).

Ecosystems such as kelp forests, mangroves and coral reefs provide habitat to fisheries which provide food and income to hundreds of millions of people worldwide. The strong linkage between increasing sea temperatures, the decline of carbonate reef frameworks (see Box 18-3), and habitat for key fisheries resources underpins a strong traceable account from global climate change to impacts on coastal fisheries (*high confidence*; see Box CC-CR, Figure 30-12, 30.5.2 - 30.5.4, 30.5.6).

Similar linkages between climate change and fisheries can be made for pelagic fisheries such as tuna. Shifts in tuna fisheries have occurred in the Indian and Pacific oceans, driven by climate variability (ENSO). The detected changes

are consistent with the thermal biology of these important species and projections of change under further changes to ocean temperature (*high confidence*, 30.5.1.1.1, 30.5.6.1, 30.6.2.1).

18.4.1.3. Food Security

Food security depends crucially on the production and storage of food. The evidence on observed climate change impacts on food production therefore has implications for food security. Further, the term food security needs to be discussed at different spatial scales, as there is enough food available per capita globally, yet a significant share of humankind is affected by permanent or periodic food shortages. Quantifying the impact of climate change on food security is extremely challenging at any scale as there are significant numbers of non-climate confounders which affect food security at various spatial scales (7.1).

One measurable indicator of food security is the global price of food. Food prices have dropped slowly throughout the last century, yet even since AR4 there have been several periods of food price increase and periodic spikes in food prices (figure 7-4). Increased demand for crops recently has been partially driven by biofuel productions, which is both mandated by policy and market driven by oil price spikes (Roberts and Schlenker, 2010; Mueller *et al*., 2011; Wright, 2011). There is some evidence that supply side fluctuations also impacted food prices (figure 7.4). While not all significant weather events result in food price spikes, high price episodes are more probable during periods with low stored stocks. This can be due to more slowly growing supply relative to demand. Government interventions, such as export bans, can exacerbate price responses to weather events (Dawe, 2008). There is some recent evidence that climate trends have had some influence on global supply. Lobell *et al*. (2011) estimated a price increase of 19% due to the impacts of temperature and precipitation trends on supply, or an increase of 6% once the beneficial yield effects of increased CO_2 over the study period were considered.

18.4.2. Cities and Urbanization

The world continues to urbanize rapidly. Both new and existing urban systems are evolving due to rapidly changing incomes, institutions and population. There is robust evidence across a set of case studies that climate has changed in many urban areas and that variability has increased, consistent with climate change projections. The most robust evidence has emerged from observational data for mean annual temperature and precipitation rates, days of extreme temperature, number of extreme rainfall events, and rate of sea level rise (8.2.2.1, 8.3). These shifts are associated with an increased probability of flooding, droughts, inland flooding, coastal flooding, storm surges, heat waves, and declines in the number of extreme cold days (see Hunt and Watkiss, 2011; Romero-Lankao and Dodman, 2011; Rosenzweig *et al*., 2011for recent reviews).

Detection and attribution of climate change impacts in cities is extremely difficult due to the large role of other confounding factors. Opportunities to discern climate change signals in cities are complicated by the pattern and pace of urbanization which have consequences for local environmental conditions such as intensification of urban heat islands, land subsidence associated with groundwater withdrawal, and heightened flooding probability resulting from increase of impervious surfaces. These conditions interact with ongoing climate change and as a result make it difficult to provide evidence and attribution agreement of climate change signals in cities given the current state of observed data and models.

18.4.3. Economic Impacts, Key Economic Sectors and Services

18.4.3.1. Economic Growth

A negative cross sectional correlation between per capita income and temperature has been observed both across countries (Nordhaus, 2006) and across regions within countries (Dell *et al*., 2009a; Dell *et al*., 2009b). Such correlations should never be interpreted as causal, because the underlying mechanisms are usually complex. In low income countries, careful tracking of incomes and temperatures over an extended period, taking into account

important confounders, shows that higher annual temperatures as well as higher temperatures averaged over 15 year periods result in substantially lower economic growth (Dell *et al.*, 2012). This effect is not limited to the level of per capita income, but also to its rate of growth.

Broadly, a 1 degree Celsius increase in annual average temperature has been found to lower economic growth in the same year by 1.3%, which is both statistically and economically significant (Dell *et al.*, 2012). Based on 15 year averages of weather, which is a measure of climate, the impacts become larger (1.9% for low income countries). The same relationships do not hold for high income countries. Generally, higher temperatures affect economic growth through impacts on the agricultural and industrial sectors (Dell *et al.*, 2012). One proposed mechanism for this is the impact of heat stress on workers in the workplace (Dash and Kjellstrom, 2011). Temperature shocks negatively affect the growth of developing countries' exports, for which 1 degree Celsius of warming in a given year reduces the growth rate of its exports by 2.0-5.7% (Jones and Olken, 2010). The export sectors most affected are agricultural and light manufacturing exports. There is no detectable effect for higher income countries (Jones and Olken, 2010).

18.4.3.2. Energy Systems

Energy production and consumption is growing rapidly globally, with much of the growth taking place in low income and emerging economies. Due to the large number of non-climate confounders, the literature on detection and attribution for the energy sector is sparse. There is a significant literature identifying the climate sensitivity of various parts of the energy sector. Higher temperatures have been shown to raise the demand for cooling and lower the demand for heating. Cooling demand is largest in the summer and it has been shown for some areas that peak loads during the summer months have increased and that this peak is highly correlated with summer maximum temperatures (Franco and Sanstad, 2008). The literature showing the opposing effects of warmer winters and summers on electricity and gas demand using statistical methods have confirmed this U-shaped relationship of energy and electricity demand in temperature for the United States and elsewhere (Isaac and van Vuuren, 2009; Akpinar-Ferrand and Singh, 2010; Deschênes and Greenstone, 2011).

Production losses from thermal power plants increase when temperatures exceed standard design criteria (e.g., Erdem and Sevilgen, 2006), as would be expected to occur more frequently under climate change. Power generation facilities may also experience performance losses and other impacts related to changes in access to and temperature of cooling water, as well as sea level rise and extreme weather events (Durmayaz and Sogut, 2006; CCSP, 2007; Kopytko and Perkins, 2011, see also 10.2). Further, solar photovoltaic cells become less efficient during hot days (Skoplaki and Palyvos, 2009).

The impacts of higher temperatures and extreme weather events on energy delivery, transmission and distribution vary across different empirical studies, facility characteristics, geographic regions, and other factors. Barges and ocean vessels that transport energy resources have been shown to be particularly vulnerable to hurricanes, storms, and flooding; pipeline performance can be affected by increasing ambient and soil temperatures, as well as extreme events (CCSP, 2007, see also 10.2). Some studies have quantified the general relationship between temperature and electricity transmission and distribution infrastructure, finding that increased temperatures can accelerate the aging of transformer insulation, lead to efficiency losses, and create power system reliability issues (Swift *et al.*, 2001; Li *et al.*, 2005; Askari *et al.*, 2009).

18.4.3.3. Tourism

Tourism is a climate sensitive economic sector and ample research has been performed to understand its sensitivity to climate change and impacts of (future) climate change on tourism, yet little to no literature has focused on detection and attribution of observed impacts (cf. Scott *et al.*, 2008, see also 10.6). A comparatively well-studied area is the climate sensitivity of wintersports in lower lying areas. For example, the increase in investment in artificial snow machines in the European Alps can be attributed with *high confidence* to a general decrease of snow depth, snow cover duration and snow fall days since the end of the 1980's for low-elevation mountain stations (Durand *et al.*, 2009; Valt and Cianfarra, 2010; Voigt *et al.*, 2011), which in turn has been attributed to anomalous

warm winter temperatures over the past 20 years (Marty, 2008). Increased variability in precipitation, shrinking glaciers and milder winters have been shown to negatively affect visitor numbers in winter sports areas in Europe and North America (Becken and Hay, 2007). Eijgelaar *et al*. (2010) argue that so-called "last chance tourism" is a strong pull for tourists to visit Antarctica to admire the glaciers while they still can. Farbotko (2010) uses a similar mechanism to explain the rise in popularity of Tuvalu as a destination choice. In contrast, Zeppel (2012) states a low level of concern for coral bleaching by tourists visiting the Great Barrier Reef.

18.4.4. Impacts of Extreme Weather Events

The impacts of extreme weather events depend on the frequency and intensity of the events, as well exposure and vulnerability. Climate change is expected to affect both the frequency and intensity of extreme weather events including extreme temperature, droughts, heavy rainfall, and tropical and extratropical cyclones (IPCC, 2012). There is *low to high* confidence that such changes have already occurred, depending on the type of extreme (WGI AR5 Chapter 10.6). However, the impacts of extreme weather events also depend on the vulnerability and exposure of systems. It is possible that climate change can affect vulnerability and exposure, but both can also be affected by non-climate confounders, most notably economic development.

18.4.4.1. Economic Losses due to Extreme Weather Events

Extreme weather events can have economic impacts arising from damage to private and public assets as well as the temporary disruption of economic activities. Although immediate economic impacts are most noticeable, long-term impacts are also possible, as are impacts beyond the area directly affected by the event. Some economic impacts are not readily monetizable and are thus excluded from most economic assessments (Handmer *et al*., 2012, their chapter 4.5.1, 4.5.3).

There is *high confidence* that economic costs of extreme weather events have increased over the period 1960-2000, with insured losses increasing more rapidly than overall losses (Handmer *et al*., 2012, their chapter 4.5.3.3, 4.5.4.1). This is also reflected by an increase in the frequency of extreme weather-related disasters over the same period (Neumayer and Barthel, 2011). Recent studies from Latin America (Mexico, Colombia, Peru) highlight both variability and positive trends in disaster frequency, (unadjusted) losses and other damage metrics (Saldaña-Zorrilla and Sandberg, 2009; Marulanda *et al*., 2010; Rodriguez-Oreggia *et al*., 2012; Huggel *et al*.). However, there is *high confidence* that the greatest contributor to increased cost is rising exposure associated with population growth and growing value of assets (Bouwer *et al*., 2007; Bouwer, 2011; Barthel and Neumayer, 2012; Handmer *et al*., 2012, their Chapter 4.2.2, Box 4.2 and 4.5.3.3).

To account for changes over time in the value of exposed assets, many studies attempt to normalize monetary losses by an overall measure of changes in asset value. Although there is considerable year-to-year variability associated with the occurrence of extreme weather events, most studies have found no detectable trend in normalized losses consistent with anthropogenic climate change. Studies of normalized insured losses, that in general meet higher data quality standards than data on overall losses due to thoroughly monitored payouts, have focused on developed countries including Australia, Germany, Spain, the US, Spain (Changnon, 2007; Changnon, 2008; Changnon, 2009a; Changnon, 2009b; Barredo *et al*., 2012; Barthel and Neumayer, 2012, see also 10.7.3; Sander *et al*., 2013), Studies of normalized losses from extreme winds associated with hurricanes in the US (Miller *et al*., 2008; Pielke Jr *et al*., 2008; Schmidt *et al*., 2010; Bouwer and Botzen, 2011) and the Caribbean (Pielke Jr *et al*., 2003), tornadoes in the US (Brooks and Doswell, 2002; Boruff *et al*., 2003; Simmons *et al*., 2012) and wind storms in Europe (Barredo, 2010) have failed to detect trends consistent with anthropogenic climate change, although some studies were able to find signals in loss records related to climate variability, such as century-scale damage and loss of life due to wildfires in Australia related to El Niño Southern Oscillation and Indian Ocean dipole phenomena (Crompton *et al*., 2010), or decadal-scale typhoon loss variablilty in the Western North Pacific (Welker and Faust, 2013).

Although there are a number of data issues that may limit the reliability of assessments of the economic impacts of extreme weather events (Crompton and McAneney, 2008; Bouwer and Botzen, 2011; Nicholls, 2011; Handmer *et*

al., 2012, their Chapter 4.5.3.3, see also 10.7.3), there is *limited evidence* of a trend in the economic impacts of extreme weather events that is consistent with a change driven by observed anthropogenic climate change.

18.4.4.2. Detection and Attribution of the Impacts of Single Extreme Weather Events to Climate Change

Although most studies of the relationship between climate change and extreme weather events have focused on changes over time in their frequency and intensity, a few studies have focused on the contribution of climate change to specific events (WGI AR5 Chapter 10.6.2). Assessing the contribution of climate change to a specific event poses particular challenges, both in terms of methodology and communication of results (Allen, 2011; Curry, 2011; Hulme *et al*., 2011; Trenberth, 2011). If climate change was among the drivers for a specific extreme weather event, there remains the question how this contribution translates into associated impacts and damages. Only a few studies have attempted to evaluate the role of climate change in the impacts of individual extreme weather events. Pall et al. (2011) and Kay et al. (2011), using observational constraints on climate and hydrologic model simulations, concluded that greenhouse gas emissions have increased the probability of occurrence of a comparable flooding event in autumn 2000 over the UK. A similar study for recent high flood years in the Okavango Delta, Botswana, found a decreased probability of high floods (Wolski *et al*., 2013). The autumn 2000 UK studies did not evaluate the relative role of other factors, however, while the Okavango study argued that the effects of land use, land cover, and water management change in the Okavango Basin were negligible.

In highly temperature-sensitive regions such as high mountains there is *high confidence* that several extreme impact events of the 20th and 21st century can be qualitatively attributed to effects of climate change, namely glacier lake outburst floods due to glacier recession and subsequent formation of unstable lakes (Evans and Clague, 1994; Carey, 2005; Bajracharya and Mool, 2009), debris flows from recently deglaciated areas, and rock fall and avalanches following the loss of mechanical support accompanying glacier retreat (Haeberli and Beniston, 1998; Oppikofer *et al*., 2008; Huggel *et al*., 2012b; Stoffel and Huggel, 2012, see also 18.3.1.3). Similar multiple-step approaches can be used to evaluate the contributions of anthropogenic emissions to recent damaging extreme events (see Table 18-4).

Irrespective of whether a specific event can be attributed in part to climate change, there is ample evidence of the severity of related impacts on people and various assets. Both low- and high-income countries have been strongly impacted by extreme weather events in recent years, but the impacts relative to economic strength have been higher in low-income countries (Handmer *et al*., 2012). Similarly, at the national scale, poor or elderly people have been disproportionately affected, as documented for Hurricane Katrina in the US in 2005 (Elliott and Pais, 2006; Bullard and Wright, 2010) or the 2003 European heat wave (Fouillet *et al*., 2008). Exacerbating effects of extreme weather events are mostly of non-climatic nature, including increasing exposure and urbanization, land-use changes including deforestation, or increasingly vulnerable infrastructure.

An illustrative case is the flood damage in New York City during the landfall of Hurricane Sandy in 2012. The storm surge hazard is expected to increase with rising local sea level as a result of anthropogenic emissions, notwithstanding any changes in associated meteorology (Lin *et al*., 2012). However, increased exposure of buildings, people, and infrastructure in New York City has probably contributed to a much larger increase in risk over the past century (Aerts *et al*., 2013). Against that increase, though, there has been a major investment in reducing vulnerability and increasing resilience, partly in response to past extreme events (Tollefson, 2013). Determining a contribution from anthropogenic climate change amongst such large competing factors, including diagnosing the forces behind adaptation, remains a major challenge.

[INSERT TABLE 18-4 HERE

Table 18-4: Illustrative selection of some recent extreme impact events for which the role of climate has been assessed in the literature. The table shows confidence assessments as to whether the associated meteorological events made a substantial contribution to the impact event, as well as confidence assessments of a contribution of anthropogenic emissions to the meteorological event. The assessment of confidence in the findings is not necessarily a conclusion of the listed literature but rather results from assessment of the literature. Assessment of the role of

anthropogenic emissions in the impact event requires a multi-step evaluation. Partly based on Coumou and Rahmstorf (2012).]

18.4.5. Human Health

IPCC AR4 (Confalonieri *et al*., 2007) concluded that there was *weak to moderate evidence* (with *low to medium confidence*) of climate change effects on three main categories of health exposures: vectors of human infectious diseases (changes in distribution), allergenic pollen (changes in phenology), and extreme heat exposures (trend in increased frequency of very hot days and heat wave events).

For pollen production, changes in phenology have been consistently observed in mid to high latitudes with, for example, earlier onset in Finland (e.g., Yli-Panula *et al*., 2009) and Spain (D'Amato *et al*., 2007; García-Mozo *et al*., 2010, see also 4.3). In North America, the pollen season of ragweed (*Ambrosia* spp.) has been extended by 13-27 days since 1995 at latitudes above 44°N (Ziska *et al*., 2011). Allergic sensitization of humans has changed over a 25 year period in Italy, but the attribution to observed warming remains unclear (Ariano *et al*., 2010).

The most direct potential health impact of climate change is through exposure to higher temperatures. The association between very hot days and increases in mortality in temperate populations is very robust but depends on factors such as geographic location, the age structure of the population, and the prevalence of air-conditioning (11.2.2). Seneviratne *et al*. (2012) concluded that there is *medium* to *high confidence* in detection of non-zero trends in increasing frequency of hot days and nights, decreasing frequency of cold days and nights, and in the duration of heat waves and warm spells over temperate subcontinental regions, and that on the global scale it is *likely* that anthropogenic emissions have had at least a minor role in these changes. However, the translation of this trend in hazard to a trend in exposure is complicated by evidence of changes in social, environmental, and behavioral factors (e.g., Carson *et al*., 2006).

Overall, Confalonieri *et al*. (2007) concluded that there was a lack of evidence for observed effects in human health outcomes, and this remains the case. Disease patterns change considerably over time due to changes in exposures (e.g. smoking patterns), control measures (vaccination, drug resistance), and population structures (population aging). Therefore, observations of trends in health outcomes provide little insight into a role of climate change. The detection of a climate-change-induced trend for any health outcome requires that changes in reporting over time need to be taken into account. Adaptation is an added confounding factor, as health agencies are mandated to intervene, and people are liable to alter exposures, as soon as risks are identified. With regard to temperature-related mortality, Christidis *et al*. (2010) examined the roles of changing exposure and health care and of anthropogenic climate change in observed trends in excess mortality during cool and warm days. They concluded that anthropogenic climate change had at most a minor role in trends in temperature-related mortality in England and Wales over the three decades, relative to a major role for the combined trends of exposure and health care; however, assessment of the existence of a minor role for anthropogenic climate change may have been sensitive to the lack of interseasonal mortality relationships in their modeling setup (Rocklöv *et al*., 2009; Ha *et al*., 2011).

There is *limited evidence* regarding the role of observed warming in changes in tick-borne disease in mid to high latitudes. The upsurge of tick borne encephalitis (TBE) in the 1980-90s in central and Eastern Europe has been attributed to socio-economic factors (human behavior) rather than temperature (Šumilo *et al*., 2008; Šumilo *et al*., 2009). Changes in the observed incidence of TBE in central Sweden remain unexplained however (Randolph, 2010). Changes in the latitudinal and altitudinal distribution of ticks in Europe are consistent with observed warming trends (e.g., Gray *et al*., 2009), but there is no evidence so far of any associated changes in the distribution of human cases of tick-borne diseases. In North America, a northward expansion of the distribution of the tick vector (*Ixodes scapularis*) was observed in the period 1996 to 2004 (Ogden *et al*., 2010).

There is *limited evidence* of a change in the distribution of rodent-borne infections in the US (plague and tularaemia) consistent with observed warming (Nakazawa *et al*., 2007). Specifically, a northward shift of the southern edge of the distributions of the diseases (based on human case data for period 1965-2003) was observed. There was no change detected in the northern edge of the distributions though.

Malaria incidence has been monitored in the Kericho region of Kenya for over three decades, with a trend toward increasing incidence in the late 1990s. A local warming trend also occurred during the end of the observation period (Omumbo *et al*., 2011). Other studies have confirmed that malaria incidence is sensitive to temperature and rainfall effects in nonlinear ways, but it is a complex ecological system, with changes in vector, human and parasite behavior that need to be considered. A mosquito-human model, however, has shown that predicted malaria cases exhibit a strongly non-linear response to observed warming (Alonso *et al*., 2011). A detailed review by Chaves and Koenraadt (2010) concludes that there is *robust evidence* that decadal temperature changes have played at least a minor role in the malarial trends of the East African highlands, arguing that it may the combination of many factors that has been crucial. However, temperature trends should nonetheless not be considered the main or sole cause of such changes in malaria in the east African highland region, and globally the dominant trend has been a contraction of the geographical range of malaria and a decrease in malaria endemicity over the past century (Gething *et al*., 2010).

18.4.6. Human Security

18.4.6.1. Violent Conflicts and Social Disruptions

A small number of studies have examined the connection between the collapse of civilizations and large-scale climate disruptions like severe or prolonged drought. DeMenocal (2001) summarized the evidence for a number of cases. However, attribution to climate change can be made with only *low confidence* due to limitations on both historical understanding and data. Similarly, a small number of studies have suggested that levels of warfare in Europe and Asia were relatively high during the Little Ice Age (Parker, 2008; Brook, 2010; Tol and Wagner, 2010; White, 2011; Zhang *et al*., 2011), but again attribution to climate can only be made with *low confidence*. There is no evidence of a climate effect on inter-state conflict in the post-WWII period.

Most of the recent research in this area has focused on the relationship between climate variability – as opposed to climate change – and civil conflict, with most studies focusing on Africa. Although some studies have established statistical relationships (Miguel *et al*., 2004; Hendrix and Glaser, 2007; Burke *et al*., 2009; Hsiang *et al*., 2011), their results have been questioned (Buhaug *et al*., 2010; Buhaug and Theisen, 2012; Slettebak, 2012; Theisen *et al*., 2012) and no consensus has been reached. Both the detection of a climate effect on civil conflict and its attribution to climate change can be made with only *low confidence*.

Very recent work has begun to examine links between climate variability and small-scale communal violence (Adano *et al*., 2012; Butler and Gates, 2012; Hendrix and Salehyan, 2012; Raleigh and Kniveton, 2012; Theisen, 2012), but it is too early attach anything but *low confidence* to the detection of a climate effect and its attribution to climate change.

Finally, a number of efforts have been made to establish a link between violent crime and high temperatures (Anderson, 1987; Field, 1992; Anderson, 2001; Rotton and Cohn, 2001; Butke and Sheridan, 2010; Breetzke and Cohn, 2012; Gamble and Hess, 2012). However, the findings remain controversial with most studies identifying other factors as explaining variations in rates of violent crime (Kawachi *et al*., 1999; Fajnzylber *et al*., 2002; Neumayer, 2003; Cole and Gramajo, 2009) and the detection of a temperature effect on violent crime and its attribution to climate change can be made only with *low confidence*.

18.4.6.2. Migration

Large population movements, in response to climatic events, are sometimes considered a human security issue. Empirical detection of such relationships has been slow because data sets on population movements are not yet well developed. Moreover, the attribution of migration to climate change is difficult because economic, political, social, demographic, and other environmental drivers interact with climatic drivers to influence migration (Black *et al*., 2011). Few studies measure or empirically demonstrate how rainfall or temperature changes cause a strengthening

or weakening of the various forces driving migration, especially income levels and income variability (Lilleør and van den Broeck, 2011).

Some large sample studies have been able to detect population movements in response to natural disasters (Smith *et al*., 2006b; Boustan *et al*., 2012) and climate-induced agricultural losses (Feng *et al*., 2012) in the United States, where data quality is high. In both the United States and African contexts, crop losses have also been associated with rural to urban population movements within a country (Barrios *et al*., 2006; Feng *et al*., 2012). By statistical attribution, Marchiori *et al*. (2012) estimate that anomalous temperature and rainfall have displaced roughly 128,000 people per year in Sub-Saharan Africa during 1960–2000.

Drought has prompted both short-distance (Tacoli, 2009) and long distance international migration, with the Mexican drought of the 1990s providing an example of the latter (Saldaña-Zorrilla and Sandberg, 2009; Feng *et al*., 2010). In Burkina Faso, temporary moves to other rural areas have increased as a result of a reduction in rainfall (Henry *et al*., 2004). Even though there is a statistically significant relationship between migration outcomes and rainfall variability, Kniveton et al. (2011) report from own fieldwork that only 27 of 3,517 households identified rainfall as a driver of migration.

18.4.7. Rural Areas, Livelihoods and Poverty

Much like for the other sectors discussed above, available research about climate related impacts on livelihood and poverty distinguishes between climate sensitivity and impacts driven by climate change (e.g. gradual temperature changes, and changes in climate variability). A climate sensitivity of livelihoods has been observed with *high confidence*, while there is a paucity of evidence about impacts of gradual climate change on livelihoods and poverty. Detection of changes in livelihood aspects is often difficult due to a lack of data. If trends are actually detected, many confounding factors contribute to detected changes. Because of the important confounders and the current limitations in attributing climate extremes and changes in variability to climate change (see 18.4.4.2), confidence in attribution of changes in livelihoods and poverty to climate change is typically *low* or *very low* (Nielsen and Reenberg, 2010).

Primarily negative impacts from historical climate variability and extremes, and to a much lesser degree from climate change, have been observed on people's natural, physical, economic, social and cultural assets (see Table 18-5). Impacted natural assets include land, water, fish stocks and livestocks (Osbahr *et al*., 2008; Bunce *et al*., 2010). There is growing concern about negative effects of climate change and ocean acidification on marine and coastal fisheries, and the livelihoods of fisherfolks (Cooley and Doney, 2009; Badjeck *et al*., 2010), however there is no literature available discussing observed impacts.

[INSERT TABLE 18-5 HERE
Table 18-5: Cases of regional livelihood impacts attributable with varying degree to weather- and climate related events, climate change or climate variability.]

Natural and physical assets (e.g. settlements) of many poor people have been affected by weather- and climate-related extreme events. Poor people living in hazard exposed areas in Africa and Latin America were affected by floods and landslides in the 1990's and 2000's with some upward trend mainly due to increased urbanization (*low to medium confidence* for increasing floods and landslides, *high confidence* for increasing number of people affected) (Douglas *et al*., 2008; Hardoy and Pandiella, 2009). Although there is evidence of a decline in average precipitation in West Africa since 1960 (Lacombe *et al*., 2012) including repeated droughts (Dietz *et al*., 2004; Armah *et al*., 2011), which in some cases has been partly attributed to anthropogenic climate forcing (Jenkins *et al*., 2005; Biasutti and Giannini, 2006), there is *limited evidence* of changes in poverty among affected small-holder and subsistence farmers that can be attributed to climate drivers such as rainfall decline and droughts.

In rural areas correlations have been found between climatic variability and extreme events and livelihood diversification in West Africa (Nielsen and Reenberg, 2010) and Mexico (Eakin, 2006) and in Mexico frequent

impacts of natural disasters correlate with substantial income drops, marginalized, grain-intensive farming and low access to credit (Saldaña-Zorrilla and Sandberg, 2009).

Climate impacts disproportionately affect poor populations, thus increasing social and economic inequalities, both in urban and rural areas, and in low-, middle- and high-income countries. Climatic factors thereby interact with aspects of race, class, gender, ethnicity or age (Nightingale, 2011). Evidence for poor people in high income nations being disproportionately affected by weather- and climate related extreme events comes, for instance, from 2005 US Hurricane Katrina (Elliott and Pais, 2006; Bullard and Wright, 2010) or drought events in Australia (Alston, 2011). Glacial lake outburst floods in the Peruvian Andes also affect different populations depending on their degree of exposure, level of vulnerability, race, ethnicity, and socio-economic class (Carey, 2010; Carey *et al.*, 2012b). There has been an observed gender bias in impacts from climate variability and extremes, due to gender specific roles within the household, communities, and wider socio-political and institutional networks (Carr, 2008; Arora-Jonsson, 2011, see also Box 13-1).

For indigenous peoples, specific rights, including the right to life, adequate food, water, health, adequate housing, and the right to self-determination, are directly implicated by the impacts of climate change and variability (Ford, 2009b, see also Box 18-5). Livelihoods of indigenous people in the Arctic have been identified as among the most severely affected by both climate change and variability, including food security aspects, traditional travel and hunting, and cultural values and references (Beaumier and Ford, 2010; Pearce *et al.*, 2010). Negative effects on social and cultural assets by climatic and non-climatic stressors have also been identified in Africa with respect to social networks of the poorest, elderly and female-headed households (Osbahr *et al.*, 2008). Impacts of rising temperatures and increased variability of weather extremes on crops and livestock of indigenous people in highlands were furthermore reported from Tibet (Byg and Salick, 2009) and the Andes of Bolivia (McDowell and Hess, 2012). Shifts from transient to chronic poverty due to climate change and variability are suggested for livelihoods and households that, unlike more affluent ones, lack appropriate response to, and ability to cope with altered seasonalities, unpredictable seasons, and extreme events such as floods and droughts (Hardoy and Pandiella, 2009).

_____ START BOX 18-5 HERE _____

Box 18-5. Detection, Attribution, and Traditional Ecological Knowledge (TEK)

Indigenous and local peoples often possess detailed knowledge of climate change that is derived from observations of environmental conditions over many generations. Consequently, there is increasing interest in merging this traditional ecological knowledge (TEK)—also referred to as indigenous ecological knowledge (IEK) or simply indigenous knowledge (IK)—with the natural and social sciences in order to better understand and detect climate change impacts (Huntington *et al.*, 2004; Parry *et al.*, 2007; Salick and Ross, 2009; Green and Raygorodetsky, 2010; Ford *et al.*, 2011; Diemberger *et al.*, 2012). TEK, however, does not simply augment the sciences, but rather stands on its own as a valued knowledge system that can, together with or independently of the natural sciences, produce useful knowledge for climate change detection or adaptation (Agrawal, 1995; Cruikshank, 2001; Hulme, 2008; Berkes, 2009; Byg and Salick, 2009; Maclean and Cullen, 2009; Wohling, 2009; Ford *et al.*, 2011; Herman-Mercer *et al.*, 2011).

Cases in which TEK and scientific studies both detect the same phenomenon offer a higher level of confidence about climate change impacts and environmental change and the value of indigenous knowledge (Huntington *et al.*, 2004; Laidler, 2006; Krupnik and Ray, 2007; Salick and Ross, 2009; Gamble *et al.*, 2010; Green and Raygorodetsky, 2010; Alexander *et al.*, 2011; Cullen-Unsworth *et al.*, 2011). For example, in Peru's Cordillera Blanca mountains, local residents and instrument-based scientific analysis both report increasingly rapid glacial recession, less snow in the upper watershed, decreased water supplies in glacier-fed basins, and an increase of falling glacier “blocks” since the latter half of the 20th century (Bury *et al.*, 2010; Carey, 2010; Baraer *et al.*, 2012; Carey *et al.*, 2012b). For another, in Tibet, many, but certainly not all, local residents observed warming temperatures, less snow, and shrinking glaciers, which are consistent with scientific interpretations (Byg and Salick, 2009). At Clyde River, Nunavut, Canada, Inuit and scientific observations have detected that wind speed has increased in recent years and that wind direction changes more often over short periods (within a day) than it did during past decades (Gearheard *et al.*, 2010). Finally, in the Canadian Arctic, Inuit sea ice experts and scientists have

both observed the thinning of multiyear sea ice, the shortening of the sea ice season, and the declining extent of sea ice cover, with Inuit observers reporting less predictability in the sea ice and more hazardous travel and hunting at ice edges (Nichols *et al*., 2004; Laidler, 2006; Krupnik and Ray, 2007; Ford *et al*., 2009; Aporta *et al*., 2011).

TEK can also inspire scientists to study new issues in the detection of climate change impacts. In one case, experienced Inuit weather forecasters in Baker Lake, Nunavut, Canada, reported that it had become increasingly difficult for them to predict weather, suggesting an increase of weather variability and anomalies in recent years. To test Inuit observations, scientists analyzing hourly temperature data over a 50 year period confirmed that afternoon temperatures fluctuated much more during springtime during the last 20 years—precisely when Inuit forecasters noted unpredictability—than they had during the previous 30 years (Weatherhead *et al*., 2010).

Despite frequent confluence between TEK and scientific observations, there are sometimes discrepancies between them. These discrepancies indicate uncertainty in the identification of climate change impacts. Attribution of impacts to anthropogenic climate change, for example, tends to have much less convergence between TEK and the natural sciences. While community members in Canada's Northwest Territories report that less ice cracking during the last decade was a result of winter warming caused by climate change, scientists have concluded that the relationship between ice cracking and air temperature is much more complex and requires more research on water temperature, ice thickness, snow cover, and ice properties in order to attribute reduced ice cracking to global climate change (Woo *et al*., 2007).

Scale is another problem in the detection of climate change: TEK and scientific studies frequently focus on different and distinct scales that make comparison difficult. Local knowledge may fail to detect regional environmental changes while scientific regional or global scale analyses may miss local variation (Wohling, 2009; Gamble *et al*., 2010). In some cases TEK and scientific studies measure or note distinct phenomenon that cannot be compared or have inaccuracies (Gearheard *et al*., 2010). Furthermore, TEK based observations and related interpretations necessarily need to be viewed within the context of the respective cultural, social, and political backgrounds (Agrawal, 1995). Therefore, a direct translation of TEK into a western science perspective is often not feasible.

_____ END BOX 18-5 HERE _____

18.5. Detection and Attribution of Observed Climate Impacts across Regions

Since the AR4, significant new knowledge about detected impacts of recent climate change has been gained from all continents of the world, assessed in the regional chapters 22-29 of this report (for relevant information on Ocean regions from Chapter 30, see 18.3.2). The following sections provide a short overview about key findings for each of the eight world regions discussed in Chapters 22-29, along with a summary of relevant recent observed climate change. Further details of regional detection and attribution findings are summarized in 18.5.9 for various collections of natural, managed, and human systems.

18.5.1. Africa

For much of Africa, knowledge about recent climate change is limited, due to weak climate monitoring, and gaps in coverage continue to exist. On the other hand, the low natural temperature variability over the continent allows earlier detection of warming signals. Thus there is *medium to high confidence* in regional warming, with *low to high confidence* in attribution to anthropogenic emissions. A main regional feature has been the drying of the Sahel during the decades following 1970, but that trend has halted during the most recent decade (see also 22.2).

African environmental systems present many strong challenges for the potential detection and attribution of responses to climate change. Given the weak spatial and temporal variations in temperature, there is smaller scope for migrational and phenological responses to anthropogenic climate change than in other parts of the world. Furthermore, high quality monitoring is relatively sparse in time and space, and is often unsuitable for detecting changes across margins and borders where responses to climate change are most expected. The dearth of studies

examining attribution questions means it is currently difficult to estimate the degree to which studies are selectively published based on results, and thus to determine whether each attribution study is only indicative of local reasons for concern or if it is more generally representative of a broader domain.

Since the AR4 there has been a particular research focus on three geographic domains: the effects of dryness in the Sahel since 1970 on tree density; the effects of surface warming and resulting increased stratification on the Great Lakes on the lake ecology; and the effect of warming on species ranges in southern Africa, where spatial temperature gradients are larger and there is more scope for range shifts as a measureable response.

18.5.2. Europe

Amongst all continents, Europe has the longest tradition in climate monitoring. Warming has been occurring across the continent in all seasons, with an associated decreasing frequency of cold extremes and increasing frequency of hot extremes (Seneviratne *et al.*, 2012). The Southern parts of the continent (the Mediterranean) have been getting drier, while northern areas have been getting wetter (23.2.2.1), with a general increase in the frequency of extreme wet events everywhere (Seneviratne *et al.*, 2012).

Significant warming-related impacts have long been observed in Northern and Central Europe, with substantial loss of Alpine glaciers, longer growing seasons, associated productivity increases and changed phenology of many plant and animal species on land as well as in the Atlantic Ocean. Higher temperatures and generally drier conditions have likely contributed to the stagnation of agricultural yields that would otherwise have been expected to increase as a consequence of improved agricultural practices and higher atmospheric CO_2. In the Mediterranean drier and hotter conditions have contributed to increased wildfires.

18.5.3. Asia

Asia spans a wide range of climate types and expected climate changes, but warming has been observed throughout the continent with northern areas amongst the fastest warming on the planet. Precipitation trends vary geographically, with a more frequent but weaker Indian monsoon (WGI AR5 Chapter 14.7.10), and contrasting increasing and drying trends over coastal and inland China (24.3.1).

Among the most wide-spread observed impacts of recent climate change in Asia are the degradation of permafrost occurring throughout its current distribution in Siberia, Central Asia and on the Tibetan Plateau, matching observations from elsewhere in the world and to a very high degree explained by warming. Substantial new evidence has been collected since AR4 on glaciers in Asia. Across most of Asia glaciers have been shrinking, except from some areas in the Karakorum and Pamir. In some rivers (e.g. in China) an increase in runoff was observed in glaciated catchments.

Plants and animals are changing their phenology and growth in many parts of Asia, largely due to climate change, many species are also shifting their distribution northwards or upwards in elevation. In the oceans of tropical Asia and around Japan, coral reefs and large seaweeds are in decline.

18.5.4. Australasia

There is *very high confidence* of warming over Australian and New Zealand during the past century, and *high confidence* in hot extremes becoming more frequent and cold extremes becoming less frequent (25.2, Table 25-1). Winters in southern areas of Australia have become drier in the past few decades and the northwest has become wetter, and precipitation increased over the south and west of both islands of New Zealand (*high confidence*). While there have been no significant trends in drought frequency over Australia, regional warming may have increased their hydrological intensity (*low confidence*, Table 25-1).

There is *high confidence* of a significant decline in late season snow depth several sites in Australia's Snowy Mountains, and a decline of glacier volume by 25% in New Zealand since the middle of the 20th century (table 25-1). In many Australian terrestrial ecosystems, some observed changes in the distributions, genetics, phenology of individual species, and in the structure and composition of some ecological communities can be attributed to recent climatic and atmospheric trends, but non-climatic drivers, such as changes in fire management, grazing and land-use, also play a significant role. The 1997-2009 drought has affected freshwater systems in the eastern states and the Murray Darling Basin, but for many freshwater systems, direct climate impacts are difficult to detect. In New Zealand, few changes in ecosystems have been attributed to climate change.

Climate change impacts have been profound in marine systems around Australia and New Zealand, involving large latitudinal shifts of climatic zones and associated biota. Many of these changes have been associated with ocean warming, although for others the impacts of interacting non-climate stresses, including habitat degradation, coastal pollution and fisheries are also significant. About 10% of the observed 50% decline in coral cover on the Great Barrier Reef has been attributed to bleaching, the remainder to cyclones and predators.

Exceptional heatwave conditions in Australia have been associated with substantial increases in excess deaths and heat-related hospital admissions (Khalaj *et al*., 2010; Loughnan *et al*., 2010).

18.5.5. North America

North America spans a wide range of climate types and observed climate changes. While the northwest of the continent has been amongst the fastest warming on the planet, the southeast of the USA has experienced slight cooling (26.2.2). Hot extremes have been becoming more frequent while cold extremes and frost days have been becoming less frequent over the past several decades. Trends in precipitation over western parts of the continent are strongly influenced by the variability of the El Niño/Southern Oscillation, with a matching drying and decreasing snowpack. The intensity of precipitation events has been increasing over most of the continent, but trends in dryness are spatially heterogeneous (26.2.2). There is *robust evidence* of an increase in intense tropical storms in the North Atlantic over the past several decades (WGI AR5 Chapter 2.6.3).

There is evidence for hydrological change in many parts of North America, particularly in catchments that are dominated by snowpack and ice. Terrestrial ecosystems have responded to warming with range shifts (upwards and polewards), changed phenology, productivity and mortality (insect outbreaks). In some regions, wildfires have become more frequent. Marine ecosystems significantly shift ranges northwards. Agricultural production is affected by increased drought conditions in the Southern US and Mexico. There is some evidence for infrastructural damage from more frequent climatic extremes.

18.5.6. Central and South America

Most of South America has been observed to be warming over the past half century, except for an observed cooling over a western coastal strip (27.2.1.1). Precipitation over much of Central and South America is strongly influenced by the El Niño/Southern Oscillation, with accompanying long-term variability. There has been in reduction in the number of dry summer months in the southern half of the continent, while observed trends over the Amazon are sensitive to the selection of time period (27.2.1.1).

Among the observed impacts of climate change in South and Central America there are some that stand with *high* or *very high confidence* in detection and attribution. These are: the retreat of tropical glaciers and ice-fields in the Andes, decreasing river flows in the western tropical Andes, increased streamflow in the La Plata basin and bleaching of coral reefs in the western Caribbean. Several impacts are associated to many confounding causes and although detection of change may be found with *high* levels of *confidence*, the confidence in attribution is *low* or *very low*. In this category are included the degrading and receding of the Amazon rainforest, mangrove degradation on the Northern coast of South America and the expansion of agricultural areas in climatically marginal regions of Argentina. With *high confidence* in detection and *medium confidence* in attribution, denoting perhaps an impact

more sensitive to climate than in the previous case, are included the increase in agricultural yields in Southeastern South America and the increase in frequency and extension of dengue fever, yellow fever and malaria.

Although the number of articles in the literature and of consolidated datasets has both increased in Central and South America during the past decade, still there are many gaps to be filled in mainly in remote regions and regarding historic temporal coverage.

18.5.7. Polar Regions

The areas of largest observed warming are all polar: the northwest of North America, northern Asia, and the Antarctic Peninsula. While this occurs against a large background of natural variability, WGI AR5 Chapter 10 conclude that it is *likely* that there has been an anthropogenic contribution to Arctic warming; for the Antarctic, however, there is *low confidence* in attribution due a sparse monitoring network, an apparent lack of warming in the continental interior, and the contrasting effects of greenhouse gas emissions and stratospheric ozone depletion (10.3.1.1.4). The nature of polar regions means that warming can lead to large changes in other aspects of the climate system, in particular the observed decrease in summer sea ice cover, earlier thaw, earlier spring runoff, and melting of permafrost (28.2).

Recent changes in the Arctic tundra hydrology are attributed to permafrost degradation caused by increasing air temperature and reduced albedo. Swamp formation, lake drainage, and ecosystem shifts are among the observed consequences. Permafrost degradation also affects traditional living for local and indigenous communities.

The ongoing reduction of sea ice cover and duration has profound impacts on the subsistence of many species in the Arctic as well as the Antarctic. Polar bears are suffering from reduced vigor and reproduction, and arctic seabird populations are facing longer flight distances for provisioning of their offspring due to phenological mismatch, resulting in decreasing reproductive success. Antarctic penguin species show decreasing numbers, attributed to shrinking stock of their main prey, the Antarctic krill, which in turn is affected by sea ice loss.

Changing snow conditions affect arctic plants and animals in various ways. Mild spells in the winter, with increasing frequency of rain on snow events and the formation of ice crusts in the snow pack has affected the populations and cyclicity of arctic grazers (voles, ptarmigans, reindeer and caribou) with cascading effects on their predators, e.g., the Arctic fox: Decreasing range of snow-beds in the Arctic summer have strong impacts on animal communities and reindeer husbandry.

The most easily detected change in the physiognomy of the arctic tundra is the ongoing increase in shrub cover as seen in many studies from the North American as well as the Eurasian Low Arctic and Subarctic, attributed to increasing temperature. In the Antarctic Peninsula, the two resident species of vascular plants have passed a summer temperature threshold, and the attribution of the observed sudden increase in production of mature seeds is not confounded by other drivers.

18.5.8. Small Islands

Despite the widely accepted high vulnerability of many small islands to climate change, including their close relationship with Coral Reefs, there are only few formal studies on observed impacts. Detection of climate change impacts in small islands is challenging due to the strong presence of other anthropogenic drivers of local environmental change. Attribution is further challenged by the strong influence of natural variability compared to incremental changes of climate drivers, and the lack of long term monitoring, high quality data.

Observations of impacts of sea level rise on small islands are scarce. In many cases phenomena which are associated with expected impacts of sea level rise such as erosion, inundation, wave overwash are also strongly linked with on-going, known climate variability and extremes and cyclic processes such as ENSO, storms and extreme tidal

phenomena. It is therefore difficult to quantify the degree to which such impacts can be attributed to climate change and sea level rise.

For example, there is evidence for higher than average sea level rise, with rates up to four times the global average (approximately 12 mm yr^{-1} between 1993 and 2009), in the tropical western Pacific region, where a large number of small island and atoll communities are located (Becker *et al.*, 2012; Meyssignac and Cazenave, 2012). However, these changes may be transient, caused by strong and persistent La Nina like conditions superimposed over sea-level rise and are therefore currently not unambiguously attributed to climate change (Becker *et al.*, 2012).

18.5.9. Impacts across Regions

In order to allow for comparison between the various regions of the world, the following synopsis regroups the main conclusions for various components of the physical, biological, and human systems. The regional synopses is divided into various systems, covering observed impacts of regional climate change for: snow, ice and mountains, rivers and lakes (Table 18-6); terrestrial ecosystems, droughts and wildfires (Table 18-7); marine ecosystems and coastal processes (Table 18-8); and human and managed systems such as food production, economic impacts, and health (Table 18-9). These assessments follow from discussions in the various sectoral and regional chapters of this report and in earlier sections of this chapter.

Broadly, there is now at least *robust evidence* for observed impacts in most of the categories of physical and biological systems listed in most of the regions. There is also evidence of observed impacts on food production in many of the regions, while detection of impacts in other human systems remains limited. Further interpretation of these regional synopses within the "Reasons for Concern" framework forms the basis of the synthesis assessment of 18.6.

18.6. Synthesis: Detected Impacts of Climate Change and Reasons for Concern

18.6.1. Approach and History

A key motivation for the effort in assessing observed changes is the possibility that observed impacts could constitute indications of future expected changes. Observed losses in glacial volume, for example, lend additional plausibility to model-based expectations that additional warming could result in additional ice loss. Due to the

complex nonlinear behavior of most environmental systems, it cannot always be assumed that past impacts scale linearly to future impacts. Likewise, absence of past impacts cannot constitute evidence against the possibility of future impacts. Nonetheless, detection and attribution of observed impacts may serve as part of the foundation for a climatic risk analysis. In order to do so, the total body of observed impacts needs to undergo a synthetic analysis pointing towards the conceivable risks.

The AR4 precursor of the current chapter (Rosenzweig *et al*., 2007) organized its efforts around a geographically distributed empirical analysis of correlation across numerous detailed and localized studies of changing systems as described in Rosenzweig *et al*. (2008). Rather than expand that approach using the quickly growing scientific literature, the goal for this synthesis is to organize findings on detection and attribution in a way that fully covers the disciplinary, sectoral and geographic diversity of observed impacts. The approach aims to establish current conditions concerning the risk analysis model formulated earlier by the IPCC through the establishment of a limited number of "Reasons for Concern" (RFC). The RFC concept was developed in IPCC-TAR (Smith *et al*., 2001), adopted for a second time in IPCC-AR4 (IPCC, 2007a), and updated in Smith *et al*. (2009). The RFCs respond directly to requests from countries that the IPCC assesses the science with respect to the United Nations Framework Convention on Climate Change's (UNFCCC) commitment to "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system" (UNFCCC, 1992), without being policy prescriptive in terms of the definition of "dangerous". For the present synthesis, the goal is not to determine the levels of warming that correspond to a particular level of impact (as done in, e.g., IPCC, 2007b, Figure SPM.2); instead this analysis seeks to establish, qualitatively, the importance of impacts already observed in relation to the critical levels for concern indicated by the red colour of each bar portrayed in IPCC (2007a), using the levels revised by Smith *et al*. (2009).

While the summary of observed impacts, taken for themselves, cannot constitute an assessment of a probability-based measure of risk for dangerous anthropogenic interference, the degree to which the earlier projected impacts now have occurred can be useful for policy-relevant conclusions about the risks (chapters 1, 19). The actual quantification of risk for a given aspect of dangerous interference depends on the metrics chosen for the societal importance of a given impact and is not part of this analysis. Instead, the degree of concern is expressed in qualitative terms only, with an assessment of confidence in the assessment using standard IPCC terminology (Mastrandrea *et al*., 2010, 18.2). This is thought to directly support the development of policy-relevant conclusions about the risks expressed by each RFC.

As described more fully in Chapter 1 and earlier documentation, the five RFCs are (1) "Risks to Unique and Threatened Systems", (2) "Risks of Extreme Weather Events", (3) "Distribution of Impacts", (4) "Aggregate Impacts", and (5) "Risks of Large-Scale Discontinuities". Their broad definitions imply significant overlap, hence some observed impacts are referred to under more than one RFC. For consistency with the earlier assessments, the definitions and naming conventions in Smith *et al*. (2009) were nevertheless followed as rigorously as possible.

18.6.2. Five Reasons for Concern

18.6.2.1. Risks to Unique and Threatened Systems

The RFC of "Risks to Unique and Threatened Systems" is concerned with the potential for increased damage to, or irreversible loss of, plant and animal species, physical systems, and human livelihoods which are known to be highly sensitive to temporal and/or spatial variations in climate. Figure 18-4 displays current evidence derived from detection and attribution studies concerning observed impacts to unique and threatened systems as a result of observed changes in climate. Changes in the three indicated physical systems have at least *high confidence* in detection and at least *medium confidence* in attribution, with regional assessments also tending to have *high confidence*. There is at least *medium confidence* in both detection and attribution for at least one each of ecosystems, physical systems, and human systems, indicating observational evidence for moderate to strong reasons for concern for all three classes.

[INSERT FIGURE 18-4 HERE
Figure 18-4: Confidence in detection and attribution of observed impacts on unique and threatened systems as a result of recent climate change. Assessments are for confidence in detection of a change and for confidence in attribution of a major role of observed climate change. Large letters denote conclusions for the full-scale system, while small letters denote conclusions for regional subsets of the systems. System changes include shrinking / receding glaciers, mountain and lowland permafrost degradation, Arctic coastal permafrost degradation, increased mortality and bleaching of warm water reef-building corals, increased shrub cover and permafrost decay in the northern tundra, increased tree mortality in the Amazon, increased tree mortality in boreal forests, changes in Arctic marine ecosystems, decline in extent of mangroves and coastal wetlands, and impacts on livelihoods of indigenous Arctic peoples. See Table 18-10 for details and references.]

The systems with strongest detection and attribution evidence cover the Arctic, warm-water coral reefs, and mountains. In the Arctic, there is at least *medium confidence* of impacts on glaciers, permafrost, the tundra, marine ecosystems, and livelihoods of indigenous peoples, reflecting macroscopic changes across both natural and human systems and across the physical and ecological subregions. Evidence for the detection and attribution of shrinkage and recession of glaciers comes from all continents, while evidence for attribution of coral bleaching spans a similarly broad area of the tropical oceans (see Table 18-10). These observed impacts confirm the reason for concern about risks to unique and threatened systems.

[INSERT TABLE 18-10 HERE
Table 18-10: Reported confidence of detection of observed changes in "Unique and Threatened Systems" and attribution of observed changes to observed climate change. Assessments are for global or the indicated regional domain, with regional variations indicated in the final column.]

18.6.2.2. Risk of Extreme Weather Events

"This RFC tracks increases in extreme events with substantial consequences for societies and natural systems. Examples include increase in the frequency, intensity, or consequences of heat waves, floods, droughts, wildfires, or tropical cyclones" (Smith *et al.*, 2009). The risk of impacts by an extreme weather event is a combination of the probability of an extreme weather hazard and the consequences of the realization of that hazard. Hence, a change in the risk of impacts of extreme weather events could be caused by a change in the probability, intensity, or sequencing of the weather event itself (which are manifestations of recent climate change), or by a change in exposure, vulnerability, or the resilience of the impacted system. It follows that assessments of change in risk to anthropogenic climate change are particularly influenced by new evidence concerning the dominant drivers of change, whether climate change is one of those major drivers or not.

In the TAR, WGII found itself unable to detect a climatic component in the causal analysis of the increasing losses from extreme weather events, but outlined instead the significant vulnerabilities that could be expected if extreme weather events would increase with future climate change (IPCC, 2001, Technical Summary). In the AR4, detection and attribution was reported in terms of likelihood and supported in terms of consequence, with the conclusion that "It is now more likely than not that human activity has contributed to observed increases in heat waves, intense precipitation events, and the intensity of tropical cyclones. There are, as well, more observations of climate change impacts from extremes than in the TAR. Responses to some recent extreme climate events have also revealed higher levels of vulnerability across the globe, producing significant loss of life and property damage in both developing and developed countries" (IPCC, 2007b).

The current assessment confirms that, in many human systems, combined changes in exposure, vulnerability, and resilience have dominated past trends in risk. For instance, while there is *high confidence* that monetary losses related to extreme weather events have increased over the past 3-4 decades (ISDR, 2009, 10.7.3, 18.4.2), it is generally accepted that climate change has not been a major driver of that change in risk: instead, trends in exposure, wealth, and vulnerability of human systems have been the major factors for the increase in losses (IPCC, 2012, 10.7.3, 18.4.2). There has been considerable recent research and assessment into various components of the overall chain involved in extreme weather risk. Table 18-11 summarizes some notable new evidence concerning changes in

hazard and damage associated with extreme weather events that has been reported in the SREX, the WGI contribution to the AR5, and throughout this WGII contribution to the AR5.

[INSERT TABLES 18-11a AND 18-11b HERE
Table 18-11a: Confidence in detection of changes in extreme weather hazard and attribution of a major role of changing greenhouse gas concentrations in the observed changes.
Table 18-11b: Confidence in detection of observed trends in damage in various systems and attribution of a major role of observed changes in extreme weather to those observed trends.]

With regard to extreme weather hazard, temperature extremes have changed in many regions as a consequence of climate change (*high confidence*), with lower confidence in weather extremes that are less directly related to temperature or that occur on smaller spatial and time scales (where the connection with global mean temperature is less secure) (Seneviratne *et al*., 2012, WGI AR5 Chapter 10.6.1). Given the documented sensitivity of many systems to hot temperatures, the increase in extreme heat hazard implies a significant reason for concern. Indeed, for some systems there is evidence that local trends in temperature extremes have had a direct impact (Table 18-11b). There is also evidence that other trends in extreme weather hazard which are closely tied to global or regional warming, such as hazards related to sea level rise or sea ice retreat, have also been leading to increased damage.

Most of the evidence of attributable changes in impact risk due to weather extremes concerns corals or Arctic systems (see Figure 18-5). Evidence in both cases is *robust*. Outside of these systems, however, evidence is *limited* and highly localised. Recent detection and attribution literature has shed light on various components of the impact risk chain, but is otherwise limited in its extent for evaluating changes in impact risk for systems other than warm-water coral reefs and Arctic systems. Overall, observed impacts confirm reasons for concern about the risks of extreme weather events.

[INSERT FIGURE 18-5 HERE

Right: confidence in detection of observed changes in damages related to extreme weather and attribution of major role to observed changes in extreme weather.]

18.6.2.3. Distribution of Impacts

This RFC concerns the disparities of impacts between regions, countries, and populations. Evidence of differentiated climate change impacts have been projected for all IPCC regions since the days of the TAR. However, because of major geographical gaps in detection and attribution evidence the TAR did not report any observed regionally differentiated impacts, and nor did the AR4. The “before present” segments of the RFC box were therefore left uncolored in both the TAR and Smith *et al*. (2009). The survey of recent studies presented in 18.5 indicates that the gap is being reduced. While evidence for detected impacts is still more exhaustive from Europe and North America, considerable confidence in conclusions has been developed elsewhere since the AR4, particularly in Central and South America and Australasia. Tables 18-6 through 18-9 summarize what we have learned from the more recent evidence, as assessed in this chapter and other chapters throughout this report based on a consistent interpretation of the underlying criteria. Figure 18-6 portrays the assessment visually.

In terms of level of confidence, it is no longer the case that observed evidence to support the regional RFC is dominated by any particular region. The number of studies and coverage of systems may still be asymmetrically distributed, but rigorous analyses of observed climate change effects and attribution (to a lesser but not insignificant degree) have emerged from Central and South America, Australasia, Asia, Africa, and Small Islands. The synthesis of assessments for natural systems in the middle-to-high range for detection and the middle-to-high range for detection and attribution spans all major regions. The number of systems covered is only an indicative metric of coverage, because many options exist for aggregation and disaggregation of evidence. Thus detection and attribution analyses currently do not provide evidence of differing severity of impacts between continents. There exists, however, a particular emphasis on evidence concerning the Arctic where systems exhibit a high sensitivity to

climate change. Given the strong levels of confidence in changes across a broad range of Arctic systems, this emphasis indicates a stronger severity of impacts on the Arctic generally.

Coverage of human and managed systems is noticeably less extensive and more concentrated in the traditionally well-studied regions. Notwithstanding these differences, the qualitative conclusion that observed impacts have now been detected and attributed with *medium* to *high confidence* across the various IPCC-defined regions of the world is new and noteworthy. These higher confidence impacts generally concern the UNFCCC's metric that "food production is not threatened"; confidence in detection and attribution of observed impacts in other human systems generally remains much lower.

Throughout its assessments, the IPCC has repeatedly noted that there is significant disparity between the vulnerability of countries, regions, and social groups, due to differences in adaptive capacity. The AR4 cited examples that indicate how impacts of extreme events differ between social groups (Wilbanks *et al.*, 2007). The current coverage of detection and attribution studies is insufficient for broad evaluation of social disparities in impacts. Additional research effort is required to more fully address the nature of differences in impacts on various groups (18.7).

[INSERT FIGURE 18-6 HERE
Figure 18-6: Confidence in detection of observed changes in natural systems (panel a) and human and managed systems (panel b) across regions, and confidence in attribution of such trends to observed climate change. Based on assessments developed in Tables 18-6 through 18-9.]

18.6.2.4. Aggregate Impacts

The original intent of the Aggregate Impacts (or Aggregate Damages) RFC was to assess economic impacts, damages, and economic risk driven by climate change at a globally aggregated level. However, while some observed impacts are calibrated using a common monetary currency, others are now directly measured in a common calibrated metric or are otherwise qualitatively comparable across the globe and thus amenable to aggregation. In recognition of this, the scope of the RFC has been expanded over time (Smith *et al.*, 2009). Consequently, a variety of globally comparable impacts are considered here.

Table 18-2 lists various aggregate systems for which: the extent is global or near-global; there is a quantitatively or qualitatively calibrated measure for comparison across space and subsystems; the detection and attribution evidence has sufficient geographical distribution for a spatially representative sample. Confidence assessments for both detection and attribution span a wide range. Confidence is highest in cryospheric systems (glaciers and permafrost), with confidence in detection at least *medium* for various ecosystem measures but confidence in attribution lower (see Figure 18-7). Within human and managed systems, confidence in attribution to observed climate change is *low or very low* because of the dominating contribution of other drivers of change, including increased wealth, changes in exposure, new crop varietals, and new technologies. Overall, detection and attribution analysis reveals evidence for concern that risk of changes in aggregate measures has already changed, but also reveals *limited evidence* of a climate change influence on aggregate measures which do not concern the cryosphere.

Overall, the synthesis of aggregated impact measures confirms the concern for globally aggregated impacts of recent climate change being detected for a variety of systems and metrics.

[INSERT TABLE 18-12 HERE
Table 18-12: Confidence in detection of impacts on aggregate impact measures and confidence in attribution of at least a minor role of climate change in those observed changes.]

[INSERT FIGURE 18-7 HERE
Figure 18-7: Confidence in detection of changes in aggregate impact measures and attribution of at least a minor role of climate change in those trends]

18.6.2.5. Risks of Large-Scale Discontinuities

The RFC of "Risks of Large-Scale Discontinuities" "represents the likelihood that certain phenomena (sometimes called singularities or tipping points) would occur, any of which may be accompanied by very large impacts" (Smith *et al.*, 2009). Such discontinuities are hence a source of future risk, as they refer to thresholds in the Earth system that, once passed, will alter the nature of the system itself. While several of the identified "tipping elements" form part of the physical climate-ocean-cryosphere system (and are discussed in WGI), there are also elements in the biosphere that exhibit non-linear behavior with potentially strong feedbacks on the Earth system (Lenton *et al.*, 2008; Leadley *et al.*, 2010).

For observed impacts, the concern translates into a question of the possible presence of "early warning signals" for discontinuities that may be derived from monitoring changes in some climate or natural systems (Collie *et al.*, 2004; deYoung *et al.*, 2008; Andersen *et al.*, 2009; Lenton, 2011). To this effect, conceptual, observational and modelling studies of climate-change-induced biome or large-scale ecological regime shifts have intensified over the last decade (deYoung *et al.*, 2008; Marengo *et al.*, 2011; e.g., Duarte *et al.*, 2012b; Mann *et al.*, 2012).

Evidence from detection and attribution analysis supports concerns that both the Arctic and the global warm-water coral reef system are experiencing irreversible regime shifts, attributable to recent climate change, while observations from the boreal and Amazon forest are less conclusive.

- For the Arctic region, new evidence indicates a biophysical regime shift is taking place, with social and economic consequences (Post *et al.*, 2009; CAFF, 2010; Callaghan *et al.*, 2010; AMAP, 2011; Duarte *et al.*, 2012b, see also 18.3.1, 24.4.2.2, 28.2). For the marine biota in the Arctic Ocean, the rapid reduction of summer ice cover is now severely affecting pelagic ecosystems as well as ice-dependent mammals such as seals and polar bears (Duarte *et al.*, 2012a). Thawing of Arctic permafrost and shrub encroachment on the tundra have both been detected with *high confidence* (18.3.2.4, 18.5.8, 24.4.2.2), driven by warming and an associated prolongation of the growing season. Wide-spread hydrological changes have been observed in the tundra region, as a result of increasing winter rains and the degradation of permafrost, leading to lake formation or disappearance within a few years' time (CAFF, 2010; Callaghan *et al.*, 2013) and cascading consequences for the tundra food webs (Post *et al.*, 2009; Callaghan *et al.*, 2013; Hansen *et al.*, 2013).
- Warm-water coral reefs have been lost at a large scale due to thermal stress and other impacts, as was noted by AR4 already. Increased mass bleaching and mortality of corals has been detected and attributed globally with *very high confidence* (see Box 18-3), with at least *high confidence* regionally in tropical Asia, Japan, the Australian Great Barrier Reef, the western Caribbean and coast of Central America, and the waters around other small tropical islands (6.3.2, 24.4.3.2, 27.3.3.1, 29.3.1.2). This irreversible loss of biodiversity has significant feedbacks within the marine biosphere, and cascading consequences for regional marine ecosystems as well as the human livelihoods which depend on them. The additional evidence for ongoing change and its attribution to warming gained since the AR4 strengthens the conclusion that coral reef loss constitutes a strong warning signal for the irreversible loss of an entire biome.
- Dieback and degradation in the Boreal forests and the Amazonian rainforest have been identified as potential tipping elements, due to their large extent and the possible feedbacks with the carbon cycle (Lenton *et al.*, 2008; Malhi *et al.*, 2009; Leadley *et al.*, 2010; Marengo *et al.*, 2011, see also 4.3.3.1, 4.3.3.4). For the boreal forest, increases in tree mortality are observed in many regions (4.3.3), including wide-spread dieback related to insect infestations in North America (26.4.1), but there is *low confidence* in detection of this as a global trend attributable to climate change. In the humid tropical forests of the Amazon basin, tree turnover (both mortality and growth) has increased during recent decades. A number of factors have likely played a role, including the direct effect of rising CO_2 on lianas, recovery from past disturbance, and changing climate. The reason for concern about the Amazon forest is the interaction between global climate change, regional climate change related to deforestation, and the high susceptibility of forests to fire, which together could lead to degradation of forests in large areas of the Amazon above deforestation itself (Malhi *et al.*, 2009). There are indications of droughts in the Amazon and evidence that dry years and deforestation increase the vulnerability of forests to fire, but there is only *very low confidence* in attribution of observed changes in tree turnover to climate change. In conclusion, there is currently

insufficient evidence from observed climate change impacts to support a climate-related warning sign of possible large-scale discontinuities in the boreal and Amazonian forest.

In the TAR, the risk of large-scale discontinuities was evaluated to be a concern only after a few degrees warming. At the time of the AR4, new understanding of physical climate processes led to a major revision of that assessment by Smith *et al*. (2009), bringing concerns forward that discontinuities could occur with much less warming. While the present analysis does not indicate the manifestation of a tipping point being reached, it does indicate significant early warning indicators for possible regime shifts in the Arctic region and for the world's warm-water coral ecosystems. Observations therefore confirm the reasons for concern about risks from large-scale singularities.

18.6.3. Conclusion

The body of scientific evidence on observed impacts of recent climate change, after rigorous assessment of scientific confidence in its attribution to recent trends, lends new qualitative support to four out of five reasons for concern established by earlier IPCC assessments. Specifically, concerns are confirmed for risks to unique and threatened systems, risks stemming from extreme weather events, globally aggregated impacts and – in terms of early warnings – risks of large-scale discontinuities. Only the spatial or social disparities covered under "distribution of impacts" are still insufficiently studied to permit a synthesis of available observations for the characterization of a global concern. While the Arctic stands out as a region with robust evidence of impacts across numerous systems, current detection and attribution literature does not address whether the severity of those impacts differs from other regions. Across RFCs, the critical evidence often comes from the same environmental systems, notably the Arctic region, warm-water coral reef systems and mountain glaciers, but there are also important observations from impacted hydrological systems and human systems including agriculture.

Detection and attribution studies evaluate the agreement between observations and process understanding, with the important requirement for direct observational evidence of the impacts. This sets a higher bar for establishing confidence in past changes than is generally used for assessing confidence in projected future changes, because observational evidence has important gaps, while the plausibility of future changes can be established on the basis of process knowledge only (WGI AR5 Chapter 10.2.5).

Despite this constraint, the evidence gathered since the AR4 on detection and attribution of observed impacts from climate change has reached a level at which it can inform evaluation of many of the aspects of present-day climate change risk as described by the RFCs. In particular, the geographic distribution of studies is reaching the point where assessment of the global nature of impacts is possible:

- There is now *robust evidence* of observed changes in natural systems in all of the regional groupings used in this report. There is at least *medium confidence* in attribution of observed changes in various components of the cryosphere to observed climate change for each of the inhabited continents. There is also at least *medium confidence* in attribution of observed changes in terrestrial ecosystems to observed climate change for six continents (exception being South America) and for some small islands, and for marine ecosystems surrounding six continents (exception being Africa) and for some small islands.
- There is *good evidence* of the detection of impacts in human systems on the inhabited continents. There is at least *medium confidence* in detection of impacts on food production in all the inhabited continents.
- While the current detection and attribution literature does not reveal observational evidence of geographical differences in the severity of climate change impacts between continents, it does indicate that the unique systems of the Arctic region and warm water coral reefs are undergoing rapid changes in response to observed warming in ways that are potentially irreversible.

18.7. Gaps, Research Needs, Emerging Issues

While the literature formalizing accepted approaches and methods for detection and attribution studies on human and natural systems is relatively recent, the underlying question is one with a long tradition: how to detect a relationship between cause (climate change) and effect (impacts)? The literature on climate change impacts has

largely focused on providing estimates of *future* impacts covering the globe and almost any possible affected human and natural system, *observed* impacts have received comparably little attention. In order to provide better guidance for the policy-relevant risk assessment of future impacts, the coverage of impacts that have already occurred needs to be strengthened

With the exception of the food system, detection and attribution studies are most scarce in human systems. While sensitivity to climate variability is clear for many important economic sectors and infrastructures, this is not mirrored in the literature available on observed impacts of climate change.

In part, this is due to the fact that human systems are extremely complex and evolving at a very rapid pace, with many other drivers and their interactions challenging assessments of the comparatively weak recent climate signals. Human systems are also capable of autonomous and planned adaptation, including adaptation to predicted climate change, complicating the diagnosis of impacts of observed climate change. The literature on observed climate adaptation response is sparse. More fundamentally, much of the research on the relation between past climate change and impacts in human systems has been of a nature that has not fit into the deterministic, quantitative detection and attribution framework adopted in earlier Assessment Reports (Stone *et al.*, 2013). Fully including human systems into a complete understanding of observed impacts should be a priority for assessing future vulnerability to climate change.

The current detection and attribution literature does not provide a sufficiently comprehensive sampling of the distribution of impacts around the world, for instance between poor and wealthy populations. This dearth of studies reflects inadequate or a lack of long term monitoring or observational systems, an insufficient network density of meteorological observations, and/or lack of research funding, together leading to limited research capability. One other important reason is that in some sub-regions, particularly in the tropics, temperature sensitivities are poorly understood because rainfall is the primary climate driver, and precipitation trends under anthropogenic climate change are not as clearly understood as temperature trends.

Another challenge lies in addressing changes in impacts of extreme weather events and their relation to climate change, as well as determining the role of climate change in special events in impact systems. In some cases difficulty arises from dominating influences of non-climate factors on the extent of actual impacts of extreme weather events and the often highly nonlinear interactions of those factors, but a general characteristic lies in the difficulty of characterizing changes in the frequency or intensity of events that occur only very rarely.

Frequently Asked Questions

FAQ 18.1: What are the main challenges in detecting climate change impacts?

Detection addresses the question of whether a system has changed beyond its expected behavior in the absence of climate change. One challenge in detection is distinguishing between a change in a system and natural variability in the system. Most natural and human systems will exhibit variability over time even in the absence of a change in external factors. Particularly over short periods of time, this kind of natural variability can give the appearance of a systematic change. For example, even in the absence of changes in external factors, some wild populations can undergo prolonged periods of boom or bust. Distinguishing natural variability from systematic change usually requires an understanding of the charateristics of the former. This can be based on an analysis of historical data or an understanding of the dynamics of the system. A second challenge to detection is distinguishing between between a change in the system that is potentially attributable to climate change and one that is due to a change in non-climatic factors. For example, wild populations may change as a result of harvesting or habitat loss unconnected to climate change. Distinguishing such changes from those potentially attributable to climate change requires an understanding of the non-climatic factors that can affect the system and how these factors have changed.

FAQ 18.2: What is the main challenge in attributing changes in a system to climate change?

Attribution addresses the question of whether changes detected in a system can be attributed to climate change. Once a climate-related effect on a system has been detected, the main challenge in attribution is determining whether this effect is due to climate change rather than natural climate variability. For example, widespread flooding

in Australia and other parts of the western Pacific during 2010 and 2011 was caused by unusually heavy rainfall. However, this heavy rainfall was found to be related to the occurrence of La Niña, part of the naturally occurring ENSO variation, and therefore the flooding is not attributable to climate change.

FAQ 18.3: Why are detection and attribution of climate impacts important?

In deciding how to respond to climate change, policy-makers and others need to understand what the future impacts of climate change will be. One way to gain understanding about the future impacts of climate is to identify impacts of climate change that has already occurred. For example, it has been predicted that climate change will cause a poleward shift in the geographical ranges of species. Detecting such a shift in response to climate change that has already occurred would tend to validate this prediction.

FAQ 18.4: Is it possible to attribute a single event, like a disease outbreak or the extinction of a species, to climate change?

Scientists are usually reluctant to attribute a single event to climate change and instead tend to focus on the frequency or severity of classes of events. One reason for this is that the scientific knowledge needed to attribute a single event to climate change is much greater than that needed to attribute a change in the frequency or severity of classes of events. For example, there is good evidence that there has been an increase in the frequency of heat waves in many parts of the world and that this increase can be attributed to climate change. However, claiming that, in the absence of climate change, a particular heat wave would not have occurred is largely beyond present scientific capabilities.

Table 18-1: Observed changes in ocean system properties and their effects, with confidence levels for detection and attribution to climate change, based on assessment in Chapter 6.2, 6.3, and summarized in 6.6.1 and Figure 6-16. Observed impacts related to temperature effects have been attributed to warming, although the relative contributions of regional climate variation and long-term global trends have not been quantified.

Process	**confidence in**		**Context**	**Ref**
	detection	**attribution**		
Impacts of ocean acidification on pelagic marine biota	*low*	*low*	e.g., reduction in foraminiferan, coccolithophores and pteropod shell weight. Attribution supported by experimental evidence and physiological knowledge	[1]
Expansion of midwater hypoxic zones	*high*	*med*	oxygen minimum zones (OMZs) caused by enhanced stratification and bacterial respiration due to effects of warming	[2]
Regional and local impacts of expanding OMZs	*medium*	*low - medium*	reduction of biodiversity, compression of oxygenated habitat for intolerant species, range expansion for tolerant taxa	[3]
Direct temperature effects on marine biota related to limited physiological tolerance ranges	*very high*	*high*	e.g., large scale latitudinal shifts of species distribution, changes in community composition; attribution supported by experimental and statistical evidence as well as physiological knowledge	[4]
Increase in global net primary production	*medium*	*low*	discrepancy between satellite observations and open ocean time-series sites; in higher latitudes, NPP is increasing due to sea ice decline and warming	[5]
Changes in microbial processes	*low*	*low*	*low confidence* and limited understanding of microbial processes, drivers and interactions	[6]
Large scale shifts in biogeochemical pathways	*low*	*low*	*low confidence* for large scale shifts in biogeochemical pathways such as oxygen production, carbon sequestration and export production, nitrogen fixation, climate-feedback by DMS production, nutrient recycling	[7]

Key references and traceable account for the statements above:[1] (Wootton *et al*., 2008; De Moel *et al*., 2009; Moy *et al*., 2009; Bednaršek *et al*., 2012); 6.2.2, 6.3.4; [2] (Stramma *et al*., 2008; Stolper *et al*., 2010); 6.2.2; [3] (Levin *et al*., 2009; Ekau *et al*., 2010; Stramma *et al*., 2010; Stramma *et al*., 2012), 6.3.3; [4] (Merico *et al*., 2004; Perry *et al*., 2005; Pörtner and Farrell, 2008; Beaugrand *et al*., 2010; Alheit *et al*., 2012); 6.2.2, 6.3.2; [5] (Behrenfeld *et al*., 2006; Saba *et al*., 2010; Arrigo and Van Dijken, 2011); 6.3.1; [6] 6.2.2.4; [7] 6.3.3;6.3.4;6.3.5

Table 18-2: Observed changes on marine species and ecosystems, with confidence levels for assessment of detection of changes and their attribution to climate change, based on assessment in Chapter 6.2, 6.3, summarized in 6.6.1 and Figure 6-16, and 30.4. Observed impacts related to temperature effects have been attributed to warming, although the relative contributions of regional climate variation and long-term global trends have not been quantified.

Process	**confidence in**		**Context**	**Ref**
	detection	**attribution**		
Range shifts of fish and macroalgae	*high*	*high*	changes in species biogeographical ranges to higher latitudes or greater depths	[1a]
Changes in community composition	*high*	*high*	due to effects of warming, hypoxia, and sea ice retreat	[1b]
Changes in abundance	*high*	*high*	observed in fish, corals and intertidal species	[1c]
Impacts on marine air breathers, e.g. walruses, penguins, and other sea-birds	*high*	*high*	observed effects include changing abundance, phenology, species distribution and turtle sex ratios, and are mostly mediated through changes in resource availability including prey	[2]
Impacts on warm-water reef-building corals	*very high*	*very high*	effects mostly attributed to warming and rising extreme temperatures, though ocean acidification may contribute	[3]
Increments in fish species richness in temperate and high latitude zones	*high*	*medium*	effect associated with loss of sea ice and latitudinal species shifts due to warming trends	[4]
Change in regional fishery catch potential due to species shifts	*high*	*high*	partly attributable to climate change, and to fishing pressure	[5]
Change in fishery catch potential following changes in net primary production	*low*	*low*	effect associated with warming	[6]

Shifts in phenology	*high / high-medium*	n/s	*medium / medium-low*	*medium / medium-low*	*medium / medium-low*	n/s
Changes in abundance and species distribution	*high / high*	n/s	*high / high*	*medium / medium-low*	*medium / medium-low*	n/s

* California and Canary systems only

Table 18-4: Illustrative selection of some recent extreme impact events for which the role of climate has been assessed in the literature. The table shows confidence assessments as to whether the associated meteorological events made a substantial contribution to the impact event, as well as confidence assessments of a contribution of anthropogenic emissions to the meteorological event. The assessment of confidence in the findings is not necessarily a conclusion of the listed literature but rather results from assessment of the literature. Assessment of the role of anthropogenic emissions in the impact event requires a multi-step evaluation. Partly based on Coumou and Rahmstorf (2012).

Year	**Region**	**Extreme impact event**		**Meteorological Event**	
		Impact / damage	**Confidence in contribution of extreme weather event to observed damage**	**Meteorological event**	**Confidence in contribution of anthropogenic emissions to extreme weather event**
2003	Europe	excess death toll exceeding 70,000 *(Robine et al., 2008)*	*very high*	hottest summer in at least 500 years (Luterbacher *et al.*, 2004; Schär and Jendritzky, 2004; Stott *et al.*, 2004; Christidis *et al.*, 2010)	*high*
2005	North Atlantic / USA	1,700 deaths and over US$100 Bn in damage (Beven *et al.*, 2008)	*very high*	record number of tropical storms, hurricanes and category 5 hurricanes since 1970 (Emanuel, 2005; Webster *et al.*, 2005; Trenberth and Shea., 2006; Pielke Jr *et al.*, 2008; Vecchi *et al.*, 2008; Landsea *et al.*, 2009; Knutson *et al.*, 2010)	*very low*
2006-2007	Europe	partial second flowering or extended flowering in 2006, early flowering in 2007 (Luterbacher *et al.*, 2007)	*high*	hottest record fall and winter in at least 500 years (Luterbacher *et al.*, 2007; Van Oldenborgh, 2007; Yiou *et al.*, 2007; Cattiaux *et al.*, 2009)	*medium*
2010	Western Russia	burned area > 12,500km (Müller, 2011)	*low*	hottest summer since 1500 (Barriopedro *et al.*, 2011; Dole *et al.*, 2011; Rahmstorf and Coumou, 2011; Otto *et al.*, 2012)	*medium*
2011	Thailand	prolonged (up to 2 month) inundation of urban and industrialized areas, insured loss US$ 8-11 B, total loss ca. US$45 (SwissRe, 2011; WorldBank, 2011)	*very high*	wettest monsoon on record in middle and upper Chao Phraya Basin (Van Oldenborgh *et al.*, 2012)	*very low*
2010	Colombia	exceptionally heavy rainfall and floods, 4 M people affected, US$ 7.8 Bn total damage (Hoyos et al., 2013)	*very high*	ENSO-related second and third highest SST in Caribean on record in late 2010; second most active storm and hurricane season (Trenberth and Fasullo, 2012)	*low*
2010	Pakistan	worst ever known floods in the region, 2000 people killed, 20 M affected, total loss US$ 40Bn (Hong *et al.*, 2011)	*very high*	Exceptionally high rainfall amounts over northern Pakistan with unusual atmospheric circulation patterns (Houze Jr *et al.*, 2011; Webster *et al.*, 2011; Galarneau *et al.*, 2012)	*very low*
2011	Queensland, Australia	>200,000 people affected, >30,000 homes flooded, damages and cost to economy US$ 2.5 – 10 B (Van den Honert and McAneney, 2011; Hayes and Goonetilleke, 2012)	*very high*	2010 wettest year on record for Queensland, with extreme precipitation in January 2011 on saturated ground; record high Southern Oscillation Index in 2010 (Van den Honert and McAneney, 2011; Cai and Van Rensch, 2012; Hayes and Goonetilleke, 2012)	*low*

Table 18-5: Cases of regional livelihood impacts attributable with varying degree to weather- and climate related events, climate change or climate variability.

Impacted Population	Climate-related driver	Impact on livelihood	Reference
Small-scale farmers, Ghana	Drought	Landscape transformation, poverty	(Tschakert *et al*., 2011)
Middle-class farmers, Australia	Drought	Landscape transformation, income loss from agriculture, social conflict, poverty	(Alston, 2011)
High Arctic native people	Warming	Changing ice and snow conditions, dwindling access to hunting grounds	(Ford, 2009a; Ford, 2009b, see also Box 18-5)
Urban populations in Maputo, Accra, Nairobi, Lagos, Kampala	Flood frequency and severity increase	Direct impacts on people and loss of physical assets (e.g. housing)	(Douglas *et al*., 2008)
Industry workers in India	Temperature variability and heat waves	Limited ability to carry out physical work, health impacts	(Ayyappan *et al*., 2009; Balakrishnan *et al*., 2010; Dash and Kjellstrom, 2011)
Farmers in Subarnabad, Bangladesh	Sea-level rise	Salt water intrusion, shift from agriculture to shrimp farming, loss of agricultural livelihoods	(Pouliotte *et al*., 2009)
Women farmers, Ghana	Rainfall-related climate variability	Pressure from husbands limiting involvement in agriculture, poverty	(Carr, 2008)
Cambodian rice farmers	Warming, rainfall-related climate variability	Shift in income generation patterns between men and women	(Resurreccion, 2011)
Poor children in Africa and Latin America	Weather and climate-related events	Food price shocks, reduced caloric intake, physical stunting, long-term effects such as reduced lifetime earnings	(Alderman, 2010)
Smallholder farmers in highlands of Bolivia	Rising temperatures and higher variability in weather and climate-related extremes	Stress on household resources due to need to respond to increasing plant pests, switching to other crop types or livestock	(McDowell and Hess, 2012)

Table 18-6: Observed impacts of climate change on snow, ice and mountains, and rivers and lakes, across eight major world regions, with confidence in detection/confidence in attribution to climate change stated for each impact. References to related chapters are given as well as key references underlying the assessment.

	Snow, Ice and Mountains	Rivers and Lakes
Africa	**Retreat of tropical highland glaciers in East Africa** *very high* / *medium confidence* [22.5.1, (Mölg *et al*., 2008; Taylor *et al*., 2009; Mölg *et al*., 2012)]	**Reduced discharge in West African rivers** *medium* / *low confidence* (d'Orgeval and Polcher, 2008; Dai *et al*., 2009; Di Baldassarre *et al*., 2010) **Decreased flood frequency in Okavango delta** *low* / *low confidence* (Wolski *et al*., 2013) **Lake surface warming and water column stratification increases in the Great Lakes and Lake Kariba** *high* / *high confidence* [22.3.2.2, (Tierney *et al*., 2010; Ndebele-Murisa *et al*., 2011; Powers *et al*., 2011)]
Europe	**Retreating glaciers in the Alps** *very high* / *high confidence*, (Bauder *et al*., 2007; Paul and Haeberli, 2008; Zemp *et al*., 2008; Zemp *et al*., 2009) **Increase in rock slope failures in Western Alps** *high* / *medium confidence* [18.3.1.4; (Fischer *et al*., 2012; Huggel *et al*., 2012a)]	**Changes in the occurrence of extreme river discharges and floods** *low* / *very low confidence* (Schmocker-Fackel and Naef, 2010; Beniston *et al*., 2011; Cutter *et al*., 2012; Vorogushyn and Merz, 2012; Kundzewicz *et al*., 2013)
Asia	**Permafrost degradation in Siberia, Central Asia, and the Tibetan Plateau** *high* / *high confidence* [Box 3-2, WGI AR5 Chapter 10.5.3, (Romanovsky *et al*., 2010; Yang *et al*., 2012)] **Mountain glaciers across Asia are shrinking** *high* / *medium confidence* [WGI AR5 Chapter 4.3.2-4.3.3; Box 3-1; (Bolch *et al*., 2012; Cogley, 2012; Kääb *et al*., 2012; Yao *et al*., 2012; Gardner *et al*., 2013; Stokes *et al*., 2013)]	**Changes in water availability in many Chinese rivers** *high* / *low confidence* [24.4.1.2; (Casassa *et al*., 2009; Zongxing *et al*., 2010)] **Increased runoff in many rivers due to shrinking glaciers in the Himalayas and Central Asia** *high* / *high confidence* [24.4.1.2; Box 3-1; (Casassa *et al*., 2009; Zongxing *et al*., 2010; Shrestha and Aryal, 2011; Zhang *et al*., 2011)] **Surface water degradation in various parts of Asia partially related to climate change** *medium* / *medium confidence* [24.4.1.2; (Prathumratana *et al*., 2008; Delpla *et al*., 2009; Huang *et al*., 2009)] **Earlier timing of maximum spring flood in Russian rivers** *high* / *high confidence* [28.2.1.1; (Shiklomanov *et al*., 2007; Tan *et al*., 2011)]
Australasia	**Reduction in glacier ice volume in New Zealand** *high* / *low confidence* [WGI AR5 Chapter 4.3.3; Table 25-1; (Nicholls, 2006; Chinn *et al*., 2012)] **Significant decline in late-season snow depth at four alpine sites in Australia (1957-2002)** *high* / *medium confidence* (Hennessy *et al*., 2008)	n/s

North America	**Observed snowpack show primarily decreasing trends** in the amount of water stored in spring snowpack from 1960-2002 *high / high confidence* (Stewart *et al*., 2005; Mote, 2006)	**Observed shift to earlier peak flow in snow dominated rivers in Western North America** *high / high confidence* [WGI AR5 Chapter 2.6.2; (Barnett *et al*., 2008)] **Runoff increases in the Midwestern and Northwestern US, decreases in Southern states** *high / medium confidence* (Georgakakos *et al*., 2013)
South and Central America	**Retreat of tropical Andean glaciers** in Venezuela, Colombia, Ecuador, Peru and Bolivia (second half of the 20th century) and glaciers and ice-fields in the extra tropical Andes (Central-South Chile and Argentina) *high / high confidence* [27.3.1.1; (Vuille *et al*., 2008; Bradley *et al*., 2009; Jomelli *et al*., 2009; Poveda and Pineda, 2009; Rabatel *et al*., 2013)] **Increased landslide frequency due to heavy precipitation in SE South America** *medium / low confidence* [27.2.1.1; (Donat *et al*., 2013; Marengo *et al*., 2013; Silva Dias *et al*., 2013)]	**Changes in extreme flows in Amazon River** *high / medium confidence* [27.2.1.1; (Rodríguez-Morales *et al*., 2010; Butt *et al*., 2011; Wang *et al*., 2011; Espinoza *et al*., 2013)] **Changes in discharge patterns in rivers in the Western Andes** due to retreating glaciers and reduced snowpack; for major river basins in Colombia discharge has decreased during the last 30-40 years *high / high confidence* [27.3.1.1; (Vuille *et al*., 2008; Bradley *et al*., 2009; Jomelli *et al*., 2009; Poveda and Pineda, 2009; Rabatel *et al*., 2013)] **Increased stream flow in Sub-basins of the La Plata River**, attributed to increasing precipitation, but also to trends in land use changes that have reduced evapotranspiration *very high / high confidence* [27.3.1.1; (Pasquini and Depetris, 2007; Krepper *et al*., 2008; Conway and Mahé, 2009; Krepper and Zucarelli, 2010; Doyle and Barros, 2011)]
Polar Regions	**Decreasing Arctic sea ice cover in summer, reduction in glacier ice volume**, due to warming *high / high confidence* [WGI AR5 Chapter 10.5.1.1; (ACIA, 2005; AMAP, 2011)] **Decreasing snow cover duration across the entire Arctic** *high / medium confidence* [28.2.3.4, 5; (AMAP, 2011; Callaghan *et al*., 2011)] **Widespread permafrost degradation**, especially in the southern Arctic *high / high confidence* (AMAP, 2011; Olsen *et al*., 2011) **Increased ice mass loss along coastal Antarctica** *medium / very low* [WGI AR5 Chapter 4.2.3, 4.4, 4.6, 10.5.2.1]	**Increased river discharge for large circumpolar rivers** (1997–2007) *high / low confidence* [28.2.1.1; (Overeem and Syvitsky, 2010)] **Winter minimum flows have risen in most sectors of the Arctic** due to enhanced groundwater input due to permafrost thawing *high / medium* [28.2.1.1; (Tan *et al*., 2011)] **Increasing surface lake water temperatures 1985–2009 and prolonged ice-free seasons**, due to warming *medium / medium confidence* [28.2.1.1; (Callaghan *et al*., 2010; Schneider and Hook, 2010)] **Thermokarst lakes disappear due to permafrost degradation in the low Arctic, while new ones are being created in areas of formerly frozen peat** *high / high confidence* (Riordan *et al*., 2006; Marsh *et al*., 2008; Prowse and Brown, 2010)

Table 18-7: Observed impacts of climate change on terrestrial ecosystems, and occurrence of drought and wildfires, across eight major world regions, with confidence in detection/confidence in attribution to climate change stated for each impact. References to related chapters are given as well as key references underlying the assessment.

	Terrestrial Ecosystems	**Drought and Wildfire**
Africa	**Tree density decreases in Sahel and semi-arid Morocco** *high / medium confidence* [22.3.2.1.2; (Gonzalez *et al*., 2012; Le Polain de Waroux and Lambin, 2012)] **Climate-driven range shifts of several southern plants and animals**: South African bird species polewards; Madagascan reptiles and amphibians upwards; Namib aloe contracting ranges. *high / medium confidence* [22.3.2.1; (Foden *et al*., 2007; Raxworthy *et al*., 2008; Hockey and Midgley, 2009; Hockey *et al*., 2011)]	**Increased drought in the Sahel since 1970, partially wetter conditions since 1990** *medium / medium confidence* [22.2.2.1; (Hoerling *et al*., 2006; Giannini *et al*., 2008; Greene *et al*., 2009; Seneviratne *et al*., 2012)] **Wildfires increase on Mt. Kilimanjaro** due to warming and drying trends *medium / low confidence* [22.5.1; (Hemp, 2005)]
Europe	**Earlier greening, earlier leaf emergence and fruiting in temperate and boreal trees** *high / high confidence* [4.4.1.1; (Menzel *et al*., 2006)] **Increased colonization of alien plant species in Europe** *medium / medium confidence* [4.2.4.7; (Walther *et al*., 2009)] **Earlier arrival of migratory birds in Europe since 1970** *medium / medium confidence* [4.4.1.1; (Møller *et al*., 2008)] **Upward shift in tree-line in Europe** *medium / low confidence* [18.3.2.1; (Gehrig-Fasel *et al*., 2007; Lenoir *et al*., 2008)]	**Increasing burnt forest areas during recent decades** *high / high confidence* (Hoinka *et al*., 2009; Koutsias *et al*., 2012)
Asia	**Changes in plant phenology and growth occur in many parts of Asia**, observed from ground observations as well as from satellites (earlier greening), particularly in the North and the East *high / medium confidence* [24.4.2.2; 4.2.1, Box 4-1; (Ma and Zhou, 2012; Panday and Ghimire, 2012; Shrestha *et al*., 2012; Ogawa-Onishi and Berry, 2013)] **Many plant and animal species have shifted their distribution**, particularly in the North of Asia, generally upwards in elevation or polewards *high / medium confidence* [24.4.2.2; (Moiseev *et al*., 2010; Chen *et al*., 2011; Jump *et al*., 2012; Ogawa-Onishi and Berry, 2013)] **Siberian larch forests are being invaded by pine and spruce during recent decades, Mongolian larches show decreasing growth** *medium / low confidence* (Kharuk *et al*., 2010; Dulamsuren *et al*., 2011; Lloyd *et al*., 2011) **Advance of shrubs into the Siberian tundra** *high / medium* confidence [28.2.3.1; (Blok *et al*., 2011)]	

Australasia	**Climate-related changes in genetics, growth distribution and phenology of many species** (earlier emergence of butterflies, change in plant flowering dates, breeding times of bird, decline in body size of passerine birds etc.) *medium / medium confidence* [table 25-3; (Green, 2010; Kearney *et al.*, 2010; Keatley and Hudson, 2012)] **Change in timing of migration of water and land birds in Australia** possibly due to changes in precipitation rather than changes in temperature *low / low confidence* [25.6.1, Table 25-3; (Chambers, 2008)] **Expansion of some wetlands and corresponding contraction of adjacent woodlands in SE Australia** *medium / low confidence* [table 25-3; (Banfai and Bowman, 2007; Bowman *et al.*, 2010; Keith *et al.*, 2010)]	**No significant change in drought occurrence in Australia** (over 20th century, using rainfall only) **or New Zealand** (since 1972, using a soil water balance model) *medium-low / n.a.* [table 25-1. 3.5.1; (Cai *et al.*, 2009; Potter *et al.*, 2010; Kingsford and Watson, 2011; IPCC, 2012)]
North America	**Species distribution shifts upward in elevation and northward in latitude across multiple taxa** *high / medium confidence* [26.4.1, 2; (Kelly and Goulden, 2008)] **Phenology changes** *high / medium confidence* [26.4.2; (Parmesan, 2006)] **Increases in tree mortality at regional scales and insect infestations in forests** *medium / low confidence* [26.4.1; (Peng *et al.*, 2011)]	**Increases in wildfire activity, including fire frequency and duration, length of fire season, and area burned** *high / medium confidence* [Box 26.2; (Westerling *et al.*, 2006)]
South and Central America	**Degrading and receding rainforest in the Amazon** *high / very low confidence* [27.2.2.1; (Etter *et al.*, 2006; Nepstad *et al.*, 2006; Oliveira *et al.*, 2007; Wassenaar *et al.*, 2007; Killeen *et al.*, 2008; Nepstad and Stickler, 2008)]	**Increase dryness for most of the west coast of South America and in the Andes between 35.6°S and 39.9°S since 1950** *medium / low confidence* [table 27-1; (Christie *et al.*, 2011; Dai, 2011)]
Polar Regions	**Increase in shrub cover in tundra in North America and Eurasia** *high / high confidence* [28.2.3.2; (Tape *et al.*, 2006; Walker *et al.*, 2006; Henry and Elmendorf, 2010; Blok *et al.*, 2011; Elmendorf *et al.*, 2012; Tape *et al.*, 2012)] **Significant advance of Arctic tree-line in latitude and altitude, due to warming**, although the pace is lower than expected due insect outbreaks, land use history *high / medium confidence* [28.2.3.3; (AMAP, 2011; Hedenås *et al.*, 2011; Van Bogaert *et al.*, 2011)] **Snow-bed ecosystems and tussock tundra are retreating, due to prolonged thawing season and less precipitation in the form of snow** *high / high confidence* [28.2.3.2; (Björk and Molau, 2007; Molau, 2010a; Hedenås *et al.*, 2011; Callaghan *et al.*, 2013)] **Animal populations in the tundra being affected by increasing occurrence of ice layers in the annual snow pack due to rain-on-snow events** *medium / medium confidence* (Callaghan *et al.*, 2013; Hansen *et al.*, 2013) **Breeding area and population size of subarctic birds has changed**, due to warming and shrub encroachment in the tundra *high / medium confidence* (Molau, 2010b; Callaghan *et al.*, 2013)	**Increasing drought in high Arctic polar deserts** *high / high confidence* [28.2.1.1; (Smol and Douglas, 2007)] **Increased frequency of wildfires in the conifer forest at the southern fringe of the Arctic**, due to increasing summer temperature *high / medium confidence* (Mann *et al.*, 2012) **Tundra wildfires are increasing in frequency in the Low Arctic,** due to increasing summer air temperature and subsequent surface drought *high / medium confidence* [28.2.3.6; (Mack *et al.*, 2011)]

	Plant species in the West Antarctic Peninsula and nearby islands have increased over the past 50 years *high / high confidence* [28.2.3.2; (Fowbert and Smith, 1994; Parnikoza *et al.*, 2009)] **Increasing phytoplankton productivity in Signy Island lake waters** *high / high confidence* [28.2.1.2; (Quayle *et al.*, 2002; Laybourn-Parry, 2003)]	
Small Islands	**Upward trend in tree-lines and associated fauna on high elevation islands** *low / low confidence* [29.3.2.1; (Benning *et al.*, 2002; Jump *et al.*, 2006)] **Changes in tropical bird populations in Mauritius, due to changes in rainfall** *medium / medium confidence* [29.3.2.1; (Senapathi *et al.*, 2011)]	**Increased drought frequency in Seychelles and Southern Jamaica** over past 30 years, decrease in rainfall over past 100 years in the Caribbean islands may have contributed to multiple water stress *low / very low confidence* [29.3.3.2; (Payet and Agricole, 2006; Cashman *et al.*, 2010; Gamble *et al.*, 2010)]

Table 18-8: Observed impacts of climate change on marine ecosystems, and coastal processes, across eight major world regions, with confidence in detection / confidence in attribution to climate change stated for each impact. References to related chapters are given as well as key references underlying the assessment.

	Marine Ecosystems	**Coastal Processes**
Europe	**Poleward shifts in the distributions** of zooplankton, fish, seabirds and benthic invertebrate, and conversion of polar into more temperate and temperate into more subtropical system Characteristics in NE Atlantic *high / high confidence* [Table 6-8, 6.3.2, 30.5.1, 18.3.3.1, (Beaugrand *et al.*, 2009; Philippart *et al.*, 2011)] **Phenology changes and retreat of colder water plankton** to the north in the Northeast Atlantic, with mean poleward movement of plankton reaching up to 200–250 km per decade between 1958–2005 *medium / medium confidence* **[**6.3.2, Table 6-8, Fig 6-16; (Beaugrand *et al.*, 2002; Edwards and Richardson, 2004; Beaugrand *et al.*, 2009; Philippart *et al.*, 2011)] **Shift in distribution of Atlantic cod** due to warming, interacting with regime shift and regional changes in Plankton Phenology in North Sea *high / medium confidence* [6.3.2, Fig 6-16; (Perry *et al.*, 2005; Pörtner *et al.*, 2008; Beaugrand *et al.*, 2009; Beaugrand *et al.*, 2010)] **Decreasing abundance of eelpout** (Helcom indicator species) in Wadden Sea *medium / high confidence* [6.3.2, Fig 6-16; (Pörtner and Knust, 2007)]	

Asia	**Coral reefs and large seaweeds decline in tropical Asian and Japanese waters** *high / high confidence* [24.4.3.2; (Krishnan *et al.*, 2011; Nagai *et al.*, 2011; Coles and Riegl, 2012)] **Shift from sardines to anchovies in Japanese Sea** *medium / medium confidence* [6.3.22, Fig 16-6; (Takasuka *et al.*, 2007; Takasuka *et al.*, 2008)]	**Coastal erosion is accelerating in Arctic Asia**, due to changes in permafrost, storm wave energy and sea-ice retreat *medium / low confidence* (Razumov, 2010; Lantuit *et al.*, 2011; Handmer *et al.*, 2012)
Australasia	**Mass bleaching of corals in the Great Barrier Reef**, changes in coral calcification rates and changes in coral disease dynamics (e.g., black band disease, white syndrome) *high / high confidence* [6.3.2, 25.6.2, Box 18-3; (Cooper *et al.*, 2008; De'ath *et al.*, 2012)] **Multiple impacts of climate change on marine ecosystems from warming oceans**, although other environmental changes may play a role. Examples are increase of growth rates in fish, range shifts of intertidal invertebrates, retreat of seaweeds, range shift in near-shore fish related to kelp decline, increasing abundance of northern marine species in Tasmania, declines in recruitment of rock lobster and of abalone, decline in growth rate and biomass of phytoplankton, retreat of macroalgae, southward expansion of some tropical seabirds in Australia *high / high confidence* (Thresher *et al.*, 2007; Figueira *et al.*, 2009; Ling *et al.*, 2009; Pitt *et al.*, 2010; Chambers *et al.*, 2011; Neuheimer *et al.*, 2011; Wernberg *et al.*, 2011; Wernberg *et al.*, 2011, see also Table 25-3)	
North America	**Northwest Atlantic fish show northward range shift** in response to warming since the 1960s, with some of the shifts being correlated with the Atlantic multidecadal Oscillation *high / medium confidence* [Table 6-8, Fig 6-16 (Nye *et al.*, 2009; Lucey and Nye, 2010; Nye *et al.*, 2011)] **Earlier onset of migration of Pink Salmon in Alaska, collapse of spawning migration of Sockeye Salmon in Fraser River, BC**, due to warming *high / high confidence* [(Eliason *et al.*, 2011; Kovach *et al.*, 2012)] **Loss of biomass of midwater fish off California Coast** *high / high confidence* [6.3.3, 6.6.3]	**Coastal roads affected by flooding** during high tides in the US, though contribution of climate change to relative sea-level rise uncertain *low / very low confidence* (Moser and Davidson, 2013)
South and Central America	**Bleaching of coral reefs in the western Caribbean near the coast of Central America** *very high / high confidence* [27.3.3.1, (Guzman *et al.*, 2008; Manzello *et al.*, 2008; Carilli *et al.*, 2009; Eakin *et al.*, 2010)]	**Mangrove degradation on Northern South American coast** *high / low confidence* (Alongi, 2008; Lampis, 2010; Polidoro *et al.*, 2010; Giri *et al.*, 2011)
Polar Regions	**Many arctic and subarctic marine non-migratory mammals (walrus, seals, whales) are negatively affected by sea ice loss** *high / high confidence* [28.2.2.1.3, (Laidre *et al.*, 2008; McIntyre *et al.*, 2011)] **Reduced growth rate and body mass, lower survival and reproductive capacity of polar bears, linked to reduced off-shore range and sea-ice loss due to warming** *high / high confidence* [28.2.2.1.2; (Amstrup *et al.*, 2010)] **Arctic seabirds experience reduced reproductive success, due to earlier sea-ice break-up** *medium / medium confidence* [28.2.2.1.1; (Gaston *et al.*, 2009; Grémillet and Boulinier, 2009)]	**Increased coastal erosion in Arctic**, due to prolonged ice-free season at shore, increased exposure to wave activity, and degrading permafrost *high / high confidence* [28.2.4, 5; 28.3.4, (Forbes, 2011)]

	Acidification of Southern Ocean waters has resulted in reduced thickness of foraminifera shells *medium / medium confidence* [6.3.4, 28.2.2.2, (Moy *et al*., 2009)] **Antarctic krill density in the Scotia Sea has declined** by ca. 30 % since the 1980s, due to reduced winter sea ice extent and duration *medium / medium confidence* (Atkinson *et al*., 2004; Trivelpiece *et al*., 2011) **Many Southern Ocean species of seals and seabirds, e.g. penguins and Albatross, show negative responses to warmer conditions** *high / medium confidence* [28.2.2.2; (Croxall *et al*., 2002; Patterson *et al*., 2003; Jenouvrier *et al*., 2005; Véran *et al*., 2007; Forcada *et al*., 2008; Trathan *et al*., 2011)]	
Small Islands	**Coral bleaching near many tropical small islands** *high / high confidence* [29.3.1.2,3; (Alling *et al*., 2007; Bruno and Selig, 2007; Oxenford *et al*., 2008)] **Degradation of mangroves, wetlands and seagrass** in small islands, mostly due to disturbances and only a lesser extent possibly due to sea-level rise *high / low confidence* [29.3.1.4; (McKee *et al*., 2007; Gilman *et al*., 2008; Schleupner, 2008; Krauss *et al*., 2010; Marbà and Duarte, 2010; Rankey, 2011)] **Degradation of freshwater dependent ecosystems**, due to saline intrusion following sea level rise and more frequent and intense hurricanes in the Florida Keys, USA *low / low confidence* [29.3.2.1; (Ross *et al*., 2009; Goodman *et al*., 2012)]	**Shoreline erosion is widespread and increasing on many small islands**, though impact of sea-level rise can presently not be discriminated from climate variability and local disturbance *high / low confidence* [29.3.1.1, 2; (Yamano *et al*., 2007; Cambers, 2009; Novelo-Casanova and Suarez, 2010; Storey and Hunter, 2010; Ford, 2012)] **More frequent inundation in low-lying flood prone areas, increasing appearance of freshwater lenses at surface** *medium / low confidence* [29.3.1.1, 2;(Webb, 2006; Webb, 2007; Yamano *et al*., 2007; Ballu *et al*., 2011)] **Increases in groundwater degradation**, mostly driven by over-pumping or pollution. Limited evidence for saline intrusion due to sea level rise or overtopping *high / low confidence* [29.3.2.2; (White *et al*., 2007a; White *et al*., 2007b; Terry and Falkland, 2010; White and Falkland, 2010)]

Table 18-9: Observed impacts of climate change on human systems across eight major world regions, with confidence in detection / confidence in attribution to climate change stated for each impact. References to related chapters are given as well as key references underlying the assessment.

	Impacts on Human Systems: Health, Food production, Infrastructure and Livelihoods
Africa	**Malaria increases in Kenyan highlands**, partly due to warming *low* / *low confidence* [22.3.5.2, (Prudhomme O'Meara *et al*., 2010; Alonso *et al*., 2011; Stern *et al*., 2011)]
	Reduced productivity of Great Lakes and Lake Kariba, partly due to warming *high* / *low confidence* [23.3.2.2, 23.3.4.4; (Descy and Sarmento, 2008; Hecky *et al*., 2010; Ndebele-Murisa *et al*., 2011; Marshall, 2012)] **Fruit-bearing trees in Sahel decline** *medium* / *medium confidence* (Wezel and Lykke, 2006; Maranz, 2009)
Europe	**Increased allergic sensitization to pollen in Northern Italy** *very low* / *very low confidence* [11.3; (Ariano *et al*., 2010)] **Shift from cold-related mortality to heat-related mortality in England and Wales** *medium* / *low confidence* [18.4.5; (Christidis *et al*., 2010)]
	Stagnation of wheat yields in some countries in recent decades, due to warming and/or drought *high* / *medium confidence* (Brisson *et al*., 2010; Kristensen *et al*., 2011) **Positive yield impacts for wheat, sugar beet and potato in the UK since 1980** *low* / *low confidence* [Fig 7-3; (Gregory and Marshall, 2012)]
Asia	**Negative impacts on aggregate wheat yields in South Asia** *medium*/*low confidence* [Fig.7-3, 7.2.1.1] **Negative impacts on aggregate wheat and maize yields in China** *low* / *low confidence* [Fig.7-3, 7.2.1.1]
	Increases in water-borne diseases have been linked to warming in Israel *low* / *low confidence* (Paz *et al*., 2007)
Australasia	**Wine-grape maturation has advanced in recent decades, partly due to warming** *high* / *medium confidence* (Webb *et al*., 2012)
North America	**Yields of grains, forage, livestock and dairy have declined due to increasing temperatures** unless where accompanied by increased precipitation; soil organic content has declined; salinity has increased; climate change has affected product quality *high* / *low confidence* [26.5.1; (Hayhoe *et al*., 2004; Lin, 2007; Hatfield *et al*., 2008; Wolfe *et al*., 2008; Schlenker and Roberts, 2009; Craine *et al*., 2010)] **Reduced economic returns from agriculture following extreme heat and storms, particularly in Mexico** *high* / *low confidence* [Boxes 26.1, 26.2, 26.4; (Swanson *et al*., 2007; Chen and McCarl, 2009)]
	Direct and indirect economic impacts of climate extremes on industry through reduced supply of raw material, the production process, the transportation of goods, and the demand for certain products *high* / *medium confidence* [26.8; (Lazo *et al*., 2011)] **Damages from climate extremes on infrastructure, especially in the transport and housing sectors** *medium* / *low* confidence [26.8; (Morton *et al*., 2011)] **Impacts of extreme events on economy, lives and livelihoods in urban and rural settlements** *medium* / *low confidence* [26.7.1, 26.7.2; (Kurz *et al*., 2008; MacDonald, 2010)]
Central and South America	**Increase in frequency and extension of dengue fever and yellow fever** *high* / *low confidence* [27.3.7.1; (Teixeira *et al*., 2009; Rodríguez-Morales *et al*., 2010; Jentes *et al*., 2011)]
	Increase in frequency and extension of malaria *high* / *medium confidence* [27.3.7.1; (Rodríguez-Morales *et al*., 2010; Poveda *et al*., 2011)]
	Increase in agricultural yields in Southeastern South America *high* / *medium confidence* [27.3.4.1; (Magrin *et al*., 2007; Barros, 2010)] **Expansion of agricultural areas in climatically marginal regions of Argentina** *high* / *low confidence* [27.3.4; (Barros, 2010; Hoyos *et al*., 2012)] **Reduction in fish stocks (Peru, Colombia, Brazil)** *low* / *very low confidence* [27.3.7.1; (Allison *et al*., 2009; Freire and Pauly, 2010)]
Polar Regions	**Impact on livelihoods of high Arctic indigenous peoples** *medium* / *medium confidence* [18.4.5, Box 18-5; (Ford *et al*., 2009; Beaumier and Ford, 2010; Pearce *et al*., 2010)]

Small Islands	**Degradation of coastal fisheries** *high* / *low confidence* [29.3.3; 18.4.5; 30.4, 6.3.2] **Casualties and damage from extreme weather events** *very high* / *very low confidence* [29.3.3]

Table 18-10: Reported confidence of detection of observed changes in "Unique and Threatened Systems" and attribution of observed changes to observed climate change. Assessments are for global or the indicated regional domain, with regional variations indicated in the final column.

Impact on unique or threatened system	**Source for overarching assessment**	**Confidence in**		**Regional details, with corresponding subsections and confidence in detection/confidence in attribution**
		detection	**attribution**	
Shrinking / receding glaciers	18.3.1	*very high*	*high*	Tropical Highland Glaciers, East Africa (22.5.1): *very high* / *medium* European Alps: *very high* / *high* Asia (24.4.2.2): *high* / *medium* New Zealand (Table 25-1): *high* / *low* North America: *high* / *high* Andean tropical glaciers and extra tropical icefields (27.3.1.1): *high* / *high* Polar glaciers: *high* / *high*
Mountain and lowland permafrost degradation	18.3.1.2	*high*	*medium*	Europe: *medium* / *medium* Siberia, Central Asia and Tibetan Plateau (24.4.2.2): *high* / *high* North America: *medium* / *medium* Southern Arctic (28.2.1.1): *high* / *high*
Arctic coastal permafrost degradation	18.3.1.2, 24.4.3.2, 28.2.1.1	*high*	*high*	
Warm water reef building corals – increased mortality and bleaching	5.3.1.6, 6.3.2.1.2, 30.3.1.1, 30.5, 30.8.2, Box 18-3	*very high*	*high*	Asia (24.4.3.2): *high* / *high* Australian Great Barrier Reef: *high* / *high* Western Caribbean (27.3.3.1): *very high* / *high* Coastal reefs surrounding small islands (29.3.1): *high* / *high*
Shrub increase and permafrost decay in Arctic tundra¸ onset of biome shift	18.3.2.4, 28.2.3.2	*high*	*high*	
Increased tree mortality in the Amazon; onset of biome shift	4.3.3	*low*	*very low*	
Increased tree mortality in boreal forests; onset of biome shift	4.3.3	*low*	*low*	
Changes in Arctic marine ecosystems	18.5.7, 28.2.2.1	*high*	*medium*	
Decline in extent of mangroves and coastal wetlands	27.3.3.1, 29.3.1.4	*very high*	*very low*	Mangrove degradation northern South American coast (27.3.3.1): *high* / *low* Impacts on mangroves and sea grasses in coastal areas of small islands (29.3.1.4): *high* / *low*
Livelihood impacts on indigenous Arctic peoples	18.4.7, Box 18-5	*medium*	*medium*	

Table 18-11a: Confidence in detection of changes in extreme weather hazard and attribution of a major role of changing greenhouse gas concentrations in the observed changes.

Observed changes in extreme weather or hydrologic hazard	**Confidence in**		**Assessment***
	detection	**attribution**	
Increasing frequency and intensity of extreme hot events	*high*	*high*	WGI AR5 Chapter 10.6.1
Decreasing frequency and intensity of extreme cold events	*high*	*high*	WGI AR5 Chapter 10.6.1
Increases in the number and intensity of heavy precipitation events	*medium*	*medium*	WGI AR5 Chapter 10.6.1
Increases in tropical cyclone activity	*low*	*low*	WGI AR5 Chapter 10.6.1
Changes in tornadoes or hail	*very low*	*very low*	Chapter 10.6.1
More intense and longer dry spells in some low and mid latitude regions	*low*	*low*	WGI AR5 Chapter 10.6.1
Changes in inland flood magnitude and frequency	*low*	*low*	3.2.3, 18.3.1.1
Increasingly frequent coastal flooding	*medium*	*low*	29.3.1.1, 29.3.2.2, 5.3.3.3

*more detailed regional information consistent with AR5 WGI Chapter 10 assessment can be found in Seneviratne *et al*. (2012)

Table 18-11b: Confidence in detection of observed trends in damage in various systems and attribution of a major role of observed changes in extreme weather to those observed trends.

Observed changes in impacts of extreme weather	**Relevant weather extremes**	**Confidence in**		**Assessment**
		detection	**attribution**	
Increased coral bleaching	Hot surface waters	*very high*	*high*	5.3.1.6, 6.3.2, Box 18-3, 24.4.3.2, 27.3.3.1, 29.3.1, 30.3.1.1, 30.5. 30.8.2
Increased beach erosion in low and mid latitudes	High storm waves and surges	*high*	*very low*	5.3.1.2
Increased erosion of Arctic coastal bluffs	Lack of sea ice protection from wind storms	*high*	*high*	24.4.3.2, 28.2, 28.3.4
Increased South American landslide frequency	Heavy precipitation	*medium*	*low*	27.2.1.1
Cascading food web effects on Arctic grazers and predators	Higher frequency of rain-on-snow events	*high*	*high*	28.2.1.1
Increased drought in high Arctic deserts	Warm spells	*high*	*high*	28.2.1.1
Increased monetary losses due to extreme weather events	Storms, floods	*very high*	*very low*	10.7, 18.4.4.2

Table 18-12: Confidence in detection of impacts on aggregate impact measures and confidence in attribution of at least a minor role of climate change in those observed changes.

Global aggregated impact measure	**Reference chapters**	**Confidence in**	
		detection	**attribution**
Glacier ice volume reduction	18.3.1.3; 3.2.2	*very high*	*high*
Shift of permafrost boundary to higher altitudes and latitudes, and increase of active layer thickness	18.3.1.3	*high*	*medium*
Increase in terrestrial net primary production and C stocks	18.3.2.2	*high*	*low*
Negative yield impacts on global wheat against trends in technology, practice, and coverage	18.4.1.1, Fig 7-3	*very low*	*very low*
Negative yield impacts on global maize against trends in technology, practice, and coverage	18.4.1.1, Fig 7-3	*low*	*low*
Small increase in marine net primary production	Table 18-1	*medium*	*low*
Change in fishery productivity	Table 18-2; Fig 30.14, 6.6.1	*high*	*low*
Increase in monetary losses due to extreme weather	18.4.4.2 and 10.7	*very high*	*very low*

Figure 18-1: Schematic of the subject covered in this chapter. The Earth system can be divided into three broad interacting systems. Direct drivers of the human system on the climate system are denoted with a red arrow; some of these drivers may also directly affect natural systems. These effects can in turn influence other systems (dashed red arrows). Further influences of each of the systems on each other (confounding factors) that do not involve climate drivers are represented by blue arrows. Examples of drivers and their impacts are given in the table. Adapted from Stone *et al*. (2013).

	Example of Drivers	Example of Impacts	
		Direct impacts	Subsequent impacts
1 1a 1b	Emission of CO_2	Warming	 Altered crop yield Shift in species phenology
2 2a 2b	Emission of CO_2	Carbon fertilization of plants	 Increase in forestry yield Change in humidity
3	Pollution of river catchment	Decrease in fisheries	
4	Plague of crop pests	Decrease in crop yield	
5	Forest fire	Increased windiness	
6	El Nino event	More wildfires	
7	El Nino event	Fisheries	

Figure 18-2: A schematic diagram comparing approaches to attribution for an ecological system. The multi-step approach differs from the single-step approach in having a discontinuity between the attributed climate change and the observed weather driving the ecological model. Adapted from Stone *et al*. (2013).

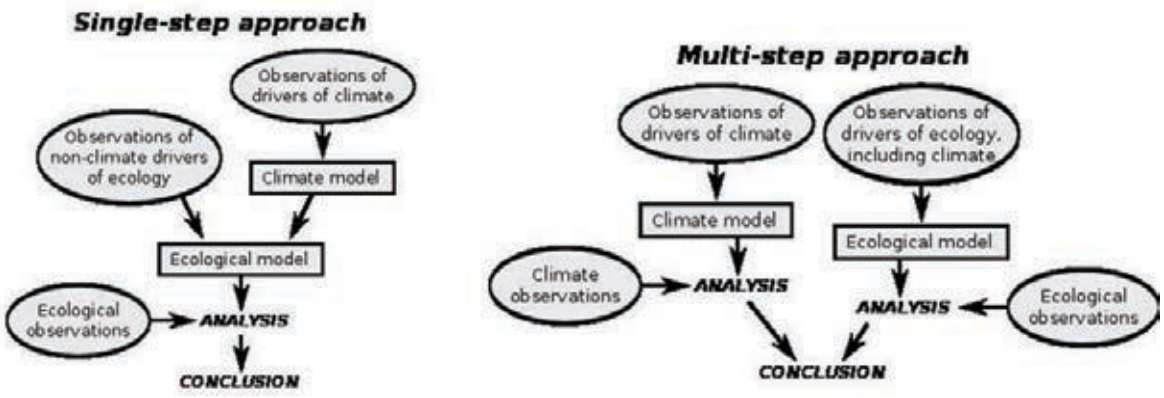

Figure 18-3: Levels of confidence in detection and attribution of observed climate change impacts for freshwater systems over the past several decades, based on expert assessment contained in this section 18.3.1 and augmented by subsections of chapter 3 as indicated. Numbered symbols refer to: Freshwater systems (18.3.1.1): 1 groundwater depletion (Ch.3.2.4), 2 changing river flow (Ch. 3.2.3), 3 changing flood frequency or intensity (Ch. 3.2.3), 4 reduction in lake and river ice duration or thickness (Ch. 18.3.1.2); Cryosphere: 5 shrinking glaciers (Ch. 3.2.2, 18.3.1.2), 6 changes in glacier lakes (Ch. 18.3.1.1), 7 erosion and degradation of arctic coastal permafrost (Ch. 18.3.1.2), 8 degradation and thaw of lowland and mountain permafrost (Ch. 18.3.1.2), Soils and rock (18.3.1.3): 9 Increasing erosion (Ch.3.2.6), 10 changes in shallow landslides (Ch.3.2.6), 11 increasing frequency of Alpine rock failures

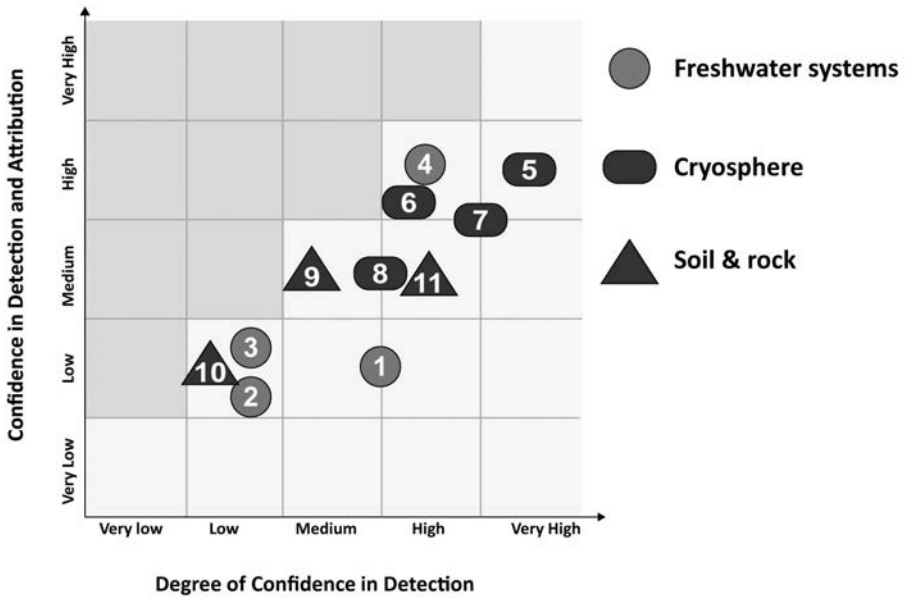

Figure 18-4: Confidence in detection and attribution of observed impacts on unique and threatened systems as a result of recent climate change. Assessments are for confidence in detection of a change and for confidence in attribution of a major role of observed climate change. Large letters denote conclusions for the full-scale system, while small letters denote conclusions for regional subsets of the systems. System changes include shrinking / receding glaciers, mountain and lowland permafrost degradation, Arctic coastal permafrost degradation, increased mortality and bleaching of warm water reef-building corals, increased shrub cover and permafrost decay in the northern tundra, increased tree mortality in the Amazon, increased tree mortality in boreal forests, changes in Arctic marine ecosystems, decline in extent of mangroves and coastal wetlands, and impacts on livelihoods of indigenous Arctic peoples. See Table 18-10 for details and references.

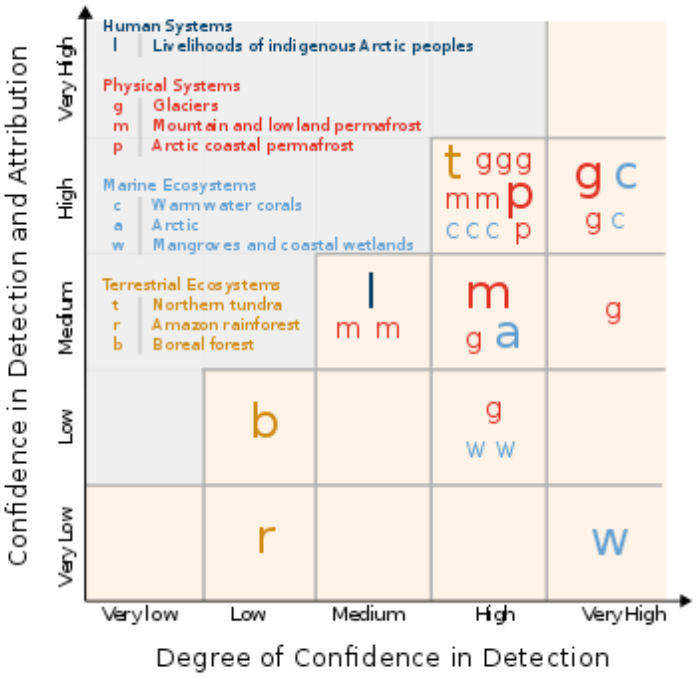

Figure 18-5: Left: confidence in detection of observed changes in extreme weather hazards and attribution of a major role of changing greenhouse gas concentrations in the observed changes. Right: confidence in detection of observed changes in damages related to extreme weather and attribution of major role to observed changes in extreme weather.

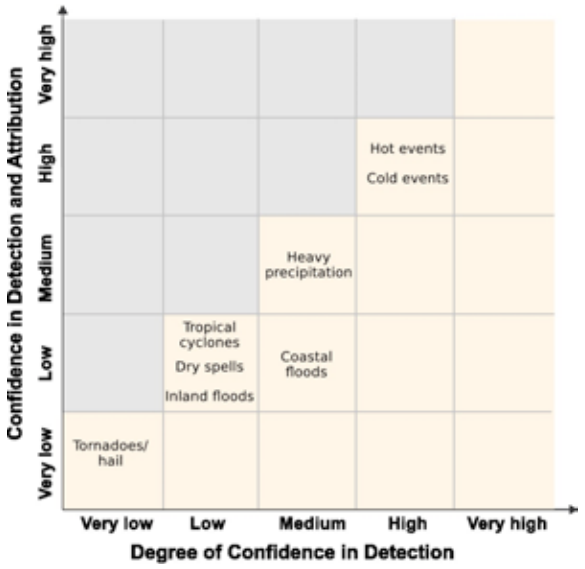

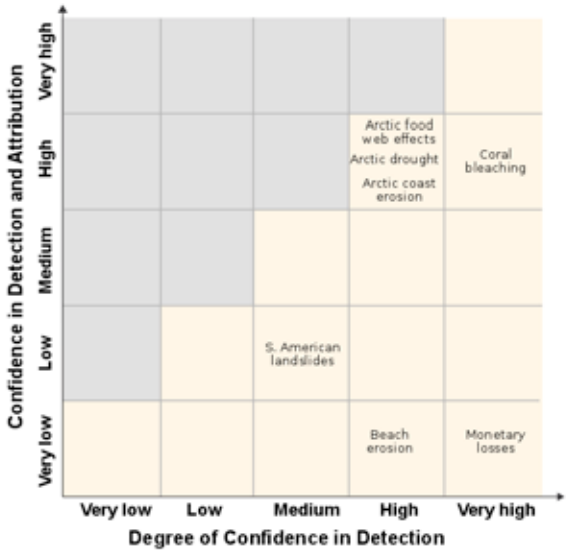

Figure 18-6: Confidence in detection of observed changes in natural systems (panel a) and human and managed systems (panel b) across regions, and confidence in attribution of such trends to observed climate change. Based on assessments developed in Tables 18-6 through 18-9.

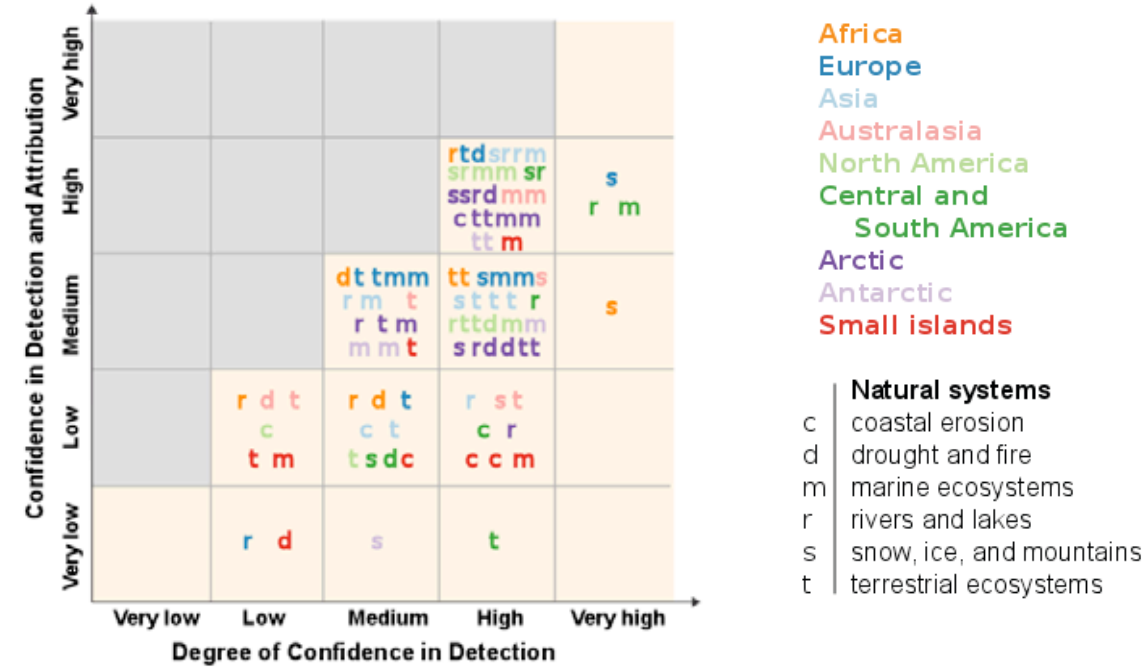
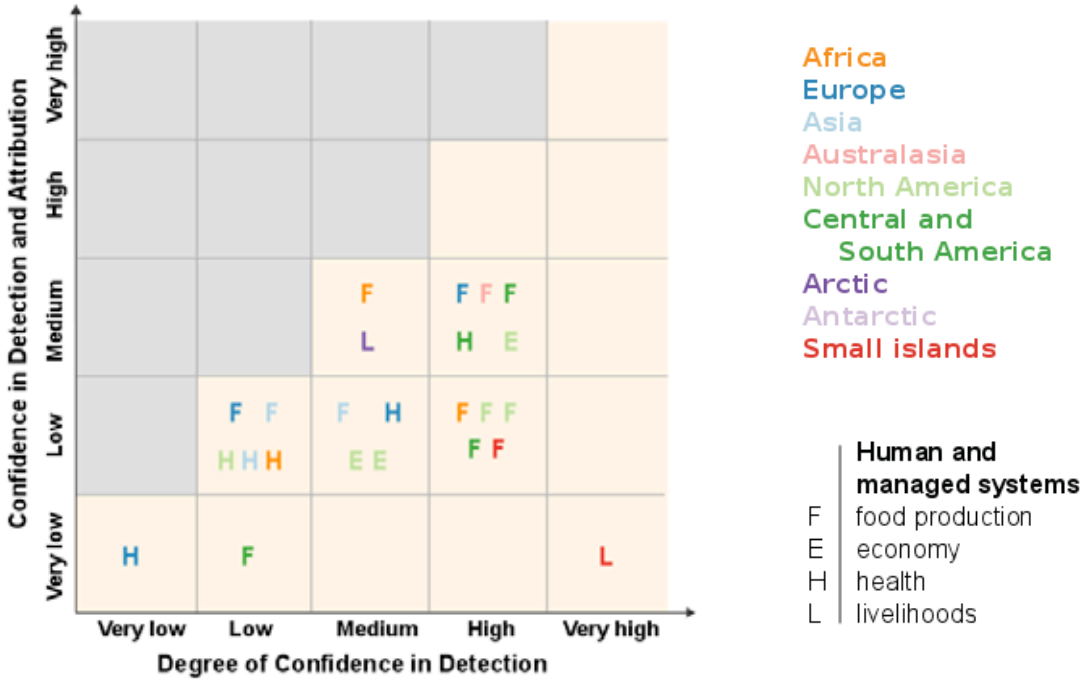


Panel a: Regional Impacts on Natural Systems



Panel b: Regional Impacts on Human Systems

Figure 18-7: Confidence in detection of changes in aggregate impact measures and attribution of at least a minor role of climate change in those trends

Executive Summary

19.1. Purpose, Scope, and Structure of the Chapter
- 19.1.1. Historical Development of this Chapter
- 19.1.2. The Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)
- 19.1.3. New Developments in this Chapter

19.2. Framework for Identifying Key Vulnerabilities, Key Risks, and Emergent and Emerging Risks
- 19.2.1. Risk and Vulnerability
- 19.2.2. Criteria for Identifying Key Vulnerabilities and Key Risks
  - 19.2.2.1. Criteria for Identifying Key Vulnerabilities
  - 19.2.2.2. Criteria for Identifying Key Risks
- 19.2.3. Criteria for Identifying Emergent and Emerging Risks
- 19.2.4. Identifying Key and Emergent Risks under Alternative Development Pathways
- 19.2.5. Assessing Key Vulnerabilities and Emergent Risks

19.3. Emergent Risk: Multiple Interacting Systems and Stresses
- 19.3.1. Limitations of Previous Approaches Imply Key Risks Overlooked
- 19.3.2. Emergent Risks
  - 19.3.2.1. Emergent Risks Arising from the Effects of Degradation of Ecosystem Services by Climate Change
  - 19.3.2.2. Emergent Risk Involving Non-Climate Stressors: the Management of Water, Land, and Energy
  - 19.3.2.3. Emergent Risks Involving Health Effects and Disease Emergence
  - 19.3.2.4. Spatial Convergence of Multiple Impacts: Multi-Impacts Hotspots
  - 19.3.2.5. Maladaptation

19.4. Emergent Risk: Indirect, Trans-Boundary, and Long-Distance Impacts
- 19.4.1. Indirect, Trans-Boundary, and Long-Distance Impacts of Climate Change Impacts on Agricultural Yields: Food Trade Patterns, Prices, Malnutrition

19.4.2. Indirect, Trans-boundary, and Long-Distance Impacts of Adaptation
19.4.2.1. Human Migration and Displacement
19.4.2.2. Conflict and Insecurity
19.4.2.3. Species Range Shifts: Consequences
19.4.3. Indirect, Trans-Boundary, and Long-Distance Impacts of Mitigation Measures
19.4.3.1. Effects on Biodiversity
19.4.3.2. Effects on Human Systems

19.5. Emerging Risks
19.5.1. Risks from Large Global Temperature Rise >=4°C Above Pre-Industrial Levels
19.5.2. Risks from Ocean Acidification
19.5.3. Risks from CO2 Health Effects
19.5.4. Risks from Geoengineering (Solar Radiation Management)

19.6. Key Vulnerabilities, Key Risks, and Reasons for Concern
19.6.1. Key Vulnerabilities
19.6.1.1. Dynamics of Vulnerability
19.6.1.2. Differential Vulnerability
19.6.1.3. Trends in Vulnerability
19.6.1.4. Risk Perception
19.6.2. Key Risks
19.6.2.1. Assessing Key Risks
19.6.2.2. The Role of Adaptation and Alternative Development Pathways
19.6.3. Updating Reasons for Concern
19.6.3.1. Variations in RFCs across Socio-Economic Pathways
19.6.3.2. Unique and Threatened Systems
19.6.3.3. Extreme Events
19.6.3.4. Distribution of Impacts
19.6.3.5. Aggregate Impacts
19.6.3.6. Large-Scale Singular Events: Physical, Ecological, and Social System Thresholds and Irreversible Change

19.7. Assessment of Response Strategies to Manage Risks
19.7.1. Relationship between Adaptation Efforts, Mitigation Efforts, and Residual Impacts
19.7.2. Limits to Mitigation
19.7.3. Avoiding Thresholds, Irreversible Change, and Large-Scale Singularities in the Earth System
19.7.4. Avoiding Tipping Points in Social/Ecological Systems
19.7.5. Limits to Adaptation

Frequently Asked Questions
19.1: How does climate change interact with and amplify pre-existing risks?
19.2: How can climate change at one location cause impacts at another, distant location?
19.3: Does science provide an answer to the question of how much warming is acceptable?

References

Executive Summary

This chapter assesses the interaction of changing physical characteristics of the climate system with evolving characteristics of human, socioeconomic, and biological systems (exposure and vulnerability) to produce risk [19.2], in relation to Article 2 of the UN Framework Convention on Climate Change. Alternative development paths influence risk by changing both the likelihood of physical impacts (through their effects on greenhouse gas emissions) and by altering vulnerability and exposure [19.2.4, Figure 19-1].

A particular focus is placed on interactions among climate change impacts in various sectors and regions, and human vulnerability and adaptation in other sectors and regions, as well as interactions between adaptation and mitigation actions. Such interactions are generally not included, or not well integrated, into projections of climate change impacts, but their consideration leads to the identification of a variety of *emergent risks* that were not previously recognized. This chapter identifies several such complex-system interactions that increase vulnerability and risk [19.3, *high confidence*]. For example:

- The risk of severe harm and loss due to climate change-related hazards and various vulnerabilities is particularly high in large urban and rural areas in low-lying coastal zones. These areas, many characterized by increasing populations, are exposed to multiple hazards and potential failures of critical infrastructure, generating new systemic risk [19.3.2.4].
- The risk of climate change to human systems is increased by the loss of ecosystem services (e.g. water and air purification, protection from extreme weather events, preservation of soils, recycling of nutrients, and pollination of crops), which are supported by biodiversity [19.3.2.1, *high confidence*].
- In some water stressed regions, groundwater stores that have historically acted as buffers against climate change impacts are being depleted, with adverse consequences for human systems and ecosystems, whilst at the same time climate change may directly increase or decrease regional groundwater resources [19.3.2.2, *high confidence*].
- Climate change adversely affects human health, increasing exposure and vulnerability to a variety of other stresses, for example by altering the prevalence and distribution of diseases that are weather and climate sensitive, increasing injuries and fatalities resulting from extreme weather events, and eroding mental health in response to population displacement [19.3.2.3, *high confidence*].
- Spatial convergence of impacts in different sectors creates impact 'hotspots' involving new interactions (*high confidence*). Examples include the Arctic (where sea ice loss and thawing disrupts transportation, buildings, other infrastructure, and potentially disrupts Inuit culture); the environs of Micronesia, Mariana Island, and Papua New Guinea (where coral reefs are highly threatened due to exposure to concomitant sea surface temperature rise and ocean acidification); and Sub-Saharan Africa (where global warming at the high end of the range projected for this century, i.e., more than 4°C above preindustrial levels, would be especially disruptive, resulting in high risk of reduced extent of croplands, reduced length of the growing season, increased hunger, and increased malaria transmission) [19.3.2.4].
- Adaptation designed for one sector may interfere with the functioning of another sector, creating new risks (*high confidence*). For example, increasing crop irrigation in response to a drying climate can exacerbate water stress in downstream wetlands, where the latter otherwise provide important water cleaning services [19.3.2.5].

Emergent risks also arise from indirect, trans-boundary, and long-distance impacts of climate change, sometimes mediated by the adaptive responses of human populations [19.4, *high confidence*]. Responses to climate change can result from localized impacts that generate distant harm via responses transmitted through human or ecological systems.

- Increasing prices of food commodities on the global market due to local climate impacts, sometimes in conjunction with demand for biofuels, decrease food security and exacerbate malnutrition at distant locations [19.4.1].
- Climate change will bear significant consequences for migration flows at particular times and places, creating risks as well as benefits for migrants and for sending and receiving regions and states (*high confidence*) [19.4.2.1].
- The possibility that climate change will alter patterns of violence is a risk emerging in the literature. The effect of climate change on conflict and insecurity has the potential to become a key risk because the reported magnitude of the influence of the climate's variability on security is large [19.4.2.2].
- Shifting species ranges in response to climate change adversely affect ecosystem function and services while presenting new challenges to conservation efforts [19.4.2.3]. Where range shifts cannot track climatic changes, species are at risk of eventual extinction (*high confidence*).

Additional risks have emerged recently in the literature related to particular biophysical impacts of climate change [19.5, *high confidence*]. These include decreasing viability of marine calcifying organisms due to ocean

acidification [19.5.2]; increasing production and allergenicity of pollen and allergenic compounds as well as decreasing nutritional quality of key food crops due to high ambient concentrations of CO_2 [19.5.3]; and the risk of adverse regional impacts arising from Solar Radiation Management implemented for the purposes of limiting global warming [19.5.4].

Consequences of global temperature rise in excess of 4°C relative to preindustrial levels can now be assessed [19.5.1]. Key risks associated with large temperature rise include exceedance of human physiological limits in some locations and nonlinear earth system responses *(high confidence)*. There may also be key risks in other sectors and regions that have not been studied in this context.

Global and local socio-economic, environmental and governance trends confirm that vulnerability and exposure of communities or social-ecological systems to climatic hazards are dynamic and thus varying across temporal and spatial scales. Effective risk reduction and adaptation strategies consider these dynamics and the inter-linkages between socio-economic development pathways and the vulnerability and exposure of people. Changes in poverty or socio-economic status, race and ethnicity compositions as well as age structures and changes in governance had a significant influence on the outcome of past crises associated with climatic hazards [19.6.1.3].

Challenges for vulnerability reduction and adaptation are particularly high in regions that have shown severe difficulties in governance. Studies confirm that countries that are classified as failed states and affected by violence are often not able to effectively reduce vulnerability. There is *high confidence* that unless governance improves in countries with severe governance failure, an increase in risk is to be expected as a result of climate changes interacting with increased human vulnerability [19.6.1.3.3].

Assessment of existing frameworks pertinent to Article 2 of the UNFCCC, based on Key Risks, Key Vulnerabilities, and Reasons for Concern, has led to evaluations of risk being updated in light of the advances since AR4, including SREX and the current report's discussions of vulnerability, human security, and adaptation, [19.6.3].

Several *key risks* resulting from the interaction of hazardous climate changes and physical impacts with the vulnerability of societies and exposed systems were identified in this chapter [19.6.2.1.].

- The risk for increased food insecurity can result from both local conditions like adverse changes in rainfall patterns and a lack of alternative sources of income for some affected households, as well as regional and national conditions like a breakdown of food distribution and storage processes [*high confidence*].
- The risks of dispossession of land – including the alteration of rural inhabitants' coping and adaptation processes - results from shifts in energy policies and global markets.
- A high risk of loss of livelihoods due to changes in climatic conditions and socioeconomic structures affecting people living in low-laying costal zones and people engaged in rain-fed agriculture in developing countries and countries with economies in transition [*high confidence*].
- The risks of increasing morbidity, mortality, and infrastructure failure as well as new systemic risks (such as the risk of heat stress as a result of power shortages during extreme events) in urban areas in both developed and developing countries [*high confidence*].
- The risk of increase in disease burden resulting from the interaction of changes in physical climate conditions like increasing temperatures with the vulnerability of people due to, for example, an aging population.

The determination of key risks as reflected, for example, in the Reasons for Concern did not previously distinguish between alternative development pathways. The development of risk profiles from Shared Socioeconomic Pathways and Representative Concentration Pathways is an important area of research that can lead to improvement in the framework developed in this chapter [19.6.3.1].

Updating of the Reasons for Concern leads to the following assessment:

- **Unique human and natural systems tend to have very limited adaptive capacity, and hence we have *high confidence* that climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C over preindustrial levels were exceeded.** In addition, there is new

and stronger evidence to support the previous judgment of *high confidence* that a warming of up to 2°C above 1990-2000 levels would result in significant impacts on many unique and vulnerable systems, and would likely increase the endangered status of many threatened species, with increasing adverse impacts and increasing risk of extinctions (and increasing confidence in this conclusion) at higher temperatures [19.6.3.2].

- **The overall risk from extreme events due to climate change has not changed significantly since AR4 but there is higher confidence in the attribution of some types of extreme events to human activity and in the assessment of the risk from extreme events in the coming decades.** In addition, there is a new appreciation for the importance of exposure and vulnerability, in both developed and developing countries [19.6.3.3], in assessing risk associated with extreme events. Many of the key vulnerabilities, key risks, and emergent risks identified in individual chapters of this report reflect differential vulnerability between groups due to, for example, age, wealth, or income status, and deficiencies in governance [19.6.1], which are particularly important in assessing this Reason for Concern and also the following one associated with the distribution of impacts.
- **Risk associated with the distribution of impacts is generally greatest in low-latitude, less developed areas, but because vulnerability is unevenly distributed within countries, some populations in developed countries are highly vulnerable to warming of less than 2°C, as noted in AR4 (*high confidence*) [19.6.3.4].**
- **Globally aggregated risk is underestimated because it does not include many non-monetized impacts, such as biodiversity loss, and because it omits many known impacts that have only recently be quantified, such as reduced labor productivity [19.6.3.5, *high confidence*]. In addition, aggregated estimates of costs mask significant differences in impacts across sectors, regions, countries and populations [19.6.3.5, *very high confidence*].** The overall assessment of aggregate risk and confidence in that assessment has not changed since AR4.
- **The risk associated with large-scale singular events such as the at least partial deglaciation of the Greenland ice sheet remains comparable to that assessed in AR4 [19.6.3.6].**

The management of key and emergent risks of climate change and Reasons for Concern includes (i) mitigation that reduces the likelihood of physical impacts and (ii) adaptation that reduces the vulnerability and exposure of societies and ecosystems to those impacts [19.7]. Advances in the assessment and implementation of mitigation measures and adaptation strategies include for the first time evaluation of avoided damages from a range of strategies.

Impacts of climate change avoided under a range of scenarios for mitigation of greenhouse gas emissions are potentially large and increasing over the 21st century [19.7.1, *high confidence*]. Among the impacts assessed here, benefits from mitigation are most immediate for ocean acidification and least immediate for impacts related to sea level rise. Since mitigation reduces the rate as well as the magnitude of warming, it also delays the need to adapt to a particular level of climate change impacts, potentially by several decades.

Under any plausible scenario for mitigation and adaptation, some degree of risk from residual damages is unavoidable (*very high confidence*). For example, no model-based scenarios in the literature demonstrate the feasibility of limiting warming to a maximum of 1.5°C with at least 50% likelihood and recent findings suggest that comprehensive adaptation to current climate risk is prohibitively expensive, indicating that adaptions to future changes are similarly constrained [19.7.2.1]. Assessments of stringent mitigation scenarios suggest that they can potentially avoid one half of the aggregate economic impacts that would otherwise accrue by 2100, and between 20-60% of the physical impacts, depending on sector and region [19.7.1].

The design of risk-management strategies could be informed by observation and projection systems that provide an actionable early warning signal of an approaching threshold response. However, there is *low confidence* in the feasibility and requirements for such systems, since studies to date are highly simplified and limited in number [19.7.3].

The risk of crossing tipping points in socio-ecological systems may be reduced by preserving ecosystem services (*medium confidence*). Tipping points are thresholds beyond which adverse impacts increase non-linearly.

Some tipping points may be avoided by limiting the level of climate change and/or removing concomitant stresses such as overgrazing, overfishing, and pollution [19.7.4] but there is *low confidence* in location of such tipping points and measures to avoid them.

19.1. Purpose, Scope, and Structure of the Chapter

The objective of this chapter is to assess new literature published since the Fourth Assessment Report on emergent risks and key vulnerabilities to climate change from the perspective of the distribution of risk over geographic location, economic sector, time period, and socioeconomic characteristics of individuals and societies. Frameworks used in previous IPCC reports to assess risk in the context of Article 2 of the UN Framework Convention on Climate Change (UNFCCC) are updated and extended in light of new literature; and additional frameworks arising in recent literature are examined. A focal point of this chapter is the interaction of the changing physical characteristics of the climate system with evolving characteristics of socioeconomic and biological systems (exposure and vulnerability) to produce risk (see Figure 19-1).

[INSERT FIGURE 19-1 HERE
Figure 19-1: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. The figure visualizes the different terms and concepts discussed in this chapter. It underscores that risks are a product of a complex interaction between physical hazards associated with climate change and climate variability on the one hand, and the vulnerability of a society or a social-ecological system and its exposure to climate-related hazards on the other. The definition and use of "key" are indicated in Box 19-2 and the glossary. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions. Both the changes in the climate system (left side) and the development processes (right side) are key drivers of the different core components (vulnerability, exposure, and physical hazards) that constitute risk (modified version of Figure 1, IPCC, 2012).]

19.1.1. Historical Development of this Chapter

The Third and Fourth Assessment Reports (TAR and AR4, respectively) each devoted chapters to evaluating the state of knowledge relevant to Article 2 of the UNFCCC (Smith *et al*., 2001; Schneider *et al*., 2007; see Box 19-1). The TAR sorted and aggregated impacts discussed in the literature according to a framework called *Reasons for Concern* (RFCs), and assessed the level of risk associated with individual impacts of climate change as well as each category or "reason" as a whole, generally as a function of global mean warming. This assessment took account of the distribution of vulnerability across particular regions, countries, and sectors. AR4 furthered the discussion relevant to Article 2 by assessing new literature and developing criteria potentially useful for policy makers in the determination of *key* impacts and vulnerabilities, i.e, meriting particular attention in respect to Article 2 (see Box 19-2 for definitions of Reasons for Concern and Key Vulnerabilities [KVs]). AR4 emphasized the differences in vulnerability between developed and developing countries but also assessed emerging literature describing vulnerability pertaining to various aggregations of people (such as by ethnic, cultural, age, gender, or income status) and response strategies for avoiding key impacts. The Reasons for Concern were updated and the Synthesis Report (IPCC, 2007) noted that they "remain a viable framework to consider key vulnerabilities". However, their utility was limited by several factors: the lack of a time dimension (i.e., representation of impacts arising from timing and rates of climate change and climate forcing), the focus on risk only as a function of global mean temperature, lack of a clear distinction between impacts and vulnerability, and importantly, incomplete incorporation of the evolving socioeconomic context, particularly adaptation capacity, in representing impacts and vulnerability.

19.1.2. The Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)

SREX (IPCC, 2012) provides additional insights with respect to one RFC (the risk of extreme weather events) and particularly the distribution of capacities to adapt to such events between countries, communities, and other groups,

and the limitations of implementation of these capacities. SREX emphasized the role of the socioeconomic setting and development pathway (expressed through exposure and vulnerability) in determining, on the one hand, the circumstances where extreme events do or do not result in extreme impacts and disasters, and on the other hand, when non-extreme events may also result in extreme impacts and disasters.

19.1.3. New Developments in this Chapter

With these frameworks already established, and a long list of impacts and key vulnerabilities enumerated and categorized in previous assessments, the current chapter has three goals: first, to recognize the dynamic nature of our understanding by assessing *emergent and emerging risks* (see Box 19-2, Table 19-3). These risks are, respectively, those which arise out of complex interactions involving climate and socioecological systems, and those which have only recently emerged in the scientific literature in sufficient detail to permit assessment. In this chapter, we consider only those emergent and emerging risks which have the potential to become relevant to interpreting Article 2 as additional understanding accumulates. For example, since AR4, sufficient literature has emerged to allow initial assessment of the relationship between climate change and conflict. The second goal is to reassess and reorganize the existing frameworks (based on Reasons for Concern and Key Vulnerabilities) for evaluating the literature pertinent to Article 2 of the UNFCCC in order to address the deficiencies cited in section 19.1.1, particularly in light of the advances in SREX and the current report's discussions of vulnerability and human security (see chapters 12 and 13) and adaptation (see chapters 14-17 and 20). From this perspective, the objective stated in Article 2 may be viewed as aiming in part to ensure human security in the face of climate change. Thirdly, this chapter will assess recent literature pertinent to additional frameworks for categorizing risk and vulnerability, particularly focusing on indirect impacts and interaction and concatenation of risk, including geographic "hotspots" (see 19.3).

In order to clarify the relative roles of characteristics of the physical climate system, like increases in temperature, precipitation, or storm frequency, and characteristics of the socioeconomic and biological systems with which these interact (vulnerability and exposure) to produce risks of particular consequences (used interchangeably here with "impacts" and "outcomes"), we rely heavily on a concept used sparingly in the TAR and AR4, *key risks* (see Box 19-2). Furthermore, we emphasize recent literature pointing to the *dynamic* character of vulnerability based on its intimate relationship to development.

We consider a variety of types of emergent risks, including for example, vulnerability to impacts arising from multiple interacting systems and stresses, indirect impacts, trans-boundary impacts, and impacts occurring at a long distance from the location of the climate change which causes them (Oppenheimer, 2012). One example which illustrates all of these properties is the extent to which climate change impacts on agriculture, water resources, and sea level affect migration flows. These shifts entail both risks and potential benefits for the migrants, for the regions where they originate, and for the destination regions (see 19.5.2.1 and 12.4). Risks include indirect impacts, like the effect of land use changes on ecosystems, occurring at the new locations of settlement, which may be near the location of the original climate impact or quite distant. Such distant, indirect effects would compound the direct consequences of climate change at the locations receiving the incoming migrants.

Box 19-1. Article 2 of the UNFCCC and the Copenhagen Accord

Article 2

OBJECTIVE
The ultimate objective of this Convention and any related legal instruments that the Conference of the Parties may adopt is to achieve, in accordance with the relevant provisions of the Convention, stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time-frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner.

Copenhagen Accord (excerpt)

To achieve the ultimate objective of the Convention to stabilize greenhouse gas concentration in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system, we shall, recognizing the scientific view that the increase in global temperature should be below 2 degrees Celsius, on the basis of equity and in the context of sustainable development, enhance our long-term cooperative action to combat climate change.

____ START BOX 19-2 HERE ____

Box 19-2. Definitions

Vulnerability - The propensity or predisposition to be adversely affected. A broad set of factors such as wealth, social status, and gender determine vulnerability and exposure to climate-related risk.

Exposure - The presence of people; livelihoods; environmental services and resources; infrastructure; or economic, social, or cultural assets in places that could be adversely affected.

Impacts - Effects on natural and human systems. In this chapter, the term is used to refer to the effects on natural and human systems of hazardous physical events, of disasters, and of climate change. Impacts are also referred to as *consequences* and *outcomes*. They are a function of exposure and vulnerability, and generally refer to adverse effects on lives, livelihoods, health status, ecosystems, economic, social and cultural assets, services (including environmental), and infrastructure due to the interaction of hazardous events or trends occurring within a specific time period and the vulnerability of a society or system exposed. We refer to the effects of climate changes on geophysical systems, such as floods, droughts, and sea level rise, as *physical impacts*.

Hazard - The potential occurrence of a natural or human-induced physical event that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, livelihoods, service provision, and environmental resources. In this chapter, hazard usually refers to climate-related events or trends or their physical impacts.

Stressors - Those events and trends which are not-climate-related but have an important effect on the system exposed and can increase vulnerability to climate-related risk.

Risk - The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk is often represented as probability of occurrence of a hazardous event(s) multiplied by the consequences if the event(s) occurs.

Risk = Probability of Event(s) X Consequences

This report assesses climate-related risks.

Key vulnerability, key risk, key impact - A vulnerability, risk, or impact relevant to the definition and elaboration of "dangerous anthropogenic interference (DAI) with the climate system," in the terminology of United Nations Framework Convention on Climate Change (UNFCCC) Article 2, meriting particular attention by policy makers in that context.

Key risks are potential adverse consequences for humans and social-ecological systems due to the interaction of hazardous climate changes and physical impacts with vulnerabilities of societies and systems exposed. Risks are not considered "key" due to high physical impact alone, absent significant vulnerability and exposure.

Vulnerabilities are considered "key" if they have the potential to combine with climate changes and physical impacts to result in severe consequences for society or social-ecological systems. Vulnerabilities that have little influence on risk would not be considered key.

Extract from Chapter 19, WGII, AR4:

Many impacts, vulnerabilities and risks merit particular attention by policy-makers due to characteristics that might make them 'key'. The identification of potential key vulnerabilities is intended to provide guidance to decision-makers for identifying levels and rates of climate change that may be associated with 'dangerous anthropogenic interference' (DAI) with the climate system, in the terminology of United Nations Framework Convention on Climate Change (UNFCCC) Article 2 (see Box 19-1). Ultimately, the definition of DAI cannot be based on scientific arguments alone, but involves other judgments informed by the state of scientific knowledge.

***Emergent Risk*:** A risk that arises from the interaction of phenomena in a complex system, for example the risk caused when geographic shifts in human population in response to climate change lead to increased vulnerability in the receiving region.

***Emerging Risk*:** A risk that has emerged only recently in the scientific literature in sufficient detail to permit assessment. For example, the initial consequences associated with these risks may have only recently been detected above the natural variability of the climate system, as is the case for certain effects of ocean acidification on calcareous organisms. For clarity, where these emerging risks arise from the interaction of phenomena in a complex system (and are thus also emergent risks) they are discussed in sections 19.3 and 19.4 relating to emergent risks.

In this chapter, the only emergent and emerging risks discussed are those which have the potential to become key risks once sufficient understanding accumulates.

Reasons for Concern – Elements of a classification framework, first developed in the IPCC Third Assessment Report, which aims to facilitate judgments about what level of climate change may be "dangerous" (in the language of Article 2 of the UNFCCC) by aggregating impacts, risks, and vulnerabilities.

Summary of Reasons for Concern (updated from TAR, WGII, Chapter 19):

"Reasons for Concern" may aid readers in making their own determination about what is a "dangerous" climate change. Each reason for concern is consistent with a paradigm that can be used by itself or in combination with other paradigms to help determine what level of climate change is dangerous. The reasons for concerns are the relations between global mean temperature increase and:

1. Risks to unique and threatened systems
2. Risks associated with extreme weather events
3. Risks associated with the distribution of impacts
4. Risks associated with aggregate impacts
5. Risks associated with large-scale singular events

19.2. Framework for Identifying Key Vulnerabilities, Key Risks, and Emergent and Emerging Risks

19.2.1. Risk and Vulnerability

Definitions and frameworks that systematize physical impacts, exposure, vulnerability, risk and adaptation in the context of climate change are multiple, overlapping, and often contested (see e.g. Burton *et al.*, 1983; Blaikie *et al.*, 1994; Twigg, 2001; Turner *et al.*, 2003a; Turner *et al.*, 2003b; UN/ISDR, 2004; Schröter, 2005; Füssel and Klein, 2006; Adger, 2006; Villagrán de León, 2006; Thomalla *et al.*, 2006; Tol and Yohe, 2006; Birkmann, 2006b; IPCC,

2007; Cutter *et al*., 2008; Cutter and Finch, 2008; ICSU - LAC, 2010a; ICSU - LAC, 2010b; Cardona, 2011; Kienberger, 2012; IPCC, 2012; Costa and Kropp, 2012; Birkmann *et al*., 2013); however, most of the concepts and the respective literature differentiates between vulnerability, risk, impacts and hazards (see e.g. Hutton *et al*., 2011; IPCC, 2012; Birkmann *et al*., 2013). The following section serves not solely as an update of existing knowledge about key vulnerabilities and key risks since the AR4, but also provides a more coherent framework to systematize these concepts and to enhance the understanding of these phenomena based on new literature, including SREX (IPCC, 2012).

The large body of literature (see above) underscores that risks to climate change are not solely externally generated circumstances to which societies respond, but rather, the results of complex interactions among societies or communities, ecosystems, and physical impacts arising from climate change (Susman *et al*., 1983; Comfort *et al*., 1999; Birkmann *et al*., 2011; UNISDR, 2011; IPCC, 2012b; Birkmann *et al*., 2013). We refer to the effects of climate changes on geophysical systems, such as floods, droughts, deglaciation, and sea level rise, as *physical impacts*. In contrast, vulnerability refers primarily to characteristics of human or social-ecological systems exposed to hazardous climatic or non-climatic events and trends (UNDRO, 1980; Liverman, 1990; Cannon, 1994; Blaikie *et al*., 1996; UN/ISDR, 2004; Cannon, 2006; Birkmann, 2006; Cannon, 2006; Thywissen, 2006; Füssel and Klein, 2006; IPCC, 2012). Ecosystems or geographic areas can be classified as vulnerable, and merit particular attention if vulnerability of humans arises from impacts on the related ecosystem services. The Millennium Ecosystem Assessment (MEA) for example identified ecosystem services that affect the vulnerability of societies and communities, such as provision of fresh water resources and air quality (MEA, 2005)

Compared to the AR4 which did not fully differentiate key vulnerabilities, impacts and risks, the new conceptualization used here provides a more coherent and precise systematization (see Figure 19-1). In addition, the framework underscores that the development process of a society has significant implications for vulnerability and risk. Climate change is not a risk per se; rather climate changes and related physical impacts interact with the vulnerability of exposed systems to determine the level of risk (see Table 19-3). Identifying key vulnerabilities facilitates estimating key risks when coupled with information about the climate and climate change. The new differentiation provides the basis for criteria developed in this chapter for assessing vulnerability and risk.

19.2.2. Criteria for Identifying Key Vulnerabilities and Key Risks

Vulnerability is dynamic and context specific, determined by human behavior and societal organization, which influences for example the susceptibility of people (e.g. by marginalization) and their coping and adaptive capacities to hazardous events and trends (see IPCC, 2012). In this regard coping mainly refers to capacities that allow a system to protect itself in the face of adverse consequences, while adaptation – by contrast – denotes a longer-term process that also involves adjustments in the system itself and refers to learning, experimentation and change (Yohe and Tol, 2002; Pelling, 2010; Birkmann *et al*., 2013). Perceptions and cognitive constructs about risks and adaptation options as well as cultural contexts influence adaptive capacities and thus vulnerability (Grothmann and Patt 2005; Rohmberg 2009; Kuruppu and Liverman 2011; see section 19.4.2.3). SREX stressed that the consideration of multiple dimensions (e.g., social, economic, environmental, institutional, cultural) as well as different causal factors of vulnerability can improve strategies to reduce risks to climate change (see IPCC, 2012, p. 17, 67-106).

Key vulnerability and key risk are defined in Box 19-2. Vulnerabilities that have little influence on overall risk would not be considered key. Similarly, the magnitude or other characteristics of physical impacts, such as glacier melting or sea level rise, are not by themselves adequate to determine key risks, since the consequences of climate change also will be determined by the vulnerability of the exposed society or social-ecological system. Key vulnerabilities and key risks embody a normative component because different societies might rank the various vulnerability and risk factors and actual or potential types of loss and damage differently (see IPCC, 2012, p. 45; IPCC, 2007, p. 785). Generally, vulnerability merits particular attention when the survival of communities, societies, or ecosystems is threatened (see UN/ISDR 2011; Birkmann *et al*., 2011). Climate change will influence both the nature of the climatic hazards societies and ecosystems are exposed to and also contribute to deterioration or improvement of coping and adaptive capacities of systems exposed to these changes. Consequently, many studies

(Wisner *et al*., 2004; Cardona, 2010; Birkmann *et al*., 2011) focus with a priority on the vulnerability of humans and societies as a key feature, rather than solely on the physical impacts of climatic change.

19.2.2.1. Criteria for Identifying Key Vulnerabilities

AR4 WGII Ch. 19 highlighted seven criteria that may be used to identify key vulnerabilities: Here we reorganize and further develop these criteria in order to improve the differentiation between key vulnerabilities, key risks and physical impacts – taking into account recent literature (Blaikie *et al*., 1994; Bohle, 2001; Turner *et al*., 2003a; Turner *et al*., 2003b; Villagrán de León, 2006; Cutter *et al*., 2008; Cutter and Finch, 2008; ICSU - LAC, 2010a; ICSU - LAC, 2010b; UNISDR, 2011; Cardona, 2011; Birkmann, 2011a; IPCC, 2012a; Birkmann *et al*., 2013). The criteria for identifying vulnerabilities as "key" used in the AR4 are: magnitude of impacts, timing of impacts, persistence and reversibility of impacts, likelihood (estimates of uncertainty) of impacts and vulnerabilities and confidence in those estimates, potential for adaptation, distributional aspects of impacts and vulnerabilities, and importance of the system(s) at risk. These criteria do not provide a systematic differentiation of vulnerability and risk. Revised criteria for assessing *key vulnerabilities* used here should provide an improved basis to distinguish between changes in the physical climate and associated physical impacts (like sea level rise), vulnerability and risk for societies or social-ecological systems. The following eight criteria are used to judge whether vulnerabilities are key:

1) *Exposure of a society, community, or social-ecological system to climatic stressors*. While exposure as used is distinct from vulnerability, exposure is an important precondition for considering a specific vulnerability as key. If a system is not at present nor in future exposed to hazardous climatic trends or events, it is less important to consider its vulnerability to such hazards. The exposure to climatic hazards and non-climatic stressors can be assessed based on spatial and temporal dimensions.
2) *Probability that societies or social-ecological systems exposed to climatic changes and associated physical impacts would experience major harm, loss and damages*. Vulnerability is considered key when there is a high probability that a climatic hazard, often in combination with non-climatic stressors (e.g. price fluctuations, migration, land-grabbing), would cause major harm to an exposed and particularly susceptible society or social-ecological system. This criterion can be made specific with vulnerability assessments. For example, communities in low-lying areas in developing countries with limited resources to adapt and a low awareness about climatic hazards are often more vulnerable than regions and communities in highly developed countries that can afford coastal protection systems (Nicholls and Small 2002; Klein *et al*., 2003, p. 109). Criteria that might be used to assess such susceptibilities or sensitivities encompass among other factors poverty and wealth status, demographic characteristics, and aspects of governance (see IPCC, 2012).
3) *Importance of the vulnerable system(s)*. Societies and people in differing regions and cultural contexts view the importance of systems, impacts, and services differently (see Kienberger, 2012). However, the identification of key vulnerabilities is less subjective when it involves those systems that are crucial for the survival of societies or when it refers to resources essential for coping and adapting to adverse consequences, such as important ecosystem services on which societies depend. For example, drought exposed-farmer households in the Sahel are heavily dependent on ecosystem services such as water and fertile soils, and some storm-exposed islands nations are highly dependent on coral reefs. Inability to replace such a system or compensate for potential and actual losses and damages is a feature of importance. Defining key vulnerabilities regarding various societal groups (as in criterion #2), or ecosystem services takes into account the contextual conditions that make these societies or exposed elements or groups highly vulnerable compared to similar systems in other contexts(Leichenko and O'Brien, 2008; O'Brien *et al*., 2009).
4) *Limited ability of societies or communities to cope with the climate-related hazards within existing capacities*. Coping refers primarily to capacities that are available here and now to reduce the negative impacts of climatic stress on communities or social-ecological systems exposed. Coping is part of the formula that determines vulnerability at any one moment in time. Coping also connotes the protection of the current system and institutional settings (see Birkmann, 2011; Birkmann et al. 2013) rather than improving these to increase capacities against climate risks (IPCC 2012, p. 51). Limits of coping provide a criterion for key vulnerabilities.

5) *Limited ability of societies to build adaptive capacities to reduce or limit vulnerability as environmental and climate conditions change*. The capacity of societies (including communities) to build adaptive capacities is a central issue when assessing vulnerability (IPCC 2007, AR4). Adaptation is a continuous process which includes – compared to coping – also learning, experimentation and change of the system exposed (Smithers and Smit, 1997; Pielke Jr, 1998; Smit *et al*., 1999; Frankhauser *et al*., 1999; Adger *et al*., 2005; Smit, 2006; Pelling, 2010). This understanding of adaptation is also based on an emerging consensus from climate change literature (Kelly and Adger, 2000; Yohe, 2002; Pelling *et al*., 2008) where coping describes actions taken within existing constraints (including vision and knowledge), while adaptation signifies expanding the boundaries of those constraints, for instance, through institutional changes (e.g. rule systems, modes of governance) (Pelling *et al*., 2008; Garschagen, 2011; Tschakert and Dietrich; 2012).

6) *Persistence of vulnerable conditions and degree of irreversibility of consequences*. Vulnerabilities are considered key when they are persistent and difficult to alter as well as having a high potential to interact with a hazardous event to produce irreversible negative changes. This is particularly the case when the susceptibility or sensitivity is high, implying that the capacities to cope or adapt are low. In this way, communities or social-ecological systems (e.g. coastal communities dependent on fishing or mountain communities dependent on specific soil conditions) may reach a tipping point that would cause a partial or full collapse of the system, including displacement (see Renaud *et al*., 2010; section 19.4.2.1).

7) *Presence of conditions that make societies highly susceptible or sensitive to cumulative stressors in complex and multiple-interacting systems*. Conditions that make communities or social-ecological systems highly susceptible to additional climatic hazards or that limit their ability to cope and adapt, such as chronic poverty or living in a failed state (e.g. during drought disaster in Somalia) should be taken into account. Also the critical dependence of societies on interdependent, interconnected infrastructure, such as those providing energy/power supply, transport and health care delivery, might lead to complex and multiple-interacting systems with low coping and adaptive capacity (see Chapter 23).

19.2.2.2. Criteria for Identifying Key Risks

Key risks are the product of the interaction of climate-related hazards with key vulnerabilities of exposed societies and communities. A risk would not be considered "key" if the climatic hazard had a low probability and/or magnitude and would affect a society, community or a social-ecological system with low vulnerability.

In contrast to the criteria for identifying key vulnerabilities, the criteria for identifying key risks take into account the magnitude, frequency and severity of hazardous climate trends, events, and physical impacts to which vulnerable systems are exposed. The following four criteria are used to judge whether risks are key:

1) *Magnitude:* Risks are key if associated negative consequences have a large magnitude, determined by a variety of metrics including human mortality and morbidity, economic loss, cultural importance, and distributional consequences (see Schneider *et al*., 2007; Below 2009; IPCC, 2012).

2) *Likelihood that risks will materialize and their timing*. Risks are considered key when there is a high probability that the hazard due to climate change will occur under circumstances where societies or social-ecological systems exposed have very limited capacities to cope or adapt. Risks which materialize in the near term may be evaluated differently than risks which materialize in the distant future, since the time available for building up adaptive capacities is different (Oppenheimer, 2005; Schneider *et al*., 2007).

3) *Irreversibility and persistence of conditions and drivers that determine risks*. Risks are considered key when there is a high probability that they would involve irreversible harm, losses and damages. Persistence of risks refers to the fact that underlying drivers and root causes of these risks cannot be rapidly reduced, or the damage to societal and social-ecological systems cannot be quickly reversed (see point 7 above). Critical infrastructures, such as electric power, communications, and transport networks in developed countries often embody systemic risks due to their interdependencies and the high dependency of vulnerable groups (e.g. elderly) on their services. Moreover, the breakdown of critical infrastructure (e.g. electricity or water supply) can also have long distance impacts (teleconnections) that may result in risks far away from the area where the critical infrastructure is located, and hence it can be more difficult to address these risks in areas potentially affected. In addition, chronic poverty and marginalization, and

insecure land tenure arrangements are drivers of vulnerability that in combination with climatic hazards determine risks which often persist over decades, for example as observed in the Sahel Zone.

4) *Limited ability to reduce the magnitude and frequency or nature of hazardous climatic events and trends and the vulnerability of societies and social-ecological systems exposed*. Risks are considered to be key when societies have very limited means through development (either by reducing emissions of greenhouse gases or improving coping and adaptation) to reduce the magnitude, frequency or intensity of risks due to climatic hazards. These hazards and the vulnerability of societies or social-ecological systems – and hence risk – are also dynamic and change over time, e.g. due to different socio-economic development processes.

19.2.3. Criteria for Identifying Emergent and Emerging Risks

A risk that arises from the interaction of phenomena in a complex system is defined here as an *emergent risk*. For example, unforeseen feedback processes between climatic change, human interventions and processes in natural systems can be classified as emergent risks if they pose a threat to human security. Alternatively, emergent risks could be linked to unprecedented situations, such as the increasing urbanization of low laying coastal areas that are prone to sea-level rise or where new pluvial flooding risk emerges due to urbanization of vulnerable areas not historically populated. An *emerging risk* is a risk that has emerged only recently in the scientific literature in sufficient detail to permit assessment. For example, the initial consequences associated with these risks may have only recently been detected above the natural variability of the climate system, as is the case for certain effects of ocean acidification on calcareous organisms. For clarity, where these emerging risks arise from the interaction of phenomena in a complex system (and are thus also emergent risks) they are discussed in sections 19.3 and 19.4 relating to emergent risks. In this chapter, the only emergent and emerging risks discussed are those which have the potential to become key risks once sufficient understanding accumulates.

19.2.4. Identifying Key and Emergent Risks under Alternative Development Pathways

Key risks are determined by the interaction of physical impacts of climate change with vulnerabilities of societies or ecosystems. Development pathways describing possible trends in demographic, economic, technological, environmental, social and cultural conditions(Hallegatte *et al*., 2011) will affect key risks because they influence both the likelihood and nature of climate changes and physical impacts, and the societal and ecological conditions determining vulnerability. Therefore some risks could be judged to be key under some development pathways but not others. Emergent and emerging risks can depend on development pathways as well, since their identification as potentially key risks may be contingent on future socio-economic conditions.

Different development pathways will lead to different key risks because they affect the magnitude, timing, and heterogeneity of physical impacts of climate change through their effects on emissions and other forcing such as land use change, and consequently on climate change (see Chapter 12, WG1). Components of development pathways such as economic growth, technical change, and policy will influence the rates and spatial distributions of emissions of greenhouse gases and aerosols, and of land use change (Chapter 5, WG3).

Development pathways will also influence the factors involved in identifying key vulnerabilities of human and ecological systems, including both sensitivity to impacts and adaptive capacity(Yohe and Tol, 2002; Füssel and Klein, 2006; Hallegatte *et al*., 2011; O'Neill *et al*., submitted). The size or scale of populations, ecosystems, or economic sectors that are vulnerable to particular impacts will depend on population growth and spatial distribution, economic development patterns, and social systems. The particular elements of the social-ecological system that are most exposed and sensitive to climate hazards, and that are considered most important, will depend on spatial development patterns as well as on cultural preferences, attitudes toward nature/biodiversity, and reliance on climate-sensitive resources or services, among other factors (Adger, 2006; Fuessel, 2009). The degree to which persistent or difficult to reverse vulnerabilities are built into social systems, as well as the degree of inequality in vulnerability across social groups or regions, also depend on elements of development pathways (Adger *et al*., 2009).

19.2.5. Assessing Key Vulnerabilities and Emergent Risks

The criteria above for assessing vulnerability and risk provide a sequence of potential assessment steps. While the first assessment phase would explore whether and how a society or social-ecological system is exposed to climate related hazards, the assessment thereafter would focus on the probability of loss and harm in case an event or events would affect a society or social-ecological system exposed. In addition, the importance of the system at risk and the ability of a society or system to cope and to adapt to these stressors would be assessed. Finally, the application of the criteria would also require the assessment of the irreversibility of the consequences, the persistence of vulnerable conditions as well as the presence of conditions that make societies susceptible. Hence, the assessment criteria focus on the inner conditions of a person, a community (e.g. age structure, poverty), or a social-ecological system as well as on the contextual conditions that influence their vulnerability (e.g. larger governance conditions and systems of norms). Examples of such key vulnerabilities and key risks drawn from other chapters of this assessment are provided in section 19.6 and particularly Table 19-3.

19.3. Emergent Risk: Multiple Interacting Systems and Stresses

19.3.1. Limitations of Previous Approaches Imply Key Risks Overlooked

Interactions between climate change impacts in various sectors and regions, and between these impacts and human adaptation in other sectors and regions, as well as interactions between adaptation and mitigation actions (the latter also considered in section 19.4.3), are generally not included, or not well integrated, into projections of climate change impacts (Warren, 2011). These interactions create emergent risks and/or key vulnerabilities not previously recognized. There is a very large number of potential interactions, and many important ones have not yet been quantified, meaning that some key risks have been overlooked. In some cases, new knowledge about these risks is just now emerging. The six interaction processes listed below, while not exclusive, are systemic and are *likely* to lead to further key vulnerabilities as well as a larger number of less significant impacts. Several of these are discussed in more detail in the following sections.

- Climate change induced biodiversity loss erodes ecosystem services, in turn affecting human systems dependent on those services. (*19.3.2.1)*
- Climate change induced changes in extreme weather events affect human systems and ecosystems, which preconditions these systems and increases vulnerability to the effects of mean climate change. Most impacts projections are based only on changes in mean climate (Rosenzweig and Hillel, 2008).
- Interactions with non-climate stressors: the interaction between climate change impacts and population/economic growth is well studied, but a large literature now addresses interactions of climate change with other factors such as land management, water management, air pollution (which has drivers in common with climate change) and energy production. (*19.3.2.2)*
- Interactions related to climate change and disease emergence. *(19.3.2.3)*
- Co-location of impacts in different sectors creating impact 'hotspots' involving new interactions. (*19.3.2.4)*
- Adaptation designed for one sector interacts with functioning of another sector (e.g. increasing irrigation to crops in response to a drying climate can exacerbate water stress in downstream areas such as wetlands, in cases where the latter provide important water cleaning services). (*19.3.2.5)*

19.3.2. Emergent Risks

19.3.2.1. Emergent Risks Arising from the Effects of Degradation of Ecosystem Services by Climate Change

Biodiversity loss is linked to disruption of ecosystem structure, function and services (Díaz *et al*., 2006; Gaston and Fuller, 2008; Maestre *et al*., 2012; Midgley, 2012). A large number of studies project how species ranges are projected to decline in size as mean climate changes (see Chapter 4), e.g. a study of 50,000 species found that 57±6% of widespread & common plants and 34±7% of widespread & common animals are projected to lose ≥50% of their current climatic range by the 2080s (Warren *et al*., in press) and there is *high confidence* that

projected climate changes imply increased extinction risk for a substantial fraction of species during the 21st century (see Chapter 4). These processes of decline in species richness and extinction will combine with damage due to climate-change induced increases in short-term extreme weather events expected for some regions, as well as (see WGI SPM and 7.6.2) increased forest losses due to fire. The resulting potential for disruption of the functionality of the ecosystems translates into an emergent risk of large-scale loss of ecosystem services in both terrestrial and marine systems (Mooney *et al*., 2009; Table 19-3, Entry 2, Chapter 19). At-risk services include water purification provided by wetlands, air purification by forests, crop pollination by insects, coastal protection from storm surge by mangroves and coral reefs, regulation of pests and disease, recycling of waste nutrients, and removal of carbon from the atmosphere (Chivian and Bernstein, 2008, Chapter 4). Biodiversity loss has now also been linked to increased transmission of infectious diseases such as Lyme, Schistosoma and hantavirus in humans, and West Nile virus in birds, creating a newly emerging dimension to the emergent risks resulting from biodiversity loss (Keesing *et al*., 2010).

The following studies provide examples of projected ecosystem service loss in the agricultural sector due to climate change: projected crop damage due to increased prevalence of pest species including *Fusarium graminearum* (a fungal disease of wheat), the European corn borer, the Colorado beetle, bakanae disease and leaf blights of rice, and the Western corn root worm (Petzoldt and Seaman, 2006; Kocmankova *et al*., 2010; Huang *et al*., 2010; Chakraborty and Newton, 2011; Magan *et al*., 2011; Aragón and Lobo, 2012); and projected declines in crop yields due to climate change effects on pollinating species (Rosenzweig and Hillel, 2008; Kuhlmann *et al*., 2012; Giannini *et al*., 2012; Abrol, 2012; Bedford *et al*., 2012). These effects are simultaneous with climate change's direct effects on yields through changing temperature, precipitation, and ambient carbon dioxide concentrations, creating an emergent risk. Climate change has caused, or is projected to cause range expansion in a number of weeds that have the potential to become invasive (Bradley *et al*., 2010a; Clements and Ditommaso, 2011). Invasive species can damage agriculture and cause extinction of other species, with attempts to control them being extremely costly (eg $120 billion annually in the USA, Crowl *et al*., 2008). Whilst the balance of gains and losses for invasive species will vary locally (Bradley *et al*., 2010b) and no single aspect stands out, any one of the mechanisms mentioned in this paragraph has the potential to cause outcomes that are very damaging and act in synergy with existing climate change impacts on agriculture. Hence, these various susceptibilities to loss of ecosystem services taken together comprise a key vulnerability, and in interaction with climate change, an emergent risk.

The global value share of pollination of crops for 2005 has been calculated as 153 billion Euro (Table 4.6). Similarly, the value of the ecosystem services of pollinators for crops and wild plants combined in the UK has been estimated at UK £430 million per year, yet this service is currently becoming less effective (NEA, 2011). Climate change impacts on pollinators therefore places these valuable services at risk, and disruption of wild plant pollination will also affects animals which are dependent upon those plants (see Chapter 4). An increase in woodland cover from 6 to 12% of the UK's land area over the past 60 years (with the reverse being a measure of the cost of degradation) was valued at £680 million per year in carbon sequestration value alone (NEA, 2011). Ecological function analysis for Chinese terrestrial ecosystems yielded estimated economic values of approximately 0.3-1.6 x 10^{13} Yuan annually for services such as CO_2 fixation, O_2 release, nutrient recycling, soil protection, water holding capacity and environmental purification (Ouyang *et al*., 2006). Similarly, the value of ecosystem services in US forests has been estimated at values ranging from US$1 to 6 billion annually for climate regulation, US$4-54 billion for biodiversity, and US$1 to 100 billion annually for recreation (Krieger, 2001). The potential loss of coral reefs (section 19.3.2.4) would result in a loss of income of $Au4 billion to the Australian economy from international tourism, of US$1.6 billion to the Caribbean economies for tourism and fishing on reefs, and loss almost equal to the value of the entire economy of the Maldives and the Seychelles (Hoegh-Guldberg *et al*., 2011). Such costs are represented only very crudely, if at all, in aggregate global models of the economic impacts of climate change where 'non-market impacts' are estimated very broadly if at all (section 19.6.3.5). These large costs show how human systems are vulnerable to loss of ecosystem services, and hence this comprises a key risk as defined in 19.2.

Some of the work on degraded ecosystems and their interaction with economic sectors examines the cost of restoring ecosystem services. For example, interviewed households along the Platte River (US) showed a willingness to pay, in terms of increased water bills, an additional US$20 per month in order to improve five ecosystem services (i.e. natural purification of water, erosion control, habitat for fish and wildlife, dilution of

wastewater, and recreation use) (Loomis *et al.*, 2000), which would provide US$19 to US$70 million dollars which greatly exceeds the estimated costs of improving degraded ecosystem services (US$1.13 to US$12.3 million). A meta-analysis of 89 studies looking at the restoration of ecosystem services measured using 526 different metrics found that restoration increased the amount of biodiversity and ecosystem services by 44 and 25% respectively, but the restored services were still lower than those in intact ecosystems (Benayas *et al.*, 2009). Hence, although restoration of damaged ecosystems may often be cost-effective, it can only partially compensate for loss of services.

Concomitant stress from land use change adds to the extinction risk from climate change, increasing the projected extinction rate (e.g. Sekercioglu *et al.*, 2012) and hence an emergent risk of ecosystem service loss. Empirical studies reveal that ecosystem impacts due to habitat loss correlate with current maximum temperature and recent precipitation decline, indicating a synergy between climate change and habitat loss effects (Mantyka-Pringle *et al.*, 2012). Due to land use change, adaptation to climate change is now impeded by the fragmented nature of natural habitats.

Land clearing also releases carbon to the atmosphere and removes carbon sinks (WGI section 6.4.3.3) such as old growth forests which would otherwise continue to accumulate carbon (Luyssaert *et al.*, 2008) in the future. A new approach has quantified the 'Greenhouse Gas Value' of ecosystems (Anderson-Teixeira and DeLucia, 2011), taking into account both fluxes and storage of carbon, implying that published values of ecosystem services from carbon sequestration have tended to underestimate their importance due to a tendency to consider only the carbon currently stored in the systems.

19.3.2.2. Emergent Risk Involving Non-Climate Stressors: the Management of Water, Land, and Energy

One of the most important interactions affecting the well-being of humans and ecosystems and the level and rate of climate change, are those involving human management of water, land, and energy. These profoundly affect the amount of carbon which can be stored in terrestrial ecosystems, the amount of water available for use by humans and ecosystems, and the viability of adaptation plans for cities or protected areas, for example. Failure to manage land, water and energy in a synergistic fashion can exacerbate climate change impacts globally (Wise et al 2008, Searchinger *et al.*, 2008; Lotze-Campen *et al.*; 2009; Warren *et al.*, 2011).

Projected changes in climate variability combined with water extraction leads to an emergent risk: that of water stress exacerbated by the removal of groundwater which serves as 'an historical buffer against climate variability' (Green *et al.*, 2011). The use of energy by the water sector, including domestic use for heating, accounts for between 5-6% of the greenhouse gas emissions of the US and India(Green *et al.*, 2011; Rothausen and Conway, 2011). Extraction and conveyance of water for irrigation is energy intensive and this demand is projected to rise as adaptation to climate change and increasing food demand drives the need for an expansion of irrigated cropland. In areas where drought is frequent, water might be provided through construction and use of de-salinisation plant. All this has implications for projected energy use and hence mitigation strategies. However, there are opportunities for adapting the agricultural sector to climate change in drying regions in ways which reduce greenhouse gas emissions, such as advanced irrigation systems(Rothausen and Conway, 2011).

The second issue is that of groundwater extraction, which is *likely* to increase as an adaptation to climate change, since current demand for surface water will not be met under various scenarios of a changed climate(Barnett *et al.*, 2008). For example, following a ten-fold increase in groundwater extraction in China, 70% of the irrigated cropland in China is now groundwater fed, and it is estimated that 0.5% of the country's greenhouse gas emissions are attributable to exploitation of this resource(Wang *et al.*, 2012). The effects of climate change on groundwater are varied with some areas expecting decreased recharge, whilst others are projected to experience increased recharge (Green *et al.*, 2011). However, in areas where extraction rates increase or recharge decreases, water tables will be depleted with consequence for ecosystems and the human systems (such as agriculture, tourism and recreation) which depend upon them, while water quality will also decrease. One projection shows insufficient water availability in Africa, Latin America and the Caribbean to satisfy both agricultural demands and environmental regulations by 2050, owing to increases in demand for water use for municipal and industrial use, combined with increases in demand for food, a situation that is exacerbated by climate change (Strzepek and Boehlert, 2010).

Concurrently, the use of water by the energy sector, by thermo-electric power generation, hydropower and geothermal energy, or biofuel production, can also be an issue (Pittock, 2011) especially in cases where energy generation is concentrated in arid regions, whilst Kelic (2009) have explored how the energy sector could best adapt to drought conditions. Other studies have addressed the energy, water, land nexus that drought conditions present to the agricultural and energy sectors (Tidwell *et al*., 2011; Skaggs *et al*., 2012).

Simulations of stringent mitigation (e.g. that required to constrain radiative forcing to 2.6 W/m^2 during the 21st century) show an economic necessity to include a major contribution from biofuels (van Vuuren *et al*., 2011). If production is not carefully managed, biofuel feedstocks can displace land for food cropping or natural, unmanaged ecosystems. Reductions of greenhouse gas emissions from biofuel production and use (compared to fossil fuels) may be offset partly or entirely for decades or centuries by emissions from the resulting indirect land-use changes (iLUC) (IPCC SRREN, 2011, Chapter 2; Bringezu *et al*., 2009; Van Vuuren *et al*., 2010a), some of which are not only indirect but have transboundary and/or distant impacts (see 19.4). The placement of a carbon tax (as a surrogate for the effect of a variety of policies) to fossil carbon only, with a goal of limiting CO_2 concentrations to 450 ppm-550 ppm, is projected to lead to large scale deforestation of all natural forests by the end of the 21st century, with conversion of most other natural ecosystems, in part due to enhanced biofuel production (Wise *et al*., 2009; Mellilo *et al*., 2009a,b). This could bring so much terrestrial carbon, converted into CO_2, in the atmosphere that it could offset partly or entirely the effect of substituting fossil fuel with biocarbon and obstruct the original goal of limiting atmospheric CO_2. If instead the tax is applied also on terrestrial carbon, the deforestation could slow down or even reverse, depending on the level of the tax. Alternatively (or additionally), land set-asides such as the Conservation Reserve Program in the US may be more effective at long-term GHG mitigation than maize-ethanol (Piñeiro *et al*., 2009).

Indirect land use changes can be reduced using the strategies for reducing food-system competition through markets, as discussed in section 19.4.1. Liquid biofuels can mitigate GHG emissions when used in place of fossil fuels such as gasoline, diesel, and more carbon-intensive fuels from tar sands and heavy oil (Cherubini *et al*., 2009). Successful mitigation, however, is highly dependent on what feedstock is used, how it is grown, and how well subsidies and incentives prioritize GHG reductions. Second-generation biofuels, those based on non-food crops (grasses, algae, timber) and agricultural residues, are expected to offer reduced emissions of GHG and other air pollutants compared to most first-generation biofuels due primarily to less adverse interactions with food-systems (Plevin, 2009; Fargione, 2010; Sander, 2010; Cherubini, 2010). Further, bioelectricity and biogas may both be more successful at mitigating GHG emissions than liquid biofuels (Power and Murphy, 2009; Campbell *et al*., 2009).

However, there are many equally compelling reasons for a country to encourage biofuel production including, among other things, competition for high oil prices, rural development and reduced oil imports – all of which could be prioritized over GHG reductions depending on the country (Cherubini *et al*., 2009). Another inherent conflict is that per-litre GHG emissions *decrease* as agriculture is further intensified through row cropping, fertilizer and pesticide use, and irrigation, while other per-litre environmental impacts *increase* (Burney *et al*., 2010; Grassini and Cassman, 2012). Conflicting biofuel deployment policies and priorities, and interactions with food-systems could therefore lead to a number of emergent risks as liquid biofuel supply increases, as shown in the Table 19-1.

[INSERT TABLE 19-1 HERE
Table 19-1: Emergent risks related to biofuel production as a mitigation strategy.]

19.3.2.3. Emergent Risks Involving Health Effects and Disease Emergence

Climate change will act through numerous direct and indirect pathways to alter the prevalence and distribution of diseases that are climate and weather sensitive. These effects will differ substantially depending on current epidemiologic profiles, reflecting the level of development and access to clean and plentiful water, food and access to adequate sanitation and health care resources. Furthermore, the impact of climate change will differ within and between regions, depending upon the adaptive capacity of critical public health infrastructure that ensures access to clean food and water.

A principal emergent global risk is malnutrition secondary to ecological changes and disruptions in food production as a result of changing rainfall patterns, increases in extreme temperatures and precipitation events (IPCC, 2012), and increased atmospheric CO_2 (Taub *et al.*, 2008; Lobell and Burke, 2010). Modeling of the magnitude of the effect of climate change on future under-nutrition in five regions in South Asia and sub-Saharan Africa in 2050 (using the SRES A2 emissions scenario) suggests an increase in moderate nutritional stunting, an indicator linked to increased risk of death and poor health (Black *et al.*, 2008), of 1% to 29% compared to a future without climate change, and a much greater impact on severe stunting of 23% for central sub-Saharan Africa and 62% for south Asia (Lloyd *et al.*, 2011). The impact of climate induced drought and precipitation changes in Mali include the southward movement of drought-prone areas which would result in a loss of critical agriculturally-productive land by 2025 and increase food insecurity (Jankowska *et al.*, 2011).

In developed countries and large, highly populated megacities with developed public health infrastructure, principal emergent risks include increased injuries and fatalities as a result of severe storms and heat waves (see 19.6.3.3); changes in vector biology and disease ecology that impact infectious diseases; water and food contamination; increased pollen production leading to increases in allergic airway diseases (see 19.5.3); and respiratory and cardiovascular morbidity and mortality secondary to degraded air quality and ozone formation (see 19.6.3.3).

Increase in heat-related morbidity and mortality subsequent to the increase in the severity, duration, and frequency of heat waves (Luber and McGeehin, 2008) in urban areas is an emergent risk. These impacts will be greatest in urban areas with a pronounced urban heat island effect (Kovats and Hajat, 2008). The coupling of the increasing vulnerability of an aging population and a global shift to urbanization will increase the risk of relatively higher mortality from exposure to excessive heat (Knowlton *et al.*, 2007).

While the association between ambient air quality and health is well established, there is an increasingly robust body of evidence linking spikes in respiratory diseases to weather events and to climate change, so that this interaction is an emergent risk. In New York City, for example, each single degree (Celsius) increase in surface temperature has been associated with a 3% increase in same-day hospitalizations due to respiratory diseases, and an increase of up to 3.6% in hospitalizations due to cardiovascular diseases (Lin *et al.*, 2009). The principal pathways through which such respiratory health outcomes will be exacerbated by climate change are through increased production and exposure to tropospheric (ground-level) ozone, smoke produced by wildfires, and increased production of pollen (D'Amato *et al.*, 2010). Many of the same populations that are vulnerable to health effects from heat waves show increased risk for effects from poor air quality induced by heat, including: the very young and the very old and those with preexisting medical conditions, including respiratory and cardiovascular disease (see 19.6.3.3).

Projected changes in precipitation, temperature, humidity, and water salinity, have potential to affect the distribution and prevalence of food- and water-borne diseases resulting from bacteria and other pathogens, and increases in the frequency and range of harmful algal blooms (Curriero *et al.*, 2001; Moore *et al.*, 2008). Climate change and increased climatic variability would affect incidence of vector-borne diseases such as plague, Lyme's disease, malaria, hantavirus, and dengue fever which exhibit distinct seasonal patterns and sensitivity to ecologic changes (Githeko *et al.*, 2000; Gage, 2008; Parham *et al.*, 2011 submitted). These changes to food, water, and vector-borne diseases represent additional emergent risks.

19.3.2.4. Spatial Convergence of Multiple Impacts: Multi-Impacts Hotspots

"Hotspot" is an equivocal term that is defined and used in various manners (see also Box 21-4 in Chapter 21 for detail). In this chapter, we define a *multi-impacts hotspot* as a region where climate-change induced impacts in one sector affect other sectors in the same region or a region where climate change impacts in different sectors are compounded, resulting in extreme or high-risk consequences. The frequent and ongoing spatial and temporal coincidence of impacts in different sectors in the same region could have consequences that are more serious than simple summation of the sectoral impacts would suggest. Such synergistic processes are difficult to identify through sectoral assessment and apt to be overlooked in spite of their potential importance in considering key vulnerabilities. For example, a large flood in a rural area may damage crop fields severely, causing food shortages(Stover and

Vinck, 2008). The flood may simultaneously cause a deterioration of hygiene in the region and the spread of water borne diseases (Schnitzler, 2007; Hashizume *et al*., 2008; Kovats and Akhtar, 2008). The coincidence of disease and malnutrition can thus create a multi-impacts hotspot for health impacts, with the elderly and children most at risk.

As a systematic approach, identification of multi-impacts hotspots could be achieved by overlaying spatial data on impacts in multiple sectors, but this cannot indicate synergistic influences and dynamic changes in these influences quantitatively. For global analysis, certain types of integrated assessment models which allow spatial analysis of climate change impacts have been used to identify regions that are affected disproportionately by climate change (Fussel, 2010; Tol and Fankhauser, 2008, Kainuma et al., 2003; Bowman et al., 2006; Warren et al., 2008). Recent efforts attempt to collect and archive spatial data on impact projections and facilitate their public use. These have created overlays for identifying hotspots with web-GIS technology (Adaptation Atlas (Vajjhala, 2009)). The Union of Concerned Scientists (2011) also identified many locations which could be classified as a multi-impacts hotspot based on robust scientific evidences published in peer-reviewed literature (Union of Concerned Scientists, 2011). There are also efforts to coordinate impacts assessments based on shared future scenarios at various spatial scales(Parry *et al*., 2004; ISI-MIP, 2012).

[INSERT FIGURE 19-2 HERE
Figure 19-2: Some salient examples of multi-impacts hotspots identified in this assessment.]

To illustrate some different types of multi-impacts hotspots where climate change impacts coincide and interact, the following examples are provided.

1) The Arctic is an example of a regional multi-impact hotspot, where the culture of indigeneous people (Crowley, 2011) is projected to be exposed to the disruption, and possible destruction of, their hunting and food sharing culture (see Chapter 28). This hotspot is due to the combination of sea ice loss and the concomitant potential extinction of the animals dependent upon the ice (Johannessen and Miles, 2011). Thawing ground is also disrupting transportation, buildings and infrastructure whilst there is increased exposure to storms. Arctic ecosystems are also at risk (Kittel *et al*., 2011).
2) Coral reefs are highly threatened due to the synergistic effects of sea surface temperature rise and perturbed ocean chemistry, which reduces calcification and also increases sensitivity to other impacts such as the loss of coral symbionts (Chapter 6). The importance of a hotspot of reef sensitivity to climate change in the area of greatest reef diversity in the world was recently highlighted in the near-equatorial Indo Pacific(Lough, 2012). A second hotspot for warming and thus damage to reefs was identified around Micronesia, Mariana Island and Papua New Guinea (Meissner *et al*., 2012).
3) Cities in deltas are often impact hotspots, being subject to sea level rise, storm surge, coastal erosion, saline intrusion and flooding. Extreme weather events can also disrupt access to food supplies, causing a malnutrition risk. Ericson *et al*. (2006); Chapter 24 revealed that over 6 million people would be at risk of enhanced inundation and increased coastal erosion in three megadeltas and 8.7 million in 40 deltas, absent measures to adapt. Examples of delta areas at risk include Mumbai, Dhaka and the Mekong (see Chapter 8, Chapter 24, and section 19.6.3.4).

General equilibrium economic models (see Chapter 10) may facilitate quantitative evaluation of synergistic influences. An analysis of the EU by the PESETA project evaluated sub-regional welfare loss by considering impacts on agriculture, coastal system, river floods, and tourism together in the CGE (Computable General Equilibrium) model, which is designed to represent interrelationships among economic activities of sectors, and indicated the largest percentage loss in Southern Europe (Ciscar *et al*., 2011)It should be noted, at any scale, choices of sectors are strongly constrained by availability of data or evaluation methods and they are not comprehensive.

19.3.2.5. Maladaptation

Maladaptation refers to adaptation strategies that increase a population's or sector's vulnerability to climate change. It can be viewed as a type of emergent risk since it arises from an interaction of a response by one group of people to climate change impacts which then interacts negatively with another group, often in a different sector or region. Maladaptation is discussed in detail in Chapter 14.7

19.4. Emergent Risk: Indirect, Trans-Boundary, and Long-Distance Impacts

Climate change impacts can have consequences beyond the regions in which they occur. Such long distance interactions may be mediated by global trade systems – the most prominent example of this is the global food trade system. However, the danger with relying only on global trade to mediate impacts is that competitive market forces do not account for considerations of justice. As prices on food, land, and other resources increase, those most in need may end up being the least able to pay (see section 19.6.1.2 on differential vulnerability). Additionally, both mitigation and other adaptation responses that are implemented on the ground can have unintended consequences beyond the locations in which they are implemented. All of these mechanisms can create emergent risks.

19.4.1. Indirect, Trans-Boundary, and Long-Distance Impacts of Climate Change Impacts on Agricultural Yields: Food Trade Patterns, Prices, Malnutrition

Climate change impacts on agriculture can have consequences beyond the regions in which those impacts are directly felt, through the global food trade system. Food access can be inhibited by rising food prices, as demonstrated during recent price rise episodes that resulted from the combination of poor weather in certain world regions combined with a demand for biofuel feedstocks, increased demand for grain-fed beef in China, and historically low levels of food stocks (Abbot and deBattisti, 2011; Adam and Ajakaiye, 2012). These episodes provide an analog elucidating how reduced crop yields due to climate variability impacts and biofuel cropping create a risk of malnutrition: hence this interaction of climate change with the food system via markets comprises an emergent risk of the impacts of climate change acting a distance. For further information see 7.2.2. on food security and 7.3.2.1.1. on how climate change can impact crop yields.

One study found that climate change may have already offset 30-years worth of technology-related increases in crop yields in Russia, Turkey, Mexico (wheat) and China (maize) (Lobell *et al*., 2011). Another study identified areas where past climate variability has induced sudden or prolonged drops in food production, e.g., Ukraine (a 13% decline in a single year due to high summer temperatures) and the Sahel (decadal scale losses due to prolonged drought and high temperatures; Battisti and Naylor, 2009). In the next few decades, areas where crop yields are projected to decline such as sub-Saharan Africa and the Sahel may come to rely more strongly on imported food (Schmidhuber and Tubiello, 2007). Whilst some studies (Jaggard *et al*., 2010) conclude that in the next few decades there may be increases in crop yields in temperate regions which may compensate in global terms for the losses in tropical regions (FAO, 2008), a recent empirical study suggests that these benefits may not be realized, based on indications that, to date, the positive effects of CO_2 fertilisation on yields and the effects of changes in precipitation and temperature have offset one another (Lobell and Field, 2007). Battisti and Naylor (2009) used climate projections from IPCC AR4 to show that by the end of the century, there is a probability of over 90% that growing season temperatures in the tropics and subtropics will exceed even the most extreme seasonal temperatures recorded from 1900 to 2006. Compared to the assessment in AR4, the evidence points to an *increased* risk that tropical and sub-tropical regions will experience significant crop yield declines due to climate change (see 7.3.2.1.1.). Taken together, regional climate change impacts on crop yields would result in increased prices of food commodities on the global market (Battisti and Naylor 2009; Lobell *et al*., 2011) even under an assumption of barrier-free ability to change the areas under cultivation (Juliá and Duchin, 2007).

Weather-induced yield losses which have affected food prices in many countries have already been documented in Australia and Europe in recent years (FAO, 2008; World Bank, 2011) – for example increasing the number of malnourished people by 75 million in 2007 (FAO, 2008). Climate change is projected to increase the frequency of extreme weather that can reduce crop yields and increase their year-to-year variability (Diffenbaugh *et al*., 2012; Urban *et al*., 2012), and there is some specific evidence that climate change induced yield losses are already affecting food prices (Lobell *et al*., 2011). Furthermore, developing countries that have limited financial capacity for trade, and/or food distribution networks may be damaged by increases in extreme weather events (FAO, 2008) leading to increased risk of poverty and malnutrition. One study used historical vulnerability to extreme weather events to project that Bangladesh, Mexico, Mozambique, Malawi, Tanzania and Zambia would be most at risk from

future extreme weather events under 21st century climate change in the SRES A2 scenario (Ahmed *et al*., 2009). Developed countries which currently enjoy imported foods from tropical regions that become affected by climate change, would see the prices of those commodities rise. More generally, pressure on land use for biofuels is *likely* to further exacerbate food prices (see section 19.3.2.2).

On longer timescales, new techniques for assessing climate change impacts on yields of soybean, maize and cotton in the United States (Schlenker and Roberts, 2009) result in higher projections of yield declines compared to studies assessed in AR4: yield losses reach 30-46% by the end of the century under a low emissions scenario, or 63-82% under a high emissions scenario. However, these approaches are not necessarily accepted as better than earlier studies (see section 7.3.2.1.1.). Global rice prices may be particularly sensitive to climate change (Chen et al 2012), potentially rising by 7-13% in the wake of projected 1.6-2.7% losses in yield resulting from a combination of climate change and sea level rise. Another study (Warren *et al*., 2011) highlights that 50% of the global area where crops could be grown is projected to become less suitable for cultivation by the end of the century if global temperatures reach 4°C. Arnell *et al*. (2013) explains that once regional temperatures exceed 1° to 3°C above 1961-1990 mean, crop suitability falls back. A recent report (Foresight, 2011a) highlights the combined agricultural land losses expected in the next 40 years, due to desertification, erosion and sea level rise (the latter leading to increased salination). The report does not estimate the percentage of agricultural land involved, but if large, such changes would further increase global food prices, increasing the risk of poverty and malnutrition (World Bank, 2011).

Producing a significant proportion of energy from biofuels without inducing pressure on food and ecosystems through indirect land use change would require increasing available agricultural supplies through either decreasing existing demand and/or increasing production through intensification/extensification. Hence, there can be important interactions between global emissions mitigation policies and land management that can either confound, or contribute to, mitigation (Van Vuuren *et al*., 2011). Markets will respond to increasing liquid biofuel production in one of two ways: either through reduction in other demands for the feedstock crop or an increase in the supply, both of which will happen as commodity prices start to rise. Accurately tracking and quantifying the direct and indirect impacts of biofuel production on the food-system has become an intense area of study since AR4. As witnessed in the United States, US maize-ethanol production increased 800% since 2000, with maize commodity prices more than tripling and harvested land growing by more than 10% (mainly at the expense of soy (USDA, 2011). Ethanol recently consumed one quarter of US maize production, even after accounting for feed by-products returned to the market (USDA, 2013). However, isolating biofuels' exact contribution to food-system changes from other factors such as extreme weather events, climate change, changing diets, and increasing population have proven difficult (Zilberman, 2011). Still, estimates of the supply and demand elasticity of basic grain commodities (Roberts and Schlenker 2009) lead to a prediction that the 2009 US Renewable Fuel standard could increase commodity prices of maize, wheat, rice, and soybeans by roughly 20%, assuming one third of the calories used in ethanol production can be recycled as animal feed (Roberts and Schlenker, 2010).

Market responses to increased commodity prices are often the same mechanisms being viewed to potentially increase supply to the point where biofuels and food production can co-exist. These strategies can be grouped as follows: increasing supply either through extensification or intensification, and decreasing demand either by lifting biofuel mandates or reducing commodity usage from other demands.

The central question with regards to increasing the supply of commodity crops is how much will come from the intensive margin (higher yields per acre), and how much will come from the extensive margin (more acres). Keeney and Hertel (2009) argue that yields respond to prices and Foley *et al*. (2011) project that closing global 'yield gaps' for 16 important food and feed crops on lower productivity lands could increase agricultural supply by 58%. On the other hand, Roberts and Schlenker (2010) find that, historically, growing area responds to exogenous price shocks. If additional supply comes in part from planting new acres, Fargonie *et al*. (2008) and Searchinger *et al*. (2008) find large CO_2 effects of indirect land use change (iLUC) – currently one of the largest concerns surrounding liquid biofuels, both due to the magnitude of its potential impact and the uncertainty in accurately quantifying it. Deforestation would result in large indirect CO_2 emissions, as does the production of biodiesel using palm oil on peatlands that are drained (Miettinen *et al*., 2012). A study of biofuel production in Brazil (Barr *et al*., 2011) finds that once pasture is incorporated in the analysis, expansion into unexploited land is minor, i.e., most of additional cropland is predicted to come from conversion of pastureland. However, loss of pasture to biofuel might also trigger

iLUC if the density of livestock operations is not increased in tandem. To the extent that biofuel feedstock crops are grown on areas that were previously fallow or degraded, the iLUC effects might be minimized and CO_2 potentially sequestered (IPCC SRREN 2012; Fargione *et al*., 2010) – although the amount, alternative uses, and potential productivity of so-called degraded lands are still contested (Dauber *et al*., 2012).

Market forces will impact demand for feedstock crops as prices increase. These reactions mirror many of the deliberate strategies to influence demand in the hopes of freeing up supply for biofuel production and/or minimize its iLUC impacts. Dietary changes could reduce the land requirements of food cropping embodied in these tradeoffs. A transition to a globally-implemented vegetarian diet would free up 2700 Mha of pasture and 100 Mha of cropland – a combined area representing approximately 70% of current agricultural and pasture land – much of which could then be used for biofuel cropping (Stehfest *et al*., 2009), whilst the remainder could revert to natural vegetation becoming a carbon sink (see 19.3.2.1). Another study found that eliminating meat from human diets could increase available calories by 49% (Foley *et al*., 2011). While extreme and an improbable response, these studies demonstrate that even small changes to diets and meat consumption could have large impacts. Reducing food-system losses might be another way demand responds to increased commodity prices. A recent FAO study found that approximately one third of food is never consumed – with losses in developed countries coming more from the consumer end (post-purchase spoilage before use) and losses in developing countries coming more from the production end (farm losses, spoilage before reaching markets) (Gustavsson *et al*., 2011). On the other hand, given that demand for biofuels is supported by mandates and subsidies, there has been a growing call for lawmakers to lift mandates or implement moratoriums on liquid biofuel development until the direct and indirect impacts on the food system, the climate and food security are better understood. A move to second-generation liquid biofuels or other forms of bioenergy such as bioelectricity or biogas, those that utilize non-food, crop residue or forest-based biomass, might help alleviate concerns. However, depending on where and how new feedstocks are grown they too could introduce their own iLUC impacts (Zilberman *et al*., 2011) and/or N_20 agricultural emissions uncertainty (Meyer-Aurich, 2012).

19.4.2. Indirect, Trans-boundary, and Long-Distance Impacts of Adaptation

Risk can also emerge from unintended consequences of adaptation (see 19.3.2.5), and this can act across distance, if for example, there is migration of peoples or species from one region to another. Adaptation responses in human systems can include land use change, which can have both trans-boundary and long distance effects; and changes in water management, which often has downstream consequences. In some cases such interactions may contribute to conflict.

19.4.2.1. Human Migration and Displacement

Human migration is one of many possible adaptive strategies or responses to climate change (Reuveny, 2007; Piguet 2010; Tacoli, 2009; McLeman, 2011), assessed in detail in Chapter 12 in the context of the many other causes of migration. Displacement refers to situations where choices are limited and movement is more or less compelled by land loss due to sea level rise or extreme drought, for example (see AR5 WGII chapter12.4). A number of studies have linked past climate variability to both local and long distance migration (see review by Lilleør and Van den Broeck, 2011). In addition to positive and negative outcomes for the migrants, migration from one region results in significant indirect, (and in some cases, long distance) effects on people and states in other regions. Consequences for receiving regions, determined by a variety of metrics, could be both positive and negative, as may also be the case for sending regions (McLeman, 2011; Foresight, 2011b; AR5 WGII Chapter 12). An emerging literature examines potential changes in migration patterns due to future climate changes, but projections of specific positive or negative outcomes are not yet available. Furthermore, recent literature underscores risks previously ignored: risk arising from the lack of mobility in face of a changing climate, and risks entailed by those migrating into areas of direct climate-related risk, like low-lying coastal deltas (Foresight, 2011b; see Chapter 12).

Climate change induced sea level rise, in conjunction with storm surges and flooding, creates a threat of temporary and eventually permanent displacement from low-lying coastal areas, the later particularly the case for small island states (Pelling and Uitto 2001; Chapter 12). The extent to which these responses are employed will depend on

whether governments develop strategies such as relocating people from highly vulnerable to less vulnerable areas nearby and conserving ecosystem services which provide storm surge protection (Perch-Nielsen 2004) in addition to so-called "hardening" such as building sea walls and storm barriers (Nordenson and Seavitt 2011). Numbers of people at risk from coastal land loss have been estimated (Nicholls and Tol, 2006; Ericson *et al*., 2006; Nicholls *et al*., 2011) but projections of resulting anticipatory migration or episodic and permanent displacement are not available.

Taken together, these studies indicate that climate change will bear significant consequences for migration flows at particular times and places, creating risks as well as benefits for migrants and for sending and receiving regions and states (*high confidence*). Urbanization is a pervasive aspect of recent migration which brings benefits but, in the climate change context, also significant risks (see 19.2.3, 19.4.1, 19.6.1, 19.6.2; 19.6.3.3; Chapter 8). While a literature projecting climate-driven migration has emerged (Chapter 12.4), there is as of yet insufficient literature to permit assessment of projected region-specific consequences of such migration. Nevertheless, the potential for negative outcomes from migration in such complex, interactive situations is an emergent risk of climate change, with the potential to become a key risk (Table 19-3, Entry 1, Chapter 19).

19.4.2.2. Conflict and Insecurity

Violent conflict between individuals or groups arises for a variety of reasons (section 12.5). A large number of quantitative empirical studies have implicated climatic events as a contributing factor to the onset or intensification of personal violence, group conflict and social instability in contexts around the world and at temporal scales ranging from a climatologically anomalous hour to an anomalous millennium (Hsiang and Burke, 2012). Because most empirical studies have been released after AR4 (Kenrick and Macfarlane, 1986; Vrij *et al*., 1994; Cohn and Rotton, 1997; Anderson *et al*., 2000; Cullen *et al*., 2000; Rotton and Cohn 2000; DeMenocal, 2001; Haug *et al*., 2003; Miguel *et al*., 2004; Levy *et al*., 2005; Miguel, 2005; Mehlum *et al*., 2006; Kuper and Kropelin, 2006; Zhang *et al*., 2006; Hendrix and Glaser, 2007; Jacob *et al*., 2007; Zhang *et al*., 2007; Grove, 2007; Yancheva *et al*., 2007; Burke *et al*., 2009; Bai and Kung, 2010; Burke and Leigh, 2010; Tol and Wagner, 2010; Hidalgo *et al*. 2010; Buckley *et al*., 2010; Bohlken and Sergenti, 2010; Patterson *et al*., 2010; Hsiang *et al*., 2011; Harari and Ferrara, 2011; Chaney, 2011; Bruckner and Ciccone, 2011; Zhang *et al*., 2011; Burke, 2011; Larrick *et al*., 2011; Buntgen *et al*., 2011; Sarsons, 2011; Couttenier and Soubeyran, 2011; Hendrix and Salehyan, 2012; Theisen, 2012; O'Laughlin *et al*., 2012; Kennett *et al*., 2012; Fjelde and von Uexkull, 2012; Dell *et al*., 2012; Ranson, 2012) the possibility that climate change will alter patterns of violence is an emerging risk. The result that high temperature exacerbates modern violence is the most consistent empirical finding, having been reported at spatial scales ranging from the individual level (Vrij *et al*., 1994; Ranson, 2012) to the communal level (O'Laughlin *et al*., 2012; Fjelde and von Uexkull, 2012) to the national level (Burke *et al*., 2009; Dell et al, 2012) to the global level (Hsiang *et al*., 2011).

It remains unknown whether climatic events contribute to the likelihood of violence through one or many of the pathways discussed in section 12.5 (Hsiang and Burke, 2012; Scheffran *et al*., 2012; Bernauer *et al*., 2012), and some authors have indicated that the identification of specific mechanisms is important for attribution and projections of future rates of violence (Sutton *et al*., 2010; Buhaug, 2010; Butzer, 2012; Gleditsch, 2012). Nonetheless, because no study has provided systematic evidence that climatic events do not influence violence and a large literature provides systematic and consistent quantitative evidence that climatic events alter rates of modern violence (Hsiang and Burke, 2012; Hsiang, Burke and Miguel, 2013), it is *likely* that climate change will alter some patterns of human conflict and insecurity.

The effect of climate change on conflict and insecurity has the potential to become a key risk because the reported magnitude of the climate's influence on security is large. Median estimates from the literature indicate that in modern contexts (1950-2010), the frequency of interpersonal violence rises roughly 4% and the frequency of intergroup conflict rises 12% for each standard deviation change in annual conditions towards warmer temperatures or more extreme rainfall (Hsiang, Burke and Miguel, 2013). Because annual temperatures around the world are expected to rise at least two standard deviations (as measured over 1950-2008) above temperatures in 2000 by 2050, [WG1 Section *11.3.2.1.2*] (Hsiang, Burke and Miguel, 2013), there is potential for large changes to global patterns of personal violence, group conflict and social instability in the future. Social, economic and political changes which

might mitigate or exacerbate this potential impact are discussed in Chapter 12.
It is *likely* that socio-economic, political or technological advancements may cause future populations to respond to their climate somewhat differently than modern populations, however the estimated influence of the global climate on rates of conflict is sufficiently large in magnitude that these advancements may need to be dramatic in order to offset the potential influence of future climate changes. For example, Hsiang *et al*. (2011) estimate that the historical impact of a three-degree Celsius warming in the equatorial Pacific is sufficiently large that offsetting its impact on annual civil conflict risk for a low-income country requires raising average incomes by more than a factor of ten.

19.4.2.3. Species Range Shifts: Consequences

One of the main adaptations of species to climate extremes and climate change is shifting to more climatically suitable areas. The resulting losses, gains, and changes in species abundance are having, and will continue to have, profound impacts on ecosystem functioning, posing risks to the services they provide (Dossena et al., 2012; Millennium Ecosystem Assessment, 2005), including those related to climate regulation (Wardle et al. 2011). One example of a key impact would be the warming-driven expansion and intensification of Mountain pine beetle (*Dendroctonus* ponderosae) outbreaks in North American pine forests. These have already caused both declines in timber harvest and led to the conversion of these forests from net carbon sinks to large net carbon sources (Kurz et al., 2008), especially from forest fires. Potential key vulnerabilities would be the projected impacts of range shifts on important resource species (e.g. marine fishes), where catch potential is predicted to increase by 30-70% in high latitude regions but decline by 40% in the tropics (where fish are important sources of protein) by 2055 (Cheung et al. 2010)), as well as new introductions of diseases to people, livestock, crops and native species (Chakraborty & Newton, 2011; Jepsen et al., 2008; Gale et al., 2009; Lafferty, 2009). Newly arrived species may prey on, outcompete or hybridize with existing biota, becoming weeds or pests in agricultural systems (Thuiller 2007; Walther et al. 2009; Chown et al. 2012). The potential emergent risks and ecological implications of species reshuffling into novel, no-analogue communities largely remain, as yet, unknown (Root & Schneider 2006; J. W. Williams & Jackson 2007).

Current legal frameworks and conservation strategies face the challenges of untangling desirable species range shifts from undesirable invasions (Webber and Scott, 2011), and identifying circumstances when movement should be facilitated versus inhibited. New agreements (e.g., Memoranda Of Understanding) may be needed recognizing climate change impacts on existing, new, or altered national trans-boundary migration, for example under the Convention of Migratory Species (UNEP/CMS, 2006). As target species and ecosystems move, protected area networks may become less effective for conserving them, necessitating re-evaluation and adaptation, including possible addition of sites, particularly those important as either 'refugia' or migration corridors (Warren et al in press, Willis & Bhagwat 2009; Hole et al. 2011; Hannah 2011). Assisted colonisation – moving individuals or populations from currently occupied areas to locations with higher probability of future persistence – is emerging as a potential conservation tool for species unable to track changing climates (Hoegh-Guldberg et al. 2008; Richardson et al. 2009; Thomas 2011). The value of these approaches, however, it contested and implementation is very limited (Loss et al. 2011). *Ex situ* collections (i.e. in zoos, botanical gardens, and seed and gene banks) have often been put forward as fall-back resources for conserving threatened species, yet the expense and the relatively low representation of global species and genetic diversity (Wyse-Jackson 2002; FAO 2010; Conde et al. 2011) minimizes the effectiveness of this technique.

19.4.3. Indirect, Trans-Boundary, and Long-Distance Impacts of Mitigation Measures

Mitigation, too, can have unintended consequences beyond its boundaries, which may affect natural systems and/or human systems (19.4.3.1, 19.4.3.2). If mitigation involves a form of land use change, then regional implications can ensue in the same way as they can for adaptation (see 19.3.2.5).

19.4.3.1. Effects on Biodiversity

Mitigation can reduce direct climate change impacts on biodiversity (Warren *et al*., 2012, ten Brink *et al*., 2010). However, especially in tropical regions, impacts on biodiversity (potential species loss) as a result of widespread habitat conversion for biofuel production could offset biodiversity impact reductions resulting from reduced levels of climate change attributable to use of such biofuels (ten Brink *et al*. 2010, Sala *et al*. 2009). Second generation bioenergy, or use of degraded land, would have reduced impacts on ecosystems (Searchinger *et al*. 2008, van Oorschot *et al*., 2010). It is possible to further offset losses due to land use change by increasing agricultural productivity, thus reducing some of the competition for land use. Tropical forests, in particular, can also be preserved under biofuel cropping strategies if the climate mitigation policy applied incorporates an economic price for emissions from land use change (Thomson *et al*., 2010). Increasing oil-yield efficiency of major biodiesel feedstocks could also reduce land pressures. See also 19.3.2.2.

Climate change mitigation through 'clean energy' substitution can have negative impacts on biodiversity. For example, poorly designed and sited wind farms (both on- and off-shore) can have population level impacts on some bird and bat species. However, these impacts can be reduced (especially on birds) and off-shore wind farms have been shown to have a positive impact on demersal fisheries (Wilhelmsson *et al*., 2006). The same can also be said for many of some other renewable energy proposals (e.g., wave energy, tidal barrages, and tidal turbines). Attention to siting and monitoring can decrease potentially large-scale negative ecological and socioeconomic impacts while maximizing positive ones. For example, the U.S. Government performed an intensive study of suitable sites for solar power on public lands in the western U.S. The end result opened 285,000 acres of public land for large-scale solar deployment while blocking development on 78 million acres to protect "natural and cultural" resources. In the case of hydropower, the construction of capital-intensive large hydroelectric dams, affects both terrestrial ecosystems within the hydroelectric reservoir and surrounding areas and the aquatic ecosystems far up- and downstream along the river system (World Commission on Dams, 2000). These impacts on biodiversity may include high deforestation rates in the surrounding landscape due to (i) new roads, power transmission lines, and new settlements to accommodate the large migrant workforce involved in building large dams, (ii) mass tree mortality within low-elevation inundated areas, and (iii) discontinuity of upstream fish migrations (World Commission on Dams, 2000; Anderson *et al*. 2006; Bertham and Goulding 1997; Finer and Jenkins 2012). In all cases, low-lying forests and savannas are disproportionately affected by the direct and indirect impacts of building and maintaining a large dam. The biodiversity losses from large dams are particularly large relative to benefits of the dams in relatively flat lowland areas where the ecological effect of dams — which is often expressed as the total inundated area (km^2) per unit of electricity produced (MW/yr) — tends to be very high. In addition to a wide range of ecological impacts, local indigenous populations are sometimes displaced from their traditional territories within the reservoir area and immediate vicinities — in direct contradiction of the UN Declaration of Indigenous Rights (UN General Assembly 2007). In sum, there is a wide range of detrimental biodiversity, carbon storage and socioeconomic consequences of augmenting hydropower generation through large dam construction, especially in tropical countries.

19.4.3.2. Effects on Human Systems

Mitigation strategies will have a range of effects on human systems, dependent on the type of mitigation strategy as well as the type of human system. Even within a particular mitigation strategy, effects may vary considerably. Reforestation that properly mimics existing forest ecosystems in structure and composition would potentially benefit human systems by stabilizing micro-climatic variation (Canadell and Raupach, 2008). It would also provide numerous benefits from the sustainable harvest of non-timber forest products (NTFPs) for food, medicine and other marketable commodities (Guariguata *et al*., 2010). However, there is a generally longer time frame and greater expense involved in recreating a diverse forest system. As mitigation measures are implemented in the future, the short-term benefits from planting monoculture stands of tree species most beneficial for climate mitigation may be given greater weight than more complex reforestation efforts. In this scenario, human systems may still benefit from improved local climate effects but not benefit from the utilization of species in a diverse forest system (Guarigata *et al*., 2010). A current example of this approach is found in China where the world's largest reforestation effort has led to dense monoculture stands of fast growing tree species through the Three North Shelterbelt Development Program (Zhang and Song, 2005). Afforestation (foresting an area that was historically not forested) creates a

similar set of costs and benefits. In both reforestation and afforestation, land tenure and ownership becomes an issue for human systems (Unruh, 2008). Relocation of human populations from agricultural lands in order to reforest would have negative consequences for those affected unless clear and thoughtful strategies are implemented. In this scenario, it would be necessary to "mitigate" the effects on human systems caused by climate mitigation. Efforts to preserve existing forests would have an overall benefit for human systems since over the long term, the costs to maintain an intact forest are much lower than the cost to restore a forest. Human populations utilizing NTFPs may continue to benefit as long as such utilization is carefully monitored for sustainability (Newton, 2008).

More generally, mitigation strategies designed to reduce dependence on carbon-intensive fuels present a very different set of circumstances in relation to human systems. The development of alternative and renewable energy sources will have significant economic and market effects which could influence food prices (see also 19.4.1). Some scenarios suggest a rise in energy costs solely due to the lower flexibility of renewable energy resources compared to fossil fuels, which would in turn affect prices in the energy-dependent agriculture sector. This would especially affect marginal populations who already devote a considerable portion of their household income to food (Hymans and Shapiro, 1976).

19.5. Emerging Risks

Emergent risks discussed above are related to multiple interacting systems and stressors (section 19.3) or to indirect and long-distance impacts (section 19.4). However, an additional set of risks has emerged in the literature recently, related to diverse aspects of climate change, including the impacts of a large temperature rise, ocean acidification and other direct consequences of CO_2 increases, and the potential impacts of geoengineering implemented as a climate change response strategy.

19.5.1. Risks from Large Global Temperature Rise >=4°C Above Pre-Industrial Levels

Most climate change impact studies have been based on climate change scenarios corresponding to global mean temperature rises of up to 3.5°C relative to 1990 (or 4°C above pre-industrial levels) (Parry *et al.,* 2004; Hare, 2006; Warren *et al*., 2006; Fischlin *et al*., 2007; Easterling *et al*., 2007). In this section, all warming scenarios are relative to pre-industrial levels unless otherwise noted. Recently the potential for larger amounts of warming has received increasing attention in the literature, motivated by the possibilities that future radiative forcing could be higher than typically considered and that positive feedbacks between climate and the carbon cycle could be strong (Betts et al. 2011; Sanderson et al., 2011). In a 4°C world, the effects of climate change on water resources and ecosystems are projected to become dominant over other drivers such as population increases and land use change (Arnell et al 2009, Bellard et al 2012).

Under a warming of 5°C, 30-40% of the global population are projected to be exposed to water stress (Gerten *et al*., submitted) under the A2 population projections. Similarly, 20-30% more people globally are expected to be affected by increased water stress, compared to those projected affected in a 2°C world (Arnell *et al*., 2011). Annual runoff is projected to fall by 40-80% variously across the Danube, Mississippi, Amazon and Murray Darling river basins, and to increase by 40% in the Nile and Ganges (Fung *et al*., 2011). The total 'drought disaster affected area' is expected to increase from 15% today to 44+/-6% in a range of scenarios which include some that reach 4°C by 2100 (Li et al 2009).

Globally, agricultural production is expected to decline in mid-high latitudes once local temperature rise exceeds 3°C (IPCC AR4) (and for lower temperature rise in the tropics), corresponding to global temperature rise below 4°C). Beyond 4°C there is high risk of marked yield loss even at high latitudes (Rotter et al. 2011, section 23.4.1). Ciscar et al (2011) estimated that a 3.5°C warming globally could reduce crop yields in Europe by 10%. There is concern that current crop modelling efforts cannot capture the non-linear responses shown by crops in response to past temperature variability, which led Schlenker and Roberts (2009) to project crop yield losses of 63-82% under 4°C warming. Today's crop models may be unable to capture well the impacts of large temperature rise (Rotter *et al.,* 2011) and also omit the concomitant effects of projected increase in pests and disease.

Under a 4°C warming, biomes in temperate zones are projected to be significantly affected, whereas under 2°C warming the effects are projected to affect mostly polar and tropical regions. Humid tropical forests are projected to lose 75% of their current extent (Zelazowski *et al*., 2011). Poleward latitudinal biome shifts of up to 400km are possible in a 4°C world (Gonzalez *et al*., 2010). Twelve to thirty-nine percent of the Earth's surface is projected to experience a novel climate (Williams *et al*., 2007) whilst on 10-48% of the Earth's surface, current climates will disappear locally as, for example, isotherms rise up mountains or towards coasts and are lost in a 4°C world. This includes highly biodiverse regions such as the Himalayas, Mesoamerica, E and S Africa, the Philippines and Indonesia. , Tropical and temperate eco-regions of exceptional biodiversity projected to experience monthly mean temperatures that deviate by between two and four standard deviations from those of the 1990s (Beaumont *et al*., 2011). Concomitantly, the climate envelopes of 60% of plants and 33% of animals are projected to shrink by more than 50% (Warren *et al*., in press.). Large climate change induced shifts in fire regimes are expected in ecosystems at 4°C. Widespread coral reef mortality is expected at 4°C, since this corresponds to CO_2 increases causing increase of about 150% in ocean acidity (World Bank 2012). Well below this threshold, at 3°C, coral reefs are expected to start to dissolve (see section 5.4.2.4). Hypoxic zones may be seen in the ocean, reducing the habitat for fish such as tuna (Stramma *et al.,* 2011). Together, these effects all point to a very extensive loss of biodiversity in a 4°C world (*high evidence, high confidence*), with concomitant loss of valuable and essential provisioning, regulating, supporting and cultural ecosystem service (*medium evidence, high confidence*). Loss of ecosystem services has negative economic and physical consequences for human agricultural and urban systems and upon human physical and mental health (Chivian and Bernstein, 2008).

An additional 250000 people are projected to be affected by river flooding in Europe in a 3.5°C world in the 2080s (Ciscar *et al*., 2011) assuming *no* population growth from today. A sea level rise of 0.5 to 1 m is *likely* by 2100 in a 4°C world (AR5 WGI Table 13.5) and would result in the inundation of many small island states.

Emerging risks associated with warming greater than 4°C above pre-industrial include the potential exceedance of human physiological limits in some areas for a global temperature rise of 7°C above pre-industrial (Sherwood and Huber, 2011); and reductions in labor productivity e.g., loss of 5% in economic output in a 6°C world (Roson and Mensbrugghe, 2010). Extreme heat waves such as that experienced in Russia in 2010 can become typical of a normal summer in a 4°C world (World Bank, 2012).

The following non-linear earth system responses would be expected to be triggered for a persistent 4°C temperature rise (a) Amazon dieback (Lenton *et al*. 2008; Malhi *et al*. 2009; Salazar and Nobre 2010) (*medium confidence*). (b) Eventual, irreversible loss of the Greenland Ice Sheet (see section 19.6.3.6, *high confidence*) (c) More widespread terrestrial carbon loss due to climate-carbon cycle feedback (AR5 WGI Ch. p.6-5, *very likely*). The chance of triggering other non-linear responses such as the collapse of the West Antarctic Ice Sheet is also greatly increased (see section 19.6.3.6).

Sub-Saharan Africa is identified as a multi-impacts hotspot in a 4°C world, with projected loss of 25-42% of plant species (Midgley and Thuiller, 2011), loss of 35% of cropland (Arnell *et al*., 2009), major reductions in growing season length (Thornton *et al*., 2011), increased risks of hunger (Sissoko *et al*., 2010, Mougou et al 2010) and areas where the probability of malaria transmission rises by 50% (Beguin, 2011). In the Upper Nile basin in Uganda, increased potential evapotranspiration as occurring under at high global temperature increases of 4°C or more is projected to decrease groundwater outflow to the river so much that the spring discharge peak disappears and the river flow regime changes from bimodal to unimodal (one seasonal peak only) (Kingston and Taylor, 2010; section 3.4.6).

More generally, simulations of climate change impacts at 4°C and above show greater and more significant impacts than at lower levels of global temperature rise (*medium evidence, high confidence*). The large projected increases in populations exposed to water stress, fluvial and coastal flooding, the potential for crop yield losses, and the projected widespread disruption of ecosystem function and services, alongside projected extinction of a significant proportion of the earth's biodiversity, would create large aggregate impacts of climate change on society generally and on the global economy (see 19.6.3.5). Furthermore, these effects will interact, risking a cascade of impacts

which may induce the crossing of tipping points in socio-ecological systems in many areas (Warren *et al*., 2011; 19.7.5), potentially increasing the scope of migration, which is sometimes disruptive, or conflict (19.4.3, 12.4, 12.5).

[INSERT TABLE 19-2 HERE
Table 19-2: Key risks from large temperature rise.]

19.5.2. Risks from Ocean Acidification

Ocean acidification is defined as "a reduction in pH of the ocean over an extended period, typically decades or longer, caused primarily by the uptake of carbon dioxide from the atmosphere" (WG1 Ch. 3; see also WG2 Glossary). It is a physical impact resulting from CO_2 emissions that poses emerging risks to marine ecosystems and the societies that depend on them. Ocean acidification impacts are a relatively new research area, and the potential for associated risks to become key is magnified by the fact that it is a global phenomenon and, without a decrease in atmospheric CO_2 concentration, it is irreversible on century timescales.

It is *virtually certain* that ocean acidification is occurring now (Dore *et al*., 2009; Byrne *et al*., 2010; Table 3.2 of WG1 Ch. 3) and will continue to increase in magnitude as long as the atmospheric CO_2 concentration increases (National Academy of Sciences, 2010). Risks to society and ecosystems result from a chain of consequences beginning with direct effects on biogeochemical processes and organisms and extending to indirect effects on ecosystems, ecosystem services, and society (Figure 19-3). The degree of confidence in assessing risks decreases along this chain due to the complexity of interactions across these scales and the relatively small number of studies available for quantitative risk assessment.

[INSERT FIGURE 19-3 HERE
Figure 19-3: The pathways by which ocean acidification affects marine processes, organisms, ecosystems, and society. Confidence in quantifying these effects (as summarized from WG2 Chapter 6) decreases with each step along the pathway.]

Most studies have focused on the direct effects of ocean acidification on marine organisms and biogeochemical processes. The overall effects on organisms can be assessed with *medium confidence* (WG2 Ch. 6), but this varies widely with process and organism, e.g., *medium confidence* that the increase in dissolved CO_2 will cause an increase in primary production, *low to medium confidence* that nitrogen fixation rates will be stimulated (depending on organism); *low to high confidence* that calcification rates will decrease (depending on organism); and *high confidence* that a decrease in pH will reduce the thermal tolerances of organisms (WG2 Ch. 6). Ocean acidification can also affect the availability of iron for marine photosynthesis and the chemical state and toxicity of some metals, although these effects are currently poorly understood (Millero *et al*., 2009, Hoffmann et al., 2012).

Far fewer studies have assessed the impacts on ecosystems and ecosystem services (Cooley, 2012), and most of these studies have focused on the economic impacts on fisheries (Cooley and Doney 2009; Cooley *et al*. 2011; Narita *et al*. 2012). For example, changes in overall availability and nutritional value of desired mollusk species could impact economies (Narita *et al*.; 2012) and food availability (Cooley and Doney, 2009; Cooley 2012). Figure 19-4 illustrates how evidence can be used to assess these risks, leading to the conclusion that risks to ecosystem services related to marine calcification are high and those related to nitrogen fixation are more uncertain. Changes in coral calcification are *likely* and we judge the potential magnitude of impacts to some ecosystem services (e.g., the role of coral reefs in supporting habitats, provisioning of fish, regulating shoreline erosion, and tourism) to be *medium to high*. Studies document significant changes in community composition, biodiversity, calcification rates, and recruitment of corals and other calcifiers caused by natural carbon dioxide seeps that produce acidification consistent with that expected to result from an atmospheric CO_2 concentration of 750 ppmv (Hall-Spencer *et al*., 2008; Fabricius *et al*., 2011). If such changes are representative of future changes to benthic calcifying systems, then the ecosystem services they provide will in turn be degraded. The loss of coral reef structure, for example, has been linked to changes in abundance and diversity of reef fishes (Jones *et al*. 2004; Wilson *et al*. 2012; Chong-Seng, *et al*. 2012).

[INSERT FIGURE 19-4 HERE
Figure 19-4: Risks of ocean acidification to ecosystems services through two effects on biogeochemical processes: (1) reductions in calcification rates (of corals) and (2) increases in nitrogen-fixation rates. Assessments are based on the estimated *likelihood* that the process will be affected by ocean acidification (horizontal axis) and the *magnitude* of the impacts on associated ecosystem services (vertical axis) should the process be affected. Heights and widths of boxes indicate the range of uncertainty in the magnitude of impacts on ecosystem services and likelihood of change in the process, respectively. Heights are greater than widths due to the lower confidence in responses of ecosystems and their services (Figure 19-3). Judgments are based on impacts expected with atmospheric CO_2 levels of 2-3x preindustrial levels (560-840 ppmv). This figure is meant to be broadly illustrative: with sufficient information Low, Medium, and High magnitudes of impacts would be defined quantitatively. The shading of the box represents the risk (*likelihood* x *magnitude*) to ecosystem services with the dashed contour showing the line of equal risk; the area above and to the right of this line is broadly indicative of key risks. Thus, the reduction in calcification due to ocean acidification is already considered a key risk to some ecosystem services, while the limited evidence regarding the nitrogen fixation response and its impacts implies that it may or may not become a key risk as uncertainty is reduced.]

In contrast, several laboratory studies show that nitrogen fixation rates increase under ocean acidification conditions (WG2 Ch. 6), but there is limited evidence for this in field studies and the magnitude of the impacts to ecosystem services (e.g. nitrogen cycling) is largely unknown, so that the risk of this impact is difficult to quantify.

19.5.3. Risks from CO_2 Health Effects

There is increasing evidence that the impacts of elevated atmospheric CO_2 on plant species will affect health via two distinct pathways: the increased production and allergenicity of pollen and allergenic compounds, and the nutritional quality of key food crops. The evidence for these impacts on plant species is increasingly robust and recent evidence in the public health literature points to the potential for these risks to be sufficiently widespread in geographical scope and large in their impact on human health to be considered an emerging risk.

Climate change is expected to alter the spatial and temporal distribution of several key allergen-producing plant species (Shea, 2008), and increased atmospheric CO_2 concentration, independent of climate effects, has been shown to stimulate pollen production(Rasmussen, 2002; Clot, 2003; Galán *et al.*, 2005; Garcia-Mozo *et al.*, 2006; Ladeau and Clark, 2006; Damialis *et al.*, 2007; Frei and Gassner, 2008). Ziska *et al.* (2000, 2003, 2012) found an association between elevated CO_2 concentrations and temperature with faster growing and earlier flowering ragweed species (*Ambrosia artemisiifolia*) along with greater production of ragweed pollen (Wayne *et al.*, 2002; Singer *et al.*, 2005; Rogers *et al.*, 2006) leading, in some areas, to a measurable increase in hospital visits for allergic rhinitis (Breton et al. 2006). Experimental studies have shown that poison ivy, another common allergenic species, responds to atmospheric CO_2 enrichment through increased photosynthesis, water use efficiency, growth, and biomass. This stimulation, exceeding that of most other woody species, also produces a more potent form of the primary allergenic compound, urushiol (Mohan *et al.,* 2006).

While climate change and variability is expected to affect crop production (see Chapter 7), emerging evidence suggests an additional stressor on the food system: the impact of elevated levels of CO_2 on the nutritional quality of important foods. A prominent example of the effect of elevated atmospheric CO_2 is the decrease in the nitrogen (N) concentration in vegetative plant parts as well as in seeds and grains and, related to this, the decrease in the protein concentrations (Cotrufo *et al.*, 1998; Taub *et al.*, 2008; Wieser *et al.*, 2008). Experimental studies of increasing CO_2 to 550 ppm demonstrated effects on crude protein, starch, total and soluble B-amylase, and single kernel hardiness, leading to a reduction in crude protein by 4 to 13% in wheat and 11 to 13% in barley (Erbs at el, 2010). Other CO_2 enrichment studies have shown changes in the composition of other macro- and micronutrients (Ca, K, Mg, Fe, Zn) and in concentrations of other nutritionally important components such as vitamins and sugars (Idso and Idso, 2001). The declining nutritional quality of important global crops is an emerging risk that has the potential to broadly affect rates of protein-energy and micronutrient malnutrition in vulnerable populations. While this emerging risk has the potential to become key, there is currently insufficient information to assess under what ambient CO_2 concentrations this risk will manifest as key.

19.5.4. Risks from Geoengineering (Solar Radiation Management)

Geoengineering refers to a set of proposed methods and technologies that aim to alter the climate system in order to alleviate the impacts of climate change (WG2 Glossary; IPCC, 2012b). It is distinct from mitigation, in that mitigation aims to reduce or prevent actions that would change the climate, such as emissions of gases and particles and changes to the land surface, while geoengineering involves deliberate changes to the climate system itself. The main benefit of geoengineering would be the reduction of climate change that would otherwise occur, and the associated reduction in impacts (Pongratz *et al.*, 2012; section 19.7.1). Here we focus on risks, consistent with the goal of this chapter.

Geoengineering is an emerging risk both because it poses risks to society and ecosystems that could be large and widespread and because, although it is not a new idea (e.g., Rusin and Flit, 1960; Environmental Pollution Panel, 1965; Budyko, 1974, and a long history of geoengineering proposals as detailed by Fleming, 2010), it has received increasing attention in the recent scientific literature, stimulated in part by suggestions that nations might consider geoengineering solutions to global warming in light of the absence of comprehensive global mitigation policy (Crutzen, 2006; Wigley, 2006). Geoengineering has come to refer to both carbon dioxide concentration reduction (CDR, discussed in detail in AR5 WG I, Chapter 6) and solar radiation management (SRM; Shepherd et al., 2009; Lenton and Vaughan, 2009; discussed in detail in AR5 WG I, Chapter 7), and both are discussed in AR5 WG I, FAQ 7.3. These two different approaches to climate control raise very different scientific (e.g. Izrael *et al.*, 2009), ethical (Morrow et al., 2009; Preston, 2013) and governance issues (Lloyd and Oppenheimer, 2012). Many approaches to CDR are better defined as mitigation than as geoengineering (AR5 WGI, Chapter 6), and CDR is thought to produce fewer risks than SRM if the CO_2 can be removed from the atmosphere efficiently and stored safely (WGI Chapter 6; Royal Society 2009). For these reasons, in addition to the more substantial recent literature on SRM's potential impacts on physical (see WGI, Chapter 7), social and ecological systems, we only address SRM in this section.

Various SRM schemes have been suggested, and are described in detail in AR5 WG I, Chapter 7. However, studies of impacts on society and ecosystems have been based on stratospheric aerosols and marine cloud brightening, two approaches that seem to have the potential to produce large-scale, effective and inexpensive cooling (Salter *et al.*, 2008; Lenton and Vaughan, 2009; McClellan *et al.*, 2012). Observations of volcanic eruptions, frequently used as an analogue for SRM (Robock *et al.*, 2013), indicate that while stratospheric aerosols can reduce the global average surface air temperature, they can also produce regional drought (e.g., Oman *et al.*, 2005; Trenberth and Dai, 2007), lead to famine (in the pre-industrial period; Oman *et al.*, 2006), cause ozone depletion (Solomon, 1999), and reduce electricity generation from solar generators that use focused direct sunlight (Murphy, 2009). Climate modeling studies confirm the risk of ozone depletion (Tilmes *et al.*, 2008, Rasch *et al.* 2008), and some find that stratospheric geoengineering would reduce summer monsoon rainfall relative to current climate in Asia and Africa, potentially threatening the food supply for billions of people (Robock *et al.*, 2008; Jones *et al.*, 2010), but others find different regional patterns (Rasch *et al.*, 2008).

Use of SRM can also pose risks as a climate change response strategy, most importantly due to the risk of rapid climate change if it fails or is halted (Wigley, 2006; Matthews and Caldeira, 2007; Robock et al., 2008; WGI Ch 7), which would be *very likely* to have large negative impacts on ecosystems (Russell et al., 2012) and could offset the benefits of SRM (Goes et al., 2011). Also, without global agreements on how and how much geoengineering to use, SRM presents a risk for international conflict. Since SRM appears to be very inexpensive (Robock *et al.*, 2009; McClellan *et al.*, 2012) geoengineering could be undertaken by non-state actors or by small states acting on their own (Lloyd and Oppenheimer, 2012), potentially producing global or regional conflict (Robock, 2008b).

19.6. Key Vulnerabilities, Key Risks, and Reasons for Concern

In this section, we present key vulnerabilities, key risks, and emergent risks that have been identified by many of the chapters of this report based on the material assessed by each. We then discuss dynamic characteristics of

vulnerability and risk, features which are influenced by development pathways in the past, present and future. These illustrative examples of climate-related hazards (or non-climatic stressors), key vulnerabilities, key risks and emergent risks in Table 19-3 are selected from a larger number provided by the chapters of this report. The table (19-3) indicates how these four categories are related as well as how they differ. The table also provides information on how key risks actually develop due to changing climatic hazards and vulnerabilities. This knowledge is an important prerequisite for effective adaptation and risk reduction strategies that have to address climate related hazards, non-climatic stressors and various vulnerabilities that often interact in complex phenomena and change over time. In addition to these examples, key risks may also arise from moderate vulnerability interacting with a very large physical impact.

19.6.1. Key Vulnerabilities

Several of the risks discussed in this and other chapters and noted in Table 19-3 arise because vulnerable people must cope and adapt not only to changing climate conditions, but to multiple, interacting stressors simultaneously (see 19.4), which means that effective adaptation strategies would address these complexities and relations.

19.6.1.1. Dynamics of Vulnerability

This sub-section deals with the meaning and the importance of dynamics of vulnerability, while section 19.6.1.3 assesses recent literature and data regarding observed trends of vulnerability mostly at a global or regional scale. The literature provides increasing evidence that structures and processes that determine vulnerability are dynamic and spatially variable (IPCC, 2012; and section 19.6.1.3). SREX states with *high confidence* that vulnerability and exposure of communities or social-ecological systems to climatic hazards related to extreme events are dynamic, thus varying across temporal and spatial scales due to influences of and changes in social, economic, demographic, cultural, environmental and governance factors (IPCC, 2012, p. 7).

Examples of such dynamics in exposure and vulnerability encompass, e.g. population dynamics, such as population growth (Table 19-3, Entry 1, Chapter 19) and increasing exposure of people and settlements in low lying coastal areas or flood plains in Asia (see Nicholls and Small 2002; Levy, 2009; Fuchs *et al*., 2011; IPCC, 2012; Peduzzi *et al*., 2012). Also, demographic changes, such as aging of societies, have a significant influence on vulnerability to heat stress (see Staffogia *et al*., 2006; Gosling *et al*., 2009). Changes in poverty or socio-economic status, race-ethnicity compositions as well as age structures had a significant influence on the outcome of past crises and in addition were modified and reinforced through disasters triggered by climate and weather related hazards. Cutter and Finch (2008) found that social vulnerability to natural hazards increased over time in some areas of the United States due to changes in socio-economic status, race-ethnicity composition, age, and density of population. Changes in the strength of social-networks (e.g., resulting in social isolation of elderly) and physical abilities to cope with such extreme events modify vulnerability (see e.g. Khunwishit, 2007).

In some cases human vulnerability might also change in different phases of crises and disasters. Hence, the factors that might determine vulnerability before the crises or disaster (drought crises, flood disaster) might differ from those that determine vulnerability thereafter (post-disaster and recovery phases). Disaster response and reconstruction processes and policies can modify vulnerability e.g. of coastal communities (Birkmann and Fernando, 2008; Birkmann, 2011b). A comprehensive assessment of vulnerability would account for these dynamics by evaluating long-distance impacts (e.g., resulting from migration or global influence of regional crop production failures following floods) and multiple-stressors (e.g. recovery policies after disasters) that often influence dynamics and generate complex crises and even emergent risks.

19.6.1.2. Differential Vulnerability

Wealth, education, race, ethnicity, religion, gender, age, class/caste, disability, and health status exemplify and contribute to the differential vulnerability of individuals or societies to climate and non-climate related hazards (see

IPCC, 2012). Differential vulnerability is, for example, revealed by the fact that people and communities that are similarly exposed face different levels of harm, damage and loss as well as success of recovery (see Birkmann, 2006). The uneven effects and uneven suffering of different population groups and particularly marginalized groups is well documented in various studies (Bohle *et al*., 1994; Kasperson and Kasperson, 2001; Thomalla *et al*., 2006; Birkmann, 2006; Sietz *et al*., 2011). Factors that determine and influence these differential vulnerabilities and exposure patterns to climate-related hazards encompass among other factors e.g. race and ethnicity(Fothergill *et al*., 1999; Elliott and Pais, 2006; Cutter and Finch, 2008), socioeconomic class (O'Keefe *et al*., 1976; Peacock, 1997; Ray-Bennett, 2009), gender (Sen, 1981), age (Jabry, 2003; Ben, 2006; Bartlett, 2008) as well as migration experience (Cutter and Finch, 2008) and homelessness (Wisner, 1998; IPCC, 2012a). These differential vulnerabilities are often attributed to specific populations at a particular scale using quantitative or qualitative assessment methodologies (Cardona, 2006; Cardona, 2008; Birkmann *et al*., 2013). Groups that are marginalized, particularly due to gender or wealth status or ethnicity, are differentially affected by physical impacts of climate change in terms of both gradual changes in mean properties and extreme events (e.g., Neal and Phillips, 1990; Enarson and Morrow, 1998; Neumayer and Plümper, 2007; Sietz *et al*., 2011b). Studies emphasize that vulnerability in terms of gender is not determined through biology, but in most cases by social structures, institutions and rule systems; hence women and girls are often (not always) more vulnerable due to the fact that they are marginalized from decision making or experience discrimination in development and reconstruction efforts (Fordham, 1998; Houghton, 2009; Sultana, 2010; IPCC, 2012a).

19.6.1.3. Trends in Vulnerability

Vulnerability and exposure of societies and social-ecological systems to physical impacts of climate change are dynamic and depend on economic, social, demographic, cultural, institutional, and governance factors (see IPCC, 2012, p.7). Population growth, rapid and unsustainable urban development, international financial pressures, increases in socioeconomic inequalities, failures in governance (e.g. corruption), and environmental degradation are trends that modify vulnerability of societies and communities (Maskrey, 1993a; Maskrey, 1993b; Maskrey, 1994; Mansilla, 1996; Maskrey, 1998; Cannon, 2006) at different scales. Consequently, many of the factors that reveal and determine differential vulnerability, such as socio-economic status, wealth, poverty, age, health conditions or migration experience and governance processes (see 19.6.1.2) are dynamic, often changing over time in terms of their spatial distribution. Consequently, identifying, assessing and reducing vulnerability requires accounting for such dynamics and changes in vulnerability over time, e.g. due to different socio-economic development trends and policies. The following section outlines observed trends in vulnerability according to different thematic dimensions (socio-economic, environmental, institutional), within the constraint that data for assessing such trends in vulnerability is still fragmentary and much of it only recently emerging.

19.6.1.3.1. Trends in socioeconomic vulnerability

Poverty is arguably one of the key factors determining vulnerability of societies to climate change and extreme events. For example, there is *high confidence* that drought risk – particularly in sub-Sahara Africa - is intimately linked to poverty and rural vulnerability (see GAR, 2011, p. 62; WRI, 2012; World Bank, 2010). Hence, the risk of loss of livelihoods and harm due to droughts is heavily influenced by the poverty patterns and livelihoods of communities exposed to drought, e.g. in Africa or Asia. Restocking by poor pastoralists' households in rural areas in Africa after a drought may take several years due to limited financial resources (see Chapter 13). Recent global studies for 119 countries found that at the international level there is a clear decrease in global poverty over the past six years (Chandy and Gertz, 2011). The number of poor people globally fell by nearly half a billion people, from over 1.3 billion in 2005 to under 900 million in 2010. This trend is expected to continue; hence at a global level most projections show a decreasing level of poverty and extreme poverty at the global scale (e.g. Chandy and Gertz 2011; Hughes *et al*., 2009). While the poverty rate at the global level is decreasing and now accounts for approximately 16 percent of the total global population (in 2010), regional differences are significant, as are differences between emerging and least develop economies. As a result, there is a growing climate-related risk in some regions due to chronic poverty. For example, the highly drought exposed region sub-Sahara Africa still has approximately 47% of its population living in poverty (poverty headcount ration at $1.25 per day; see World Bank

2012) and already has been defined as a global risk hotspot (see WRI, 2011; WRI, 2012). Moreover, even national-level poverty statistics provide little information about the actual distribution of poverty in a specific country, for example regarding rural-versus-urban areas or different ethnic and age groups. Income distribution trends show significant increases in inequality in some countries in Africa and particularly in Asia, such as in China, India, Indonesia and Bangladesh (World Bank, 2012). In Asia and South East Asia (e.g, China, Indonesia or Bangladesh) this trend overlaps with climate impact hotspots in terms of people currently exposed to floods and tropical cylcones as well as sea-level rise (Förster *et al*., 2011; Peduzzi *et al*., 2012; IPCC, 2012a). Assessing vulnerability in these countries requires in-depth analysis of trends and distribution patterns of poverty, income disparities and exposure of people to changing climatic hazards.

New socio-economic vulnerabilities are emerging in some countries, for example in developed countries, where the impoverishment of the middle class can be observed or where poverty is newly increasing among, for example, elderly people that have limited physical means to cope with climatic hazards.

Health conditions of individuals and population groups affect vulnerability to climate change by limiting capacities to cope and adapt to climate hazards. Although at a global scale the percentage of people undernourished is decreasing (FAO, 2012) and this trend is expected to continue(Hughes *et al*., 2009), the regional and national differences are significant: between 2010-12, 870 million people remained chronically undernourished. Particularly in countries highly exposed to current and projected climate-related hazards, such as droughts in Africa, more than one third of the population is undernourished (FAO, 2012, p. 10; Hughes *et al*., 2009). Moreover, trends in HIV/AIDS, tuberculosis and malaria are also observed in regions that are highly exposed to climatic hazards, such as Africa and South-East Asia. These multi-hazard contexts may require new approaches in climate change adaptation; for example, countries exposed to these health risks often face significant limitations with regard to their health systems(Vitoria *et al*., 2009) as indicated by the incidence of malaria and HIV/AIDS, in some cases of epidemic proportions.

While these trends mainly point to particularly severe vulnerabilities in developing countries, studies regarding extreme heat vulnerability and other challenges related to urbanization also underscore that developed and industrialized countries face increasing challenges to adapt. Extreme heat events, characterized by consecutive days with abnormally high temperatures, are projected to increase in duration, intensity, and extent (AR5 WGI SOD 11.3.2) signaling an emergent public health risk, particularly for urban populations. Advanced age represents one of the most significant risk factors for heat-related death (Bouchama and Knochel, 2002), since beside limited thermoregulatory and physiologic heat-adaptation abilities, elderly also have often reduced social contacts, and higher prevalence of chronic illness and poor health (Khosla and Guntupalli, 1999; Klinenberg, 2002; O'Neill, 2003). The trend towards an aging society, for example in Japan or Germany, therefore increases the vulnerability of these societies to extreme heat stress. Another demographic trend affecting vulnerability to extreme heat is high population growth rates in urban areas, where populations are expected to grow disproportionately over the coming decades (United Nations, 2008). By 2030, approximately 60% of the projected global population of 8.2 billion is expected to live in cities (United Nations, 2006).

19.6.1.3.2. Trends in environmental vulnerability

The environment provides a range of ecosystem services (see e.g. MEA, 2005) that are at risk due to climate change. Societies and communities in some regions that heavily rely on the quality of ecosystem services, such as rural populations dependent on rain fed agriculture where drying is projected (see also Table 19-3, Entries 1 and 2, Chapter 19, and Chapters 7, 13 and 26), are *very likely* to experience increased risk from climate change. Large proportions of the world's rural population – particularly in developing countries – depend on ecosystem services and functions. Although a global overview is still impossible, recent reports (UNDP, 2007; IPCC, 2012a) underscore that a number of current environmental trends threaten human well-being and thus increase human vulnerability (UNEP, 2007). Many communities have suffered considerable losses due to extreme weather events in combination with the degradation of ecosystems and ecosystem services in the past. For example, agricultural productivity, food security, livelihoods and health are being affected by land degradation which often starts with soil sealing with artificial surfaces, erosion, salinization, fire risk, over production, and land fragmentation resulting from both natural

and human-caused changes in climate, soil, vegetation conditions and economic and population pressures (Salvati and Zitti, 2009). In addition, coastal degradation is increasing the exposure of coastal communities to hazards (World Risk Report, 2012) particularly in Asia, e.g., severe degradation of coral reefs. Moreover, the extinctions of species and the loss of biodiversity pose a threat of diminution of genetic pools that otherwise buffer the adaptive capacities of social-ecological systems dependent on these services in the medium and long-run (e.g. in terms of medicine and agricultural production).

19.6.1.3.3. Trends in institutional vulnerability

Institutional vulnerability refers among other issues to the role of governance. Governance is increasingly recognized as a key factor that influences vulnerability and adaptive capacity of societies and communities (Kahn, 2005; WRI, 2011). Severe climate change risks and vulnerabilities to climate change occur in countries that are characterized by failed governance. Countries classified as failed states are often not able to guarantee their citizens basic standards of human security (see Chapter 12) and consequently do not provide support in crises or disaster situations for vulnerable people. At a global level the Failed State Index(Fund for Peace, 2012; Foreign Policy, 2012) as well as the Corruption Perception Index (Transparency International, 2012) are used to characterize institutional vulnerability and governance failure. Trends in the Failed State Index from 2006 to 2011 show that countries with severe problems in the functioning of the state cannot easily shift or change their situation. Countries characterized in the literature as substantially failing in governance or in some particular aspects of governance, such as Somalia and Sudan, Haiti or Pakistan have shown in the past severe difficulties in dealing with extreme events or supporting people that have to cope and adapt to severe droughts, storms or floods (see e.g. Lautze *et al*., 2004; Ahrens and Rudolph, 2006; Khazai *et al*., 2011, p. 30-31; Menkhaus, 2010, p. 320-341). Studies at the global level confirm that countries classified as failed states and affected e.g. by violence are not able to effectively reduce poverty compared to countries without violence (see World Bank, 2011). Hence, governance failure and violence as characteristics of institutional vulnerability have significant influence on socio-economic, and therefore climatic vulnerability. Furthermore, corruption has been identified as an important factor that hinders effective adaptation policies and crisis response strategies (World Risk Report, 2011). There is *high confidence* that unless governance improves in countries with severe governance failure, an increase in risk is likely to occur as a result of climate changes and increased human vulnerability.

19.6.1.4.Risk Perception

Risk perceptions influence the behavior of people in terms of risk preparedness and adaptation to climate change (Burton *et al*., 1993; van Sluis and van Aalst, 2006; IPCC, 2012a). Factors that shape risk perceptions and therewith also influence actual and potential responses (and thus vulnerability and risk) include a) interpretations of the threat, including the understanding and knowledge of the root cause of the problem, b) exposure and personal experience with the events and respective negative consequences, particularly recently (i.e., availability) c) priorities of individuals, d) environmental values and value systems in general (see e.g. O'Conner 1999; Grothmann and Patt, 2005; Weber, 2006; Kuruppu and Liverman 2011). Furthermore, Weber (2010) argues that the perceptions of risk and reactions to such risk and actual events are also shaped by motivational processes (Weber, 2010). In this context people will often ignore predictions of climate-related hazards if those predictions fail to elicit emotional reactions. In contrast, if the event or forecast of such an event elicits strong emotional feelings of fear, people may overreact and panic (see Slovic *et al*., 1982; Slovic, 1993; Slovic, 2000; Weber, 2006). Public perceptions of risks are not solely determined by the "objective" information, but rather are the product of the interaction of such information with psychological, social, institutional, and cultural processes and norms which are partly subjective, as demonstrated in various crises in the context of extreme events (Kasperson *et al*., 1988; Sagiya 2011; Funabashi and Kitazawa, 2012; Hibbs, 2012). Risk perceptions particularly influence and increase vulnerability in terms of false perceptions of security. Finally, it is important to acknowledge that everyday concerns and satisfaction of basic needs may prove more pressing than attention and effort toward actions to address longer-term risk factors e.g., climate change(Maskrey, 1989; Wisner *et al*., 2004; Maskrey, 2011). Rather, peoples' worldviews and political ideologies guide attention toward events that threaten their preferred social order (Douglas and Wildavsky, 1982; Kahan, 2010).

19.6.2. Key Risks

19.6.2.1. Assessing Key Risks

Key risks arise from the interaction of climate-related hazards and key vulnerabilities of societies or communities exposed (see Figure 19-1). Various chapters in this report have dealt with key risks from their specific chapter perspectives. In this regard it is difficult to provide a comprehensive overview. Rather, the following section highlights selected key risks in order to illustrate how key risks develop and why they are seen as fundamental in this report. Based on the input from other chapters and our evaluation of existing literature, the following key risks were identified:

- Risk of increased food insecurity (Chapter 7 and 13)
- Risk of dispossession of land (Chapter 13)
- Risk of loss and degradation of resource bases (e.g. water) and related livelihoods (Chapter 13, 24)
- Risk of increasing infrastructure failures and systemic risk (Chapter 23)
- Risk of serious harm and losses in urban areas, particularly in urban coastal environments (Chapter 26)
- Risk of increased disease burden (Chapter 23)
- Risk of loss of terrestrial, aquatic and marine ecosystems (Chapter 6, 22)
- Risk of species extinction (Chapter 6, 22)

An important common characteristic of all these key risks is that they are determined by influences of hazards due to of changing climatic conditions and climate variability on the one hand and the vulnerability of societies, communities and social-ecological systems, e.g. in terms of livelihoods, infrastructure, and management systems on the other. The following examples should underscore this systematic approach to identifying key risks.

[INSERT TABLE 19-3 HERE
Table 19-3: A selection of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in various chapters in this report (Chapter 4, 6, 7, 8, 11, 13, 19, 22, 23, 24, 25, 26). Key risks are determined by hazards and stressors interacting with vulnerability and exposure of human systems, infrastructure, and ecosystems or species. The table underscores the complexity of risks determined by various climatic hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, demographic changes or tolerance limits of species and ecosystems which often provide important services to vulnerable communities, generate the context in which climatic change related harm and loss can occur. The table illustrates that current global megatrends (e.g. climate change, urbanization and demographic changes) in combination and in specific development context (e.g. in low-laying coastal zones), can generate new systemic risks that go far beyond existing adaptation and risk management capacities, particularly in highly vulnerable regions.]

Risks of increased food insecurity emerge in various chapters and are linked to changes in e.g. rainfall patterns (temporally and spatially) that creates major stress for rainfed agriculture, particularly for those groups that have little access to alternative modes of income or income earning activities (Chapter 13). In addition, the risk of food insecurity can also be determined by the partial or total breakdown of food distribution and storage processes (Chapter 7) and limited coping and adaptation capacities. These examples also show that key risks might not solely be determined by local conditions, but also national or even regional capacities and limits on ability to manage crop failures and food shortages.

The *risks of dispossession of land* is also closely linked to rural livelihoods and the fact that shifts in energy policies and global markets might constrain access to agricultural land. The lack or limited access to land has contributed to risk when people face extreme events, such as major floods in Pakistan, since land is often used as a resource supporting coping and adaptation processes. Hence the dispossession of and limited access to agricultural land is seen in this report (e.g. Chapter 13) as a key risk in the light of climate change.

Such factors can also increase the *risk of loss of livelihoods*. Overall, there is *high confidence* that the risk of loss of livelihoods is high for people in low-laying coastal zones as well as for people engaged in rain-fed agriculture in developing countries and countries in transition due to changes in climatic conditions as well as socio-economic structures. These changes are already observed in large Delta regions, such as the Mekong Delta, where a strong migration towards urban areas is taking place due to socio-economic challenges farmers face as well as environmental changes such as salinization, saltwater intrusion and flooding linked to sea level rise.

Key risks identified in this report also encompass phenomena that are related to urban areas and infrastructure in developed and developing countries such as the *risks of increasing morbidity and infrastructure failure* as well as *new systemic risks*. In the context of extreme weather events, risks in the transport, energy and health sector are identified that emerge due to the interdependency of the different sectors, e.g. on energy supply (see Chapter 23). The potential for power shortages and the low adaptive capacity of power supply systems adds to the risk of heat stress during extreme events. These phenomena have been observed in both developing and developed countries. In this regard high temperature extremes in combination with ongoing urbanization trends, aging populations and vulnerable infrastructure increase the potential for infrastructure failure and the risk of morbidity and mortality (see Chapter 22 and 25).

The *risk of increase in disease burden* is also a primary example of the interaction of changes in the physical climate conditions and the vulnerability of people. Recent studies (see Chapter 22) underscore that increasing temperature affects the health of exposed, vulnerable groups due to heat stress (see also section 19.3). The impact of heat stress on an aging populations, such as during the heat wave disaster in 2003 in Europe, illustrates how changing climatic conditions interact with trends in population structure to create key risks.

Globally, the widespread and systemic observed and projected impacts of climate change on biodiversity and ecosystems (see Chapter 4, sections 6.3.1, 6.3.3 and 6.3.4) comprise a key risk in terms of the global loss of provisional, regulating, supporting and cultural ecosystem services. For example, regionally, increasing temperatures in combination with vulnerable aquatic systems and vulnerable aquatic ecosystem services contribute to *a key risk due to the loss of aquatic ecosystems and the services they provide for coastal livelihoods*. Newer studies regarding the degradation of coastal reefs (WRI, 2012) underscore that the degradation levels are particularly high in countries where many people depend on these resources and are also characterized by a high exposure to coastal hazards and a high vulnerability, such as the Philippines and Indonesia.

19.6.2.2. The Role of Adaptation and Alternative Development Pathways

As discussed in section 19.2.4, the identification of key risks depends in part on the underlying socio-economic conditions assumed to occur in the future, which can differ widely across alternative development pathways. This section assesses literature that compares impacts across development pathways, compares the contributions of anthropogenic climate change and socio-economic development (through changes in vulnerability and exposure) to climate-related impacts, and examines the potential for adaptation to reduce those impacts. Based on this assessment, there is *high confidence* both that risks vary substantially across plausible alternative development pathways and that the relative importance of development and climate change varies by sector, region and time period, but in general both are important to understanding possible outcomes. In some cases, there is substantial potential for adaptation to reduce risks, with development pathways playing a key role in determining challenges to adaptation, including through their effects on ecosystems and ecosystem services (Rothman *et al.*, submitted).

Direct comparison of impacts across alternative development pathways shows, for example, that socio-economic conditions are an important determinant of the impacts of climate change on food security, water stress and the consequences of extreme events and sea level rise. The effect of climate change on the number of people at risk from hunger generally spans a range of +/- 10-30 million across the four marker SRES scenarios, each of which assumes different socio-economic futures, but becomes as high as 120-170 million in some analyses based on a scenario (A2) with high population growth (Schmidhuber and Tubiello, 2007). Similarly, the number of people exposed to water stress in a global study is sensitive to population growth assumptions (Arnell and Lloyd-Hughes, Submitted), as are projected water resources in the Middle East under an A1B climate change scenario (Chenoweth

et al., 2012). Assessments of the risks from river flooding depend on alternative future population and land use assumptions (Bouwer *et al.*, 2010; te Linde *et al.*, 2011), and sea level rise impacts depend on development pathways through their effect on the exposure of both the population and economic assets to coastal impacts, as well as on the capacity to invest in protection (Anthoff *et al.*, 2010).

The view that development pathways are an important determinant of risk related to climate change impacts is further supported by two other types of studies: those that examine the vulnerability of subgroups of the current population, and those that compare the relative importance of climate and socio-economic changes to future impacts. The first type finds that variation in current socio-economic conditions explains some of the variation in risks associated with climate and climate change, supporting the idea that alternative development pathways, which describe different patterns of change in these conditions over time, should influence the future risks of climate change. For example, socio-economic conditions have been found to be a key determinant of risks to low-income households due to climate change effects on agriculture (Ahmed *et al.*, 2009; Hertel et al., 2010), to sub-populations due to exposure to heterogeneous regional climate change (Diffenbaugh *et al.*, 2007), and to low-income coastal populations due to storm surges (Dasgupta *et al.*, 2009). Assessments of environmentally induced migration have concluded that migration responses are mediated by a number of social and governance characteristics that can vary widely across societies (Warner, 2010; see 19.4.2.1, 12.4).

The second type of study finds that within a given projection of future climate change and change in socio-economic conditions, typically both are important to determining risks. In fact, the effect of the physical impacts of climate change on globally-aggregated changes in food consumption or risk of hunger have been found to be small relative to changes in these measures driven by socio-economic development alone (Schmidhuber and Tubiello, 2007; Nelson *et al.*, 2010). Similarly, future population growth is found to be an equally (Murray *et al.*, 2012) or more (Fung *et al.*, 2011; Shewe *et al.*, submitted) important determinant of globally-aggregated water stress than the level of climate change, and growth in population and wealth is expected to largely drive potential future damages from tropical cyclones (Bouwer *et al.*, 2007; Pielke Jr., 2007). At the regional level, socio-economic development has also been found to be equally or more important than climate change to impacts in Europe due to sea level rise, through coastal development (Hinkel *et al.*, 2010); heat stress, especially when acclimatization (Watkiss and Hunt, 2012) or aging (Lung *et al.*, In Press) is taken into account; and flood risks, through land use and distributions of buildings and infrastructure (Feyen *et al.*, 2009; Bouwer *et al.*, 2010). Climate change was the dominant driver of flood risks in Europe when future changes in the value of buildings and infrastructure at risk were excluded from the analysis (te Linde *et al.*, 2011; Lung *et al.*, In Press) or when biophysical impacts such as stream discharge, rather than its consequences, were assessed (Ward *et al.*, 2011).

Until recently few studies have addressed the combined impacts of climate change and land use on ecosystems (Warren *et al.*, 2011). Studies of land use change scenarios alone project a large increase in extinction rates in the coming decades (Sala *et al.*, 2000; MEA, 2005), and by the end of the century climate change is generally projected to be an even stronger driver of extinction than is land use change. A study of land bird extinction risk found some sensitivity to four alternative land use scenarios, but by 2100 risk was dominated by the climate change scenario (Sekercioglu, 2008). A study of European land use found that while land use outcomes were more sensitive to the assumed socio-economic scenario, consequences for species depended more on the climate scenario (Berry *et al.*, 2006). Since development often drives land use change, future development that reduces vulnerability in human systems without taking ecosystem preservation into account will often directly reduce ecosystem services, in turn impacting on human systems. Ecosystem based adaptation and development can reduce vulnerability whilst avoiding or minimising ecosystem service loss.

Explicit assessments of the potential for adaptation to reduce risks have indicated that there is substantial scope for reducing impacts of several types, but the capacity to undertake this adaptation is dependent on underlying development pathways. Assessments of the impacts of sea level rise, for example, show that if development pathways allow for substantial investment of resources in adaptation through coastal protection, as opposed to accommodation or abandonment strategies, a substantial reduction in impacts can be an economically rational response for large areas of coastline globally (Nicholls *et al.*, 2008a, 2008b; Anthoff *et al.*, 2010; Nicholls and Cazenave, 2010) and in Europe (Bosello *et al.*, 2012b). For the specific case of sea level rise impacts in Europe, adaptation in the form of increasing dike heights and nourishing beaches was found to reduce the number of people

affected by coastal flooding by a factor of 110 to 228, and total economic damages by a factor of 7 to 9 (Hinkel *et al.*, 2010). In contrast, in some areas with higher current and anticipated future vulnerability such as low-lying island states and parts of Africa and Asia, impacts are expected to be greater and adaptation more difficult (Nicholls *et al.*, 2011).

Similarly, the risk to food security in many regions could be reduced if development pathways increase the capacity for policy and institutional reform, although most impact studies have focused on agricultural production and accounted for adaptation to a limited and varying degree (Lobell *et al.*, 2008; Nelson *et al.*, 2009; Ziervogel and Ericksen, 2010). A study of response options in Sub-Saharan Africa identified substantial scope for adapting to climate change associated with a global warming of 2 °C above pre-industrial levels(Thornton *et al.*, 2011), given substantial investment in institutions, infrastructure, and technology, but was pessimistic about the prospects of adapting to a world with 4 °C of warming (Thornton *et al.*, 2011; see also section 19.6.1). Improved water use efficiency and extension services have been identified as the highest priority agricultural adaptation options available in Europe(Iglesias *et al.*, 2012) and a potentially large role for expanded desalination has been identified for the Middle East (Chenoweth *et al.*, 2012).

19.6.3. Updating Reasons for Concern

The Reasons for Concern (RFCs) are five categories of impacts, or characteristics of impacts, that were introduced in the IPCC TAR(Smith *et al.*, 2001)in order to facilitate interpretation of Article 2 by aggregating a wide range of individual consequences of climate change into a smaller number of broad categories. In AR4, new literature related to the five RFCs was assessed, leading in most cases to confirmation or strengthening of the judgments about their relevance to defining dangerous anthropogenic interference(Schneider *et al.*, 2007; Smith *et al.*, 2009)RFCs are related to the framework of key risks, physical impacts, and vulnerabilities used in this chapter because each RFC is understood to represent a broad category of key risks to society or ecosystems associated with a specific type of physical impact (extreme events, large-scale singular events), system at risk (unique and threatened systems), or characteristic of risk to social-ecological systems (aggregate impacts on those systems, distribution of impacts to those systems). For example, the RFC for extreme events implies a concern for risks to society and ecosystems posed by extreme events, rather than a concern for extreme events *per se*.

In this section we assess new literature related to each of the RFCs, concluding that, compared to judgments presented in AR4 and literature published soon afterward (Smith *et al.*, 2009)levels of risk associated with extreme events, distributional impacts, and large-scale singular events are similar but can be assessed with higher confidence; risks for aggregate damages are similar but confidence in the assessment unchanged, despite the availability of additional studies; and risks to unique and threatened systems are higher above 2°C than assessed previously (see Figure 19-5). We also conclude that because risks depend not only on physical impacts of climate change but also on vulnerabilities of societies and ecosystems to those impacts, RFCs as a reflection of those risks depend on both factors as well (see also 19.1).

19.6.3.1. Variations in RFCs across Socio-Economic Pathways

The determination of key risks as reflected in the Reasons for Concern (RFCs) has not previously been distinguished across alternative development pathways. In the TAR, RFCs took only autonomous adaptation into account(Smith *et al.*, 2001)An update based on literature assessed in AR4 concluded that the RFCs reflect more steeply increasing risk with global average temperature change in each category (Smith *et al.*, 2009; Schneider *et al.*, 2007, AR4 WG2 Chapter 19), but this conclusion was not based on a change in the assessment of future development pathways but rather on evidence of some impacts already becoming apparent, higher likelihoods of some biophysical impacts, and improved identification of currently vulnerable populations.

However, the RFCs represent risks that are determined by both the physical impacts of climate change and the vulnerability of social and ecological systems to climate change stresses. Figure 19-6 illustrates this dependence on vulnerability in a modified version of the burning embers diagram that has been used to characterize risks associated

with RFCs (Smith *et al*., 2001; Smith *et al*., 2009). Current literature is not sufficient to support confident assessment of specific RFCs using this approach; rather, we discuss for each RFC below the degree to which literature supports the general features of such a diagram shown here. In particular, for a given amount of temperature change, risk will be higher for socio-economic conditions producing higher vulnerability and exposure, and lower for futures with lower vulnerability and exposure.

As literature accumulates, it could inform new versions of this figure applied to specific RFCs. For example, studies that employ particular scenarios of socio-economic conditions could be categorized according to the levels of vulnerability represented by those scenarios(van Vuuren *et al*., 2012) to locate results along the horizontal axes, while climate conditions assumed in those studies would locate results along the vertical axis. As with previous versions of the burning embers, however, this new figure does not address issues related to rates of climate change or to when impacts might be realized. The updates of RFCs in 19.6.3.2-19.6.3.6 which follow (and illustrated in Figure 19-5) do not account for differences in vulnerability across development paths; rather, they are based on the same assessment framework as used in AR4 and Smith *et al*. (2009).

[INSERT FIGURE 19-5 HERE
Figure 19-5: The dependence of risk associated with a Reason for Concern (RFC) on the level of climate change, updated from TAR and Smith *et al*. (2009). The color scheme indicates the additional risk due to climate change (with white to purple indicating the lowest to highest level of risk, respectively). The levels of risk illustrated reflect the judgments of Chapter 19 authors. Purple color, introduced here for the first time, reflects the assessment that unique human and natural systems tend to have very limited adaptive capacity (Chapters 4, 24), and hence we have *high confidence* that climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C were exceeded.]

[INSERT FIGURE 19-6 HERE
Figure 19-6: Illustration of the dependence of risk associated with a Reason for Concern (RFC) on the level of climate change and vulnerability of society. This figure is schematic; the degree of risk associated with particular levels of climate change or vulnerability has not been based on a literature assessment, nor associated with a particular RFC. The vulnerability axis is relative rather than absolute: "Medium" vulnerability indicates a future development path in which vulnerability changes over time driven by moderate trends in socio-economic conditions. "Low" and "High" vulnerability indicate futures that are substantially more optimistic or pessimistic, respectively, regarding vulnerability. We assume that judgments made in other burning ember diagrams of the RFCs (Smith *et al*., 2001, 2009) including Figure 19-5, which do not explicitly take changes in vulnerability into account, are consistent with Medium future vulnerability. Arrows and dots illustrate the use of SRES scenario-based literature to locate particular impact or risk assessments on the figure according to the evolution of climate and socio-economic conditions over time.]

19.6.3.2. Unique and Threatened Systems

Unique and threatened systems include a wide range of physical, biological and human systems that are restricted to relatively narrow geographical ranges and are threatened by future changes in climate (Smith *et al*., 2001). Loss of or damage to such systems are key risks when these systems have great importance to other systems and to society, and because in some cases such loss or damage would be irreversible. AR4 stated with *high confidence* that a warming of up to 2°C above 1990-2000 levels would result in significant impacts on many unique and vulnerable systems, and would increase the endangered status of many threatened species, with increasing adverse impacts (and increasing confidence in this conclusion) at higher temperatures (Schneider *et al*., 2007). Since AR4, there is new and stronger evidence to support this judgment, particularly regarding species and ecosystems, which is now cited in sections 19.6.3.4 and 19.6.3.5 relating to distributional and aggregate impacts of climate change, because the evidence now suggests that climate change impacts on ecosystems is systemic and pervasive, and affects most ecosystems worldwide, not only unique and threatened ecosystems.

Since AR4 there has been increased understanding (see Chapter 4) confirming areas where natural ecosystems are *particularly* vulnerable to climate change and extinctions are *likely* or *very likely* to occur, for example the Wet

Tropics of Queensland, Australia (a World Heritage Area), SW Australia, and the Australian alpine zone (Klausmeyer and Shaw, 2009; Hughes, 2011) where even 1°C of local warming is projected to have negative effects. High extinction risks continue to be identified for the Fynbos and succulent Karoo areas of South Africa for both plants and insects (Midgley and Thuiller, 2011; Kuhlmann *et al.*, 2012; Huntley and Barnard, 2012)Recent research has identified tropical ecosystems, including both tropical wet and dry forests (Deutsch *et al.*, 2009; Wright et al., 2009; Kearney *et al.*, 2009, Toms *et al.*, 2012) and tropical island endemics (Fordham and Brook, 2010) as particularly vulnerable. A study estimated that 600-900 tropical bird species could be committed to extinction if GMT rises by 3.5°C by 2100, mostly in Central America, tropical parts of Mexico and the Andes, and the Brazilian Atlantic forest(Şekercioğlu *et al.*, 2012). For these birds, and for unique ecosystems (e.g. biodiversity hotspots) more generally, extinctions are projected to rapidly increase once global temperatures exceed 2°C above pre-industrial levels(Warren *et al.*, 2011; Şekercioğlu *et al.*, 2012). Since IPCC AR4, there is increasing evidence of the climate risks to polar and mountain regions, including now the Himalayas (Colwell *et al.*, 2008; Shrestha and Aryal, 2011) and to Mediterranean systems(Klausmeyer and Shaw, 2009; Maiorano *et al.*, 2011). Amongst vertebrates, amphibians are still considered the most vulnerable taxon (IPCC AR4, Warren *et al.*, in press.). Coral reef ecosystems are still considered amongst the most vulnerable of unique systems (see section 5.4.1.6), with corals' evolutionary responses to changing conditions being outpaced by climate change (Hoegh-Guldberg, 2012) resulting in projections of extensive reef decline throughout the 21st century, and reef dissolution projected to begin if CO_2 concentrations reach 560 ppm (see section 5.4.1.6). Mangroves continue to be considered particularly at risk, and the combined effect of damage to corals and mangrove threatens unique human communities (see sections 4.3.3, 22.3.3.1).

Regarding physical systems, there is a *high confidence* that an increase in annual mean global surface temperature greater than 2°C above present will eventually lead to a nearly ice-free Arctic Ocean in late summer, and a seasonally ice-free Arctic Ocean within the next 50 years is a very distinct possibility (AR5 WGI Chapter 12; section 19.6.3.6). CMIP5 projections of Arctic sea ice melt project faster loss, more consistent with observations than did the CMIP3 projections used in AR4 (AR5 WGI Chapter 12). Since Arctic sea ice is of critical importance to local peoples and Arctic ecosystems, hence there is a greater threat to the hunting and food sharing culture of the Inuit population and the ecosystems upon which they depend (Crowley, 2011) than was envisaged in AR4.

Similarly, owing to higher projections of sea level rise than in AR4 (AR5 SOD Ch.13), small island states are at greater risk of inundation than previously thought, and a global temperature rise in excess of 1.5°C would fail to protect many islands from inundation (section 24.9.2).

There is new evidence about the risks to human and ecological systems dependent on glacial meltwater. Rapid deglaciation is already occurring (see section 18.5.3). Significant loss of glacial cover in central Asia is possible by the end of the century under the higher climate change scenarios considered by IPCC AR4 (see section 24.9.3). Loss of glacial cover will affect water supplies in arid regions where meltwater contributes significantly to water supplies (Kassel, 2010). Thus projections of glacier melt by mid-century and its hydrological consequences, using an A1B SRES scenario, found projected reductions in meltwater flow from Himalayan glaciers which, if realized, would threaten the food security of 60 million people in the Brahmaputra and Indus basins (Immerzeel *et al.*, 2010) Such threats to water security in parts of Asia(Chakraborty and Newton, 2011; Shrestha *et al.*, 2012) and similar conditions in the foothills of the Andes have implications for tourism, hydropower and agriculture (Chevallier *et al.*, 2011).

This assessment is summarized in the left hand bar in Figure 19-5. Similar to findings of AR4 and Smith *et al.* (2009) but with increased confidence, current literature supports a "yellow" level of risk (moderate risk to some species and systems at recent temperatures), since there are already widespread observed impacts of climate change on unique and threatened systems. A transition to red is located at 1°C, indicating the increasing risk to small islands, coral reefs, the Arctic and unique natural ecosystems as temperature increases. A transition to purple is located around 2°C, to reflect the projected escalating risks referred to above. Unique human and natural systems tend to have very limited adaptive capacity (Chapters 4, 24), and hence we have *high confidence* that climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C were exceeded.

19.6.3.3. Extreme Events

Extreme weather events (e.g., heat waves, intense precipitation, tropical cyclones) trigger impacts that can pose key risks to societies that are exposed and vulnerable. SREX (IPCC, 2012) and the WGI AR5 provide comprehensive assessments indicating overall small changes compared to AR4 in the projected frequency of occurrence, duration, intensity, and extent of extreme events (IPCC, 2012 Chapter 3; AR5 WGI SOD). SREX also clarifies the factors which contribute to vulnerability, and assesses approaches to addressing the latter. The WGI AR5 SOD assesses the physical hazard aspect of risk, stating that, "There has been a strengthening of the evidence for human influence on temperature extremes since AR4 and it is now judged *very likely* that human influence has contributed to the observed changes in temperature extremes since the mid-20th century."(WGI SOD p.10-3). The likelihood of projected 21st century changes in extremes has not changed markedly since AR4 (WGI SOD, Chapters 10,12), but for the first time near term changes (through 2035) are assessed. Among the conclusions are, "It is *very likely* that in the next decades the frequency of warm days and warm nights will increase, while the frequency of cold days and cold nights will decrease at the global scale."(AR5 WGI SOD 11-6) For instance, increases of ~30% occur in the rate of exceedence of daily maximum temperatures above the historical 90th percentile by 2040 (WGI SOD fig. 11-22). WGI also states with respect to temperature extremes that, "This trend will *likely* be visible in an increasing number of regions in the near term" and with regard to precipitation extremes that "in the near term, it is *likely* that the frequency and intensity of heavy precipitation events will increase at the global scale." (WGI SOD, p.11-6). In addition, SREX (Figure SPM 4B) projects a reduction in return period for historical once-in-20-yr precipitation events by about 1/3 by 2046-65. Based on these assessments of the physical hazard alone, we find increased confidence in the AR4 assessment of the risk from extreme events. We also have increased confidence in the AR4 assessment of the risk arising in the near term from the *distribution of impacts* from extreme events because, by their very nature, these events change in a locally and temporally variable fashion with, e.g., a larger change in extreme temperatures at higher latitudes (SREX Figure SPM 4A).

SREX also reviewed literature on the relationship of risk of extreme events to changes in vulnerability and exposure (SREX sections 4.5.4, 4.5.6). For example, growth of megacities both concentrates vulnerability and generates "synchronous failure" which spreads beyond the immediate vicinity of extreme events. Thus increases in local vulnerability and exposure to extreme precipitation can lead to a disproportionate increase in overall risk (SREX sections 4.3.5.1, 9.2.8; Douglas *et al*., 2008; Douglas, 2009; Hallegate *et al*., 2011; Ranger, 2011). Similarly, megacities increase nighttime temperature extremes via the urban heat island effect (SREX section 4.4.5.2) while also enhancing exposure to high air pollution levels (SREX section 9.2.1.2.3). Taken together, evidence supports a worsening of air pollution risk under RCP scenarios in Asian megacities over the next few decades (WGI SOD section 11.3.5.2). This evidence supports a conclusion of disproportionate increase in risk as exposure and vulnerability increase.

Based largely on evidence discussed in AR4, Smith *et al*., (2009) assessed the risk of extreme weather events to increase already at recent temperature and to become large with less than 1°C warming above 1990 temperature, as supported by more recent literature (WGI SOD fig 11-22), which indicates an increase in currently observed 90th-percentile daily maximum temperature exceedences of more than 15% above historical values. Higher confidence expressed in AR5 on attribution of some types of extreme events to human activity, along with the assessment of increased likelihood of temperature and precipitation extremes over the next few decades when GMT (and local temperature) increases are projected to generally remain below 1°C, result in increased confidence in assigning a "yellow" level of risk at recent temperatures in Figure 19-5 and a transition to red beginning below 1°C, consistent with Smith *et al*., (2009). While the additional effect of changes in vulnerability and exposure has not been quantified, based on evidence reviewed in SREX, we judge that modest increases in the social elements of risk would support increasing the level of risk indicated in Figure 19-5 near recent temperatures. The same logic leads us to conclude that decreases in vulnerability and exposure would raise the red-to-yellow transition to higher temperatures.

19.6.3.4. Distribution of Impacts

The potential distribution of impacts is a category of climate change consequences that includes key risks to particular societies and social-ecological systems that may be disproportionately affected due to unequal distribution of vulnerability and of physical climate impacts. AR4 concluded that there is *high confidence* that low-latitude, less-developed areas are generally at greatest risk and found that, because vulnerability to climate change is also highly variable within countries, some population groups in developed countries are also highly vulnerable even to a warming of less than 2°C (Schneider *et al*., 2007). These conclusions remain valid and are now supported by more impact studies that explicitly consider differences in socio-economic conditions across regions or populations that affect vulnerability across regions or populations.

Economic (including insured) disaster losses associated with weather, climate, and geophysical events are higher in developed countries, while fatality rates and economic losses expressed as a proportion of GDP are higher in developing countries (SREX-SPM), a finding that emphasizes the importance of exposure to risk to human systems.

For levels of global temperature rise between 1.5 and 4°C over preindustrial levels, agricultural yields may increase in some regions and decrease in others in ways that may be difficult to compensate for through international trade (Battisti and Naylor, 2009; Penny *et al*., 2010). Areas where there is a significant risk of a decline in regional food security for a global warming of 1.5-2°C(Hare *et al*., 2011) include those surrounding the Namib (Brauch, 2006); the southern half of Russia (Dronin and Kirilenko, 2011); North Africa (Mougou *et al*., 2011, Iglesias *et al*., 2011); the West African Sahel (Ben Mohamed, 2011; Sissoko, 2011), sub-Saharan Africa (Müller *et al*., 2011), South Asia (Lal, 2011), and Bangladesh (Mirza, 2011). Crop yields are expected to decline in Australia (Risbey, 2011; Steffen *et al*., 2011). There are also emerging risks to agriculture generally due to flooding, and of pests and tropospheric ozone (Reilly *et al*., 2007; Avnery *et al*., 2011; Lal, 2011; Sutherst *et al*., 2011; sections 7.3.2.1.2, 7.3.2.2). Whilst particular regions may be more prone to coastal flooding or tropospheric ozone damage, pests and disease may unpredictably affect any region at any time.

The first global scale analysis of climate change's impacts on almost 50,000 species of plants and animals has highlighted that species which are widespread geographically are also at risk (Warren *et al*., in press), not only endemics, which have tended to be the focus of many previous studies, implying a significant and widespread loss of ecosystem services(Gaston and Fuller, 2008; Allesina *et al*., 2009), comprising a new emergent risk (Table 19-3, Entry 2, Chapter 19).

Since AR4, new evidence has emerged highlighting the magnitude of risk of impacts in particular regions, for example in relation to the potential for regional impacts upon ecosystems (see 19.6.3.2), megadeltas, and agricultural systems, which is exacerbated by the potential for changes in the monsoon systems (see 19.6.3.5; WG I SOD 12.5.5.). Hence, overall there is increased evidence that low-latitude and less-developed areas generally face greater risk than higher-latitude and more-developed countries (Smith *et al*., 2009). At the same time it has been found that developed countries have less resilience to, for example, recently experienced extreme weather events than previously thought, creating more localised issues of differential vulnerability in particular areas of the developed world. For this reason, and since climate change impacts are already beginning to emerge in observations (see Chapter 2), the transition from white to yellow levels of risk in Figure 19-5 is now assessed to occur at recent temperatures, and the transition from red to yellow is between 1 and 2°C, both as indicated in Smith *et al*., (2009).

19.6.3.5. Aggregate Impacts

The RFC pertaining to aggregate impacts includes risks to society or ecosystems that are aggregated globally into a single metric, such as monetary damages, lives affected, or lives lost, although most aggregations in the literature are carried out in monetary terms. Estimates of the aggregate, economy-wide risks of climate change since AR4 continue to exhibit a *low level of agreement*. Studies at the sectoral level have been refined with new data and models, and have assessed new sectors.

For example, impacts on the health sector have not previously included the direct effects of heat and humidity on productivity. New studies indicate that there is *high confidence* that these effects will have a negative impact on global economic output and human welfare (see 10.9.2.1). Heat- and humidity-related declines in available workdays of up to 19% by the middle of the century have been projected in some regions (Kjellstrom et al., 2009; SRES A2 scenario). When considering effects of disease as well, labor productivity losses are projected to lead to a global output loss of ~1.8% with ~3°C of global average warming above pre-Industrial levels and ~4.6% with ~6°C of warming (Roson and Mensbrugghe, 2012).

AR4 stated with medium confidence that approximately 20-30% of the plant and animal species assessed to date are at increasing risk of extinction as global mean temperatures exceed a warming of 2-3°C above pre-industrial levels (Fischlin *et al*., 2007). Since AR4 the literature has expanded in many ways with respect to climate change impacts on biodiversity. Firstly, new literature has added to the evidence of increased extinction risk, for example to species in unique and threatened systems (see 19.6.3.2) and in tropical, polar and mountain ecosystems (see 19.6.3.2). Secondly there are many more detailed studies quantifying extinction risks, of which several include also studies on possible adaptive measures to support conservation (e.g. Hunter *et al*., 2010; Amstrup *et al*., 2010; Pearman *et al*., 2011; Lenoir *et al*., 2008; Balint *et al*., 2011; Barnosky *et al*., 2012; Ledit *et al*., 2012; Norberg *et al*., 2012; Bellard *et al*., 2012). More studies have scrutinized previously known caveats and tried to asses their role in either under- or overestimating notably extinction risks (e.g. Beale et al., 2008; Cressey, 2008; Randin *et al*., 2009; He and Hubbell, 2011; Harte and Kitzes, 2012), including the role of evolution (Norberg *et al*., 2012), while others have stressed the relevance of past climate change insights for this issue (e.g. Barnosky *et al*., 2012) with varying success (e.g. Botkin *et al*., 2009; Willis and Bhagwat, 2009; Willis *et al*., 2010). Overall, the AR4 statement relating to extinction risk still stands.

There is increased evidence of observed climate change impacts (including those arising from changes in climate variability) on ecosystems, including range loss in plants and animals and changes in phenology(Gange *et al*., 2007; Foden *et al*., 2007; Pudas *et al*., 2008; Devictor *et al*., 2008; Kusano and Inoue, 2008; Beckage *et al*., 2008; Thibault and Brown, 2008; Kelly and Goulden, 2008; Moreno-Rueda *et al*., 2009; Furgal and Prowse, 2009), and on ecosystem composition and function (Blaum *et al*., 2007; le Roux and McGeoch, 2008; Vittoz *et al*., 2009; de Sassi and Tylianakis, 2012; Table 19-3, Entry 2, Chapter 19). Much new work has focused on synergistic impacts of climate-change induced increases in fire, drought, disease, and pests (Flannigan *et al*., 2009; Krawchuk *et al*., 2009; Hegland *et al*., 2009; Koeller *et al*., 2009). All this evidence accrues to a projection of more severe aggregate impacts of climate change on ecosystems and their services globally than in AR4.

New work has demonstrated that the expected large turnovers of up to 60% in marine species assemblages in response to unmitigated (SRES A1B) climate change by the 2050s, combined with shrinkage of fish body weight of 14–24% (Cheung *et al*., 2009; Cheung *et al*., 2012) put marine ecosystem functioning at risk with negative consequences for fishing industries, coastal communities and wildlife that are dependent on marine resources(Lam *et al*., 2012).

Assessments of risks to coastal populations due to sea level rise have advanced through the application of more geographically detailed coastal databases in models that include adaptation options (Hinkel and Klein, 2009). One global study found that without investment in coastal protection, under the SRES A1B population scenario 50 cm of globally uniform sea level rise would displace about 72 million people by 2100, while 2 m of globally uniform sea level rise would displace about 187 million people. The incremental annual costs of protection are estimated at $25 billion/year and $270 billion/year [in 1995 USD], respectively (Nicholls et al., 2011; A1B scenario). Similarly, an assessment of risks from tropical cyclones projected a doubling of cyclone damages globally due to climate change alone, (0.01% of global GDP), and a further doubling due to expected increases in GDP and related exposure, on top of present day baseline damages of $26 billion/yr (Mendelsohn et al., 2012; A1B scenario).

Assessments of economy-wide consequences of climate change report results either as total damages or as marginal damages, the latter represented by the social cost of carbon (SCC). Estimates of global aggregate impacts from integrated assessment models (Figure 19-7) exhibit *a low level of agreement* (Ackerman et al., 2011; Anthoff and Tol, 2010b; Bosello et al., 2012; Hope, 2013a, 2013b; Nordhaus, 2008, 2010; Roson and Mensbrugghe, 2012; Waldhoff et al., 2013). Sectoral breakdowns also exhibit *a low level of agreement* (Figure 19-8) (Anthoff and Tol,

2010b; Anthoff et al., 2013; Nordhaus, 2007, 2008; Roson and Mensbrugghe, 2012). There is *very high confidence* that aggregate estimates of costs mask significant differences in impacts across sectors, regions, countries and populations. For this reason, as well as the existence of only a few studies with sectoral detail that employ alternative development pathways, it is difficult to detect a monotonic relationship between vulnerability and aggregate risks at the global scale. In some locations and amongst some groups of people with high exposure and high vulnerability, net costs per capita will be significantly larger than the global average (Anthoff *et al*., 2009; Nordhaus, 2011; Warren, 2011).

[INSERT FIGURE 19-7 HERE
Figure 19-7: Representative global damage estimates, shown as a percentage loss of global output as a function of temperature, from integrated assessment models employing their own reference scenarios. PAGE 2009: (Hope, 2013a, 2013b). FUND 3.8: (Anthoff and Tol, 2010b; Anthoff *et al*., 2013; Waldhoff *et al*., 2013). RICE 2010: (Nordhaus, 2010). CRED: (Ackerman et al., 2011). ENVISAGE: (Roson and Mensbrugghe, 2012). GECON: (Nordhaus, 2006). ICES: (Bosello *et al*., 2012a). For PAGE 2009 and FUND 3.8, the shaded region indicates the range spanned by the 5th and 95th percentile of outputs in Monte Carlo mode. For CRED 1.3, the shaded region indicates the range spanned by four alternative damage functions. In CRED at 6°C, mean damages are 32% of GDP and the largest of the four damage functions yields 50% loss of GDP.]

[INSERT FIGURE 19-8 HERE
Figure 19-8: Breakdown of damages at 2.5°C above pre-industrial by sector in the DICE 2007 calibration (Nordhaus, 2007; Nordhaus, 2008), FUND 3.8 (Anthoff and Tol, 2010b; Anthoff *et al*., 2013; Waldhoff *et al*., 2013) modal damages and ENVISAGE (Roson and Mensbrugghe, 2012), reflecting a *low level of agreement* among the integrated assessment models used to estimate global aggregate damages. Note that the DICE calibration does not include damages due to changes in water resources as distinct from temperature impacts on agriculture and forestry, and FUND and ENVISAGE do not include expected catastrophic damages. Representations of changes in energy demand, coastal/sea level impacts, health and labor productivity impacts, and impacts on settlements, ecosystem and tourism are included in all three models. Grey lines span the 5th to 95th percentile of estimates from FUND. The 95th percentile of energy sector damages in FUND is 2.2% of GDP.]

Uncertainty in estimates of global aggregate impacts is further increased because most IAMs exclude a number of potentially significant factors(Yohe, 2008; Füssel, 2010; Kopp *et al*., 2012), including the consequences of earth system tipping points (Kopp and Mignone, 2012; Lenton and Ciscar, 2013), intersectoral and interregional interactions (see section 19.3) (Bosello *et al*., 2012; Warren, 2011), and imperfectly substitutable environmental goods, which reflect the fact that impacts on (for example) ecosystems cannot be replaced 1-for-1 by an increased consumption of material goods (Kopp *et al*., 2012; Sterner and Persson, 2008; Weitzman, 2010). Additionally, studies lack evidence for extrapolating damages from temperature increases at which impact studies have been carried out to higher temperatures (Ackerman and Stanton, 2012; Ackerman *et al*., 2010; Kopp *et al*., 2012; Weitzman, 2010). There is *high confidence* that the exclusion of these factors together lead to an underestimate of global aggregate impacts. In addition, adaptation is treated differently across modeling studies (Bosello *et al*., 2010; de Bruin *et al*., 2009; Füssel, 2010; Hope, 2006; Patt *et al*., 2010) and affects aggregate damage estimates in ambiguous ways.

Alternative measures of global aggregate damages have been proposed based upon historical and geographic relationships between temperature and economic growth. *Limited evidence* suggests that higher temperatures decrease economic growth rates in low-income countries by ~1.3%-2.5%/year per 1°C (Dell et al., 2009, 2012; Hsiang, 2010) (see 10.9.2.1 and 18.4.2.1). Consistent with studies on the relationship between temperature and labor productivity, higher temperatures appear to reduce both agricultural and industrial output in low-income countries; they also appear to increase political instability, which will also contribute to decreased economic growth (Dell *et al*., 2012). Modest changes in economic growth rate can accumulate to large changes in output over time, although the studies conducted to date do not address the possibility of long-term adaptation.

The social cost of carbon (SCC) is an alternative index of aggregate damages that monetizes the expected welfare impacts of a marginal increase in carbon dioxide emissions in a given year (i.e., the welfare loss associated with an additional tonne of CO_2 emitted), aggregated across space, time, and probability (e.g., Newbold *et al*., 2010;

Nordhaus, 2011a; Tol, 2011; Kopp and Mignone, 2012). As of AR4, a survey of 103 estimates of the SCC from 28 published studies found a mean of $25/tonne CO_2 and a 95th percentile value of $95/tonne CO_2 (Tol, 2005). Numerical estimates of the SCC published since AR4 continue to span a large range. Peer-reviewed estimates (as compiled by Tol, 2011, 2013, with the addition of estimates from Kopp *et al.* 2012) range from -$2 to $1000/tonne CO_2, with most estimates between $4 and $50/tonne CO_2 (in inflation-adjusted 2010 dollars, for CO_2 emissions occuring in the first fifteen years of the twenty-first century) (Ackerman and Munitz, 2012; Ackerman and Stanton, 2012; Anthoff and Tol, 2010a; Anthoff *et al.*, 2009a, 2009b, 2009c; Cai et al., 2012; Hope, 2008a, 2013b, 2008b; Kopp et al., 2012; Marten and Newbold, 2012; Narita *et al.*, 2009, 2010; Newbold *et al.*, 2010; Nordhaus, 2008, 2010; Stern and Taylor, 2007; Tol, 2011, 2012, 2013).

Uncertainty in SCC estimates is high due to the uncertainty in underlying total damage estimates, under-representation of uncertainty in socio-economic scenarios, under-representation in some models of uncertainty in climate/carbon cycle, fidelity issues regarding the reduced-form climate/carbon cycle models used in the principal IAMs (Hof *et al.*, 2011; Marten, 2011; van Vuuren et al., 2011; Warren *et al.*, 2010), and low level of agreement regarding the appropriate framework for aggregating impacts over time (discounting), regions (equity weighing), and states of the world (risk aversion). Quantitative analyses have shown that SCC estimates can vary by at least ~2x depending on assumptions about future demographic conditions (Interagency Working Group on the Social Cost of Carbon, United States Government, 2010), at least ~3x due to the incorporation of uncertainty (Kopp *et al.*, 2012, p.2012), and at least ~4x due to differences in discounting (Tol, 2011) or alternative damage functions (Ackerman and Stanton, 2012). A further source of uncertainty is whether and how the possibility of catastrophic damages is accounted for (Dietz, 2010; Nordhaus, 2011b; Weitzman, 2009), which requires bounding potential losses with a parameter akin to the value of a statistical life (representing, essentially, willingness to pay to avoid human extinction) (Dietz, 2010; Kopp *et al.*, 2012, p.2012). Without such a parameter, SCC estimates incorporating risk aversion and potential catastrophic impacts can be unboundedly high.

Thus the risk for aggregate damages is similar to that expressed in AR4 and Smith *et al.*, (2009) as indicated in Figure 19-5, with confidence in the assessment unchanged.

19.6.3.6. Large-Scale Singular Events: Physical, Ecological, and Social System Thresholds and Irreversible Change

Large-scale singular events (sometimes called “tipping points”) are abrupt and drastic changes in physical, ecological, or social systems in response to smooth variations in driving forces (Smith *et al.*, 2001; Smith *et al.,* 2009). Combined with widespread vulnerability and exposure, they pose key risks because of the potential magnitude of the consequences, the rate at which they would occur, and the limited ability of society to cope with them.

Regarding singular events in physical systems, AR4 expressed *medium confidence* that at least partial deglaciation of the Greenland ice sheet, and possibly the West Antarctic Ice Sheet (WAIS), would occur over a period of time ranging from centuries to millennia for a global average temperature increase of 1-4°C (relative to 1990-2000), causing a contribution to sea-level rise of 4-6 m or more (Schneider *et al.*, 2007). Recent studies are consistent with these judgments but provide a more nuanced view (see WGI SOD Chapter. 13). At the current time, the Greenland ice sheet is making about twice the contribution to sea level rise as the Antarctic ice sheet (Shepherd *et al.*, 2013). Recent studies (Kopp *et al.* 2009; McKay *et al.*, 2011; Dutton and Lambeck 2012) suggest a comparable contribution from the two ice sheets during the Last Interglacial, which provides a partial analog for 21st century warming. One study (Robinson *et al.*, 2012) lowered the threshold for near-complete melting of the Greenland ice sheet to 0.8-3.2°C above preindustrial temperatures from 1.9-5.1°C global warming in AR4. Expert elicitations (Kriegler *et al.*, 2009) and other approaches (Good *et al.*, 2011) have led to assessments that a complete melting of Greenland is *unlikely* below 2°C and *likely* above 4°C compared to recent temperatures. The question of whether the melting of Greenland is irreversible, once a significant fraction of ice has been lost remains contested(Lunt *et al.*, 2004; Ridley *et al.*, 2010; Robinson *et al.*, 2012). AR5 notes that a significant decay of the ice sheet may be irreversible (AR5 WGI SOD SPM-17). A threshold for the disintegration of WAIS remains difficult to identify due to shortcomings in modeling the dynamical component of ice loss. Extreme exposure and vulnerability to the

magnitude of sea level rise associated with loss of a significant fraction of either ice sheet is found worldwide (Nicholls and Tol, 2006).

There is also additional evidence regarding singular events in other physical systems. Feedback processes in the Earth system cause accelerated emissions of methane from wetlands, terrestrial permafrost and ocean hydrates but temperature sensitivity of these processes is not known and progress in determining this has been slow. However, the risk of a substantial carbon release from these processes increases with warming. Model results indicate additional cumulative methane emissions due to these sources potentially becoming comparable to cumulative direct anthropogenic emissions on a century timescale but no sudden, large release short of millennial timescales (AR5 WGI SOD 6.4, Figure 6.37; O'Connor *et al*., 2010, Archer *et al*., 2009, Zhang *et al*., 2009).

AR4 stated that Arctic summer sea ice disappears almost entirely in some projections by the end of the century (AR4 WGI 10.3); AR5 finds there is also a *high confidence* that an increase in annual mean global surface temperature greater than 2°C above present will eventually lead to a nearly ice-free Arctic Ocean in late summer. A seasonally ice-free Arctic Ocean within the next 50 years is a very distinct possibility, even though later dates cannot be excluded (AR5 WGI 12-5). Whether or not the physical process is reversible, effects of ice loss on biodiversity may not be.

Large uncertainties remain in estimating the probability of a shutdown of the Atlantic meridional circulation. One expert elicitation finds the chance of a shutdown to be between 0 and 60% for global average warming between 2-4°C, and between 5 and 95% for 4-8°C of warming relative to 2000(Kriegler *et al*., 2009). AR5 assesses a collapse of the AMOC during this century as *very unlikely*, and *unlikely* that a collapse would occur in succeeding centuries under scenarios considered (AR5WGI SOD SPM-15).

Recent observational evidence confirms the susceptibility of the Amazon to drought and fire (Adams *et al*., 2009), and recent improvements to models provide increased confidence in the existence of a tipping point in the Amazon from forest to grassland as the dominant ecosystem (Jones *et al*., 2009; Lapola *et al*., 2009; Malhi *et al*., 2009). One recent study suggests that the Amazon may be less susceptible to crossing a tipping point than previously thought (Cox *et al*., 2013), although this is contingent upon the role of CO_2 fertilisation being as strong as models project.

Risks to biological systems include species extinction (see 19.6.3.2), and regime shifts, which are sometimes classified as large-scale singular events. Such tipping points will occur in different ecosystems with different levels of warming (Warren *et al*., 2010). Although there is still uncertainty over when such points might be crossed, a significant increase in extinction rates is considered *likely* for GMT rise of more than 2°C above pre-industrial levels.

Based on the weight of the above evidence, we judge that the risk from large-scale singular events remains comparable to that assessed in AR4, as indicated by Smith *et al*. (2009) and Figure 19-5.

19.7. Assessment of Response Strategies to Manage Risks

The management of key and emerging risks of climate change can include mitigation that reduces the likelihood of climate changes and physical impacts and adaptation that reduces the vulnerability of society and ecosystems to both. Key risks, impacts, and vulnerabilities to which societies and ecosystems may be subject will depend in large part on the mix of mitigation and adaptation measures undertaken, as will the nature of Reasons for Concern (19.6). This section therefore assesses relationships between mitigation, adaptation, and the residual impacts that generate key and emerging risks. It also considers limits to both mitigation and adaptation responses, because understanding where these limits lie is critical to anticipating risks that may be unavoidable. Potential impacts involving thresholds for large changes in physical, ecological, and social systems (19.6.3.6) are particularly important elements of key risks, and the section therefore assesses response strategies aimed at avoiding or adapting to them.

19.7.1. Relationship between Adaptation Efforts, Mitigation Efforts, and Residual Impacts

Evaluating the potential mixes of mitigation, adaptation, and impacts is made complicated by the fact that it requires joint consideration of alternative outcomes for both climate change and socio-economic development. Such an approach is further complicated because socio-economic development pathways will influence future emissions, land use change, and therefore climate change (WGIII, Chapter 5), and in turn climate change will influence development pathways through feedbacks on social and economic systems, including policy responses (AR5 WGII Chapter 2, Chapter 20).

One perspective on these relationships is provided by studies of the benefits of mitigation, i.e., the impacts avoided by mitigation, which sometimes also account for adaptation. Avoided impacts vary significantly across regions due to (a) differing levels of regional (as opposed to global) climate change, (b) differing numbers of people and levels of resources at risk in different regions (e.g. presence of unique ecosystems or the size of the human population exposed to impacts), and (c) differing sensitivities and adaptive capacities of humans, species or ecosystems in different regions. Similarly, residual impacts will differ between sectors due to (a) different levels of sensitivity and (b) differing levels of adaptive capacity. They will also differ over time depending on which aspect of the physical climate system is driving them. Benefits accrue most rapidly for impacts associated with ocean acidification, less rapidly for those associated with change in temperature and/or precipitation, and least rapidly for impacts associated with sea level rise such as coastal flooding, loss of mangroves and coastal wetlands (AR5 WGI SOD Figure 6.41). Sea level rise responds very slowly to mitigation efforts so that mitigation can reduce the rate of sea level rise but under most emissions scenarios, cannot halt it altogether (Meehl *et al*., 2012). Global temperature can be stabilized as a result of mitigation efforts, but even if anthropogenic CO_2 emissions were reduced to zero, global average temperature would not decline significantly from its peak over a century timescale (Matthews and Caldeira, 2008; Solomon *et al*., 2010). Ocean acidification responds more quickly to changes in emissions of CO_2 than does global temperature, with the rise in pH ceasing several decades after stringent emission reductions begin (Bernie *et al*., 2010).

Figure 19-9 gives an example of sectoral variation within three global analyses of the avoided impacts of climate change resulting from efforts to implement stringent mitigation (Arnell *et al*., 2013; Warren *et al*., in press; Warren *et al*., submitted). The figure shows the impacts avoided by reducing greenhouse gas emissions from either SRES A1B or SRES A1FI scenario, to one in which global greenhouse gas emissions peak in 2016 and are reduced thereafter at 5% annually, constraining global mean temperature rise to 2ºC above pre-industrial levels. In all three studies, global temperatures are simulated to reach between 4º and 5.6ºC above pre-industrial by 2100, consistent with WGI AR4, whilst under the pathways peaking in 2016 it reaches just above 2ºC. Global average sea level rises by 47-55cm by 2100 in the scenarios with no mitigation, with the increase reduced to 30 cm by the most aggressive mitigation pathway. Overall, the impacts avoided increase over time and by the end of the century range from 20-70% below SRES A1B base case impacts, or 30-80% below SRES A1FI base case impacts, across sectors (Figure 19-9). Specifically Arnell (2013) identified large benefits for crop productivity, exposure to coastal and fluvial flooding, and energy use for cooling, where impacts avoided relative to an A1FI baseline ranged from 60 to 80% by 2100 (Figure 19-9), whilst avoided impacts were smaller for water availability (20%). Similarly Warren *et al*. (2012) found that 60% of the impacts on biodiversity, in terms of projected loss in species range in 2100, can be avoided if warming can be limited to 2 degrees above pre-industrial levels (Figure 19-9). The proportion of impacts avoided *at the global scale* was relatively robust for most indicators across different climate model patterns, but the absolute magnitude of avoided impacts varied considerably.

[INSERT FIGURE 19-9 HERE
Figure 19-9: Climate change impacts avoided by a mitigation scenario compared to two no-mitigation cases (SRES A1B and A1FI scenarios), showing the uncertainty due to regional climate change impacts projection with 7 GCMs. Since increases and decreases in water stress, flood risks and crop suitability are not co-located and affect different regions, these effects are not combined. From Arnell *et al*., 2013, Warren *et al*., in press, Warren *et al*., submitted.]

All three studies (Arnell *et al*. 2013; Warren *et al*., in press*;* Warren *et al*., submitted), which considered emission reduction rates of between 2 and 5% annually, showed that fewer impacts can be avoided when global emissions do not peak until 2030, even if emissions are reduced at 5% thereafter, than if emissions peak in 2016 and are reduced

at 2% annually thereafter. A complementary economic analysis with the PAGE integrated assessment model showed that if global emissions peak in 2016, around one half of the economic impacts that would otherwise accrue by 2100 can be avoided, but if mitigation is delayed so that emissions peak in 2030, only around a third of the impacts can be avoided regardless of whether equity weightings are used in the economic model (Warren *et al*., submitted).

The above finding of the importance of an early peaking date for global emissions in avoiding climate change impacts, is consistent with an underlying independent finding that the later global emissions peak, the faster emissions must subsequently be reduced to obtain the same probability of meeting a given constraint on global temperature rise (Kalbekken and Rive, 2007; Vaughan *et al*., 2009; Huntingford *et al*., 2012). Example findings from these three studies are that (i) a 20 year delay in reducing emissions leads to a requirement of a 5-11 times greater emissions reduction to stay below identical levels of warming (ii) delaying the peaking date of global emissions from 2015 to 2025 leads to a requirement of more than doubling the post-peak emission reduction rate to maintain a 50% probability of constraining global temperature rise to 2°C above pre-industrial levels. The common finding of a tradeoff between emission reduction rate and the date at which global emission peak reflects the relatively fixed relationship between total cumulative CO_2 emissions and peak temperature change (WG1, Chapter 12).

Other studies have also quantified the benefits of mitigation. Taking the socioeconomic trends in the A2 scenario and exploring futures with and without climate change policy shows that mitigation can reduce by 80-95% the people additionally at risk of hunger in 2080 in the SRES A2 scenario (mostly in Africa), corresponding to a global saving of an estimated 23-34 billion US$ in terms of agricultural output (Tubiello and Fischer, 2007). Benefits varied regionally and were negative in some cases, for example in developed countries due to a positive, though uncertain, effect of CO_2 fertilisation. Similarly, mitigation was found to reduce overall potential welfare losses in the EU from 0.4-1% to 0.2-0.3%(Ciscar *et al*., 2011) with losses in the agricultural sector changing to gains, and the numbers of additional people affected by fluvial flooding decreasing from 318-396,000 annually to 251-276,000 annually. Fung *et al*. (2011) and Arnell *et al*. (2009) both found that projected climate change induced increases in water stress globally for a global temperature rise of 4°C above pre-industrial levels would be halved were global temperature rise to be constrained to 2°C.

Overall this suggests that early, stringent mitigation can avoid a large proportion of the impacts of climate change that would otherwise occur during the second half of the 21st century, irrespective of whether impacts are measured in physical or economic terms. Studies showed that because mitigation reduces the rate of temperature increase, stringent mitigation could increase by 3 to 4 decades the time available for adaptation to a particular level of global temperature rise and thus impacts (Arnell *et al*. 2013, Warren *et al*., in press). A limitation of all these studies, is the uneven treatment of adaptation, which has been explored thoroughly in the context of sea level rise (Nicholls *et al*., 2011) but less well in other contexts.

Mitigation scenarios in category 1 tend to constrain global temperature rise to between A and B degrees C above pre-industrial, significantly reducing the likelihood of occurrence of the following climate change impacts (list tbc) and the breaching of the following tipping points in the earth system (list tbc). Scenarios in category 2 on the other hand constrain global temperature rise to between C and D, also reducing these outcomes, but to a less significant extent. Scenarios in categories 4 to 6 are projected to result in temperature rise of above 4°C and would allow significant risks to persist in all the key areas listed in Table 19-3. Scenarios in category 3 produce modest reductions in the risks (Figure 19-10).

[INSERT FIGURE 19-10 HERE
Figure 19-10 (forthcoming): relates the categories of mitigation scenario considered in AR5 WGIII, to global temperature outcomes (consistent with the WGI calculations; data taken from Chapter 6 - WGIII). It also relates these temperature outcomes to some salient projected climate change impacts for the different levels of global temperature rise, focusing on those impacts which are less affected by the socioeconomic development pathway.]

19.7.2. Limits to Mitigation

Mitigation possibilities are not unlimited. Assessment of maximum feasible mitigation (and lowest feasible emissions pathways) must account for the fact that feasibility is a subjective concept encompassing technological, economic, political, and social dimensions (Hare *et al.,* 2010, UNEP Chapter 2). Most mitigation studies have focused on technical feasibility, for example demonstrating that it is possible to reduce emissions enough to have at least a 50% chance of limiting warming to less than 2 °C relative to pre-industrial (den Elzen and van Vuuren, 2007; Clarke *et al*., 2009; Edenhofer *et al*., 2010; Hare *et al*., 2010; O'Neill *et al*., 2010). Such scenarios lead to pathways in which global emissions peak within the next 1-2 decades and decline to 50-80% below 1990 levels by 2050, and in some cases exhibit negative emissions before the end of the century. In contrast, no integrated assessment model-based scenarios in the literature demonstrate the feasibility of limiting warming to a maximum of 1.5 °C with at least 50% likelihood (UNEP, 2010; Ranger et al., 2012). The highest emission reduction rates considered in most integrated modeling studies that attempt to minimize mitigation cost is typically between 3 and 4% but with larger values not ruled out (den Elzen et al. 2010), whilst other studies highlight that for an additional cost higher rates may be achievable (Climate Change Committee, 2008, O'Neill *et al.,* 2010).

However, most studies of feasibility include a number of idealized assumptions, including availability of a wide range of mitigation technologies such as large-scale renewable energy, carbon capture and storage, and large-scale biomass energy. Most also assume universal participation in mitigation efforts beginning immediately, economically optimal reductions (i.e., reductions are made wherever they are cheapest), and no constraints on policy implementation. Any deviation from these idealized assumptions can significantly limit feasible mitigation reductions(Knopf *et al*., 2010; Rogelj *et al*., 2012). For example, delayed participation in reductions by non-OECD countries made concentration limits such as 450 ppm CO_2eq (roughly consistent with a 50% chance of remaining below 2 °C relative to pre-industrial), and in some cases even 550 ppm CO_2eq, unachievable in some models unless temporary overshoot of these targets were allowed(Clarke *et al*., 2009) but not in others (Waldhoff and Fawcett, 2011). Technology limits, such as unavailability of CCS or limited expansion of renewables or biomass makes stabilization at 450 ppm CO_2eq (or 2 °C with a 50% chance) unachievable in some models (Krey and Riahi, 2009; van Vliet *et al*., 2012). Costs may also become unacceptably high; for example, if low carbon power plants and other infrastructure were limited to new installations (as opposed to replacement of existing stock), the maximum emissions reduction rate would be limited to about 3%/yr (Davis *et al*., 2010). Similarly, if the political will to implement coordinated mitigation policies within or across a large number of countries is limited, peak emissions and subsequent reductions would be delayed (Webster, 2010).

These considerations have led some analysts to doubt the plausibility of limiting warming to 2 °C (Anderson and Bows, 2008; Tol, 2009; Anderson and Bows, 2011). "Emergency mitigation" options have also been considered that would go beyond the measures considered in most mitigation analyses (van Vuuren and Stehfest, 2009; Swart and Marinova, 2010). These include drastic emissions reductions achieved through limits on energy consumption (Anderson and Bows, 2011) or geoengineering through management of the earth's radiation budget (19.5.4; WGI Chapters 6, 7).

19.7.3. Avoiding Thresholds, Irreversible Change, and Large-Scale Singularities in the Earth System

Section 19.6.3 highlighted the reasons for concern related to non-linear changes in the Earth system, whereby anthropogenic forcings might cause irreversible and potentially rapid transitions. The risk of triggering these transitions generally increases with increasing anthropogenic climate forcings / climate change (Lenton *et al*., 2008; Kriegler *et al*., 2009; Levermann *et al*., 2011). Reducing greenhouse gas emissions is projected to reduce the risks of triggering such transitions. Adaptation (see 19.7.2.2) could reduce their potential consequences, but the efficacy of adaptation might be limited, for example for rapid transitions.

Several studies have sought to identify levels of atmospheric greenhouse gas concentrations or global average temperature change that would limit the risks of triggering these transitions (e.g., Keller *et al*., 2008; Kriegler *et al*., 2009; Lenton *et al*., 2008). It is important to distinguish between triggering and experiencing a threshold response

because model simulations suggest that there can be sizeable delays between the two (e.g., Lenton et al., 2008). A risk assessment based on expert elicitation (Lenton *et al*., 2008) finds that limiting global mean temperature increase to approximately 3°C above present values would considerably reduce the risks of triggering examples of potential climate threshold responses such as an Amazon rainforest dieback, a melting of the West Antarctic ice sheet (WAIS), a collapse of the thermohaline circulation / Atlantic meridional overturning circulation (THC/AMOC; see also 19.6.3.6), and disruptions of the Sahara/Sahel and West African monsoon and the El Niño-Southern Oscillation systems. Staying below this 3°C temperature limit does not entirely eliminate the risks of triggering these events (Hansen *et al*., 2008; Kriegler *et al*., 2009; Levermann *et al*., 2012; Zickfeld *et al*., 2010). In addition, this 3 ºC limit could still result in considerable risks of triggering threshold responses such as a disintegration of the Greenland Ice Sheet or a melting of the Arctic summer sea-ice (See 19.6.3.6; Lenton *et al*., 2008; Levermann *et al*., 2012). Past anthropogenic climate forcings may have already triggered some climate threshold responses (Lenton et al., 2008; Urban and Keller, 2010). In particular, evidence from the Last Interglacial suggests that 2°C may be a more appropriate indicator of high risk for a WAIS disintegration (Kopp *et al*., 2009; McKay *et al.,* 2011), a temperature limit that may be difficult to achieve with high probability (see section 19.7.2.1). In general, there is *low confidence* in the location of such temperature limits due to disagreements among experts. Estimates of such temperature limits can change over time (Oppenheimer et al., 2008) and may be subject to overconfidence that can introduce a downward bias in risk estimates of low-probability events (Morgan and Henrion, 1995). The climate threshold responses can interact (e.g., Kriegler *et al*., 2009). Other climate change metrics (e.g., rates of changes or atmospheric carbon dioxide concentrations) can also be important in the consideration of response strategies (Lenton, 2011a; McAlpine *et al*., 2010; Steffen *et al*., 2011).

Several analyses have performed risk- and decision-analyses for specific thresholds, mostly focusing on a persistent weakening or collapse of the THC/MOC (Bahn *et al*., 2011; McInerney *et al*., 2012; Urban and Keller, 2010; Zickfeld and Bruckner, 2008). Experiencing a THC/MOC collapse has been assessed as *very unlikely* in this century and *unlikely* in subsequent centuries under scenarios considered in AR5 (AR5 WGI SOD SPM-15). However, due to the long response time of the THC/MOC, the probability of triggering an eventual collapse within a certain time period can be substantially higher than the probability of experiencing it (Urban and Keller, 2010). A probabilistic analysis sampling a subset of the relevant uncertainties concluded that reducing the probability of a collapse within the next few centuries to one in ten requires emissions reductions of roughly 60% relative to a business-as-usual strategy by 2050 (McInerney and Keller, 2008). Bruckner and Zickfeld (2009) show that, under their worst-case assumptions about key parameter values emissions mitigation would need to begin within the next two decades to avoid reducing the overturning rate by more than 50%. Threshold risk estimates and risk-management strategies are sensitive to factors such as the representation of the uncertainties and the decision-making frameworks (McInerney *et al*., 2012; Polasky *et al*., 2011). Other analyses have examined how the consideration of threshold events affects response strategies. For example, the design of risk-management strategies could be informed by observation and projection systems that would provide an actionable early warning signal of an approaching threshold response. Learning about key uncertain parameters (e.g., climate sensitivity or impacts of a threshold response) can considerably affect risk-management strategies and have a sizeable economic value of information (Keller *et al*., 2004; Lorenz *et al*., 2012). However, there is *low confidence* in the feasibility and requirements for such systems due to the limited number of studies and their focus on highly simplified situations (Keller and McInerney, 2008; Lenton, 2011b, Lorenz *et al*., 2012). In some decision-analytic frameworks, knowing that a threshold has been crossed can lead to reductions in emissions mitigation and a shift of resources toward adaptation and/or geoengineering (Guillerminet and Tol, 2008; Keller *et al*., 2004; Lenton, 2011b; Swart and Marinova, 2010).

19.7.4. Avoiding Tipping Points in Social/Ecological Systems

Tipping points (see Glossary) in socio-ecological systems are defined as thresholds beyond which impacts increase non-linearly to the detriment of both human and natural systems. They pose a particularly important risk because they can be initiated rapidly without warning, inducing a need for rapid response from human systems. Because human and ecological systems are linked by the services that ecosystems provide to society (Lubchenko and Petes, 2010; McLeod and Leslie 2009), tipping points may be crossed when either the ecosystem services are disrupted and/or the social/economic networks are disrupted (Renaud *et al*., 2010). Climate change provides a stress on these services and networks that increases the potential for tipping points to be crossed, although they may be crossed due

to other types of stresses even in the absence of climate change. For example, in dryland ecosystems, overgrazing has caused grassland-to-desert transitions in a number of locations (Pimm, 2009).

The crossing of tipping points due to climate change can be avoided by preserving ecosystem services through (i) limiting the level of climate change and/or (ii) removing concomitant stresses such as overgrazing, fishing, habitat destruction, and pollution. Most of the literature currently focuses on strategy (ii), and there is limited information about the exact levels of climate change that specific coupled socio-economic systems can withstand. Examples of strategy (ii) include maintaining the resilience of coral reefs or pelagic cephalopod populations by the removal of stress from fishing (Andre *et al.,* 2010; Anthony *et al.,* 2011; section 6.3.5.1, section 30.6.3.1) or expanding protected area networks in the tropics (Brodie *et al.,* 2012). Similarly, risks to seabird populations due to climate change impacts on fish (prey) populations could be lessened by reducing concomitant fishing stress (Cury *et al.*, 2011). In some cases, it is possible to use management to reverse the crossing of a tipping point, for example by adding an appropriately chosen amount of sediment to a submerged salt marsh (Stagg and Mendelssohn, 2010). However, strategy (ii) generally becomes ineffective once climate changes beyond a certain threshold that is not well known and varies across socio-ecological system. Furthermore, some systems may contain multiple thresholds (Renaud *et al.*, 2010) that may be crossed as stresses increase.

Other literature focuses more generally on the need for adopting a resilence-based management approach in both marine and terrestrial ecosystems (Walker and Salt 2006; Lubchenko and Petes 2010; Allen *et al.* 2012; Selig *et al.,* 2012). For regime shifts in ecosystems, a high level of biodiversity increases ecosystems' resilience and can enable them to recover after crossing a tipping point (Brierley *et al.*, 2009; Lubchenko and Petes, 2010). Regime shifts have already occurred in several marine food webs (Byrnes *et al.*, 2007; Alheit *et al.*, 2009, Green *et al.,* 2008, section 6.3.5.1) as a result of (observed) changes in sea surface temperature, changes in salinity due to change in runoff, and (separately) natural climate variability, and/or overfishing, showing how future climate change will analogously affect species composition and hence ecosystem functioning and potentially biogeochemical cycles. Removal of concomitant stress such as nutrient loading can reduce the chance of a regime shift (Jurgensone *et al.*, 2011) for example in coral reef ecosystems (De'ath *et al.*, 2012). Appropriate ecosystem monitoring that looks for a slowing down in the recovery of systems from small changes (Nes and Scheffer, 2007) or measures whether an appropriate indicator value is too low or too high, (Biggs *et al.,* 2008) may give warning that a system is a approaching a regime shift, allowing intervention of type (ii) above to be implemented (Brock and Carpenter, 2010; Cuttal and Jayaprakash, 2008). Indicators that could be used for such monitoring have been identified for the desertification process in the Mediterranean (Alados *et al.*, 2011) and for landscape fire dynamics (Zinck *et al.*, 2011, McKenzie and Kennedy, 2012).

19.7.5. Limits to Adaptation

Chapter 16.2 and 16.5 provide a thorough assessment of the literature on limits to adaptation. Discussions are beginning on the nature of such limits, e.g. in terms of different dimensions of the limits of adaptation, including financial or economic limits to adapt, but also social and political or cognitive limits of adaptation. Limits of adaptation (see e.g. Adger, 2009) are also recognized in terms of specific geographies, for example small island developing states and their limited ability to adapt to increasing impacts of sea level rise, the limits of adaptation of urban agglomerations in low-laying coastal zones (see e.g. Birkmann, 2010b), or in relation to loss of water supplies as a result of glacier retreat (Orlove, 2009). Overall, limits of adaptation have a close link to key vulnerabilities and key risks, since limits of adaptation are influenced by key vulnerabilities, such as identified in the cross-chapter table 19.3, and contribute to the development of key risks.

Frequently Asked Questions

FAQ 19.1: How does climate change interact with and amplify pre-existing risks?

The size of a risk depends on the probability that people or societies will be exposed to a triggering weather or climate-related trend or event and their vulnerability to damage and loss occurring as a result. For example, people living near certain coastal areas are more likely to be exposed to storm surge from tropical cyclones than those living

inland. Exposure to potentially damaging physical events and vulnerability to those damages taken together constitute risk.

Climate change can amplify climate risks by changing the likelihood that damaging physical events or trends will occur, altering patterns of exposure of vulnerable people and societies to such events, or increasing their vulnerability to a number of risks not directly related to climate change. For example, older populations are more vulnerable than younger ones to a variety of climate and non-climate stresses. The increased incidence of extreme heat as the climate warms will further raise the relatively high risk of death from heat stress in this vulnerable group and simultaneously make them yet more vulnerable to other stresses like air pollution (absent anticipatory adaptation measures like increased availability of air conditioning). An example of indirect effects of climate change on risk is provided by the interaction of vulnerability due to poverty and associated risk of malnutrition with climate change abatement policy. Poverty increases people's vulnerability to malnutrition during periods of rising grain prices. Climate change has already given rise to government policies encouraging expansion of biofuel production based on fermentation of corn. Resulting increases in demand for corn contribute to higher corn prices and may indirectly increase incidence of malnutrition in vulnerable populations.

FAQ 19.2: How can climate change at one location cause impacts at another, distant location?

Impacts of climate change are felt locally and directly where the events and trends related to a changing climate occur. However, such impacts may cause responses on the part of humans, societies, and ecosystems and species which reverberate elsewhere and cause important indirect impacts at great distance from the initial climate impact. For example, a changing climate may lead to reduced crop productivity in some regions, reducing agricultural commodities supplied from that region and increasing demand for and price of the same or substitute crops grown in distant regions. In that case, a distant, indirect impact is transmitted by price changes in the global commodities markets. In a second example, people may migrate in response to impacts of climate change such as drought, leading to potential for both positive and negative consequences at receiving regions that may be far from the point of origin of the migrants. (Chapter 19.3, 19.4)

[Placeholder for a schematic figure here illustrating distant, indirect impacts]

FAQ 19.3: Does science provide an answer to the question of how much warming is acceptable?

The question of how much warming is acceptable is raised in Article 2 of the UN Framework Convention on Climate Change (UNFCCC). The criteria for determining what constitutes, in the words of Article 2, "dangerous anthropogenic interference with the climate system" are based both on science and human values. Science can determine, within a range of uncertainty, how much monetary loss might occur if tropical cyclones grow more intense or heat waves more frequent, for example. But comparing damages across communities, countries, or larger regions depends on how each political, social, or cultural entity values the losses. Comparing loss of property to loss of life is even more difficult and controversial, particularly when damage to future generations is involved. The purpose of this chapter is to highlight key risks and vulnerabilities that science has identified; however it is up to people and governments to determine how these potential impacts should be valued. For example, agreements reached by governments since 2009, meeting under the auspices of the UNFCCC, have recognized "the scientific view that the increase in global temperature should be below 2 degrees Celsius" (Chapter 19.1, UNFCCC, Copenhagen Accord).

Table 19-1: Emergent risks related to biofuel production as a mitigation strategy.

Issue number	Issue description	Nature of emergent risk	Reference
(i)Biofuel production	Potential for enhancement of greenhouse gas emissions	Does not contribute to mitigation	Wise *et al.,* 2009 Mellilo *et al*., 2009 Khanna *et al.,* 2011
(ii) Policies targeting only fossil carbon	Competition for land, reducing natural forest and impacting on biodiversity	Emerging risk of biodiversity loss due to mitigation-driven land use change	Wise *et al*., 2009 Mellilo *et al*., 2009 Lapola *et al*., 2010 Fargione *et al*., 2010
(iii) Food/fuel competition for land	Competition for land driving up food prices and impacting on numbers of people at risk of hunger	Emerging risk of food insecurity due to mitigation-driven land use change	Hertel *et al.,* 2010, Searchinger *et al.,* 2008
(iv) Biofuels production effects water resources	Competition for water impacting on biodiversity and food cropping	Emerging risk of biodiversity loss and food insecurity due to mitigation-driven water stress	Fargione *et al*., 2010, Fingerman *et al*., 2010
(v) Land conversion causes air pollution	Potential for increased production of tropospheric ozone	Emerging risk of biodiversity loss and food insecurity due to mitigation-driven damage caused by tropospheric ozone	Hewitt *et al*., 2009, Cancado *et al*., 2006
(vi) Fertilizer application	Potential for increased emissions of N2O	Offsets some benefits of other mitigation measures	Donner and Kucharik 2008, Searchinger *et al*., 2008, Fargione *et al*., 2010
(vii) Invasive properties of biofuel crops	Potential to become an invasive species	Unintended consequences that damage agriculture and/or biodiversity	Barney and Ditomaso 2008, Council for Agricultural Science and Technology 2007, Raghu *et al*., 2006

NOTES:

(i) First-generation biofuel consumption has been projected to increase by up to 170-220% by 2020 and up to 250-620% by 2030 (IEA, 2009), with the larger numbers corresponding to the implementation of a limit of 450ppm for CO_2 concentrations. Second generation biofuels are thought not to be commercially viable for large scale production until after 2020. Biofuels presently occupy about 2.2% of global cropland (33 million ha), whilst the area under cultivation itself is expanding at some 3.4 million ha/yr (FAO, 2010) due to rising demand for food. Hence, such large projections for increase in biofuel production have profound implications for land use. If this biofuel induced land use change removes primary forest, the net contribution of the biofuel cropping towards climate change mitigation may be negative. The potential scope of the impact on a global scale is revealed in one study (Wise *et al*.,2009) that considers a scenario leading to conversion of more than 40% of global land area to biofuel production by 2095.

(ii) Large scale conversion of natural forest induced by a carbon tax that does not include terrestrial carbon would have a severe impact on biodiversity (see section 19.4.3.3.) through the destruction of most remaining natural ecosystems (Wise *et al*., 2009). In Brazil, the biofuel expansion resulting from such a scenario would be expected to impinge upon the Cerrado, the Amazon and the Atlantic rainforest all three of which have high biodiversity and high levels of endemism (Lapola *et al*., 2010). Concessions of large areas for biofuel production have been made in the Brazilian Amazon, Papua New Guinea, and Madagascar, all of which are biodiversity hotspots (Koh et al. 2009). Biodiversity is reduced by about 60% in U.S. corn and soybean fields and by about 85% in Southeast Asian oil palm plantations compared to unconverted habitat (Fitzherbert *et al*., 2008; Fletcher *et al*., 2010; Fargione, 2010).

(iii)Displacement of agricultural land for biofuel crops would influence world food supply and prices (Hertel *et al*., 2010, Searchinger *et al*., 2008), as actually occurred during the food price crisis of 2007/2008 (Pimentel, 2009), thus increasing risks of malnutrition. A new assessment of agricultural land availability projects that by 2050, substantial areas of agricultural land will be lost to urbanization, desertification, sea level rise and increasing salt water intrusion (Foresight 2011) which will act to increase competition between cropping for food and biofuels. Mellilo *et al*. (2009) project that up to twice as much carbon loss can occur as result of this indirect land use change, than from the direct land use change associated with biofuel production. Some biofuel feedstocks such as wastes, residues, cover crops, and forest thinnings (Tilman *et al.,* 2009) are not in competition with cropland.

(iv) The water requirements of many biofuel crops are substantial (Fargione *et al*., 2010, Fingerman *et al*., 2010) and hence there would be potential for conflict with efforts to allocate water for domestic, industrial, agricultural and natural wetlands particularly where irrigation is required (Yang *et al*., 2012, Poudel *et al*., 2012).

(v) Where rainforest is converted to oil palm plantations, or where land is converted to sugarcane ethanol production, emissions of the precursors of tropospheric ozone increase (Hewitt *et al*., 2009, Cancado *et al*., 2006).

(vi) Where biofuels displace nitrogen-fixing crops such as soybean, fertiliser application will increase, leading to increased N_2O emissions and nitrogen runoff into rivers and oceans (Donner and Kucharik 2008). At the same time, displacement of food crops, in combination with reduced yields due to climate change impacts, would encourage farmers to increase yields through application of larger amounts of fertiliser, particularly in countries where there is a supply shortfall (Deryng *et al*., 2011) which in turn increases greenhouse gas emissions.

(vii) Land use change also has direct effects on local climate: for example, new urban developments caused an intensification and expansion of the area experiencing extreme temperatures, mainly increasing nighttime temperatures, by as much as 10 K. (Grossman and Clarke 2010).

(viii) Traits that make a plant a good candidate for biomass production also make it a potential invasive species (Barney and Ditomaso 2008; Council for Agricultural Science and Technology, 2007; Raghu *et al*., 2006). This could result in damage to nearby ecosystems or agricultural systems.

Table 19-2: Key risks from large temperature rise.

Sector	**Region**	**Key Risk**
Agriculture	Globe	Decline in agricultural production
Water	Globe	20-30% increase in exposure to water stress; 40-80% declines in runoff in Danube, Mississippi, Amazon and Murray-Darling rivers; Drought affected area 44+/-6% of earth's terrestrial surface
Ecosystems	Tropics	Widespread coral reef mortality
Ecosystems	Globe	Climate space is lost upon 10-48% earth's surface; 60% plants and 33% animals projected to lose >50% of climatic range;
Health	Globe, Urban Areas	To be provided with next draft

Table 19-3: A selection of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in various chapters in this report (chapter 4, 6, 7, 8, 9, 11, 13, 19, 22, 23, 24, 25, 26). Key risks are determined by hazards and stressors interacting with vulnerability and exposure of human systems, infrastructure, and ecosystems or species. The table underscores the complexity of risks determined by various climatic hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, demographic changes or tolerance limits of species and ecosystems which often provide important services to vulnerable communities, generate the context in which climatic change related harm and loss can occur. The table illustrates that current global megatrends (e.g. climate change, urbanization and demographic changes) in combination and in specific development context (e.g. in low-laying coastal zones), can generate new systemic risks that go far beyond existing adaptation and risk management capacities, particularly in highly vulnerable regions.

Examples of Hazards/Stressors, Key Vulnerabilities, Key Risks and Emergent Risks (using input from chapter 4, 6, 7, 8, 9, 11, 13, 19, 22, 23, 24, 25, 26)			
Hazard/ Stressor	**Key vulnerabilities**	**Key risks**	**Emergent risks**
Terrestrial and inland water systems (chapter 4)			
Rising air, soil, and water temperature	Exceedence of eco-physiological climate tolerance limits of species, increased viability of alien organisms	Loss of native biodiversity, increase in alien organism dominance	Cascades of native species loss due to interdependencies
	Epidemiological response to spread of temperature-sensitive vectors (insects)	Novel or much more severe pest and pathogen outbreaks	Interactions between pest, drought and fire interactions can lead to new risks and large negative impacts on ecosystems
Change in seasonality of rain	Vulnerability of plants and ecosystem services, due to mismatch of plant life strategy to growth opportunities	Changes in plant functional type mix leading to biome change with respective risks	Fire-promoting grasses and summer fuels in winter-rainfall areas
Ocean Systems (chapter 6)			
Rising water temperature, increase of (thermal and haline) stratification, and marine acidification [6.1.1] *(also Chapter 24)*	Tolerance limits of endemic species surpassed, increased abundance of invasive organism, high vulnerability of warm water coral reefs and respective ecosystem services for coastal communities [6.2.2, 6.2.5]	Loss of endemic species, mixing of ecosystem types, increased dominance of invasive organisms, loss of coral cover and associated ecosystem with reduction of biodiversity [6.3.2]	Enhancement of risk due to interactions, e.g., acidification and warming on calcareous organisms [6.3.5]
	Shifted productivity zones and species distribution ranges, largely from low to high latitudes [6.1.3], shifting fishery catch potential with species migration [6.5.2, 6.5.3]	Unknown productivity and services of new ecosystem types [6.4, 6.5.3]	Enhancement of risk due to interactions of drivers, warming, hypoxia, acidification, new biotic interactions [6.3.5, 6.3.6]
Expansion of oxygen minimum zones and coastal dead zones with stratification and eutrophication [6.1.1]	Hypoxia tolerance limits of larger animals surpassed, habitat contraction and loss for midwater fishes and benthic invertebrates [6.2.5]	Loss of larger animals and plants, shifts to hypoxia adapted, largely microbial communities with reduced biodiversity [6.3.3]	Enhancement of risk due to expanding hypoxia in warming oceans [6.3.5]
Enhanced harmful algal blooms in coastal areas due to rising water temperature	Increasing vulnerability of important ecosystems and valuable services due to	Enhanced frequency of dinoflagellate blooms and respective losses and	Disproportionate enhancement of risk due to interactions of various

[6.4]	already existing multiple stresses [6.3.5, 6.4]	degradations of coastal ecosystems and ecosystem services [6.4]	stresses [6.3.5]
Food security and food production systems (chapter 7)			
Rising average temperatures and more frequent extreme temperatures.	All elements of the food system from production to consumption vulnerable for key grain crops.	Crop failures, breakdown of food distribution and storage processes.	Increase in the global population to ca. 9 billion combined with rising temperatures and other trace gases such as ozone affecting food production and quality. Upper temperature limit to the ability of some food systems to adapt. [7.1, 7.2, 7.4, 7.5]
Urban areas (chapter 8)			
Inland flooding	Urban areas with large numbers of poor, uninsured people exposed to flood events including low-income informal settlements. Environmental health consequences from overwhelmed, aging, poorly maintained and inadequate urban drainage infrastructure and widespread impermeable surfaces. Inadequate local governance. Increased mosquito and water borne diseases.	Increasing urban flooding with increasing volume and velocity of flood waters on the one hand and increasing vulnerability on the other leads to key risks particularly in urban areas with large number of poor and exposed to flooding.	Larger and more frequent flooding impacting much larger population. Impacts reaching the limits of insurance; shift in the burden of risk management from the state to those at risk leading to greater inequality and property blight, abandonment of urban districts and the creation of high risk/high poverty spatial traps.
Coastal flooding (including sea level rise and storm surge)	High concentrations of people, businesses and physical assets including critical infrastructure in low-lying and unprotected coastal zones including low-elevation coastal zones in addition to vulnerability noted in previous example.	Flooding interacts with highly vulnerable people and areas that are likely lead to multiple negative consequences and hence key risks. Storm surges often causing the most serious floods	Sea level rise increasing risk over time, increasing concentration of population and economic activities on the coasts. Reaching the limits of insurance; shift in risk management from the state to those at risk leading to consequences noted above.
Heat and cold including Urban Heat Island (UHI)	Increasing urban population of infants, young children, older age groups, expectant mothers, people with compromised immune system at risk from higher temperatures (especially in heat islands) and unexpected cold spells. Inability of local organizations for health, emergency services and social services to adapt to new risk levels.	In heat waves with higher or more prolonged high temperatures or cold spells - mortality and morbidity increasing, including shifts in seasonal patterns and concentrations.	Extension and variability of heat waves and less frequent and thus unexpected cold spells, increasing risks over time for most locations. Low-income groups often facing greatest difficulties avoiding risks
Water shortages and drought in urban regions	Urban dwellers lacking water piped to their premises. Urban areas with water	Loss of functionality to urban water provision services and industry with	Urban viability may be threatened by loss of freshwater sources –

	shortages and constraints on increasing supplies. Lack of capacity and resilience in water management regimes including rural-urban linkages. Dependence on water resources in energy production systems.	human and economic impacts. Damage to urban ecology and its utility including urban and peri-urban agriculture.	including many cities dependent on glacier meltwater
Changes in urban meteorological regimes lead to enhanced air pollution	Health impacts from increases in exposure to high pollution levels with impacts most serious among physiologically susceptible populations. Urban governments' not implementing pollution controls.	Mortality and morbidity, lowered quality of life. May undermine the competitiveness in global cities to attracting key workers and investment.	Complexity and compounding of health crises.
Geo-hydrological hazards (salt water intrusion, mud/landslides, subsidence)	Vulnerability of local structures and networked infrastructure impacted by systems-level environmental change. Inability of many low-income households to move to safer housing on safer sites	Increasing risk of damage to networked infrastructure (water, sanitation, drainage, communications. transport, energy), property and human loss due to geo-hydrological hazards and the vulnerability of people and local structures.	Potential for large local and aggregate impacts via knock on effects for urban activities and wellbeing.
Storms with higher wind speeds	Sub-standard buildings and physical infrastructure and the services and functions they support. Old and hard-to-retro-fit buildings and infrastructure in cities. Local government unable or unwilling to give attention to disaster risk reduction	Damage to dwellings, businesses and public infrastructure. Loss of function and services. Challenges to recovery, especially where insurance is absent.	Challenges to individuals, businesses and public agencies where the costs of retrofitting are high leading budgetary competition and potential for tensions between development and risk reduction investments.
Changing hazard profile including novel hazards and new multi-hazard complexes	Newly exposed populations and infrastructure, especially those with limited capacity for multi-hazard risk forecasting and where risk reduction capacity is limited, e.g., where risk management planning is overly hazard specific including where physical infrastructure is predesigned in anticipation of other risks.	Risks from failures within coupled systems e.g., reliance of drainage systems on electric pumps, reliance of emergency services on roads and telecommunications, psychological shock from unanticipated risks.	Loss of faith in risk management institutions. Potential for large events that are magnified by a lack of preparation and capacity to respond.
Compound slow-onset hazards including rising temperatures and variability in temperature and water availability	Large sections of the urban population in low- and middle-income nations with livelihoods or food supplies dependent on urban and peri-urban agriculture.	Damage to or degradation of soils, water catchment capacity, fuel wood production, urban and peri-urban agriculture and other productive or protective eco-system services. Knock-on impacts for urban and peri-urban livelihoods and urban health.	Collapsing of peri-urban economies and ecosystem services with wider implications for urban service provision and disaster risk reduction.
Changes in temperature and precipitation leading to	Large urban population at risk from food and	Increases in exposure to these diseases	Growing incapacity of public health system to

changed conditions for disease propagation	waterborne diseases and to malaria, dengue and other vector borne diseases		address this and simultaneous increase in exposure to other impacts such as flooding
Rural areas (chapter 9)			
Drought in pastoral areas, changes in rangeland composition [9.3.3.1, 9.3.5.3.1]	Encroachment on pastoral rangelands, inappropriate land policy, misperception and undermining of pastoral livelihoods, conflict over natural resources, all driven by remoteness and lack of voice.	Inability to cope with drought, leading to famine. Changes in herd dynamics. Loss of revenues from livestock trade.	Impacts on livelihoods through animal disease in pastoral areas.
Effects of climate change on fish stocks; impacts of tropical storms on settlements and fishing gear. [9.3.3.1, 9.3.5.3.3]	Artisanal fisheries affected by pollution, mangrove loss, competition from aquaculture, neglect of sector by governments and researchers, complex property rights.	Declining catches and incomes for artisanal fisherfolk.	Reduced dietary protein for those consuming artisanlly-caught fish.
Water shortages and drought in rural areas [9.3.5.2.1.]	Rural people lacking access to drinking and irrigation water. Lack of capacity and resilience in water management regimes (institutionally driven).	Reducing agricultural productivity and/or income of rural people, mostly those depending on irrigated agriculture or high-yield varieties. Food insecurity.	Impacts on livelihoods driven by interaction with other factors (water management institutions, water demand). Human health.
Human health (chapter 11)			
Increasing frequency and intensity of extreme heat *(also chapter 19)*	Older people living in cities are most vulnerable to heat waves, and their population projected to triple from 2010-2050.	Increased mortality and morbidity during heat waves, particularly in those with pre-existing conditions	Overloading of health and emergency services. Mortality, morbidity and productivity loss, particularly in manual workers in hot climates
Increasing temperatures, increased variability in precipitation	Food insecurity translates into malnutrition, which is among the largest disease burdens in poorer populations.	Progress in reducing mortality and morbidity from malnutrition may slow or reverse and constitutes a new key risk	Combined impacts of climate impacts, population growth, plateauing productivity gains, land demand for livestock, biofuels, persistent inequity, and on-going food insecurity for the poor
Increasing temperatures, changing patterns of precipitation	Water- and vector-borne disease highly sensitive to meteorological conditions	Changing spatial and temporal distribution hampers disease control, exposes non-immune populations	Rapid climate and other environmental change may promote emergence of new pathogens
Increased variability in precipitation	Diarrhoea facilitated by higher temperatures, unusually high or low precipitation	Progress in reducing diarrhoea morbidity is compromised	Increased rate of failure of water and sanitation infrastructure leading to higher diarrhoea risk
Livelihood and poverty (chapter 13)			
Changing rainfall patterns (temporally and spatially)	High dependence on rain-fed agriculture. Little access	Crop failure, food shortage, severe famine	May coincide with global food insecurity or periods of

	to alternative modes of income.		excessive global food prices which means that coping strategies may not work. Adaptation mechanisms such as crop insurance (risk spreading) may collapse.
Soaring demand (and prices) of biofuels due to climate change policies.	Unclear and/or insecure land tenure arrangements.	Risk of dispossession of land due to "land grabbing" in developing countries.	Creation of large groups of landless farmers unable to support themselves. Social unrest due to disparities between intensive energy production and neglected food production.
Increasing frequency of extreme events (droughts, floods). For example if 1:20 year drought/flood becomes 1:5 year flood/drought.	Livelihoods subject to damage to their productive assets (e.g. in case of droughts – herds of livestock; if floods – dykes, fences, terraces).	Risk of the loss of livelihoods and harm due to shorter time for recovery between extreme. Pastoralists restocking after a drought may take several years; in terraced agriculture, need to rebuild terraces after flood, which may take several years.	Collapse of coping strategies with risk of collapsing livelihoods. Adaptation mechanisms such as insurance fail due to increasing frequency of claims.
Emergent risks and key vulnerabilities (chapter 19)			
Warming and drying (degree of precipitation changes uncertain) [AR5 WGI TS.5.3, WGI SPM, WGI 11.3, WGI 12.4]	Limits to coping capacity to deal with reduced water availability; increasing exposure and demand due to population increase; conflicting demands for alternative water uses; socio-cultural constraints on some adaptation options [19.2.2, 19.3.2.2, 19.6.1.1, 19.7.5]	Risk of harm and loss due to livelihood degradation from systematic constraints on water resource use that lead to supply falling far below demand. In addition limited coping and adaptation options increase the risk of harm and loss. [19.3.2.2]	Negative outcomes to sending and/or receiving regions from migration of populations due to limits on agricultural productivity and livelihoods [19.3.2.2, 19.4.2.1]
Changes in regional and seasonal temperature and precipitation over land [AR5 WGI TS.5.3, WGI SPM, WGI 11.3, WGI 12.4]	Dependence of communities on ecosystem services [19.2.2.1, 19.3.2.1]	Large scale species richness loss over most of the global land surface. 57±6% of widespread & common plants and 34±7% of widespread & common animals likely to lose ≥50% of their current climatic range by the 2080s leading to loss of services [19.3.2.1]	Widespread loss of ecosystem services: including *provisioning*, such as food and water; *regulating*, such as the control of climate and disease; *supporting*, such as nutrient cycles and crop pollination; and *cultural*, such as spiritual and recreational benefit [19.3.2.1, 19.6.3.4]
Africa (chapter 22)			
Increasing Temperature	Health of exposed and vulnerable groups (increased exposure to heat, change in the transmission dynamics of vector-borne diseases)	Increase in disease burden – changes in the patterns of infection Decrease in outdoor worker productivity due to high temperature, increase in heat related morbidity and mortality	Emerging and re-emerging disease epidemics
	Vulnerability of aquatic	Loss of aquatic ecosystems	

	systems and vulnerability of aquatic ecosystem services due to increased water temperatures	and risks for people who might depend on these resources	
Extreme Events, e.g. floods and flash floods	Vulnerable and exposed urban areas, particularly in informal settlements	Increasing harm and losses due to water logging in terms of sudden volumes of rain	Due to water logging and contamination, compounded increase of the risk of epidemics
Europe (chapter 23)			
Extreme weather events *(also Chapter 19)*	Limited coping and adaptive capacity as well as high sensitivity of different sectors, e.g. transport, energy and health sector	Stress on multiple sectors can cause systemic risks due to interdependencies between the different sectors	Disproportionate intensification of risk due to increasing interdependencies
Climate change increases the spatial distribution and seasonality of pests and diseases	Vulnerability of plants and animals exposed to pests and diseases	Increases in crop losses and animal diseases or even fatalities of livestock	Increasing risks due to limited response options and various feedback processes in agriculture, e.g. use of pesticides or antibiotics to protect plants and livestock increases resistance of disease vectors
Extreme weather events and reduced water availability due to climate change	Low adaptive capacity of power systems might lead to limited energy supply as well as higher supply costs during such extreme events and conditions	Increasing risk of power shortages due to limited energy supply, e.g. of nuclear power plants due to limited cooling water during heat stress	Continued underinvestment in adaptive energy systems might increase the risk of mismatches between limited energy supply during these events and increased demands, e.g. during a heat wave
Asia (chapter 24)			
Thawing of permafrost due to rising temperature in northern Asia.	Existence of structures and infrastructures on the permafrost and high dependences of civil life on them	Instability of or damages to the structures and infrastructures	Projected exacerbation of instability of residential buildings, pavements, pipelines used to transport petroleum and gas, pump stations and extraction facilities
Projected increase in frequency of various extreme events (heat-wave, floods and droughts) and sea level rise *(also Chapter 19)*	Convergence of livelihood and properties into coastal megacities, especially into area that is not protected against natural hazards sufficiently	Loss of human life and life stocks due to coastal floods accompanied by increasing vulnerabilities caused by occurrence of other extreme events like heat-wave and droughts	Projected increase in disruption of basic services such as water supply, sanitation, energy provision, and transportation system, which themselves could increase vulnerabilities
Australasia (chapter 25)			
Warming and drying in southern Australia and parts of New Zealand (uncertain degree of precipitation change) [25.2, Table 25-1]	Increasing build-up of combustible material in CO_2-enriched environment, increased ignition rate and combustibility, increasing exposure of human systems to these changes [25.6.1,	Increased damages to ecosystems and settlements and risks to human life from wildfires [25.6.1, Box 25-6, 25.10.2]	Increasing risk from compound extreme events across time, space and governance scales, and cumulative adaptation [25.10.2, 25.10.3, Box 25-9]

	Box 25-6]		needs
Warming and increased temperature high extremes in Australia [25.2, Table 25-1, Figure 25-5]	Urbanization, aging of population and vital infrastructure [25.3, Box 25-9, 25.10.2]	Increase in morbidity, mortality and infrastructure failure during heat waves [25.8.1, 25.10.2]	
Potential for sea level rise beyond 2100 exceeding 1m [25.2, AR5 WGI Chapter 13]	Long lifetime of coastal infrastructure, concentration and further expansion of coastal population and assets; conflicting priorities and time preferences constraining adaptation options; limited scope for managed retreat in highly developed areas [25.3, Box 25-1]	Widespread damages to coastal infrastructure and low-lying ecosystems [Box 25-1, 25.10.2]	
North America (chapter 26)			
Increases in frequency and/or intensity of extreme events, such as hurricanes, river and coastal floods, heat waves and droughts [26.2] *(also Chapter 19)*	Declining state of physical infrastructures in urban areas as well as increases in income disparities [26.7]	Risk of serious harm and losses in urban areas, particularly in coastal environments due to enhanced vulnerabilities of social groups and physical systems combined with the increases of extreme weather events [26.8]	Inability to reduce vulnerability in many areas results in increase in risk greater than change in physical hazard [26.8]
Higher temperatures, decreases in runoff and lower soil moisture due to climate change [26.2, 26.3]	Increasing vulnerability of small landholders in agriculture [26.5]	Increased losses and decreases in agricultural production increase food and job insecurity for small landholders and social groups in that region [26.5]	Increasing risks of social instability and local economic disruption due to internal migration [26.2, 26.8]

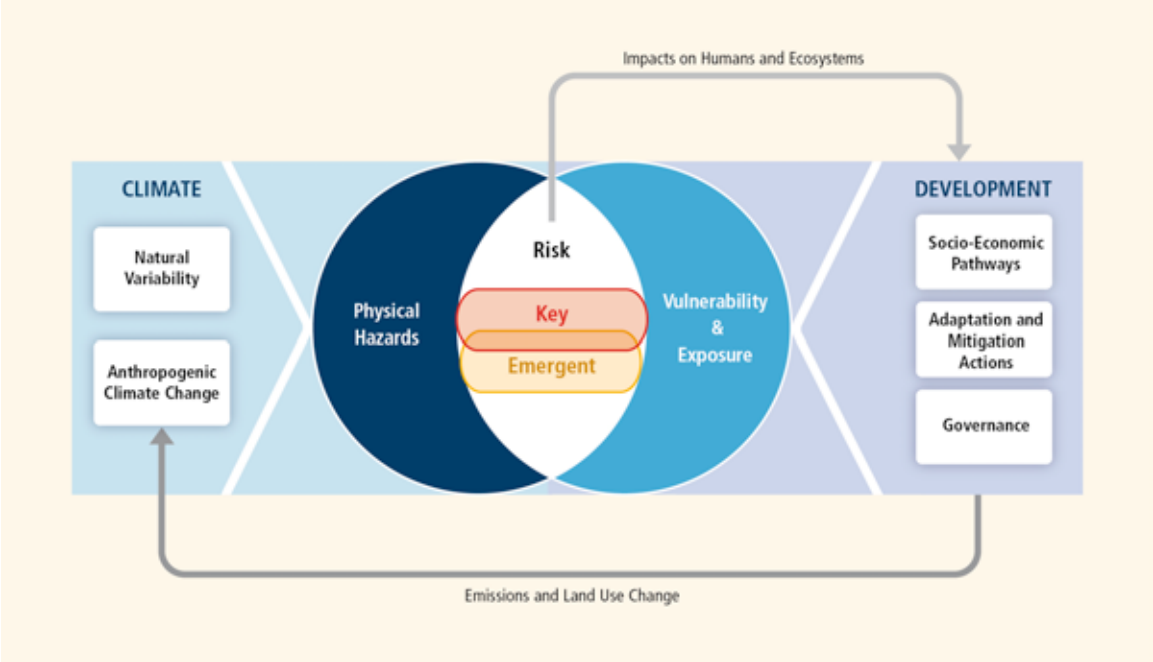

Figure 19-1: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. The figure visualizes the different terms and concepts discussed in this chapter. It underscores that risks are a product of a complex interaction between physical hazards associated with climate change and climate variability on the one hand, and the vulnerability of a society or a social-ecological system and its exposure to climate-related hazards on the other. The definition and use of "key" are indicated in Box 19-2 and the glossary. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions. Both the changes in the climate system (left side) and the development processes (right side) are key drivers of the different core components (vulnerability, exposure, and physical hazards) that constitute risk (modified version of Figure 1, IPCC, 2012.

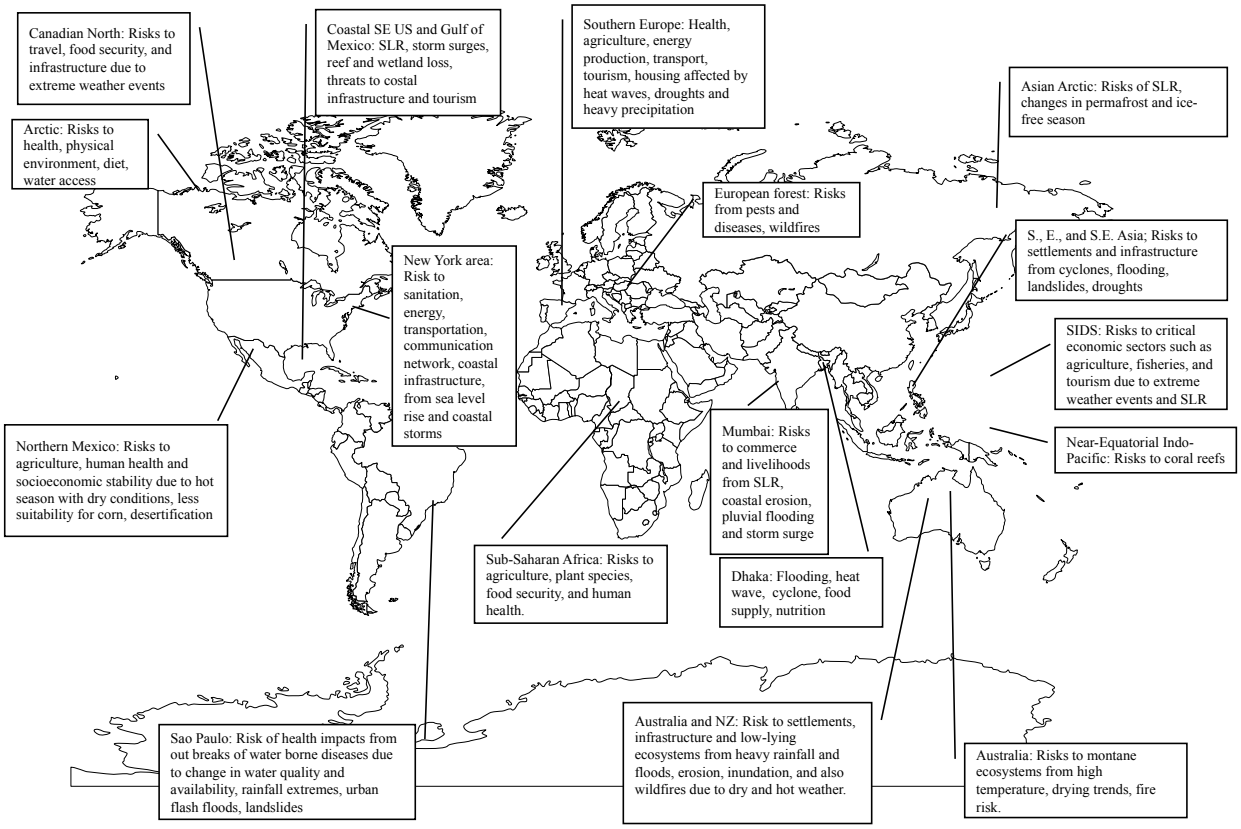

Figure 19-2: Some salient examples of multi-impacts hotspots identified in this assessment.

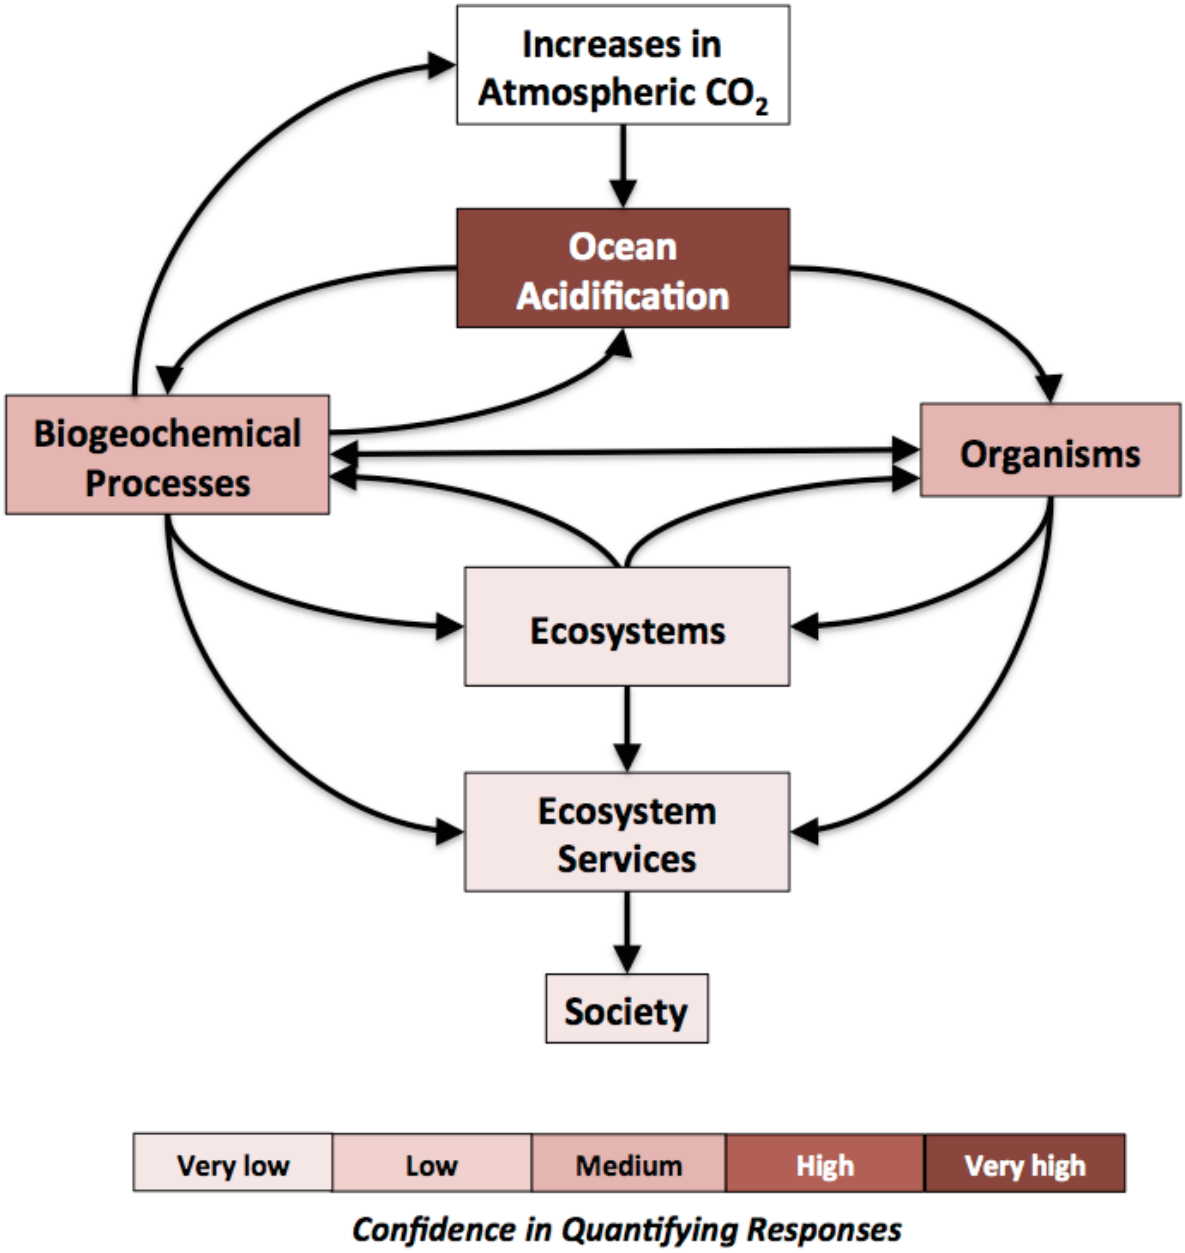

Figure 19-3: The pathways by which ocean acidification affects marine processes, organisms, ecosystems, and society. Confidence in quantifying these effects (as summarized from WG2 Chapter 6) decreases with each step along the pathway, and is very low for effects on ecosystems, ecosystem services, and society.

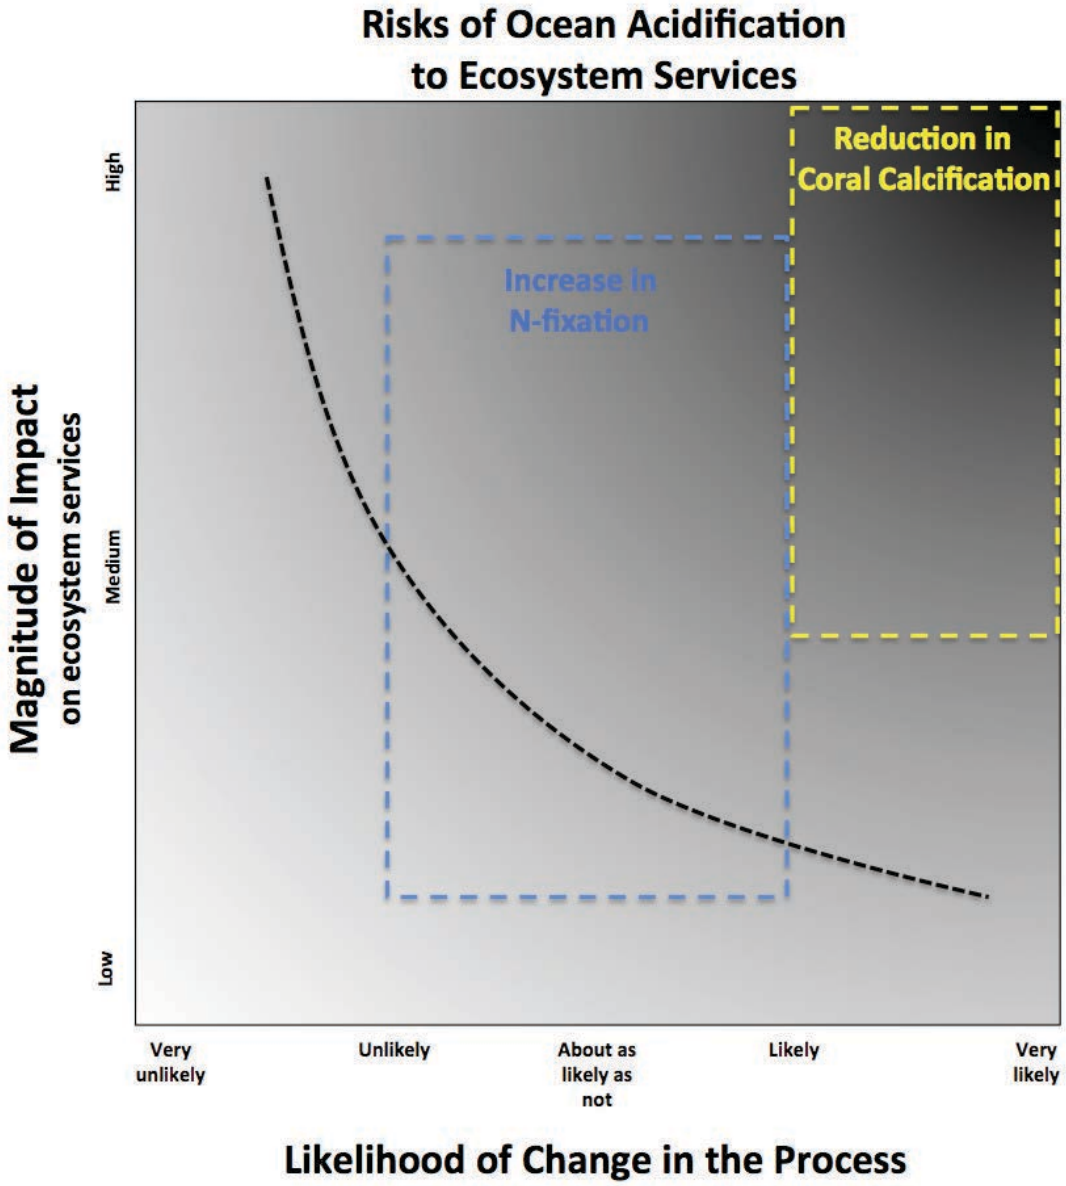

Figure 19-4: Risks of ocean acidification to ecosystems services through two effects on biogeochemical processes: (1) reductions in calcification rates (of corals) and (2) increases in nitrogen-fixation rates. Assessments are based on the estimated *likelihood* that the process will be affected by ocean acidification (horizontal axis) and the *magnitude* of the impacts on associated ecosystem services (vertical axis) should the process be affected. Heights and widths of boxes indicate the range of uncertainty in the magnitude of impacts on ecosystem services and likelihood of change in the process, respectively. Heights are greater than widths due to the lower confidence in responses of ecosystems and their services (Figure 19-3). Judgments are based on impacts expected with atmospheric CO_2 levels of 2-3x preindustrial levels (560-840 ppmv). This figure is meant to be broadly illustrative: with sufficient information Low, Medium, and High magnitudes of impacts would be defined quantitatively. The shading of the box represents the risk (*likelihood* x *magnitude*) to ecosystem services with the dashed contour showing the line of equal risk; the area above and to the right of this line is broadly indicative of key risks. Thus, the reduction in calcification due to ocean acidification is already considered a key risk to some ecosystem services, while the limited evidence regarding the nitrogen fixation response and its impacts implies that it may or may not become a key risk as uncertainty is reduced.

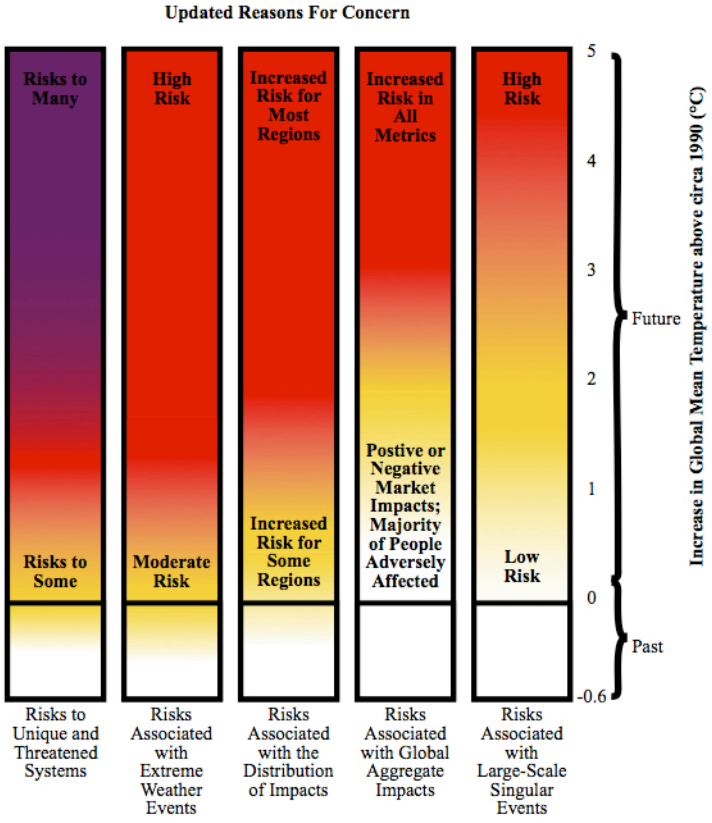

Figure 19-5: The dependence of risk associated with a Reason for Concern (RFC) on the level of climate change, updated from TAR and Smith *et al.* (2009). The color scheme indicates the additional risk due to climate change (with white to purple indicating the lowest to highest level of risk, respectively). The levels of risk illustrated reflect the judgments of Chapter 19 authors. Purple color, introduced here for the first time, reflects the assessment that unique human and natural systems tend to have very limited adaptive capacity (Chapters 4, 24), and hence we have *high confidence* that climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C were exceeded.

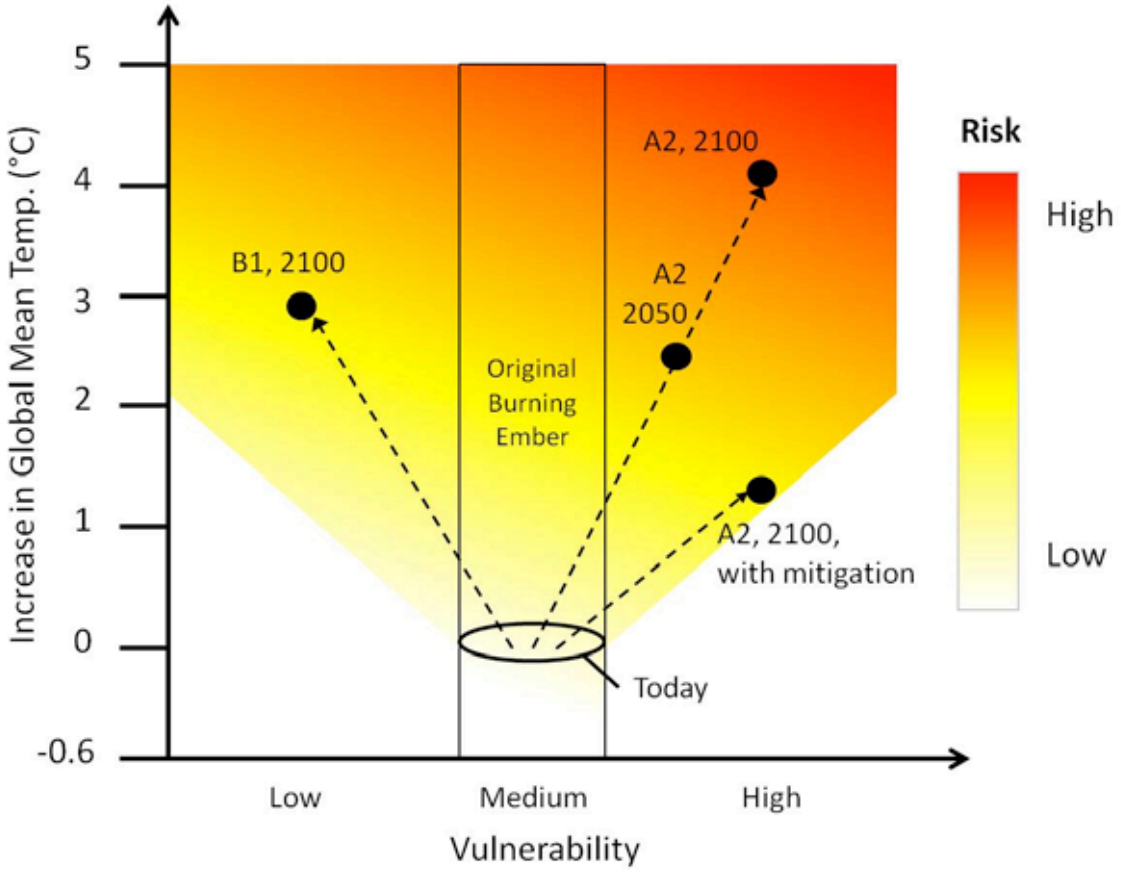

Figure 19-6: Illustration of the dependence of risk associated with a Reason for Concern (RFC) on the level of climate change and vulnerability of society. This figure is schematic; the degree of risk associated with particular levels of climate change or vulnerability has not been based on a literature assessment, nor associated with a particular RFC. The vulnerability axis is relative rather than absolute: "Medium" vulnerability indicates a future development path in which vulnerability changes over time driven by moderate trends in socio-economic conditions. "Low" and "High" vulnerability indicate futures that are substantially more optimistic or pessimistic, respectively, regarding vulnerability. We assume that judgments made in other burning ember diagrams of the RFCs (Smith *et al.*, 2001, 2009) including Figure 19-5, which do not explicitly take changes in vulnerability into account, are consistent with Medium future vulnerability. Arrows and dots illustrate the use of SRES scenario-based literature to locate particular impact or risk assessments on the figure according to the evolution of climate and socio-economic conditions over time.

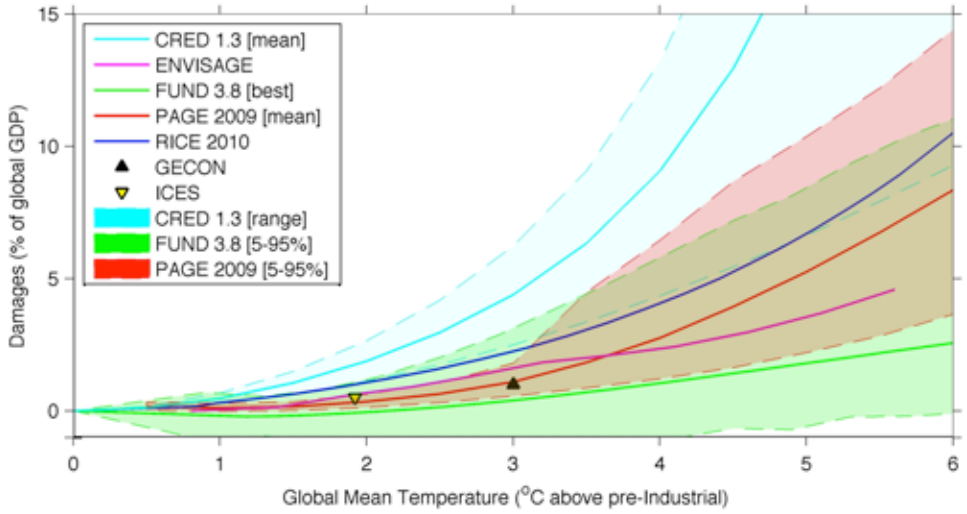

Figure 19-7: Representative global damage estimates, shown as a percentage loss of global output as a function of temperature, from integrated assessment models employing their own reference scenarios. PAGE 2009: (Hope, 2013a, 2013b). FUND 3.8: (Anthoff and Tol, 2010b; Anthoff et al., 2013; Waldhoff et al., 2013). RICE 2010: (Nordhaus, 2010). CRED: (Ackerman et al., 2011). ENVISAGE: (Roson and Mensbrugghe, 2012). GECON: (Nordhaus, 2006). ICES: (Bosello et al., 2012). For PAGE 2009 and FUND 3.8, the shaded region indicates the range spanned by the 5th and 95th percentile of outputs in Monte Carlo mode. The area of overlap between PAGE 2009 and FUND 3.8 is indicated in brown. For CRED 1.3, the shaded region indicates the range spanned by four alternative damage functions. In CRED at 6°C, mean damages are 32% of GDP and the largest of the four damage functions yields 50% loss of GDP.

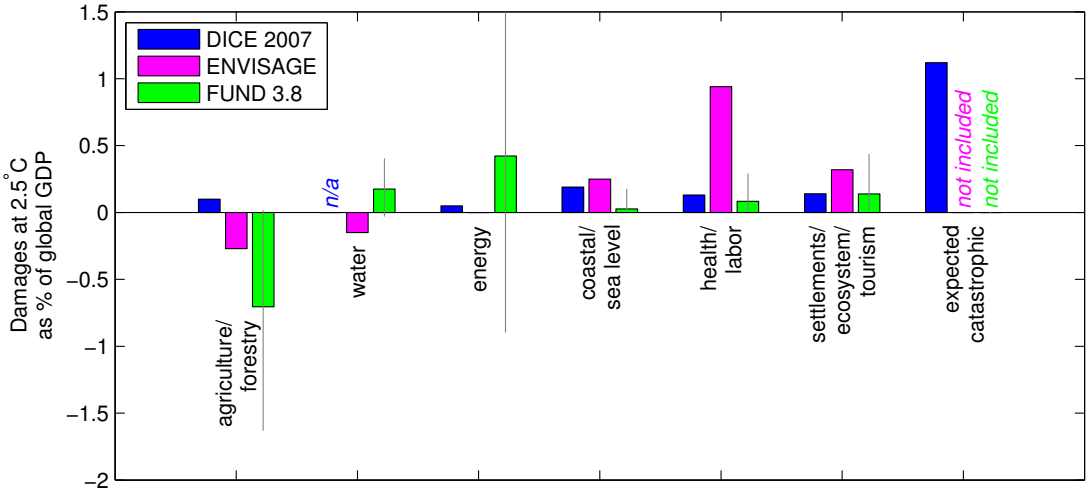

Figure 19-8: Breakdown of damages at 2.5°C above pre-industrial by sector in the DICE 2007 calibration (Nordhaus, 2007, 2008), FUND 3.8 (Anthoff and Tol, 2010b; Anthoff et al., 2013; Waldhoff et al., 2013) modal damages and ENVISAGE (Roson and Mensbrugghe, 2012), reflecting a *low level of agreement* among the integrated assessment models used to estimate global aggregate damages. Note that the DICE calibration does not include damages due to changes in water resources as distinct from temperature impacts on agriculture and forestry, and FUND and ENVISAGE do not include expected catastrophic damages. Representations of changes in energy demand, coastal/sea level impacts, health and labor productivity impacts, and impacts on settlements, ecosystem and tourism are included in all three models. Grey lines span the 5th to 95th percentile of estimates from FUND. The 95th percentile of energy sector damages in FUND is 2.2% of GDP.

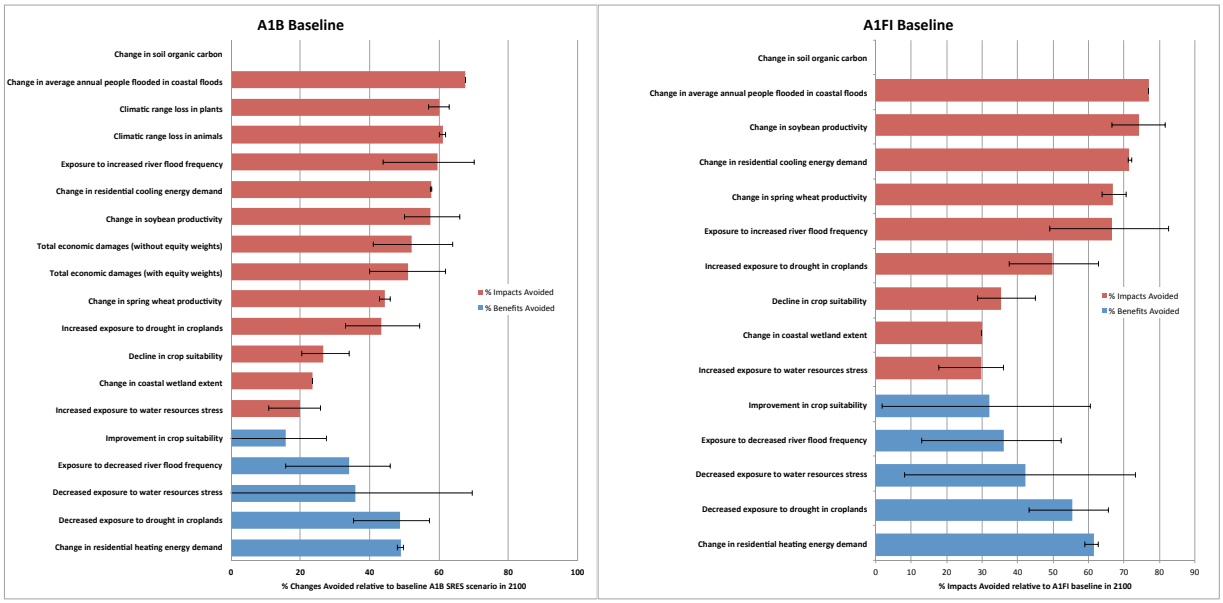

Figure 19-9: Climate change impacts avoided by a mitigation scenario compared to two no-mitigation cases (SRES A1B and A1FI scenarios), showing the uncertainty due to regional climate change impacts projection with 7 Global Circulation Models (GCMs). Since increases and decreases in water stress, flood risks and crop suitability are not co-located and affect different regions, these effects are not combined. From Arnell *et al.*, 2012, Warren *et al.*, in press, Warren *et al.*, submitted.

[Figure 19-10 provided in the next draft]

Figure 19-10**:** relates the categories of mitigation scenario considered in AR5 WGIII, to global temperature outcomes (consistent with the WGI calculations; data taken from Chapter 6 - WGIII). It also relates these temperature outcomes to some salient projected climate change impacts for the different levels of global temperature rise, focusing on those impacts which are less affected by the socioeconomic development pathway.

Executive Summary

Climate change calls for new approaches to sustainable development that take into account complex interactions between climate and social and ecological systems. Climate-resilient pathways for development are evolutionary processes for managing change within complex systems. They are rooted in iterative processes of identifying vulnerabilities to climate change impacts; taking appropriate steps (a) to reduce vulnerabilities in the context of development needs and resources and (b) to increase the options available for vulnerability reduction and coping with surprises. Such responses include monitoring emerging climate parameters and their implications, monitoring the effectiveness of vulnerability reduction efforts (including both adaptation and mitigation), and revising risk reduction responses on the basis of continuing learning. Because uncertainties about climate effects and other driving forces affecting development are likely to make conventional development interventions (e.g. specific, multi-decadal strategies and annual or multi-year static plans) non-sustainable over time, fostering climate will require innovative approaches. This process may involve a combination of incremental changes and, as necessary, significant transformations. Such processes and responses will include both climate change risk reduction through mitigation and adaptation and also changes in sustainable development pathways themselves to increase their resilience.

This chapter integrates a variety of complex issues in assessing climate-resilient pathways in a variety of regions at a variety of scales: sustainable development as the ultimate aim, mitigation as the way to keep climate change impacts moderate rather than extreme, adaptation as a response strategy to cope with impacts that cannot be (or are not) avoided, and elements of sustainable development pathways that contribute to climate-resilience. In most cases, vulnerability reduction and appropriate risk management approaches will differ from situation to situation, calling for a multi-scale perspective built solidly on fine-grained contextual realities. But most situations share at least one fundamental characteristic: threats to sustainable development are greater if climate change is substantial than if it is moderate – and opportunities for sustainable development are greater if climate change is moderate rather than substantial.

This chapter's assessment findings are the following. Although they are based on a high level of consensus in source materials and in the expert communities, the amount of supporting evidence is usually limited by the fact that so many aspects of sustainable development and climate change mitigation and adaptation, considered together over periods many decades into the future, are surrounded by issues that are beyond past and current observation and experience. The task of this chapter is to move out into uncharted territory.

Because climate change is a growing threat to development, it is a high priority to identify and pursue climate-resilient pathways for sustainable development (*high confidence*; *high agreement, medium evidence*). Because climate change can no longer be avoided, some impacts on development are already being observed, and they are virtually certain to increase. Added to other stresses on sustainable development, effects of climate change will make sustainability more difficult to achieve for many locations, systems, and affected populations, related to such objectives as poverty reduction, health, and livelihood security; but climate-resilient pathways can improve prospects for sustainable development. [20.2]

Climate-resilient pathways include (a) actions to reduce climate change and its impacts and (b) actions to assure that effective risk management and adaptation can be implemented and sustained (*high confidence*;

***high agreement, medium evidence*).** Adaptation and mitigation have the potential to both contribute to and impede sustainable development, and sustainable development strategies and choices have the potential to both contribute to and impede climate change responses. Both kinds of responses are needed, working together to reduce risks of disruptions from climate change. [20.3, 20.4]

In some cases, each of the two categories of responses is likely to benefit the other as well, offering potentials for co-benefits from integration (*moderately high confidence*; *medium high agreement, medium evidence*). Development pathways that are resilient with respect to a wide range of challenges and threats are more likely to be climate-resilient, while climate change risk reduction can contribute to strengthening capacities for risk management in other regards as well. Strategies to achieve each goal have the potential to reinforce the other, but windows of opportunity may narrow with time. [20.2.1, 20.3.3]

Prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation (*high confidence*; *high agreement, medium evidence*). As the magnitude of climate change grows, the challenges to climate resilience grow; and above some high level of climate change, the impacts on most systems would be great enough that climate-resilience is no longer possible for many systems and locations. [20.6.1]

Because climate change vulnerabilities are significant for many areas, systems, and populations, climate-resilient pathways will often require transformations in order to assure sustainable development (*high confidence*; *high agreement, medium evidence*). Significantly large and/or rapid increases in climate extremes and climate-related extreme weather events are less amenable to incremental adaptations to climate change and will often require more transformational change if development is to be sustained without major disruptions. [20.5]

At a global scale, climate-resilient pathways will include both climate change adaptation and mitigation. At sub-global scales, climate-resilient pathways will involve a range of actions appropriate to potentials for vulnerability/risk reduction at those scales (*high confidence*; *high agreement, medium evidence*). Although at a global scale both mitigation and adaptation are essential, relatively local scales in many developing regions have limited capacities to include mitigation in their climate-resilience strategies because they contribute very little to the causes of climate change. At all scales, however, actions are important to assure that effective risk management can be implemented and sustained. [20.2.3, 20.6.1]

Although outcomes from specific actions are often uncertain, strategies and actions can be pursued now that will move toward climate-resilient pathways while at the same time helping to improve human livelihoods, social and economic well-being, and responsible environmental management (*high confidence*; *high agreement, medium evidence*). Actions at the present time will emphasize co-benefits and iterative learning, with risk management strategies and capacities refined continually on the bases of growing evidence, knowledge, and experience. [20.6.2]

Meanwhile, what is known about integrating climate change mitigation, climate change adaptation, and sustainable development is dwarfed by what is not known (*high confidence*; *high agreement, strong evidence*). Improving the base of knowledge about relationships and potentials for progress with climate resilience is a high priority, as a basis for adaptive learning and action. [20.7]

20.1. Introduction

Following summaries of *what we know* about climate change impacts, vulnerabilities, and prospects for adaptation (Chapter 18) and of *what we should be most worried about* (Chapter 19), this concluding topical chapter of the Working Group II Fifth Assessment Report summarizes what is currently known about options regarding *what to do* in responding to these risks and concerns.

In terms of "what to do" to minimize climate change and threats to development now and in the future, this chapter identifies and discusses climate-resilient pathways. Climate-resilient pathways are evolutionary processes for

managing change within complex systems in order to reduce disruptions and enhance opportunities. They are rooted in continuing, interactive processes of identifying vulnerabilities to climate change impacts; taking appropriate steps to reduce vulnerabilities in the context of development needs and resources, building capacity to increase the options available for vulnerability reduction and coping with unexpected threats; monitoring emerging climate parameters and their implications and the effectiveness of vulnerability reduction efforts; and revising risk reduction responses on the basis of continuing learning. This process may involve a combination of incremental changes and, as necessary, significant transformations (see sections 20.2.3.1 and 20.6.2; for related UNFCCC language, see Box 20-1). As such, climate-resilient pathways include two essential elements:

- Actions to reduce climate change and its impacts, including both mitigation and adaptation
- Actions to assure that effective risk management institutions, strategies, and choices will be identified, implemented, and sustained as an integrated part of development processes.

_____ START BOX 20-1 HERE _____

Box 20-1. UNFCCC Goals for Climate-Resilient Pathways

Climate resilient pathways are trajectories of combined mitigation and adaptation that are consistent with the aims of sustainable development and which do not traverse the threshold of "dangerous anthropogenic interference with the climate system" as specified in Article 2 of the Convention.

Article 2 of the United Nations Framework Convention on Climate Change presents the ultimate objective as the, '*stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.'* According to the Convention, the climate system must not be dangerous in order to "allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner". Article 3.4 recognizes that "Parties have a right to, and should promote sustainable development." The Copenhagen Accord of 2009 states, "To achieve the ultimate objective of the Convention to stabilize greenhouse gas concentration in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system, we shall, recognizing the scientific view that the increase in global temperature should be below 2 degrees Celsius, on the basis of equity and in the context of sustainable development, enhance our long-term cooperative action to combat climate change."

The Cancun Agreements Decision 1/CP.16 confirms this with a view that "… recognizes … deep cuts in global greenhouse gas emissions are required according to science, and as documented in the Fourth Assessment Report of the IPCC, with a view to reducing global greenhouse gas emissions so as to hold the increase in global average temperature below 2°C above preindustrial levels…consistent with science…[and] also recognizes the need to consider, in the context of the first review… strengthening the long-term global goal on the basis of the best available scientific knowledge.

The 2011 Conference of the Parties in a decision known as the Durban Platform increases the strength of the language in the decision 1/CP.17 to conclude, "… climate change represents an urgent and potentially irreversible threat to human societies and the planet and thus requires to be urgently addressed … with a view to accelerating the reduction of global greenhouse gas emissions.... This decision was followed by the decisions adopted in Doha at the 18th Conference of the Parties that noted w*ith grave concern* the significant gap between the aggregate effect of Parties' mitigation pledges in terms of global annual emissions of greenhouse gases by 2020 and aggregate emission pathways consistent with having a likely chance of holding the increase in global average temperature below 2 °C or 1.5 °C above pre-industrial levels. As such, the current UNFCCC negotiations have adopted +2°C or 1.5 C as the desirable target upper limit and equated this with "dangerous" in Article 2.

_____ END BOX 20-1 HERE _____

In many cases, each of the two categories of responses has the potential to benefit the other as well, offering potentials for win-win kinds of integration, although mechanisms and institutions are needed to address cases where the two elements have negative effects on each other and to assure that positive synergies are realized. Because

climate change challenges are significant for many areas, systems, and populations, climate-resilient pathways will generally require transformations in order to assure sustainable development – beyond incremental approaches.

The chapter shows how climate-resilient pathways can recognize the relationship between mitigation, adaptation and sustainable development and invoke transformative actions to deliberately avoid dangerous climate change and its impacts. It examines the attributes and characteristics of pathways for sustainable development that are resilient to impacts of climate change, including potentials and possible limitations. In doing so, the chapter integrates a variety of complex issues in assessing climate-resilient pathways in a variety of regions at a variety of scales: sustainable development as the ultimate aim, mitigation as the way to keep climate change impacts moderate rather than extreme, adaptation as a response strategy to cope with impacts that cannot be (or are not) avoided, and development pathways as contexts that shape choices and actions.

The chapter is organized in six parts: climate change as a threat to sustainable development, assessing links between sustainable development and climate change as well as defining climate resilient pathways (20.2), contributions to resilience through climate change responses (20.3), contributions to resilience through sustainable development strategies and choices (20.4), determinants of resilience in the face of serious threats (20.5), challenges in moving toward climate-resilient pathways (20.6), and priority gaps in knowledge (20.7).

Several of the terms that are central to this chapter have been defined earlier in the Working Group 2 Fifth Assessment Report, including climate, adaptation, and mitigation. In addition, by "resilient" we mean a system's capacity to anticipate and reduce, cope with, and respond to and recover from disruptions (IPCC SREX, 2012). For literatures on "sustainable development," see section 20.2.1 below. A summary definition is development that achieves continuing improvements in human well-being and assures a sustainable relationship with a physical environment that is already under stress, reconciling tradeoffs among economic, environmental, and other social goals through institutional approaches that are equitable and participative in order themselves to be sustainable.

20.2. Climate Change as a Threat to Sustainable Development

Climate-resilient pathways bring together (a) sustainable development as the larger context for societies, regions, nations, and the global community with (b) climate change effects as threats to (and possibly opportunities for) sustainable development and responses to reduce those effects that would undermine future development and even offset already achieved gains.

20.2.1. Links between Sustainable Development and Climate Change

20.2.1.1. Objectives of Sustainable Development

Understandings of sustainable development have developed considerably, particularly over the past two decades, as the short- and long-term implications of climate change and extreme events have become better understood, although empirical evidence of progress with sustainable development is often elusive. The discussion of sustainable development in the IPCC process has evolved since the First Assessment Report, which focused on the technology and cost-effectiveness of mitigation activities, and the Second Assessment Report (SAR), which included issues related to equity and to environmental and social considerations. The Third Assessment Report (TAR) further broadened the treatment of sustainable development by addressing issues related to global sustainability, and the Fourth Assessment (AR4) included chapters on sustainable development in both WG II and III reports, with a focus on both climate-first and development-first literatures, although integration of the two working group perspectives remains a work in progress.

"Sustainable development" is a concept rooted in many decades of concerns about balance in the relationships between society and nature (e.g., Brown, 1981). These concerns grew during the 1960s and 1970s in connection with observations of a declining quality of the environment coupled with increasing needs for natural resources as human populations expand and energy-.and other input-intensive living standards rise. Early initiatives (particularly

in industrialized countries) focused the quality of water, air, management of hazardous materials and other individual attributes of the environment. In those decades, some of the outcomes from the initiatives included an array of regulations intended to manage and improve resource management, a movement toward recycling of consumable resources, and an emphasis on renewable energy as a substitute for energy production that consumed non-renewable fossil fuel resources (Frey and Linke, 2002).

The Brundtland Report defines sustainable development as that which meets the needs of the present without compromising the ability of future generations to meet their own needs (WCED, 1987). The report recognizes that poverty is one of the main causes of environmental degradation and that equitable economic development is key to addressing environmental problems both in developing and developed region (Halsnaes et al., 2008; Lafferty and Meadowcroft, 2010). From a practical perspective, sustainable development has been "operationalized" through Agenda 21, which is a comprehensive plan of action adopted at the 1992 Earth Summit by more than 178 governments (Sitarz, 1994). In June 2012, participants in the "Rio+20" conference issued a statement urging countries to renew their commitment to sustainable development.

Although the existing global discourse and practice around sustainable development has helped to establish some commonly held principles, the concept itself remains elusive and contested (e.g., Hopwood, Mellow, and O'Brien, 2005; Jabareen, 2008). For example, sustainable development has been criticized as being vague and immeasurable; and its connections with continued economic growth have drawn suspicion from those who believe sustainable development is a strategy to slow or limit development in the developing world, those who think that current trends in consumption patterns are themselves non-sustainable (e.g., Robinson, 2004), and those who believe that current institutional controls and linkages are seriously counterproductive (Scrieciu et al., 2011; Barker, 2008; O'Hara, 2009). Whereas some authors equate sustainable development with equity and values through which climate policies can be implemented (see IPCC Working Group III: Chapter 4), in practice some national authorities interpret sustainable development as the goal of pursuing economic development through the models embraced in industrialized countries.

With time, two factors have become evident (Brown, 2011**;** Grist, 2008; Sanwal, 2012). First, development has the potential to fundamentally alter global environmental systems, including climates (IPCC, 2007); and second, the basic model of development continues to aspire to the fossil-fuel intensive systems in place in most industrialized countries – from food production, trade, transport, and household consumption. This model still largely define development processes in practice, adding to challenges in realizing "sustainable" development. Until these two factors are reconciled, it may be difficult to attain climate-resilient pathways in either industrialized or developing countries, with associated consequences (Marston, 2012; Grist, 2008**).**

One way that sustainable development pathways can contribute to climate resilience is by pursuing consumption patterns that assure social and economic development without being wasteful of natural resources and the environment. It is possible that, rather than letting consumption be driven by familiar patterns of resource demands, the desired objectives of consumption might be met in ways that require lesser quantities of resources and produce lesser quantities of environmental emissions (Kates, 2000; also see Leiserowitz, Kates, and Parris, 2005).

Overall, development is a means to social and economic ends, not (usually) an end in itself; the objective is to develop in order to increase the abundance and reliability of services that are important to well-being, such as food, shelter, productivity, and enjoyment (Sen, 1999; Morgan and Farsides, 2009). For example, we do not develop improved energy systems because we want to consume kilowatts of electricity for their own sake; we consume them because they deliver comfort, convenience, and other qualities that we desire (Von Bernard and Gorbaran, 2010). Within the context of a changing climate, continued use and unlimited expansion of the limited resources of this planet does not seem consistent either sustainable development or climate resilient development (Ehrenfeld, 2008; Gilbert, 2006; also see Victor, 2008 and Victor and Rosenbluth, 2007).

There is a growing debate about economic growth and material consumption. Sustainable development is all about lifestyles, ways of life, and human well-being, which in turn are associated with – but not necessarily defined by -- the consumption of natural and material resources (e.g., Easterlin, 1974 and 2001; Adger, 2010; also see IPCC Working Group III: Chapter 4). One point of view in social research suggests that ever-increasing material

consumption does not necessarily bring greater happiness or satisfaction or material comfort (DeLeire and Kalil, 2010; Cafaro, 2010; Huesemann, 2006). On the other hand, in many cases growth in consumption, especially among populations with incomes rising from low levels, is greatly beneficial (Clark, Frijters, and Shields, 2008; and Deaton, 2008). Measuring human well-being as a dimension of sustainable development that is not entirely captured by monetary income and level of consumption remains both a challenge and a need (Dolan and White, 2007; Fleurbaey, 2009).

20.2.1.2. Risks and Threats Posed by Climate Change, Interacting with Other Factors and Driving Forces

As the extent of implications of climate change become better-understood (Chapter 18) and as particular reasons for concern have begun to come into focus (Chapter 19), climate change has been increasingly seen as an issue for sustainable development – with the potential either to aid or impede its successful implementation (e.g., Halsnaes et al., 2008; Munasinghe, 2010). The links between sustainable development and climate adaptation and mitigation are cross-cutting and complex. First, the effects of climate change may derail current sustainable development policy and potentially offset already achieved gains (World Bank, 2010; also see Boxes 20-2 and 20-3). For example, effects of climate change on key ecological resources and systems can jeopardize sustainable development in systems closely linked to natural capital. Second, mitigation has the potential to keep these threats at a moderate rather than extreme level, and adaptation will enhance the ability of different systems to cope with the remaining impacts, therefore modulating negative effects on sustainable development (IPCC, 2007). Third, many of the conditions that define vulnerability to climate impact and the ability to respond to them are firmly rooted in development processes (e.g., structural deficits and available assets and entitlements) (Brooks et al., 2005; Lemos et al., forthcoming; Chapter 15). Fourth, sustainable development intersects with many of the drivers of climate change, especially regarding energy production and consumption and the ability to mitigate emissions (IPCC SRREN, 2012; also see Chapter 9). Fifth, because several of the desirable conditions for successful mitigation and adaptation may overlap with those of sustainable development (e.g. implementation of no-regrets interventions, equitable distribution of resources, increased adaptive capacity and livelihood capitals), systems where sustainable development has been prioritized may provide a more conducive context for the implementation of successful mitigation and adaptation (Brown, 2011). Finally, climate mitigation and adaptation, if planned and integrated well, have the potential to create opportunities to further foster sustainable development (see section 20.3.3 below). Under the threat of climate change, sustainable development depends on changes in social awareness and values that lead to innovative actions and practices, including increased attention to both disaster risk management and climate change adaptation in anticipation of (and in response to) changes in climate extremes (IPCC SREX, 2012). Understanding how to enhance positive feedbacks between mitigation, adaptation, and sustainable development while minimizing negative feedbacks is an essential part of planning for and pursuing climate-resilient pathways. In the following paragraphs, we discuss these links in light of empirical research and specific examples (Boxes 20-2 and 20-3). While some of the links described above have been contemplated in the scholarly literature, there remain considerable gaps on our knowledge base to inform climate-resilient pathways.

_____ START BOX 20-2 HERE _____

Box 20-2. Key Reasons for Concern about Climate Change Effects on Sustainable Development

Chapter 19 of this report identifies key vulnerabilities to climate change that might affect sustainable development. Recognizing that the distribution of such impacts can be uneven and variable across space, time, and a number of dimensions of vulnerability, the major concerns about effects on sustainable development include:

- Risks to glaciers and the human systems supported by their meltwater
- Risks from extreme weather events
- Deterioration of regional food security
- Increased water stress in some areas
- Impacts on human health
- Losses of endangered species and biodiversity.

Cross-cutting concerns include aggregate impacts, the distribution of impacts, and large-scale singular events associated with system thresholds and irreversible change.

_____ END BOX 20-2 HERE _____

_____ START BOX 20-3 HERE _____

Box 20-3. Connecting Representative Concentration Pathways (RCPs) with Shared Socioeconomic Pathways (SSPs)

The climate change science community has developed a new set of visions of a range of climate futures, called "Representative Concentration Pathways" or RCPs, intended to replace the rich families of SRES scenarios (IPCC, 2000) that were used extensively by IPCC and others for a decade. As reported in Moss et al., 2010, the RCPs include four representative pathways to illustrate the range of possible climate futures, defined in terms of approximate radiative forcing levels. These scenarios represent a broad range of potential climate outcomes, both over the near term (to 2035) and longer term (2100 and beyond).

To accompany these RCPs and provide context for assessing impacts of such futures, the climate change science community is also developing a set of representative socioeconomic futures, reflecting different pathways of economic intensity, capacity for societal problem-solving, and other dimensions of socioeconomic futures, called Shared Socioeconomic Pathways (SSPs), each defined by a storyline and supported by qualitative and quantitative characterizations (Kriegler et al., 2012; Ebi et al., forthcoming; O'Neill et al., forthcoming). In principle, it will be possible to compare socioeconomic conditions (SSPs) with climate forcings (RCPs) to evaluate such issues as differences in needs and challenges for mitigation or the feasibility of adaptation associated with different contexts regarding driving forces (see section 20.6.1).

_____ END BOX 20-3 HERE _____

The relationship between climatic change and development policy has often been theorized as essentially twofold. On the one hand, climate change will affect development policy as needs to respond to negative, and perhaps positive, impacts arise (Schipper, 2007; Burton et al., 2002; Halsnaes and Verhagen, 2007). On the other hand, development policy critically shapes carbon emission paths, the ability to develop sustainable adaptation and mitigation options, and to build overall adaptive capacity (Bizikova, Robinson, and Cohen, 2007; Garg et al., 2009; Metz and Kok, 2008; Lemos, et al., 2007). Because of the recognized relationship between development and climate change drivers and responses, some authors have called for a "political economy of climate change" that takes into consideration ideas, power, and resources at different scales from the local to the global (e.g., Tanner and Allouche, 2011).

Enhancing resilience to respond to effects of climate change includes adopting good development practices that are consonant with building sustainable livelihoods and, in some cases, challenging current models of development (Boyd et al., 2008; McSweeny and Coomes, 2011). Moreover, promoting development pathways that are both equitable and sustainable is also a key to addressing climate change (Wilbanks, 2003; Nelson et al., 2007). Yet, whereas climate change impacts are often strongly correlated with threats to sustainability, the debate on climate change has tended to run separately from the wider sustainability discourse (Cohen et al., 1998; IPCC, 2001). Integrating sustainable development and overall climate change policy can be all the more relevant if "cross-linkages between poverty, the use of natural capital and environmental degradation" are recognized (Veeman and Politylo, 2003: 317; also see Matthew and Hammill, 2009). Especially in less developed countries/regions, the relationship between vulnerability to climate impacts and development is often inclusive and mutually dependent as such realities as low per capita income and inequitable distribution of resources; lack of education, health care, and safety; and weak institutions, unequal power relations and weak democracy fundamentally shape sensitivity, exposure and adaptive capacity to climate impact – along with other factors influencing risks (Garg et al., 2009; McSweeny and Coomes, 2011; Adger et al., 2003; Kates, 2000). In these regions, reducing risks that affect resource-dependent communities is increasingly viewed as a necessary,but insufficient way to tackle the myriad of problems associated with climate change impacts (Jerneck and Olsson, 2008). Building the capacity of individuals,

communities and governance systems to adapt to climate impacts is both a function of dealing with developmental deficits (e.g. poverty alleviation, reducing risks related to famine and food insecurity, enabling/implementing public health and mass education and literacy programs) and of improving risk management (e.g. alert systems, disaster relief, crop insurance, climate forecasts) (Mirza, 2003; Schipper and Pelling, 2006). Hence, especially in less developed regions, it is important not only to understand the relative importance of different kinds of interventions (climate and non-climate) in building adaptive capacity but also the potential positive and negative synergies between them (Lemos et al., forthcoming).

While research increasingly highlights the intersection between vulnerability, adaptive capacity and developmental structural deficits, however, there is also growing recognition that the intractability of many of these problems may inhibit the development of climate-resilient pathways. For example, research by Wolf et al. (2009) on climate change responses in western Canada shows that self-efficacy and ecological citizenship play an important role in the identification and implementation of sustainable responses to water scarcity. In contrast, inequitable distribution of power among those affected by climate impact can suppress innovative decisions about the future by limiting their participation in designing solutions. Research focusing on disaster response in Mexico shows that alienation of individuals is instrumental to creating a compliant citizenry, and that resilience is undermined by a limited breadth of learning and experimentation, centralized power, and limited economic diversity (Pelling and Navarrete, 2011). In Northeast Brazil, the fact that local traditional politics relied on client-list relationships with drought-affected households to maintain power suggests that there was little incentive for policies that dramatically decreased their level of vulnerability (Tompkins, Lemos, and Boyd, 2008). Omolo (2010) argues that in the northwestern Kenya, in pastoralist societies of Turkana, in spite of increasing numbers of women headed households, participation of women in key decisions such as investment, resource allocation, and planning on where to move or settle in the aftermath of drought and floods is still quite low. A serious concern is that our inability to readily address these kinds of structural problems may limit options for future generations of marginalized social groups to be active agents of a climate resilient future. In this sense, it is critical to understand how existing path-dependent trajectories (e.g., socio-technical, behavioral, institutional) that form the contextual basis for climate change action at different scales (Burch, 2010) may inhibit (or help) the realization of future climate resilient pathways.

A number of studies recognize that not every possible response to climate change is consistent with sustainable development, in that some strategies and actions may have negative impacts on the well-being of others and future generations (Eriksen et al., 2011; Gardiner et al., 2010). For example, some mitigation measures, such as changing the composition of the atmosphere through geoengineering, could influence large-scale weather systems and create potentially dangerous conditions or new problems for many others (Gardiner et al., 2010, Carlin, 2007; Brovkin et al., 2009; de Sherbinin et al., 2011; also see Box 20-6). Likewise, some adaptation measures, such as using more surface water or groundwater for irrigation, may have negative effects on other users and more rapidly deplete scarce natural resources that could come under increasing pressure with climate change (Eriksen et al., 2011). The consequences of responses to climate change, whether related to mitigation or adaptation, can negatively influence future vulnerability, unless they are linked to the wider context of sustainable development (Bizikova et al., 2010). Here, the role of values in responding to climate change becomes important from a variety of perspectives, including intergenerational, particularly when those currently in positions of power and authority assume that their prioritized values will be shared by future generations (O'Brien, 2009). Acknowledging the importance of intergenerational equity, it has been argued that participatory processes and 'deliberative democracy' can include the concerns, values and perceptions of a wide range of stakeholders, raising some of the ethical impacts attached to climate related risks (Backstrand, 2003; also see Deere-Birebeck, 2009). Such an approach could have a bearing on the way risks are assessed and addressed at the science-policy interface, with significant implications for sustainable development. In light of the complex interactions among climate change responses and sustainable development, there is a need for more holistic responses that place human well-being and security at the forefront, while building on existing strengths and capacities (Tompkins and Adger, 2004; O'Brien et al., 2010). This entails integrating multiple objectives and policy goals and the way to assess them to promote sustainable responses to climate change that contribute to resilience (Meadowcroft, 2000; Tompkins and Adger, 2004; Pinter et al., 2011).

A reality in many countries may be that development – which seeks to increase economic wealth – can enhance the capacity to adapt while at the same time adding to greenhouse gas emissions. Yet, the World Development Report 2010 suggests that climate change responses have the potential to contribute to sustainable development as, for

example, in the case of financial assistance with transition to low-carbon growth paths (World Bank, 2010) or in the case of mitigation policies that could increase income and/or enhance the quality of growth in vulnerable groups such as REDD (Reducing Emissions from Deforestation and Forest Degradation in Developing Countries). And while vulnerable sectors such as agriculture give us particular reasons for concern (see Box 20-4), they may offer opportunities in some instances to reduce climate related risks and threats by integrating both adaptation and mitigation strategies as a lever for reducing poverty and promoting climate resilient pathways. Particularly necessary is addressing institutional and social capacities for responding to both climate change impacts and mitigation responses. For example, Chhatre and Agrawal (2009) show that climate change mitigation can benefit livelihoods if ownership of forest commons is transferred to local communities. These kinds of possible implications of climate change connect with drivers of sustainable development, and in turn social and economic dimensions of development affect the likelihood of effective responses to climate change risks (see Box 20-4). Moreover, some interventions related to climate change responses aim to combine goals of sustainable development, climate change adaptation, and climate change mitigation into "triple win" approaches that highlight overlaps between these goals. Examples include mechanisms such as the Clean Development Mechanism (CDM) and Joint Implementation (JI) (e.g., Millar, Stephenson, and Stephens, 2007), which seek to offset carbon emissions, build adaptive capacities of local communities, and provide sustainable development dividends despite mixed results in terms of accomplishing these goals in practice (Corbera and Brown, 2008). Specifically in the case of the CDM, robust empirical research shows that while the goal of offsetting carbon emissions has been relatively successful, generating sustainable development dividend has been difficult. For example, after examining sixteen existing CDM projects around the world, Sutter and Parreno (2007) found that whereas they are likely to meet 72% of their emissions reduction goals, less than 1% iarelikely contribute significantly to sustainable development in the host country. Furthermore, their research suggests that there might be an actual tradeoff between the goals of efficient generation of carbon emissions certificates (CERs) and the broader generation of the sustainable development dividend (also see Winkelman and Moore, 2011). Because relationships among the three goals can lead to both positive and negative consequences, it is important to unravel conditions that lead to desirable outcomes (Chhartre and Agrawal, 2009) (see section 20.3.3). Moreover, the fact that currently available institutional arrangements that combine mitigation and sustainable development such as the CDM are not achieving their win-win goals indicates the need for rapidly developing means for evaluating, changing and improving what is not working (Pressman and Wildavsky, 1984).

Box 20-4. Case Studies from China

Water-saving irrigation has enhanced the climate change adaptation capacity, improved ecosystem services, and promoted regional sustainable development in China:

- ***Water-Saving Irrigation Measures in Cropland Adaptation to Climate Change***
  Water-saving irrigation is one effective measure to deal with the water scarcity and food security issues caused by climate change (Hanjra and Qureshi, 2010; Tejero et al., 2011). Given an increase in non-agricultural water consumption, China's agriculture could be faced with a severe shortage of water resources (Xiong et al., 2010). Through water-saving irrigation practices, water saved from 2007-2009 added up to 30.7-34.92 Gm^3 for each year, which accounted for 5.6%~11.8% of the national total water consumption. For example in 2009, according to current agricultural water consumption conditions, the saved water enabled expansions of the irrigated cropland by 3.80-7.80 Mhm^2 and increase grain production by 14.68-30.15 Mt, enough to meet one year grain needs of 73-151 million people (Zou et al., 2012) (Table 20-1). Besides, the performance of water saving irrigation from 2007-2009 saved about 9.59-20.85 Mt of standard coal and reduced 21.83-47.48Mt CO_2 emissions, which not only alleviated electric and diesel pressure in rural area but also reduced agricultural GHG emissions Therefore, water-saving irrigation has had a positive effecct in dealing with climate change and sustainable development (Zou et al., 2012).
  [INSERT TABLE 20-1 HERE
  Table 20-1: Effectiveness of water-saving irrigation dealing with climate change (Zou et al., 2012).]
- ***Water-Saving Irrigation Measures in Alpine Grassland for Adapting to Climate Change***
  Northern Tibet is the headwater region for the Yangtze, Nu (Salween River), Lancang (Mekong River), and numerous other rivers and high mountain lakes (Gao et al., 2009). Sustaining environmental conditions in the region is of vital importance not only for Tibet but also for China as a whole. Being a fragile ecosystem,

the alpine grassland ecosystem in Northern Tibet is extremely sensitive to climate change and human activity. In recent years, the rise in precipitation and temperature results has led to the melting of glaciers and expansion of inland high mountain lakes, contributing to alpine grassland degradation in Northern Tibet (Gao et al., 2010). Among many grassland protection measures, alpine grassland water-saving irrigation measures could be effective in redistributing and making full use of increased precipitation and lake water in the dry period, which would reduce the negative effects of climate change and make full use of favorable conditions (Editorial Board of National Climate Change Assessment, 2011). A three-year demonstration of alpine grassland water-saving irrigation measures showed that alpine grassland yield nearly doubled (Figure 20-1b) while the plant species increased from 19 to 29, helping to protect and restore the alpine grassland ecosystem and ecosystem services and to promote regional socio-economic sustainable development in Northern Tibet (Gao et al., 2012).

[INSERT FIGURE 20-1 HERE

Figure 20-1: The demonstration of alpine grassland water-saving irrigation measures for adaptation to climate change in Northern Tibet.]

_____ END BOX 20-4 HERE _____

Given these connections, there is growing consensus in the literature about a need to integrate development and climate policies; however, the means to achieve this integration differ. One option is the "development first" approach which suggests that the incorporation of climate concerns within prevalent development interventions is the best option, since development is usually the highest priority (Kok et al., 2008). In this approach, governments take into consideration tradeoffs between different dimensions of sustainability and look for climate-inclusive policy options that offer positive synergies with development, aiming at both low greenhouse gas emissions and low vulnerabilities to climate impacts (if their development paradigms are flexible enough to expand in such a way). Lessons from this literature also emphasize the contextual and place-based character of these processes and the need to understand opportunities and constraints relative to local, national, and global priorities (Wilbanks and Sathaye, 2007). Factors constraining the 'mainstreaming' of climate adaptation into development include discrepancies between immediate development goals and future climate change scenarios, especially in less developed regions and emerging economies. They also include a growing disconnect between donors' goals and developing countries' own development agendas (Agrawala, 2004; Klein, Schipper, and Desai, 2005), potentially inhibiting the development of robust local institutions that can effectively integrate or mainstream climate change policy into to their development priorities. Many developing countries lack technical assistance and capacity development to support their climate change agendas and to identify and manage risks. Often, programs tend to be poorly coordinated, fragmented, and bureaucratic, thus accentuating the isolation that vulnerable communities feel with regard to access to such programs, and even where programs are reasonably well-coordinated bureaucratic complexities can cause communities to be overlooked (Chukwumerije and Schroeder, 2009). Other factors -- such as lack of financial and human resources, unclear distribution of costs and benefits, fragmented management, mismatches in scale of governance and implementation, lack and unequal distribution of climate information, and trade-offs with other priorities – may also limit the smooth mainstreaming of climate adaptation action into development (Agrawala and van Aalst, 2008; Bizikova et al., 2007; Eakin and Lemos, 2006; Kok et al., 2008; Metz and Kok, 2008). Finally, empirical evidence suggests that the relationship between development variables and climate change responses can be a mixture of positives and negatives, if development variables are not managed well (Garg et al., 2009). For example, in a study of the relationship between malaria incidence, development and climate variables in India, Garg et al. (2009) found that while some development interventions such as increased availability of irrigation canals and dams can negatively affect the incidence of malaria and water-borne diseases, others such as higher per capita income can reduce negative health impacts of climate change significantly – although the distribution of benefits can differ between types of interventions (also see Campbell-Landrum and Woodruff, 2006). Understanding how development variables intersect with climate responses is especially important because governments and other actors rarely make decisions in isolation; rather they respond to multiple stressors both in rural and urban environments (Agrawal, 2008; Eakin, 2005; Wilbanks and Kates, 2010). Moreover, some evidence suggests that, in practice, decision-makers (from heads of households to policy-makers) often do not place climate change at the top of their priority list of critical issues to address (Garg, Shukla, and Kapshe, 2007; Kok et al., 2008), although in some regions (e.g., in Africa) special climate-oriented bureaus are being placed strategically in the offices of government leaders. For instance, in Kenya and Tanzania climate change coordination units have been created in high-level

scales of government. These institutional arrangements constitute a growing realization of the strategic place that climate change issues occupy in some countries in Africa. The growing importance of climatic change in shaping social and governmental policy agendas has resulted in many examples of specific interventions to respond to climate change both in developed and developing regions (Ayers and Huq, 2009; Burch, 2010; Dang, Michaelowa, and Tuan, 2003), for reasons that appear to vary widely.

20.2.3. Climate-Resilient Pathways

20.2.3.1. Framing Climate-Resilient Pathways

Climate-resilient pathways connect climate change consequences with development pathways (see IPCC Working Group III: Chapter 4). They are evolutionary processes for managing change within complex systems. Pathways follow a direction; this may be toward unintended consequences of previous actions (e.g., global temperature increases of 2°C or more) or toward intended goals or visions (e.g., sustainable development). Unintended consequences are common in complex systems, where feedbacks, teleconnections, cross-scale linkages, and thresholds, and nonlinearities can result in non-linear effects that were not anticipated (Folke et al., 2002; Scheffer et al., 2009; Lenton, 2011a). Climate-resilient pathways reflect an intended goal that takes into account the knowledge that increasing atmospheric concentrations of greenhouse gas will have long-term implications for sustainable development (IPCC Working Group I). Reflecting evolutionary uncertainties, they are rooted in iterative responses that involve identifying vulnerabilities to climate change impacts; assessing opportunities for reducing risks; and taking actions that are consistent with the goals of sustainable development.

The pursuit of climate-resilient pathways may involve a combination of incremental changes and transformative responses that take into account: 1) current and anticipated changes in both climate averages and extremes; 2) the dynamic development context that influences social vulnerability, risk perception, conflict resolution, and resilience; and 3) recognition of human agency and capacity to influence the future. This last point is significant, as humans have the capacity to manage risk and to decrease vulnerability through both mitigation and adaptation, as well as through choices of development goals and strategies (IPCC SREX, 2012). Given the non-linear impacts associated with increasing global temperatures, the threats to sustainable development are likely to become greater over time (Wilbanks et al., 2007; Stafford et al., 2010). This may require transformational adaptations, i.e., responses that change the nature, composition, and/or location of threatened systems in order to maintain the potential for sustainable development (Smit and Wandel, 2006; Stringer et al., 2009; NRC, 2010a; Pelling, 2010; IPCC SREX, 2012: see section 20.5).

Climate resilient pathways call for decisions and actions that take into account both short- and long-term time horizons. Near-term responses may emphasize climate change mitigation and relatively low-cost adaptations that present development co-benefits (Van Aalst, Cannon, and Burton, 2008; NRC, 2010a). Anticipating long-term responses calls for monitoring emerging impacts and risks combined with adaptive management, learning, leadership and contingency planning (NRC, 2010a; IPCC SREX, 2012).

20.2.3.2. Elements of Climate-Resilient Pathways

As climate change continues on its current path toward relatively significant impacts (NRC, 2010b), climate-resilient pathways will become increasingly challenging, requiring explicit attention to responses in virtually all regions, sectors, and systems in order to avoid disruptions of development processes. Climate-resilient pathways include two overarching attributes: (1) actions in order to reduce climate change and its impacts, including both mitigation and adaptation, and (2) actions to assure that effective risk management institutions, strategies, and choices can be identified, implemented, and sustained as an integrated part of development processes (Edenhofer et al., 2012). Box 20-5 lists a number of attributes of climate-resilient pathways categorized into awareness and capacity, resources and practices. Each of the items is amenable to strategy development in appropriate national, regional, and local contexts. For example, in many cases effective response to extreme events is likely to benefit both from iterative problem-solving and bottom-up engagement in risk management, and from human development

to enhance capacities for risk management and adaptive behavior (Tompkins, Lemos, and Boyd, 2008). Folke (2006) characterizes resilience as a process of innovation and development. Pathways should therefore be continuously moving toward a more adapted and less vulnerable state; in some instances, there may be stages of slow development followed by periods where progress increases speed. Further, the nonlinearity or randomness of climate impacts necessitates a system that allows for the flexibility to adapt to unexpected and even extreme events (Hollings, 1973). This is especially true in light of political, economic or resource constraints, where pathways at the local level will need to not only be flexible but also practical and feasible in both the short term and long term. One of the most challenging aspects of climate-resilient pathways is that they exist in distinctive local contexts, where they are shaped by external linkages that connect them across geographic scales and time. For example, resilience cannot be achieved in a few privileged places if it is not achieved in others, because instabilities in adversely impacted situations will spill over to other situations through such effects as resource supply constraints, conflict, migration, or disease transmission (Wilbanks, 2009; IPCC SREX, 2012: Chapter 7).

_____ START BOX 20-5 HERE _____

Box 20-5. Elements of Climate-Resilient Pathways for Sustainable Development

Awareness and capacity

- A high level of social awareness of climate change risks
- A demonstrated commitment to contribute appropriately to reducing global net GHG emissions, integrated with national development strategies
- Institutional change for more effective resource management through collective action
- Human capital development to improve risk management and adaptive capacities
- Leadership for sustainability that effectively responds to complex challenges

Resources

- Access to scientific and technological expertise and options for problem-solving, including effective mechanisms for providing climate information and services
- Access to financing for appropriate climate change response strategies and actions
- Information linkages in order to learn from experiences of others with mitigation and adaptation

Practices

- Continuing, institutionalized vulnerability assessments and risk management strategy development and refinement based on emerging information and experience
- Monitoring of emerging climate change effects and contingency planning for possible significant impacts and needs for transformational responses
- Policy, regulatory, and legal frameworks that encourage and support distributed voluntary actions for climate change risk management
- Effective programs to assist the most vulnerable populations and systems in coping with impacts of climate change

_____ END BOX 20-5 HERE _____

Climate resilient pathways are in fact a process, not an outcome (Manyena, 2006), involving both incremental and transformational changes. The pathways therefore need to be built on a foundation of constantly advancing knowledge, where information is adjusted based on changing scientific knowledge climate parameters and altering social, economic and natural resource situations (Berkes, 2007). While some measures will be reactive, the main elements of a pathway are intentional and proactive; anticipating future change and developing appropriate plans and responses. Although payoffs from specific long-term pathways may be unknown, strategies and actions can be pursued now that will contribute significantly to moving toward climate-resilient pathways while helping to improve human livelihoods, social and economic well-being, and responsible environmental management (section 20.6.2).

20.3. Contributions to Resilience through Climate Change Responses

Climate change responses include mitigation, adaptation, and integrated mitigation and adaptation strategies. Related to these responses but generally considered a separate response issue is "geoengineering" (Box 20-6).

_____ START BOX 20-6 HERE _____

Box 20-6. Considering Geoengineering Responses

To the extent that climate change mitigation is not fully successful in moderating the rate of increase in GHG emissions, and if climate change adaptation is not successful in coping with the resulting impacts without socially unacceptable pain and distress, policymakers may be faced with demands to find further ways to reduce climate change and its effects.

Such options include expansions of mitigation and/or adaptation to include geoengineering: intentional large-scale interventions in the earth system either to reduce the sun's radiation that reaches the surface of the earth or to increase the uptake of carbon dioxide from the atmosphere. An example of the former is to inject sulfates into the stratosphere. Examples of the latter include facilities to scrub carbon dioxide from the air and chemical interventions to increase uptakes by oceans, soil, or biomass (UK Royal Society, 2009; IPCC Working Group III: Chapter 6).

Discussions of geoengineering have only recently become an active area of discourse in science, despite a longer history of efforts to modify climate (Schneider, 1996, 2009; Keith, 2000). Many of the possible options are known to be technically feasible, but their side-effects are exceedingly poorly understood (NRC, 2010b; MacCracken, 2011; Vaughan and Linten, 2011). For example, interventions in the atmosphere might not be unacceptably expensive, but they might affect the behavior of such earth system processes as the Asian monsoons (Robock et al., 2008; Brovkin et al., 2009). Interventions to increase uptakes, such as scrubbing carbon dioxide from the earth's atmosphere, might be socially acceptable but economically very expensive. Moreover, it is possible that optimism about geoengineering options might invite complacency regarding mitigation efforts (Barrett, 2008).

In any case, implications for sustainable development are largely unknown. Even though some advocates argue that geoengineering is needed now in order to avoid irreversible impact such as the loss of ocean corals, the more general view is that this is a research priority rather than current decision-making option (NRC, 2010b). The challenge is to understand what geoengineering options would do to moderate global climate change – and also to understand what their ancillary effects might be – so that, if policymakers find some decades from now that social responses to climate change have not been sufficient to avoid severe disruptions and, as a result, there is a need to consider rather dramatic technology alternatives, our understanding of potential costs and benefits for sustainable development is far better than it is now. Some observers propose that research efforts should include limited experiments with geoengineering options, but agreement has not been reached about criteria for determining what experiments are appropriate (e.g., Blackstock and Long, 2010).

_____ END BOX 20-6 HERE _____

20.3.1. Mitigation

In IPCC's assessment reports, mitigation is the subject of Working Group III, to which the reader is referred for comprehensive information about options and strategies for reducing GHG emissions and increasing GHG uptakes by the earth system. For this chapter, the issue is how climate change mitigation relates to sustainable development, which was addressed by Chapter 12 of Working Group III's Fourth Assessment Report (IPCC 2007) and is also the focus of Chapter 4 of its Fifth Assessment Report, including attention of equity issues.

In general terms, mitigation is recognized to be important for sustainable development in two ways (Riahi, 2000). First, it reduces the rate and magnitude of climate change, which reduces climate-related stresses on sustainable development, including effects of climate extremes and extreme events (IPCC SREX, 2012). For example, in 2009

many smaller developing nations argued at UNFCCC COP 15 that stabilizing the global atmospheric concentration of carbon dioxide at 450 parts per million (ppm), projected to result in approximately a 2ºC increase in global mean temperature, would lead to unacceptable impacts on their prospects for sustainable development. Although the 450 ppm target appeared to be favored by many larger countries, some low-lying island nations would cease to exist in the face of the eventual sea-level rise that could result from that temperature increase. For these countries, any concentration level above 350 ppm (projected to result in approximately a 1.5ºC increase) was considered unacceptable given the risks (Liverman and Billett, 2010). In this sense, mitigation is a critically important part of climate change risk management (Washington et al., 2009; Lenton, 2011b; Peters et al., 2013). Second, trajectories for technological and institutional change in order to reduce net GHG emissions interact with development pathways. In some cases, strategies to promote low-carbon growth (e.g., Table 20-2) may be congruent with sustainable development in urban settings, such as green growth strategies that reduce local and regional air pollution, enhancing prospects for multi-level governance and integrated management of resources, and encouraging broader participation in development processes (Seto et al., 2010; Lebel, 2005). In other cases, such effects as higher energy prices associated with transitions from fossil fuels to renewable energy sources have the potential to have adverse effects on local and regional economic and social development (IPCC SRREN, 2012: Chapter 9). The challenge for climate-resilient pathways is to identify and implement mixes of technological and governance options that reduce net carbon emissions and at the same time support sustainable economic and social growth in a context where rising demands need to be combined with technology transitions without disrupting the development process. For example, such strategies as increasing carbon uptakes in the soil through better agricultural management practices – which can reduce net emissions – can improve soil water storage capacity and also reduce the workload of women, and practices such as conservation tillage can also increase water retention in drought conditions and help to sequester carbon in soils **(**Halsnaes et al., 2008**).**

However, mitigation and development also interact in a third way in that different groups and countries' ability to implement mitigation critically depends on their 'mitigative capacity' (Yohe, 2001): their "ability to reduce anthropogenic greenhouse gas emissions or enhance natural sinks" or the "skills, competencies, fitness, and proficiencies that a country has attained which can contribute to GHG emissions mitigation" (Winkler et al., 2007). Here, many of the determinants of mitigative capacity are fundamentally shaped by different countries' level of development, including their current level of emissions, their stock of human, financial and technological capital, such as the ability to pay for mitigation; the magnitude and cost of available abatement opportunities; the regulatory effectiveness and market rules; the education and skills base; the suite of mitigation technologies available; the ability to absorb new technologies, and the level of infrastructure development (see Box 20-3).

[INSERT TABLE 20-2 HERE
Table 20-1: Examples of national plans for low carbon growth (Araya, 2010).

20.3.2. Adaptation

Adaptation is the subject of four chapters of this Working Group II Fifth Assessment Report (14-17), to which the reader is referred for comprehensive descriptions of concepts, options, strategies, and examples of adaptation practices. For this section, we focus on the intersection between adaptation and sustainable development.

Overall, adaptation is linked to sustainable development in several ways. First, the ability of individuals, communities and governance systems to adapt to climate change impact is predicated on a number of capacities that enable the design and implementation of different types of intervention to prepare and respond to climate impact (Wilbanks et al., 2007). Globally and nationally, many of these determinants of adaptive capacity (e.g. human capital, information and technology, material resources and infrastructure, organization and social capital, political capital, wealth and financial capital, institutions and entitlements) (Smit and Pilifozofa, 2001; Yohe and Tol, 2002; Eakin and Lemos, 2006) significantly overlap with indicators of development. However, building these capacities both in developed and less developed regions has implications to sustainable development in terms of increasing the consumption of materials and potential negative effects on ecosystems (e.g. building of new infrastructure and increasing consumption).

Second, building adaptive capacity may critically contribute to the improvement of the well-being of both social and ecological systems by bettering livelihoods and reducing pressure on the environment, especially in less developed regions (see section 20.40.3). Regarding social systems, it is important to consider not only the factors that enable the building of different capacities (e.g. institutions and governance) but also how to guarantee that those who need it the most have access to them (Gupta et al., 2010; Nelson et al., 2007). It is also vital to understand how different capacities influence each other (positively and negatively) (Lemos et al., forthcoming) and how they may affect the long-term resilience of social-ecological systems (Adger et al., 2011; Box 20-5 illustrates the relationship between building technology and infrastructure capacities and long-term resilience and sustainability of agricultural social-ecological systems in China). Indeed, adaptation can be vitally important in reducing stresses on development processes, especially in vulnerable areas where it can help to promote and support sustainable development. For example, where adaptation planning stimulates participatory social processes, including equity and legitimacy discussions regarding different adaptation options, it can encourage communities to think more clearly about broader sustainable development goals and pathways (NRC, 2010a).

Third, given recent trends in GHG emissions and projections of climate futures that suggest impacts of climate change will be serious and widespread (e.g., Auerswald, Konrad, and Thum, 2011; Smith et al., 2011), adaptation may require considering transformational changes, in which potentially impacted systems move to fundamentally new patterns, dynamics, and/or locations (Schipper, 2007; Kates, Travis, and Wilbanks, 2012; Park et al,, 2012; Marshall et al., 2012). Desirable adaptation strategies may vary according to climate change threat, location, impacted system, the geographical scale of attention, and the time frame of strategic risk management planning (Heltberg, Siegel, and Jorgensen, 2009; Thomalla et al., 2006; NRC, 2010a). It is important that transformational adaptation policy at different scales takes into consideration the goals of sustainable development both by fostering positive synergies and by avoiding negative feedbacks between them, especially because some adaptation options might lead to inequitable and unsustainable outcomes (Thomas and Twyman, 2005; Eriksen et al., 2011; Eriksen and Brown, 2011) (for a more detailed discussion see sections 20.3.3 and 20.4.4). Moreover, adaptation at one scale may negatively affect vulnerability in another. For example, in Vietnam, policies for forestry protection and the construction of electric dams while benefiting low land areas (by regulating flooding) have critically constrained the access to land and forest products to mountain populations, decreasing their adaptive capacity (Beckman, 2011).

Indeed, adaptation pathways can foster food and water security, human health, and air and water quality and natural resource management, while promoting gender equality and other desirable outcomes. However, creating the conditions for the emergence of such outcomes will require better integration between the goals of adaptation and sustainable development at all scales. By selecting environmentally friendly materials; promoting energy, water and other resource conservation; promoting re-use and recycling; minimizing waste generation; protecting habitat and addressing needs of marginalized groups (Bizikova et al., 2007; Seto et al., 2010), adaptation can contribute to win-win or even triple win options that can support a diverse array of development goals (see section 20.3.3).

20.3.3. Integrating Climate Change Adaptation and Mitigation for Sustainable Risk Management

Recent research suggests that mitigation and adaptation are likely to be more effective when they are designed and implemented in the context of other interventions within the broader context of sustainability and resilience (Wilbanks and Kates, 2010; Asian Development Bank, 2012). Moreover, studies focusing on the intersection between sustainable development and climate policy point out that integration between the two is a desirable although complex path (Halsnaes et al., 2008; Wilson and McDaniels, 2007; Ayers and Huq, 2009; Beg et al., 2002). Wilson and McDaniels (345) suggest three reasons to integrate across adaptation, mitigation and sustainable development: (1) many dimensions of the *values* that are important for decision-making are common to all three decision contexts; (2) impacts from any one of the three decision contexts may have important *consequences* for the other contexts; and (3) the *choice among alternatives* in one context can be a means for achieving the underlying values important in the other contexts.

A key factor in integrating climate change adaptation and mitigation into sustainable risk management is to understand the processes of decision making at different scales. The distribution of costs and benefits of mitigation and adaptation differ -- e.g., mitigation benefits more global, adaptation benefits often more localized , the research

and policy discourses are often unrelated, and the constituencies and decision-makers are often different (mitigation may involve powerful industrial stakeholders from the energy sector concentrated at higher levels of decision making, while adaptation may involve more dispersed stakeholders at the local level across sectors) (Wilbanks, et al., 2007). To significantly reduce total global emissions, mitigation decisions must be taken either by major emitters, or by groups of countries. At the national and international level, the direct responsibility to curb the main drivers of global climate change are dispersed across countries (Banerjee, 2012). In contrast, adaptation often falls to practitioners where local responsibility is clearer, although it often depends on support from national and global scale (Tanner and Allouche, 2011).

In many cases, the challenge of fostering synergies while avoiding negative feedbacks is most likely to come into focus in place-based discussions of climate change responses and development objectives such as localities and small regions (Wilbanks, 2003; Bulkeley and Schroeder, 2012). Globally, a particular hurdle is applying available mitigation resources only for reducing emissions beyond that which would have occurred without those resources ("*additionality*") while recognizing that access to resources for adaptation efforts should take into account the critical role of *co-benefits* in supporting development in other ways while at the same time reducing vulnerabilities to climate change impacts (NRC, 2010a; also see section 20.4.1).

Choices in integrating adaptation and mitigation will vary according to the circumstances of each locality (de Boer et al., 2010). In the more highly vulnerable countries, adaptation may be seen as the highest priority because there are immediate benefits to be obtained by reducing vulnerabilities to current climate variability and extremes as well as future climate changes. In the case of developed countries, adaptation initiatives have often been seen as a lower priority because it is perceived that there is abundant adaptive capacity (Naess et al., 2005). Yet major loss and damage in some industrialized countries related to climatic variability and extremes between 2010 and 2012 challenge this perception (e.g., Hurricane Sandy, tornadoes, and drought in the US in 2011 and 2012). Mitigation may be seen as more acute political question—involving well-organized stakeholders concerned about costs—in countries that contribute a large proportion of GHG emissions.

As indicated above, one emerging strategy to integrate between climate and development policies is the design of "triple-win" interventions that seek to achieve an appropriate mix of mitigation and adaptation within the context of sustainable development (Pyke et al., 2007; Swart and Raes, 2007). Swart and Raes (2007) suggest a number of factors that should be taken into consideration when evaluating combined adaptation and mitigation policy designs, including: (1) *avoiding trade-offs* - when designing policies for mitigation or adaptation, (2) *identifying synergies*, (3) *enhancing response capacity*, (4) *developing institutional links* between adaptation and mitigation - e.g. in national institutions and in international negotiations, and (5) *mainstreaming* adaptation and mitigation considerations into broader sustainable development policies. The potential for climate-resilient pathways may already be limited, however, in part because of path dependency stemming from choices on mitigation, adaptation, and political interpretations and subsequent choices around "sustainable" development (Barker, 2008; Swart et al., 2003); and in many cases interventions have not delivered win-win results because tradeoffs were not avoided (Warner, van der Geest, et al., 2012).

In synthesizing evidence from a series of empirical articles focusing on the intersection between mitigation and adaptation (M&A), Wilbanks and Sathaye (2007) argue that mitigation and adaptation pathways might be alternatives in reducing costs, complementary and reinforcing to each other (e.g., improvements in building energy efficiency), or competitive and mutually contradictory (e.g., coastal protection vs. reductions in sea level rise). In Bangladesh, for example, waste-to-compost projects contribute to mitigation through reducing methane emissions; to adaptation through soil improvement in drought-prone areas; and to sustainable development through the preservation of ecosystem services (Ayers and Huq, 2009; also see Vergara et al., 2012, regarding possible development benefits of mitigation and adaptation in Latin America and the Caribbean). The scale of these examples is often local, however, and longer-term success of these pathways will depend on the broader context of mitigation and facilitation of adaptation options (Metz, 2002).

When integrating across the goal of finding climate resilient pathways (and win-win solutions), decision-makers often need to address issues of scale, along with trade-offs in values such as economic profitability versus stability of food and livelihood security (e.g. in agricultural policy), relationships between development ends and means,

uncertainty and path dependencies, and institutional complexity (Klein, Schipper, and Desai, 2005; Tol, 2004; Wilson and McDaniels, 2007). They also need to consider the possibility of ancillary co-benefits, complementarities and potential contradictions, opportunity costs, and unknown negative and positive feedbacks (for example interactions among options and paybacks (NRC, 2010a; Kok et al., 2008; Wilbanks and Sathaye, 2007; Swart and Raes, 2007; Rosenzweig and Tubiello, 2007; IPCC, 2007: Chapter 18). Current research is examining tradeoffs and complementarities between mitigation and adaptation in different sectors. In the energy sector, for instance, Kopytko and Perkins (2011) have examined to what extent the siting of nuclear power plants might constrain future adaptation to sea-level rise. Others ask how the production of biofuels might affect local adaptation (La Rovere, Avzaradel, and Monteiro, 2009); agriculture and water (Rounsevell et al., 2010; Turner et al., 2010; Rosenzweig and Tubiello, 2007; Falloon and Betts, 2010; Shah, 2009); conservation (Rounsevell et al., 2010; Turner et al., 2010); use of mitigation programs to finance adaptation (Hof et al., 2009); and the urban environment (Biesbroek, Swart, and van der Knaap, 2009; Hamin and Gurran, 2009; Roy, 2009; Romero-Lankao et al., 2011).

20.4. Contributions to Resilience through Sustainable Development Strategies and Choices

Although climate change responses can contribute significantly to climate-resilient development pathways, some of the key elements of resilience lie in sustainable development implementation, which can make resilience either more or less achievable. Examples of ways that development strategies and choices can contribute to climate resilience include being capable of resolving tradeoffs among economic and environmental goals (e.g., Bamuri and Opeschoor, 2007), assuring effective institutions in developing, implementing, and sustaining resilient strategies, and enhancing the range of choices through innovation (e.g., Hallegatte, 2009; Chuku, 2009; Folke et al., 2002).

20.4.1. Resolving Tradeoffs between Economic and Environmental Goals

Sustainable development pathways will be more climate-resilient if they develop and utilize socioeconomic and institutional structures that are effective in resolving tradeoffs among social, economic, and environmental goals – a central tenet of sustainable development (section 20.2.1.1).

There is a longstanding assumption that economic growth is in conflict with environmental management (Victor and Rosenbluth, 2007; Hueting, 2010). Much of this thinking can be traced back to Malthus and his assertions that population growth (and associated consumption) would expand at an increasing rate until the limits of the earth's capacity were reached (Malthus, 1798). The very idea of sustainable development itself springs from a need to respond to such Malthusian ideas. The views expounded in the Brundtland Report, for example, are that development should not be unconstrained but should rather be modified into a "sustainable" form (WCED, 1987). Views about relationships between economic growth and environmental protection range widely from arguments that sustainable development is inconsistent with continued economic growth (e.g., Robinson, 2004) to arguments that economic growth and associated technological innovation can enhance options for environmental management (Lovins, 2011). Obviously, relationships between affluence and environmental protection are complex, as poverty can lead to land degradation and affluence can afford support for nature preservation, while economic growth is built on levels of resource extraction and use that require significant changes in environments. Sustainable development cannot escape continuing tensions between economic growth and environmental management goals, where strongly held views across society often differ so fundamentally that conflict results unless social processes and institutional mechanisms are effective in resolving s host of tradeoffs (Boyd et al., 2008), with both values and processes varying according to development context.

Examples of frameworks of thought often related to addressing tradeoffs are multi-metric valuation and co-benefits (see also Ness et al., 2007, regarding tools for sustainability assessment, and Pew Center, 2010):

- *Multi-metric valuation*. In evaluating development pathways, there are often needs to combine a number of dimensions associated with different valuation metrics and information requirements, such as monetary measures of returns and non-monetary metrics of risk. Fields ranging from aquatic ecology to risk assessment and financial management have developed tools for such complex valuations, including graphical mapping (e.g., Rose, 2010) and the construction of multi-metric indexes (e.g., an index of "biotic

integrity": Johnston et al., 2011). More commonly in collective decision-making, however, analytical-deliberative group processes are used to evaluate, weight, and combine different dimensions and metrics qualitatively (NRC, 1996).

- *Co-benefits*. An issue in both climate and development policy, related in some cases to access to financial support (e.g., Miller, 2008), is the fact that a specific resilience-enhancing action may have benefits for both development and for addressing concerns about climate change . International funding for mitigation projects has historically adopted the concept of "additionality," which takes the position that financial support should be limited to those climate change response benefits that are *in addition to* what would be happening in development processes otherwise (e.g., Muller, 2009). This general concept (e.g., "incremental" costs and benefits) has been applied in financial support for adaptation as well. A co-benefits approach, on the other hand, takes the position that actions which benefit *both* development and climate change responses simultaneously should be encouraged and that a combination of both kinds of benefits should increase the attractiveness of a proposed action (section 20.3.3; also see http://www.kyomecha.org/cobene/e/cobene.html and IPCC Working Group III: Chapter 6). For example, mechanisms such as REDD are designed to achieve both carbon emissions reduction and to benefit livelihoods of those living in forested areas. However, empirical research shows that the evidence of the correlation between carbon storage and livelihoods benefits is mixed (Chhartre and Agrawal, 2009). Tools for analyzing such issues are associated with research on "externalities" (e.g., Baumol and Oates, 1989), but participative planning and decision-making usually incorporate a co-benefits perspective as a matter of course.

In practice, tradeoff issues may or not be resolved in coherent ways (Metz, 2002). In many cases, resolutions emerge through untidy social processes of evolution and attrition, reflecting dynamics of values, power, control, and surprises, rather than through formal analysis. In some cases, tradeoffs are addressed with the assistance of scenario development, the creation of descriptive narratives, and other projections of future contingencies (IPCC SREX: Chapter 8), along with participative vulnerability assessments (NRC, 2010a).

20.4.2. Assuring Effective Institutions in Developing, Implementing, and Sustaining Resilient Strategies

Climate resilience will benefit from institutions that are effective and flexible in the face of a wider range of challenges for problem-solving and issue resolution as well. "Institutions" refer not only to formal structures and processes but also to the rules of the game as well as the norms and cultures that underpin environmental values and belief systems. Ostrom (1986) defines institutions as the rules, norms and practices defining social behavior in a particular context, the action arena. Institutions define roles and provide social context for action and structure social interactions (Hodgson, 2003). Definitions of sustainability are largely shaped by institutional values, cultures and norms. Institutions also critically define our ability to govern and manage the resources and systems that shape adaptation, mitigation and sustainable development. Adopting an adaptation and mitigation pathway requires strong institutions that are able to foster an enabling environment through which adaptive and mitigative capacities can be built (Gupta et al., 2010; IPCC, 2007: Chapter 20). Implicit in institutional resilience is the capacity of the exposed unit and the players within an action arena to devise rules that allows them to recover from environmental shocks, and equally ones that provides incentives and benefits that equitably distributes resources across social groups (Denton, forthcoming; McSweeny and Coomes, 2011). Hence, the trajectory to a resilient pathway needs an institutional leap, one that knowingly set rules, seeks to innovate, monitor and evaluate strategies for managing climate impacts.

Transformative action and change in integrating sustainable development within a framework of climate resilient pathways is in fact rooted in strong and viable institutions and within an institutional context that adaptively manages the allocation of resources and processes of change. Institutions at different levels have been the object of societal pressures and challenges relating to environmental change. Local institutions are particularly adroit in coping with multiple changes. These changes often force local actors and organizations to rethink their institutional arrangements and make adjustments that will allow them to cope with multiple vulnerabilities (McSweeny and Coomes, 2011). Organizational mechanisms are central to building linkages between local level adaptation action and national level planning; however, in six cases studies in West Africa and Latin America, Agrawal et al. (2011)

found that while these connections are missing in almost all the countries studied, external policy support can catalyze adaptation action through three types of intervention mechanisms– information, incentives, and institutions.

Institutions for integrated climate-resilient pathways are therefore not limited to governmental institutions; in fact, in many cases a majority of the key decisions are made and implemented by non-governmental actors, from the private sector to communities and families. For instance, in projects supported by the IDRC/DfID Climate Change Adaptation in Africa Programme (CCAA), in both Tanzania and Morocco, local governments are providing improved seeds that are drought resistant to vulnerable groups and financially supporting initiatives at community level (Denton, forthcoming). Embarking on a climate resilient pathway may necessitate including local institutions as part of the governance regime. Similarly, as local communities become more exposed to climate extremes and variability, they are already adapting to the negative impacts of climate variability and change. However, a sustainable route depends largely on the organisational capacity of vulnerable groups and their ability to translate challenges into opportunities. For example, in Morocco, where local communities have strong institutions, such as in the Tabant mountain community, they were found to be adapting collectively; but where institutions were less effective and weak, as in the arid plain of Lamzoudia, adaptation action was characterised by individual initiatives (Denton, forthcoming)

In particular, local institutions crucially influence the ability of communities to adapt and benefit from adaptation and mitigation programs in rural and urban settings (Agrawal, 2008; Chhartre and Agrawal, 2009; Corbera and Brown, 2008). For instance, institutions tend to play an influential role in shaping farmers' decisions and helping them make strategic choices with several implications for livelihoods and sustainable development (Agrawal, 2008). In rural areas, current socioeconomic dynamics, rapid population growth, commercialized agriculture, new agricultural trends and technological advancements in agriculture have meant that local institutions have seen a change in their role in governing environmental management in adaptive governance. Local institutions are themselves in a state of flux as they are subjected to uncertainties in climatic condition (Senaratne and Wickramasinghe, 2010*)*. However, in developing countries, particularly in Africa, where traditional knowledge could moderate this uncertainty, it is often not recognized as a reference point for managing climate risks and emerging threats. In Kenya, the importance of indigenous knowledge, given increased uncertainty and climate related risks, has compelled national agencies such as the Kenyan Meteorological Agencies and vulnerable groups such as the indigenous communities commonly known as rainmakers to form strategic reciprocal links. By working closely together to calibrate their forecasts and test the efficacy of the results against climate change impacts on agricultural productivity, the two groups have been able to demonstrate the benefits of western science and traditional knowledge systems to ensure maximum effectiveness (Ziervogel and Opere, 2010). In addition, participatory processes which call for a deliberative form of decision making among stakeholders are well suited to the governance culture necessary for effective adaptation and mitigation. Scholars have found that deliberative processes of democracy provide greater efficacy in decision-making and lead to more sustainable outcomes. They argue that some deliberative democracy methods can bring diverse stakeholders together- lay, expert and indigenous knowledge - thus putting in place a more communicative model of science (Benn, Dunphy, and Martin, 2009), although stakeholder participation does not always lead to consensus (Rowe and Frewer, 2004).

In addition, institutions are also needed to handle the large flows of funds and other resources that are associated with managing and improving the delivery systems that will allow people and organizations to take advantage of opportunities that will trigger a set of actions to combat the negative impacts of climate change. The complexity of different resource flows and distributional effects related to adaptation and mitigation is at the heart of the sustainable development debate, with numerous implications for equity and justice (O'Brien and Leichenko, 2003; Roberts and Parks, 2006). The nature and dynamics of climate change call for institutions that are able to facilitate the enhancement of adaptive capacity and 'allow society to modify its institutions at a rate commensurate with the rapid rate of environmental change' (Gupta et al., 2008). Institutional 'renewal' is essential to achieve a degree of social cohesion and transformation. A case study in Morocco, under the Climate Change Adaptation in Africa (CCAA), showed that the `Cellule de Littoral`, created to serve as a consultative committee on coastal development in Morocco, has gained some recognition at both local and national levels as it is integrated formally into the institutional framework for the implementation of Integrated Coastal Zone Management Plans of Action (Denton, forthcoming).

An institutional response to climate change is even more fundamental in common pool property resources especially in river basin management. River basins are considered as public goods. However, in a changing climate many river basins are subjected to increased precipitation or water scarcity that is affecting both marine life as well as livelihoods structures of the most vulnerable. A climate resilient pathway is one that will not only manage biophysical changes, but address inherent institutional asymmetries that can further reinforce current inequalities in the way common pool resources are managed.

The quality and performance of institutions are largely predetermined by the rules they follow and the suitability of these rules based on the biophysical and social setting. In addition, the evaluative mechanism in place as checks and balances and the players within the institutions and their receptiveness to follow the rules are all necessary preconditions for climate resilient pathway. For example, the monitoring capacity of the institution/s, as well as mediation capacity and the degree to which these are embedded at different scales across the governance regime will largely determine its adaptive capacity and sustainability. Thus, the vulnerability of large river basins will largely depend on the changing biophysical conditions, but also on institutional architecture that is put in place to manage risks and build resilience. For instance, Schlager et al argue that compacts that have fixed allocation rules tend to exhibit greater vulnerability to climate change mainly because the system is far too rigid and does not allow for much flexibility in dealing with the changing hydrologic regime. Building resilience to climate change impacts are largely predetermined by the flexibility of the institutions to change the rules according to the changing biophysical and social setting. For instance, states such as Colorado in the United States, have dealt with water scarcity more efficiently mainly because users of the basin have access to venues that allow them to design and review current rules (Schlager, E. and Heikkila, 2011).

It is, however, important to note that institutional arrangements are not the only determining factor in bringing about transformational change. For instance, Agrawal et al. argues that there is a strong likelihood that technological improvements and institutional arrangements can positively affect the causal relationship between ecological sustainability and social equity (also see Agrawal and Benson, 2011).
Common problems with institutional roles include a frequent incompatibility of current governance structures with many of those that may be necessary for promoting social and ecological resilience' and the fact that 'adaptive ecosystem management overturns some major tenets of traditional management styles which have in many cases operated through exclusion of users and the top-down application of scientific knowledge in rigid programmes' (Tompkins and Adger, 2004: 10).

20.4.3. Enhancing the Range of Choices through Innovation

Finally, climate resilience will in most cases depend on innovation, developing new ideas and options or adapting robust familiar ideas and options to meet emerging new needs and to respond to surprises (also see IPCC Working Group III: Chapter 6). As indicated in the previous section, integrated strategies for climate resilience can benefit from considering possibilities to develop new options through social, institutional, and technological innovation. For example, if a climate-resilient pathway for a particular region calls for coping with greater water scarcity, innovations might consider changes in water rights practices, improving the understanding of groundwater dynamics and recharge, improving technologies and policies for water-use efficiency improvements, and in coastal areas the development of more affordable technologies for desalination (NRC, 2010a; Lebel, 2005). One key issue for risk management, therefore, is assessing needs for and possible benefits from targeting innovation efforts on critical vulnerabilities.

Innovations can include both technological and social changes, which in many cases are closely related (Rohracher, 2008; Raven et al., 2010), as technology and society evolve together (Kemp, 1994). An important characteristic of such socio-technical transitions are the interactions and conflicts between new, emerging systems and established regimes, with strong actors defending business as usual (IPCC SREX, 2012; Kemp, 1994; Perez, 2002).

Effective use of innovations depends on more than idea and/or technology development alone. Unless the options, the skills required to use them, and the institutional approaches appropriate to deploy them are effectively transferred from providers to users, effects of innovations – however promising – are minimized (IPCC SREX,

2012). Challenges in putting science and technology to use for sustainable development have received considerable attention (e.g., Nelson and Winter, 1982; Patel and Pavit, 1995; NRC, 1999; International Council for Science, 2002; and Kristjanson et al., 2009). These studies emphasize the wide range of contexts that shape both barriers and potentials and the importance of "co-production" of knowledge, integrating general knowledge with local knowledge, experience, and expertise. If obstacles related to intellectual property rights can be overcome, however, the growing power of the information technology revolution could accelerate the transfer of technologies and other innovations (linked with local knowledge) in ways that would be very promising for strengthening local resilience (Wilbanks and Wilbanks, 2010).

20.5. Determinants of Resilience in the Face of Serious Threats

Climate change is not the only threat facing societies in the 21st century; many households, communities and regions are addressing poverty, inequality, and a confluence of economic, demographic, social and cultural changes. As discussed in Chapter 13, future impacts of climate change and extreme events can slow down the pace of poverty reduction in urban areas, further erode food security, and jeopardize sustainable development. IPCC's Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (IPCC SREX, 2012) concluded that – due to climate change – climate extremes and extreme events will pose increasing challenges for natural and human systems. Successful responses to climate change will involve both incremental and transformational adaptations, with the latter dependent upon the timing and ambition levels of global greenhouse gas mitigation efforts, as well as on the choice of development pathways (Rogelj et al., 2013; Peters et al., 2013; Box 20-3).

20.5.1. Relationships between the Magnitude and Rate of Climate Change and Requirements for Transformational Adaptation

Climate-resilient pathways recognize a wide range of stressors and threats, including those linked to economic, political, social and technological changes. The complexity of these non-linear, interacting changes introduces both uncertainty and surprises. Resilience is a concept that that takes into account how a system, community, or individual can deal with disturbance, uncertainty and surprise over time (Folke et al., 2010; Walker and Salt, 2006). It can be defined as the ability of a social, ecological, or socio-ecological system and its components to anticipate, prevent, reduce, accommodate, adapt or recover from the effects of a hazardous event in a timely and effective manner (see Glossary). Anticipation focuses on real or imagined changes that are different from the present situation or status quo. Scenario development, storylines, and other anticipatory systems can be used to identify potential future outcomes based on an analysis of systemic, interacting changes (Miller, 2007; van Vuuren et al., 2012; Kriegler et al., 2012; IPCC SREX, 2012: Ch8). Prevention considers the social, economic, cultural, and political costs of anticipated futures and addresses them within an ethical framework (Gardiner 2004; Warner, van der Geest, et al., 2012). It is a conservative action that is dependent upon risk analysis frameworks (See Chapter 1, Chapter 2), as well as on understandings of the barriers and limits to adaptation (see Chapter 16).

In the absence of prevention, resilience involves reducing, accommodating, adapting to or recovering from the outcomes of climate change. For example, current strategies to reduce vulnerability to increased flooding involve new ways of accommodating water in landscapes (Delta Commission, 2008), and new types of adaptations to changes in the frequency and magnitude of floods (Environment Agency, 2009; Milly et al., 2008). The distinction between incremental adaptation and transformational adaptation is significant: Incremental adaptation can be considered extensions of actions and behaviors that already reduce losses or enhance benefits associated with climate change, often where the goal is to maintain the essence and integrity of an incumbent system or process at a given scale (Kates et al., 2012; Park et al., 2012). Transformational adaptation, in contrast, includes actions that change the fundamental attributes of a system in response to actual or expected impacts of climate change. These may involve adaptations at a greater scale or intensity than previously experienced; adaptations that are new to a region or system; or adaptations that transform places or lead to a shift in the location of activities (Kates et al., 2012). Such transformations are expected to occur when the rate and magnitude of climate change threatens to overwhelm the resilience of existing systems, or when vulnerability is high (Kates et al., 2012). There is growing

evidence that climate change is going to be significant enough for many locations and systems that climate-resilient pathways will have to consider transformational change in advance of disruptive impacts in order to reduce risk and vulnerability (see Chapters 14-17). Transformational adaptation often occurs in continuous interaction with incremental adaptations (Park et al., 2012, see IPCC SREX, 2012, Figure 8-1). However, the rate and magnitude of climate change can influence the resilience of the system, in some cases undermining the capacity to adapt to change, and introduce limits to adaptation (Adger et al., 2009; Marshall et al., 2012).

Estimates of loss and damages associated with climate variability and change over time suggest that the rate and magnitude of climate change has significance for sustainable development (IPCC SREX, 2012; Beddoe et al., 2009; Warner, van der Geest, et al., 2012). The severity of climate change is influenced by the rate and timing of greenhouse gas emissions (Kriegler et al., 2012). Model results based on integrated scenarios that take into account geophysical, technological, social and political uncertainties indicate that achieving the often-discussed 2°C average global temperature increase calls for mitigation of emissions through increased energy efficiency and lower energy demand well before 2020 (Rogelj et al., 2013; Peters et al., 2013; section 20.6.1). In the absence of ambitious mitigation efforts, the future impacts of climate change can be expected to be non-linear, with the potential for crossing thresholds and tipping points (Lenton, 2011a). Although thresholds or tipping points in complex systems are difficult to predict, studies from a variety of disciplines indicate some generic properties associated with transitions between different states. Indicators of critical transitions include an increase in recovery times from disturbances, and changes in spatial patterns (Scheffer et al., 2009).

Because of the large negative impacts of crossing climate tipping points, such scenarios are important to include in risk assessments and response strategies. An analysis of historical collapses of ancient states or civilizations indicates that transformations at a large social or spatial scale are associated with multi-causality with cascading feedbacks, and that collapses can be avoided by through collective strategies that contribute to socio-ecological resilience (Butzer and Endfield, 2012; Butzer, 2012; Dugmore et al., 2012). Such resilience calls not only for adaptability, but also for transformability (Folke et al., 2010; Westley et al., 2011). Consequently, in addition to transformational adaptation and transformations to low-carbon societies, there is increased attention to the importance of transformations for global sustainability, which in many cases include social transformations (Folke et al., 2009; Pelling, 2010; Westley et al., 2011).

20.5.2. Elements of and Potentials for Transformational Change

Given the risks of climate change and associated impacts on natural and managed resources and systems, human settlements, industry, infrastructure, health, well-being, and human security, and given the limits to adaptation discussed in Chapter 16, there are increasing calls for deliberate transformations towards global sustainability (Raskin et al., 2002; WBGU, 2011; Westley et al., 2011; O'Brien, 2012). Global sustainability includes the goals of sustainable development, but considers them within the context of planetary and social boundaries (Rockström et al., 2009; Leach et al., 2012). Transformation is defined as a change in the fundamental attributes of a system, often based on altered paradigms, goals, or values. Transformations can occur in technological or biological systems, financial structures, and regulatory, legislative, or administrative regimes (see glossary). Transformation in wider political, economic and social systems can either open up or close policy spaces for more resilient and sustainable forms of climate responses, particularly where contemporary development pathways are identified and addressed as part of the root causes of vulnerability (Pelling, 2010; IPCC SREX, 2012: Chapter 8).

There is an extensive literature on transitions and transformations, covering a variety of sectors and factors that influence changes in systems and behaviors (Calvin et al., 2009; Berkhout et al., 2010; Shove and Walker, 2010; Pelling 2010; Geels, 2002; IPCC Working Group III: Chapter 6). Transformation can be triggered by events, but often they are long-term processes (Loorbach, 2007). Factors that may improve prospects for both initiating and sustaining transformations can include dramatic focal events that catalyse attention to vulnerabilities; the presence of other sources of stress that also encourage considerations of major changes; and supportive social contexts such as the availability of understandable and socially acceptable options, access to resources for action, and the presence of incentives. Transformation is also linked to adaptive leadership, empowerment and collaboration within and across institutions, organizations and groups (IPCC SREX, 2012: Chapter 8; Heifetz et al., 2010; Kates et al., 2012; Moser

2013). Other key elements associated with transformations include adaptable institutions (cultural, economic and governance), all types of capital, diversity in landscapes, seascapes and institutions, learning platforms, collective action and networks, as well as reflexivity and the capacity to take perspectives (Loorbach 2007; Folke et al., 2010; Westley et al., 2011; Schlitz et al., 2010). Many of the elements of climate resilient pathways discussed in Box 20-5 can, in fact, support transformation.

While transformations may be reactive, forced or induced by random, stochastic factors, they may also be deliberately created (Folke et al., 2010; O'Brien, 2012; Kates et al., 2012). Deliberate transformations can take place across interacting spheres, referred to by O'Brien and Sygna (forthcoming) as the practical, political and personal spheres of transformation (see Figure 20-2). The practical sphere includes social and technological innovations, behavioral changes, and institutional and managerial reforms that directly influence outcomes. Although this is where most attention is currently focused, transformations in this sphere are challenging because they seldom question or address larger systems and structures. Consequently, the lines between business-as-usual and transformation in this sphere are easily blurred. The political sphere represents the economic, political, legal, social and cultural systems that define the boundaries within which practical transformations take place. It is within this sphere where problems and solutions are identified and defined, and where value conflicts are often experienced and resolved. The political sphere is often a reflection of dominant cultural beliefs and worldviews that are seldom recognized or questioned. These involve transformations in the personal sphere, which includes individual and collective beliefs, values and worldviews that shape the ways that systems and structures are viewed, as well as the practical solutions that are considered possible. Transformations in this sphere often represent paradigm shifts that can influence both political and practical interventions. Whether in relation to transformational adaptation, transformation to low-carbon societies, or transformations to global sustainability, attention to all three spheres is considered necessary in response to the observed and anticipated impacts of climate change (Beddoe et al., 2009). As discussed in the next section, climate resilient pathways may involve conflicting goals and visions for the future, and not every transformation is considered equally ethical, equitable or sustainable. The normative dimension of climate change responses and climate resilient pathways is thus an important part of both discussions and actions related to sustainable development.

[INSERT FIGURE 20-2 HERE

20.6. Toward Climate-Resilient Pathways

20.6.1. Alternative Climate-Resilient Pathways

Climate-resilient pathways consist of future trajectories of development that combine adaptation and mitigation in the context of sustainable development implementation. At any scale (local or regional) there are multiple paths leading to the same total amount of climate resilience: alternative stable states (Hollings, 1973). At any time period along a pathway, more or less resilience maybe observed at specified points within the system (or locality), while the total amount of resilience within the entire system remains unchanged (Folke, 2006). Each potential alternative pathway can be strengthened and evaluated based on certain risk management characteristics/elements, the capacity to: a) foresee risk/vulnerability, b) decrease climate change impacts, c) respond rapidly to unpredictable, uneven and extreme events, d) include considerable amounts of proactive adaptation, and e) evolve in support of societal advancement and balanced environmental management.

Many of the choices involved in framing and supporting attempts to increase and sustain climate resilience are made largely at global and national levels, but many of the actions to sustain resilience are made at local levels. The global pathways that emerge are accumulations of these local and national choices. In these processes, path dependence is strong enough such that risk management decisions in the near term are more likely to lead to resilience if long term objectives are included as well as a wider spatial scale up to and including the global level.

A central issue in considering alternative pathways is the extent to which they may fail to meet a criterion of climate resilience. Or to put the question more simply, "are there any boundaries on the envelope of climate resilience"? The

answer is highly scale dependent. We have a carbon legacy in the atmosphere, and total prevention/avoidance of impacts is now unachievable (Dickinson, 2007). At any level of stabilization of GHG concentrations, with even the strongest emissions reduction targets, some localities or systems or populations will be vulnerable to disruptions because there is in effect no limit below which universal prevention of residual loss and damages can be assured. Transformational change will therefore need to be a key component in nearly all alterative climate resilient pathways.

In the event that global surface mean temperatures rise through +2ºC to +4ºC and higher (Schneider, 2009; New et al., 2012; Anderson and Bows, 2008), sustainability will become significantly more difficult to achieve (food security is a notable example: Chapter 7). For example, a business-as-usual future society where unsustainable development paths are the norm, where technology transfer between countries is lacking, population growth increases rapidly, GHGs emission go unabated, and institutions and governance structures are ineffective at creating effective climate change policies, would almost certainly result in losses so widespread that development pathway would not be resilient (Riahi et al., 2011; Arnell et al., 2013). A pathway that included these elements would fall outside the 'boundaries of the envelope of climate resilience'.

Within these boundaries, climate-resilient pathways can be made up of a collective of alternative choices at the regional level, where they are dependent upon specific demographics, potential for economic development and growth, ecological and ecosystem services, access to natural resources, institutional and governance structures, and technological development and transfer. The concept of Shared Socioeconomic Pathways (SSPs) at the global level offers one framework for considering alternative mixes of actions in support of climate resilience (Box 20-3). SSPs consider alternative socioeconomic pathways according to dimensions related to both the resource intensity of economic growth and the effectiveness of institutions in resolving tradeoffs (Kriegler, et al., 2012). Five notional pathways have been developed to illustrate a range or possible futures, as a basis for discussion, with each SSP following a distinct storyline (Figure 20-3). These dimensions can then be related to socioeconomic challenges confronting climate change mitigation and adaptation (as one aspect of sustainable development). In Figure 20-3, Pathway 1 has relatively limited challenges to both adaptation and mitigation, while Pathway 3 has substantial challenges to both adaptation and mitigation. Any pathway characterised by low challenges to both is likely to be climate- resilient at the global scale and in many local or national situations. A pathway characterised by high challenges to both adaptation and mitigation is less likely to be climate-resilient at the global scale and in many localities and countries.

[INSERT FIGURE 20-3 HERE
Figure 20-3: A notional depiction of alternative climate-resilient sustainable development pathways (lower left). Regarding SSPs, see Box 20-3; SSPs are representations of alternative socioeconomic pathways within which climate change responses might evolve.]

Considering alternative climate-resilient pathways cannot be separated from levels of climate change. In principle, most climate change scientists, decision-makers, and stakeholders agree that: (a) there is a level of climate change that is low enough that climate resilience for most systems could be achieved without enormous efforts and widespread transformational adaptation; (b) there is a level of climate change that is high enough that climate resilience cannot be expected to cope with severe impacts on most systems (e.g., Rockstrom et al., 2009); and (c) between those two levels the challenges to climate resilience grow as the level of climate change rises. Scientists do not, however, agree on what magnitude of climate change (e.g., average global warming) defines each of the two levels. Some experts support the view (Box 20-1 and section 20.3.1) that any level above 2 degrees C would mean impacts that are incompatible with sustainable development (Metz et al., 2002**).** IPCC's Fourth Assessment Report concluded that there is an approximate threshold, between 2.5 and 3 degrees C of warming, above which impact concerns are severe but below which concerns are less severe (IPCC, 2007). Other scientists are unconvinced that system sensitivities to climate parameters such as temperature increase are well-enough understood to support any specific warming threshold (e.g., NRC, 2010c), and some scientists and policymakers are unconvinced that adaptive response capacities are well-enough understood to support determinations of limits to adaptation and resilience (Chapter 16). Most experts in all three groups, however, agree that prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation (e.g., New et al., 2012).

20.6.2. Implications for Current Sustainable Development Strategies and Choices

Although payoffs from specific long-term pathways may be uncertain at this time, such uncertainties need not preclude actions now. Climate-resilient development pathways are not about actions taken in the future, but rather about the strategies and choices that are taken today. The range of potential climate outcomes, discussed in Box 20-3, will have dramatically different implications for human security, as well as for the health and status of species and ecosystems (IPCC WGII, AR5). Increasingly, the literature linking climate change to greenhouse gas concentrations shows that the emissions in the coming decades will be decisive for future climate outcomes (Anderson and Bows, 2008; Meinshausen et al., 2009; Solomon et al., 2009).

In fact, waiting to take action may reduce the range of choices for climate resilient pathways in the future (NRC, 2011b). The IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX), 2012, makes the case that a "solution space" exists now for considering possible strategies that would increase climate resilience while at the same time helping to improve human livelihoods and social and economic well-being. It suggests that a process of iterative monitoring, evaluation, learning, innovation, and contingency planning will reduce climate change disaster risks, promote adaptive management, and contribute significantly to prospects for climate-resilient pathways. The solution space emphasizes the linkages between different strategies, recognizing that no single approach alone is likely to be sufficient.

Meanwhile, in some parts of the world, current failures to address effects of emerging climate stressors are already leading toward adaptation strategies that erode bases for sustainable development Damage and loss patterns are not limited to future vulnerabilities; in many areas they are impeding food production and other essential development services in ways that are clearly non-sustainable (Warner and Afifi 2012a; Warner, van der Geest, et al., 2012).

In discussing approaches to sustainability in the context of climate extremes, the SREX report draws attention not only to the role of incremental change, but also to transformation, which is defined as "the altering of fundamental attributes of a system (including value systems; regulatory, legislative, or bureaucratic regimes; financial institutions; and technological or biological systems) (IPCC SREX, p. 564). Climate-resilient development pathways that deliberately address mitigation and adaptation through both incremental and transformative strategies are likely to present more options for sustainable development than those pathways that reactively respond to the challenges of climate change.

20.7. Priority Research/Knowledge Gaps

Simply stated, what is known about integrating climate change mitigation, climate change adaptation, and sustainable development is dwarfed by what is not known. If national and global decision-makers wish to realize potentials from a fusion of these three imperatives, then research should be a very high priority indeed. The most salient research need is to improve the understanding of how climate change mitigation and adaptation can be combined with resilient sustainable development pathways in a wide variety of regional and sectoral contexts (Wilbanks, 2010). One starting point is simply improving the capacity to characterize benefits, costs, potentials, and limitations of major mitigation and adaptation options, along with their external implications for equitable development, so that integrated climate change response strategies can be evaluated more carefully (Wilbanks et al., 2007; NRC, 2011). What are the major tradeoffs? What are the potential synergies? How do implications of integrated mitigation/adaptation strategies vary with location, climate change risks and vulnerabilities, scale, and development objectives and capacities? (e.g., Hugé et al., 2011). In these regards, the best of global science needs to be combined with national and local expertise to advance knowledge related to climate-resilient pathways.

Related to this general priority are at least three specific research needs:

1) Research on how to reconcile the importance of synergies between climate change adaptation and mitigation actions with widespread use of the concept of additionality, e.g., how to establish criteria for access to financial support for adaptation that incorporates the development importance of co-benefits. For

example, such research could inform discourses about differences between adaptation and development in ways that enable the flow of financial resources to support adaptations: e.g., how to acknowledge co-benefits in allocating investment resources without inviting every party seeking development investment to use climate change as an opportunity (NRC, 2010a).

2) Advances in conceptual and methodological understandings of, and tools to support research on, multiple drivers of development pathways and climate change impacts; possible feedback effects among mitigation, adaptation, and development; and possible thresholds/tipping points that could cause particular challenges for development (NRC, 2009, 2010a).
3) Advances in knowledge about how to respond sustainably to climate change extremes and extreme events, when and where they pose development challenges that would appear to require transformative changes in impacted human and/or environmental systems. What might the options be, and how can they be facilitated where they should be considered? (e.g., Pelling, 2010).

Further research needs include:

- Research attention to potentials for technological and institutional innovations to ease threats to sustainable development from climate change impacts and responses. In other words, how might climate change responses represent opportunities for innovative development paths? How might technological development be part of a strategy for development/climate change response integration? (Wilbanks, 2010)
- Research on strategies for institutional development, including improving understandings of how social institutions affect resource use (NRC, 2009), improving understandings of risk-related judgment and decision-making under uncertainty (NRC, 2009), and best practices in creating institutions that will effectively integrate climate change responses with sustainable development outcomes such as participation, equity, and accountability
- Research on strategies for the implementation of adaptive management for development. Examples of important research needs include improving the understanding of respective roles and interactions between autonomous response behavior and policy initiatives, improving the body of empirical evidence about how to implement changes that are judged to be desirable: e.g., adaptive management and governance capacity, and improving the understanding of differences between retrofitting older infrastructures (the challenge in many industrialized countries) and designing new infrastructures (the challenge in many rapidly developing countries) (IPCC SREX, 2012: Chapter 8).
- Research to improve the understanding of how to build social inclusiveness into development/climate change response integration. As suggested above, research is needed on issues of social values/climate justice/equity/participation and how they intersect with the deployment of mitigation, adaptation interventions and sustainable development policy in different regional/sociopolitical contests (IPCC SREX, 2012: Chapter 8).
- Research on factors that influence deliberate transformations that are ethical, equitable, and sustainable (O'Brien, 2012; Kates, Travis, and Wilbanks, 2012).
- The development of structures for learning from emerging integrated climate change response/development experience: e.g., approaches and structures for monitoring, recording, evaluating, and learning from experience, identifying "best practices" and their characteristics (NRC, 2010a; IPCC SREX, 2012: Chapter 8; Hilden, 2011).

Finally, it is very possible that progress with global climate change mitigation will not be sufficient to avoid relatively high levels of regional and sectoral impacts, and that such conditions would pose growing challenges to the capacity of adaptation to avoid serious disruptions to development processes. If this were to become a reality later in this century, one response could be a rush toward geoengineering solutions. In preparation for such a contingency, and perhaps as an additional way to show how important progress with mitigation will be in framing prospects for sustainable development in many contexts, there is a very serious need for research on geo-engineering costs, benefits, a wide range of possible impacts, and fair and equitable structures for global policymaking and decision-making (UK Royal Society, 2009; Kates, Travis, and Wilbanks, 2012).

But a fundamental aim of research to improve capacities for climate-resilient pathways for sustainable development is to avoid such an unfortunate outcome. It seeks to do so by strengthening the base of knowledge that underlies and

supports effective actions by viewing climate change mitigation, climate change adaptation, and sustainable development in an integrative and mutually supportive way.

Frequently Asked Questions

FAQ 20.1: Why are climate-resilient pathways needed for sustainable development?

Sustainable development requires managing many threats and risks, including climate change. Because climate change can no longer be avoided and, in fact, is a growing threat to development, sustainability will be more difficult to achieve for many locations, systems, and populations unless development pathways are pursued that are resilient to effects of climate change.

FAQ 20.2: What is a climate-resilient pathway?

A climate-resilient pathway for development is a continuing process of change management, combining flexibility, innovativeness, and participative problem-solving with effectiveness in mitigating and adapting to climate change. If effects of climate change are relatively severe, this process is likely to require considerations of transformational changes in threatened systems if development is to be sustained without major disruptions.

FAQ 20.3: Are there things that we can be doing now that will put us on the right track toward climate-resilient pathways?

Yes. We can carry out participative vulnerability assessments, look for ways to reduce vulnerabilities to effects of climate change that have other development benefits as well, monitor emerging climate changes and adaptive responses to improve our understanding of risks, and revise our vulnerability assessments and risk management strategies continually on the basis of growing evidence, knowledge, and experience. In many cases, these activities can be linked with other issues for sustainable development as well.

Executive Summary

Regional responses to climate change are acutely affected by the information flow between disciplines, sectors and across scales. To bridge these requires special attention to communicating concepts, language, and the formulation of information tailored from one sector for another. Chapter 21 forms one such interface through framing a critical assessment of the regional context of thematic and sectoral issues in a decision-making context.

The climate system may be global in extent, but its manifestations – through atmospheric processes, ocean circulation, bioclimatic zones, daily weather and longer-term climate trends – are assuredly regional or local in their occurrence, character and implications. Explicit recognition of geographical diversity is therefore an imperative for any scientific assessment of anthropogenic climate change. [21.2.1] An understanding of the context in which risk plays out, and the alternative options that may be considered to manage it, are thus not an afterthought, but a defining feature of an appropriate climate analysis, requiring a close interplay between decision-makers and providers of climate change and climate risk information. In this context, understanding and responding to regional change requires recognition of key concepts, and of the relative strengths and weaknesses of information at the appropriate scales. [21.2.2]

There is diversity in knowledge about adaptation, vulnerability and impacts among and within regions around the world. Evidence available for different global regions on adaptation, vulnerability and impacts varies in terms of robustness, quantity, scope, and regional representativeness. [21.3.3] There is mounting evidence that human adaptation is very likely to be occurring as an autonomous response to ongoing climate change in some regions.

The scales at which political decisions about climate change need to be made are frequently at odds with the definitions of regions. Climate change transcends political boundaries and is highly variable from region to region in terms of impacts and vulnerability. Likewise adaptation policies, options, and mitigation strategies are strongly region dependent and tied to local and regional development issues. [21.3.2] Climate change policy at regional

scales is constrained by the dual challenge in achieving integration at multiple administrative scales from global through national to local (multi-level governance), and across different sectors (policy coherence). [21.3]

Cross-regional phenomena are very likely to be crucial for understanding the ramifications of climate change at regional scales, and its impacts and policies of response. [21.4] These include global trade and international financial transactions, which are linked to climate change as a direct or indirect cause of anthropogenic emissions, as a predisposing factor for regional vulnerability, through their sensitivity to climate trends and extreme climate events, and as an instrument for implementing mitigation and adaptation policies. Migration is also a cross-regional phenomenon, whether of people or of ecosystems, both requiring trans-boundary consideration of their causes, implications and possible interventions to alleviate human suffering and promote biodiversity.

Significant improvements have been made in the amount and quality of climate data that are available for establishing baseline reference states of climate-sensitive systems. [21.5.3] These include new and improved observational datasets, rescue and digitisation of historical datasets, and a range of improved global reconstructions of weather sequences. However, despite improvements, some questions remain unclear. For example, confidence in global precipitation estimates is low to medium due to incompleteness of data, and when all land areas are filled in using reconstruction methods, land precipitation shows little change since 1900 (in contrast to the AR4 assessment of a small increasing trend), along with a high degree of spatial and temporal variability in the trends.

Improved detection and attribution methods have shown that it is *extremely likely* that human activities have caused most of the global warming (more than 50%) since the 1950s and that this warming is not due to internal variability alone. The human influence on warming is *likely* over every inhabited continent (there are insufficient data to make an assessment over Antarctica). It is also *likely* that the human influence has altered sea level pressure patterns and related circulations. Attribution of changes in hydrological variables is less confident due to the lack of data though a human influence on zonal patterns of global and on high northern latitude precipitation changes has been detected (WGI Chapter 10).

Confidence in past and projected changes at regional scales is dependent on location and the variable being considered. Changes in global land surface air temperature exceed changes in global mean surface air temperature with continental interiors showing the largest changes. The increase in intensity of precipitation (and thus risk of flood) and summer drought occurrence over mid-continental land areas is a robust signature of global warming, both in observations for recent decades and in model projections. There is still little confidence in past trends and near term projections of tropical cyclone frequency and intensity. The mean regional pattern of sea surface salinity has been enhanced, with saline surface waters in the evaporation-dominated mid-latitudes becoming more saline, and relatively fresh surface waters in rainfall-dominated tropical and polar regions becoming fresher. It is virtually certain that the biogeochemical state of the ocean has changed (WGI Chapter 3). The uptake of CO2 by the ocean has resulted in a gradual acidification of seawater, with observations showing declines in pH in the mixed layer between -0.0015 and -0.0024 yr^{-1}. The retreat of Arctic ice in all seasons has continued, and the thickness, concentration and volume of arctic ice have also decreased. Conversely, the total extent of Antarctic ice has increased slightly with strong regional differences. Retreat of mountain glaciers is widespread, with varying rates across regions, and uncertainty about the global rate. Several hundred glaciers globally have completely disappeared in the last 30 years. Climate models indicate a nearly ice-free Arctic at the end of summer for warming greater than 2C. The models show no evidence of critical thresholds in the transition from perennial ice-covered to a seasonally ice-free Arctic Ocean beyond which further sea ice loss is unstoppable and irreversible. Projections of decrease in Northern Hemisphere spring snow covered area in the CMIP5 models are fairly coherent.

The uncertainty in near term climate projections is dominated by internal variability of the climate system, initial ocean conditions and inter-model response, rather than GHG forcing. The internal variability grows in importance at smaller spatial and temporal scales. The CMIP5 ensemble includes a new set of multidecadal near term prediction experiments (up to 2035) with initialized ocean state (WGI Chapter 11). Results from these experiments and analyses of un-initialized simulations show some evidence for the predictability of yearly to decadal averages of temperature both for the global average and for some geographical regions.

The time-mean rate of GMSL rise during the 21st century is *very likely* to exceed the rate observed during 1971–2010, under all the RCP scenarios. [21.3.3] The ocean thermal expansion and glacier melting is *likely* to make the largest contributions to this rise. By the end of the 21st century it's *very likely* that over about 95% of the oceans will undergo sea level rise. The impacts of this sea-level rise, however, will also be a function of local and regional conditions, including coastal subsidence (or coastal uplift) and patterns of development near the coast.

The uncertainties inherent in climate model projections of regional climate changes have not decreased from AR4. [21.3.3] In some cases, the addition of regional forcings (e.g. topography) has increased some uncertainties.

The expanded use of multiple scenario elements beyond that of only climate scenarios still has unresolved issues. [21.5.3] Among these are the model-to-model variability of the integrated assessment models used to generate representative concentration pathways and shared socioeconomic pathways. This variability, and its consequences for impacts and adaptation analyses, or for understanding potential future climates, is largely unexplored.

Climate models continue to produce a range of projected futures where for some variables and locations the sign of projected change may differ from one model to another. [21.5.3] However, in many instances this indicates a lack of significant change compared to the natural variability for that region. The degree to which the model uncertainty can be reduced remains an open question.

Uncertainties of future climate remain centred on uncertainties over future climate forcing from emissions and concentrations, the climate system response to forcing, and the natural internal variability of the climate system. [21.5.3] The likelihood of reducing uncertainty in future emissions and concentrations appears low, and future scenarios are mainly presented as having equal plausibility. Uncertainty in the climate system uncertainty has multiple sources in constrained understanding of the system dynamics, in how the system components are modelled, and in the parameterization of processes.

Downscaling of coarse resolution global climate reconstructions and models has advanced to bring information closer to the temporal and spatial resolution requirements for projecting many regional impacts. [21.5.3] This information remains weakly coordinated, and current results indicate models can have significant errors in their high resolution reconstructions of the current climate.

Hotspots draw attention, from various perspectives and often controversially, to locations judged to be especially vulnerable to climate change. [21.4.4] Hotspots is an approach that has been used to indicate locations that stand out in terms of impacts, vulnerability or adaptive capacity (or all three). The approach exists in many fields and the meaning and use of the term hotspots differs, though their purpose is generally to set priorities for policy action and for further research. In the context of climate change, hotspots have been defined with respect to: climate changes themselves, biodiversity, health and disease, disasters, and food production and food security. Hotspots can be very effective as communication tools, but may also suffer from methodological weaknesses. They are often subjectively defined, relationships between indicator variables may be poorly understood and they can be highly scale-dependent. In part due to these ambiguities, there has been controversy surrounding the growing use of hotspots, particularly in relation to prioritising regions for climate change funding.

Improved regional scale climate information is now available to provide a more coherent picture of past and future regional changes with associated uncertainties. [21.3.3, 21.5.3] More targeted analysis of climate projections for impact assessment studies have been carried out, from which the leading messages to emerge include

- A strong regional variability of projected change is found for surface climate variables. Different indexes combining sets of climate variables and statistics indicate the emergence of various climate change hot-spots at different times in the future. Better process understanding is needed to increase confidence in the identification of climate change hot-spots (i.e. regions in which potential climate change impacts on the environment or different activity sectors can be particularly pronounced or where climate is especially responsive to global change).

- Broad regional patterns of late 21st century temperature and precipitation change projections, as well as changes in temperature and precipitation extremes, from the latest generation GCM simulations (CMIP5) are generally in line with previous projections available in the AR4.
- Preliminary analysis of decadal prediction experiments in the CMIP5 ensemble show that decadal predictability of unforced regional precipitation and temperature patterns over land is very low. Indications of some predictability of ocean temperatures of up to 10 years lead time is however found over some ocean basins
- A larger set of global and regional (both dynamical and statistical) model projections allow a better characterization of uncertainties than in the AR4, and more methods are available to produce probabilistic projections of changes for use in IAV assessment work.
- Projected changes in the oceans, sea level and cryosphere are also consistent, at least qualitatively, with previous estimates from the AR4 and with improved observations of recent past trends. Quantitative values of projected changes may however differ from the AR4 due to the availability of better models and larger ensembles, especially at the regional scale.
- Climate change is expected to substantially affect regional air quality, for example near surface ozone concentrations, however this effect also depends strongly on future emissions.

There is significant new information on many of the physical non-climatic factors, especially those that are components of the new RCPs used in the CMIP5. [21.5.3] Non-climatic factors relevant to assessing a system's vulnerability general involve a complex mix of physical and socio-economic influences. Often these are continually evolving and thus generally only a reference point in time rather than a reference state over a period of time can be defined. Improvements in observations of other factors have also occurred but, as with climate information, in many cases the quality is regionally dependent and there are resolution deficiencies. The literature on characterizing vulnerability on sub-national and regional scales is mixed – but it is clear that there is significant variation in vulnerability due to variability in wealth, income, social factors, and access to governance.

The derivation of the RCP's and the parallel process for scenario development has enabled the climate modeling community to consider explicit mitigation scenarios for the first time in systematic model intercomparisons. [21.5.3] Substantial regional information of economic activity, development trajectories, and emissions are available for analysis, but remain largely unexplored. The RCP's are known not to be unique pathways to the identified radiative forcing targets. Model to model variability of the IAM's used to generate the RCP's is also largely unexplored.

Achieving emission targets without putting a price on carbon emissions from land-use has the potential to lead to very large reductions in forested area, and much higher overall costs for mitigation, compared to meeting the same targets while putting a price on all carbon emissions. [21.5.3] Similarly, substantial regional variation in the availability of technologies exists, but the differences in how these are represented regionally is largely unexplored. A process (shared socioeconomic pathways, SSP's) has been initiated to identify shared assumptions and global scenarios for use in both mitigation and adaptation research. But although progress has been made, the vast majority of the impacts, adaptation, and vulnerability literature since AR4 continues to be based on the SRES.

Bulk transport of products, whether by air, sea or over land, is now highly likely to be a non-trivial contributor to emissions of greenhouse gases and aerosols. [21.4.1] Furthermore, the relocation of manufacturing has transferred net emissions via international trade from developed to developing countries and most developed countries have increased their consumption-based emissions faster than their domestic (territorial) emissions.

Contested definitions and alternative approaches to describing vulnerability to climate change pose problems of interpretating vulnerability indicators. [21.5.1] There are numerous studies that use ndicators to define aspects of vulnerability, quantifying these across regonal units (e.g. by country or municipality), often weighting and merging them into vulnerability indices and presenting them regionally as maps. However, methods of constructing indices are subjective, often lack transparency and can be difficult to interpret. Moreover, indices commonly combine indicators reflecting current conditions (e.g. of socio-economic capacity) with other indicators describing

projected changes (e.g. of future climate or population), and have failed to reflect the dynamic nature of the various variables used as indicators.

The variability of vulnerability across regions, and across subpopulations within regions preclude general statements about the factors that control that variability, and how they might evolve in the future. [21.5.1] Trade and financial flows influence both vulnerability and adaptive capacity, and also the regionalization of emissions. At the same time, international and cross-regional financial instruments are being used to attempt to build adaptive capacity as well as mitigation capacity. Human migration in reaction to climate-driven phenomena, or extreme weather events, is usually within nations, but under some circumstances, can extend across nations. The migration of ecosystems in response to changes in climate emphasizes the need for cross-regional cooperation of conservation and resource management institutions.

21.1. Introduction

The framing of this chapter places the discussion of both global and regional issues in a decision-making context. This context identifies different scales of decisions that are made (e.g. global, international, regional, national) and the different economic or impact sectors that are often the objects of decision-making (e.g. agriculture, water resources, energy).

Within this framing, the chapter then provides three levels of synthesis. First is an evaluation of the state of knowledge of changes in the physical climate system, and the degree of confidence that we have in understanding those changes on a regional basis that is relevant to decision-making. The second is a discussion of the regional context of the sectoral discussions in Part A of Working Group II. The third is to discuss the regional variation revealed in subsequent chapters of Part B. In so doing, the goal is to examine how each regional chapter addresses decision-making issues in similar or different ways, and whether there is commonality of experience among regions that could be useful for decision-making.

Having analyzed similarities and differences among IPCC regions, the chapter then discusses trans-regional and cross-regional issues that affect both human systems (e.g. trade and financial flows) and natural systems (e.g. ecosystem migration). Finally, the chapter evaluates methodologies for assessing regional vulnerabilities and adaptations, impact analyses, and the development and application of scenarios of the future. These evaluations provide guidance for understanding how such methods might ultimately be improved, so that the confidence in research about possible future conditions and consequences might ultimately improve.

21.2. Defining Regional Context

The climate system may be global in extent, but its manifestations – through atmospheric processes, ocean circulation, bioclimatic zones, daily weather and longer-term climate trends – are assuredly regional or local in their occurrence, character and implications. Explicit recognition of geographical diversity is therefore an imperative for any scientific assessment of anthropogenic climate change. Moreover, the decisions that are or could be taken on the basis of climate change science play out on a range of scales, and the relevance and limitations of information on both biophysical impacts and social vulnerability differ strongly from global- to local-scale, and from one region to another. The following sections emphasize some of the crucial regional issues to be pursued in Part B of this report.

21.2.1 Decision-Making Context

This is the first full IPCC assessment to devote a single part of a report to regional aspects of climate change that cut across topics in all three IPCC Working Groups. Hence, this part of the report attempts to address many of the regional dimensions of the climate change issue that are regarded as relevant to decision making. Naturally, a lot of emphasis is placed on informing national and international climate change policy making, but the demand for information to support practical decision-making has assumed an increasingly sub-national focus. However, while

expeditious use of case studies can provide useful illustrations of local-scale phenomena, geographical comprehensiveness is necessarily ruled out in this assessment. Instead, responsibility for compiling and disseminating local information rests with regional and national experts, while this report seeks to highlight robust examples of these, wherever possible.

A good understanding of the decision-making context is essential to define the type of information on climate change related risks required from physical climate science and impacts, adaptation and vulnerability assessments (e.g. IPCC, 2012a). While the importance of considering the decision-making context is a general issue for all impacts, adaptation and vulnerability assessments (cf. the chapters in Part A), it is especially important in the context of regional and sub-regional issues. Many studies are still driven by global data and assessment methods, whereas there is considerable variation in regional, national and local decision-making contexts, as well as across different groups of stakeholders and sectors. There is a growing body of scientific information on how to provide the most relevant climate risk information to suit specific decision-making processes (e.g., Willows and Connell, 2003; ADB, 2005; Kandlikar *et al*., 2011 decision-making).

Table 21-1 illustrates the range of actors involved in decision-making to be informed by climate information at different scales in different sectors, ranging from international policy makers and agencies, to national and local government departments, to civil society organizations and the private sector at all levels, all the way to communities and individual households. The implications of climate change touch on almost all sectors of society, so the figure illustrates how policy makers face a dual challenge in achieving policy integration – vertically, through multiple levels of governance, and horizontally, across different sectors (Table 21-1). Many of the barriers to effective climate response are to be found in these two dimensions. For instance, in the vertical dimension, while a growing number of European countries have developed national adaptation strategies in recent years, the implementation of adaptation measures at a local level has lagged behind, because responsibility and resources for adaptation at the local level have yet to be properly assigned (Biesbroek *et al*., 2010). In contrast, horizontal integration (policy coherence – Mickwitz *et al*., 2009) often flies in the face of conventional practice, with sectoral policies that are designed to advance social or economic goals (e.g. development of an improved road network) frequently at odds with goals set in other sectors (e.g. environmental targets to limit greenhouse gas emissions or to reduce infrastructural exposure to flood risk). Finally, implicit in the framing of Table 21-1, is the temporal dimension of decision, manifested through their scheduling, cost and ultimate effectiveness. Though this dimension is not shown in Table 21-1, it is a crucial element to consider in interpreting both the types of response options facing decision-makers (for example, contrasting a one-off, long-term major infrastructural investment against multiple, incremental and flexible short-term measures) as well as the information used to inform those decisions.

[INSERT TABLE 21-1 HERE
Table 21-1: Dimensions of the institutions and actors involved in climate change decision-making, including example entries referred to in chapters of this volume. Vertical integration can occur within as well as between levels. Decison-making domains are illustrative. Modified and extended from Mickwitz (2009).]

Many climate change risk assessments have traditionally been undertaken either in the context of international climate policy-making (especially the United National Framework Convention on Climate Change – UNFCCC), or by (or for) national governments. In those cases, climate risk information commonly assumes a central role in the decision-making, for instance to inform mitigation policy, or for plans or projects designed specifically to adapt to a changing climate. More recently, increasing attention has been paid to more sector- or project-specific risk assessments, intended to guide planning and practice by a range of actors. In those contexts, climate may often be considered as only one contributor among a much wider set of considerations for a particular decision. In such cases, there is uncertainty about not only the future climate, but also many other aspects of the system at risk. Moreover, while analysts will seek the best available climate risk information to inform the relative costs and benefits of the options available to manage that risk, they will also need to consider the various constraints to action faced by the actors involved.

Some decision-making contexts, such as the design of large infrastructure projects, may require rigorous quantitative information to feed formal evaluations, often including cost-benefit analysis (e.g. PriceWaterHouseCoopers 2010), for more examples see also chapter 17). Others, especially at local level, such as decision-making in traditional

communities, are often made more intuitively, with a much greater role for a wide range of social and cultural aspects, and may benefit much more from experience-based approaches, participatory risk assessments, or story-telling to evaluate future implications of possible decisions (e.g. Van Aalst *et al.,* 2008, World Bank, 2010). Multi-criteria analysis, scenario planning, and flexible decision paths offer options for taking action when faced with large uncertainties or incomplete information, and can help bridge adaptation strategies across scales (in particular between the national and local level).In most cases, an understanding of the context in which the risk plays out, and the alternative options that may be considered to manage it, are not an afterthought, but a defining feature of an appropriate climate risk analysis, which requires a much closer interplay between decision-makers and providers of climate risk information than often occurs in practice (e.g., Cardona *et al.,* 2012; Hellmuth *et al.,* 2010; Mendler de Suarez *et al.,* 2012).

These different decision-making contexts also determine the types of information required, including the climate variables of interest and the geographic and time scales on which they need to be provided. Many climate change impact assessments have traditionally focused on changes over longer time horizons (often out to 2100, though recently studies have begun to concentrate more on mid-century or earlier). In contrast, most decisions taken today have a planning horizon ranging from a few months to about two decades (e.g Wilby et al., 2009). For many such shorter-term decisions, recent climate variability and observed trends are commonly regarded as sufficient to inform adaptation (e.g. Hallegatte, 2009). However, in so doing, there is often scope to make better use of observed climatological information as well as seasonal and maybe also decadal climate forecasts (e.g. Wang *et al*., 2009; Ziervogel *et al*., 2010; Mehta *et al*., 2011; Kirtman *et al*., in prep., HLT, 2011). For longer-term decisions, such as decisions with irreversible long-term implications and investments with a long investment horizon and substantial vulnerability to changing climate conditions, longer-term climate risk information is needed (e.g. Reeder and Ranger, 2010). However, while that longer-term information is often used simply to plan for a best-guess scenario to optimize for most likely conditions, there is increasing attention for informing concerns about maladaptation (Barnett and O'Neill, 2010) and sequencing of potential adaptation options in a wider range of possible outcomes, requiring a stronger focus on ranges of possible outcomes and guidance on managing uncertainties, especially at regional, national and sub-national levels (Hall *et al*., 2012; Gersonius *et al*., 2013).

Section 21.3 summarises different approaches to impacts, vulnerability and adaptation assessment that have been applied at different scales in studies assessed in this volume, paying special attention to information contained in the regional chapters.

21.2.2. Defining Regions

As the preceding discussion implies, the most effective treatment of regional aspects of the observed and projected physical climate, its impacts and response options may frequently be at odds with the scales at which decisions actually need to be made. Earlier attempts by IPCC author teams to reconcile this mismatch are described below.

There has been an evolution in the treatment of regional aspects of climate change in IPCC reports (Table 21-2) from a patchwork of case examples in the First Assessment Report (FAR) and its supplements, through to attempts at a more systematic coverage of regional issues following a request from governments, beginning with the Special Report on the Regional Impacts of Climate Change in 1998. That report distilled information from the Second Assessment Report (SAR) for ten continental scale regions, and the subsequent Third (TAR) and Fourth (AR4) assessments each contained comparable chapters on impacts, adaptation and vulnerability in the Working Group (WG) II volumes. WG I and III reports have also addressed regional issues in various chapters, using different methods of mapping, statistical aggregation and spatial averaging to provide regional information.

[INSERT TABLE 21-2 HERE
Table 21-2: Selected examples of regional treatment in previous IPCC Assessment Reports and Special Reports (SR). Major assessments are subdivided by the three Working Group reports, each described by generic titles.]

Part B of this WG II Fifth Assessment (AR5) is the first to address regional issues treated in all three WGs. It comprises chapters on eight regions plus open oceans. These are depicted in Figure 21-1.

[INSERT FIGURE 21-1 HERE
Figure 21-1: Map showing regions described in chapters 22-30 of Part B (colours) with numbered [26] open polygons defining sub-regions over land used to summarise projected changes in climate in this chapter Note that regional specifications are approximate, as aspects of some regions or territories are treated in more than one chapter. Supplementary material contains more details of chapter assignment (Table S21-1) as well as co-ordinates of the polygons (Table S21-2).]

Some of the main topics demanding a regional treatment are:

- *Climate*, typically represented by sub-continental regions, a scale at which trends in observations tend to be fairly robust, and at which signal:noise ratios for projections from global models may also offer some confidence. While maps are widely used to represent climatic patterns, regional aggregation of this (typically gridded) information is still required to summarise the processes and trends they depict. Examples, including information on climate extremes, are presented elsewhere in this chapter, with systematic coverage of all regions provided in supplementary material. Excerpts from maps produced for an atlas of global and regional climate projections accompanying the WG I report (Collins *et al*., in prep.) can also be found in several regional chapters of this volume. In Figure 21-1, the sub-continental regions used for summarising climate information are overlaid on a map of the nine regions treated in Part B.
- *Other aspects of the climate system*, such as the cryosphere, oceans, sea level, and atmospheric composition, especially given the importance of regional changes, for example, in sea ice cover for navigation, in land movements and local ocean currents that may counter or reinforce global sea level rise, or in air pollution that can be a major regional driver of atmospheric radiative forcing as well as having a confounding effect (often localised) on plant and human health.
- *Climate change impacts* on natural resource sectors, such as agriculture, forestry, ecosystems, water resources and fisheries, which often require a classification of regional types to distinguish contrasting environmental conditions, and the livelihoods and human interventions that accompany them. Here, it is common to classify regions according to biogeographical characteristics (e.g. biomes, climatic zones, physiographic features like mountains, river basins or deltas, or combinations of these).
- *Adaptive capacity*, which is a measure of society's ability to adjust to the potential impacts of climate change, sometimes characterised in relation to social vulnerability (Füssel, 2010),, and typically represented through the use of socio-economic indicators. The regional dimensions of adaptive capacity are often displayed as maps contrasting statistical data collected, modelled or aggregated at the scale of a given administrative unit (national maps with municipal comparisons – O'Brien *et al*., 2006; e.g., global maps showing national comparisons – Füssel, 2010´).
- *Emissions* of greenhouse gases and aerosols and their cycling through the Earth system have a crucial regional expression that requires combining socio-economic data on human activities responsible for anthropogenic emissions with biogeochemical monitoring of material and gas fluxes worldwide. Since these activities are known to be responsible for anthropogenic climate change, and given that national and international policies are being designed to modify human activities, the regional units of most relevance for governments are those that provide comparison between political and economic regional groupings worldwide.
- *Global scenarios* of the major socio-economic, technological and land use drivers that affect anthropogenic emissions as well as influencing societal vulnerability to the impacts of climate change, rely heavily on integrated assessment models (IAMs) of the global energy–environment–socioeconomic system. Quantitative scenarios derived from such models need to be aggregated into regional units of relevance to stakeholders wishing to interpret and apply such scenarios. SRES was the most comprehensive scenario development exercise conducted to date to serve the climate change community, though the scenarios themselves are provided in common only for four world regions. New scenarios are under development by the global research community, and these are being designed to have more regional detail than SRES (Moss *et al*., 2010 – see Box 21-1).
- Finally, *human responses to climate change through mitigation and adaptation* demand both global and regional approaches, as emphasised in the Articles of the UNFCCC and manifest in international financing to support climate policy (not only through UNFCCC-related financial mechanisms, but also via bilateral development agencies and multilateral development banks). However, governments require access to

useable knowledge that can be applied at national and local scales. That is a regional challenge beyond the scope of an IPCC report alone, but for which these assessments should provide the appropriate context.

These give a flavour of the different approaches that are commonly employed in specifying regional units of analysis. Detailed examples of these will be referred to throughout this chapter and the regional chapters that follow. Some of the more important international political groupings of countries and territories are described and catalogued in supplementary material.

Box 21-1. A New Framework of Global Scenarios for Regional Assessment

The major socio-economic driving factors of future emissions and their effects on the global climate system were characterized in the TAR and AR4 using scenarios derived from the IPCC Special Report on Emissions Scenarios (SRES – IPCC, 2000). Scenarios were developed in a linear process, whereby socio-economic scenarios were constructed to represent key drivers of emissions, model estimates of emissions were converted to atmospheric concentrations of greenhouse gases and aerosols that in turn were used as input to climate models for simulating the climate response to the forcings. Finally, IAV assessments were conducted using combinations of the socio-economic, atmospheric composition, climate and related projections such as land cover and sea level, downscaled to the region of interest. More recently a new approach to developing climate and socio-economic scenarios has been adopted in which atmospheric concentrations were developed first (Representative Concentration Pathways or RCPs – Moss et al., 2010), thereby allowing climate modeling work to proceed much earlier in the process. Different possible Shared Socio-economic Pathways (SSPs) were to be determined later, recognizing that more than one socio-economic pathway can lead to the same concentrations of greenhouse gases and aerosols.

Four different RCPs were developed, corresponding to four different levels of radiative forcing of the atmosphere by 2100 relative to pre-industrial levels, expressed in units of Wm^{-2}: RCP 8.5, 6.0, 4.5, and 2.6 (van Vuuren et al., 2012). These embrace the range of scenarios found in the literature, and all except RCP 8.5 also include explicit stabilization strategies, which were missing from the SRES set.

In addition, five SSPs have been proposed, representing a wide range of possible development pathways (van Vuuren et al., submitted). An inverse approach is applied, whereby the SSPs are constructed in terms of outcomes most relevant to IAV and mitigation analysis, depicted as challenges to mitigation and adaptation (Chapter 19, Figure 19-x). Narrative storylines for the SSPs have been outlined (O'Neill et al., submitted) and preliminary quantifications of the socio-economic variables are underway (O'Neill et al., 2012). Priority has been given to a set of *basic* SSPs with the minimum detail and comprehensiveness needed to provide inputs to IAV and integrated assessment models, primarily at global or large regional scales. Building on the basic SSPs, a second stage will construct *extended* SSPs, designed for finer-scale regional and sectoral applications (O'Neill et al., submitted).

An overall scenario architecture has been designed for integrating RCPs and SSPs (Kriegler et al., 2012; van Vuuren et al., submitted; van Vuuren et al., 2012), for considering mitigation and adaptation policies using Shared Policy Assumptions (SPAs – Kriegler et al., submitted) and for providing relevant socio-economic information at the scales required for IAV analysis (van Ruijven et al., submitted). Additional information on these scenarios can be found in other chapters of this report (Chapter 1, Section 1.1.3, Chapter 19, Box 19-3) and elsewhere in the assessment (Blanco et al., in prep.; Collins et al., in prep.; Kunreuther et al., in prep.). However, due to the time lags that still exist between the generation of RCP-based climate change scenarios, and the development of SSPs, few of the IAV studies assessed in WG II actively use these scenarios. Instead, most of the scenario-related studies in the assessed literature still rely on the SRES. As such, for purposes of comparison it can be instructive to attempt an approximate mapping of the SRES scenarios onto the new scenario framework (see Figure 1 – Carter et al., submitted). On the horizontal axis, SRES socio-economic characteristics are matched to those of SSPs grouped according to low, medium or high challenges for adaptation (O'Neill et al., submitted; van Vuuren et al., 2012). On the vertical axis, mapping of SRES onto the RCPs is based on radiative forcing by 2100 (chapter 1, this volume). Cells in the matrix indicate SRES mappings that coincide on both axes. Note that no SRES scenarios result in forcing as low as RCP

2.6, though SRES mitigation scenarios have been applied in a few climate model experiments (e.g. the E1 scenario – Johns et al., 2011).

_____ END BOX 21-1 HERE _____

21.2.3. Introduction to Methods and Information

There has been significant debate about the definitions of key terms (Janssen and Ostrom, 2006), such as vulnerability (Adger, 2006), adaptation (Stafford Smith et al,. 2011), adaptive capacity (Smit and Wandel, 2006) and resilience (Klein et al., 2003). One explanation is that the terms are not independent concepts, but defined by each other, thus making it impossible to remove the confusion around the definitions (Hinkel 2011). The differences in the definitions is based on the different entry points for looking at climate change risk (IPCC, 2012). Figure 21-2 shows four possible entry points to adaptation science, policy and practice (based on Hinkel et al, submitted). Each of these attracts a separate set of actors and researchers and relies on different sets of methods and tools.

[INSERT FIGURE 21-2 HERE
Figure 21-2: Entry points for adaptation science, policy, and practice (based on Hinkel et al, submitted).]

Table 21-3 shows two ways to think about vulnerability, demonstrating that different objectives (e.g., improving well being and livelihoods or reducing climate change impacts) lead to different sets of questions being asked. This results in the selection of different methods to arrive at the answers. The two approaches portrayed in the middle and right hand columns of Table 21-3 have also been characterised in terms of top-down (middle column) and bottom-up (right column) perspectives, with the former identifying physical vulnerability and the latter social vulnerability (Dessai and Hulme 2004). In the middle column, the development context is the starting point (i.e., social vulnerability), on top of which climate change occurs. The task is then to identify what changes are needed in the development pathways in order to reduce vulnerability to climate change. On the right, the climate change impacts are the starting point for the analysis, revealing that people and/or ecosystems are vulnerable to climate change. One of the differences is a difference in time-frames, where a climate change focussed approach tends to look to the future to see how to adjust to expected changes, whereas a vulnerability focussed approach is centred on addressing the drivers of current vulnerability. A similar approach is described by McGray et al (2009).

[INSERT TABLE 21-3 HERE
Table 21-3: Two possible entry points for thinking about vulnerability to climate change (adapted from Füssel 2007).]

The information assessed in this chapter stems from different entry points, framings and conceptual frameworks for thinking about risk. They merge social and natural science perspectives with transdisciplinary ones. There is no single 'best' conceptual model: the approaches change as scientific thinking evolves. The IPCC itself is an example of this: IPCC SREX presented an approach that has been adjusted and adapted in Chapter 19 of this volume. Chapter 2 describes other conceptual models for decision making in the context of risk. While this diversity in approaches enriches our understanding of climate change, it can also create difficulties in comparisons. For instance, findings that are described as vulnerabilities in some studies may be classified as impacts in others; lack of adaptive capacity in one setting might be described as social vulnerability in another.

21.3. Synthesis of Key Regional Issues

This section highlights regional distributions of key issues and briefly considers related methodological issues. It focuses on material contained in the regional chapters of this volume, and considers the advantages or disadvantages

of analysing information about vulnerability, impacts and adaptation at a global or large-region scale. The value of taking a regional and global approach to vulnerability, impacts and adaptation is the ability to compare and contrast sub-regions. For example, regionally distributed impacts information can be assessed in conjunction with examinations of regional political economies to provide a context for understanding implications of impacts. Underpinning such analyses is an appreciation of ongoing and projected regional changes in the physical climate system.

Determining what belongs to a region or sub-region is addressed in 21.2, but deserves mention in the context of how to represent causal links of a geographical nature across regions and within them. Although climate change will affect different places in different ways, there will be spillover effects from one location to the next (Government Office for Science, 2011). For instance, a spillover effect occurs when there is a significant drought in a food-exporting country leading to food scarcity or insecurity in other countries (Sasson, 2012).

An examination of the nine regional chapters included in this volume of AR5 indicates that there is diversity in knowledge about climate change and its vulnerabilities, impacts and adaptation responses among and within different regions of the world. Research findings available for different global regions vary in terms of robustness, quantity, scope, and regional representativeness. With a substantial component of climate research devoted to global modelling, large scale aspects of regional climate are gradually becoming better understood over time. However, advances in knowledge about the finer details of regional climate change and its manifestations, have been more uneven, due in part to regional differences in data availability, resources and capacity.

Most regions have been conducting impacts studies for longer than they have been concerned with adaptation, so there is more region-specific information available on impacts. Some of the general issues that can be identified include the generality of much adaptation knowledge, and the limited amount of region-generated knowledge; differences in knowledge about social versus ecological vulnerability and impacts; and the difficulty of making general statements about regions that have high variability in terms of national poverty levels and adaptive capacity, such as Asia. The review below is limited to the literature that has been assessed by the regional chapters, and aims to highlight key issues to demonstrate either similarities or differences among regions. When regional chapters have omitted to describe these issues in their chapters, the assumption is that insufficient literature exists to provide evidence for any statement, but the information could also have been omitted for lack of space or because other issues are more relevant.

Aside from analyses that are conducted purely out of academic interest, most of the IAV studies assessed in this volume have been undertaken to serve a specific target audience. Thus, they can be regarded as providing information that might potentially be useful for decision-makers operating across a variety of sectors and levels of organisation (cf. Table 21-1). Here, an attempt is made to organise this information according to the broad research approach applied, distinguishing impacts and vulnerability approaches from adaptation approaches. Studies are then categorised according to scales of application ranging from global to local, which in turn helps to define the types of target audience intended. Table 21-4 has been constructed using these criteria, and is populated with examples of IAV studies drawn from other chapters in the volume as well as from a broader literature. This configuration then allows for an approximate matching of items in this Table with some of the dimensions of decision-making depicted in Table 21-1.

[INSERT TABLE 21-4 HERE

Table 21-4: Dimensions of assessments of impacts and vulnerability and of adaptation drawn upon to serve different target audiences (cf. Table 21-1). Scales refer to the level of aggregation at which study results are presented. Entries are illustrations of different types of study approaches reported and evaluated in this volume, with references given both to the original studies and to the chapters in which they are cited. Aspects of some of the studies in this table are also alluded to in section 21.5.]

The following sub-sections offer a brief synopsis of the approaches being reported in the different regional chapters, starting with impacts and vulnerability studies and then moving to adaptation studies. Table 21-4 serves as a rough template for organsing this discussion. Section 21-3-3 then provides an analysis of advances in understanding of the

physical climate system for the different regions covered in chapters 22-30, introducing new regional information to complement the large-scale and process-oriented findings presented by Working Group I.

21.3.1. Vulnerabilities and Impacts

21.3.1.1. Observed Impacts

The first step taken by many researchers undertaking climate change impact assessments, before attempting to estimate future impacts, is to investigate how past and ongoing variations in climate may have affected a given exposure unit. This is also the approach adopted in many of the regional chapters in this volume, and there is also a separate chapter in Part A of the volume (chapter 18) dedicated to this topic

The evidence linking observed impacts on biological, physical and (increasingly) human systems to recent and ongoing regional climate changes has become more compelling since the AR4 (see chapter 18). One reason for this is the improved reporting of published studies from hitherto under-represented regions of the world, especially in the tropics (Rosenzweig and Neofotis, 2013). That said, the disparity is still large between the copious evidence being presented from Europe and North America, as well as good quality data emerging from Australasia, polar regions, many ocean areas and some parts of Asia and South America, compared to the much sparser coverage of studies from Africa, large parts of Asia, central and South America and many small islands. On the other hand, as the time series of well-calibrated satellite observations become longer in duration, and hence statistically more robust, these are increasingly providing a near global coverage of changes in surface characteristics such as vegetation, hydrology, and snow and ice conditions that can usefully complement or substitute for surface observations (see Table 21-2 and chapter 18 for examples). Changes in climate variables other than temperature, such as precipitation. evapotranspiration and CO_2 concentration, are also being related to observed impacts in a growing number of studies (Rosenzweig and Neofotis, 2013). For example, ecosystem responses would be expected to follow closely any long-term trends in precipitation and water availability in some tropical and sub-tropical regions, and although trends are often confounded by modes of climatic variability such as ENSO, some evidence for precipitation-related impacts is reported from Australia (in chapter 26) and southern South America [chapter 27).

Other regional differences in observed changes worth pointing out include trends in relative sea level, which is rising on average globally (Church *et al.*, in prep.), but displays large regional variations in magnitude, or even sign, due to a combination of influences ranging from El Niño/La Nina cycles to local tectonic activity, making general conclusions about ongoing and future risks of sea level change very difficult to draw across diverse regional groupings such as small islands (see chapter 29). There are also regional variations in another ongoing effect of rising CO_2 concentration – ocean acidification, due to temperature dependence of the carbon flux to the ocean, with cooler, high latitude oceans experiencing the most rapid fluxes (chapter 30). Calcifying organisms are expected to show responses to these trends in future, though few recent trends are apparent that can be attributed to acidification effects alone. Finally, although problematic to disentangle from other potential explanatory factors, there is also mounting evidence that human adaptation is occurring as an autonomous response to ongoing climate change in some regions (e.g. draining glacial lakes to ameliorate the risk of flash flooding triggered by accelerated melting, sowing crops earlier in the spring to exploit warmer conditions, or changing reservoir operations to mitigate floods). These issues are touched on in chapters 18, 23, 25.

21.3.1.2. Future Impacts and Vulnerability

21.3.1.2.1. Impact models

The long-term monitoring of environmental variables, as well as serving a critical role in the detection and attribution of observed impacts, also provides basic calibration material used for the development and testing of impact models. These include process-based or statistical models used to simulate the biophysical impacts of climate on outcomes such as crop yield, forest productivity, river runoff, coastal inundation or human mortality and morbidity (see chapters 2-7; 11). They also encompass various types of economic models that can be applied to

evaluate the costs incurred by biophysical impacts (see, for example, chapters 10 and 17). There are also integrated assessment models (IAMs), Earth System Models, and other more loosely linked integrated model frameworks that might incorporate several different biophysical impacts as well as economic and perhaps other processes (e.g. climate, land use change, global trade) and the various interactions and feedbacks between them. For descriptions of these, see chapter 17 and (Flato *et al*., in prep.).

21.3.1.2.2. Vulnerability mapping

A second approach to projecting potential future impacts, is to construct vulnerability maps. These usually combine information on three components: exposure to a hazard – commonly defined by the magnitude of climate change, sensitivity to that hazard -- the magnitude of response for a given level of climate change, and adaptive capacity – describing the social and economic means to withstand the impacts of climate change (IPCC, 2001). Key indicators are selected to represent each of the three components, which are typically combined into a single index of vulnerability. Indicators are usually measured quantities taken from statistical sources (e.g. income, population), or have been modelled separately (e.g. key climate variables). Vulnerability indices have received close scrutiny in several recent reviews (Füssel, 2010; Hinkel, 2011; Malone and Engle, 2011; Preston *et al*., 2011), and a number of global studies have been critiqued by Füssel (2010).

A variant of vulnerability mapping is risk mapping. This commonly identifies a single indicator of hazard (e.g. a level of flood expected with a given return period), which can be mapped accurately to define those regions at risk from such an event (e.g. in a flood plain). Combined with information on changing return periods of such events under a changing climate would enable some estimate of altered risk to be determined.

21.3.1.2.3. Experiments

A final approach for gaining insights on potential future impacts, concerns physical experiments designed to simulate future altered environments of climate (e.g. temperature, humidity and moisture), and atmospheric composition (e.g. CO_2, surface ozone and sulphur dioxide concentrations). These are typically conducted to study responses of crop plants, trees and natural vegetation,. using open top chambers, greenhouses or free air gas release systems (Craufurd *et al*., 2013).

21.3.1.2.4. Scale issues

Impact models operate at a range of spatial and temporal resolutions, and while their outputs are sometimes presented as fine resolution maps, key model findings are rarely produced at the finest resolution of the simulations (i.e. they are commonly aggregated to political or topographic units of interest to the target audience, e.g. watershed, municipality, national or even global). Aggregation of data to coarse-scale units is also essential for allowing comparison of outputs from models operating at different resolutions, but it also means that sometimes quite useful detail may be overlooked when model outputs are presented at the scale of the coarsest common denominator. Conversely, if outputs from impact models are required as inputs to other models, the outputs may need to be harmonized to a finer grid than the original data. In such cases, downscaling methods are commonly applied. This was the case, for example, when providing spatially explicit projections of future land use from different IAMs for climate modellers to apply in the CMIP-5 process (see Box 21-1 – Hurtt *et al*., 2011). It is also a common procedure used in matching climate model outputs to impact models designed to be applied locally (e.g. over a river basin or an urban area).

Even if the same metrics are being used to compare aggregate model results (e.g. developed versus developing country income under a given future scenario) estimates may have been obtained using completely different types of models operating at different resolutions. Moreover, many models that have a large-scale coverage (e.g. continental or global) may nonetheless simulate processes at a relatively fine spatial resolution, offering a potentially useful source of spatially explicit information that is unfamiliar to analysts working in specific regions, who may defer to

models more commonly applied at the regional scale. Examples include comparison of hydrological models with a global and regional scope (Todd *et al*., 2011) and bioclimatic models of vascular plant distributions with a European and local scope (Trivedi *et al*., 2008). Vulnerability mapping exercises can also be undermined by the inappropriate merging of indicator datasets that resolve information to a different level of precision (e.g. Tzanopoulos *et al*., 2013). There is scope for considerably enhanced cross-scale model intercomparison work in the future, and projects such as AgMIP (Rosenzweig *et al*., 2013) and ISI-MIP (Schiermeier, 2012, – see section 21.5) have provision for just such exercises.

21.3.2. Adaptation

Although a large portion of adaptation knowledge, for instance, is based on conclusions from case studies in specific locations, the conceptual findings are typically applied globally. Much of this theory on adaptation guides understandings in the different regions. This is especially the case for developing regions. Thus, regional approaches to adaptation vary in their degree of generality. One of the most striking differences between regions in terms of adaptation is the extent to which it has been studied and implemented. Australia and Europe have invested heavily in research on adaptation, and the result is a rich body of literature published by local scientists. The ability to advance in adaptation knowledge may be related to the amount and quality of reliable climate information, the lack of which has been identified as a constraint to developing adaptation measures in Africa. Many case studies, especially of community-based adaptation, stem from Asia and Africa, but the majority of this work has been undertaken and authored by international non-governmental organisations, frequently featuring their own project work, as well as by non-local researchers. In Africa, most adaptation work is considered to be pilot, and seen as part of learning about adaptation, although there has been significant progress since the AR4.

Most regional chapters report lags in policy work on adaptation. While most European countries have adaptation strategies, few have been implemented. Lack of implementation of plans is also the case for Africa. In North, Central and South America, adaptation plans are in place for some cities. In Australasia, there are few adaptation plans. At the same time, civil society and local communities have the opportunity to play a role in decision making about adaptation in Europe and Asia. In Africa, social learning and collective action are used to promote adaptation. Adaptation is observed as mostly autonomous (spontaneous) in Africa, although socio-ecological changes are creating constraints for autonomous adaptation. There is a disconnect in most parts of Africa between policy and planning levels. In the case of UNFCCC-supported activities, such as National Adaptation Programmes of Action, few projects from the African and Asian least developed countries have been funded, thus limiting the effectiveness of these investments. Several chapters (Africa, Europe, North America, Central and South America and Small Islands) explicitly point out that climate change is only one of multiple factors that affect societies and ecosystems and drives vulnerability or challenges adaptation.

Some chapters (Polar Regions, North America, Australasia) emphasise the challenges faced by indigenous peoples and communities in dealing with climate change. Although they are described as having some degree of adaptive capacity to deal with climate variability, shifts in lifestyles combined with a loss of traditional knowledge leave many groups more vulnerable to climate change. Also, traditional responses have been found to be maladaptive because they are unable to adjust to the rate of change, or the broader context in which the change is taking place, as seen in the Arctic. In response to changing environmental conditions, people are taking on maladaptive behaviour – for instance, by going further to hunt because of changed fish-stocks and thus exposing themselves to greater risk, or changing to different species and depleting stocks. The limits to traditional approaches for responding to changing conditions has also been observed in several Small Island States.

Most populated regions have experience with adaptation strategies in agriculture, where exposure to the impacts of climate variability over centuries provides a starting point for making adjustments to new changes in climate. Water and land use management strategies stand out in the literature in common across all of the main continental regions.

The link between adaptation and development is explicit in Africa, where livelihood diversification has been key to reducing vulnerability. At the same time, there is evidence that many short-term development initiatives have been responsible for increasing vulnerability. Other chapters mention constraints or barriers to adaptation in their regions.

For example, the low priority accorded to adaptation in parts of Asia, compared to more pressing issues of employment and education, is attributed in part to a lack of awareness of the potential impacts of climate change and the need to adapt, a feature common to many regions. All developing regions cite insufficient financial resources for implementing adaptation as a significant limitation.

21.3.3. Regional Aspects of the Physical Climate System

This section is intended to provide a summary assessment of regional climate information, particularly regarding cross regional aspects and new emerging knowledge since the AR4, to place the regional chapters in a broader context. It is not intended to provide a detailed region-by-region assessment of information, which can be found in the WGI Chapter 14, the WGI Atlas and the WGII regional chapters. Also, as noted in 21.2.2 there are many different ways in which regions can be defined. However, many of these regional definitions are relevant to decision making and so generating climate change information for such regions is relevant to climate policy. This issue is explored using the example of African economic regions in Box 21-2. Similarly some emphasis is also given to material deriving from dynamical and statistical downscaling work which is often of greater direct relevance for IAV applications than coarser resolution global climate model data.

_____ START BOX 21-2 HERE _____

Box 21-2. Developing Regional Climate Information Relevant to Political and Economic Regions

In most world regions, countries form political and/or economic groupings and coordinate activities within these groups with stated aims such as furthering the interests of the constituent nations and their peoples. Such groupings provide a natural forum for coordinating action on transboundary issues within their region or responding to influences external to it. Climate is an important factor in the economies of many nations and the lives of their peoples and is well understood to have both transboundary dimensions and to involve remote influences. This has long been recognised, with national and regional weather-forecasting being highly dependent on globally coordinated activities, more recently with the advent of the WMO-sponsored Regional Climate Outlook Forums (Ogallo et al., 2010) and Global Framework for Climate Services (Hewitt et al., 2012). These links are also being made regionally. For example, the Intergovernmental Authority on Development (IGAD) of the countries of the Greater Horn of Africa (GHA) recognizes that the region is prone to extreme climate events such as droughts and floods which have severe negative impacts on key socio-economic sectors in all its countries. In response it has set up the IGAD Climate Prediction and Applications Centre (ICPAC) to provide and support application of early warning and related climate information for the management of climate-related risks (for more details see http://www.icpac.net/). As socio-economic factors are important contributors to both the vulnerability and adaptability of human and natural systems, it clearly makes sense to summarise and assess available climate and climate change information for these regions as it will be relevant to policy decisions taken within these groupings on their responses to climate change.

The accompanying figure presents summary climate change information for 5 political/economic regions covering much of Africa. These are the Common Market for Eastern and Southern Africa (COMESA6), the Economic Community of Central African States (ECCAS), the Economic Community of West African States (ECOWAS), the Southern African Development Community (SADC) and the Arab Maghreb Union (UMA). Each graph shows observed7 and simulated variations in past and projected future annual average temperature and precipitation. Generally the observed regional temperature variations reflect global changes, with warming from 1901 to 1940, followed by a relatively stable period until 1970 and then steady warming thereafter. Consistent with simulations available for the AR4 (Christensen et al. 2007), the observed warming is contained within the envelope of the simulations of global climate models driven with observed changes in all known external drivers (pink band) in all five regions. The 1901-1940 warming in these simulations is partly distinguishable from what would have been expected if anthropogenic activities had not interfered with the climate, as estimated by simulations with observed changes in natural external drivers only (blue band). In all five regions there is a distinct difference by the beginning of the 21st century, which is projected to continue to widen if emissions broadly follow the RCP4.5 or RCP 8.5 emissions pathways (light blue and red bands). In contrast, precipitation has generally remained steady, relative to

its year-to-year variability, without major changes driven by anthropogenic emissions in either the past or future as estimated from the climate model simulations. Exceptions are an observed drying over ECOWAS between the 1960s and 80s (Greene et al. 2009, Hoerling et al. 2006) and a simulated drying of about 15% over the 150-year period over UMA. It should also be noted that, unlike temperature, observed precipitation variability sometimes lies outside the envelope of the simulations from the models, which is consistent with the simulations representing precipitation effectively averaged over larger areas than is represented by the sparse station data underpinning the observed estimates.

[INSERT BOX 21-2 FIGURE HERE
Box 21-2 Figure Caption: Observed and simulated variations in past and projected future annual average precipitation and temperature over five African regions, Common Market for Eastern and Southern Africa (COMESA), the Economic Community of Central African States (ECCAS), the Economic Community of West African States (ECOWAS), the Southern African Development Community (SADC) and the Arab Maghreb Union (UMA). Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations, taken from the CMIP5 archive (Taylor et al. 2012), driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30) and by two of the RCM emissions/ concentrations scenarios (van Vuuren et al., 2011), "RCP4.5" (68) and "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. The regions are described in Chapter 22 (section 22.1.2) but the COMESA region labelled here covers COMESA north and includes Rwanda, Uganda, and Kenya. Precipitation is included for land territories only, while temperature is included for both land and exclusive economic zone territories. The observational datasets used are GISTEMP (Hansen et al. 2010), HadCRUT3 (Brohan et al. 2006), and MLOST (Smith et al. 2008) for temperature, and CMAP (Xie and Arkin 1997), CRU TS 3.10 (Mitchell and Jones 2005), GPCP v2.2 (Adler et al. 2003), and PRECL (Chen et al. 2002) for precipitation. These suffer in some areas from sparse monitoring coverage.]

The information presented here is illustrative of an approach to presenting a simple summary of observed and projected or predicted climate changes for political/economic regions. The graphs convey important information on the ability of the models to reproduce the observed trends in temperature, that they simulate significantly lower temperatures without the anthropogenic forcings and how future temperatures under typical business as usual emissions paths will continue to rise. The main messages on precipitation are that for most regions the models project that future variations in the annual average will be similar to those simulated for the past and that the models may not capture all of the observed precipitation variability. Without further refinement, this information would suggest that future precipitation scenarios should be significantly informed by the past observed variability. However, at least two additional factors should be taken into account. The first is that these results do not convey information on trends or projected changes in precipitation on seasonal or shorter time-scales . Secondly, theoretical and model evidence indicates that it is not unreasonable to expect that in a warming climate many regions could experience changes in precipitation variability and extremes even with no changes in the average (Allen and Ingram, 2002).

_____ END BOX 21-2 HERE _____

Understanding the confidence that can be placed in climate information used in assessing climate vulnerability and impacts and decision making on adaptation is of crucial importance. This information is relevant and used over a very wide range of scales and it comes with a similarly wide range of confidence. Using a similar classification of spatial scales to that presented in Table 21-4, Table 21-5 provides a summary overview of the levels of confidence that are seen in two of the basic climate variables of relevance, surface temperature and precipitation. This information is drawn from the extensive assessment and supporting literature from the IPCC SREX report, the AR5 WG1 report and some discussion of relevant methodologies and related issues and results are also presented in section 21.5.

[INSERT TABLE 21-5 HERE
Table 21-5: Reliability of climate information on temperature and precipitation over a range of spatial and temporal scales. Reliability is assigned to one of seven broad categories from Very High (VH) to Medium (M) through to

Very Low (VL). Reliability of information on past climate depends on the availability and quality of observations and in general is higher for temperature as it is easier to observe and a temperature observation at a given location is more representative of temperatures in the surrounding areas than a precipitation observation. In the case of future climate change, which relies on using models of the climate system run into the future, reliability depends on the ability of these models to simulate well the processes that lead to these changes. Again, information on temperature is generally more reliable but this is due to there being more confidence in our ability to simulate the past changes in temperature and our understanding of the processes that cause these changes than is the case for precipitation.

There are significant variations in the reliability of past and future climate information at different temporal and spatial scales, in general at finer scales the information tends to be less reliable given the need for either a greater density observations or models maintaining accuracy at high resolutions. Also, there are significant geographical variations, again the root cause being different for information on past climate than on future climate change. For past climate observation availability and quality is again key and in many regions, especially for precipitation, there are issues with either or both. For future climate change, data availability is less of an issue with the advent of large ensembles of climate model projections but quality can be a significant problem in some regions where the models perform poorly and there is little confidence that the processes driving the projected changes are accurately captured. [Table is an incomplete placeholder pending more complete information from WG1 and other sources]]

In a regional context, the results developed by the AR5 WG1 Chapter 14, Regional Phenomena, are particularly relevant including their evaluation of confidence in models' ability to simulate temperature, precipitation and phenomena together with an assessed implication for the general level of confidence in projections for 2080-2099 of regional temperature and precipitation (Table 21-6).

[INSERT TABLE 21-6 HERE
Table 21-6: Placeholder for a table to be derived from the AR5 WG1 Ch14 table (still in development by WG1) evaluating confidence in GCM simulations and projections of temperature and precipitation and linked regional climate phenomena currently being finalised for the final draft of that chapter.]

21.3.3.1. Atmosphere and Land Surface

21.3.3.1.1. Observed changes and attribution of causes

New estimates of global surface air temperatures for the period of 1901-2010 give an estimated warming of about 0.8 C, and about 0.5 C for the period 1979-2010, when estimated by a linear trend, while the warming for the period 1986-2005 (reference period) compared to 1886-1905 is 0.66 +/- 0.06. Positive annual temperature trends are found over most land areas, particularly since 1979, except regions of central-northern Australia and central western South America (WGI Chapter 2). Relatively large trends have occurred over Europe, the Sahara and middle East, central and northern Asia.

Confidence in global precipitation estimates is low to medium due to incompleteness of data, however when all land areas are filled in using reconstruction methods, land precipitation shows little change since 1900, in contrast to the AR4 assessment of a small increasing trend. The NH mid to high latitudes show an increasing trend, although confidence is also low due to incompleteness of data. Observed precipitation trends show a high degree of spatial and temporal variability, with the occurrence of both positive and negative values (WGI Chapter 2).

Improved detection and attribution methods have shown that it is *extremely likely* that human activities have caused most of the global warming (more than 50%) since the 1950s and that this warming is not due to internal variability alone. The human influence on warming is *likely* over every inhabited continent (there are insufficient data to make an assessment over Antarctica). It is also *likely* that the human influence has altered sea level pressure patterns and related circulations. Attribution of changes in hydrological variables is less confident due to the lack of data though a human influence on zonal patterns of global and on high northern latitude precipitation changes has been detected (WGI Chapter 10).

21.3.3.1.2. Long-term projections

Analyses of the CMIP5 ensembles have shown that, in general, the mean temperature and precipitation change patterns are similar to those found for CMIP3, with a pattern correlation between CMIP5 and CMIP3 ensemble mean late 21st century change greater than 0.9 for temperature and greater than 0.8 for precipitation (WGI Chapter 12). This implies that the regional characteristics of change in the CMIP5 ensemble lead to conclusions generally consistent with those found in the AR4. Given the increased comprehensiveness and higher resolution of the CMIP5 models this adds an element of robustness to the projected changes.

Some of the main characteristics of the projected late 21st century temperature and precipitation changes derived from the CMIP5 ensemble can be broadly summarized as follows (from WGI Chapter 12 and the Atlas) with further details provided in Box 21-3 and accompanying supplementary material.

Temperature

Global-mean surface temperatures for 2081–2100 (relative to 1986–2005) will *likely* be (5–95% range of the CMIP5 models) : 0.2–1.8°C (RCP2.6), 1.0–2.6°C (RCP4.5), 1.3–3.2°C (RCP6.0), 2.6–4.8°C (RCP8.5).

Changes in global land surface air temperature exceed changes in global mean surface air temperature with continental interiors show the largest changes (Figure 21-3). Regions that exhibit relatively high temperature changes (often 50% or more larger than the global mean) are high latitude NH land areas and the Arctic (especially in DJF), Central North America, portions of the Amazon, Mediterranean, and Central Asia in JJA.

[INSERT FIGURE 21-3 HERE
Figure 21-3. CMIP5 ensemble median ratio of local:global average temperature change in the period 2070-2100 relative to 1961-90 under the RCP8.5 emissions/concentrations scenario. The values are displayed on a common 2.5ºx3.75º grid onto which each models' data were regridded and they were calculated as follows: (i) for each model calculate the local change between 1961-90 and 2070-2100 at each grid cell and divide by the global average change over the same period; (ii) identify the median value across the ensemble at each grid cell.]

Precipitation

Changes in precipitation are regionally highly variable, with many areas projected to experience positive change and others exhibiting negative changes (Box21-3). The high latitudes will *very likely* experience greater amounts of precipitation, many mid-latitude arid and semi-arid regions will *likely* experience reduced precipitation, many moist mid-latitude regions will *likely* experience increased precipitation (AR5 WG1 Ch 12).

Basic information on observed historical changes and projected 21st century changes by the CMIP5 ensemble is presented in each of the following regional chapters, and Box 21-3 provides a description of this material.

_____ START BOX 21-3 HERE _____

Box 21-3. Summary Regional Climate Projection Information

To provide some context on observed and future climate changes relevant to the risks associated with climate change vulnerability and impacts and the decision-making on adaptations being planned and implemented in response to these risks summary figures on observed and projected changes in temperature and precipitation are presented in the following regional chapters. These figures show observed changes in annual average surface air temperature and precipitation over the inhabited continental regions for 1986-2005 compared to 1906-1925 and then projections of these annual average variables under two future emissions/concentrations scenarios (RCP 4.5 and 8.5) and two time periods (2046-2065 and 2081-2100, compared to 1986-2005). An example of one of these figures is

given below for Africa (Figure 1). Observed changes are displayed when significant (see details in figure caption below)

[INSERT BOX 21-3 FIGURE 1 HERE

Box 21-3 Figure 1 Caption: Observed and projected changes in annual average temperature and precipitation over Africa. The observations are taken from the CRU TS 3.1 dataset (Harris et al., 2012) and the projections from the CMIP5 multi-model archive (Taylor et al. 2012). Projected changes are shown for the mid-21st century (2046-2065) and the late-21st century (2081-2100) from a baseline period of 1986-2005 under the RCP 4.5 and 8.5 emissions/ concentrations scenarios (van Vuuren et al., 2011). For the observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through to 1925. For the CMIP5 projections, four classes of results are displayed:

1) White indicates areas where for >66% of models the change in annual average precipitation is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Thus in these regions more than 2/3 of models show no significant change (using this measure of significance) in annual average precipitation. However, note that this does not imply no significant change in precipitation averaged over seasonal or shorter time-scales such as months to days.
2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions more than 2/3 of models show a significant change in annual average precipitation but less than 2/3 agree on whether annual average precipitation will increase or decrease.
3) Colors with circles indicate the change in annual average precipitation averaged over all models in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. In these regions more than 2/3 of models show a significant change in annual average precipitation and more than 2/3 agree (but less than 90%) agree on whether annual average precipitation will increase or decrease.
4) Colors without circles indicate the change in annual average precipitation averaged over all models in areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether annual average precipitation will increase or decrease.

For models which have provided multiple realizations for the climate of the recent past and the future, results from each realisation are first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated.]

These figures provide a very broad overview of the projected regional climate changes but in dealing with only annual averages they are not able to convey any information about projected changes in seasonal or shorter timescales. In addition, they are derived solely from the CMIP5 GCMs and do not display any information from the CMIP3 database which is still very relevant to the IPCC WG2 as CMIP3 data are widely used in many of the studies assessed within the AR5 WG2 report. To provide extra context on projected future climate changes which deals with these issues two additional sets of example figures are presented here which display temperature and precipitation changes at the seasonal and daily timescale.

Projected seasonal changes are displayed as area averages over the regions defined in the IPCC SREX report, “Managing the risks of extreme events and disasters to advance climate change adaptation” (IPCC 2012), and compare these for the four RCP scenarios and three of the SRES scenarios (Figure 2). In this example provided for the SREX regions which lie in Central and South America (see Figure 21.1 for their geographical ranges), regional average changes in temperature and precipitation for the period 2071-2100 compared to a baseline of 1961-1990 are plotted for the four standard three months seasons with each CMIP3 or CMIP5 projected change represented by a symbol. (Thirty year periods were chosen for consistency with the figures displayed below showing changes in daily temperatures and precipitation.) Symbols showing the CMIP3 model projections are all grey but differ in shape depending on the driving SRES concentrations scenario and those showing the CMIP5 projections differ in colour depending on the driving RCP emissions/concentrations scenario (see figure legend for details). Figures presenting similar information for the SREX regions contained in the other inhabited continents are presented in supplementary figures S-Box21-CMIP5-boxplots.

[INSERT BOX 21-3 FIGURE 2 HERE
Box 21-3 Figure 2 Caption: Regional average change in seasonal mean temperature and precipitation over five regions covering South and Central America for the period 2070-2100 relative to 1961-90 in GCM projections from the CMIP5 ensemble under four RCP scenarios (van Vuuren et al., 2011) compared with GCM projections from the CMIP3 ensemble under three SRES scenarios (IPCC, 2000). Regional averaged are based on SREX region definitions (see Figure 21-RegAmplFac). Temperature changes are given in ºC and precipitation changes in mm/day with axes scaled relative to the maximum changes projected across the range of models.]

Projected changes in daily temperature and precipitation are presented for two example indices, the 90th percentiles of the daily maximum temperature and daily precipitation amounts on wet days (a wet day is defined as a day when more than 1mm of rain falls and defining the statistic of interest for wet days only allows data from regions with only a few rainy days per year to be easily included in the calculations). Due to concerns over the number of events that need to be sampled to generate robust statistics on changes in extremes (Kendon et. al, 2008) changes in these indices were calculated over 30 year periods (1961-1990 for the baseline and two future periods, 2041-2070 and 2071-2100) and the analysis was focused on the less extreme daily events. For consistency with the example summary regional figure, Figure 1, projected changes were calculated for RCPs 4.5 and 8.5 and the results are displayed as a map for a given continental region and also regional averages over the SREX regions within that continent. Two examples are provided, for temperature changes over N America (Figure 3) and precipitation changes over Asia (Figure 4), and a full set can be found in supplementary figures S-Box21-CMIP5-dailychanges.

Box 21-3 Figure 4 Caption: The frequency of 'very wet days' (defined here as the 90th percentile of daily precipitation on wet days during a baseline period of 1961-1990 with wet days defined as days with 1mm of precipitation or more) projected for the 2071-2100 period by the CMIP5 GCMs. Top: Ensemble median frequency of 'very wet days' during 2070-2100 under RCP8.5. Bottom: Box-and-whisker plots indicate the range of regionally-averaged 'very wet day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5. Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of 'Very wet days' of 10% is represented on the graphs by the dashed line.
[Figure displayed is a semi-placeholder. Final figure will have box-plots arranged around the map.]]

_____ END BOX 21-3 HERE _____

Studies have also attempted to obtain regional information based on pattern scaling techniques in which regional temperature and precipitation changes are derived as a function of global temperature change. For example, in a recent paper Harris et al. (2012) used a Bayesian method complemented by pattern scaling and performance-based model weighting to calculate Probability Density Functions (PDFs) of temperature and precipitation change over sub-continental scale regions (Figure 21.4) under the A1B emission scenario based on an ensemble of simulations constrained to observations for the late 21st century. Although most impact studies might need local rather than sub-continental scale information, Figure 21.4 illustrates how the identification of the evolution of different percentiles of the distribution might be especially useful for risk assessment studies. Pattern scaling is indeed a valuable tool to estimate mean regional changes and associated uncertainty. It was for example used to calculate PDFs of temperature and precipitation change over different regions by Watterson (2008), Watterson and Whetton (2011), Watterson (2011), and Giorgi (2008).

[INSERT FIGURE 21-4 HERE
Figure 21-4: Evolution of the 5%, 17%, 33%, 50%, 66%, 83% and 95% percentiles of the distribution functions for annual surface air temperature changes (upper panel) and annual precipitation (lower panel) for the Giorgi-Francisco (2000) regions and the globe with the A1B forcing scenario. Twenty year means relative to the 1961-1990 baseline are plotted in decadal steps using a common y-axis scale. The 5%, 50% and 95% percentile values for the period 2080-2099 are displayed for each region. (From Harris et al. 2012)]

21.3.3.1.3. Near-term decadal predictability

Compared to CMIP3, CMIP5 has an additional emphasis on near-term climate change, including intitialized experiments aimed at assessing decadal predictability. The uncertainty in near term projections is dominated by internal variability of the climate system, initial ocean conditions and inter-model response, rather than GHG forcing, and in fact the internal variability grows in importance at smaller spatial and temporal scales (Hawkins and Sutton 2009, 2010). Conversely, GHG forcing uncertainty becomes increasingly important on longer time scales, especially for surface air temperature (Hawkins and Sutton, 2009, 2010). Global warming for the period of 2016-2035 compared to 1986-2005 based on the CMIP5 multi model ensemble is *likely* of 0.4-1.0ºC, *more likely than not* closer to the lower end 0.4 C, and spatial patterns of near term warming are generally consistent with the AR4 (WGI Chapter 11). Differences across RCPs are small and about 50% of the warming is understood as the committed response to past emissions (WGI Chapter11). In terms of precipitation change patterns, it is more *likely than not that* in the next decade's precipitation will increase in regions of high precipitation and decrease in relatively dry regions (WGI Chapter 11).

The CMIP5 ensemble includes a new set of multidecadal near term prediction experiments (up to 2035) with initialized ocean state (WGI Chapter 11). Results from these experiments and analyses of un-initialized simulations show that there is a medium amount of evidence of the predictability of yearly to decadal averages of temperature both for the global average and for some geographical regions. Multi-model results for precipitation indicate a generally low level of predictability, except for some regions at higher northern latitudes and longer timescales. There is medium evidence that the Atlantic Multidecadal Variability (AMV) and Pacific Decadal Variability (PDV) patterns of climate variation exhibit predictability on timescales up to a decade (WGI Chapter 11). It is also shown that indices of global-mean temperature and Atlantic multi-decadal variability have statistically significant positive correlation with observations for most forecast periods (i.e., four-year averages ranging from 1–4 to 6–10 years) considered. At the regional scale, the retrospective prediction experiments for forecast periods of 1 to 10 years have statistically significant correlations with the observations (greater than 0.6, significant at the 95% confidence level) over much of the globe for temperature and over several regions for precipitation. [Section 11.2.2]. The correlation is improved by the ocean initialization over the North Atlantic, regions of the South Pacific and small continental areas of the Northern Hemisphere for temperature, while the effect of initialization for precipitation is negligible.

21.3.3.1.4. Changes in hydroclimate and extreme events

Changes in the characteristics of surface hydroclimatology, and especially extremes, are fundamental for an assessment of related impacts. Based on an analysis of observations, global and regional climate model simulations, Giorgi et al. (2011) defined an index of hydroclimatic intensity (HY-INT) incorporating a combined measure of precipitation intensity and mean dry spell length. They found that a ubiquitous global and regional increase in HY-INT was a strong hydroclimatic signature in model projections consistent with observations for the late decades of the 20th century, suggesting that HY-INT may be an important hydroclimatic indicator of global warming for use in detection/attribution and impact studies. The increase in intensity of precipitation (and thus risk of flood) and summer drought occurrence over mid-continental land areas is a robust signature of global warming, both in observations for recent decades and in model projections (Trenberth 2011).

CMIP5 projections of temperature extremes essentially confirm results from the CMIP3, namely a decrease in the frequency of cold days and nights, an increase in the frequency of warm days and nights, an increase in the duration of heat waves and an increase in the frequency and intensity of high precipitation events, both in the near term and

far future (SREX Report, WGI Chapter 12). Some relevant summary statistics on CMIP5 projections of changes in daily temperature and precipitation extremes over the main continents and the SREX regions (Figure 21.1) are introduced in Box 21-3 and accompanying supplementary material.

Concerning tropical cyclones, there is still little confidence in past trends and near term projections of tropical cyclone frequency and intensity (Senevirante et al 2012; SREX Report). The global tropical cyclone frequency is projected to either not change or decrease and show different responses at the basin scale (Knutson et al. 2010). Concurrently, a *likely* overall increase in maximum wind speed and precipitation is expected, but region-specific conclusions are still uncertain (Knutson et al. 2010).

Regional circulations, such as the monsoon, are expected to change. Seth et al. (2011) and Sobel and Camargo (2011) found in the CMIP3 ensemble of 21st century projections a redistribution of precipitation from spring (early monsoon phase) to summer, mature phase in both northern (North America, West Africa and Southeast Asia) and southern (South America, Southern Africa) hemisphere monsoon regions. More generally, model projections indicate a prevailing decrease of the intensity of monsoon circulation, but an increase of monsoon rain due to the greater water-holding capacity of the atmosphere along with later monsoon onset leading to longer monsoon seasons (WGI Chapter 14).

21.3.3.1.5. Major modes of variability

ENSO is the mode of variability that has received most attention from a climate impacts point of view with significant effects on human and natural systems (http://iri.columbia.edu/climate/ENSO/societal/index.html). Seasonal forecasting of El Niño behavior has significant skill (AR4-WG1 Chapter 8) and is used to providing advanced warnings of its impacts worldwide. Recent research has underscored the complexity of the ENSO system and provided some explanation for this, such as the non-symmetric amplitude between El Nino and La Nina (An, 2005, WGI Chapter 14). While we do not have definitve answers regarding the effect of anthropogenic forcing on ENSO, we know that it experiences decadal and longer term modulations that occur with relatively small changes in the mean climate state of the tropical Pacific. Model improvements in the reproduction of ENSO are evident in some of the models used for the CMIP5 simulations. For example CCSM4 shows good performance in reproducing the asymmetry between El Nino and La Nina durations (Deser et al., 2011). Although model projections indicate that ENSO remains a major mode of tropical variability, there is little evidence to indicate changes forced by GHG warming which are outside the natural modulation of ENSO occurrences.

The North Atlantic Oscillation (NAO) is a major model of variability for the northern Hemisphere mid-latitude climate. Model projections indicate that the NAO phase is *likely* to become slightly more positive (WGI Chapter 14) due to GHG forcing, but the NAO will be dominated by its large natural fluctuations. Model projections indicate that the Southern Annular Mode (SAM), a major model of variability for the southern hemisphere, is *likely* going to weaken as ozone concentrations recover through the mid-21st century (WGI Chapter 14).

21.3.3.1.6. Results from dynamical and statistical downscaling experiments

Dynamical and statistical downscaling techniques have been increasingly applied to regional climate change simulations, often as part of multi-model intercomparison projects. In this regard a new international program has been implemented, the COordinated Regional Downscaling Experiment (CORDEX, Giorgi et al. 2009), that will provide a framework for the assessment of dynamical and statistical downscaling techniques and the production of a new generation of climate projections over regions worldwide for use in impact and adaptation work. A few papers have already become available describing the first CORDEX experiments over different domains, and it is expected that CORDEX will in fact become a reference framework for downscaling experiments in the same way that CMIP5 is for global model experiments.

A large number of RCM-based climate projections for the European region were produced as part of the European projects PRUDENCE (Christensen et al. 2007; Deque et al. 2007) and ENSEMBLES (Hewitt 2005; Deque and

Somot 2010) where multiple RCMs have been run as driven by different GCMs for various scenarios . They all provide a generally consistent picture of seasonally and latitudinally varying patterns of change, which Giorgi and Coppola (2007) summarized with the term "European Climate Change Oscillation (ECO)", consisting of a dipole pattern of precipitation change, with decreased precipitation to the south (Mediterranean) and increased to the north (Northern Europe) following a latitudinal/seasonal oscillation centered over the Mediterranean in winter and moving northward to central Europe in summer. As a result, the Mediterranean region is projected to be much drier and hotter than today in the warm seasons (Giorgi and Lionello 2008), and central/northern Europe much warmer and wetter in the cold seasons (Kjellstrom and Ruosteenoja, 2007). An increase of interannual variability of precipitation and summer temperature is also projected throughout Europe, with a decrease in winter temperature variability over Northern Europe (Schar et al. 2004; Giorgi and Coppola 2007; Lenderink et al. 2007). The broad patterns of change in regional model simulations generally follow those of the driving global models (Christensen and Christensen 2007; Deque et al. 2007), however fine scale differences related to local topographical, land use and coastline features are produced. For example, east-west winter precipitation change dipoles are projected across the Appenine chain as a result of the effect of this mountain system (Gao et al. 2006; Coppola and Giorgi 2010). These RCM simulations also projected an increase in a broad range of climate extremes (Beniston et al. 2007), such as heat waves, maximum drought length and number of hot days, especially over Central and Southeastern Europe and the Mediterranean (Gao et al. 2006; Beniston et al. 2007; Kjellstrom et al., 2007; Diffenbaugh et al., 2007), precipitation intensity and extremes especially over Central, Western and Northern Europe (Frei et al. 2006; Beniston et al. 2007, Buonuomo et al. 2007; Fowler et al. 2007; May 2008; Fowler and Ekstrom 2009; Kysely and Beranova, 2009; Kendon et al. 2010; Hanel and Buishand 2011; Kysely et al. 2011). Studies have also consistently shown that the distribution of seasonal temperature anomalies in the future is expected to be broader than today, particularly over central and southern Europe. This will lead, along with a shift of the distribution, to a higher frequency and intensity of extreme hot and dry summers (e.g. Schar et al. 2004; Seneviratne et al. 2006; Beniston et al. 2007; Coppola and Giorgi 2010), for which a substantial contribution is given by land-atmosphere feedbacks (Seneviratne et al. 2006; Fischer et al. 2007; Seneviratne et al. 2010; Hirschi et al. 2011; Jaeger and Seneviratne 2011). In general, the Mediterranean region is consistently projected to be much more arid than today (Rowell and Jones 2006; De Castro et al. 2007; Giorgi and Lionello, 2008; Gao and Giorgi 2008; Onol and Semazzi 2009; Trnka et al. 2011), and coupled atmosphere-ocean RCM simulations indicate that ocean feedbacks can significantly amplify the regional climate change signal over different regions of Europe (Somot et al. 2008). Concerning storminess projections , some studies based on ensembles of RCM simulations indicate a prevailing increase in winter mean daily and peak wind speed over Northern Europe (Rockel and Woth 2007; Albrecht et al. 2010, Bengtsson et al. 2009, Ulbrich et al. 2009), while more mixed results are found over the Mediterranean (Lionello et al. 2008; Giorgi and Lionello 2008). Recently, the first set of high resolution (dx = 12.5 km) projections over the EURO-CORDEX domain have been completed (Jacob et al. 2013). Both for the RCP8.5 and RCP4.5 scenarios the temperature and precipitation change patterns are generally consistent with those found for the ENSEMBLES project, further strengthening the robustness of those results.

As part of the ENSEMBLES and AMMA projects, 9 RCMs were run for the period 1990-2050 (A1B scenario) over domains encompassing the West Africa region with lateral boundary conditions from different GCMs. The RCM-simulated West Africa monsoon showed a wide range of response in the projections, even when the models were driven by the same GCMs (Paeth et al. 2011) (Figure 21.5). Although at least some of the response patterns may be within the natural variability, this result along with the fact that the model biases were not strongly tied to the driving GCMs suggests that for Africa, and probably more generally the tropical regions, local processes and how they are represented in models play a key factor in determining the precipitation change signal. Similar conclusions were found for an all-Africa RCM simulation of 1980-2100 (A1B scenario) by Mariotti et al. (2011) as well as a climate change projection over South Africa with a variable resolution model (Engelbrecht et al. 2009). Diallo et al. (2012) showed that ensemble averaging of RCM simulations tends to compensate systematic errors from the individual models and provide more consistent results. They found a prevailing decrease in peak monsoon rainfall over the western Sahel for the early decades of the 21st century in an ensemble of 4 RCM simulations driven by different GCMs. These results indicate that uncertainties in projections of the hydrologic cycle of Africa remain high and need large ensembles of model simulations in order to be fully characterized.

Statistical downscaling techniques have also been applied to the Africa region (Hewitson and Crane 2006; McKellar et al. 2007; Lumsden et al. 2009; Steynor et al. 2009). In general, methodological developments since the AR4 have

been limited (see, for example reviews in Paeth et al., 2011, and Brown et al., 2008) and activities have focused more on the applications (e.g. Mukheibir, 2007, Nawaz et al, 2007, Gerbaux et al, 2009) for regional specific activities in the context of IAV work. Some promising developments relate to combining dynamical and statistical approaches, as for example in Paeth and Diederich (2010), who use an extended weather generator to optimize inputs to a hydrological model for application in west Africa. New work is also emerging that is not specific to Africa, but inclusive of all terrestrial regions. For example, Benestad (2011) developed a global downscaled product for station locations across all continents based on CMIP3, and draws a range of conclusions for regions including Africa, although the robustness of the statistical downscaling relationship for a number of locations is weak. Other activities are underway for similar globally extensive downscaling based on new CMIP5 GCMs with the purpose of producing gridded products (Ref to be eventually added here). However, the majority of statistical downscaling has been related to application of existing data products and is mostly not reported in the peer reviewed scientific literature, being found instead in the grey literature of project and institutional reports.

[INSERT FIGURE 21-5 HERE
Figure 21-5: Linear changes (i.e. changes obtained by fitting the time series at each grid point with straight lines) of annual precipitation during the 2001-2050 period from 10 individual RCM experiments and the MME mean under the A1B emission scenario. The top middle panels also account for projected land cover changes (see Paeth et al. 2011 for further explanation). Note that the REMO trends in both panels arise from a three-member ensemble whereas all other RCMs are represented by one single simulation. Trends statistically significant at the 5% level are marked by black dots. (From Paeth et al. 2011)]

Several RCM experiments have been conducted for the South America continent, also as part of the CLARIS project (Menendez et al. 2010; Nunez et al. 2009; Sorensson et al. 2010; Marengo et al. 2009, 2010), and time-slice high resolution GCMs have been analyzed over the continent (Kitoh et al. 2011). In addition, pattern scaling was used to produce climate change scenarios over Southern South America (Cabre et al. 2010). Overall these studies revealed varied patterns of temperature and precipitation change, depending on the global and regional models used, however a consistent change found in many of these studies was an increase in both precipitation intensity and extremes, especially in areas where mean precipitation was projected to also increase.

The Central American region has emerged as a prominent climate change hot-spot since the AR4, especially in terms of a consistent decrease of precipitation projected by most models. Regional model studies focusing specifically on Central America projections are however still sparse. For example Campbell et al. (2010) performed a downscaling study on two GCMs finding some robust precipitation changes, such as a general drying in June-October, which is consistent with the more general analysis of CMIP3 results by Rauscher et al. (2008) and Rauscher et al. (2011) who however found that most of the precipitation reduction there occurred in June-July, just before the August mid-summer drought.

For both the South America and Central America regions, a first ensemble of RCM CORDEX projections were produced by Coppola et al. (2012), Fuentes-Franco et al. (2013) using different driving global models, different regional model configurations and the RCP8.5 and RCP4.5 scenarios. Preliminary analysis of the results showed that the change signals, especially for precipitation, were sensitive not only to the driving GCM fields, but also to the internal model physics, and in particular to the representation of land surface processes and feedbacks and the response of convection to SST forcing. This adds an element of uncertainty to the interpretation of fine scale change patterns that needs to be assessed with the use of large RCM ensemble. Diro et al. (2013) also showed that the simulation of tropical storms in the Atlantic and Pacific are sensitive to the convection scheme used. When using the better performing schemes, they found that the frequency of tropical cyclones decreased in the tropical Atlantic and eastern Pacific coastal areas while it increased over the central Pacific and northern Atlantic, with these changes being mostly driven by the changes in SST and wind shear. The experiments also shown a consistent increase in the frequency of intense and long lasting tropical storms.

Since the AR4 there has been considerable attention given to producing higher resolution future projections of climate change over North America through the application of RCMs and higher resolution global time slices. The North American Regional Climate Change Assessment Program (NARCCAP) has been a major multi-institutional effort using a number of different RCMs (with a resolution of 50 km) driven by different global climate

models (GCMs) from the CMIP3 dataset, over the domain of most of North America (Mearns et al., 2009; 2012). Results indicate considerable variations in future climate based on the different RCMs, even when driven by the same GCM (Figure 21.6). In winter there tends to be more agreement across the GCMs and the RCMs for change in precipitation compared to in the summer, when the RCMs tend to depart more distinctly from the future projections of the GCMs (Mearns et al., 2013; De Elia and Cote 2010). This may indicate a lack of robustness in the projected precipitation changes in summer, but in-depth process level analysis will be necessary to determine this. There is also a tendency for the uncertainty across the driving GCMs to dominate for winter temperature and precipitation, but the uncertainty across the different RCMs dominates in the summer season. More detailed investigations of subregions of the NARCCAP domain have also been performed (e.g. Solowski and Pvelski 2012; Rawlins et al. 2012) Bukovsky et al. (2013) investigated the behavior of the NARCCAP models with regard to the North American Monsoon and was able to separate out the effects of the driving GCMs and the RCMs regarding error propagation. The GCM-RCM combinations that better produced the monsoon characteristics tended to indicate decreases in monsoon rainfall.

[INSERT FIGURE 21-6 HERE
Figure 21-6: Change in summer (JJA) average temperature (2041-2070 minus 1971-2000) from (top left) the NCAR CCSM3, (top right) the MM5 regional climate model driven by the CCSM3; (bottom left) the WRF model, driven by CCSM3, and (bottom right) the Canadian CRCM, driven by CCSM3. Temperature is in °C. Data from the NARCCAP program. (From Mearns et al., 2009, 2013)]

Other regional modeling efforts for sub-regions of North America include those of Hostetler (in preparation), Caya and Biner (2011) Subin et al. (2011), Salathé et al., (2008, 2010), Dominguez et al. (2010), De Elia et al. (submitted), Lofgren et al. (in preparation). In the realm of statistical downscaling and spatial disaggregation, considerable efforts have been devoted to applying techniques for the entire US and parts of Canada (e.g., Maurer et al., 2007; Hayhoe et al., 2010). These methods are particularly useful for driving impacts models, since they are produced at very high resolutions (e.g., 10 km), but usually only include temperature and precipitation. Comparisons among the spatial disaggregation techniques and dynamical downscaling are underway including the differential effects on impacts and adaptation planning (e.g., Barsugli et al., in progress).

Numerous high resolution RCM projections have been carried out over the East Asia continent, and some of these tend to produce results that are actually not in line with those from GCMs. For example, Ashfaq et al. (2009) used an RCM with 25 km grid spacing to find that enhanced greenhouse forcing resulted in a predominant suppression of South Asia summer monsoon precipitation, a delay in monsoon onset and a an increase in monsoon break periods, while most GCMs tend to produce increased South Asia monsoon precipitation (WGI Chapter 14). These were mostly attributed to a weakening of the monsoon flow and a suppression of the dominant intraseasonal oscillatory modes. As another example, Gao et al. (2011) completed a climate projection at 20 km grid spacing over East Asia and found that while the forcing GCM produced a prevailing increase in summer monsoon precipitation, in agreement with most GCM-based projections, the nested RCM showed large areas of decreased summer precipitation amounts in response to the high resolution topographical forcing of the Tibetan Plateau and other topographical complexes. Similarly a series of double nested RCM scenario simulations were performed for the Korea peninsula reaching a grid spacing of 20 km (Im et al. 2007a; 2008a,b; 2010; 2011a,b). They indicated a complex fine scale structure of the climate change signal, particularly for precipitation, also forced by local topographical features and a consistent increase in intense and extreme precipitation events. While it is difficult to clearly establish whether the RCM simulations are more credible, which would require large ensembles, all these high resolution RCM experiments do point out the importance of regional and local topographical forcings in modulating the response of regional circulations, e.g. the monsoon, and of local phenomena, e.g. tropical convection.

Both RCM and variable resolution model experiments have been conducted over the Australian continent or some of its sub-regions (Watterson et al. 2008; Nunez and Mc Gregor 2007; Song et al. 2008), showing that a local fine scale modulation of the large scale climate signal occurs in response to topographical and coastal forcings. Statistical downscaling has been applied for a number of focused studies over Australia. Timbal et al (2008) evaluate the consistency between statistical downscaling and projections from the GCMs using two different statistical downscaling methods. They find that along with the higher resolution of the downscaling, the downscaled and direct

model projections are largely consistent across the 15 GCMs used, and averaged across the southwest of Western Australia, indicate a general decline of precipitation. More recently Yin et al (2010) focus on new methodological developments in downscaling, using an adapted Self Organizing Map procedure based on Hewitson and Crane (2006), and in common with other statistical downscaling studies finds the most notable challenge is downscaling precipitation in arid zones.

21.3.3.2. Oceans and Sea Level

Contributions to global sea level rise include thermal expansion, glacier and ice cap melting, Greenland ice sheet and Antarctic iceberg calving and ice sheet melting. Regional sea level change can be quite different from global sea level change due to changes in circulations and associated wind stress, changes to the geoid and crustal subsidence and rebound (WGI Chapter 3).

From paleo records there is evidence that during the last 3 million years global mean sea level (GMSL) was more than 6 m higher than present, with global mean temperatures being 2-3 C warmer than present. The rate of GMSL rise has increased in the last 200 years, to about 1.7 +/- 0.2 mm/year during the 20th century and 2.8-3.6 mm/year since 1993 (WGI Chapter 3). Since 1970 the greatest contributions to GMSL (combined 80%) rise have been from ocean warming/expansion and glacier melting, however the rate of the contributions from Greenland and Antarctica ice has been increasing since the 1990s. An important advance compared to the AR4 is the closure of the observations budget for recent decades due to an improved set of observations, in particular the GRACE satellite data. In addition, estimates of 20th century GMSL increase from AOGCM simulations are now much closer to observations due to better understanding and modeling of relevant processes (WGI Chapter 11). The mean regional pattern of sea surface salinity has been enhanced, with saline surface waters in the evaporation-dominated mid-latitudes becoming more saline, and relatively fresh surface waters in rainfall-dominated tropical and polar regions becoming fresher.

Evidence is strong that the biogeochemical state of the ocean has changed (WGI Chapter 3). The ocean inventory of anthropogenic carbon dioxide has increased, from 114 ± 22 PgC in 1994 to 151 ± 26 PgC in 2010 and this is in broad agreement with the expected change resulting from the increase in atmospheric CO2 concentrations and change in atmospheric O2/N2 ratios (WGI Chapter 3). The uptake of CO2 by the ocean has resulted in a gradual acidification of seawater, with observations showing declines in pH in the mixed layer between -0.0015 and -0.0024 yr^{-1}.

Concerning GMSL projections (WGI Chapter 13), under all the RCP scenarios, the time-mean rate of GMSL rise during the 21st century is *very likely* to exceed the rate observed during 1971–2010, with ocean thermal expansion and glacier melting *likely* to make the largest contributions to this rise. For the period 2081 to 2100 compared to 1986 to 2005, GMSL rise is *likely* to lie in the range 0.29–0.55 m for RCP2.6, 0.36–0.63 m for RCP4.5, 0.37-0.64 for RCP6.0, and 0.48–0.82 m for RCP8.5. The upper end of this range is higher than in the AR4, but the confidence in these estimates is still limited due to limited understanding of some key processes, such as rapid changes in ice sheet dynamics and the differences between estimates with semi-empirical and process-based models, with the former giving higher upper estimates (higher than 1.0 m).

Projections of regional sea level changes, both based on the CMIP3 and CMIP5 models, indicate a large regional variability of sea level rise (even more than 100% of the GMSL rise), with areas undergoing much larger or smaller rise than the global average in response to different regional processes (WGI Chapter 13). However, by the end of the 21st century it's *very likely* that over about 95% of the oceans will undergo sea level rise, with the remaining 5% experiencing a decline mostly in high latitude regions and 75-80% of coastlines experiencing a sea level rise within 20% of the GLSL one.

Regional sea level changes for the next decades will largely be dominated by internal dynamical variability of the climate system, while on longer time scales changes in regional sea level will likely be dominated by changes in ocean dynamics. Some preliminary analysis of the CMIP5 ensembles, for example, indicates area of maximum

steric sea level rise in the Northern Atlantic, the northwestern Pacific off the East Asia coasts, the eastern coastal oceanic regions of the Bay of Bengal and the western coastal regions of the Arabian Sea (WGI Chapter 13).

Some analysis of the past decades indicate that the increase in storm surges and extreme sea level events is generally in line with the increase in mean sea level (Menendez and Woodworth 2010; Lowe et al. 2010; Woodworth et al. 2011). Dominant modes of variability, such as ENSO and the NAO, are also found to significantly affect extreme sea levels in a number of regions (Lowe et al. 2010). Some low lying areas, such as Venice (Carbognin et al. 2010) and the deltaic regions of the Bay of Bengal (Unnikrishnan and Shankar 2007), show trends in sea level much higher that the global average, also because eof subsidence in some cases (e.g. Venice). Positive wave height trends are found in many areas of the North Atlantic, North pacific, U.S. coasts and Southern ocean, with modulation associated with main modes of climate variability. Projections of storm surges in European coasts have used RCM-produced wind fields to force storm surge models, and prevailing increases in extreme storm surges were found (Debernard and Roed 2008; Wang et al. 2008). However changes in storm surges are tied to changes in atmospheric circulations, and may be highly regionally dependent. Increase of GMSL is likely to affect storm surges and increase the frequency of extreme sea level events.

Projections of changes in the Atlantic Meridional Overturning Circulation (AMOC) from the CMIP5 models indicate that it is *very likely* that the AMOC will weaken in the 21st century as a result of increased GHG concentrations (by 20-30% in the RCP4.5 scenario and 36-44% in the RCP8.5) but it is *very unlikely* that it will undergo an abrupt transition or collapse for the scenarios considered (WGI Chapter 12).

21.3.3.3. Air Quality

Changes in air pollutants such as near surface ozone and particulate material may have effects on human health, agriculture and natural ecosystems. These changes may depend on changes in emissions or changes in climatic and meteorological conditions affecting transport and removal of the pollutants. Therefore the issues of climate change and air quality are deeply interconnected (Giorgi et al. Meleux 2007).

Since the AR4 the interest in climate-air quality interactions has increased and more studies have become available addressing the issue of the effects of both climate and emission changes on air quality. Most of these studies focused on the continental United States and Europe, and utilized both global and regional climate and air quality models run in off-line or coupled mode. Regional modeling studies over the United States or some of its sub-regions include, for example, those of Hogrefe et al. (2004), Knowlton et al. (2004), Steiner et al. (2006), Dawson et al. (2006), Lin et al. (2008), Weaver et al. (2009), Zhang et al. (2008), while examples of global modeling studies include Murazaki and Hess (2006), Stevenson et al. (2006), Shindell et al. (2006), Doherty et al. (2006). Weaver et al. (2009) provide a synthesis of simulated effects of climate change on ozone concentrations in the U.S. using an ensemble of regional and global climate and air quality models. These studies indicate a predominant increase in near-surface ozone concentrations, particularly in the Eastern U.S. (Figure 21.7) mostly tied to higher temperatures and corresponding biogenic emissions. An even greater increase was found in the frequency and intensity of extreme ozone concentration events, which are the most dangerous for human health.

Examples of regional studies of air quality changes in response to climate change over Europe include Langner et al. (2005), Forkel and Knocke (2006) , Szopa and Hauglustaine (2007), and Meleux et al. (2007), Carvalho et al. (2010), Engartd et al. (2009), Andersson and Engardt (2010), Kruger et al. (2008), Athanassiadou et al. (2010). All these studies indicated the potential of large increases in near surface summer ozone concentrations especially in Central and Southern Europe due to much warmer and drier projected summer seasons (Figure 21-8).

[INSERT FIGURE 21-7 HERE
Figure 21-7: Mean (top panels) and standard deviation (bottom panels) in future-minus-present (2081-2100 minus 1981-2000) MDA8 summer ozone concentrations across (left-hand panels) all 7 experiments (5 regional and 2 global) and, for comparison purposes (right-hand panels) not including the WSU experiment (which simulated July only conditions). (From Weaver et al. 2009)]

[INSERT FIGURE 21-8 HERE
Figure 21-8: Difference in average summer daily ozone mean (left panel) and peak (right panel) concentration over Europe due to climate change, (2071-2100 minus 1961-1990), A2 scenario. (From Meleux et al. 2007)]

In general, while a consistently predominant increase of ozone concentrations due to climate change was found in these experiments, results were more mixed and regionally/seasonally dependent for other pollutants such as PM, sulfur and nitrogen compounds. It should be mentioned that most studied addressed the issue of climate effects on ozone without changes in anthropogenic emission. However, these are likely to change as well, and thus modulate the climate-related signals.

21.3.3.4. Cryosphere

The cryosphere is one of the most sensitive components of the climate system to global warming, and this response, which has profound implications for changes in sea level rise and atmospheric circulations, is determined by very complex processes, some of which are still poorly understood (e.g. ice flow dynamics).

New and improved data have become available since the AR4 to evaluate changes in the cryosphere (WGI Chapter 4), most notably the GRACE satellite ones, which have allowed more accurate assessments of the ice sheet mass balance. These improved observations show that the retreat of Arctic ice in all seasons has continued, at a rate of 3.9% per decade annually and 12.2% per decade during the summer during the period 1979-2011. The thickness, concentration and volume of arctic ice have also decreased, with a decrease in mean winter thickness by 48% between 1980 and 2009. Conversely, the total extent of Antarctic ice has increased slightly (1.4% per decade) between 1979 and 2011, with strong regional differences.

Retreat of mountain glaciers is widespread, with varying rates across regions, and uncertainty about the global rate. In particular, increasing loss of glacier mass has been observed in recent decades over Central Europe, Alaska, the Canadian Arctic and the Southern Andes. Several hundred glaciers globally have completely disappeared in the last 30 years.

Because of better techniques and more data, confidence has increased in the measurements of Greenland and Antarctica ice sheets. These indicate that parts of the Antarctic and Greenland ice sheets have been losing mass over the last two decades and contribute to global sea level rise. During 1993-2012, Greenland lost on average 123 ± 22 Gt yr-1 (0.34 mm/year of SLE) and Antarctica lost 65 ± 33 Gt yr-1 (0.18 mm/year of SLE). In the GRACE period 2005–2010, the losses were higher, 228 ± 54 Gt yr-1 in Greenland and 112 ± 58 Gt yr-1 in Antarctica. These were mostly caused by changes in ice flow in Antarctica, and a mix of changes in ice flow and increases in snow/ice melt in Greenland. Ice shelves in the Antarctic peninsula are also continuing a long-term trend of retreat and partial collapse started some decades ago. In total global SLR due to the contributions of Greenland and Antarctic ice sheets was 1.2+/- 0.2 mm/year for 1993-2010 and 1.7 +/1 0.5 mm/year for 2005-2010 (WGI Chapter 4).

New data, both in situ and from satellite confirm a decrease in snow cover extent in most months, particularly in spring (8% in 1970-2010 compared to 1922-1970), with marked regional and seasonal variations and with a decline in the duration of northern hemisphere snow season of about 5.3 days per decade (WGI Chapter 4). During the past three decades, significant permafrost degradation occurred. Permafrost temperature has increased (up to 3°C since the late-1970s in some regions of the Arctic) and the areal extent of permafrost is declining. The thickness of seasonally frozen ground has decreased in the 20th century across the Russian European North and from 1960 to the present on the Qinghai-Xizang (Tibetan) Plateau. The thaw season has expanded by more than two weeks from 1988 through 2007 across central and eastern Asia.

Twenty first century projections of cryosphere changes based on the CMIP5 ensemble show long-term reductions in Northern Hemisphere sea ice areal coverage in both hemispheres, from 39% for RCP2.6 to 94% for RCP8.5 in September and from 9% to 35% in February by the end of the century (WGI Chapter 12). The models indicate a nearly ice-free Arctic at the end of summer for warming greater than 2C. The CMIP5 models also better capture the rapid decline in summer Arctic sea ice observed during the last decades than CMIP3 models. Future projections of

Southern Hemisphere sea ice remain comparatively more uncertain, with the CMIP5 multi-model ensemble projecting, for the end of the 21st century, a decrease in Southern Hemisphere sea ice extent from 14% for RCP2.6 to 57% for RCP8.5 in February and from 9% to 29% in September, and a large inter-model scatter. The models show no evidence of critical thresholds in the transition from perennial ice-covered to a seasonally ice-free Arctic Ocean beyond which further sea ice loss is unstoppable and irreversible. Projections of decrease in Northern Hemisphere spring snow covered area in the CMIP5 models are fairly coherent (decrease of about 7% in RCP2.6 and 25% RCP8.5 by 2100). Surface permafrost area is projected to decrease between 37% (RCP2.6) to 81% (RCP8.5) by 2100.

21.4. Cross-Regional Phenomena

Thus far, this chapter has covered climate change-related issues that have a regional expression in one part of the world or another. In principle, these issues can be studied and described, *in situ*, in the regions in which they occur. However, there is a separate class of issues that transcends regional boundaries and demands a different treatment. In order to understand such cross-regional phenomena, knowledge is required of critical but geographically remote associations and of dynamic cross-boundary flows. The following sections consider some examples of these phenomena, focusing on trade and financial flows and migration. Though these issues are treated in more detail in Part A of this report, they are restated here in Part B to stress the importance of a global perspective in appreciating climate change challenges and potential solutions at the regional scale.

21.4.1. Trade and Financial Flows

Global trade and international financial transactions are the motors of modern global economic activity, and are inextricably linked to climate change through a number of interrelated pathways: (i) as a direct or indirect cause of anthropogenic emissions, (ii) as a predisposing factor for regional vulnerability to the impacts of climate change, (iii) through their sensitivity to climate trends and extreme climate events, and (iv) as an instrument for implementing mitigation and adaptation policies.

21.4.1.1. International Trade and Emissions

The contemporary world is highly dependent on trading relationships between countries in the import and export of raw materials, food and fibre commodities and manufactured goods. A rapidly growing world population and expanded economic activity in many developing countries during the past two decades has fuelled increasing demand for imports. The engines of manufacturing are now located in developing countries with a young and relatively cheap workforce, with only high value products retaining competitiveness in the developed world. Even during a period of general recession since 2008, economic development in many emerging, export-led economies (e.g. China, India, Ghana and Brazil) succeeded in bucking the global trend (World Bank, 2012).

Bulk transport of these products, whether by air, sea or over land, is now a non-trivial contributor to emissions of greenhouse gases and aerosols. Furthermore, the relocation of manufacturing has transferred net emissions via international trade from developed to developing countries (see Figure 21-9), and most developed countries have increased their consumption-based emissions faster than their domestic (territorial) emissions (Peters *et al.*, 2011). This regional transfer of emissions is commonly referred to in climate policy negotiations as "carbon leakage" (Barker *et al.*, 2007), though only a very small portion of this can be attributed to climate policy ("strong carbon leakage"), a substantial majority being due to the effect of nonclimate policies on international trade ("weak carbon leakage" – Peters, 2010). A particular example of strong carbon leakage concerns the conversion of land use from the production of food to bioenergy crops. These crops sequester carbon otherwise extracted from the ground as fossil fuels, but in the process displace demand for food production to land in other regions, often inducing land clearance and hence an increase in emissions (Searchinger *et al.*, 2008), though the empirical basis for this latter assertion is disputed (see Kline and Dale, 2008).

[INSERT FIGURE 21-9 HERE
Figure 21-9: Growth rates from 1990-2008 of international trade, its embodied CO_2 emissions and net emissions transfers from Annex B and non-Annex B countries compared to other global macrovariables, all indexed to 1990 (Peters et al., 2011).]

21.4.1.2. Trade and Financial Flows as Factors Influencing Vulnerability

The increasingly international nature of trade and financial flows (commonly referred to as globalisation), while offering potential benefits for economic development and competitiveness in developing countries, also presents high exposure to climate-related risks for some of the populations already most vulnerable to climate change. Examples of these risks, explored further in Chapters 7-9, 12 and 13 of Part A, include:

- Severe impacts of food price spikes in many developing countries (including food riots and increased incidence of child malnutrition) such as occurred in 2008 following shortfalls in staple cereals, due to a coincidence of regional weather extremes (e.g. drought) in producer countries, the reallocation of food crops by some major exporters for use as biofuels (an outcome of climate policy – see previous section) and market speculation (Ziervogel and Ericksen, 2010). Prices subsequently fell back as the world economy went into recession, but spiked again in early 2011for many of the same reasons (Trostle *et al.*, 2011), with some commentators predicting a period of rising and volatile prices due to increasing demand and competition from biofuels (Godfray *et al.*, 2010).
- A growing dependence of the rural poor on supplementary income from seasonal urban employment by family members and/or on international financial remittances from migrant workers (Davies *et al.*, 2009). These workers are commonly the first to lose their jobs in times of economic recession, which automatically decreases the resilience of recipient communities in the event of adverse climate conditions.On the other hand, schemes to provide more effective communication with the diaspora in times of severe weather and other extreme events can provide rapid access to resources to aid recovery and reduce vulnerability (Downing, 2012).
- Some aspects of international disaster relief, especially the provision of emergency food aid over protracted periods, has been cited as an impediment to enhancing adaptive capacity to cope with climate-related hazards in many developing countries (Schipper and Pelling, 2006). Here, international intervention, while well-intentioned to relieve short-term stress, may actually be counter-productive in regard to the building of long-term resilience.

21.4.1.3. Sensitivity of International Trade to Climate

Climate trends and extreme climate events can have significant implications for regional resource exploitation and international trade flows. The clearest example of a major prospective impact of climate change concerns the opening of Arctic shipping routes as well as exploitation of mineral resources in the exclusive economic zones (EEZs) of Canada, Greenland/Denmark, Norway, Russia and the USA (Figure 21-10a, and see Chapter 28). For instance, the CCSM4 climate and sea ice model has been used to provide projections under RCP4.5, RCP6.0 and RCP8.5 forcing (see Box 21-1) of future accessibility for shipping to the sea ice hazard zone of the Arctic marine environment defined by the International Maritime Organization (Stephenson *et al.*, 2013 – Figure 25-10a). Results suggest that moderately ice-strengthened ships (Polar Class 6), which are estimated under baseline (1980-1999) conditions to be able to access annually about 36 % of the IMO zone, would increase this access to 45-48 % by 2011-2030, 58-69% by 2046-2065 and 68-93% by 2080-2099, with almost complete accessibility projected for summer (90-98% in July-October) by the end of the century (Stephenson *et al.*, 2013). Estimates are also presented for three major cross Arctic routes: the Northwest Passage, Northern Sea Route (which is part of the Northeast Passage), and Trans-Polar Route (Figure 21-10a). This could represent significant distance savings for trans-continental shipping currently using routes via the Panama and Suez Canals (Stephenson *et al.*, 2011). Indeed, in 2009 two ice-hardened cargo vessels – the Beluga Fraternity and Beluga Foresight – became the first to successfully traverse the Northeast Passage from South Korea to the Netherlands, a reduction of 5,500 km and 10 days compared to their traditional 20,000 km route via the Suez Canal, translating into an estimated saving of some $300,000 per ship, including the cost of standby icebreaker assistance (Smith, 2009; Det Norsk Veritas, Beluga). A projection

using an earlier version of the sea ice model under the SRES A1B scenario, but offering similar results (with forcing comparable to RCP 6.0), is presented in Figure 21-11b, which also portrays winter transportation routes on frozen ground. These routes are heavily relied upon for supplying remote communities and for activities such as forestry and, in contrast to the shipping routes, are projected to decline in many regions (Figure 21-10b).

[INSERT FIGURE 21-10 HERE
Figure 21-10: (a) Marine exclusive environmental zones (EEZs – dashed lines) of Canada, Greenland/Denmark, Norway, Russia, and the USA, and location of the Northwest Passage, Northern Sea Route, Trans-Polar Route, and international high seas within the IMO Guidelines Boundary for Arctic shipping (thick black border). After Stephenson (2013). (b) Projected change in accessibility of maritime and land-based transportation by mid-century (2045-2059 relative to 2000-2014) using the Arctic Transport Accessibility Model and CCSM3 climate and sea ice estimates assuming an SRES A1B scenario. Green areas denote new maritime access to Polar Class 6 vessels (light icebreaker); white areas remain inaccessible. Red delimits areas of lost winter road potential for ground vehicles exceeding 2 metric tonnes (Stephenson et al., 2011).]

A second illustration of how the risk of adverse climate changes may have contributed to anticipatory adaptive actions affecting countries in other regions of the world and potentially influencing commodity markets, relates to the purchase or renting of large tracts of productive land in parts of Africa, Latin America, Central Asia and Southeast Asia by countries in Europe, Africa, the Gulf and South and East Asia (De Schutter, 2009; Cotula *et al.*, 2011; Zoomers, 2011). While there is clearly a profit motive in many of these purchases (i.e., cheap and fertile land and the opportunity to cultivate high value food or biofuel crops), there is also a concern that domestic agricultural production in some countries will be unable to keep pace with rapid growth in domestic demand and changing dietary preferences, especially in agricultural regions affected by frequent shortfalls due to droughts, floods and cyclones (Cotula *et al.*, 2011), or threatened by sea-level rise (Zoomers, 2011). Land acquisition on such a large scale raises a number of ethical issues relating to local access to food and the appropriate and sustainable management of the land (Deininger and Byerlee, 2012). These issues have led the UN Special Rapporteur on the right to food to recommend a list of eleven principles for ensuring informed participation of local communities, adequate benefit sharing and the respect of human rights (De Schutter, 2009). This issue is elaborated with respect to rural areas, in Chapter 9 and livelihoods and poverty, in Chapter 13.

Extreme climate phenomena that may be harbingers of similar and more frequent events in a warmer world, already exact devastating consequences in some regions that extend well beyond country boundaries. A recent event that disrupted international trade and commodity flows was the severe 2010/2011 flooding in eastern Australia (Giles, 2011; Queensland Floods Commission of Inquiry, 2012; and see Chapter 25), which combined with damaging cyclones in Queensland and Western Australia curtailed numerous mining operations and damaged transportation networks, leading to declines in both thermal and metallurgical coal exports (by 31% and 19%, respectively, relative to the previous quarter – ABARES, 2011) with a sharp rise in their monthly price between November 2010 and January 2011 (Index Mundi, Coal). The severe weather was the primary factor contributing to a fall in Australian GDP of 1.2% during January-March 2011 compared with a rise of 0.7% in the preceding three-month period (Australian Bureau of Statistics, Australian National). Other examples of how extreme climate events can affect international trade are reported by Oh and Reuveny (2010) and Handmer et al. (2012).

21.4.1.4. International Transactions as Instruments of Regional Climate Policy

International policies to curb climate change and to adapt to its impacts, are increasingly looking to cross-border mechanisms to encourage action (and see Chapters 14-17). The European Union Emissions Trading System (EU ETS) is the first and largest international scheme for the trading of greenhouse gas emission allowances, covering some 11,000 power stations and industrial plants in 30 countries and accounting for almost half of the EU's CO_2 emissions and 40% of its total greenhouse gas emissions (European Commission, 2012). The Clean Development Mechanism (CDM) allows industrialised countries (Annex B Parties, cf. Supplementary material) to invest in emission-reduction projects in developing countries, which earn certified emission reduction (CER) credits, each equivalent to one tonne of CO_2. These CERs can be traded and sold to meet part of the emission reduction targets of the Annex B Parties under the Kyoto Protocol.

21.4.2. Human Migration

There has been considerable debate in recent years around the postulate that anthropogenic climate change and environmental degradation could lead to mass migration (Perch-Nielsen *et al*., 2008; Feng *et al*., 2010; Warner, 2010; Black *et al*., 2011; Government Office for Science, 2011; Assan and Rosenfeld, 2012). The issue is treated at length in Chapters 8, 9, 12 and 13 of Part A, so only a few aspects are touched on here, to highlight the growing significance of migration in all regions of the world.

Four possible pathways through which climate change could affect migration are suggested by (Martin, 2009):

1) Intensification of natural disasters
2) Increased warming and drought that affects agricultural production and access to clean water
3) Sea-level rise, which makes coastal areas and some island states increasingly uninhabitable
4) Competition over natural resources, leading to conflict and displacement of inhabitants.

Abundant historical evidence exists to suggest that changes in climatic conditions have been a contributory factor in migration, including large population displacements in the wake of severe events such as Hurricane Katrina in New Orleans, Louisiana in 2005 (Cutter *et al*., 2012), Hurricane Mitch in Central America in 1998 and the northern Ethiopian famines of the 1980s (McLeman and Smit, 2006). However, the evidence is not clear cut (Black, 2001), with counter examples also available of migration being limited due to economic hardship (e.g. during the Sahel drought of the mid-1980s in Mali – Findley, 1994).

The spatial dimension of climate-related migration is most commonly internal to nations (e.g. from affected regions to safer zones – Naik, 2009). In this context it is also worth pointing out that internal migration for other (predominantly economic) reasons may actually expose populations to increased climate risk. For instance, there are large cities in developing countries in low elevation coastal zones that are vulnerable to sea level rise. Increased migration to these cities could exacerbate the problems with the migrants themselves being especially vulnerable (Nordås and Gleditsch, 2007; UNFPA, 2007).

Migration can also be international, though this is less common in response to extreme weather events, and where it does happen it usually occurs along well established routes. For example, emigration following Hurricane Mitch tripled from Honduras and increased from Nicaragua by 40%, mainly to the southern States of the US – already a traditional destination for migrants, and was aided by a relaxation of temporary residency requirements by the United States (Naik, 2009).

The causal chains and links between climate change and migration are complex and can be difficult to demonstrate (e.g., Perch-Nielsen *et al*., 2008; Piguet, 2010; Tänzler *et al*., 2010; ADB, 2012; Oliver-Smith, 2012), though useful insights can be gained from studying past abandonment of settlements (McLeman, 2011). Thus projecting future climate-related migration remains a challenging research topic (Feng *et al*., 2010). There are also psychological, symbolic, cultural and emotional aspects to place attachment, which are well documented from other non-climate causes of forced migration, and are also applicable to cases of managed coastal retreat due to sea-level rise (e.g., Agyeman *et al*., 2009). Furthermore, forced migration appears to be an emerging issue requiring more scrutiny by governments in organising development co-operation, and to be factored into international policy making as well as international refugee policies. For example, it has been suggested that the National Adaptation Plans of Action (NAPAs) under the UNFCCC, by ignoring transboundary issues (such as water scarcity), and propounding nationally-orientated adaptation actions (e.g. upstream river management, to the detriment of downstream users in neighbouring countries), could potentially be a trigger for conflict, with its inevitable human consequences. Moreover, currently there is no category in the United Nations High Commission for Refugees classification system for environmental refugees, but it is possible that this group of refugees will increase in the future and their needs and rights will need to be taken into consideration (Brown, 2008). The Nansen Initiative, put forward jointly by Norway and Switzerland at a 2011 ministerial meeting, pledges "to cooperate with interested states and relevant actors, including UNHCR, to obtain a better understanding of cross-border movements provoked by new factors such as climate change, identify best practices and develop a consensus on how best to protect and assist those

affected ", and may eventually result in a soft law or policy framework (Kolmannskog, 2012 environmental). However, migration should not always be regarded as a problem; in certain circumstances where it contributes to adaptation (e.g. through remittances) it can be part of the solution (Laczko and Aghazarm, 2009).

21.4.3. Migration of Natural Ecosystems

One of the more obvious consequences of climate change, is the displacement of biogeographical zones and the natural migration of species (see Chapters 4 and 6). General warming of the climate can be expected to result in migration of ecosystems towards higher latitudes and upward into higher elevations. Species shifts are already occurring in response to recent climate changes in many parts of the world (Rosenzweig *et al.*, 2008), with average poleward shifts in species' range boundaries of 6 km per decade being reported (Parmesan *et al.*, 2011).

Study of the estimated shifts of climatic zones alone can provide insights into the types of climatic regimes to anticipate under projected future anthropogenic climate change. By grouping different combinations and levels of climatic variables, it is possible not only to track the shifts in the zones in which they occur, but also to identify newly emerging combinations of conditions not found at the present day (novel climates) as well as combinations that may not survive global climate change (disappearing climates – Williams *et al.*, 2007). These analyses can help define what types of climatic niches may be available in the future and where they will be located. Such a spatial analogue approach (cf. Carter *et al.*, 2007) can delimit those regions that might currently or potentially (in the future) be susceptible to invasion by undesirable aquatic (e.g., EPA, 2008) or terrestrial (e.g., Mainka and Howard, 2010) alien species or alternatively might be candidates for targetting translocation (assisted colonisation) of species endangered in their native habitats (e.g., Brooker *et al.*, 2011; Thomas, 2011). However, there are many questions about the viability of such actions, including genetic implications (e.g., Weeks *et al.*, 2011), inadvertent transport of pests or pathogens with the introduced stock (e.g., Brooker *et al.*, 2011) and risk of invasiveness (e.g., Mueller and Hellmann, 2008).

The ability of species to migrate with climate change must next be judged, in the first instance, against the rate at which the climatic zones shift over space (e.g. Loarie *et al.*, 2009 – Figure 21-11). For projecting potential future species shifts, this is the most straightforward part of the calculation. In contrast, the ecological capacity of species to migrate is a highly complex function of factors, including their ability to:

- Reproduce, propagate or disperse
- Compete for resources
- Adapt to different soils, terrain, water quality and daylength
- Overcome physical barriers (e.g. mountains, water/land obstacles)
- Contend with obstacles imposed by human activity (e.g. land use, pollution or dams).

[INSERT FIGURE 21-11 HERE
Figure 21-11: The velocity of shifting climatic zones due to climate change based on the average of 16 global climate models for an A1B emissions scenario and temporal gradients computed for 2050-2100. (Loarie et al., 2009).]

Conservation policy under a changing climate is largely a matter of promoting the natural adaptation of ecosystems, if this is even feasible for many species given the rapidity of projected climate change. Studies stress the risks of potential mismatching in responses of co-dependent species to climate change (e.g., Schweiger *et al.*, 2012) as well as the importance of maintaining species diversity as insurance for the provision of basic ecosystem services (e.g., Traill *et al.*, 2010; Isbell *et al.*, 2011). Four priorities have been identified for conservation stakeholders to apply to climate change planning and adaptation (Heller and Zavaleta, 2009): (i) regional institutional coordination for reserve planning and management and to improve landscape connectivity; (ii) a broadening of spatial and temporal perspectives in management activities and practice, and actions to enhance system resilience; (iii) mainstreaming of climate change into all conservation planning and actions; and (iv) holistic treatment of multiple threats and global change drivers, also accounting for human communities and cultures. The regional aspects of conservation planning transcend political boundaries, again arguing for a regional (rather than exclusively national) approach to adaptation policy. This issue is elaborated in Chapters 4 and 14.

21.4.4. Hotspots

Hotspots is an approach that has been used to indicate locations that stand out in terms of impacts, vulnerability or adaptive capacity (or all three). The approach exists in many fields and the meaning and use of the term hotspots differs. The term typically relates to a geographical location, which emerges as a concern when multiple layers of information are compiled. For example, the Consultative Group on International Agricultural Research (CGIAR) Research Program on Climate Change Agriculture and Food Security (CCAFS) mapped hotspots of food insecurity and climate change in the tropics (Ericksen et al, 2011). Other studies look at how climate change can influence disease risk (de Wet et al 2001), extinctions of endemic species (Malcolm et al 2005), and disaster risk (Dilley 2006). The purpose of the hotspots is to set priorities for policy action and for further research (de Sherbinin, submitted; Dilley 2006, Ericksen et al 2011, see www.climatehotmap.org).

Hotspots generally refers to a geographical location, but could also be used to refer to a topic, such as a type of ecosystem or farming system (eg. biofuels), a style of armed conflict (eg. guerrilla warfare) or seasonally distributed diseases (eg. malaria). This bends the definition of 'spot' but reflects the same approach: that certain circumstances result in certain levels of exposure or sensitivity to climate change. Below are some ways in which hotspots are used:

Climate Change: A climate change hotspot can describe (a) a region for which potential climate change impacts on the environment or different activity sectors can be particularly pronounced or (b) a region whose climate is especially responsive to global change (Giorgi 2006). Since the AR4, a number of studies attempted to identify "Climate change Hotspots" at subcontinental scale following the latter definition. For example, Giorgi (2006), Diffenbaugh et al. (2008), Giorgi and Bi (2009), Xu et al. (2009) and Diffenbaugh and Scherer (2011) used different regional climate change indexes including changes in mean and interannual variability of temperature and precipitation to calculate late 21st century climate change "hot-spots" based on the CMIP3 ensemble accounting for multiple GCMs, scenarios and realizations. Among the most prominent hot-spots identified were the Mediterranean Basin, Central America, Central Africa, the Northern high latitude regions, the southwestern United States, Southeast Asia and the Tibetan Plateau. A new climate change hot-spot analysis of the CMIP5 ensemble was carried out by Diffenbaugh and Giorgi (2012), who extended the methodology of Giorgi (2006) and Diffenbaugh et al. (2008) by adding metrics of seasonal extremes and considering the temporal evolution and emergence of hotspots (Figure 21.12). They found that the Amazon, the Arctic, the Sahel and tropical West Africa, and the Tibetan Plateau are persistent regional climate change hotspots which emerge early in the 21st century of the RCP8.5 forcing pathway and persist throughout the rest of the century, suggesting that they are robust to varying levels of global warming. Areas of southern Africa, the Mediterranean, and Central America/western North America also emerged as prominent regional climate change hotspots but mostly in response to high levels of forcing. This contrasting persistence and emergence of hotspots in response to increasing radiative forcing highlights the relevance of regional climate heterogeneity for climate change mitigation and adaptation strategies. Others have defined climate change hotspots as locations where impacts of climate change are 'well pronounced and well documented' (UCS 2011). De Sherbinin (submitted) notes that because hotspots often overlay projections of climate change with current vulnerability, there is a disconnect in timescales.

[INSERT FIGURE 21-12 HERE
Figure 21-12: The relative aggregate climate change between the 1975-2005 period and the 2010-2039, 2040-2069 and 2070-2099 periods of RCP8.5. The aggregate climate change is calculated using the Standard Euclidean Distance (SED) across the 28-dimensional climate space formed by 7 climate variables in each of 4 seasons. The absolute values of change in each variable are normalized to the maximum global absolute value prior to calculating the SED. The SED values are then normalized to the maximum global SED value. Only land grid points north of 60°S are used in the normalizations (From Diffenbaugh and Giorgi 2012).]

Biodiversity and Conservation: A biodiversity hotspot – the original use of this concept – is a recognised unit of analysis for guiding policy and investment decisions, developed by Meyers (1988). It refers to a region that is biologically diverse and typically under some sort of threat from human activity, climate change, or other drivers.

Health and Disease: Hotspots of disease can describe incidence rates, death rates, areas where certain viruses are likely to emerge, among other things. They can be coupled to climate change, biodiversity change, population growth, human-animal proximity, or to other drivers. A study on emerging infectious diseases (EIDs) identified hotspots as regions where new EIDs are likely to originate, in order to guide decisions makers where to allocate global resources to pre-empt, or combat, the first stages of disease emergence (Jones et al 2008).

Disasters: Disasters hotspots are identified as geographic areas that are most vulnerable to hazards (Dilley et al 2006). The purpose of disasters hotspots is to encourage development agencies and policy makers to incorporate disaster risk management into investment plans and decisions (Arnold et al 2005).

Food production, Food security: Areas of food production that are affected by pressures such as urbanisation, environmental degradation, water scarcity or climate change can be identified as hotspots of food insecurity, such as by CGIAR CCAFS (Ericksen et al 2011). Similarly, adverse implications of agriculture on environment have been described as 'agri-environmental hotspots'. FAO (2010) defines agri-environmental hotspots as 'locations where human activities are detrimental to the sustainability of an ecosystem or the human activities depending on it'. The rationale for identifying such hotspots is that 'they may gradually evolve into extremely tense socio-economic situations associated with a severe degradation of the natural resources base and food security' (FAO 2010). Fraser et al (2013) combine hydrological modelling with quantitatively modelled adaptive capacity (defined as the inverse of sensitivity to drought) to identify vulnerability hotspots for wheat and maize.

21.5. Critical Analysis of Approaches to Regional Impacts, Adaptation, and Vulnerability Studies and Their Uncertainties

Assessing climate vulnerability or options for adapting to climate impacts in human and natural systems requires an understanding of all factors influencing the system and how change may be effected within the system or applied to one or more of the external influencing factors. This implies the need, in general, for a wide range of climate and non-climate information and then determining how this may be used to enhance the resilience of the system. Previous sections have defined the context in which these systems operate, synthesized key regional and cross-regional knowledge and issues. This section focuses on advances in the methods and information that underpin these findings, initially examining methods to study vulnerability and adaptation and assess impacts. This is followed by assessments of new information on, and thinking related to: (a) baseline and recent trends in factors needed to assess vulnerability and define impacts baselines; and (b) future scenarios used to assess impacts, changes in vulnerability and options for adaptation; and then assessment of the credibility of the various types of information presented.

21.5.1. Vulnerability and Adaptation Analyses

Multiple methodologies exist for assessing vulnerability and adaptive capacity (Schipper et al 2010, UNFCCC 2008) and many have now become well-established approaches. Choice of method is influenced by objective and starting point (see Table 21-3) as well as the type of information available. Qualitative assessments require different inputs from quantitative assessments. Qualitative information cannot always be translated to quantitative information, and vice versa, yet both qualitative and quantitative approaches can be used to answer the same questions.

The comparison of vulnerability and adaptive capacity across regions requires some common baseline from which to judge relative levels of vulnerability and adaptive capacity – a type of measurement. Measuring adaptive capacity has not been explored in the same way, and often adaptive capacity is assumed to be a component of vulnerability (based on the vulnerability definition in IPCC 2001). Qualitative and quantitative studies are used to identify why people are vulnerable and how, and are typically the basis for determining strategies for reducing vulnerability and adapting to climate change. Indicators have been used to make this comparison. This section reflects briefly on indicators.

Several attempts at developing vulnerability indicators and indices have been made (Birkmann et al. 2011; Chen et al. 2011; Barr et al 2010; Cardona, 2007; Luers et al 2003; Lawrence *et al.,* 2003, Villa and McLeod, 2002, Downing *et al*. 2001, Atkins *et al.,* 2000; Moss *et al*. 1999). Representation of vulnerability on a map or through an index is the most common way to show global vulnerability information and requires quantification of selected variables in order to measure them against a selected baseline, even though quantification of some qualitative information may not be possible (Hinkel, 2011; Edwards et al, 2007; Luers et al 2003,). Maps of vulnerabilities where hazards or projected climate change impacts are overlain with population density suggests that everyone has an equal probability of being affected by a hazard or by climate change impacts, ie. that everyone is equally at risk. Vulnerability is differentiated according to factors such as gender, age, livelihood or access to social networks (Cardona et al 2012; Wisner et al 2005), which can be a challenge to incorporate into indicators, and therefore choice of indicators of or proxies for vulnerability will determine what the result looks like. One approach that is used to create regional comparisons is an index approach that measures different variables to create indicators of vulnerability. The index is the composite of several normalised indicators (Rygel et al 2006, Adger et al 2004). The approach has been critiqued extensively because giving different weights to the indicators depends on expert opinion and this can result in different countries appearing more or less vulnerable, as Fuessel (2010) found in reviewing different vulnerability maps. Lack of full understanding of what drives vulnerability means that indicators can give misleading or incorrect information about vulnerability (Böhringer and Jochem, 2007).

Luers et al (2003) propose the idea of ex-post measure of vulnerability, using the number of people killed in a storm as an indicator that they were vulnerable. A deductive analysis of the situation would suggest that they were killed because (a) they were exposed to the storm, (b) they were sensitive to the storm, (c) they had low capacity to escape the storm or (d) the storm had a very high impact. However, a low impact storm could also result in deaths if the people were especially sensitive or exposed. Their deaths could also simply be explained by being in the wrong place at the wrong time, which suggests that ex-post analysis can indicate only the state of vulnerability of the people killed at the moment they were killed, and not anything else. Conversely, an ex-ante analysis of vulnerability to a storm might suggest that old people, people who will not want to evacuate their houses because they do not want to risk losing their assets (such as livestock) or people who have a lack of knowledge of where to go and what to do in an emergency, would be the most sensitive and exposed. Even with these characteristics, the outcome does not necessarily lead to death, since they could also be rescued, their area could be unaffected by the storm, or they could survive anyway. In other words, identifying a single characteristic or even several may not give a sufficient picture of vulnerability for decision making, even on a local level.

Vulnerability indicators developed to date have been unable to reflect the dynamic nature of the various variables used as indicators. This is illustrated in the case of the (in)ability to characterise how the selected indicators contribute to determining vulnerability over time. Importantly, the relative importance of the indicator may change from season-to-season (eg, access to irrigation water) or gradually or rapidly become obsolete. Hinkel's (2011) review of literature on vulnerability indicators suggests that vulnerability has been confused as a proxy for unsustainable or insufficient development, which means that simple measurements are seen as sufficient to tell a story about vulnerability. Hinkel (2011) suggests that the simplification of information to create vulnerability indicators is what limits the utility of vulnerability indicators.

Adaptation is considered to be tightly linked with development (Adger et al 2003b, Schipper 2007) and a significant portion of adaptation approaches emerge from activities in developing countries. The metrics of adaptation is a topic of considerable interest for the purpose of funding prioritisation, monitoring progress in adjusting to climate change and identifying suitable adaptation options (IGES 2008).

Adaptation assessment as a process is described more extensively in chapters 2, 14, 15, and 17, and this section addresses the usefulness of indicators for understanding adaptation at a regional and global level. Most adaptation assessments rely on assessing adaptive capacity (Yohe and Tol 2002), based on some variables that are often transformed into indicators, success of implementation of adaptation projects (often also based on a set of indicators) or 'functions' that countries should follow to attain resilience (WRI 2009).

As a way of understanding adaptive capacity further, numerous types of indicator systems have been developed. These are used both to measure adaptive capacity as well as to identify entry points for enhancing it (Adaptation

Sub-Committee, 2011; Lioubimtseva and Henebry, 2009; Swanson et al., 2007; Adger and Vincent, 2005; Eriksen and Kelly, 2007) For example, the Global Adaptation Index, developed by the Global Adaptation Alliance (GAIN, n.d.) uses a national approach to assess vulnerability to climate change and other global challenges and compare this with a country's 'Readiness to improve resilience' (GAIN, n.d.) for the purpose of assisting public and private sectors to prioritise financial investments in adaptation activities.

Indicators can be a useful starting point for a discussion on what qualifies as an appropriate proxy for capacity, in order to determine what sort of factors act as barriers and drivers. When rooted in the poverty and livelihoods discourse on vulnerability (Chambers, 1989; Swift, 1989), proxies for capacity look very similar to indicators of development, despite the significant argument about the causal structure of vulnerability, which underscores that vulnerability is not the same as poverty (Chambers, 1989; Ribot, 1996). Resources may be for enhancing 'the capacity and endurance of the affected people to cope with adversities' (Ahmed and Ahmad 2000: 100), but equating vulnerability with poverty creates a false association between lack of development and lack of capacity (Magnan, 2010).

A special case of the use of indicators concerns the identification of hotspots. This is a concept used in numerous fields to describe locations that stand out as important for the analytical lens that is being applied (see section 21.4.4, above). The purpose of doing hotspot analysis varies across different fields, but they are typically the outcome of the combination of different sets of variables with a geographical reference. In climate change, hotspots are being used with increasing frequency to help distinguish priority locations for funding (de Sherbinin, submitted). The presentation of hotspots differs according to multiple factors, including the scale of analysis (from specific houses to entire ecosystems), the number of variables examined (two or more), whether the information refers to measured or projected hotspots. Hotspots can contrast with "cool spots", where the inverse situation can be found, and can be ranked when they are derived from numerical values (e.g., number of crimes committed). Hotspots are another way of comparing regions, and the subjective nature of ranking locations as more urgent for climate change investment than others is controversial and can be considered politically-motivated (Klein 2009). In part, this is also because the identification of hotspots raises important methodological issues, discussed earlier in this section, with regard to the limitation of using indicators to give an illustration that integrates impacts with qualitative dimensions of vulnerability. De Sherbinin (submitted) points out that hotspot maps are commonly used as communications tools, but the tentative nature and the on-going process of knowledge generation that they represent is frequently not understood by the audience, who see the maps as a description of how things are or will be.

Certain areas are considered hotspots because of their regional or global importance. These can be defined by population size and growth rate, contributions to regional or global economies, productive significance (e.g., food production) as well as by disaster frequency and magnitude, and projected climate change impacts. Variables identified to represent these issues can be controversial, and relationships between variables may not always be fully understood. For instance, the CCAFS hotspot map introduced in section 21.4.4 uses stunted growth as a proxy for food insecurity (Ericksen et al 2011), but other variables could also have been selected, and could have resulted in different locations being identified as hotspots (Füssel, 2009). Scale matters in representing hotspots and will look differently on a global scale than on a finer scale (Arnold et al., 2006).

21.5.2. Impacts Analyses

In recent years, as adaptation considerations have risen up the policy agenda, there has been increased scrutiny of the methods and tools applied in impact assessment, especially quantitative models that are used to project the biophysical and socio-economic impacts of future climate change (see chapter 2), but also encompassing qualitative methods, including studies of indigenous knowledge (Galloway McLean, 2010, and see chapter 12). In an advance from previous assessments, different types of impact models are now being applied for the first time in many regions of the world. This is largely due to burgeoning international development support for climate change vulnerability and adaptation studies (Fankhauser, 2010). It is also related to a surge of interest in regional economic assessments in the wake of the Stern review (Stern, 2007) as well as to the evolution of climate models into earth system models that incorporate a more realistic representation of land surface processes (Flato *et al.*, in prep.) and their increased application to study hydrological (chapter 3), ecophysiological (chapter 4) and cryological (chapter 28) impacts.

21.5.2.1. Framing of Impact Studies

Potential impacts have been simulated for single as well as multiple sectors, at spatial scales ranging from site or household to global, and over a range of temporal scales and time horizons (Table 21.3). A majority of impact studies still follow the conventional approach described in section 21.2.3 (left hand side in Table 21-3), whereupon future impacts are modelled based on a set of assumptions (scenarios) about future climate and socioeconomic conditions. However, an increasing number of impact studies are being undertaken that follow a "socio-institutional" approach to adaptation planning (Downing, 2012) as reflected on the right hand side of Table 21-3, which emphasises adaptive flexibility and climate resilience as an acknowledgement of the often intractable, "deep" uncertainties implicit in many projections of future change (e.g., Donley *et al*., 2012; Garrett *et al*., 2013; Gersonius *et al*., 2013).

Adaptation assessment is addressed in section 21.5.1, but it should be noted that impact modelling studies commonly treat aspects of adaptation as well, either explicitly as modelled options, or implicitly as built-in autonomous responses (Dickinson, 2007; White *et al*., 2011). Furthermore, with an anthropogenic signature being attributed to ongoing climate changes in many regions (Bindoff *et al*., in prep.), and with growing evidence that these changes are having impacts on natural and human systems in many more regions of the world than reported in the AR4 (chapter 18, and see Rosenzweig and Neofotis, in press), there is now a real possibility in some regions and sectors to test the projections of impact models against the observed impacts of recent climate change (e.g., Araújo *et al*., 2005; Barnett *et al*., 2008; Lobell *et al*., 2011), which is also an essential element in the attribution of observed impacts (see chapter 18).

21.5.2.2. Uncertainties Attributable to Future Climate Projections

Much of the literature regarding uncertainty in impacts analyses has focused on the uncertainties in impacts that result from the uncertainties in future climate (Mearns et al., 2001a; Carter et al., 2007), and this literature continues to grow since AR4, particularly in the realm of agriculture and water resources (e.g., Wetterhall et al., 20011; Ferrise et al., 2011; Ficklin et al., 2012; Littell et al., 2011, Osborne et al., 2013), but also in other areas such as flood risk (Ward et al., 2013). Furthermore, research has moved forward to establish which uncertainties about future climate are most important to the resultant uncertainties about crop yields (e.g., Lobell and Burke, 2008). These uncertainties regarding future resources have now been applied to adaptation studies as well (Howden et al., 2007).

The use of a greater number of climate scenarios either from global or regional models is now found in many more studies. For example, in the area of impacts of climate change on water resources a number of studies have used more global models (Gosling et al., 2010; Bae et al., 2011; Arnell, 2011) or ensembles of regional climate models (Olsson et al., 2011), and thus present estimates of impact for between 10-25 different climates for a given emissions scenario. The use of probabilistic quantification of climate uncertainties has produced estimates of probabilities of changes in future resources such as agriculture and water (e.g., Watterson and Whetton, 2011; Tebaldi and Lobell, 2008). Some studies have developed probability distributions of future impacts by combining results from multiple climate projections and, sometimes, different emissions scenarios, making different assumptions about the relative weight to give to each scenario (Brekke et al., 2009).

Nobrega et al. (2011) apply a number of pattern-scaled GCMs to study the impacts of climate change on water resources in the Rio Grande Basin in Brazil. They used 6 different GCMs and 4 different SRES emissions scenarios and applied them to a large-scale hydrologic model, and found that choice of GCM was the major source of uncertainty in terms of river discharge. Through the CLARIS project (Menendez et al., 2010) multi-regional model climate change scenarios over South America will soon be used for a wide range of climate change impacts studies (e.g., Dengue fever, Degallier et al., 2010).

21.5.2.3. Uncertainties Attributable to Impact Models

With an ever-increasing number of projections of future climate change impacts appearing in the literature, and considering the unprecedented rate and magnitude of climate change projected for many regions, some authors have begun to question both the robustness of the models being applied (e.g., Heikkinen *et al.*, 2006; Fitzpatrick and Hargrove, 2009; Watkiss, 2011a) as well as the methods used to represent key uncertainties in model projections (e.g., Arnell, 2011; Rötter *et al.*, 2011; White *et al.*, 2011). This may reflect a relative low level of co-ordinated activity in the testing and intercomparison of impact models since the mid-1990s, following earlier efforts in the International Geosphere Biosphere Programme (e.g., Kabat *et al.*, 1995; VEMAP Members, 1995; Jamieson *et al.*, 1998) and other notable exceptions (e.g., Mearns et al., 2001b; Tebaldi and Lobell, 2008). However, in recent years there has been a strong resurgence of interest and activity, with several prominent international research efforts initiated, including the Agricultural Model Intercomparison and Improvement Project, involving crop and economic models at different scales (AgMIP – Rosenzweig *et al.*, 2013), the Carbon Cycle Model Intercomparison Project (C^4MIP) and its follow up (Friedlingstein *et al.*, 2006; Sitch *et al.*, 2008; Arora *et al.*, 2013) and the Water Model Intercomparison Project (WaterMIP – Haddeland *et al.*, 2011). Modelling groups from these projects are also participating in the Inter-Sectoral Impact Model Intercomparison Project, which is focusing initially on intercomparing global impact models for agriculture, ecosystems, water resources, health and coasts under RCP- and SSP-based scenarios (see Box 21-1), but will also consider regional models in a second phase of work (ISI-MIP – Schiermeier, 2012).

For example, in AgMIP preliminary results looking at five different wheat models at a site in Mexico indicate that the results for projections of yield to the mid-21st century are more sensitive to the differences in the crop models than to the differences among the different global climate models used (Rosenzweig et al., 2013). WaterMIP compared five global hydrologic and six land surface models to determine the uncertainty across these models in a climate change context for hydrological variables such as runoff and evapotranspiration. Results comparing the models for an observed period indicated substantial differences in the models' estimates in these key parameters (Haddelenad et al., 2011).

21.5.2.4. Effect of Combined Uncertainties

As is standard practice in climate modelling, a growing number of researchers are now applying multiple impact model and perturbed parameter ensemble approaches to future projections (e.g., Araújo and New, 2007; Jiang *et al.*, 2007; Palosuo *et al.*, 2011), usually in combination with ensemble climate projections treated discretely(e.g., New *et al.*, 2007; Graux *et al.*, 2013; Tao and Zhang, 2013) or probabilistically (e.g., Luo *et al.*, 2007; Fronzek *et al.*, 2009; Børgesen and Olesen, 2011; Ferrise *et al.*, 2011; Wetterhall *et al.*, 2011).

21.5.2.5. Evaluating the Robustness of Impact Models

Drawing inspiration from more than two decades of internationally co-ordinated efforts by climate modellers in the Atmospheric (AMIP) and then Coupled (CMIP) Model Intercomparison Projects (Gates *et al.*, 1998; Meehl *et al.*, 2005; Taylor *et al.*, 2012), these new impact MIPs, and other initiatives like them, have the common purpose of mobilising the research community to address some of the long-recognised but pervasive problems commonly encountered in climate change impact modelling. A sample of recent papers illustrate the variety of issues being highlighted, including forest model typology and comparison (Medlyn *et al.*, 2011), crop pest and disease modelling and evaluation (Sutherst *et al.*, 2011; Garrett *et al.*, 2013), modelling responses to extreme weather events (Lobell *et al.*, 2010; Asseng *et al.*, submitted), field experimentation for model calibration and testing (Long *et al.*, 2006; Craufurd *et al.*, 2013) and data quality considerations for model input and calibration (Lobell, 2013). Greater attention is also being paid to methods of economic evaluation of the costs of impacts and adaptation. Cost estimates have been reported at scales ranging from global (e.g., UNFCCC, 2007; Nelson *et al.*, 2009; Parry *et al.*, 2009; Fankhauser, 2010; Füssel, 2010; Patt *et al.*, 2010), through regional (e.g., EEA, 2007; World Bank, 2010; Ciscar *et al.*, 2011; Watkiss, 2011b), to national (SEI, 2009; GCAP, 2011) and local level (e.g., Perrels *et al.*, 2010).

21.5.3. Scenario Development and Application

21.5.3.1. Baseline Information and Context – Current State and Recent Trends

This section deals with defining baseline information relevant to the assessment of climate change vulnerability, climate change impacts and adaptation to climate change. Baseline here means the reference state or behaviour of a system, e.g. the current biodiversity of an ecosystem, or the reference state of factors (such as climate elements or agricultural activity) which influence that system (see also Glossary entry). In the pure climate context, the phrase pre-industrial baselines is used to define the (reference state of the) climate prior to changes in the atmospheric composition (from its baseline pre-industrial state), for example when the UNFCCC defines a reference for measuring global average temperature rises. An historical baseline refers to climate of a particular period, e.g. a WMO climate normal period such as 1961-1990 as a reference to define climate changes in recent decades, and if derived from a climate model then the model would include consistent changes in atmospheric composition. In an adaptation context, a baseline could be the impacts on a system under a given amount of climate change prior to changes in non-climate factors (e.g. improved early warning systems, modified infrastructure) aimed at reducing the impacts. This section does not consider methods for calculating baselines involved in assessing vulnerability of, impacts in and adaptations to systems – but methods for deriving the information on climatic and non-climatic factors used to calculate these baselines.

There are several important properties of baselines to consider when assessing methods to derive relevant information. Defining a reference state sufficiently well that it provides for a good measure of a system's vulnerability or for testing whether significant changes have taken place often requires that much of the variability of the system needs to be captured. Thus the information used to establish this reference state must account for the variability of the factors influencing the system; in the case of climate factors often this requires 30 years of data and sometimes substantially more (e.g. Kendon et al., 2008). Also the temporal and spatial properties of the system under investigation will influence the information required to establish a reliable baseline. Many systems operate at or depend on high resolution information, for example the high spatial resolution of urban drainage systems or organisms within an ecosystem sensitive to temperature extremes require information at the sub-daily time-scale.

Clearly, in defining baselines for assessing climate change impacts, vulnerability or adaptation, a wide range of information will be required as the systems being studies generally comprise interacting physical and human components influenced by climatic and non-climatic factors. For example the assessment of options to respond to river flooding will require information on some or all of the following: past and future rainfall/river flow sequencing and river channel modifications; likelihood of riverside development; viability of property insurance; regional or national finances; effectiveness of relevant institutions. In this case information is required on climate and other physical aspects of the system as well as social and economic factors, and this will generally be so. The rest of this section then assesses methods to derive climatic and then non-climatic information relevant to establishing these baselines and the reliability of this information.

21.5.3.1.1 Climate baselines and their credibility

Fundamental to the study of climate change impacts is to establish an "impact baseline", the behaviour of the system under a reference climate. The baseline information defining this reference climate may be derived from either or a combination of observations or models, with the spatial and temporal resolution generally prescribed by the source, and the choices generally depending on the application. For example Challinor et al. (2004) use observed weather inputs at the daily timescale and coarse spatial resolution with a crop model to demonstrate its ability to simulate a realistic range of yields under historical climate variability to motivate using the model to estimate quantitatively the effect on yields of perturbed climates (e.g. Challinor et al., 2006). Arnell et al. (2003) used a range of climate baselines to study the effect of different choices on the characteristics and ranges the impacts (and paid less attention to the validation of the impacts baselines). In a further example Bell et al., (2009) use high quality observed data at daily timescale and 5 km resolution to demonstrate the ability of a river flow model to simulate an accurate baseline over a 1km river network in order to establish confidence in the impacts model. This is then used with less accurate

climate model-derived baselines that are then compared with results when using climate-model derived futures (Bell et al., 2012). In this case the impacts model is being used with plausible time-series of climate variables to derive realistic (though not necessarily accurate) high resolution baseline and future river flows and thus ranges of climate change impacts which can be considered realistic responses to the imposed climate perturbations. In a more comprehensive study of impacts of climate change in selected UK rivers, Kay and Jones (2012) used different baselines from the UKCP09 scenarios (Murphy et al., 2009) and noted that the changes were similar when using either weather generator or RCM baseline information. However, a greater range of projected changes resulted when using high time-resolution (daily rather than monthly) information (Figure 21-13), underscoring the importance of including the full spectrum of climate variability when assessing climate impacts.

[INSERT FIGURE 21-13 HERE
Figure 21-13: The range of percentage change in flood peaks for nine UK catchments at the a) 2-year and b) 20-year return period. Box-and-whisker plots are used to summarise results when using 10,000 UKCP09 Sampled Data (Murphy et al. 2009) change factors (red) and 100 sets of UKCP09 current and future Weather Generator time-series (cyan). Also plotted, are the results when using 11 sets of RCM-derived change factors (red crosses) and when using 11 sets of RCM current and future times-series (green rectangles). The box delineates the 25^{th}-75^{th} percentile range and the whiskers the 10^{th}-90^{th} percentile range, with the median (50^{th} percentile) shown by the line dividing the box. Additional markers outside the whiskers indicate the minima and maxima, if within the plotted range of -50 to +100. The points derived from the RCM results are joined for the corresponding members of the RCM ensemble (grey lines), and the medians for these methods are shown by black horizontal bars.]

These examples show that a good description of the baseline climate, i.e. in general including information on its variability on timescales of days to decades, is important for developing the reference state or behaviour of a climate-sensitive system for determining impacts on or the vulnerability of the system. This has motivated significant efforts to enhance the quality, length and homogeneity of observed climate records (also important for monitoring, detecting and attributing observed climate change, AR5-WG1 Chapter 2-5 and 10)) and to make these data more easily available. This has included derivation of new observational datasets such as APHRODITE (a gridded rain-gauge based dataset for Asia, Yatagai, et al., 2012), coordinated analysis of regional climate indices and extremes by CLIVAR's ETCCDI (http://www.clivar.org/organization/etccdi, see e.g. Zhang et al., 2011) and data rescue work typified by the ACRE initiative (Allen et al., 2011) which has resulted in analysis and digitization of many daily or sub-daily weather records from all over the world. For some datasets error estimates have been developed (e.g. Morice et al., 2012 for the HadCRUT near-surface temperature record) and for others such as precipitation, increased focus on improving existing datasets such as GPCC (Rudolf et al., 2011) and developing new ones (e.g. TRMM (Huffman et al., 2010) or APHRODITE, Yatagi et al.; 2012) enables observational uncertainty to be estimated. This allows us to more accurately quantify the amplitude of natural variability important for detecting trends or establishing impacts or vulnerability baselines.

Another area of significant progress has been in the development of improved and new global reanalyses. These use weather forecast models constrained by observations from across the globe and available through a period of time to reconstruct the evolution of the weather over the globe. A significant new development in this field has been the use of digitized surface pressure data from ACRE by the 20^{th} Century Reanalysis (20CR) project (Compo et al., 2011) to reconstruct the global evolution of the weather from 1871 to present day. 20CR provides the basis for, at any location, estimating historical climate variability from the sub-daily to the multi-decadal timescale (Figure 21-14) and hence developing robust estimates of the baseline sensitivity of a system to the climate and addressing related issues such as establishing links between historical climate events and their impacts. Other advances include new reanalyses (http://reanalyses.org/) with a focus on developing higher quality reconstructions for the more recent period. They include a new European Centre for Medium Range Weather Forecasts (ECMWF) Reanalyses (ERA) dataset, ERA-Interim (Dee et al., 2011) for the period 1979-2011, the NASA Modern Era Reanalysis for Research and Applications (MERRA), 1979-present (Rienecker et al., 2011), the NCEP Climate Forecast System Reanalysis (CFSR), 1979-Jan 2010 (Saha et al., 2010) and regional reanalyses such as the North American Regional Reanalysis (NARR) (Mesinger et al., 2006) and EURO4M (http://www.euro4m.eu/).

Variables from the first generation of reanalyses often contained discontinuities in time (often resulting from changes in the observations they used) thus clearly were not suitable for defining trends (Thorne and Vose, 2010)

and needed to be used with caution to define climate baselines. In addition, reanalyses combine observations, generally with global coverage, with models and thus those outputs less directly constrained by the observations are subject to model error. For example, precipitation derived from the ECMWF's ERA15 and ERA-40 reanalyses did contain significant biases which have been much reduced in the more recent ERA-Interim dataset (Dee et al., 2011). As with recent efforts on observational datasets, the production of several reanalyses from different international centres (AR5-WG1 Box 2.3) means that the uncertainty in their of climate baselines can be estimated. In the case of 20CR (Compo et al., 2011) a 56 member ensemble of reconstructions was calculated. This is useful in assessing the credibility of the reanalysis in the regions in the early part of the 140-year reconstruction where there were sparse (or no) observations and also to give an estimate of the inherent uncertainty in detail provided by these reanalyses even where there are good observations.

[INSERT FIGURE 21-14 HERE
Figure 21-14: Time series of seasonally averaged climate indices representing three modes of large-scale climate variability: (a) the tropical September to January Pacific Walker Circulation (PWC); (b) the December to March North Atlantic Oscillation (NAO); (c) the December to March Pacific North America (PNA) pattern. Indices (as defined in Brönnimann etal. (2009) are calculated (with respect to the overlapping 1989–1999 period) from various observed, reanalysis and model sources: statistical reconstructions of the PWC, the PNA and the NAO, see Brönnimann et al. (2009) for details, (all cyan); 20CR (pink); NCEP–NCAR reanalyses (NNR; dark blue); ERA-40 (green); ERA-Interim (orange). The dark-grey dashed line and grey shading represent the ensemble mean and spread from a climate model ensemble with a lower boundary condition of observed seas-surface temperatures and sea-ice from the HadISST dataset (Rayner et al. 2003), see Brönnimann etal. (2009) for details. The model results provide a measure of the predictability of these modes of variability from sea-surface temperature and sea-ice alone and demonstrate that the reanalyses have significantly higher skill in reproduces these modes of variability.]

As noted in the introduction, the scale of the system being investigated often implies the need for high temporal and spatial resolution climate information, either observed or simulated, to calculate its baseline or reference behaviour. Observed high-resolution climate baselines are not available in many regions or for all variables required (e.g. Washington et al. 2006, World Weather Watch 2005). Even when datasets exist, they often only provide monthly mean data and thus lack temporal variability and often lack sufficient spatial resolution. The recent reanalyses provide globally complete and temporally detailed reconstructions of the climate of the recent past but generally lack the spatial resolution which would enable them to represent the fine details of weather events often important when modeling the response of systems sensitive to climate. However, they can be combined with either statistical or dynamical downscaling (see e.g. Maraun et al., 2010, AR5-WG1 Chapter 9) to provide higher resolution simulations of the variables required consistent with the (usually reasonably accurate estimate of the) large-scale drivers from the reanalyis. Available observations can then be used to estimate the error in the downscaled simulation.

An example of this methodology is given by Duryan et al., 2010 for West Africa who analyse results from nine regional climate models driven by ERA-Interim for the period 1990-2007 for a region encompassing West and much of Central Africa. Many models show significant biases (Figure 21-15) and thus may not be considered sufficiently accurate to provide the required additional detail on the climate baselines for the region. Advances in this area should be expected through the WCRP-sponsored Coordinated Regional Downscaling Experiment (CORDEX) project (http://wcrp.ipsl.jussieu.fr/SF_RCD_CORDEX.html and see Giorgi et al., 2009) with the initial experiment recommended being to apply the downscaling methods to the ERA-Interim over all land and enclosed sea areas using common domains for dynamical downscaling.

[INSERT FIGURE 21-15 HERE
Figure 21-15: Observed 1990-2007 annual precipitation climatology from GPCC (Rudolf et al., 2011), top left, and, in the remaining panels, related systematic errors in 9 individual regional climate model simulations driven by the ERA-Interim reanalyses (Dee et al., 2011) and in the multi-model ensemble mean (Duryan et al., 2010).]

Climate baseline information can also be derived directly from climate models, either global models or via downscaling of their outputs. Significant international activity on establishing the credibility of the climate simulations of these models is enabled through the coordination activities of the Coupled Model Intercomparison

Project (e.g. CMIP5, Taylor et al., 2009) and has shown improvements in the quality of this information since AR4 (AR5-WG1 Chapter 9). The issue raised above of credibility of climate information from a spatial resolution perspective is relevant here, though there has been some improvement since CMIP3/AR4 with many of the models now running at 100-150km resolutions. Again, this may be addressed by downscaling these simulations (which has been facilitated by improved data capture from the CMIP5 models for CORDEX, Giorgi et al., 2009) and the credibility of this information can be established by similar validation procedures (AR5-WG1 Chapter 9). In theory, one would expect that validation of a reanalysis downscaling should provide a more accurate picture of a models performance though this can be complicated by reanalysis errors (Cerezo-Mota et al., 2010) or differences between reanalyses (Mearns et al., 2012).

With downscaling providing climate baselines at high temporal and spatial resolutions, these can be used directly to assess the impacts of the projected high-resolution climate changes. Historically, the more usual approach has been to use observed baselines and then add climate changes derived from climate projections to these and then calculate the impact using this perturbation of the observed baselines. This was the only viable approach to take when high resolution input data were required to assess impacts or vulnerability and only coarse resolution GCM-based projections were available. Now high-resolution projections are becoming increasingly available both direct and perturbed baseline approaches can be used (see e.g. Kay and Jones, 2011). The direct approach has the disadvantage that the baseline climate will often contain significant errors and their influence on the calculated impact will need to be addressed. The perturbed baseline approach has the disadvantage that in order to calculate a plausible future climate accounting for the full detail of projected climate change the perturbations applied should account for changes in those aspects of climate variability that the system being studied is sensitive to (see e.g. Hawkins et al., 2013). Thus it is important to consider not just the quality of the baseline but what influence the choice of baseline may have on the assessment of vulnerability or the calculation of climate change impacts.

21.5.3.1.2. Non-climatic baselines and their credibility

Given the diversity of non-climatic influences on many climate-sensitive systems baseline information on a wide range of factors will often be required. For example agriculture, water resources, ecosystems and health are all affected by a diverse range of (non-climatic) physical factors and socio-economic influences. Example of physical factor are availability of irrigation systems for agriculture, effectiveness of disease prevention, atmospheric composition (e.g. affecting air quality or CO_2 availability for plant growth) and land-cover/use (e.g. defining the urban environment or availability of agricultural land). Relevant socio-economic factors include demography, level of social, educational and economic development, political/governance background and available technology. Thus to provide a comprehensive assessment of how or whether a climate-sensitive system can adapt to climate change it is necessary to assess its vulnerability in respect of all non-climatic factors that may influence it and information is required on the baseline state of these factors to enable the reference behaviour of a system to be established. (See also TAR WG2 Chapter 13 and AR4 WG2 Chapter 2.)

Significant work has been undertaken to collect and make this information available. For the socio-economic factors, local and national governments and international agencies (e.g. UN agencies, World Bank - http://data.worldbank.org/data-catalog) have been collecting data on the human-related factors for many decades and similarly information on technological developments is widely available. In some situations these factors are evolving quickly and the baseline is taken as the reference state at a particular point in time rather than aggregated over a longer period. In the case of the physical factors, information on many of these have been refined and updated as they are critical inputs to deriving the climate forcings in the Representative Concentration Pathways (RCPs, van Vuuren et al., 2011) used in the CMIP5 (Taylor et al., 2009) experiments. For example these included updated information on land-use change (Hurtt et al., 2011), atmospheric composition (Meinshausen et al., 2010) and aerosols (Grainer et al., 2011, Lamarque et al., 2011). Other aspects of the physical environment in many areas have been well-studied and detailed records are available (e.g. through improved satellite observations and observational processing or via research by international bodies e.g. FAO assessing agriculture and forestry systems). However, much like with climate observations, there are still areas of the world which are less well-observed where rescuing and/or making available old records of the physical environment is of significant value as is making new or more detailed observations.

Given the multi-stressor environment in which assessments of climate change vulnerability and adaptivity are being made, there needs to be consideration of multiple plausible non-climate futures. In this situation a future baseline can be defined, e.g. a given socio-economic scenario, to establish, along with future climate scenarios, a reference state of future vulnerability or adaptive capacity. This then allows the impact of alternative socio-economic futures, such as the story-lines associated with the Special Report on Emissions Scenarios (SRES, IPCC, 2000) and the new Shared Socio-economic Pathways (SSPs), on future vulnerability or adaptation options to be assessed.

A key step in assessing adaptation to climate change in a system is defining information on the non-climatic factors which influence its vulnerability: i.e. the importance of the non-climatic baseline information being assessed here is how it defines the baseline vulnerability of the system and so how changes in these factors can allow it to adapt to climate change, i.e. compensate for/take advantage of increased/reduced climate vulnerability. Given the diversity of climate-sensitive systems as explained above, it is not possible to assess methods for deriving all non-climatic baselines relevant to vulnerability and adaptation studies.

In some cases, this information will be able to be derived from available data sources and in other cases it will be deficient (e.g. in resolution) or missing. The rest of this section will concentrate on presenting several studies which demonstrate some of these cases as a guide to the importance of relevant non-climatic baselines and how they can be derived and interpreted.

The issue of establishing an appropriate non-climatic baseline, in this case in the physical environment, is illustrated in the example of a study of climate change impacts on flow in the River Thames in the UK. Despite increases in temperature and a major change in the seasonal partitioning of rainfall over the Thames basin there is no long-term trend in annual maximum flows over a 126 year series (Marsh 2004). In the 19th century summer rainfall was on average greater than in winter, a situation reversed by the end of the 20th century due to respectively negative and positive precipitation trends which would be expected to have influenced maximum flows. An investigation of the physical environment found that it had been significantly modified as part of river management activities with increases in channel capacity of 30% over 70 years leading to fewer floods in the lower Thames. In this case, establishing the current level of vulnerability of the Thames to flooding required a detailed investigation to determine the appropriate baseline for the physical factor (river channel capacity) influencing this vulnerability.

Another example involves a study of the potential for adaptation in response to projected climate change impacts on crop yields (Challinor et al., 2009). The relevant non-climatic factor in this case was technological, the availability of alternative crop varieties. Detailed field studies demonstrated that the current germplasm included varieties with a wide range of tolerance to higher temperatures (Badigannavar et al., 2002). This established an agricultural technology baseline which demonstrated the potential to reduce vulnerability in the system to compensate for the projected climate change impact.

The relevance of future baselines is demonstrated in the assessment of the economics of climate change as presented in the report of the same name, also known as the Stern report (Stern 2007). For example, a baseline of technological improvement was assumed in determining the costs of mitigation. Also, as noted by Mendelsohn (2007), it makes assumptions (i.e. defines a baseline) about future economic growth in order to establish the costs of projected impacts or damages. In such cases, applying variations from these baselines allows the sensitivity of the findings of such studies to the proposed future baselines to be tested.

21.5.3.2. Development of Scenarios and Projections

Since the AR4 there have been several new developments in the realm of scenarios and projections: 1) a new approach to the construction of global scenarios for use in climate change analysis, initiated with the development of representative concentration pathways (RCPs); 2) the development and application of a greater number of higher resolution climate scenarios from regional climate model simulations; and 3) further use of multiple scenario elements as opposed to use of climate change scenarios only and greater focus on multiple stressors. Scenarios of land-use change are also deserving of more attention and are also discussed below.

21.5.3.2.1. New approach to scenario development

For both the TAR and AR4, the main socio-economic and emissions scenarios used were derived from SRES (Nakicenovic et al., 2000). More recently a new approach to developing climate and socio-economic scenarios was adopted. This new approach changed the familiar linear structure, wherein socio-economic scenarios were constructed, these were used to calculate emissions through application of Integrated Assessment Models (IAMs), and from the concentration of greenhouse gasses and aerosols, climate models would simulate the climate response to the forcings. In the new approach, concentrations of greenhouse gases were developed first (Representative Concentration Pathways, Moss et al., 2010), which allowed the climate modeling work to proceed much earlier in the process. Different possible socio-economic pathways were to be determined later, and it was recognized that more than one socio-economic pathway could lead to the same concentrations of greenhouse gases and aerosols. The process of determining the socio-economic scenarios is ongoing (US NAS, 2010). Four different RCPs were developed, corresponding to 4 different levels of forcing (by 2100) based on watts/m2: RCP 8.5, 6.0, 4.5, and 2.6. These embrace the range of scenarios found in the literature, and they also include explicit stabilization strategies, which were missing from the SRES set. In addition, a set of Shared Socio-economic Pathways (SSPs) is being developed that would characterize a wide range of possible development pathways. More information on these scenarios may be found in Chapter 19 (Box 19-3) of WG2, the WG3 Report, and WG1, Chapter 12, section 12.3.1.3, and Box 21-1 in this chapter. However, due to the time lags that still exist between the generation of the climate change scenarios, and completion of the development of the related socio-economic scenarios, few of the impacts/adaptation studies assessed in WG2 actively use these scenarios. Most of the assessed literature is still based on the SRES climate and socio-economic scenarios

21.5.3.2.2. High-resolution scenarios

There have been large numbers of new simulations with regional climate models (see section 21.4.1.1), e.g., over Europe (ENSEMBLES), over North America (NARCCAP), over Asia (RMIP), over South America (CLARIS and Marengo et al. 2011), over India (HIGHNOON), and these are now being used in impacts and adaptation studies (e.g., Miles et al., 2010, Morse et al., 2009). The CORDEX program (Giorgi et al. 2009) is providing an international coordination of high resolution dynamical downscaling of the CMIP5 global models for all regions of the world. The continent of Africa has been the point of departure for the program, but as indicated in section 21.4.1.1, a number of simulations over Europe, and other continents have also already been produced.

There have also been applications of simpler downscaling techniques (e.g., the delta method, Mearns et al., 2001; and the Bias Correction Spatial Disaggregation method, BCSD, Maurer et al., 2002, 2007). The desire for higher resolution information is largely assumed to result from the needs for impacts and adaptation, but of course, particularly with regard to dynamical downscaling, the purpose is often to produce superior simulations that take into account higher resolution forcings, such as complex topography (e.g., Salathé et al., 2010) or more details in land-atmosphere feedbacks such as in West Africa (Taylor et al. 2011). Applications of some of these new higher resolution results are discussed in the section below. It must be noted that the different means of attaining high resolution climate information for use in impacts and adaptation studies have been noted for a long time (e.g., Giorgi and Mearns, 1991; Giorgi et al, 2001) but there remains many uncertainties on the relative merits of these different techniques, and particularly a paucity of information on when to use what method.

Application of high-resolution climate information

There are now a number of studies that have used dynamically downscaled information of impacts and adaptation planning. A rather complete analysis of climate impacts including possible adaptations in the Pacific North West of North America was recently conducted (Miles et al., 2010) that used both simple downscaling of the global climate model simulations from CMIP3 (Mote and Salathé, 2010) but also two different dynamically downscaled scenarios (Salathé et al., 2010). The dynamically downscaled scenarios were particularly useful for the assessment of effects

of climate change on storm water infrastructure (Rosenberg et al., 2010). Other aspects of the future aside from climate change were used in some of the sectoral analyses, such as population increase to 2025 for effects of climate on energy resources (Hamlet et al., 2010) and climate change along with air pollution scenarios for effects on human health (Jackson et al., 2010 The European PESETA program (Christensen et al. 2012) employed several RCM climate change simulations from the PRUDENCE program to investigate the impacts of climate change over Europe for agriculture, river flooding, human health, and tourism.

The ENSEMBLES project (Christensen et al., 2010) and its suite of high resolution climate projections have spawned a number of impacts studies, such as the effect of climate change on potential energy demand for heating and cooling in the Mediterranean, forest fire risk in Fennoscandia, property damage due to wind storms, crop yields and water resources in Poland, and risk of wheat yield shortfall in the Mediterranean region (Morse et al., 2009). Means of assessing risks of impacts using probabilistic information formed part of many of these projects.

The ENSEMBLES project and AMMA project (Polcher et al., 2011) developed a strong collaboration in order to provide new regional climate scenarios for use in impacts studies for West Africa. Moreover, large inter-comparison initiatives favoured the evaluation of model components relevant for impact studies, such as land-surface and chemistry models (Ruti et al., 2011).

The United Kingdom Climate Program (UKCP09) has used a combination of parameter permutation experiments (PPEs) based on the HadCM3 global climate model and multi-model ensembles (MMEs), as well as regional climate model results to develop probabilities of changes in temperature and precipitation at a 25 km resolution (Murphy et al., 2009) for all of the UK. This information is being used to determine probabilities of different impacts of climate change and possible adaptations. Results of individual regional climate model simulations are also available. A number of case studies using the UKCP09 scenarios have been developed. For example, Bell et al., (2011) used the results from 11 RCM simulations to determine potential changes in river flows throughout the UK for the A1B emissions scenario.

While the majority of articles published based on the NARCCAP suite of simulations over North America has been on climate analysis, a growing number of articles on climate impacts is appearing including impacts of climate change on available wind energy (Pryor and Barthelmie, 2011; Rasmussen et al., 2011), road safety (Hambly et al., 2012), hydrology (Burger et al., 2011; Shrestha et al., 2011), forest drought (Williams et al., 2012), and human health (Li et al., 2012).

21.5.3.2.3. Use of multiple scenario elements and focus on multiple stressors

Many more impacts and adaptation studies now use multiple scenario elements, as opposed to climate change scenarios alone. Some of the most common types of study that uses multiple scenario elements are those concerned with world hunger, where population change, land use, and economic conditions in various parts of the world make up important elements in addition to climate change (e.g., Parry et al., 2004). Arnell (2004) also used multiple aspects of the SRES scenarios in a study of global water resources, another context where population changes and future economic conditions would be critical to the study. Another type of study that commonly makes use of multiple aspects of scenarios are urban heat island and climate change studies concerned with human health (e.g., Knowlton et al., 2008; Rosenzweig et al., 2009). Recently, McCarthy et al. (2010) considered population increase up to 2050, as well as expanded urban areas to determine effects of climate change on urban heat islands. In the European Impacts Program PRESETA multiple aspects of the SRES scenarios (e.g., population and socio-economic conditions) were considered for some of the impacts areas such as human health (Watkiss and Hunt, 2012). The use of multiple scenario elements is associated with the issue of multiple stressors, which is discussed below.

One of the issues that remain somewhat unresolved is that of downscaling scenario elements. The SRES scenarios have been downscaled for Europe, for example (van Vuuren and O'Neil, 2006), but such downscaling has not been accomplished for all areas. The economic activity information in the SSP's (see above) has also been downscaled to 0.5 degree grids in some cases, but not all. This information, however, has not yet been examined carefully in the impacts and vulnerability literature (Ebi et al., submitted). (See van Vuuren et al., 2010 for a review of issues related

to downscaling of socioeconomic data). Moreover, vulnerability studies often consider other scenario elements on very local scales, and tend to use other, local sources for these scenario elements, which may or may not be consistent with the larger scale scenario elements. See the discussion of credibility of scenario elements in section 21.5.3.3.2 below.

The recognition of the importance of viewing climate change in the context of multiple stressors has increased over time. In AR4 this topic was, naturally, discussed in terms of sustainability (Chapter 20) and adaptation (Chapter 17). In the AR5 the issue of multiple stressors is incorporated into most regional and sectoral chapters, and those related to adaptation. Multiple stressors can have independent, synergistic, or antagonistic effects on particular impact areas. Typical stressors, aside from climate change, include changes in population, migration, land use, economic factors (particularly affecting adaptive capacity), technological development, social capital, air pollution, and governance structures, among others. Magrin, Marengo et al. (2011) clearly identify land-use change and shifts in major socio-economic conditions as stressors of equal importance to climate change in considering future conditions in Latin America. In the new chapter on ocean systems Portner, Karl et al. (2011) indicate the central importance of numerous changes in addition to climate (e.g., changes in nutrients), that are strongly affecting ocean ecosystem health. Hijioka, Lin et al. (2011) identify rapid urbanization, industrialization and economic development as major multiple stressors that will likely be compounded by climate change in Asia. The importance of simultaneous changes of frequency in excessive heat events and increases in air pollution have been well documented in the context of human health (Jackson et al., 2010). Human health studies in general tend to require a multiple stressor approach (Morello-Frosch, et al., 2011).

Many of the multiple stressor studies are regional or local in scope. For example Ziervogel and Taylor (2008) examined multiple stressors in South Africa, taking a survey approach. They examined two different villages in Sekhukune and found that a suite of stressors are present in the two villages, such as high unemployment, health status (e.g., increased concern about AIDs), and access to education. Concerns about climate change were only present in the context of other impacts such as availability of water. In a study on the Great Lakes region, additional stressors included land use change, population increase, and point source pollution (Danz et al., 2007). They proposed an integrated measure of multiple stresses for the region. Mawdesly et al. (2009) in considering wildlife management and biodiversity conservation note that reducing pressure from stressors other than climate change can maximize flexibility for adaptation to climate change. Stressors in this area are many, including invasion of non-native species, land-use change, and human population increases and shifts. Baker et al. (2008) note the importance of multiple stressors in the case of coral bleaching; these include sedimentation, turbidity, and nutrient loading in addition to shifts in climate. Nelson and Palmer (2007) discuss the effect of the stressors of increased watershed imperviousness, reduction in riparian vegetation, and increased siltation on water temperatures of streams, which in turn affects their suitability as a habitat. Shifts to warm-water species will result. Eakin and Wehber (2009) consider the effects of changes in demographic factors such as age structure and education level in two agricultural case studies in Latin America.

This increased focus on multiple stressors obviously increases the need for a much wider range of data and wider range of projections for the wide range of stressors, across multiple spatial scales.

21.5.3.2.4. Projections of land-use change

Land-cover and land-use are related in multiple ways to the regional distribution of vulnerabilities, both because they are intrinsically part of the distribution of natural resources and of goods and services from ecosystems (e.g. Scholes et al 2005, Janetos et al 2005), but also because they are changing rapidly as a consequence of both societal demands for those goods and services, and because of variability in the climate system. While documenting global patterns of land-cover change has been a focus for observational research for many years in particular ecosystem types (e.g. forests in Lepers et al. 2005, Hansen et al.), the projections of land-use and land-cover change have typically either focused on human-driven changes (Rindfuss 2008) or on the sensitivity of ecosystems to climate variability, but rarely both. Land-use and land-cover histories have been harmonized for use in future simulations as part of the RCP process (Hurtt et al 2011).

More recent literature begins to address new aspects of land-use and land-cover change as those processes relate to greenhouse gas mitigation actions. Meinshausen et al (in press), Van Vuuren et al. (2011), Thomson et al. (2010), and Wise et al. (2009) present scenarios of land-use and land-cover change that have focused on how those changes are also consequences of decisions about greenhouse gas mitigation, especially the potential for expansion of purpose-grown bioenergy crops. The extent and rapidity of spread of purpose-grown bioenergy crops in these studies using integrated assessment models is largely a function of economic behavior- specifically, whether a price is associated with terrestrial carbon as well as fossil fuel emissions, or whether a price is only associated with fossil fuel emissions. In some models, (Thomson et al 2010, Wise et al 2009), bioenergy crops are used for electricity generation when coupled with geological capture and sequestration. This is not a general result, however, as all integrated assessment models do not represent that particular combination of technologies. In model results that have large expansions of purpose-grown bioenergy crops, there is also a larger expansion of cropland for food production to satisfy the demand for food from growing human populations. This result is due to the fact that the competition for arable land forces agriculture onto less suitable lands and lowers their per hectare productivity. However, while the interaction between land-use, bioenergy crops, and agricultural productivity is beginning to be investigated, the interaction with the climate system itself is still largely unexplored, so our understanding of these interactions is still in a very preliminary stage. Hibbard et al (2010) present an analysis of the major uncertainties and research gaps in addressing this interaction.

21.5.3.3. Uncertainties and Credibility of Projections and Scenarios

21.5.3.3.1. Uncertainties and credibility regarding future climate

From the viewpoint of developing projections of long-term climate change, there are primarily three sources of uncertainty. This section discusses these three sources, comments on how the uncertainty has been quantified (if it has been), indicates how credible current estimates are and indicates whether we can reasonably expect reductions in these sources of uncertainty.

Future emissions and concentrations of greenhouse gases and aerosols

Future climate forcing (derived from emissions and concentrations) will be shaped primarily by: emissions of greenhouse gases, aerosols, and short-lived species into the atmosphere; and processes that control the composition of the atmosphere, such as atmospheric chemistry, terrestrial and marine components of the carbon cycle, and nitrogen cycles. Factors that influence the scale of future anthropogenic emissions include the scale of economic activity, the technologies with which human societies generate and use energy, and the public policy environment in which human activities are conducted. Hence, predicting emissions of GHG and aerosols requires being able to predict how the entire human world will develop in the future, a truly daunting task fraught with multiple profound uncertainties. This would also include determining future populations, gross domestic product (GDP), and the development of future technologies. There is not much chance of reducing these uncertainties for the long-term future. There has been an understandable reluctance to quantify the uncertainty in the emissions of greenhouse gases and aerosols, although some elements contributing to final emissions estimates have been quantified, for example, of population (also see section 21.5.3.3.2 below). Nevertheless, future emissions have mainly been presented as scenarios having equal plausibility (Parson et al., 2007). This was the case with the SRES scenarios, and is presently the case with the RCPs and SSPs (van Vuuren et al 2012, Adger et al 2011). See section 21.5.3.3.2 below for a more thorough discussion of the credibility of the elements of socio-economic scenarios.

Climate system response to forcing

Climate system uncertainty is explored through the application of global and regional climate models. While most of these models are carefully constructed to incorporate many climate-related processes and are carefully evaluated, they do not necessarily respond in the same way to a given future forcing scenario. These differences are due to scientific uncertainties about how the climate system works, differences in the way various subsystems are modeled

(e.g., land surface processes) and differences in how unresolved processes are parameterized (e.g., convection). These uncertainties are explored and characterized by analyzing the results of different types of ensembles of climate model simulations. The most common is the multi-model ensemble (MME) based on simulations with different climate models that are subjected to the same future radiative forcing. These MMEs play a central role in the analyses that contribute to the various IPCC assessments (e.g, sets of simulations from CMIP3 and CMIP5 for the AR5 Reports). There are also ensembles developed from a single climate model whose parameters are varied in systematic ways, which are referred to variously as Parameter Permutation Experiments or Perturbed Physics Ensembles (PPE) (e.g., Murphy et al., 2007).

While the climate models used to generate simulations for the AR5 are more complete than ever before (Chapter 9 WG1) (e.g., most now have fully closed carbon and nitrogen cycles, thus reducing the uncertainty regarding final concentrations in the atmosphere), there are still processes that are known to be important but are not incorporated due to incomplete understanding of the process or difficulty in modeling the process. For example, most of the CMIP5 models still do not include the explicit modeling of glacier and ice sheet dynamics (see WG 1 Chapter 9, section 9.1.3.2.8). Hence, projections of sea level rise from such models are bound to be incomplete and therefore limited. (However, better estimates are made in the AR5 using offline land ice sheet models). Other such missing processes include possible occurrence of catastrophic events such as the collapse of the Greenland Ice Sheet. Another example is that the global climate models are still limited in terms of resolution which can be important for capturing relevant processes as demonstrated in a recent study with improved vertical resolution allowing better representation of the stratosphere which then significantly influenced the projected changes in the climate over Europe (Scaife et al. 2011).

Obtaining robust predictions of climate change (i.e. at least a clear understanding of the direction of change of precipitation preferably with a level of uncertainty quantification), requires combining the projections with detailed analysis and understanding of the drivers of the changes. The most successful example of this is the application of the attribution of observed global and regional temperature changes using global models incorporating known natural and anthropogenic climate forcing factors (AR4 WG1). The global model's ability to reproduce the observed variations in temperature, the quantification of the influence of the different forcings factors and how well these influences are captured in the models provide for:

- Confidence that models capture correctly the physical processes driving the changes and thus in their ability to project future changes;
- A method of quantifying the range of sensitivities of the climate system to the different forcings factors and thus how it is likely to respond to scenarios of changes in these forcing factors.

In this situation, a robust message was derived due to having a clear understanding of the drivers of observed changes and all models reproducing these along with the direction and, to a reasonable degree of accuracy, the magnitude of the change.

Through a careful analysis of the drivers of projected changes, similar robust messages can be derived for precipitation change. Rowell and Jones (2006) performed a detailed analysis of the drivers of projected European drying in summer and concluded this signal to be robust as the dominant processes were driven by warming. In a similar analysis Kendon et al. (2010) concluded that the signal of increased daily precipitation in Europe in winter was also robust.

IPCC AR4 stated clearly that temperatures and sea-level are predicted to increase (i.e. providing quantified levels of confidence in the range in which these increases are expected to lie) and thus this information has high credibility. This is due to model simulations reproducing observed trends in these variables, an understanding of the physical drivers of these trends and that the models represent these well.

In some cases, for example precipitation on a regional scale, the sign of the change may differ from one model to another. However, it is important to note that in many cases, the difference in direction of change in precipitation simulated by, for example, two different models, indicates a lack of significant change in the precipitation compared to the natural variability in a particular region (Tebaldi et al. 2011).

Yet, it is also the case that some contrasts in direction of change are significant. In some situations, future projections may go in opposite directions to each other with neither possibility able to be excluded on the basis of our physical understanding of the drivers of these changes. For example, McSweeney et al., (2011) found that in an ensemble of GCM projections over south-east Asia, all models simulated the important monsoon processes and rainfall well but projected both positive and negative changes in monsoon precipitation and significantly different patterns of change. In this case no information on observed trends or more detailed process understanding was available but there has been little effort to analyse trends and projected changes in south-east Asia and thus the current issue of contradictory projections could be clarified with some targeted research.

Model projections may also be less consistent or inconsistent with available observations. In these cases, the projected information is less credible as explained in the following examples:

- In some cases drivers of historical change are not known so there is a lack of physically based understanding of the past to use in the assessment of confidence in the models' ability to simulate regional climate change. An example of this is the reason for the significant drying trend seen in the Sahel from the 1960s to the 1990s. Whereas statistical analysis has demonstrated the role of sea-surface temperatures (SSTs) in driving Sahel rainfall variability, and some relevant mechanisms identified, models driven by observed SSTs fail to capture the full magnitude of the drying trend (e.g. Held et al. 2005). Thus our understanding of the system and its drivers is incomplete which complicates the interpretation of future projected changes in this region (e.g. Biasutti et al., 2009, Druyan, 2010). This implies that other processes are important and thus research is required to identify these and ensure that they are correctly represented in the models. Without knowing what these processes are and thus that the models are representing all relevant processes, projections of rainfall changes over this region cannot be considered reliable.
- A more extreme case is where future projections all go in the opposite direction to the observed changes and an example of this is seen over part of the continental US which has seen cooling trends in past few decades (AR4 WG1) though the projected changes indicate a warming. This is not necessarily a contradiction though the lack of similar cooling trends in many climate models again indicates there is a process that is not being captured in the models and needs to be identified and included in the future. Then the influence of the process in projections of future climate change needs to be assessed in order to provide confidence in the sign and magnitude of any changes.

In these cases where future projections differ significantly or go in opposite directions, it is still important to provide information on the range of changes. The likelihood that temperatures (and sea-level) will continue to rise in the future is sufficient to motivate a response to these predicted changes and, in general, information on other climate variables will also be required. Thus it is important to be able to characterize the range of plausible changes in these other variables.

One approach is to use a Bayesian probabilistic framework to combine the range of information that may include differences in direction of change in precipitation in a global climate model (e.g. Tebaldi and Knutti, 2007, Harriss et al., 2012) or in a global model and then a regional model driven by the global model (e.g., Déqué and Somot (2010). Another is to identify a subset of available models whose response characterises the range of projected futures (e.g. McSweeney et al., 2011).

It is expected that with model improvements (e.g., including more important processes and modeling processes more completely) that the uncertainty due to climate (model) response will be reduced over time in certain ways. However, this does not necessarily mean that all metrics of uncertainty will be reduced at once. It is quite possible that improving the representation of processes will not immediately result in reduction of uncertainties regarding the likely range of temperature change in central Kansas in 2050, for example (Mearns, 2010). One of the FAQs presented in Chapter 1 of WG1 discusses this issue in more detail.

Internal variability

Long-term projections of climate change are subject to uncertainty resulting from the internal variability of the climate system. The relative role of this type of uncertainty compared to the other sources of uncertainty (climate

model response uncertainty and forcing uncertainty), are a function of the future time horizon being considered and the spatial scale of analysis (Hawkins and Sutton, 2009; 2011). Here we use the term natural or internal variability to refer to unforced variability internal to the climate system. Hence this definition does not include variability related to the occurrence of natural phenomenon, such as volcanoes. Internal variability is usually explored by running sets of climate model simulations (ensembles) using different initial conditions for each simulation. Traditionally the number of ensemble members has not been large (e.g., around 3 in the CMIP3 data set), but the number has increased in the CMIP5 set of simulations to about 7. However, some recent research has explored larger numbers of ensemble members (e.g., Deser et al., 2010) and has thus come up with improved measures of natural variability. In this case 40 different members were produced, which represent how much the climate can vary based on random internal variations. The variations across ensemble members can be considerable on various spatial scales, and there is considerable evidence that this kind of uncertainty may not be particularly reducible (Deser et al. 2012). The issue of internal variability is more thoroughly discussed in WG1 Chapter 12, section 12.1.1.2.

21.5.3.3.2. Credibility and uncertainties regarding socioeconomic scenario elements

Credibility

The fact that scenarios serve both as tools of investigation for the scientific community and as the basis of information on possible futures for decision-makers introduces additional demands for the credibility of scenarios beyond that typically required of other scientific studies (van Ruijven et al. forthcoming).

Cash et al. (2003) distinguish three criteria for effectively linking scientific knowledge to policy action: credibility, salience, and legitimacy. Credibility refers to the scientific adequacy of a policy-relevant study. Salience refers to the relevance of a study's findings to the needs of decision-makers, while legitimacy refers to the perception that the study was produced in a manner that is respectful of divergent values and beliefs. Cash et al. (2003) find these attributes to be tightly coupled and suggest that efforts to enhance one criterion normally introduce tradeoffs for the others. Studies examining the performance of scenarios in climate change research across all three of these criteria are rare, but a general conclusion has been that most effort has been expended on credibility with much less attention to salience and legitimacy (Hulme and Dessai 2008, Garb et al. 2008, Girod et al. 2009).

Perhaps partially in recognition of the limitations that scenarios have had historically with salience and legitimacy, new scenarios for future climate change research will have a dramatically new structure. Under the parallel process (Moss et al. 2010), research streams that developed independently around climate scenarios (inspired by representative concentration pathways, or RCPs; see van Vuuren et al. 2011) and socioeconomic scenarios (shared socioeconomic pathways, or SSPs; see O'Neill at al. forthcoming) will be brought together to enable integrated analyses of mitigation, adaptation, and residual impacts. (See Box 21-1 for an overview of the new scenarios). RCPs aim to be the concept that coheres climate and socioeconomic elements together for reference scenarios (i.e. alternative futures assuming no new climate policy; see Ebi et al. forthcoming and van Vuuren et al. forthcoming). In principle, such coherence is possible, as RCPs can serve as both inputs to climate modeling and as target outputs to IA modeling. Additionally, one of the main conclusions of the SRES (Nakicenovic et al. 2000) supports this aspect of the new scenario design, as fairly different socioeconomic conditions could give rise to similar emissions trajectories. Subsequent studies have arrived at similar results (van Vuuren et al. 2008).

However, heeding the warning of tradeoffs from Cash et al. (2003), it remains to be seen if enhancements to scenario salience may result in diminished scientific credibility. It is unclear how difficult it will be to bring independently developed climate and socioeconomic scenarios together in an internally consistent manner during the integration phase (O'Neill and Schweizer 2011). Additionally, the SSP framework (O'Neill et al., forthcoming) introduces another layer of complexity by labeling SSPs describing globally aggregated trends as "basic" versions, while more elaborate SSPs, which will be geared toward sector-specific or more regional and localized analyses, will contain additional socioeconomic detail and are called "extended" SSPs. The possibility that additional details in extended versions of the SSPs could upset the internal consistency of the basic SSPs cannot be dismissed, and such problems will only be uncovered as the SSPs are further developed and used.

In this regard, recent scholarship has suggested that the exclusion of some socioeconomic details in socioeconomic scenario studies can affect the internal consistency, and therefore the credibility, of a study overall. This is due to the common practice of Story and Simulation (SAS; Alcamo 2008) for scenarios, where narrative descriptions of alternative futures serve as the inspiration for socioeconomic simulations. At the initial stage of story development, the first internal consistency test is that these stories be plausible. Thereafter, integrated assessment (IA) models attempt to replicate qualities of these stories. The ability of the IA model to simulate the story is viewed as a more rigorous test for internal consistency. Conventional wisdom is that so long as IA models are able to simulate the conditions described in the story, the story (and hence its assumed combinations of socioeconomic elements) has been demonstrated as internally consistent and therefore credible. Thus, a strength of SAS is that it marries the malleability of stories to the rigors of simulation (Raskin et al. 2005). As noted in the AR4, stories in SAS can offer a point of entry for multi-scalar scenario analyses (Lebel et al., 2005; Kämäri et al., 2006). Despite these benefits, some scholars have pointed out a potentially serious deficiency in the practice of SAS, as stories often include details that make them plausible which IA models do not include (Kok 2009, Schweizer and Kriegler 2012, Schweizer and O'Neill forthcoming). The exclusion of some details in IA models may affect the determination of whether a story is plausible (Lloyd and Schweizer, forthcoming) let alone internally consistent. For example, one of the findings of Schweizer and Kriegler (2012), who employed a systematic method for assessing the internal consistency of the qualitative aspects of scenarios, is that assumptions regarding social priorities (e.g. contrasting hypothetical worlds that are economically versus environmentally focused) can make the difference between marginal and strong internal consistency for SRES scenarios with the lowest emissions profiles.

Along with the new research opportunities that will be made possible under the new scenario process, the scientific community must also revisit what credibility means across extended SSPs, basic SSPs, and SSP+RCP scenario combinations. Scholarship on environmental scenario exercises crossing geographical scales suggests that linkages between scenarios at different scales can be hard or soft (Zurek and Heinrichs 2007), where downscaling would be an example of a hard linkage while other similarities between scenarios would be soft linkages. In the context of the new scenario framework, some thought has been given to the circumstances under which strong internal consistency should be retained (e.g. global SSP+RCP scenarios) and when it may be relaxed (e.g. the internal consistency of a provincial vulnerability assessment, based on extended SSPs + regional RCP climate projections, with global SSP+RCP scenarios) (van Vuuren et al. 2012). Nevertheless, how to apply flexible interpretations of scientific adequacy and maintain scenario credibility is relatively uncharted territory for scenario-based environmental change assessments. There will be a need for studies to document best practices in this respect and for the scientific and policy communities to move toward consensus.

In conclusion, we find that few studies have assessed the performance of scenarios and their reception by decision-makers, whether focusing on credibility (e.g. internal consistency) or also considering salience and legitimacy. The new scenario process will also introduce new complexities for scenarios, and attention should be paid to what these complexities may mean for scenario credibility.

Quantifications of uncertainties of scenario elements and scenarios

Since AR4, little has changed over the controversy for whether probability density functions (pdfs) should be assigned to emissions pathways or other socioeconomic scenario elements (e.g. population growth, income growth) (Parson et al., 2007). Where studies have incorporated probabilities, they have done so in a variety of ways. Some propose or have demonstrated probabilistic estimates for socioeconomic scenario elements. A study by van Vuuren et al. (2008) applied conditional probabilistic estimates for socioeconomic scenario elements that would be consistent with alternative SRES storylines. Van Vuuren et al. (2008) were careful to comment that the purpose of such conditional probabilities is not to evaluate the likelihood of the underlying storylines but to explore other topics such as the ranges of emissions for different storylines. In contrast, Morgan and Keith (2008) have proposed that likelihoods for scenarios could be obtained through a subjectivist approach, where probabilities are obtained from experts. In this vein, some expert elicitation studies regarding technological change (Curtright et al. 2008, Anadon et al. 2011), including those combined with economic modeling (Böhringer et al. 2009, Baker et al. 2009), have further demonstrated that experts could assign subjective probability judgments to alternative future outcomes. Other examples of uncertainty quantification include probability estimates for the feasibility of achieving temperature or

concentration targets (Keppo et al. 2007, O'Neill et al. 2009). In these latter cases, socioeconomic elements in emissions scenarios are not treated probabilistically; instead, assumptions about climate sensitivity or perfect foresight are adjusted, and an IA model is run multiple times. The frequency of the model runs in the ensemble that achieve the temperature or concentration targets provide probabilistic estimates for achieving the policy targets.

Because there are multiple ways to quantify uncertainties in scenarios, the new parallel design for socioeconomic and climate scenarios may or may not pose challenges for further uncertainty quantification. Although decoupled socioeconomic and climate scenarios may make it difficult to determine probabilities for climate scenarios based on a probabilistic analysis of socioeconomic scenarios alone, other opportunities for probabilistic analyses will be retained. For example, it would be possible to do conditional probabilistic studies with socioeconomic scenarios independently and determine probabilistic ranges for emissions. If subjective probabilities for socioeconomic scenario elements were also introduced, it would be possible to conclude conditions under which particular emissions scenarios would be expected to be more likely. In the latter case, likelihood judgments for emissions scenarios may be translatable to likelihood judgments for RCPs, and therefore, related climate projections.

21.6. Knowledge Gaps and Research Needs

The issues of the regional context of climate change are arguably the thematic area most in need of attention to advance adaptation response, policy, and decision making. The needs range from the practical questions requiring applied research, to more fundamental theoretical questions. Table 21.4 identifies leading foci that currently constrain the adaptation community, and where a solid advance of knowledge advance would contribute to substantial value for the broad adaptation community.

[INSERT TABLE 21-7 HERE
Table 21-7: Leading knowledge gaps and related research needs.]

Frequently Asked Questions

FAQ 21.1: Should we be concerned about impacts of climate change in other parts of the world?

Short answer: Regional impacts of climate change, both adverse and beneficial, may have ramifications in other parts of the world. Different types of impacts can be of importance to a variety of interest groups. Cross-regional concerns about four types of impacts can be distinguished: 1) Concerns about large-scale geophysical impacts, 2) Concerns about socio-economic and geopolitical impacts, 3) Concerns about social instability due to rapid-onset events, and 4) Concerns internationally about impacts occurring locally. Some illustrations of these are provided below, along with the types of groups who might show interest.

Long answer: Climate change is a global phenomenon, but the expression of that change and its impacts on natural systems and society varies enormously from place to place and over different time scales. Some impacts may be gradual responses to long-term trends, sometimes referred to as "slow-onset" impacts. More prominent, though also more difficult to attribute to a changing climate, are "rapid-onset" impacts of extreme weather events[1] such as droughts, floods or storms. In both cases, regional climate change has direct impacts on systems and communities that are exposed to that change in the same region. However, such impacts can also have implications much farther afield, sometimes in completely different parts of the world. The reasons for this relate to key regional interdependencies that are present both in the global physical climate system as well as in economic, social and political systems that are themselves becoming increasingly globalised. Cross-regional concerns about four types of impacts can be distinguished:

1) *Concerns about large-scale geophysical impacts*. Some types of geophysical impact can have large-scale repercussions well beyond the regions in which they occur. A well-known example of this is the melting of land-based ice, which is contributing to sea-level rise (and adding to the effects of thermal expansion of the oceans), with implications for low-lying areas far beyond the polar and mountain regions where the melting is taking place. These impacts are ongoing and are projected to take centuries or millennia to slow down or

halt, which would require that climate change stabilisation be achieved first. The types of actors with an interest in these impacts include policy-makers involved in discussions about reducing global greenhouse gas emissions in order to stabilise the climate, decision-makers needing to formulate strategies for coastal management and flood protection under rising sea levels, or insurers offering coverage for flooding, erosion and related risks.

2) *Concerns about socio-economic and geopolitical impacts*. Local, slow-onset impacts of climate change may also trigger higher-order responses that have wider social, economic and geopolitical implications. For example, there has been much debate in recent years on the question of environmental refugees, where the argument has been put forward that climate change is degrading environments in some regions to such an extent that the livelihoods of local populations have or will become unsustainable, and they are forced to migrate to other regions. While there is evidence of international migration in the wake of extreme events such as hurricanes (e.g. population displacement from central America to the United States following Hurricane Mitch in 1998), the evidence for longer-term climatic causes of migration is disputed, and is also confounded by the growing phenomenon of economic migration. Nonetheless, geopolitically this is an issue of increasing importance to national and international policy makers.

   A second example of a regional impact of climate change with socio-economic and security implications is the accelerated shrinkage of Arctic sea ice that has been observed in recent years. This is projected to continue into the future under sustained regional warming, opening Arctic shipping routes as well as providing access to valuable mineral resources in the exclusive economic zones of countries bordering the Arctic. For example, under some scenarios, it is estimated that moderately ice-strengthened ships could have almost complete summer access to Arctic routes such as the Northwest Passage, Northern Sea Route and Trans-Polar Route by the end of the 21st century, representing significant savings for trans-continental shipping currently using routes via the Panama and Suez Canals. On the other hand, there are also numerous risks that would accompany such commercial exploitation, including shipping accidents, pollution, threats to livelihoods among indigenous communities, and general degradation of an already fragile environment. National governments, representatives of indigenous peoples, international freight carriers, resource extraction industries and environmental agencies are among the parties having a stake in these future developments.

3) *Concerns about social instability due to rapid-onset events*. A third class of local impacts with global ramifications, are those that are caused by rapid-onset, extreme weather events, which may curtail production of some key commodities that are traded internationally, leading to shortages of supply and hence increased prices to consumers. For instance, there are recent examples of price spikes in some basic food commodities that caused local unrest among consumers in some parts of the developing world. Though these price rises were triggered by weather-related crop failures in exporting regions, the underlying causes of reduced food supply are more complex, and include reallocation of food crops by some major exporters for use as biofuels, national trade protection policies, as well as market speculation. Some key actors with an interest in such events might include bodies regulating international commodities trading, national governments, regional trading blocs, public law and order authorities, and aid agencies.

4) *Concerns internationally about impacts occurring locally*. Some impacts are local and may have little or no immediate effect outside the regions in which they occur. Nonetheless, they may be of concern to actors outside that region for a range of reasons, including: (i) disaster relief (e.g., to ameliorate the impacts of malnutrition or disease brought on by weather-related events), (ii) environmental protection (e.g., conservation of locally threatened and valued species), (iii) enhancing adaptive capacity (e.g. through capacity building and other development projects that enhance resilience to climate change), or (iv) exploiting potential opportunities (e.g. through foreign investment in agricultural production in regions where future climate change impacts may be beneficial for productivity). Here, some key actors who might wish to consider such impacts include national and international development agencies, humanitarian organisations, multi-national corporations, and environmental organisations.

[FOOTNOTE 1: Although extreme weather events on their own can be very difficult to attribute to anthropogenic climate change, long-term trends in such events are projected by climate models (Cross reference?), and in some cases are already being observed (see FAQ 2.2, Chapter 2, WG I).]

FAQ 21.2: Is the highest resolution projection the best to use? [placeholder draft]

Short answer: *A common perception is that higher resolution equates to more information. Unfortunately data does not equal information, and more high resolution data does not necessarily equal more information. Hence, while there are many methods that can increase resolution, it is not a given that there will be more skill in the final product. For example, simple approaches such as interpolation or perturbing observed data fields with GCM information increase the resolution but add no high resolution climate change information. Using downscaling methods will add a high resolution component but there will be an extra error associated with the additional method applied which needs to be considered. More importantly, if downscaling is applied to only one or two GCMs then the resulting high resolution scenarios are unlikely to span the full range of projected changes that a large GCM ensemble would indicate are plausible futures. Thus for many applications, such as understanding the full envelope of possible impacts resulting from our current best estimates of plausible change in a regional climate system, lower resolution data can be more informative. At the end of the day, no one data set is best, and it is through the integration of multiple sources of information that robust understanding of change is developed.*

Long answer: placeholder pending a support graphic/cartoon being developed

FAQ 21.3: Are earlier assessments still valid? [placeholder draft]

Short answer: [to be drafted]

Long answer: The IPCC has conducted four major Assessments, starting in 1990, and each has included the equivalent of a Working Group 2 Report. The current report represents the fifth assessment. The reports through time have increased in length, scope, and complexity. But the essential goal of the reports has a core commonality. In the first report, it is stated that the 'responsibility of Working Group II is to describe the environmental and socioeconomic implications of possible climate changes over the next decades caused by increasing concentrations of greenhouse gases' (IPCC 1990). By the Third and Fourth Assessments, the WG2 Assessments had expanded to explicitly consider vulnerability and adaptation, in addition to impacts. In the second report both mitigation and adaptation were considered in WG2, but the sections on adaptation were very basic. So we see that the organization of the Working Groups, including their remits, has changed over time. But our concern in this FAQ is whether the content of the earlier reports are still valid, not whether the structure of the reports has significantly changed. Within the Second Report (SAR) concerns regarding vulnerability and adaptation were already present, as were many concepts that received more intensive coverage in the later reports, such as multiple stressors, adaptive capacity, and vulnerability. But the earlier reports (IPCC 1990, 1995) tended to be much less quantitative than later reports, and provided less detail on a regional scale. Yet many of the concerns expressed in later reports (2001, 2007, 2014) are already adumbrated in the earlier ones (e.g., negative impacts on human health from increased heat waves, decreased water resources and strains on cropping systems, changes in ecosystem composition). By the 2001 Report, much more detailed regional analysis was taken on, and the structure of a sectoral section and a regional section came into being, along with a detailed chapter on adaptation. Also greater attention was placed on how uncertainties are expressed and quantified. By the 2007 report, the major new theme of assessment of observed changes and responses in natural and managed systems became a subject of its own, although it was introduced in the Third Assessment Report (TAR). Also by the time of the TAR, greater emphasis was placed on the concept of sustainability as a broader framework through which climate change impacts should be viewed.

[Placeholder for figure of different IPCC assessments, and the new elements that emerged with each report]

The overall message of this FAQ would be that yes, in a general sense, the earlier assessments are still valid, but the assessments have become much more complete over time, evolving from making very simple, general statements about sectoral impacts, through greater concern with regions regarding impacts and vulnerabilities, through to greater emphasis on sustainability, equity, and deeper examination of adaptation options. Finally in the current report (IPCC 2014) we see four chapter on adaptation, and a much more explicit treatment of the challenges of decision-making. The progression of the reports reflects tremendous scientific progress and deep learning from one report to the next. Obviously one can learn the most about impacts, vulnerability, and adaptation in the context of climate change by looking at the most recent report. It is certainly much more complex and complete in its

treatment of defining societies challenges in the face of climate change, possible adaptation, and how to maintain a sustainable world even with the challenges of climate change. So, the earlier reports are for the most part valid, but they appear incomplete and somewhat naïve compared to our most recent efforts. Observing the progress represented by each new report is a validating experience in and of itself.

FAQ 21.4: What information should I take into account for climate risk management for the 20-year time horizon?

Short answer: For climate-affected decisions that play out over the coming 20 years, it is important to be aware that the climate is changing. Climate trends over the recent past may provide guidance on what is expected in the near future if the reasons for these trends are known and are expected to intensify. Also, any climate model projections in which there is confidence for climate variables of importance are potentially useful. However, climate trends and model projections will at most provide only some relevant information for managing risk for the 20-year time horizon. To effectively manage these risks, it is important to (i) properly characterize the decision-making context, including trends in vulnerability and exposure to climate and weather phenomena (ii) understand the natural variability in the key climate variables as well as any robust predictions of changes; (iii) where relevant, make use of forecasting on shorter timescales if early-warning systems are or could be important in managing the risks involved.

Long answer: How to manage risks for decisions with a 20-year time horizon clearly depends on the specific decision-making context. It is essential to first characterize the vulnerability to climate conditions of the issue being addressed, and to determine how climate conditions interact with other factors, which may be changing more rapidly than the climate itself. For example, if the issue is design of contingency plans for disasters in a rapidly growing city, vulnerability will depend on the people and assets at risk in a particular location, including the types of buildings and land use. If the issue is agriculture investments (say, a switch of crops), vulnerability will also depend, for instance, on market conditions, the availability of credit and insurance.

A second element that clearly depends on a good understanding of the decision-making context, is to assess which climate variables matter most. If the issue is design of contingency plans for disasters, it is clearly the extremes that matter most; in the case of agriculture it may be average seasonal rainfall, but also seasonal onset, or maximum daily rainfall.

Thirdly, once that decision-making context, and the climate variables that matter most to the risks being addressed, are clear, it is important to recognize that the climate of today, and of the next 20 years, is already different from the past climate. Basic statistics based on historical records may not provide the best guess for the climate will look like in the next 20 years.

On the other hand, on their own, the changes in climate conditions as projected by climate models for the period between now and the middle or even the end of the century, may not provide the best guidance, either. Taken over just 20 years, the long-term trends are often relatively small compared to the natural variability in the climate system. And while so-called decadal predictions, based on climate models that are initialized using current climate system observations, are improving, their skill is still low.

In simple terms, for many decisions to be taken with a 20-year time horizon, climate change primarily means that uncertainty about the precise conditions to expect is increasing. For some variables, such as average temperature, the trends may be pretty clear: there is a higher chance of higher average temperatures, and of high temperature extremes. For others, such as rainfall and particularly rainfall extremes for instance, the uncertainty is much higher.

So what climate information can be used to manage risks under these circumstances?

First of all, it is essential to properly characterize historical climate variability: how has the climate varied in the past (including extremes, and looking at seasonal, annual and decadal variability). Assessing possible risk management options for robustness under that range of conditions is often a very important first step (and most often much more important than simply focusing on the projected trend due to climate change).

Secondly, for many climate variables, forecasting on shorter timescales, such as regular weather forecasts, and in some regions seasonal forecasts, may provide good indications of what to expect in the relatively near term, which also helps manage some of these risks, including the rising uncertainties.

Thirdly, it is important to be aware of observed trends to get a sense of how the climate may already have been changing. This can be a challenge, somewhat depending on the climate variables of interest, and particularly in regions with more limited data, in terms of coverage and timespan. For instance, if only a 20 years of observational data is available, it will not be possible to confidently interpret, let alone extrapolate a trend.

For some climate variables, climate models may provide additional guidance on how things may already have changed, and what to expect for the coming 20 years. Rather than interpreting these results as a prediction of the precise conditions that will happen, they are often best used as a guide for the direction of change, and thus of the wider envelope of conditions that should be taken into account when making decisions that will be more robust in the conditions to expect in the coming 20 years.

In order to assess the confidence that should be attached to these model projections, it is often important to cross-compare different models, and to know how well these models have performed in simulating the same variables in the same region in the past. This often requires expert judgment. Regional assessments of observed and projected changes in some key climate variables, such as summarized in IPCC reports [include specific chapter references], may provide a rough indication of the direction of change, or the uncertainties, that should be taken into account to aim for more robust decisions in a changing climate.

Finally, decisions with an apparent 20-year time horizon may actually have long-term consequences. For instance, as an investment decision to build a coastal tourist resort with an economic lifetime of 20-years, may actually have severe long-term implications, in this example by changing ecosystems and coastal morphology, but also by triggering different settlement patterns and infrastructure in the surrounding areas. It is becoming increasingly important to take account of such longer-term dimensions of risk in shorter-term decisions, and avoid maladaptation.

FAQ 21.5: How do I find out how vulnerable my region is (am I a hot spot)?

Box CC-RC. Regional Climate Summary Figures

[Noah S. Diffenbaugh (USA), Daithi Stone (Canada), Filippo Giorgi (Italy), Bruce Hewitson (South Africa), Richard Jones (UK), Geert Jan van Oldenborg (Netherlands)]

The WGII regional climate summary figures draw on climate model simulations archived in Phase 5 of the Coupled Model Intercomparison Project (CMIP5) (Taylor et al. 2012). The CMIP5 simulations are also the basis for the figures presented in Annex I of the WGI contribution (*Atlas of Global and Regional Climate Projections*). The CMIP5 archive includes output from approximately three dozen climate models, including atmosphere-ocean general circulation models (AOGCMs), AOGCMs with coupled vegetation and/or carbon cycle components, and AOGCMs with coupled atmospheric chemistry components. The number of models from which output is available, and the number of realizations of each model, varies between the different CMIP5 experiments.

In contrast to CMIP3 (which used the IPCC SRES scenarios), CMIP5 uses the Representative Concentration Pathways (RCPs) (van Vuuren et al. 2011) to simulate the climate response to possible changes in forcing over the 21st century. The WGI Atlas focuses on RCP4.5, with supplemental analysis of RCP2.6, RCP6.0, and RCP8.5. The WGII regional climate figures compare RCP4.5 and RCP8.5, using the same baseline, mid-21st-century, and late-21st-century time periods as the WGI Atlas (1986-2005, 2046-2065, 2081-2100). The RCPs exhibit overlapping likelihood of global warming in the mid-21st-century period (including median warming of 1.4˚C and 2.1˚C above the late-20th-century baseline in RCP4.5 and RCP8.5, respectively) (Rogelj et al. 2012), but divergent likelihood of global warming in the late-21st-century period (including median warming of 1.8˚C and 3.8˚C above the late-20st-century baseline in RCP4.5 and RCP8.5, respectively) (Rogelj et al. 2012). Given that real emissions have tracked on or above RCP8.5 in recent years (Peters et al. 2013), the regional climate figures are focused on the middle (RCP4.5) and upper end (RCP8.5) of the range of RCPs available in CMIP5.

The regional climate figures show the mean annual temperature and precipitation, categorizing differences in the CMIP5 simulation of the baseline and future periods into four classes. The classes are constructed based on the IPCC uncertainty guidance, which provides a quantitative basis for assigning likelihood statements (Mastrandrea et al. 2011). The classifications in the figures are constructed to parallel the 66-100% ("likely") and 90-100% ("very likely") probability ranges identified in the IPCC uncertainty guidance.

However, there are a number of plausible assignments of likelihood in a multi-model ensemble (e.g., (Knutti et al. 2010)). The classifications in the regional climate figures are based on two interpretations of likelihood reflected in the literature. The first interpretation is the likelihood that the climate in the future period is different than the climate in the baseline period (e.g., (Tebaldi et al. 2011). The regional climate figures use the percentage of models for which the simulated change exceeds two standard deviations of the simulated baseline variability as the measure of probability that the simulated future climate is statistically different than the simulated baseline climate. The second interpretation is the likelihood of the sign of change (e.g., (Christensen et al. 2007; Field et al. 2012). The regional climate figures use the percentage of models that exhibit the same sign of change as the measure of probability of increase or decrease in a given quantity.

The four classifications depicted in the regional climate figures are:

1) White indicates areas where less than 66% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability.
2) Gray indicates areas where greater than 66% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability, and less than 66% of the models agree on the sign of difference.
3) Colors with circles indicate areas where greater than 66% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability, and greater than 66% of the models agree on the sign of the difference. The color contour shows the magnitude of the multi-model mean difference between the future and baseline periods.
4) Colors without circles indicate areas where greater than 90% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability, and greater than 90% of the models agree on the sign of the difference. The color contour shows the magnitude of the multi-model mean difference between the future and baseline periods.

Only those models that have archived output from the historical, RCP4.5 and RCP8.5 experiments are included. For each of the included models, all realizations are used. For a given model, the mean and variability of each realization is first calculated for each period. The mean of the individual-realization mean and variability values are then calculated across the realizations of that model in each period, yielding model-mean mean and variability values derived from the timeseries of each realization (rather than from the mean of the timeseries). The difference between the model-mean in the future and baseline periods is then calculated for each model, and compared with each model's model-mean baseline variability. (Prior to analysis, each realization of each model is first interpolated to a common 1˚ geographical grid using linear interpolation.)

Because the regional climate figures quantify differences between 20-year periods, the measure of baseline variability is chosen to reflect the variability between 20-year periods in the baseline climate forcing. Given that the baseline period is selected as 1986-2005, the baseline variability is calculated as the standard deviation between the 20 20-year periods ending in the years 1986 through 2005 (1967-1986, 1968-1987, … , 1986-2005). Although the 20 20-year periods are not independent, they reflect the population of 20-year periods within the recent climate forcing regime, and a 20-year period that is more than two standard deviations removed is considered to be reflective of a different climate.

In addition to maps of the CMIP5 simulations, the regional climate figures also include maps of observed temperature and precipitation differences between the baseline period (1986-2005) and the early 20th century (1906-1925). The observational analyses use the CRU TS3.10.01 gridded station-based temperature and precipitation data (CRU 2012). On the observational panel, white indicates areas where the difference between the baseline and early-20th-century periods does not exceed two standard deviations of the early-20th-century variability. Colors indicate areas where the difference between the baseline and early-20th-century periods exceeds two standard deviations of

the early-20th-century variability, with the color contours showing the magnitude of the difference. For the observational analyses, the early-20th-century variability is calculated as the standard deviation between the 20 20-year periods beginning in the years 1906 through 1925 (1906-1925, 1907-1926, … , 1925-1944).

[INSERT FIGURE RC-1 HERE
Figure RC-1: Change in annual temperature. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

[INSERT FIGURE RC-2 HERE
Figure RC-2: Change in annual precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

America, C. Asia); MRC – Mekong River Commission For Sustainable Development; Lake Victoria Basin Commission

Table 21-2: Selected examples of regional treatment in previous IPCC Assessment Reports and Special Reports (SR). Major assessments are subdivided by the three Working Group reports, each described by generic titles.

IPCC report [references]	**Year**	**Treatment of regions**
First Assessment Report (FAR) [1, 2, 3]	1990	*Climate*: Climate projections for 2030 in 5 sub-continental regions; Observations averaged for northern/southern hemisphere, by selected regions and by 20° latitude x 60° longitude grid boxes
		Impacts: Agriculture by continent (7 regions); Ecosystem impacts for 4 biomes; water resources for case study regions; Oceans and Coastal Zones treated separately
		Responses: Emissions scenarios by 5 economic groupings; Energy and Industry by 9 regions; Coastal Zone and Wetlands by 20 world regions
Supplements to FAR [4, 5]	1992	*Climate*: IS92 emissions scenarios by 7 world regions
		Impacts: Agriculture by continent (6 regions); Ocean Ecology by 3 latitude zones; Questionnaire to governments on current activities on impacts by 6 WMO regions
***SR**: Climate Change 1994* [6]	1994	Evaluation of IS92 emissions scenarios by 4 world regions: OECD, USSR/E. Europe, China/Centrally Planned Asia and Other.
Second Assessment Report (SAR) [7, 8, 9]	1995	*Climate*: Gridded proportional circle maps for observed climate trends (5° latitude/ longitude); climate projections for 7 sub-continental regions
		Impacts, Adaptations, Mitigation: Energy production statistics by 10 world regions; Forests, Wood Production and Management by three zones: Tropical, Temperate, Boreal; separate chapters by physiographic types: Deserts, Mountain Regions, Wetlands, Cryosphere, Oceans, and Coastal Zones and small islands; country case studies, Agriculture by 8 continental-scale regions; Energy supply by 8 world regions
		Economic and Social Dimensions: Social Costs and Response Options by 6 economic regions
***SR**: Regional Impacts* [10]	1998	10 continental-scale regions: Africa, Arctic and Antarctic, Australasia, Europe, Latin America, Middle East and Arid Asia, North America, Small Island States, Temperate Asia, Tropical Asia. Subdivisions applied in some regions; Vegetation shifts mapped by 9 biomes; Baseline (1990) Socio-Economic data provided by country and for all regions except polar.
***SR**: Land-Use Change and Forestry* [11]	1998	9 Biomes; 15 land-use categories; National and Regional case studies.
***SR**: Aviation* [12]	1999	Observed and projected emissions by 22 regional air routes; Inventories by 5 economic regions
***SR**: Technology Transfer* [13]	2000	Country case studies; Indicators of technology transfer by 6-7 economic regions
***SR**: Emissions Scenarios* [14]	2000	4 SRES world regions defined in common across integrated assessment models; 11 sub-regions; Driving Factors by 6 continental regions
Third Assessment Report (TAR) [15, 16, 17]	2001	*Climate*: gridded observations of Climate trends; 20 example Glaciers; 9 Biomes for Carbon Cycle; Circulation Regimes for model evaluation; 23 "Giorgi" regions for regional climate projections
		Impacts, adaptation and vulnerability: Example projections from 32 "modified-Giorgi" regions; Basins by continent; 5 Coastal types; Urban/Rural Settlements; Insurance by economic regions; 8 continental-scale regions equivalent to 1998 Special report but with single chapter for Asia; Subdivisions used for each region (Africa, Asia and Latin America by climate zones; North America by 6 core regions and 3 border regions)
		Mitigation: Country examples; Developed (Annex I) and Developing (non-Annex I); Various economic regions; Policies, Measures and Instruments by 4 blocs: OECD, Economies in Transition, China and Centrally Planned Asia, and Rest of the World.
***SR**: Ozone Layer* [18]	2005	Various economic regions/countries depending on sources and uses of chemicals;
***SR**: Carbon Capture and Storage* [19]	2005	CO_2 sources by 9 economic regions; potential storage facilities: by geological formation, by oil/gas wells, by ocean depth,; costs, by 4 economic groupings

Fourth Assessment Report (AR4) [20, 21, 22]	2007	*Climate*: Land-use types for surface forcing of climate; Observations by 19 "Giorgi" regions; Modes of variability for Model Evaluation; Attribution of climate change by 22 "Giorgi-type" regions and by 6 ocean regions; Climate statistics for 30 "Giorgi-type" regions; PDFs of projections for 26 regions; summary graphs for 8 continental regions
		Impacts, adaptation and vulnerability: Studies reporting observed impacts by 7 IPCC regions; comparison of TAR and AR4 climate projections for 32 Giorgi regions; Ecosystems by 11 biomes; Agriculture by latitudinal zone; Examples of Coastal mega-Deltas; Industry and settlement by continetal region; 8 continental regions, as in TAR, but Small Islands not Small Island States; Sub-regional summary maps for each region, using physiographic, biogeographic or geographic definitions; Example vulnerability maps at sub-national scale and globally by country.
		Mitigation: 17 global economic regions for GDP; Energy supply by continent, by economic regions, by 3 UNFCCC groupings; Trends in CO_2 emissions (and projections) , waste and carbon balance by economic regions.
***SR**: Renewable Energy Sources and Climate Change Mitigation* [23]	2012	Global maps showing potential resources for renewable energy: land suitability for bioenergy production, global irradiance for solar, geoethermal, hydropower, ocean waves/tidal range, wind); Various economic/continental regions: installed capacity (realised vs. potential), types of technologies, investment cost, cost effectiveness, various scenario-based projections; Country comparisons of deployment and uptake of technologies, share of energy market.
***SR**: Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation* [24]	2012	Trends in observed (tables) and projected (maps and tables) climate extremes (Tmax, Tmin, heat waves, heavy precipitation and dryness) by 26 sub-continental regions covering most land areas of the globe; Attribution studies of return periods of extreme temperatures for 15 "Giorgi-type" regions; Gridded global maps of projected extremes of temperature, precipitation, windspeed, dry spells and soil moisture anomalies; Continental-scale estimates of projected changes in impacts of extremes (floods, cyclones, coastal inundation) as well as frequencies of observed climate extremes and their estimated costs); Distinctions drawn between local, country and international/global actors with respect to risk management and its financing.
***Fifth Assessment Report (AR5)** – this assessment*	2014	*Climate*:
		Impacts, adaptation and vulnerability: Nine continental-scale regions, eight as in AR4 plus open oceans.
		Mitigation:

1. IPCC (1990c); 2. IPCC (1990a); 3. IPCC (1990b); 4. IPCC (1992b); 5. IPCC (1992a); 6. IPCC (1994) 7. IPCC (1996c); 8. IPCC (1996b); 9. IPCC (1996a); 10. IPCC (1998b); 11. IPCC (1998a); 12. IPCC (1999); 13. IPCC(2000a), 14. IPCC (2000b); 15. IPCC (2001c); 16. IPCC (2001a); 17. IPCC (2001b); 18. IPCC/TEAP (2005); 19. IPCC (2005); 20. IPCC (2007c); 21. IPCC (2007a); 22. IPCC (2007b); 23. IPCC (2012b); 24. IPCC (2012a)

Table 21-3: Two possible entry points for thinking about vulnerability to climate change (adapted from Füssel 2007).

Context	Climate change impacts perspective	Vulnerability perspective
Root problem	Climate change	Social vulnerability
Policy context	Climate change mitigation, compensation, technical adaptation	Social adaptation, sustainable development
Illustrative policy question	What are the benefits of climate change mitigation?	How can the vulnerability of societies to climatic hazards be reduced?
Illustrative research question	What are the expected net impacts of climate change in different regions?	Why are some groups more affected by climatic hazards than others?
Vulnerability and adaptive capacity	Adaptive capacity determines vulnerability	Vulnerability determines adaptive capacity
Reference for adaptive capacity	Adaptation to future climate change	Adaptation to current climate variability
Starting point of analysis	Scenarios of future climate change	Current vulnerability to climatic stimuli
Analytical function	Descriptive, positivist	Explanatory, normative
Main discipline	Natural science	Social science
Meaning of 'vulnerability'	Expected net damage for a given level of global climate change	Susceptibility to climate change and variability as determined by socioeconomic factors
Vulnerability approach	Integrated, risk-hazard	Political economy
Reference	McCarthy et al (2001)	Adger (1999)

Table 21-4: Dimensions of assessments of impacts and vulnerability and of adaptation drawn upon to serve different target audiences (cf. Table 21-1). Scales refer to the level of aggregation at which study results are presented. Entries are illustrations of different types of study approaches reported and evaluated in this volume, with references given both to the original studies and to the chapters in which they are cited. Aspects of some of the studies in this table are also alluded to in section 21.5.

Approach/audience: Scale:	Impacts/vulnerability	Adaptation	Target audience
Global	Resource availability[1,2,3] Impact costs[4,5,6,7] Vulnerability/risk mapping[8,9,10] Hotspots analysis[11]	Adaptation costs[4,5,7]	- Policy negotiations - Development aid - Disaster planning - Capacity building
Continental/ biome	Observed impacts[12,13,14] Future biophysical impacts[15,16] Impact costs[5,15] Vulnerability/risk mapping[17]	Adaptation costs[5] Modelled adaptation[18]	- Capacity building - International law - Policy negotiations - Regional development
National/ state/province	Observed impacts[19,20,21] Future impacts/risks[22,22,23] Vulnerability assessment[23] Impact costs[24]	Observed adaptation[25] Adaptation assessment[23,26]	- National adaptation plan/strategy - Nat. Communication - Legal requirement - Regulation
Municipality/ basin/patch/ delta/farm	Hazard/risk mapping[27] Pest/disease risk mapping[28] Urban risks/vulnerabilities[29]	Adaptation cost[27] Urban adaptation[29,30]	- Spatial planning - Extension services - Water utilities - Private sector
Site/field/tree/ floodplain/ household	Field experiments[31]	Coping studies[32,33] Economic modelling[34] Agent-based modelling[35]	- Individual actors - Local planners

Table 21-5: Reliability of climate information on temperature and precipitation over a range of spatial and temporal scales. Reliability is assigned to one of seven broad categories from Very High (VH) to Medium (M) through to Very Low (VL). Reliability of information on past climate depends on the availability and quality of observations and in general is higher for temperature as it is easier to observe and a temperature observation at a given location is more representative of temperatures in the surrounding areas than a precipitation observation. In the case of future climate change, which relies on using models of the climate system run into the future, reliability depends on the ability of these models to simulate well the processes that lead to these changes. Again, information on temperature is generally more reliable but this is due to there being more confidence in our ability to simulate the past changes in temperature and our understanding of the processes that cause these changes than is the case for precipitation.

There are significant variations in the reliability of past and future climate information at different temporal and spatial scales, in general at finer scales the information tends to be less reliable given the need for either a greater density observations or models maintaining accuracy at high resolutions. Also, there are significant geographical variations, again the root cause being different for information on past climate than on future climate change. For past climate observation availability and quality is again key and in many regions, especially for precipitation, there are issues with either or both. For future climate change, data availability is less of an issue with the advent of large ensembles of climate model projections but quality can be a significant problem in some regions where the models perform poorly and there is little confidence that the processes driving the projected changes are accurately captured.

Scale	**Temporal**	**Annual**		**Seasonal-Monthly**		**Daily**	
Spatial	**Variable / Era**	**Temp**	**Precip**	**Temp**	**Precip**	**Temp**	**Precip**
Global	Past	VH	H	VH	H	N/A	N/A
	Future change	VH – direction H – amount	H – direction MH – amount	VH – direction H – amount	H – direction MH – amount	N/A	N/A
Regional, Large river basin	Past	VH-H depends on observation availability	H-L depends on observation availability	VH-H depends on observation availability	H-L depends on observation availability	VH-H depends on observation availability	H-L depends on observation availability
	Future change	VH – direction H – amount	H-L depends on capture of processes	VH – direction H – amount	H-L depends on capture of processes	VH – direction MH – amount	H-L depends on capture of processes
National, State	Past	VH-H depends on observation availability	H-L depends on observation availability	VH-H depends on observation availability	H-L depends on observation availability	VH-H depends on observation availability	H-VL depends on observation availability
	Future change	VH – direction H – amount	H-L depends on capture of processes	VH – direction H – amount	H-L depends on capture of processes	H – direction MH – amount	H-VL depends on capture of processes
City, County	Past	VH-H depends on observation availability	H-VL depends on observation availability	VH-H depends on observation availability	H-VL depends on observation availability	H-MH depends on observation availability	H-VL depends on observation availability
	Future change	H – direction MH – amount	H-VL depends on capture of processes	H – direction MH – amount	H-VL depends on capture of processes	H – direction M – amount	M-VL depends on capture of processes
Village, Site/field	Past	VH-H depends on observation availability	H-VL depends on observation availability	VH-H depends on observation availability	H-VL depends on observation availability	H-MH depends on observation availability	H-VL depends on observation availability
	Future change	H – direction MH – amount	H-VL depends on capture of processes	H – direction MH – amount	H-VL depends on capture of processes	H – direction M – amount	M-VL depends on capture of processes

Table 21-6: Placeholder for a table to be derived from the AR5 WG1 Ch14 table (still in development by WG1) evaluating confidence in GCM simulations and projections of temperature and precipitation and linked regional climate phenomena currently being finalised for the final draft of that chapter.

Table 21-7: Leading knowledge gaps and related research needs.

	Knowledge Gap	Research need
1	There is no clear understanding of how to integrate the data products from multi-model multi-method research for producing climate change projections. This results in data products of conflicting time and space resolution scales, with differing dependencies and assumptions, and resultant non-equivalency of variables. At present each product is individually plausible and mostly defensible in-so-far as it has physical basis within the assumptions of the method. However, at decision-relevant scales the products collectively indicate a wide range of outcomes with high uncertainty and contradictions and are thus not strongly actionable.	The approaches on how to understand the source of spread and contradiction in the information at scales relevant to users. This raises the strong need to find ways to identify the value signal within the noise of the multi-model multi-method climate projections methods, and build robust messages that are user-relevant and actionable.
2	Limits to predictive information. The community engaged in developing regional climate change projections have forded ahead with increasing sophistication of tools and models, yet at the regional and adaptation decision scales the signal to noise ratio has not advanced commensurately (e.g. Maslin and Austin, 2012). The inherent uncertainty of the emerging projections is poorly articulated (or even absent), and where provided is likely an under-estimate of the true range of uncertainty.	Means to identify the limit of predictive information, and/or articulate the real uncertainty inherent in and information product, are important to inform response to climate change, and understand when climate information is useful at the scales of need. Research is critically needed to distinguish apart the inherent blend of stochastic and deterministic variability and change of the regional climate, which is intrinsically a function of scale, variable, and application.
3	The attributes of regional change through which impacts are manifest, such as the intensity, persistence, distribution, recurrence, and frequency, are poorly understood. The information conveyed to the adaptation community is dominated by aggregates in time and space (e.g. SREX regional averages, or time averages), which hide the important attributes underlying these aggregated changes. In part this is a consequence of (1) and (2) above.	The research need is for greater nuance in the understanding of the data to unpack the regional projections into terms relevant for impacts and adaptation. For example, how is the shape of the distribution of weather events changing (not just the extremes), or information on the stability of critical global teleconnection patterns that contribute to the variability of a region.
4	The historical record for many regions, especially those regions most vulnerable to climate change, is poor to the extent that the historical record is at best an estimate with unknown uncertainty. This severely undermines the development of regional change analysis, limits the evaluation of model skill, and presents a weak baseline against which to assess change signals.	The research need focuses on how to best integrate the multiplicity of historical data, including data rescue, raw observations, processed gridded products (e.g. CRU and GPCP), satellite data, and reanalysis data sets. For any given region data sets present different views of the past, and may even contradict each other. Research such as Zhang et al (2012), which evaluates different reanalysis products, indicates the value that can be attained for advancing understanding of the data veracity at regional scales.
5	Model projections of regional climate change impacts seldom have uncertainty ranges attached to estimates. Even if these are provided, they rarely distinguish the relative contributions of impact model uncertainty and climate projection uncertainty.	There is a need for more rigorous and comprehensive uncertainty analysis of impact models, accounting for both parameter and structural uncertainties. Model inter-comparison exercises offer one means for examining structural uncertainty.
6	Model sensitivity studies and inter-comparison exercises are beginning to reveal fundamental flaws and omissions in some impact models in the representation of key processes that are expected to be important under projected climate changes. For example, high temperature constraints, and CO2 and drought effects on agricultural yields are poorly represented in many crop models.	New field and chamber experiments are required, with controlled atmospheric composition and climate conditions, using modern and potentially adapted cultivars, to improve understanding of key processes operating in crop plants and soils under changed environments. Such experiments are needed across a range of biogeographical and edaphic zones in different regions of the world.
7	New global scenarios are under development, based on climate projections for different representative concentration pathways (RCPs) and socio-economic scenarios based on shared socio-economic pathways (SSPs). However, there is currently little or no guidance on how these projections are to be accessed or applied in IAV studies. Moreover, as yet, quantitative SSPs are available only for large regions (basic SSPs), and regional SSPs that are consistent with the global SSPs have not yet been developed (extended SSPs).	Extended SSPs for major sub-continental regions of the world, including variables that define aspects of adaptive capacity and guidance on how to combine RCP-based regional climate projections with regional SSPs to form plausible regional scenarios for application in IAV analysis.

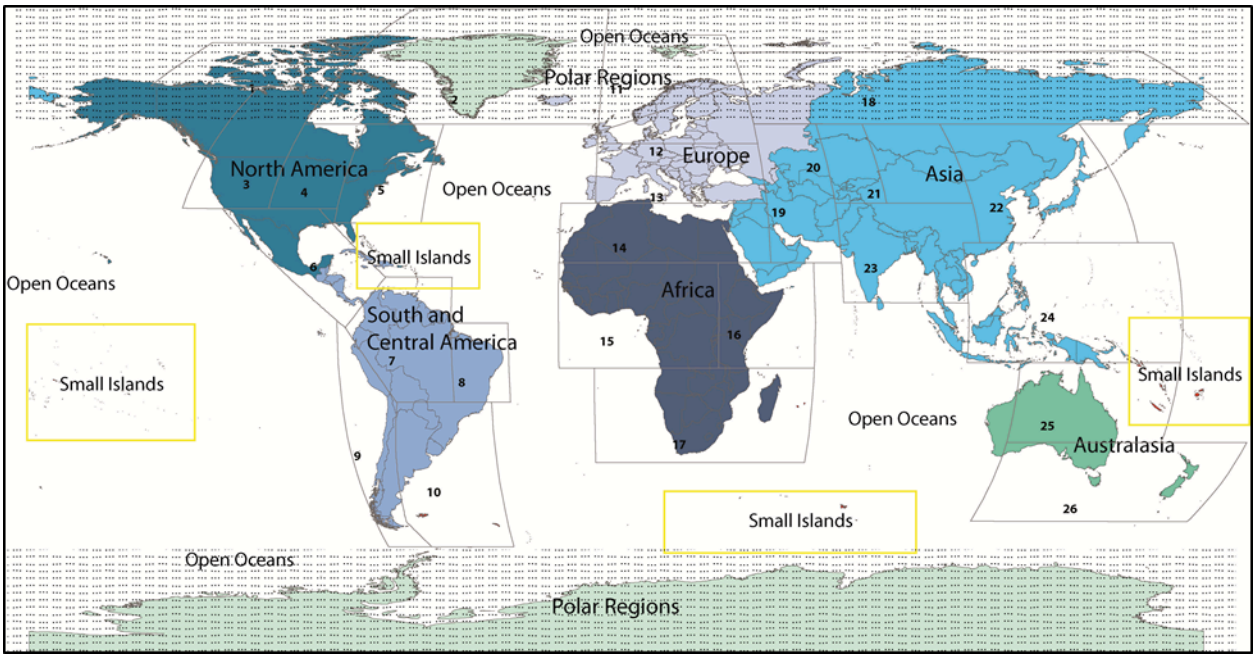

Figure 21-1: Map showing regions described in chapters 22-30 of Part B (colours) with numbered [26] open polygons defining sub-regions over land used to summarise projected changes in climate in this chapter Note that regional specifications are approximate, as aspects of some regions or territories are treated in more than one chapter. Supplementary material contains more details of chapter assignment (Table S21-1) as well as co-ordinates of the polygons (Table S21-2).

Figure 21-2: Entry points for adaptation science, policy, and practice (based on Hinkel et al, submitted).

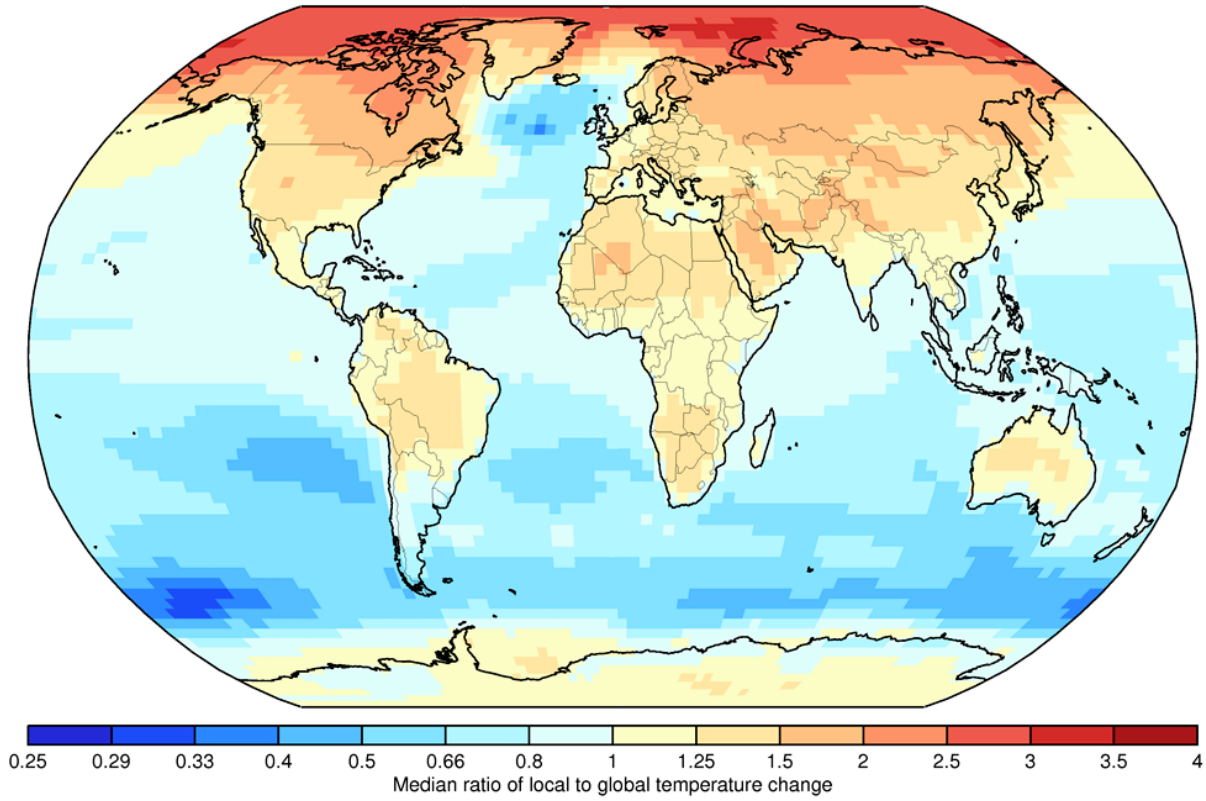

Figure 21-3. CMIP5 ensemble median ratio of local:global average temperature change in the period 2070-2100 relative to 1961-90 under the RCP8.5 emissions/concentrations scenario. The values are displayed on a common 2.5ºx3.75º grid onto which each models' data were regridded and they were calculated as follows:
1) For each model calculate the local change between 1961-90 and 2070-2100 at each grid cell and divide by the global average change over the same period;
2) identify the median value across the ensemble at each grid cell.

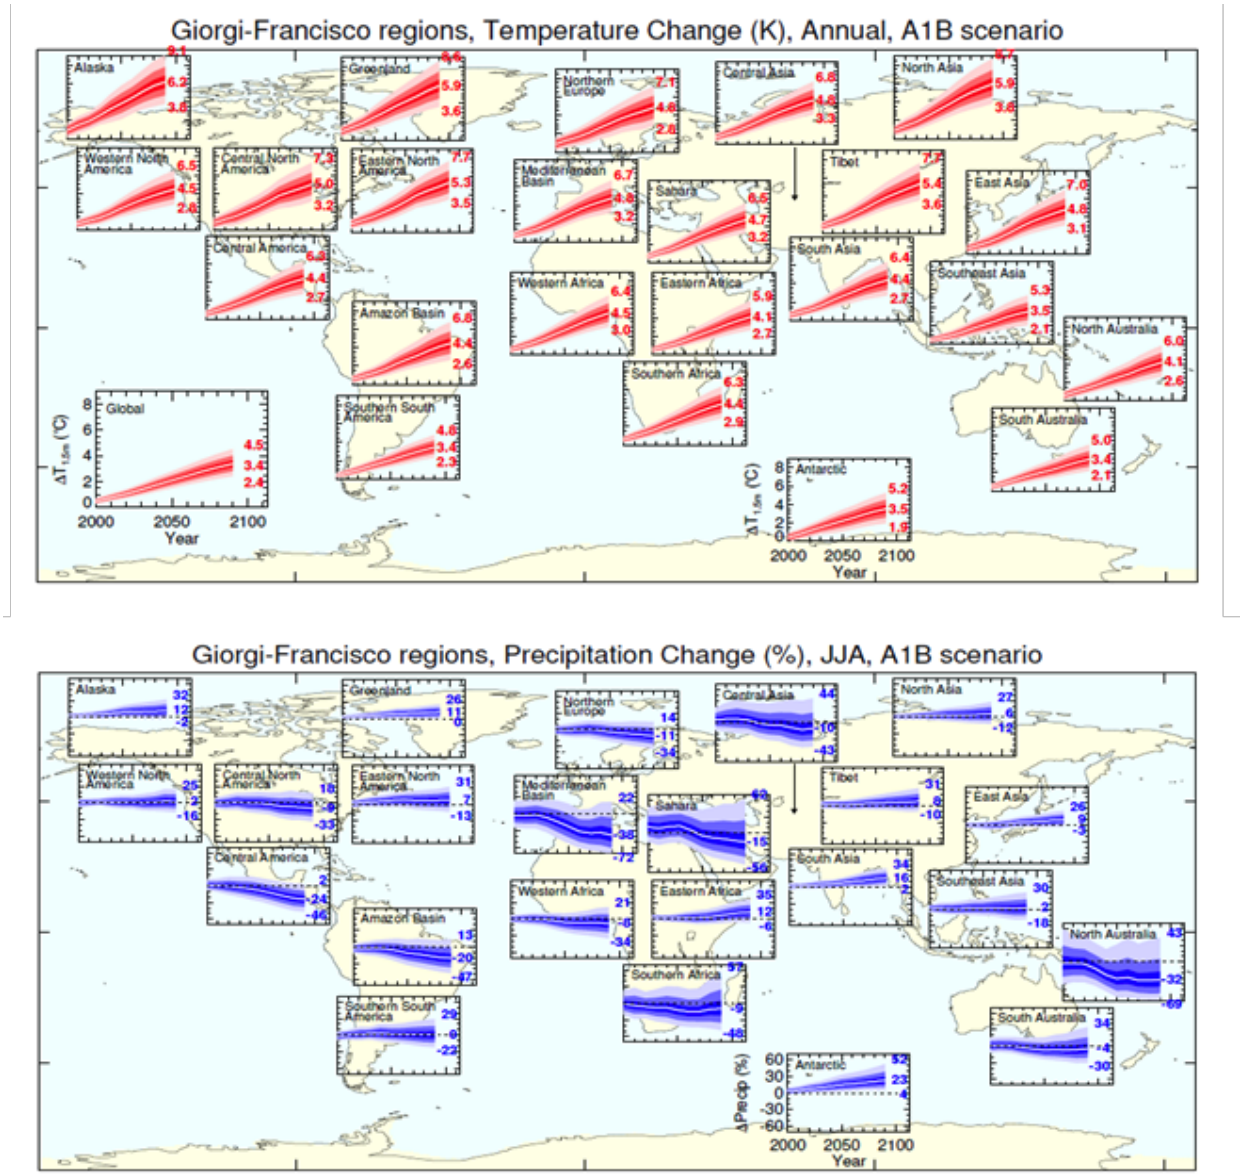

Figure 21-4: Evolution of the 5%, 17%, 33%, 50%, 66%, 83% and 95% percentiles of the distribution functions for annual surface air temperature changes (upper panel) and annual precipitation (lower panel) for the Giorgi-Francisco (2000) regions and the globe with the A1B forcing scenario. Twenty year means relative to the 1961-1990 baseline are plotted in decadal steps using a common y-axis scale. The 5%, 50% and 95% percentile values for the period 2080-2099 are displayed for each region. (From Harris et al. 2012)

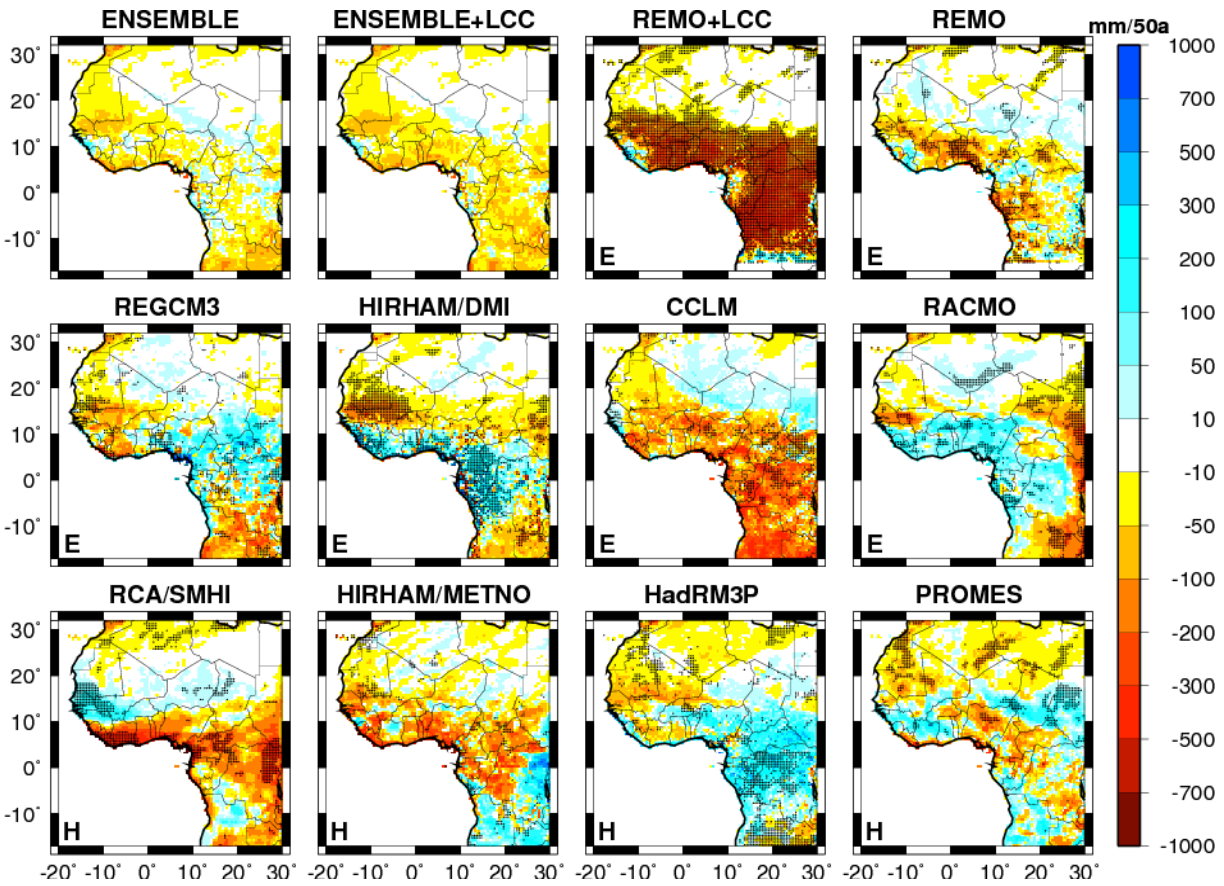

Figure 21-5: Linear changes (i.e. changes obtained by fitting the time series at each grid point with straight lines) of annual precipitation during the 2001-2050 period from 10 individual RCM experiments and the MME mean under the A1B emission scenario. The top middle panels also account for projected land cover changes (see Paeth et al. 2011 for further explanation). Note that the REMO trends in both panels arise from a three-member ensemble whereas all other RCMs are represented by one single simulation. Trends statistically significant at the 5% level are marked by black dots. (From Paeth et al. 2011)

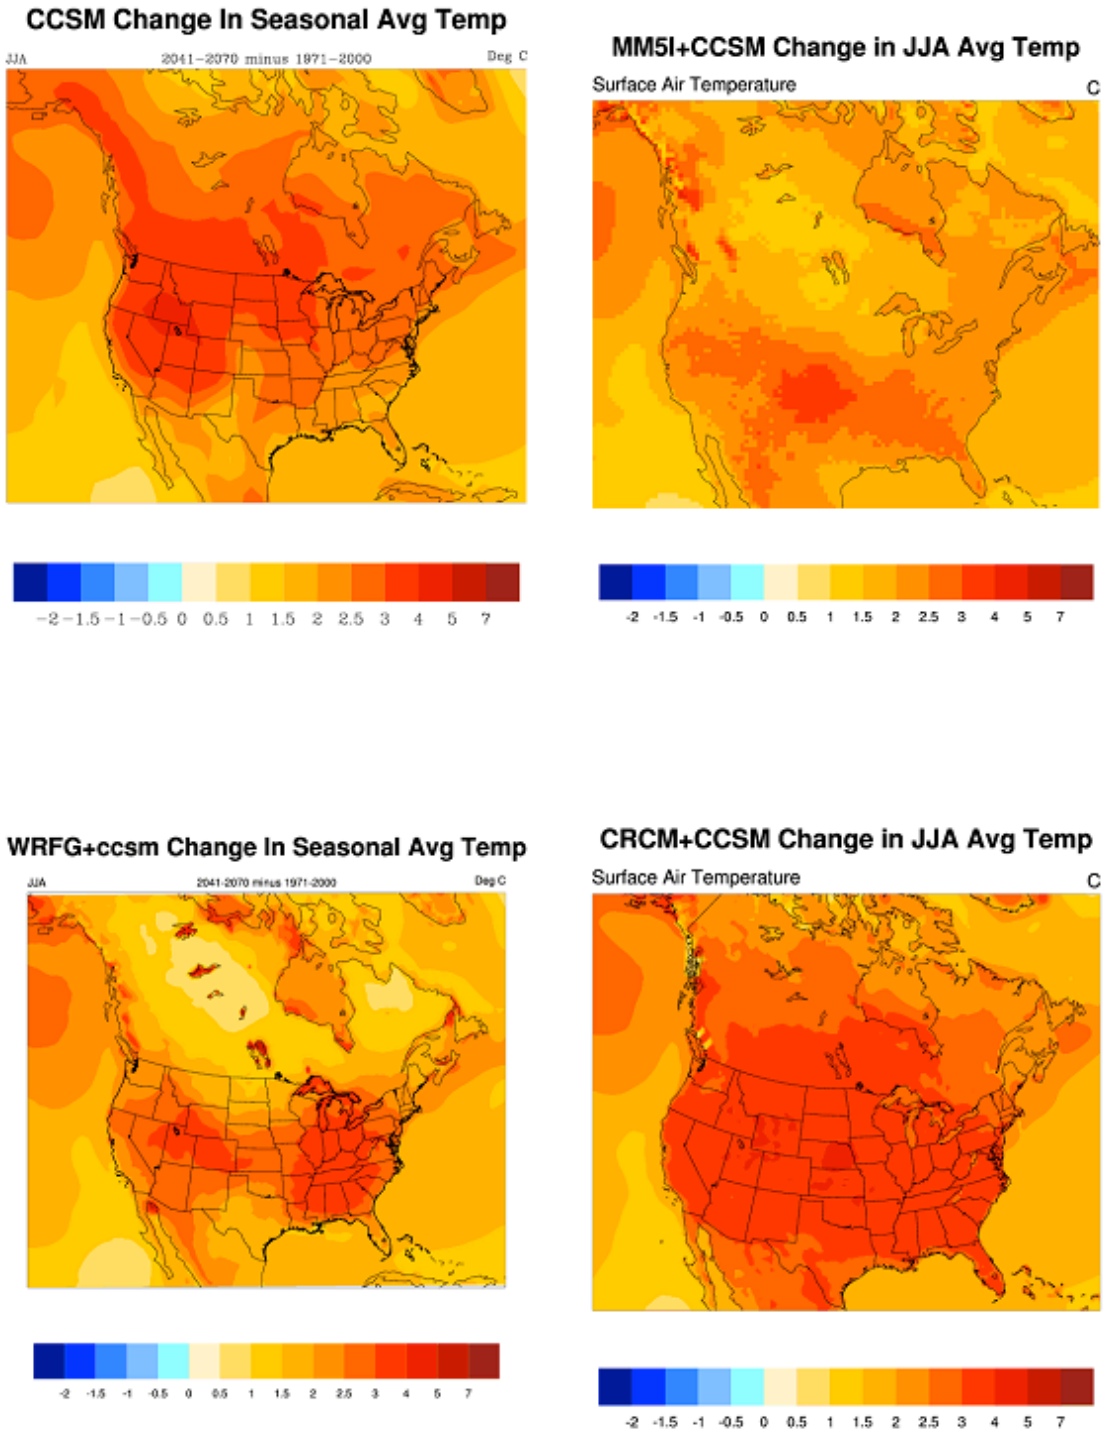

Figure 21-6: Change in summer (JJA) average temperature (2041-2070 minus 1971-2000) from (top left) the NCAR CCSM3, (top right) the MM5 regional climate model driven by the CCSM3; (bottom left) the WRF model, driven by CCSM3, and (bottom right) the Canadian CRCM, driven by CCSM3. Temperature is in °C. Data from the NARCCAP program. (From Mearns et al., 2009, 2013)

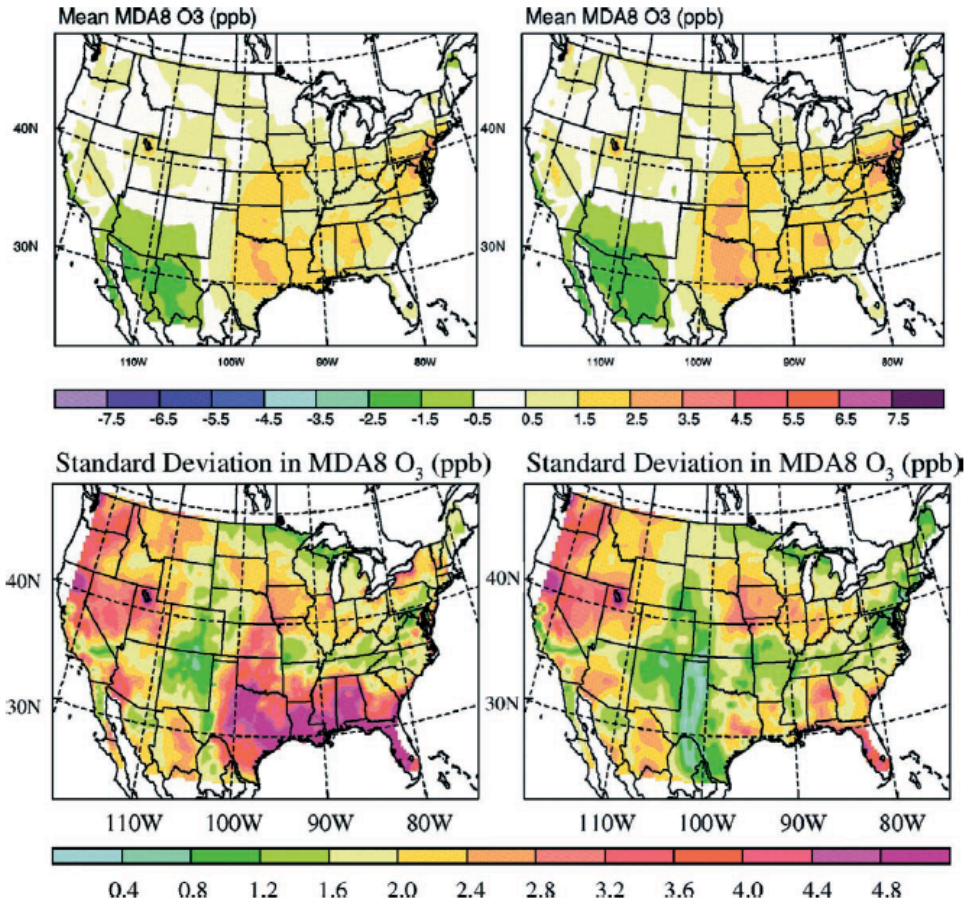

Figure 21-7: Mean (top panels) and standard deviation (bottom panels) in future-minus-present (2081-2100 minus 1981-2000) MDA8 summer ozone concentrations across (left-hand panels) all 7 experiments (5 regional and 2 global) and, for comparison purposes (right-hand panels) not including the WSU experiment (which simulated July only conditions). (From Weaver et al. 2009)

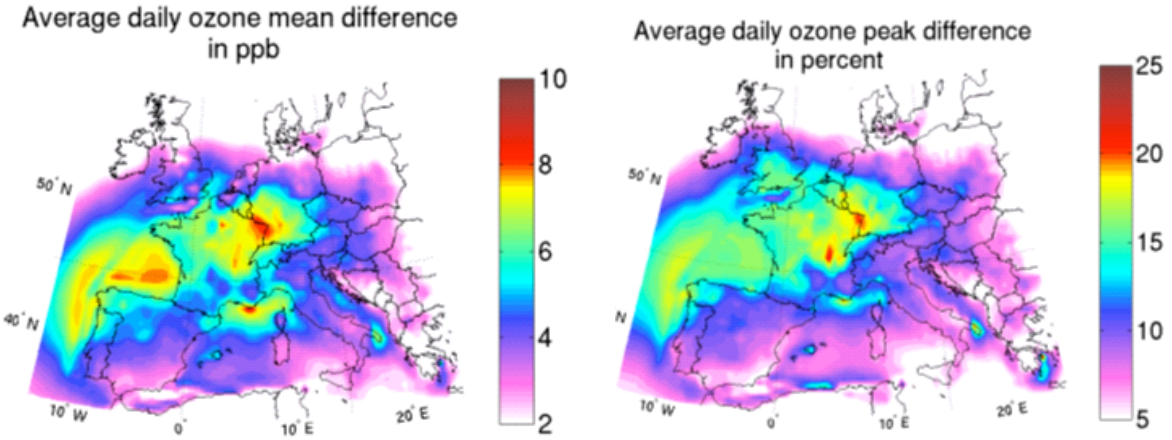

Figure 21-8: Difference in average summer daily ozone mean (left panel) and peak (right panel) concentration over Europe due to climate change, (2071-2100 minus 1961-1990), A2 scenario. (From Meleux et al. 2007)

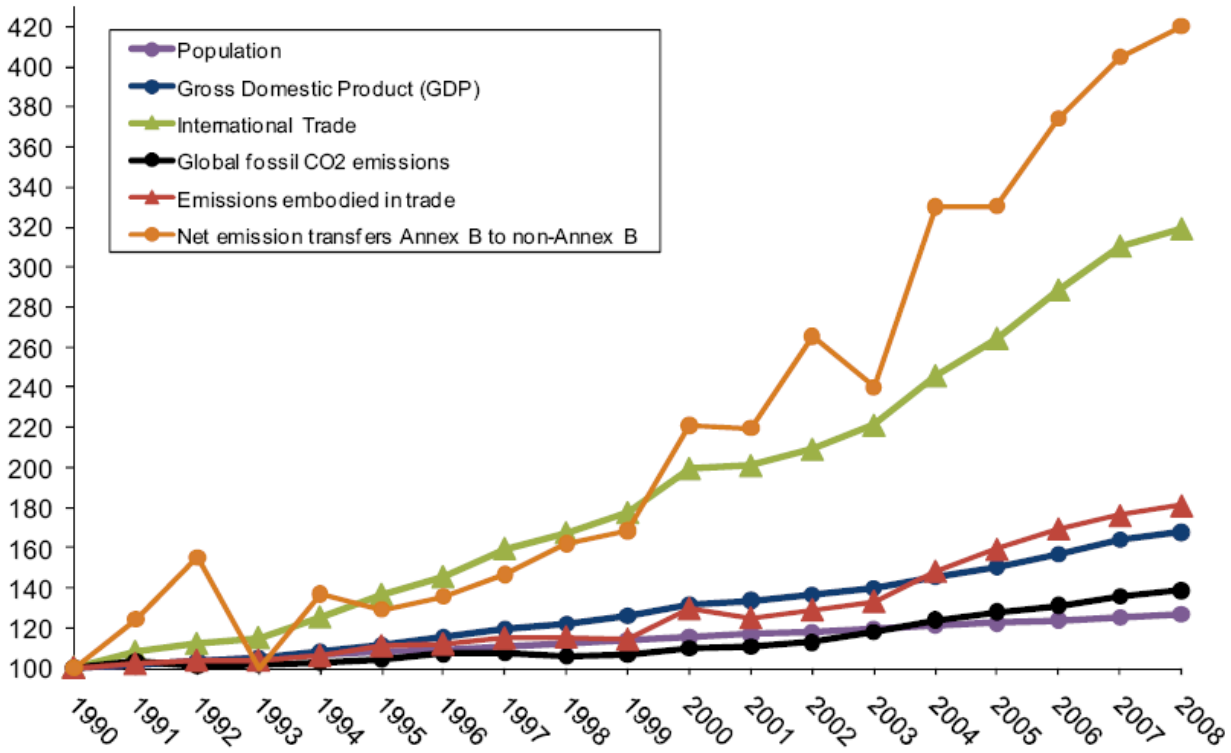

Figure 21-9: Growth rates from 1990-2008 of international trade, its embodied CO_2 emissions and net emissions transfers from Annex B and non-Annex B countries compared to other global macrovariables, all indexed to 1990 (Peters et al., 2011).]

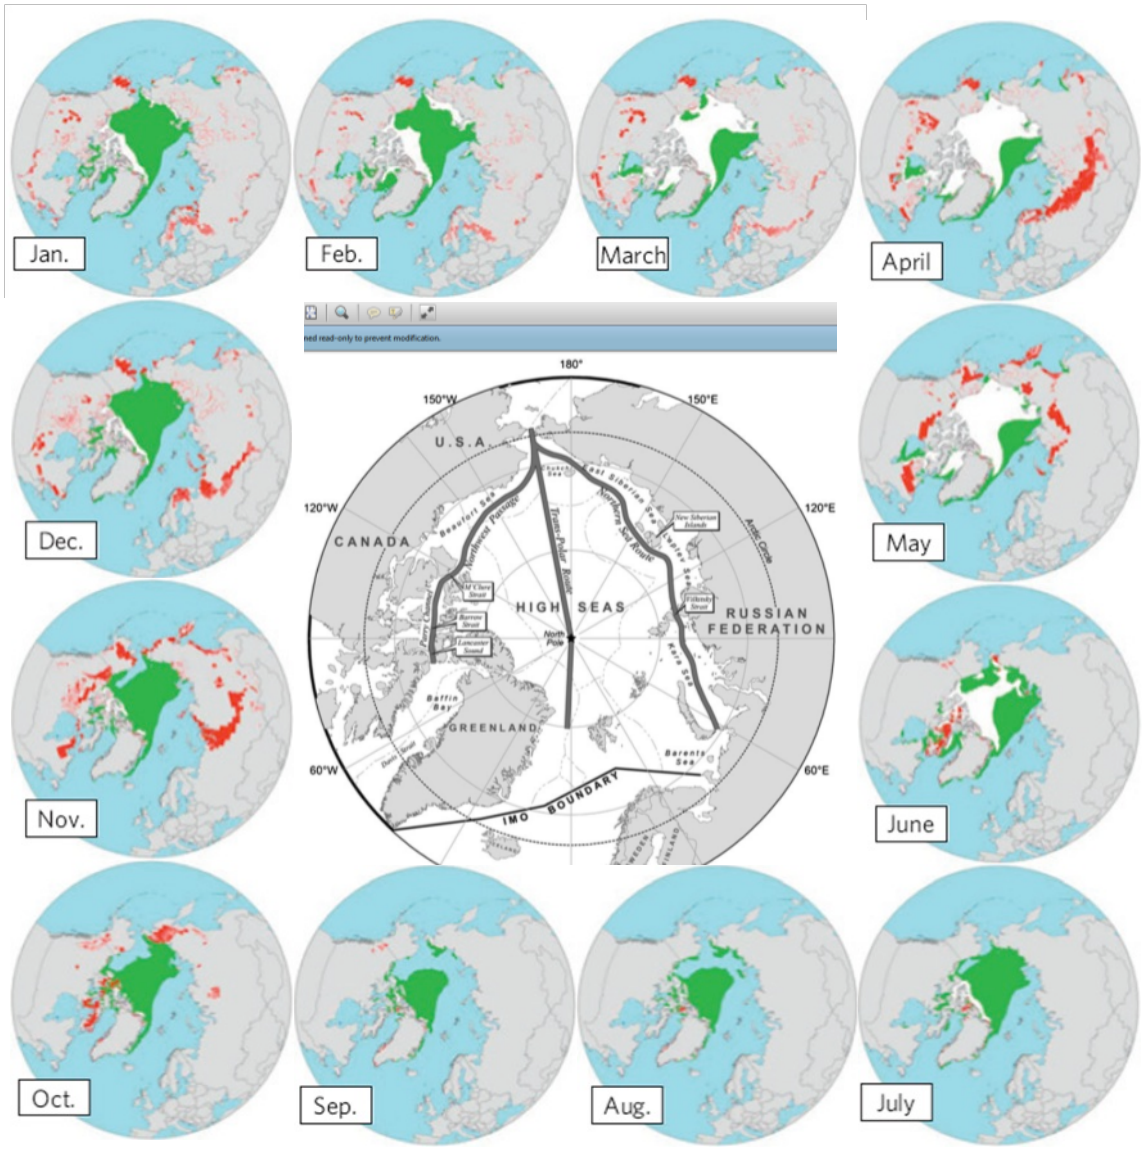

Figure 21-10: (a) Marine exclusive environmental zones (EEZs – dashed lines) of Canada, Greenland/Denmark, Norway, Russia, and the USA, and location of the Northwest Passage, Northern Sea Route, Trans-Polar Route, and international high seas within the IMO Guidelines Boundary for Arctic shipping (thick black border). After Stephenson (2013). (b) Projected change in accessibility of maritime and land-based transportation by mid-century (2045-2059 relative to 2000-2014) using the Arctic Transport Accessibility Model and CCSM3 climate and sea ice estimates assuming an SRES A1B scenario. Green areas denote new maritime access to Polar Class 6 vessels (light icebreaker); white areas remain inaccessible. Red delimits areas of lost winter road potential for ground vehicles exceeding 2 metric tonnes (Stephenson et al., 2011).

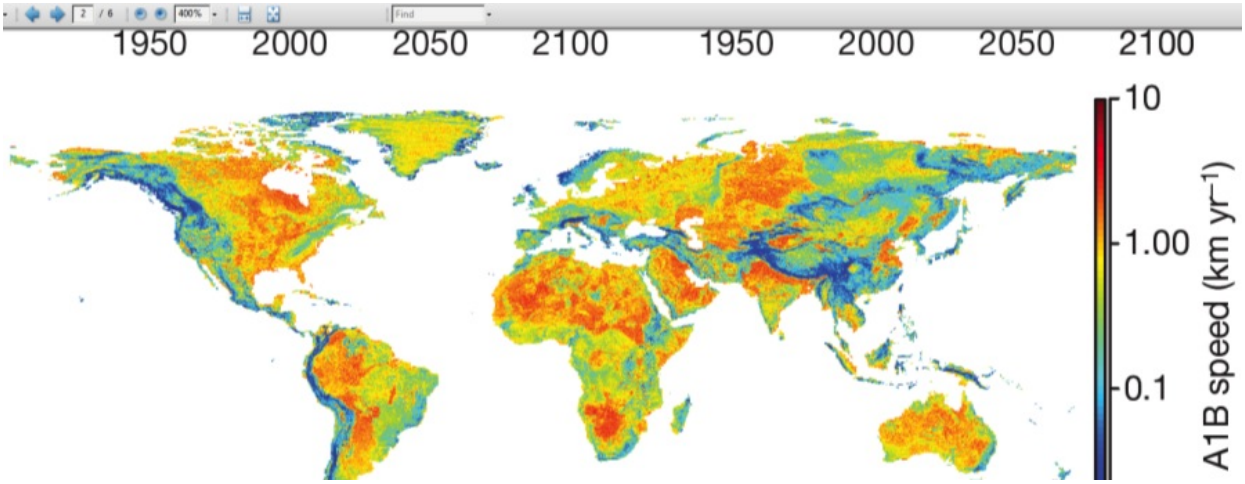

Figure 21-11: The velocity of shifting climatic zones due to climate change based on the average of 16 global climate models for an A1B emissions scenario and temporal gradients computed for 2050-2100. (Loarie et al., 2009).

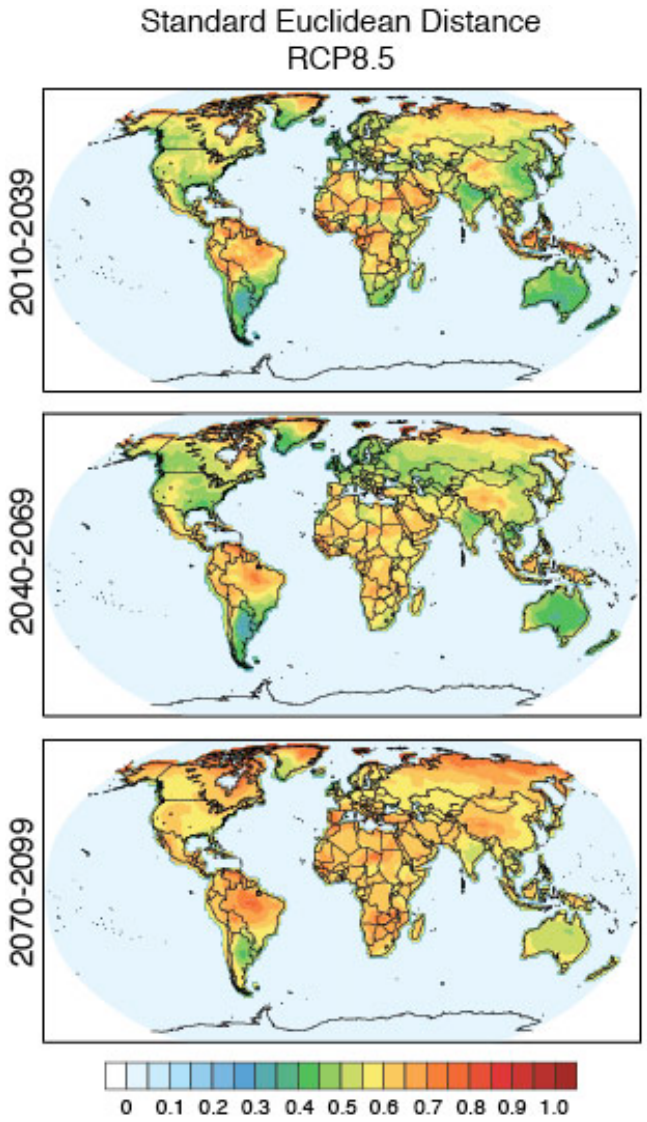

Figure 21-12: The relative aggregate climate change between the 1975-2005 period and the 2010-2039, 2040-2069 and 2070-2099 periods of RCP8.5. The aggregate climate change is calculated using the Standard Euclidean Distance (SED) across the 28-dimensional climate space formed by 7 climate variables in each of 4 seasons. The absolute values of change in each variable are normalized to the maximum global absolute value prior to calculating the SED. The SED values are then normalized to the maximum global SED value. Only land grid points north of 60˚S are used in the normalizations (From Diffenbaugh and Giorgi 2012).

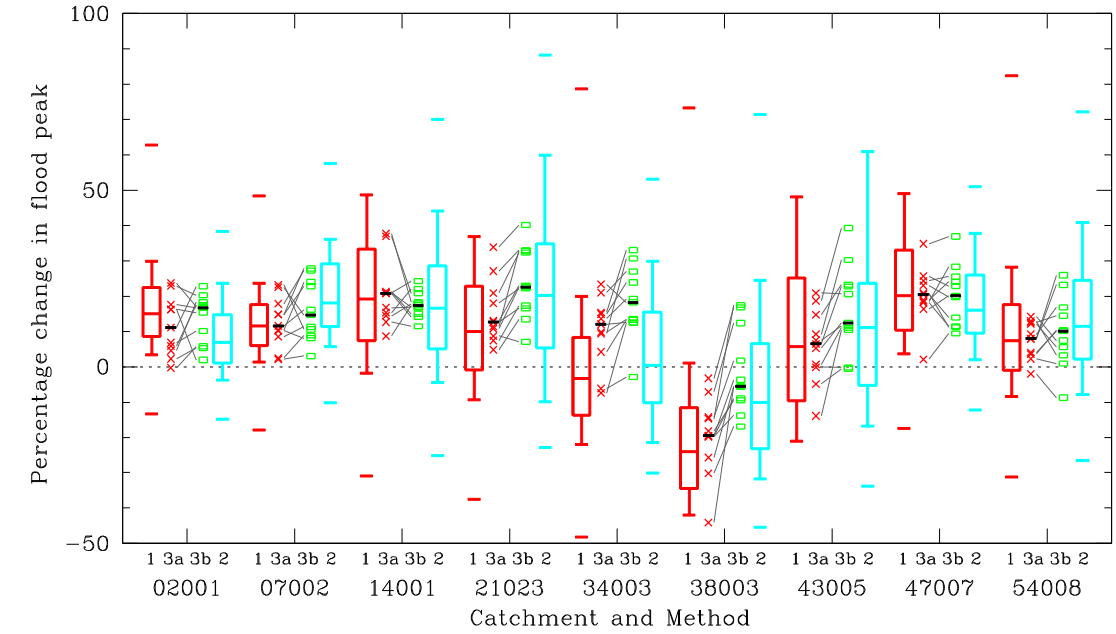
a) 2-year return period



b) 20-year return period

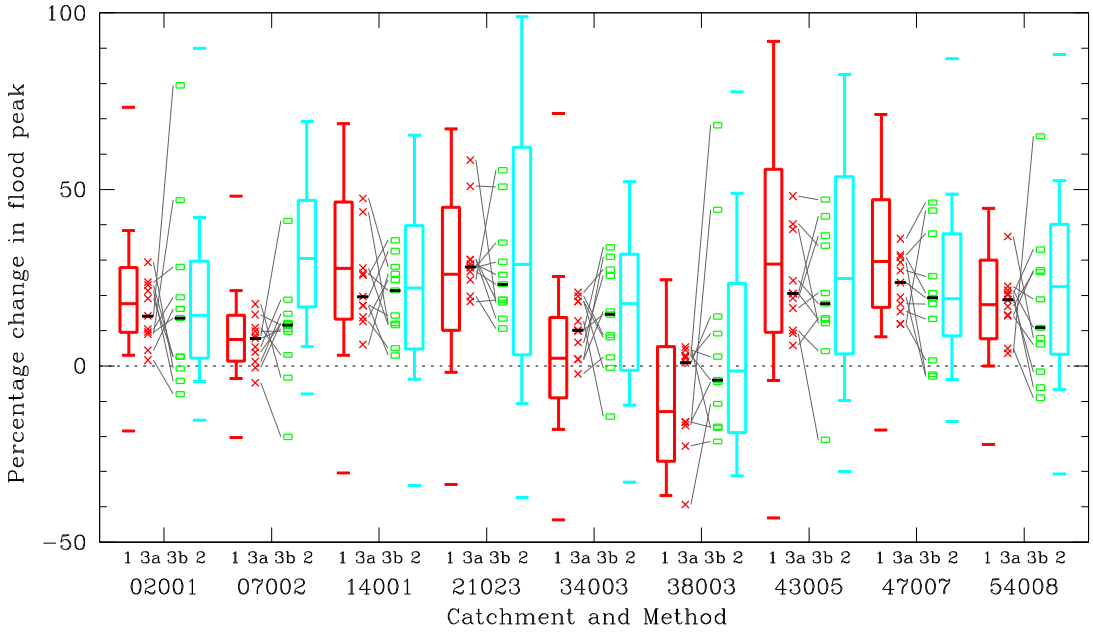


Figure 21-13: The range of percentage change in flood peaks for nine UK catchments at the a) 2-year and b) 20-year return period. Box-and-whisker plots are used to summarise results when using 10,000 UKCP09 Sampled Data (Murphy et al. 2009) change factors (red) and 100 sets of UKCP09 current and future Weather Generator time-series (cyan). Also plotted, are the results when using 11 sets of RCM-derived change factors (red crosses) and when using 11 sets of RCM current and future times-series (green rectangles). The box delineates the 25th-75th percentile range and the whiskers the 10th-90th percentile range, with the median (50th percentile) shown by the line dividing the box. Additional markers outside the whiskers indicate the minima and maxima, if within the plotted range of -50 to +100. The points derived from the RCM results are joined for the corresponding members of the RCM ensemble (grey lines), and the medians for these methods are shown by black horizontal bars.

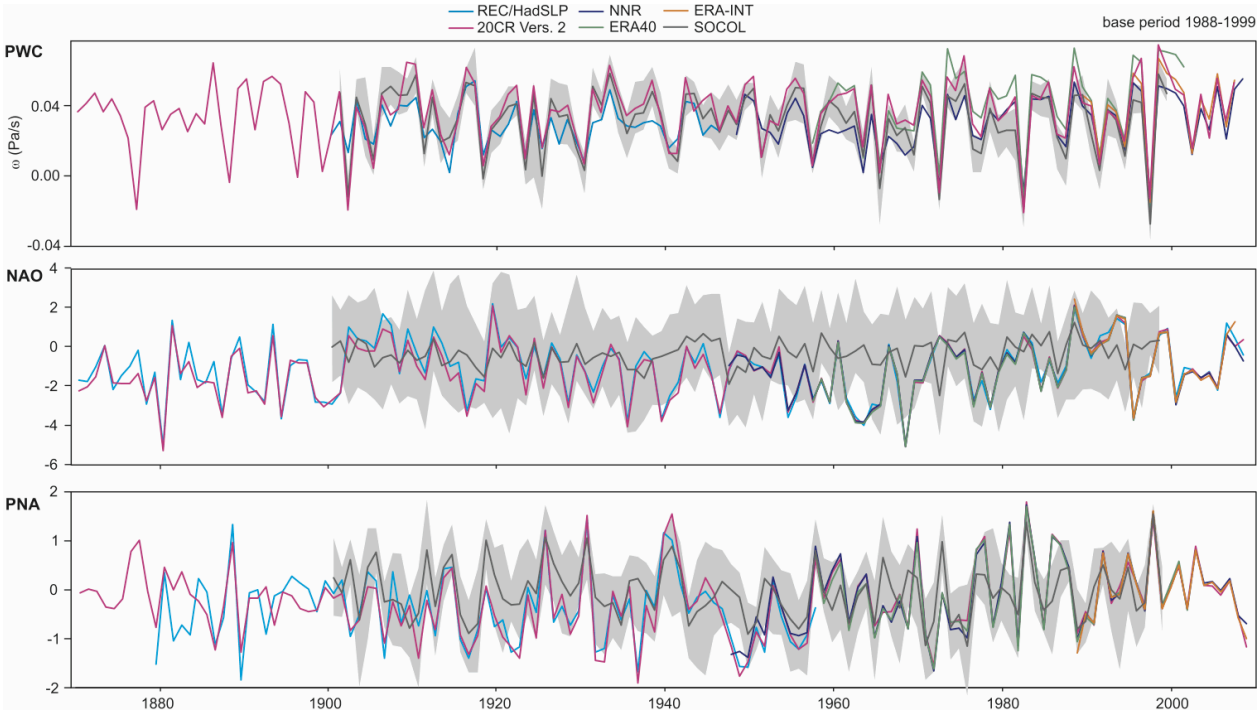

Figure 21-14: Time series of seasonally averaged climate indices representing three modes of large-scale climate variability: (a) the tropical September to January Pacific Walker Circulation (PWC); (b) the December to March North Atlantic Oscillation (NAO); (c) the December to March Pacific North America (PNA) pattern. Indices (as defined in Brönnimann etal. (2009) are calculated (with respect to the overlapping 1989–1999 period) from various observed, reanalysis and model sources: statistical reconstructions of the PWC, the PNA and the NAO, see Brönnimann et al. (2009) for details, (all cyan); 20CR (pink); NCEP–NCAR reanalyses (NNR; dark blue); ERA-40 (green); ERA-Interim (orange). The dark-grey dashed line and grey shading represent the ensemble mean and spread from a climate model ensemble with a lower boundary condition of observed seas-surface temperatures and sea-ice from the HadISST dataset (Rayner et al. 2003), see Brönnimann etal. (2009) for details. The model results provide a measure of the predictability of these modes of variability from sea-surface temperature and sea-ice alone and demonstrate that the reanalyses have significantly higher skill in reproduces these modes of variability.

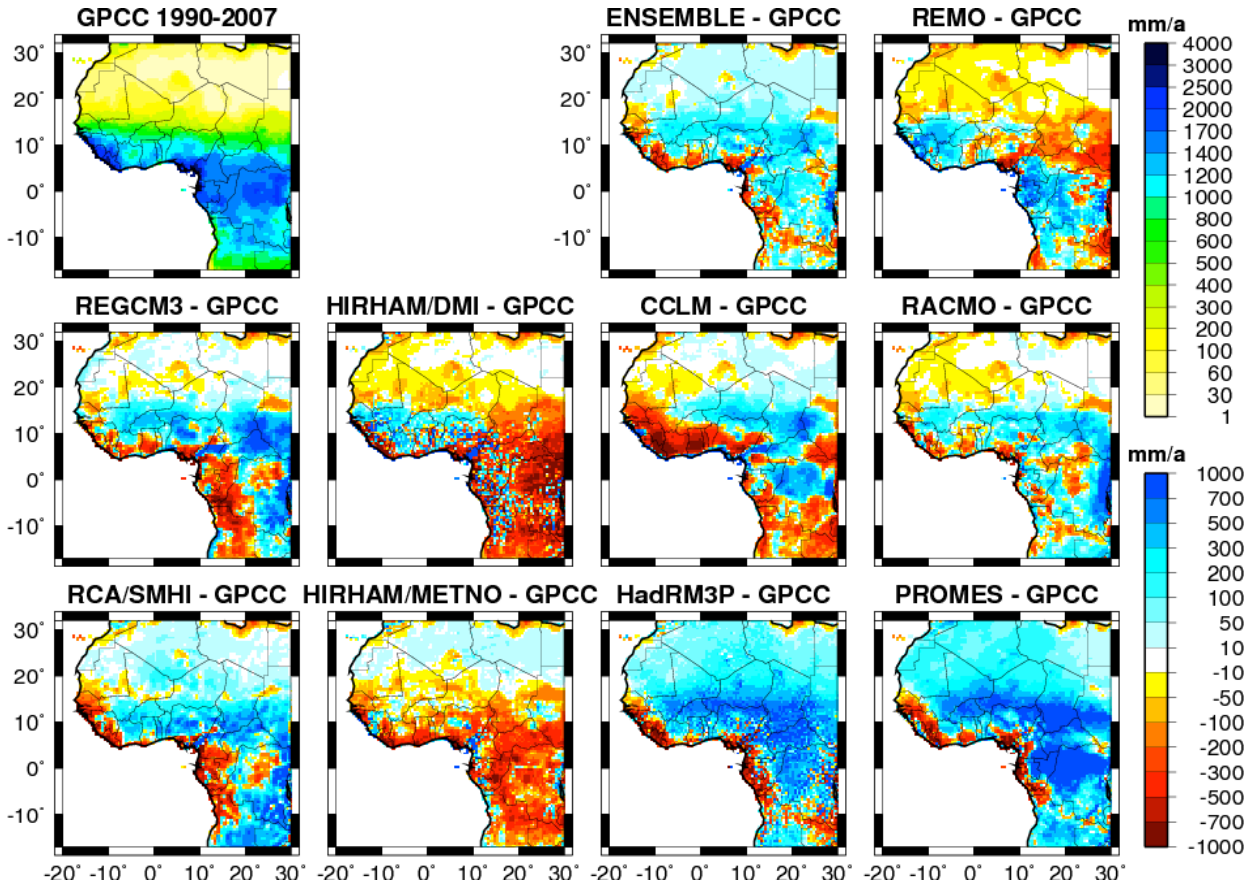

Figure 21-15: Observed 1990-2007 annual precipitation climatology from GPCC (Rudolf et al., 2011), top left, and, in the remaining panels, related systematic errors in 9 individual regional climate model simulations driven by the ERA-Interim reanalyses (Dee et al., 2011) and in the multi-model ensemble mean (Duryan et al., 2010).

	Challenges to adaptation:		Low	Medium	High
			SSP1/SSP5	SSP2	SSP3/SSP4

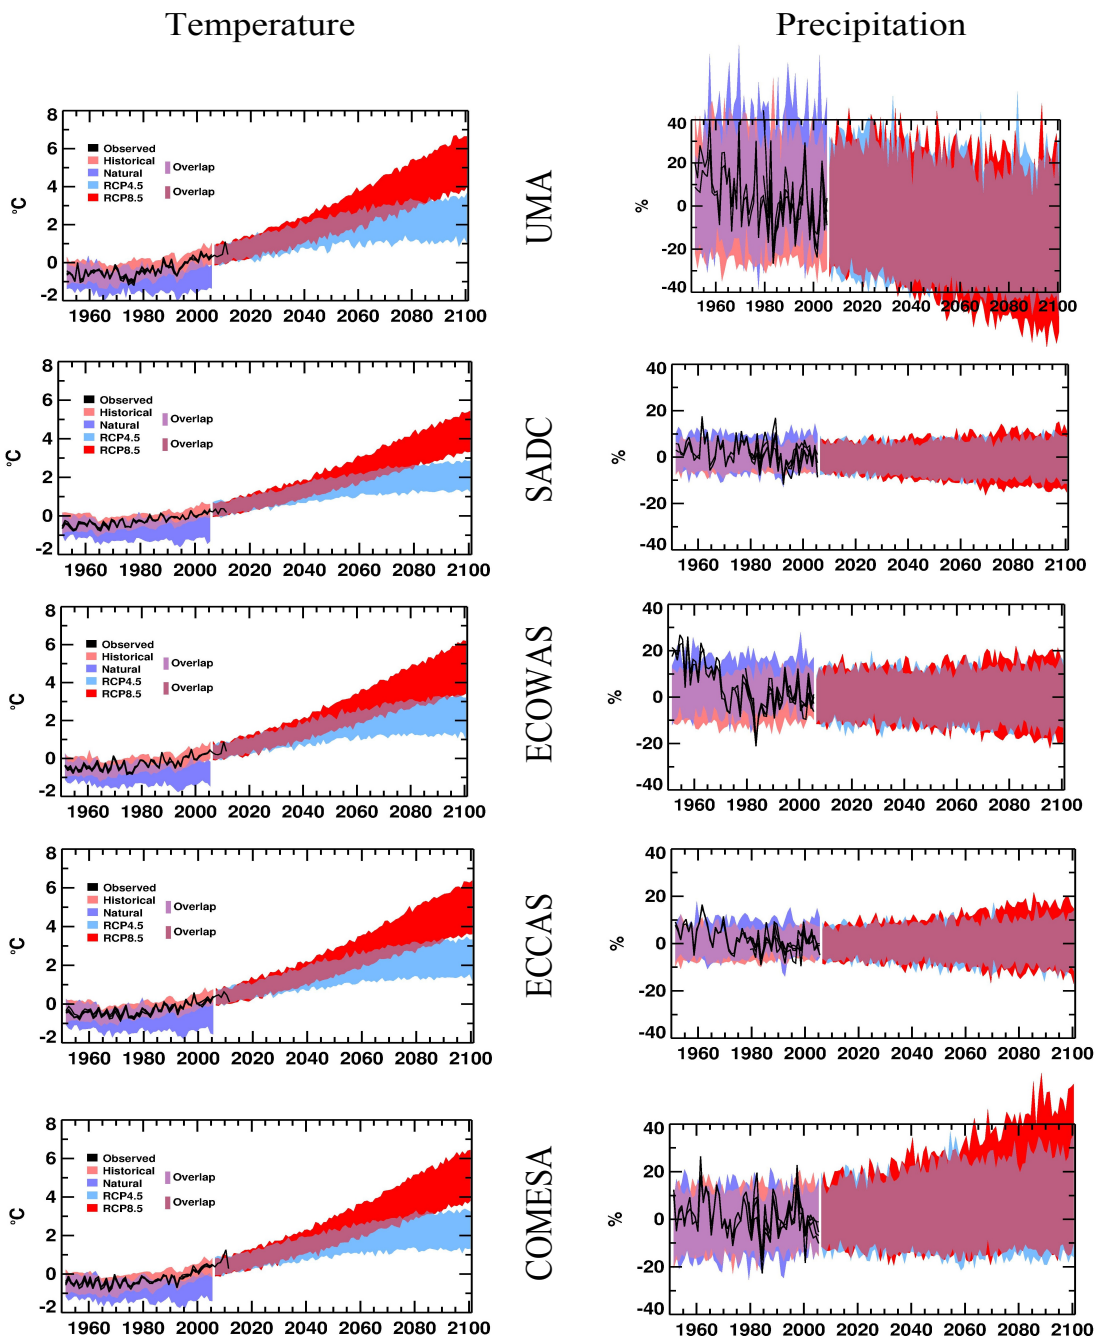
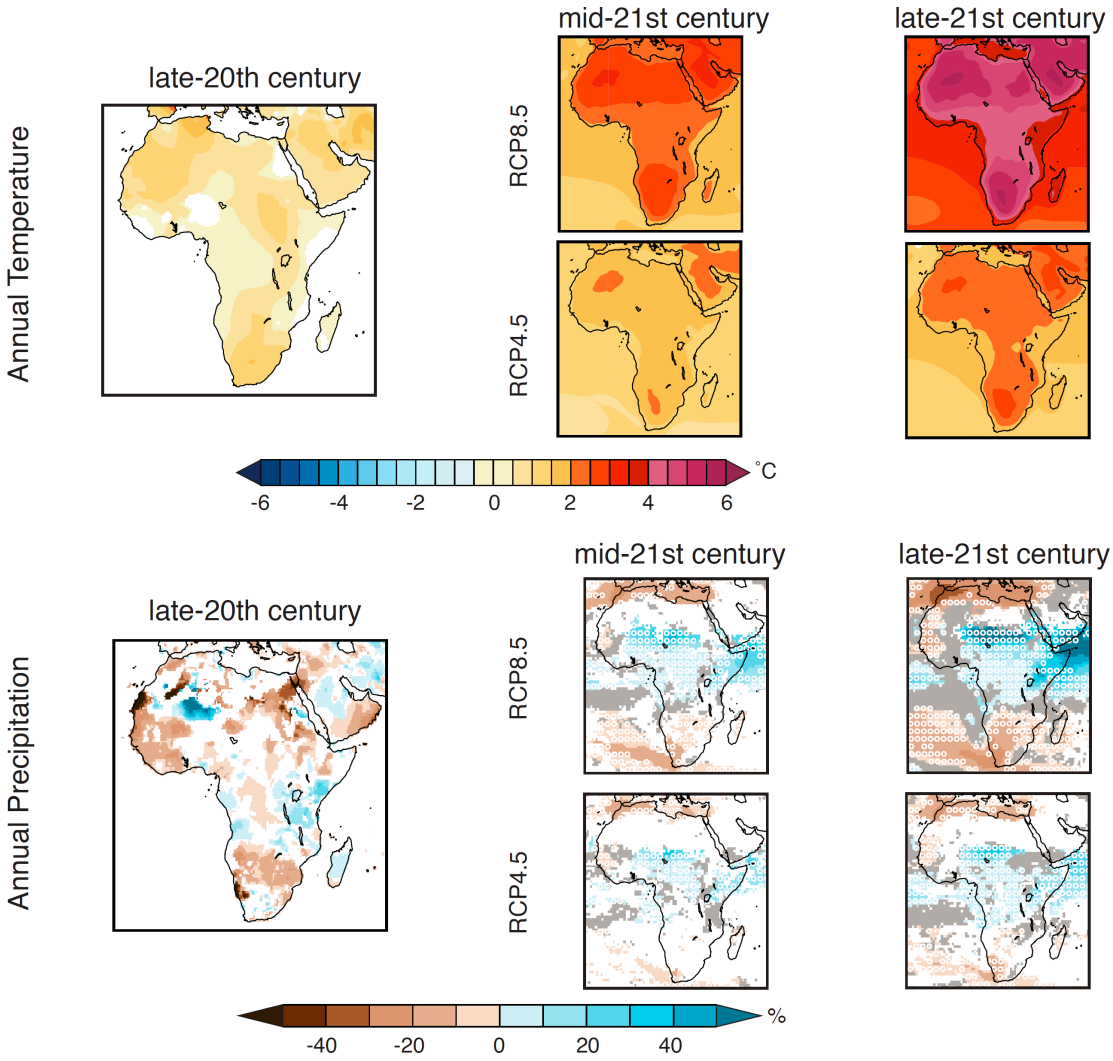
Box 21-1 Figure Caption: Approximate mappings of the SRES scenarios onto the new SSP/RCP framework (for details, see text). After Carter et al. (submitted).



Box 21-2 Figure Caption: Observed and simulated variations in past and projected future annual average precipitation and temperature over five African regions, Common Market for Eastern and Southern Africa (COMESA), the Economic Community of Central African States (ECCAS), the Economic Community of West African States (ECOWAS), the Southern African Development Community (SADC) and the Arab Maghreb Union (UMA). Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations, taken from the CMIP5 archive (Taylor et al. 2012), driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30) and by two of the RCM emissions/ concentrations scenarios (van Vuuren et al., 2011), "RCP4.5" (68) and "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. The regions are described in Chapter 22 (section 22.1.2) but the COMESA region labelled here covers COMESA north and includes Rwanda, Uganda, and

Kenya. Precipitation is included for land territories only, while temperature is included for both land and exclusive economic zone territories. The observational datasets used are GISTEMP (Hansen et al. 2010), HadCRUT3 (Brohan et al. 2006), and MLOST (Smith et al. 2008) for temperature, and CMAP (Xie and Arkin 1997), CRU TS 3.10 (Mitchell and Jones 2005), GPCP v2.2 (Adler et al. 2003), and PRECL (Chen et al. 2002) for precipitation. These suffer in some areas from sparse monitoring coverage.



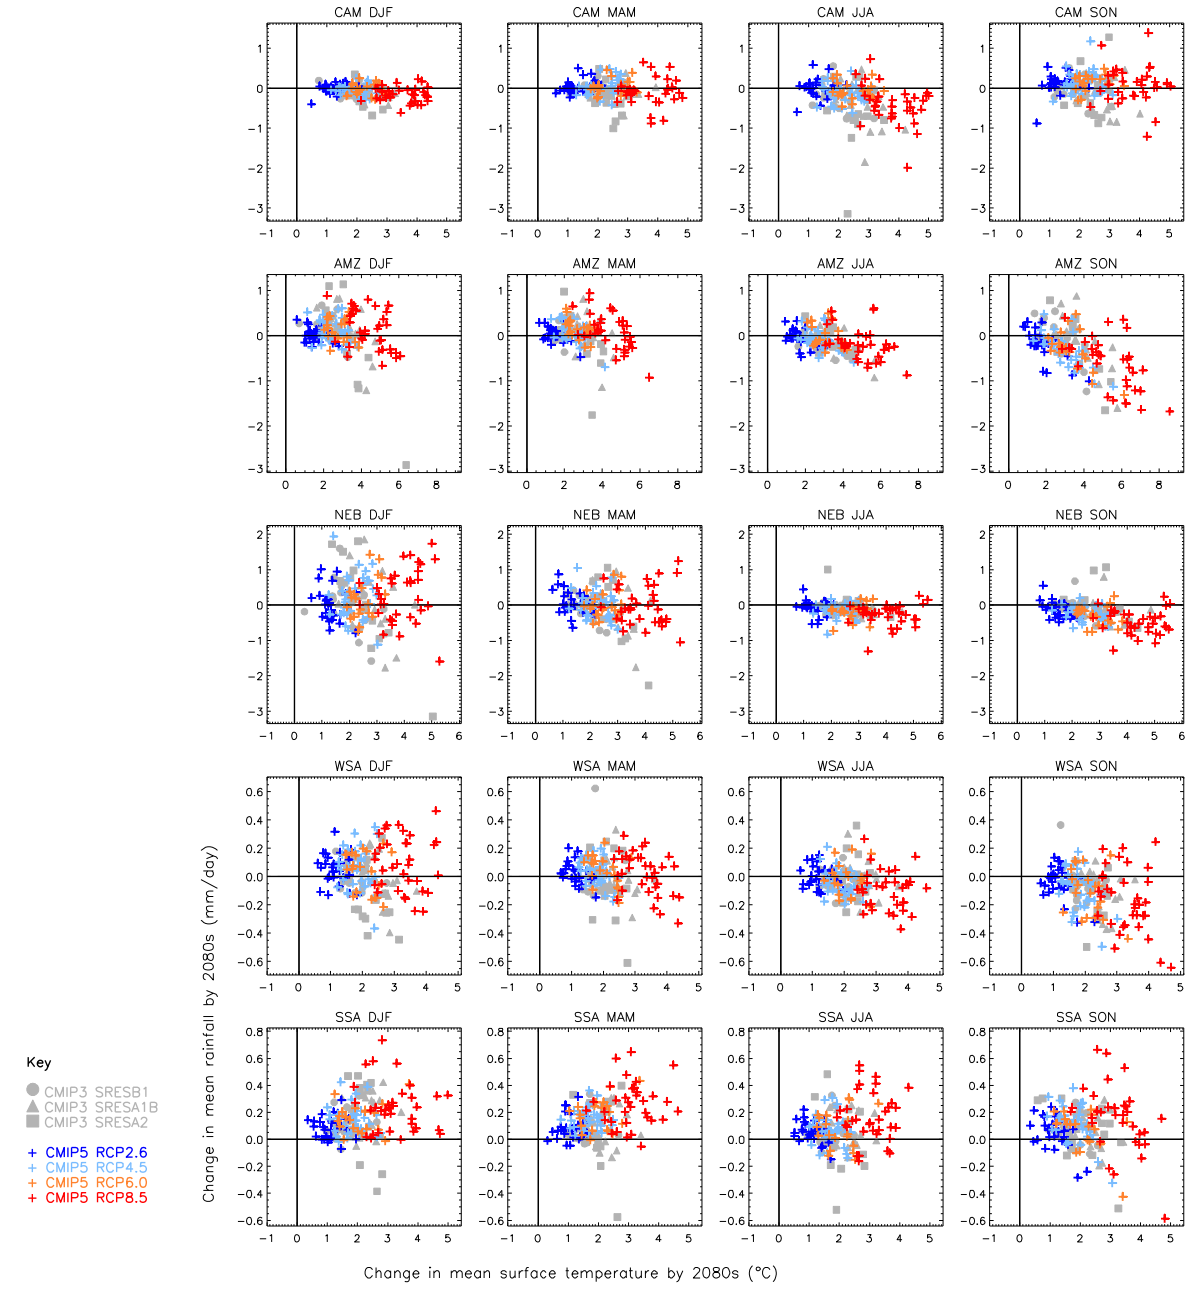
Box 21-3 Figure 1 Caption: Observed and projected changes in annual average temperature and precipitation over Africa. The observations are taken from the CRU TS 3.1 dataset (Harris et al., 2012) and the projections from the CMIP5 multi-model archive (Taylor et al. 2012). Projected changes are shown for the mid-21st century (2046-2065) and the late-21st century (2081-2100) from a baseline period of 1986-2005 under the RCP 4.5 and 8.5 emissions/ concentrations scenarios (van Vuuren et al., 2011). For the observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through to 1925. For the CMIP5 projections, four classes of results are displayed:

1) White indicates areas where for >66% of models the change in annual average precipitation is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986

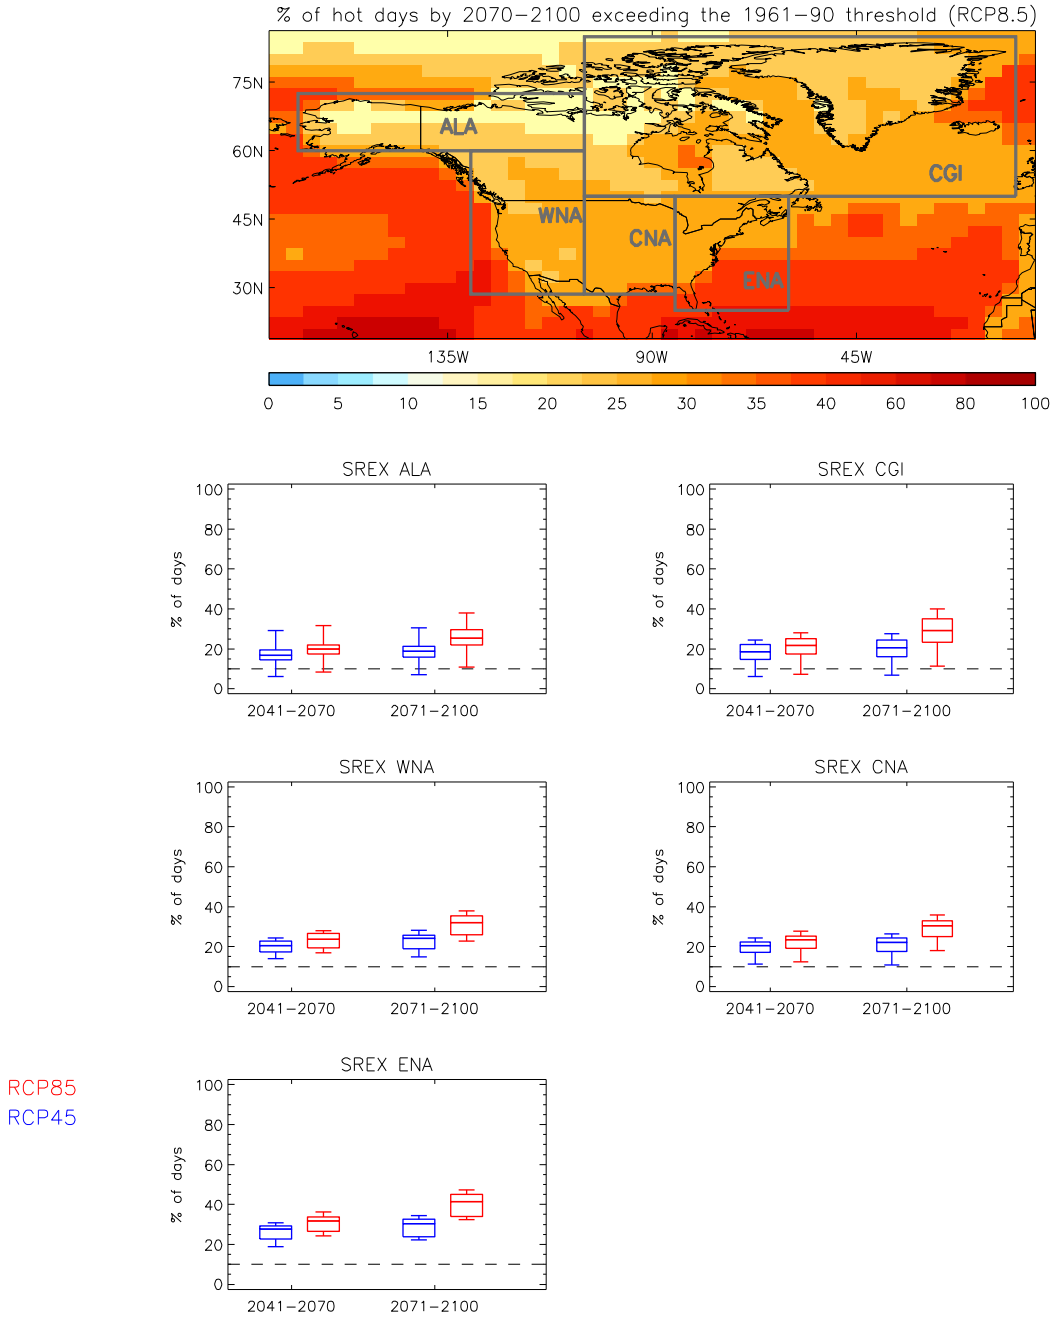
through 2005. Thus in these regions more than 2/3 of models show no significant change (using this measure of significance) in annual average precipitation. However, note that this does not imply no significant change in precipitation averaged over seasonal or shorter time-scales such as months to days.

2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions more than 2/3 of models show a significant change in annual average precipitation but less than 2/3 agree on whether annual average precipitation will increase or decrease.
3) Colors with circles indicate the change in annual average precipitation averaged over all models in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. In these regions more than 2/3 of models show a significant change in annual average precipitation and more than 2/3 agree (but less than 90%) agree on whether annual average precipitation will increase or decrease.
4) Colors without circles indicate the change in annual average precipitation averaged over all models in areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether annual average precipitation will increase or decrease.

For models which have provided multiple realizations for the climate of the recent past and the future, results from each realisation are first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated.

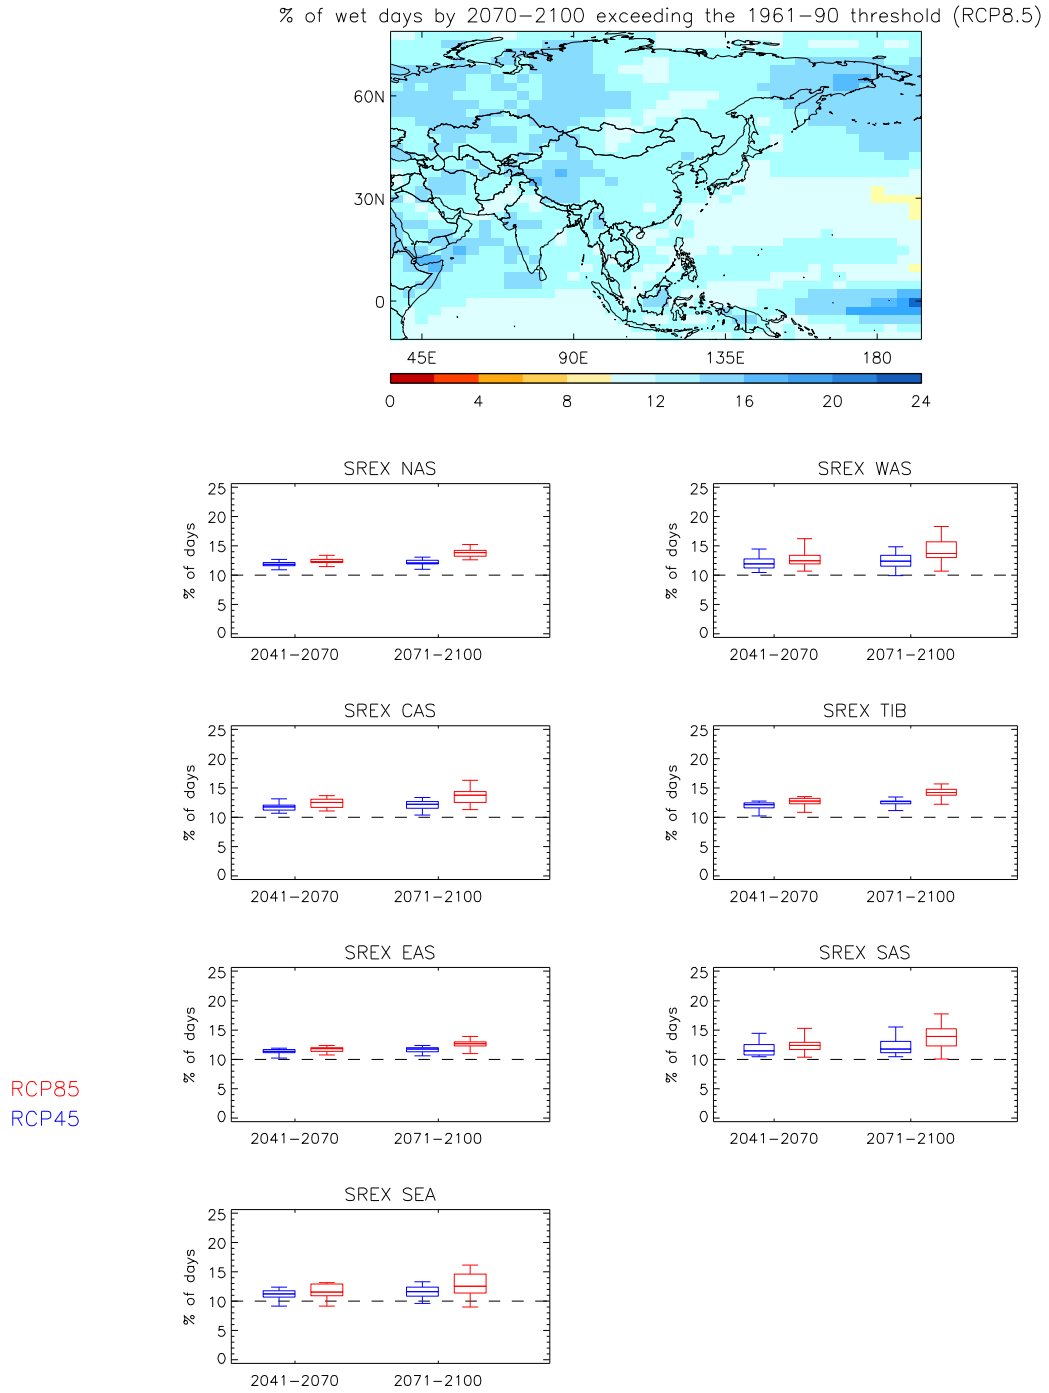


Box 21-3 Figure 2 Caption: Regional average change in seasonal mean temperature and precipitation over five regions covering South and Central America for the period 2070-2100 relative to 1961-90 in GCM projections from the CMIP5 ensemble under four RCP scenarios (van Vuuren et al., 2011) compared with GCM projections from the CMIP3 ensemble under three SRES scenarios (IPCC, 2000). Regional averaged are based on SREX region definitions (see Figure 21-RegAmplFac). Temperature changes are given in ºC and precipitation changes in mm/day with axes scaled relative to the maximum changes projected across the range of models.



[Figure displayed is a semi-placeholder. Final figure will have box-plots arranged around the map.]

Box 21-3 Figure 3 Caption: The frequency of 'hot days' (defined here as the 90th percentile daily maximum temperature during a baseline period of 1961-1990) projected for the 2071-2100 period by the CMIP5 GCMs for North America. Top: Ensemble median frequency of 'hot days' during 2070-2100 under RCP8.5. Bottom: Box-and-whisker plots indicate the range of regionally-averaged 'hot-day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5. Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of 'Hot days' of 10% is represented on the graphs by the dashed line.



[Figure displayed is a semi-placeholder. Final figure will have box-plots arranged around the map.]

Box 21-3 Figure 4 Caption: The frequency of 'very wet days' (defined here as the 90th percentile of daily precipitation on wet days during a baseline period of 1961-1990 with wet days defined as days with 1mm of precipitation or more) projected for the 2071-2100 period by the CMIP5 GCMs. Top: Ensemble median frequency of 'very wet days' during 2070-2100 under RCP8.5. Bottom: Box-and-whisker plots indicate the range of regionally-averaged 'very wet day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5. Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of 'Very wet days' of 10% is represented on the graphs by the dashed line.

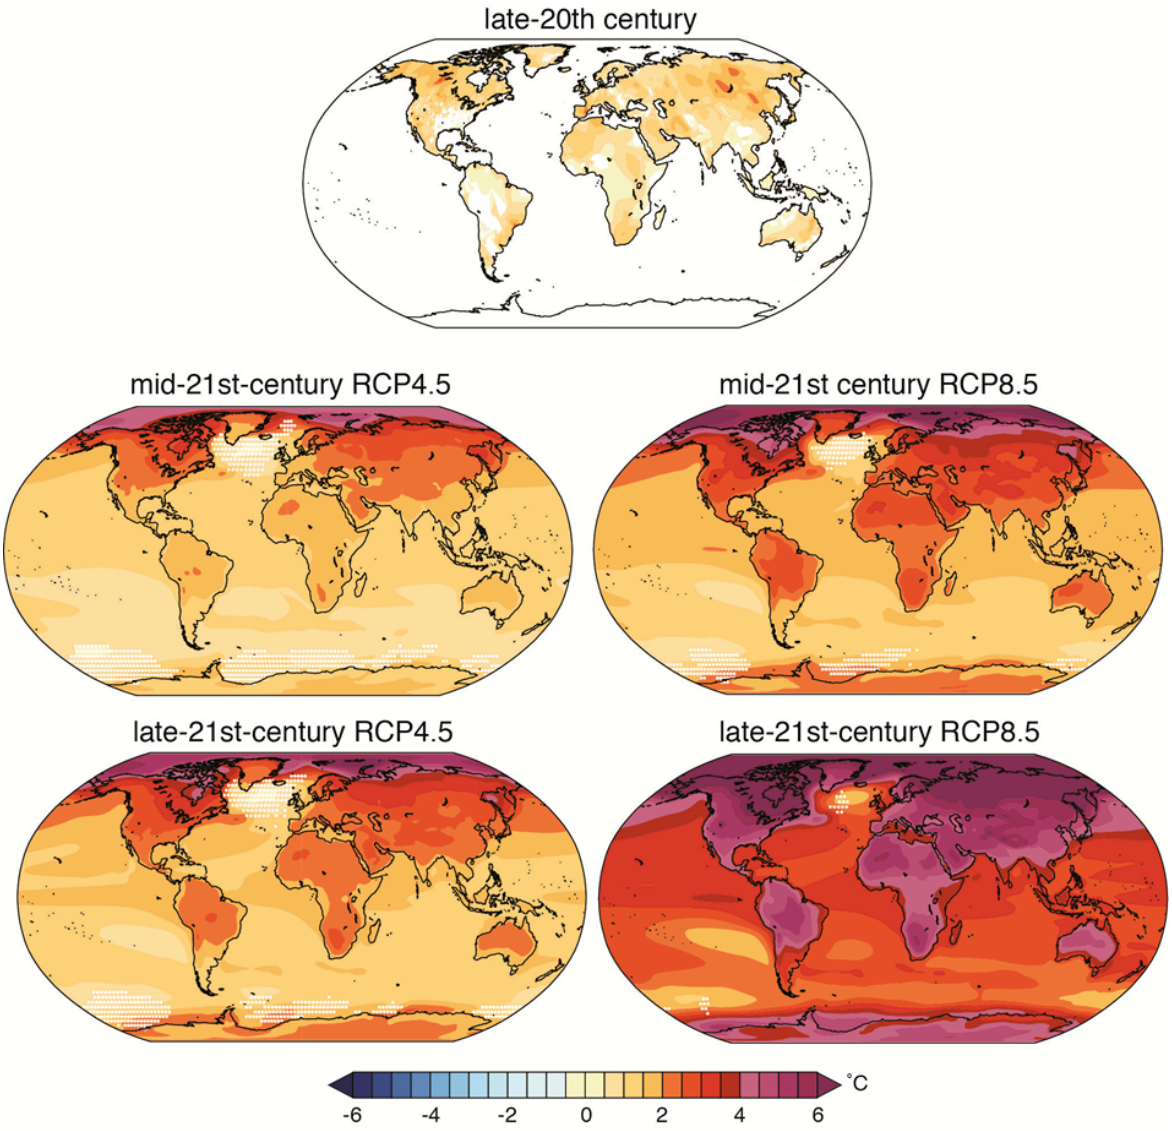


Figure RC-1: Change in annual temperature. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

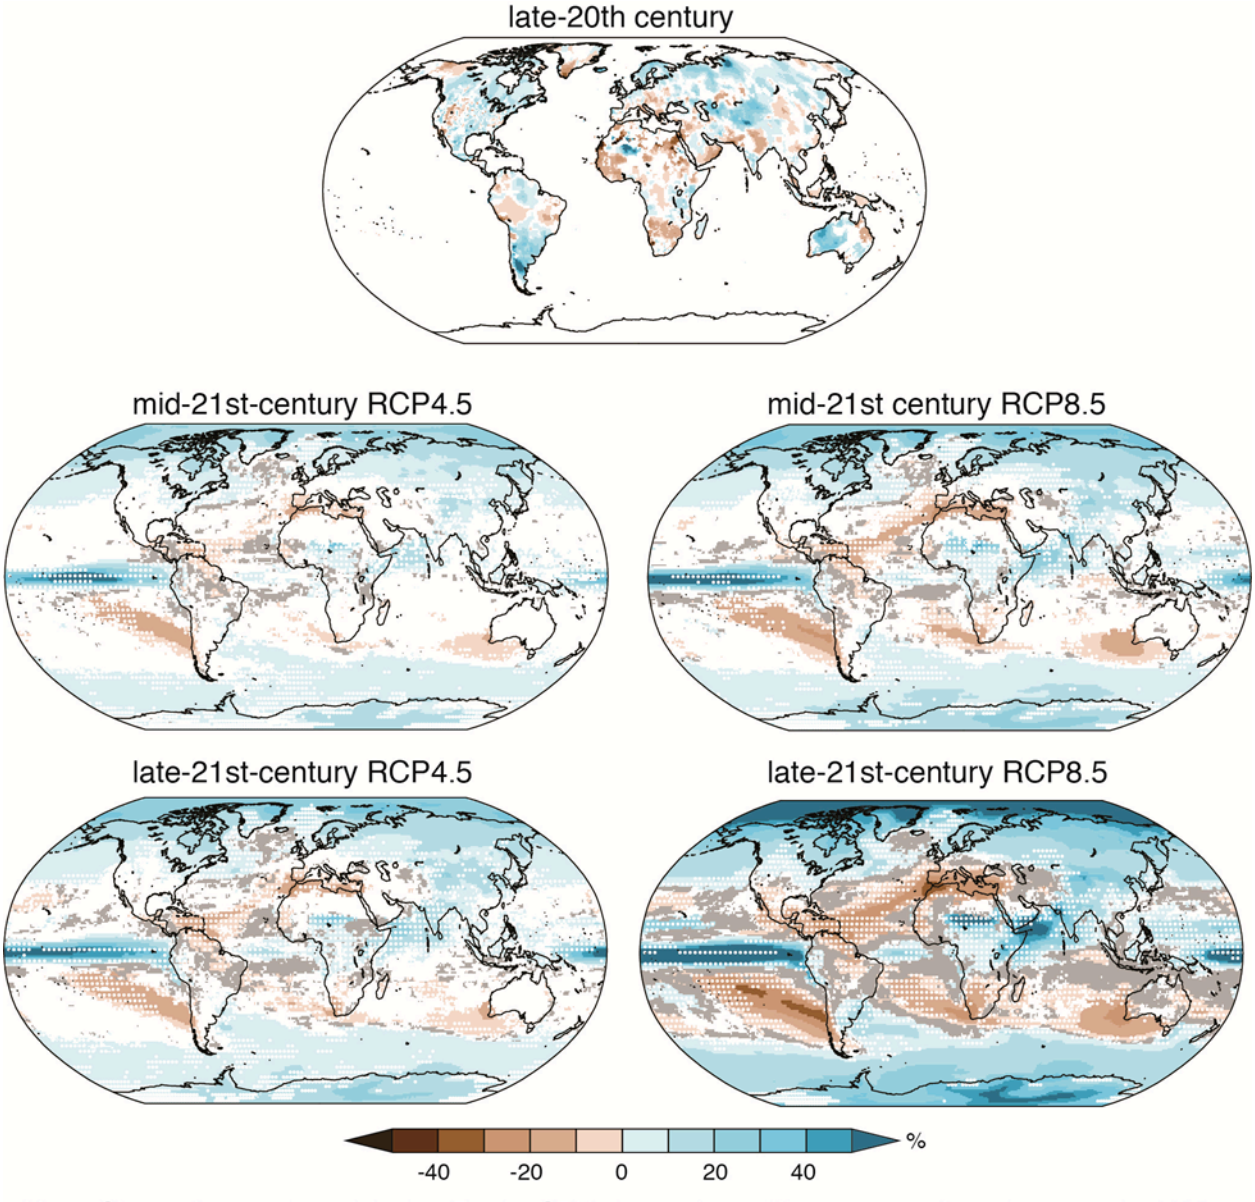

Figure RC-2: Change in annual precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

Executive Summary

Evidence of warming over land areas, consistent with anthropogenic climate change, has increased (*high confidence*). Decadal analyses of temperatures strongly point to an increased warming trend across the continent. In addition, changes in the seasonality and amount of precipitation have also been observed in sub-regions of Africa that include reduced long rains over parts of Eastern Africa and reduced summer precipitation over parts of Southern Africa. [22.2.1.1, 22.2.2.1]

Temperature rise by the end of this century are likely to exceed a 2° C threshold (*medium confidence*). Warming projections under medium and high Representative Concentrations Pathways (RCP) for GHG emissions indicate that extensive areas of Africa (medium RCP) and all of Africa (high RCP) will exceed 2° C by the last two decades of this century. Under a high RCP, that exceedence could occur by mid-century across much of Africa. [22.2.1.2, 22.2.2.2]

Attainment of the Millennium Development Goals (MDGs) in Africa would strengthen the region's resilience to various external shocks, including climate change. Vital links exist between climate change and the MDGs in Africa. On one hand climate change may adversely affect progress toward reaching the MDGs, while slow development can exacerbate the effects of climate change in the region (*confidence level to be added*). [22.3.1]

Africa as a whole has made significant progress on a number of MDGs, including education and gender equality and empowerment of women. However, slower progress has been made on MDGs such as the eradication of extreme poverty and hunger, and improvements in health and environment such as an increase in sanitation and basic housing facilities for poor populations including people living in slums. Moreover, progress toward the MDGs conceals high levels of spatial and group disparities, as improvement in development indicators is skewed in favor of higher-income groups and urban populations (*high confidence*). [22.3.1]

The impacts of climate change, mainly through sea level rise, combined with other extreme events (such as high tide levels and high storm swells) have the potential to threaten coastal zones, particularly coastal towns (*high confidence*). The example of the Kwa Zulu Natal coast (South Africa), where Durban is located, which was damaged by a combination of high water level and high storm swell in March 2007, is indicative of what could happen. **Evidence is growing that the costs of these impacts will increase for economic sectors and people living in these zones (medium confidence). [22.3.2.3.1, 22.3.7]**

Ocean ecosystems, in particular coral reefs, will be affected by climate change-induced ocean acidification as well as changes in upwelling, thus affecting crucial economic activities (mainly fisheries; *medium confidence*). [22.3.2.3.2, 22.3.4.4]

The impact of climate change on water availability in Africa is uncertain (*high confidence*). Water resources are subjected to high hydro-climatic variability over space and time, and are a key constraint on the continent's continued economic development. Water is the primary medium through which early and subsequent climate change impacts will be felt by people, ecosystems, and economies. Many of the fragile terrestrial and aquatic ecosystems in Africa are implicitly or explicitly water-dependent. The impacts of climate change will be superimposed onto already water-stressed catchments with complex land uses, engineered water systems, and a strong historical socio-political and economic footprint. Strategies and plans of action to adapt to climate change through an integrated approach to land and water management are urgently needed to establish effective resilience to the projected impacts of climate change. [22.3.2.2, 22.3.3]

Progress is being achieved on managing risks to food production from current climate variability but these will likely not be sufficient to address long-term risks from climate change (*high confidence*). Livelihood-based approaches for managing risks to food production from multiple stressors, including rainfall variability, have increased substantially in Africa since the IPCC's Fourth Assessment Report (AR4). While these efforts can improve the resiliency of agricultural systems in Africa over the near term, these adaptations are likely to be insufficient for coping with risks from long-term climate change, which will be variable across regions and farming system types. Nonetheless, processes such as collaborative, participatory research that includes scientists and farmers, strengthening of communication systems for anticipating and responding to climate risks, and increased flexibility in livelihood options, which serve to strengthen coping strategies in agriculture for near-term risks from climate variability, provide potential pathways for adaptive capacities for climate change. [22.4.5.4, 22.4.5.7, 22.4.6, 22.6.1]

Recent evidence further strengthens a key finding from the AR4 that "agricultural production and food security (including access to food) in many African countries and regions are likely to be severely compromised by climate change and climate variability" (*high confidence*). Temperature rise and a reduction in growing season length by mid-century are very likely to significantly reduce crop productivity with strong adverse effects on food security. New evidence is also emerging that fisheries and high-value perennial crops could also be adversely affected by temperature rise, and that the pressure of pests and diseases on crops and livestock is expected to increase as a result of climate change and other factors. Moreover, new challenges to food security are emerging as a result of strong urbanization trends on the continent and increasingly globalized food chains, which require better understanding of the multi-stressor context of food and livelihood security in Africa. [22.3.4]

Evidence is growing that climate change is likely to increase the burden of a wider range of health outcomes (*high agreement, medium confidence*). Findings on malaria are similar to the AR4, emphasizing the spatial and temporal spread of malaria in the East Africa Highlands and increased transmission intensity in South Africa. Leishmaniasis incidence in North Africa has been found to have a significant positive relation with rainfall pattern and changes in the frequency of epidemics and spatial spread to urban areas and to sub-Saharan Africa. Indirectly, climate change could increase the burden of malnutrition, which will have the highest toll on children and women. **Climate change is a multiplier of existing vulnerability to health outcomes (*high confidence*) including inadequate water and sanitation coverage, food security, and access to health care and education.** Improvements in these existing vulnerabilities will decrease the impacts of climate change on health. [22.3.5]

In all regions of the continent, national governments are initiating governance systems for adaptation and responding to climate change (*medium evidence, high agreement*). Some progress has been made on national and sub-national policies and strategies beyond the initial National Adaptation Programmes of Action, and on mainstreaming adaptation into sectoral planning, for example in the health sector. **Institutional frameworks cannot yet effectively coordinate the range of adaptation initiatives being implemented, resulting in a largely ad hoc and project-level approach, which is often donor-driven and may not result in local or national ownership (*medium agreement, medium evidence*).** While institutions for collaborative governance are developing, a separation remains between policy formulation and vulnerable people adapting autonomously on the ground, exacerbated by low levels of capacity in local governments to deal with complex socio-ecological change. National policies are often at odds with autonomous local adaptation strategies, which can act as a barrier to adaptation, especially where cultural, traditional and context-specific factors are ignored (*high confidence*). [22.4.4]

While a wide range of adaptation options, approaches, and decision tools are being tested and implemented at different scales across Africa, these have not yet been taken to a scale that would address the complex vulnerabilities and needs identified (*medium evidence, high agreement*). Efforts such as disaster risk reduction, social protection, adaptation technologies, climate-resilient infrastructure, ecosystem restoration, and livelihood diversification are reducing vulnerability and enhancing resilience, but this is still largely confined to local scales and isolated initiatives. Ecosystem-based approaches and pro-poor integrated adaptation-mitigation initiatives hold promise for a more coherent approach to adaptation; and emphasis on highly vulnerable groups such as children and an enhanced policy environment for community-based adaptation can promote equity goals. **Coastal adaptation has the potential to considerably reduce projected impacts in the coastal zones (*high confidence*).** Adaptation

in the health sector will build on existing public health interventions as well as specific adaptation measures such as early warning systems. [22.4.5]

In addition to technological and infrastructural approaches, evidence has increased of the importance of 'soft path' options and flexible and iterative learning approaches for effective adaptation (*medium evidence, medium agreement*). 'Soft' measures include harnessing ecosystem services for climate proofing, such as coastal afforestation and catchment restoration. Learning approaches being explored include action research, participatory adaptation planning, and adaptive management, and may involve co-production of knowledge – such as combining local and traditional knowledge with science, and conflict resolution. Attention to the cultural, ethical, and rights considerations of adaptation has also increased. [22.4.5]

The inadequacy of developmental strategies to counter current climate risks reinforces the need for strong inter-linkages between adaptation and development, and for low-regrets adaptation strategies that produce developmental co-benefits (*high confidence*). [22.4.3]

Growing understanding of the multiple interlinked constraints on increasing adaptive capacity is beginning to indicate potential limits to adaptation in Africa (*limited evidence, high agreement*). Climate change combined with other external changes (environmental, social, political, technological) may overwhelm the ability of people to cope and adapt, especially if the root causes of poverty and vulnerability are not addressed. The risks of maladaptation are increased by development interventions that often fail to consider how different types of change interact and undermine the ability of people to cope with multiple stressors. Evidence is growing for the effectiveness of flexible and diverse development systems that are designed for reducing vulnerability, spreading risk, and building adaptive capacity. These points indicate the need for new development trajectories that place climate resilience, ecosystem stability, equity and justice at the centre of development efforts. [22.4.6]

Human security of people in Africa will increasingly be threatened by the impacts of climate variability (*high agreement, medium* to *robust evidence*). Food and health insecurity, migration and displacement, and violent conflict are particular areas of concern for the African continent. The impacts of climate change have the potential to increase food insecurity and distributional conflicts. Evidence is growing that displacement and migration patterns due to climate change-related drivers will be subject to substantial shifts. **The degree of adaptation will be decisive with regard to the risks related to human security in Africa**. Based on the multi-model CMIP5 analysis, which indicates that temperature rise will exceed a 2ºC threshold across Africa by the middle to end of this century, the risks for human security will be high to very high by 2080-2100 and medium to high by 2030-2040. [22.3.6]

Institutional capacities and governance mechanisms need to be strengthened with respect to the ability of national governments and scientific institutions in Africa to absorb and effectively manage large amounts of funds allocated for adaptation, in order that the effectiveness of adaptation initiatives is assured (*medium confidence*). Indigenous and rural poor communities in remote locations, the urban poor living in precarious settlements, and displaced persons, especially women and children, are those most adversely affected by climate change while they are actually meant to be the main beneficiaries of adaptive action. It is therefore imperative that strong institutional capacity to manage climate finance funds be made a priority. The potential for ineffective and mismanaged climate finance funds are – among other reasons – rooted in the level of complexity, uncertainty, and novelty that surrounds many climate issues. [22.4.4.3, 22.6.2]

22.1. Introduction

22.1.1. Structure of the Regions

The African continent (including Madagascar) is the world's second largest and most populous continent (1 billion in 2009, representing 14.7% of the world's population) behind Asia. It is composed of 55 countries (of which 5 are small island states) of which 33 belong to the Least Developed Countries (LDCs). The continent is organized at the regional level under the African Union (AU).[1] The AU's Assembly of Heads of State and Government has officially recognized eight Regional Economic Communities (RECs) (Ruppel, 2009; Nwauche, 2009). Except for the Sahrawi

Arab Democratic Republic,[2] all AU member states are affiliated with one or more of these RECs. These RECs include the Arab Maghreb Union (AMU), with 5 countries in Northern Africa; the Community of Sahel-Saharan States (CEN-SAD), grouping 25 countries; the Common Market for Eastern and Southern Africa (COMESA), grouping 19 countries in Eastern and Southern Africa; the East African Community (EAC), with 5 countries; the Economic Community of Central African States (ECCAS), with 10 countries; the Economic Community of West African States (ECOWAS), with 15 countries; the Intergovernmental Authority on Development (IGAD); and the Southern African Development Community (SADC), with 15 countries. The regional subdivision of African countries into REC's is a structure used by the AU and the NEPAD (New Partnership for Africa).

[FOOTNOTE 1: Due to the controversies regarding the Sahrawi Arab Democratic Republic, Morocco withdrew from the Organization of African Unity (OAU) in protest in 1984 and, since South Africa's admittance in 1994, remains the only African nation not within what is now the AU.]

[FOOTNOTE 2: Although the Sahrawi Arab Democratic Republic has been a full member of the OAU since 1984 and remains a member of the AU, the republic is not generally recognized as a sovereign state. While most African states have recognized the republic (e.g., Namibia and South Africa), several others have withdrawn their former recognition (e.g., Cape Verde, the Seychelles), and some have temporarily frozen diplomatic relations (e.g., Costa Rica, Ghana), pending the outcome of a respective United Nations (UN) referendum that would allow the people of Western Sahara to decide the territory's future status. The republic has no representation in the UN.]

22.1.2. Major Conclusions from Previous Assessments

22.1.2.1. Regional Special Report and Assessment Reports 1 – 4 / Chapter 9

The first evaluation of the potential impacts of climate change in Africa was done for the IPCC special report on regional climate change (Zinyowera *et al.*, 1997). This report presented mainly the sensitivity of water resources and coastal zones to some climatic parameters. Since the report was published, climate change was considered as an additional burden on an already stressful situation. Lack of data on energy sources, the uncertainties linked to the climate change scenarios (mainly for precipitation), the need for a better integration of studies, and the necessary links between science and decisionmakers were underlined as major challenges for Africa. In the Third Assessment Report, specific chapters were dedicated to regions, Africa being one (Desanker *et al.*, 2001). In the third report, the main focus is on the potential impacts of climate change and vulnerability for the six sectors considered (water resources, food security, natural resources and biodiversity management, health, human settlements and infrastructure, and desertification). Literature on adaptation strategies was included in the assessment for each of these sectors. That desertification was considered as a sector expressed the threats of desertification and droughts to the economy of the continent. Globally, most of the adaptation options suggested were linked with better management of the different resources. The main gaps and needs, such as capacity building, data needs, and the development of integrated analysis, as well as the consideration of other languages, were identified. The Fourth Assessment Report (AR4) confirmed that the vulnerability of the continent was mainly due to its low adaptive capacity (Boko *et al.*, 2007). It considered the different sources of vulnerability, encompassing socioeconomic causes (demographic growth, governance, conflicts, etc.) and examined the impacts of climate change on various sectors (energy, tourism and coastal zones are considered separately). The potential impacts of extreme weather events (droughts and floods) were also considered in AR4. The question of adaptation costs was raised, as well as the need for mainstreaming climate change adaptation into national development policies. Two case studies were analyzed, on food security and traditional knowledge. The first emphasized that climate change could affect the three main components of food security while the second case study illustrated that African communities have prior experience with climate variability, although this knowledge will be sufficient to face climate change impacts. A list of needs was also identified regarding future studies: better knowledge of climate variability; more studies on the impacts of climate change on water resources, energy, biodiversity, tourism, and health; the links between different sectors (e.g., between agriculture, land availability, and biofuels); developing links with the disaster reduction community; increasing interdisciplinary analysis of climate change; and strengthening institutional capacities.

22.1.2.2. Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)

Due to the high vulnerability of the African continent to the negative effects of climate change, the Special Report of the IPCC on managing the risks of extreme events and disasters to advance climate change adaptation (IPCC, 2012) is of particular relevance. According to the report, confidence in observed trends in daily temperature extremes in Africa generally varies from *low* to *medium* depending on the region (Seneviratne *et al*., 2012). In southern Africa, there is *medium confidence* that droughts will intensify in the 21st century in some seasons, due to reduced precipitation and/or increased evapotranspiration (Seneviratne *et al*., 2012).

22.2. Observed Climate Trends and Future Projections

22.2.1. Temperature

22.2.1.1. Observed Trends

Over the last 100 years Africa's temperature has increased by 0.5°C (Desanker *et al*., 2001; Clark, 2006; Kniveton *et al*., 2009; Mohamed, 2011; Grab and Craparo, 2011; Hoffman *et al*., 2011). Near-surface air temperature anomalies in Africa were significantly higher for the period 1995–2010 compared to the period 1979–1994 (Collins, 2011). Over West Africa, warming is likely due to natural variability or human activity, rather than a result of variations in the El Niño-Southern Oscillation. Min and Hense (2007) found strong evidence of an anthropogenic signal in continent-wide temperature increases in the 20th century. Over most regions of Africa, such a signal appears in the frequency of unusually hot seasons (Stott *et al*., 2011) and the increase in the number of droughts occurring in the Sahel since 1970 is well documented (Greene *et al*., 2009).

Anyah and Qiu (2012) indicate that both equatorial and southern parts of the eastern Africa region have been experiencing a significant increase in temperature since the beginning of the early 1980s. Similarly, recent reports from the Famine Early Warning Systems Network (FEWS NET) indicate that there has been an increase in seasonal mean temperature over time in many areas of Ethiopia, Kenya, South Sudan, and Uganda (Funk *et al*., 2011; Funk *et al*., 2012). In addition, warming of the surface temperature and an increase in the frequency of extreme warm events has been observed for countries bordering the western Indian Ocean between 1961 and 2008 (Vincent *et al*., 2011).

In recent decades, most of southern Africa has also experienced upward trends in annual mean, maximum, and minimum temperature over large extents of the subregion during the last half of the 20th century, with the most significant warming occurring during the last two decades (Zhou *et al*., 2010; Collins, 2011; Kruger and Sekele, 2012). Minimum temperatures have increased more rapidly relative to maximum temperatures, which has decreased the diurnal temperature range over inland southern Africa (New *et al*., 2006) is influenced by decreases in surface solar heating (Zhou *et al*., 2010). A reduction in cold night occurrences is consistent with an increase in minimum temperatures (Kruger and Sekele, 2012).

22.2.1.2. Projected Trends

James and Washington (2012) find that in the context of a 1°C to 4°C global temperature increase by the end of the century, temperatures in Africa are projected to rise more than the global average, particularly in the more arid regions. Coupled Model Intercomparison Project phase 3 (CMIP 3) models, in the A1B middle-of-the-road scenario indicate that by the end of the 21st century, summer temperatures in the Sahel will be higher than any in recorded history (Battisti and Naylor, 2009; Biasutti and Sobel, 2009). Oguntunde and Abiodun (2013) project a drier climate during the rainy season and a wetter climate during the dry season between 2030 and 2050, and a warmer climate over the Niger River basin (NRB) in all months.

Climate model projections from the IPCC Special Report: Emissions Scenarios (SRES) A2 and B1 emissions scenarios over Ethiopia show warming in all four seasons across the country, which may cause a higher frequency of

heat waves as well as higher rates of evaporation (Conway and Schipper, 2011). Projected minimum temperatures over equatorial eastern Africa are more than 2°C higher than the 1981–2000 average by the middle and end of the 21st century (Anyah and Qiu, 2012). Elshamy et al. (2009) projected a temperature increase over the upper Blue Nile of between 2°C and 5°C at the end of the century.

Mean warming in Southern Africa is projected to exceed global warming in all seasons (Sillmann and Roeckner, 2008; Watterson, 2009; Mariotti *et al.*, 2011; James and Washington, 2012; Orlowsky and Seneviratne, 2012). Furthermore, towards the end of the 21st century, the projected warming, which is greater than 4ºC under the highest radiative forcing, far exceeds natural climate variability (Moise and Hudson, 2008). Higher warming rates are evident over the semi-arid southwestern parts of the subregion covering northwestern South Africa, Botswana, and Namibia. These areas are thus projected to become even drier in the future climate (Moise and Hudson, 2008; Engelbrecht *et al.*, 2009; Watterson, 2009; Shongwe *et al.*, 2009). Accelerated warming is consistent with reduced surface evaporative cooling. Observed and simulated variations in past and projected future annual average temperature over five African regions (UMA, SADC, ECCAS, ECOWAS, SADC and COMESA) are captured in Figure 22-2. Multi-model CMIP5 analysis indicates that temperature rise will exceed a 2°C threshold across Africa by the middle to end of this century (Figure 22-1).

[INSERT FIGURE 22-1 HERE
Figure 22-1: Observed and simulated variations in past and projected future annual average precipitation and temperature. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

[INSERT FIGURE 22-2 HERE
Figure 22-2: Observed and simulated variations in past and projected future annual average precipitation and temperature over five African regions (Arab Maghreb Union- AMU, Common Market for Eastern and Southern Africa – COMSEA, Southern African Development Community – SADC, Economic Community of West African States – ECOWAS, Economic Community of Central African States – ECCAS). Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3. The regions are described in 22.1.2, but COMESA-north covers COMESA north and inclusive of Rwanda, Uganda, and Kenya. Precipitation is included for land territories only, while temperature is included for both land and exclusive economic zone territories.]

22.2.2. Precipitation

22.2.2.1. Observed Changes

At the beginning of the 21st century, Sahel rainfall was recorded as being moderately stable around the 1961–1990 average of 371 mm, although this period was about 25% drier than earlier decades of the 20th century. Recent

studies of rainfall trends across the Sahel confirm a decrease in rainfall associated with a decrease in the number of rainy days (Mohamed, 2011). Observations of the Guinea coast reveal a clear depreciation of the length of the rainfall break in August that defines the bimodal nature of the wet season in the southern part of Nigeria. The two- to three-week period of temporary rainfall cessation is gradually declining into a relatively insignificant two- to three-day break (Chineke *et al*., 2010).

Precipitation in eastern Africa shows a high degree of spatial variability dominated by a variety of physical processes (Hession and Moore, 2011). Williams and Funk (2010) and Funk et al. (2008) indicate that over the last three decades rainfall has decreased over eastern Africa during the 'long-rains' season, which usually lasts from March to May/June. The suggested physical link to the decrease in rainfall is the rapid warming of Indian Ocean sea surface temperature (SST), which causes an increase in convection and precipitation over the tropical Indian Ocean and thus contributes to increased subsidence over eastern Africa and a decrease in rainfall during March to May/June (Funk *et al*., 2008; Williams and Funk, 2010). Similarly, Lyon and DeWitt (2012) show a decline in the March–May seasonal rainfall over eastern Africa, with particular attention to the abrupt decline of precipitation during the long-rains of 2011. Summer (June–September) monsoonal precipitation has declined substantially throughout much of the Great Horn of Africa over the last 60 years (during the 1948–2009 period; Williams *et al*., (2012)) as a result of the changing sea level pressure (SLP) gradient between Sudan and the southern coast of the Mediterranean Sea and the southern tropical Indian Ocean region (Williams *et al*., 2012). These results are contrary to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (AR4) findings, which indicate a precipitation increase over eastern Africa (Christensen *et al*., 2007). Lyon and DeWitt (2012) conclude that recent east African precipitation trends differ from projected climate model trends because recent cooling in the eastern equatorial Pacific offsets the equatorial Pacific SST warming that is projected by CMIP3 Global Circulation Models (GCMs) in future scenarios.

During the second half of the 20th century, a 20% reduction in late summer precipitation as well as increased aridity has been reported over the western parts of southern Africa, extending from Namibia, through Angola, and toward the Congo (Hoerling *et al*., 2006). The drying is associated with an upward trend in tropical Indian Ocean SSTs. Modest downward trends are found along Botswana, Zimbabwe, and western South Africa. Apart from changes in total or mean summer rainfall, certain intra-seasonal characteristics of seasonal rainfall such as onset, duration, dry spell frequencies, and rainfall intensity as well as delay of rainfall onset have changed (Tadross *et al*., 2005; Thomas *et al*., 2007; Tadross *et al*., 2009; Kniveton *et al*., 2009). An increasing trend in daily rainfall intensity is compensating for the increase in the frequency of dry spells (New *et al*., 2006).

22.2.2.2. Projected Changes

Precipitation projections show high inter-model variation in both the amplitude and direction of change, but in all models precipitation changes are enhanced as global temperatures increase, and the degree of response is regionally specific. Paeth and Thamm (2007) report that until 2025 a considerable reduction in precipitation over most of tropical Africa can be expected. The reduction will amount to more than 20 to 40% of the annual total and be most concentrated in the Congo Basin and the Sahel. Diallo et al. (2012) and Caminade and Terray (2010) report that the western Sahel will undergo substantial drying in the future mostly due to a decrease in peak monsoon rainfall. Projected midsummer drought over the Guinean Coast region is partly related to a weakened monsoon flow, which is a function of SST gradients (Patricola and Cook, 2010a).

Shongwe et al. (2011) suggest that there will be a wetter climate with more intense wet seasons and less severe droughts over eastern Africa during October November December (OND) and March April May (MAM) seasons, with some uncertainty about the rate of change. Patricola and Cook (2010b) predict severe drying over most parts of Uganda, Kenya, and South Sudan in August and September by the end of the 21st century as a result of a weakening Somali jet and Indian monsoon. Climate model projections over Ethiopia indicate a wide range of rainfall spatial pattern changes (Conway and Schipper, 2011). As indicated by Elshamy et al. (2009) GCMs do not agree on the direction of precipitation change in the upper Blue Nile basin between 2080 and 2098.

Precipitation projections exhibit higher spatial and seasonal dependence than temperature scenarios (Orlowsky and Seneviratne, 2012). In the annual mean, models show a dry signal over the climatologically dry southwest, extending northeastward from the desert areas in Namibia and Botswana (Moise and Hudson, 2008; Engelbrecht *et al.*, 2009; James and Washington, 2012; Orlowsky and Seneviratne, 2012). During the austral summer months, dry conditions are projected in the southwest while wetter conditions, within natural climate variability (Moise and Hudson, 2008), are projected in the southeast of South Africa (Hewitson and Crane, 2006; Engelbrecht *et al.*, 2009). Consistent with the AR4, drier winters are projected over a large area in southern Africa as a result of the poleward displacement of mid-latitude storm tracks (Moise and Hudson, 2008; Engelbrecht *et al.*, 2009; Shongwe *et al.*, 2009; Seth *et al.*, 2011; James and Washington, 2012). Rainfall decreases are also projected during austral spring months, implying a delay in the onset of seasonal rains over a large part of the summer rainfall region of Southern Africa (Shongwe *et al.*, 2009; Seth *et al.*, 2011). The sign, magnitude, and spatial extent of projected precipitation changes are dependent on the coupled general circulation model (CGCM) employed, due primarily to parameterization schemes used and their interaction with model dynamics (Hewitson and Crane, 2006; Rocha *et al.*, 2008). However, CGCMs do converge on their synoptic-scale circulation response to radiative forcing which, when downscaled, project that the eastern parts of South Africa will become wetter toward the end of the 21st century (Hewitson and Crane, 2006). Multi-model CMIP5 analysis indicates the potential for wide-scale changes in precipitation across Africa by the middle to end of this century (Figure 22-1). Observed and simulated variations in past and projected future annual average precipitation over five African regions (UMA, ECCAS, ECOWAS, SADC and COMESA) are captured in Figure 22-2.

22.2.3. Extreme Events

Climate extremes such as droughts and floods, which are aggravated by climate change and variability, are being experienced more frequently over eastern Africa (Funk *et al.*, 2008; Williams and Funk, 2010; Shongwe *et al.*, 2011; Lyon and Dewitt, 2012). Recent research has suggested that continued warming in the Indian–Pacific warm pool is likely to contribute to more frequent East African droughts, such as the 2011 drought, during the spring and summer seasons.

An increase in warm extremes and a decrease in cold extremes in recent decades is consistent with the general warming trend over southern Africa (New *et al.*, 2006; Tebaldi *et al.*, 2006; Kruger and Sekele, 2012). The probability of austral summer heat waves over South Africa increased over the last two decades of the 20th century compared to 1961 to 1980 (Lyon, 2009). Enhanced heat wave probabilities are associated with deficient rainfall conditions that tend to occur during El Niño events.

Future projections indicate that all heat wave indices and warm spell durations will increase, suggesting an increased persistence of hot days toward the end of the century (Tebaldi *et al.*, 2006; Orlowsky and Seneviratne, 2012). An increase in sensible heat flux relative to latent heat flux is related to this, a condition favorable for a higher frequency and/or intensity of heat waves (Lyon, 2009). Future precipitation projections demonstrate changes in the scale of the rainfall probability distribution, indicating that extremes of both signs will become more likely in the future (Kay and Washington, 2008). The southwestern regions are projected to be at a high risk of severe droughts during the 21st century and beyond (Hoerling *et al.*, 2006; Shongwe *et al.*, 2011). Intense floods are projected over northern Mozambique, Malawi, and southern Tanzania. Large uncertainties surround likely changes in tropical cyclone landfall from the southwest Indian Ocean that have resulted in intense floods during the 20th century.

22.3. Vulnerability and Impacts

This section highlights how Africa is vulnerable (since the main drivers of vulnerability have not changed since AR4) and the main observed and potential impacts of climate change on natural resources and ecosystems, as well as on different economic sectors. Figure 22-3 summarizes the main conclusions regarding observed changes in regional climate and their relation to anthropogenic climate change (described in 22.2) as well as regarding observed changes in natural and human systems and their relation to observed regional climate change (described in this section). Detection and attribution of anthropogenically-driven climate change is highest for temperature measures.

In many regions, evidence is constrained by limited monitoring. However, impacts of observed precipitation changes are amongst the observed impacts with the highest assessment of confidence, implying that some of the potentially more significant impacts of anthropogenic climate change for Africa are of a nature that challenges detection and attribution analysis (18.5.1).

[INSERT FIGURE 22-3 HERE
Figure 22-3: Summary of detection and attribution assessments of the relation of observed climate change over Africa with anthropogenic emissions (left) and of the relation of observed changes in natural and human systems with observed regional climate changes (right). All detection assessments are against a no-change reference and all attribution assessments for a major role of anthropogenic emissions (left) or observed regional climate change (right), except for "change in disease incidence" for which the detection assessment is relative to what would have been expected based on changes in livelihoods and health care and for which the attribution assessment is for a minor role of climate change in disease incidence. COMESA-n covers the half of COMESA north of and including Rwanda, Uganda, and Kenya. Discussion of these assessments are in 22.2, 22.3, 22.5.1, WGI AR5 Chapter 10, SREX 3.3, SREX 3.5, and 18.5.1. The detection and attribution assessments follow the specifications described in 18.2.]

22.3.1. Socioeconomic and Environmental Context

Socioeconomic development in Africa may strengthen its resilience to various external shocks, including climate change. In 2009, the Human Rights Council adopted Resolution 10/4[3] which noted the effects of climate change on the enjoyment of human rights, and reaffirmed the potential of human rights obligations and commitments to inform and strengthen international and national policy making.

[FOOTNOTE 3: U.N. Doc. A/HRC/10/L.11.]

The impacts of climate change on human rights have been explicitly recognised by the African Commission on Human and Peoples' Rights (hereafter African Commission) in its Resolution on Climate Change and Human Rights and the Need to Study its Impact in Africa (ACHPR/Res 153 XLV09). The 1981 African (Banjul) Charter on Human and Peoples' Rights (hereafter African Charter) protects the right of peoples to a 'general satisfactory environment favorable to their development' (Article 24). The recognition of this right and the progressive jurisprudence by the African Commission in environmental matters underline the relevance and linkage between climate change and human rights (Ruppel, 2012). Strong links exist between climate change and the MDGs: climate change may adversely affect progress toward attaining the MDGs, while slow progress in attaining most MDGs has a negative impact on the resilience and adaptive capabilities of African individuals, communities, states, and nations and consequently decreases their adaptive capacity to climate change.

The African continent has managed to make significant progress on some MDGs but not all. Aggregate trends in Africa's progress toward the MDGs conceal high levels of spatial and group disparities, and progress on all indicators is skewed in favor of higher-income groups and urban populations, which means further marginalization of already excluded groups (United Nations *et al*., 2008; African Development Bank *et al*., 2010; World Bank and International Monetary Fund, 2010). As a whole, the continent is experiencing a number of demographic and economic constraints (Muchena *et al*., 2005; Fermont *et al*., 2008). The population of the continent has more than doubled since 1980; exceeding one billion in 2011 and expected to reach 2.9 billion by the year 2050 if fertility were to remain constant (United Nations Department of Economic and Social Affairs, 2011). The global economic crisis is adding other constraints on economic development efforts resulting in increased loss of livelihood and widespread poverty (Moyo, 2009; Easterly, 2009; Adesina, 2010). The percent of the population below the poverty line has decreased from 56.5% in 1990 to 47.5% in 2008 (excluding North Africa), however a significant proportion of the population living below the poverty line remains chronically poor (Economic Commission for Africa *et al*., 2012). And although poverty in rural areas has declined from 64.9% in 1998 to 61.6% in 2008, it is still double the prevailing average in developing countries in other regions (IFAD, 2010).

African agriculture, which is the main economic activity in terms of employment share, is 95% rain fed (UNEP, 2008). Stagnant agricultural yields, relative to the region's population growth, have led to a fall in per capita food availability since the 1970s (United Nations *et al*., (2008); Figure 22-4).[4] In addition, the recent rise in global food prices aggravates food insecurity among the poor, increasing the risk of malnutrition and its consequences (United Nations *et al*., 2008). For example, it was estimated that the global rise in food prices has contributed to the deaths of an additional 30,000 to 50,000 children suffering from malnutrition in 2009 in sub-Saharan Africa (Friedman and Schady, 2009; UNSCN, 2009; World Bank and International Monetary Fund, 2010; UNDP *et al*., 2011). This situation may be complicated further by changes in rain variability and extreme weather events affecting the agriculture sector (Yabi and Afouda, 2012).

Figure 22-4: Number of undernourished people in Africa between 1994/1996 and 2010/2012
Source: www.fao.org/fileadmin/templates/ess/foodsecurity/Food_Security_Indicators.Xlsx.]

[FOOTNOTE 4: Lack of extension services for farmers in Africa can also prevent the utilization and spread of innovations and technologies that can help mitigate climate change.]

Africa has made much progress in the achievement of universal primary education, however, the results are unevenly distributed. The net enrollment rate in primary education has increased from 65% in 1999 to 83% in 2008, with an 18% improvement in sub-Saharan Africa. Nevertheless, a considerable number of children, especially girls from poor backgrounds and rural communities, still do not have access to primary education (United Nations *et al*., 2008). From the livelihood perspective, African women are vulnerable to the impacts of climate change because they shoulder an enormous but imprecisely recorded portion of the responsibility for subsistence agriculture (Viatte *et al*., 2009).[5] Global financial crises, such as the one experienced in 2007/2008, may cause job losses in the formal sector and men may compete for jobs in the informal sector that were previously undertaken by women, making them more vulnerable (African Development Bank *et al*., 2010).

[FOOTNOTE 5: For instance, more than 84% of women in sub-Saharan Africa, compared with 71% of men, are engaged in such jobs. In Northern Africa, even though informal or self-employment is less predominant, the gender gap is stark, with almost twice as high a proportion of women as men in the more vulnerable informal and self-employed status (53% of women compared with 28% of men) (UN DESA, 2010).]

Efforts to combat AIDS, tuberculosis, and malaria under the MDGs have led to progress in preventing and treating these diseases (African Development Bank *et al*., 2010), however, malaria is still endemic in most African countries and represents a major cause of morbidity and mortality.

Deforestation in Africa over the periods 1990–2000 and 2000–2010 has affected 4.1 and 3.7% of total forest area, respectively (UNDP *et al*., 2011). The rich biodiversity of the forests remains endangered by the high rate of deforestation and forest degradation as well as a decline in primary forests. Monitoring of biodiversity is weak in Africa, such that almost 50% of medicinal plants surveyed in 2009 – used by 80% of the population – faced extinction (UNEP, 2012).

Significant efforts have been made to improve access to safe drinking water and sanitation in Africa, with access to safe drinking water increasing from 56 to 65% between 1990 and 2008, with sub-Saharan Africa nearly doubling the number of people using an improved drinking water source – from 252 to 492 million over the same period. Despite such progress, significant disparities in access to safe water and sanitation, between not only urban and rural but also between large- and medium- and small-sized cities, still exist (UNDP *et al*., 2011). Use of improved sanitation facilities, meanwhile, is generally low in Africa, reaching to 41% in 2010 compared to 36% in 1990 (UNDP *et al*., 2011).

22.3.2. Ecosystems

Regarding the vulnerability and impacts of climate change on ecosystems, it is recognized that interactions between the different drivers of ecosystems behavior are complex, which makes the prediction of the impacts of climate change more difficult (see Chapter 4). In AR4, the chapter on Africa indicated that extensive pressure is exerted on different ecosystems by human activities (deforestation, forest degradation, biomass for energy) as well as processes inducing changes like fires or desertification. Even if the trend is toward better preservation of ecosystems and a decrease in degradation (like deforestation), pressures linked, for example, to agriculture and food security, energy demand, and urbanization are increasing, putting these ecosystems at risk. This chapter emphasizes a few findings regarding the vulnerability and impacts of these ecosystems, including terrestrial, freshwater, and coastal/ocean systems.

22.3.2.1. Terrestrial Ecosystems

A shift in the geographic location or extent of a biome can signal a substantial change in climate and fundamentally alter habitats and the provision of ecosystem services to people. While field research has detected numerous elevation and latitudinal shifts in biomes around the world attributable to climate change more than to human land use change (Gonzalez *et al*., 2010), only a few efforts have examined biome shifts in Africa. At sites across West and Central Africa, field research on tree species distributions from 1960 to 2000 detected a southward shift of three biomes: tropical savanna (Sahel), tropical woodland (Sudan), and tropical deciduous forest (Guinea) – and attributed the shift to anthropogenic climate change (Gonzalez *et al*., 2012). Field data from Burkina Faso also suggest possible southward biome shifts of the Sahel and Sudan consistent with, but not formally attributed to, climate change (Wezel and Lykke, 2006; Maranz, 2009). Land use change may be a factor in the Burkina Faso sites.

A number of studies indicate that precipitation is the primary factor determining tree cover in African savannas, woodlands, and forests (Bucini and Hanan, 2007; Sankaran *et al*., 2008; Good and Caylor, 2011; Greve *et al*., 2011). Disturbances that substantially modify the climatic limits of biomes include fire, grazing, agricultural cultivation, and timber harvesting (Bucini and Hanan, 2007; Sankaran *et al*., 2008; Ahrends *et al*., 2010; Ellis *et al*., 2010; Groen *et al*., 2011; Staver *et al*., 2011; Favier *et al*., 2012).

Projected changes in precipitation and disturbance under climate change may substantially alter the nduextent and locations of biomes. Projections of potential future vegetation indicate the wide vulnerability of ecosystems in Africa to future biome shifts. A set of dynamic global vegetation models (DGVMs) and one equilibrium model project biome changes over 5 to 10% of the land in Africa from around 1990 to 2100 for a range of the Coupled Model Intercomparison Project phase three (CMIP3) general circulation model (GCM) runs of the IPCC Special Report on Emissions Scenarios (SRES) emissions scenarios (Hély *et al*., 2006; Scholze *et al*., 2006; Alo and Wang, 2008; Delire *et al*., 2008; Sitch *et al*., 2008; Scheiter and Higgins, 2009; Gonzalez *et al*., 2010; Bergengren *et al*., 2011). An analysis of the vulnerability of ecosystems to biome shifts that combined 1901–2002 historical climate change and 1990–2100 DGVM projections estimated that 12% of African land area is highly to very highly vulnerable to biome shifts and that over 100 million people live in those areas (Gonzalez *et al*., 2010) (Figure 22-5). An equilibrium vegetation model analysis for West Africa estimated that, under the A2 emissions scenario, some 10 to 50% of the land in Africa is vulnerable to biome shifts (Heubes *et al*., 2011). Projections generally agree on latitudinal shifts in vegetation, degradation of tropical biomes, and vulnerability of the unique biomes of South Africa. An earth system model forced by 15 CMIP4 GCM runs projects a global expansion of warm deserts by 10 to 34% by 2100, with much of this due to a southward expansion of the Sahara (Zeng and Yoon, 2009). Niche modeling of tropical rainforests under a 4ºC warming projects expansion in Africa up to 50% of rainforest area for 14 CMIP3 GCM runs and contraction of up to 15% of rainforest area for 3 CMIP3 GCM runs. The Congo rainforest generally shows resilience, due to high temperature tolerances and mitigation of water stress by increases in equatorial precipitation (Zelazowski *et al*., 2011).

[INSERT FIGURE 22-5 HERE
Figure 22-5: (a) Potential changes in vegetation between the periods 1961-1990 and 2071-2100, where any of nine combinations of three GCMs (CSIRO Mk3, HadCM3, MIROC 3.2 medres) and three emissions scenarios (B1, A1B,

A2) project change. This is the worst case in comparison to the case of complete agreement of the nine combinations. (b) Vulnerability of ecosystems to biome shifts based on historical climate (1901-2002) and projected vegetation (2071-2100), where all nine GCM-emissions scenario combinations agree on the projected biome change. Source: Gonzalez *et al.* (2010).]

As a first-order response to continental warming, species may be expected to shift their ranges poleward and up mountain slopes, however it has been difficult to directly attribute this shift to climate change. Hockey and Midgley (2009) and Hockey et al. (2011) do find that some South African bird species have moved farther south over recent decades, but that many of these shifts can be explained by other factors; in particular, there is evidence of a very strong response to recent and ongoing land use change. Foden et al. (2007) find that an aloe of the Namib is experiencing a range contraction that is consistent with increased heat-related mortality at its warming tropical extreme coupled with an inability to expand poleward quickly enough to compensate. Meanwhile, Raxworthy et al. (2008) note a general upslope movement of amphibian species on a Madagascan massif for which local warming appears to be the most parsimonious explanation. Validation of niche model results against field observations shows limitations to model accuracy (Hanspach *et al.*, 2011).

22.3.2.1.1. Forests

The impacts of climate change on forests are not clear since some studies predict an increase in productivity while others indicate the reverse (Chidumayo *et al.*, 2011). Forest cover in Africa currently stands at 675 million hectares, which represented 21% of global carbon forest biomass in 2010 and 17% of the world forest area, with the Congo basin in Central Africa being the world's second largest continuous block of tropical rain forest (AMCEN and UNEP, 2006; FAO, 2011; Chidumayo *et al.*, 2011). Forests play a key role in the livelihoods of local communities depending on them (over 30 million indigenous people such as Pygmies in the Congo Basin Forest, and 70% of the total population in Africa; Chidumayo *et al.,* (2011)), providing food (bush meat, roots, tubers, fish, insects, fruits); wood (mainly for cooking and building; wood removal in Africa as fuelwood represented 33% of the global total of fuelwood removal); medicinal products (Colfer *et al.,* 2006; Dudley *et al.,* 2008; Nasi *et al.,* 2008; Manyatsi and Hlophe, 2010; FAO, 2011); other non-timber products; soil conservation; and water quality. They also are important for national economies (forests represent about 6% of gross domestic product (GDP)). For example, in Africa, industrial woods represented about 10% of wood removal that, together with fuelwood, amounted to US$ 2.9 billion in 2005 (FAO, 2011). The loss of forestlands has a dual consequence for climate change by contributing to emission levels and loss of vital carbon sinks and by reducing the adaptive capacity of communities that depend on forest resources.

Forest integrity in Africa is highly threatened by both climate and non-climatic factors. Between 2000 and 2010, the annual deforestation rate was 0.49% despite the fact that there is an increasing trend in Africa of the area planted to forest (2.5% of total forest area), and also for conservation of biodiversity (14%) (FAO, 2011). However, the pressure on these resources is supposed to increase given the needs – among others – for food but also for biofuels. It is also currently recognized that the question of policies (e.g., land tenure) and strategic plans for development will be crucial for the future of forests in Africa (Agrawal *et al.,* 2008; Kalame *et al.,* 2008; Sunderlin *et al.,* 2008; Unruh, 2008; Suivi, 2010; Larson, 2011; Paumgarten and Shackleton, 2011; Somorin *et al.*, 2012). Forests are at the crossroads between development and conservation.

In Africa, the major contribution of greenhouse gases is from deforestation, which contributes 20% to global emissions (Chidumayo *et al.*, 2011). This importance of forests was recognized through the Reducing Emissions from Deforestation and forest Degradation (REDD+) mechanism under the United Nations Framework Convention on Climate Change (UNFCCC). The first experiences indicate the need to synthesize actions toward mitigation and adaptation in the forest sector (Bwango *et al.*, 2000; Guariquata *et al.*, 2007; Nkem *et al.*, 2007; Nyong *et al.*, 2007; Nkem *et al.*, 2008; Biesbroek *et al.*, 2009; Oyden and Innes, 2009; Chia, 2011; Richard *et al.*, 2011). There is also a need to address other causes of forest degradation such as drought (Allen *et al.*, 2010; Martínez-Vilalta *et al.*, 2012).

22.3.2.1.2. Desertification in the Sahel

Analyses of the impacts of climate change and desertification on Sahel vegetation examine two types of trends: (1) short-term changes in grasses and other herbaceous vegetation since 1981; and (2) long-term changes in trees and other woody vegetation since the 1950s.

The remotely sensed normalized difference vegetation index (NDVI), an indicator of herbaceous vegetation, increased at many locations in the Sahel from 1981 to 2007 (Seaquist *et al*., 2006; Heumann *et al*., 2007; Ahmedou *et al*., 2008; Fensholt *et al*., 2009; Bégué *et al*., 2011; de Jong *et al*., 2011). The length of the growing season decreased in that time, suggesting that a more intense but shorter season caused any increase in herbaceous vegetation (de Jong *et al*., 2011). In Mali, increased crop area may have contributed to the increase in NDVI (Bégué *et al*., 2011). Rain-use efficiency (RUE) also seems to show increases at sites in the Sahel from 1981 to 2007 (Prince *et al*., 2007; Fensholt and Rasmussen, 2011). The correlation of RUE with rainfall and higher Sahel rainfall in the 2000s may explain an increasing RUE, so the recent increase may not reflect a reversal of land degradation (Hein and De Ridder, 2006; Fensholt and Rasmussen, 2011; Hein *et al*., 2011). Two characteristics of the NDVI data series constrain interpretation of the NDVI and RUE results. First, NDVI in the Sahel mainly tracks interannual variability of herbaceous vegetation (Anyamba and Tucker, 2005), but not necessarily the long-term condition of perennial vegetation (Gonzalez *et al*., 2012). Second, NDVI coverage began in 1981 at the time of a severe Sahel drought. Interdecadal variability of rainfall led to increases in the 1980s and 1990s, causing the NDVI time series to reflect a short-term rebound from the drought, but not necessarily a long-term recovery (de Jong *et al*., 2011; Fensholt and Rasmussen, 2011).

Tree density and tree species richness indicate vegetation condition over longer time periods than NDVI because trees often withstand years of stress before dying (Allen *et al*., 2010). Field counts of trees, historic aerial photos, and recent satellite images show that tree density has declined since the 1950s at sites in Mali (Ruelland *et al*., 2011) and Senegal (Vincke *et al*., 2010; Gonzalez *et al*., 2012). Field surveys also show that arid species have expanded since the 1950s in Burkina Faso (Wezel and Lykke, 2006; Maranz, 2009; Gonzalez *et al*., 2012), Chad (Gonzalez *et al*., 2012), Mauritania (Gonzalez *et al*., 2012), Niger (Wezel and Lykke, 2006; Gonzalez *et al*., 2012), and Senegal (Gonzalez, 2001; Wezel and Lykke, 2006; Vincke *et al*., 2010). These changes have shifted the Sahel, Sudan, and Guinea zones southward toward moister areas (Gonzalez *et al*., 2012). At one site in Mali, however, tree density did not decrease between 1984 and 2006 (Hiernaux *et al*., 2009). Analyses of temperature, precipitation, population density, and soil indicate that climate dominates in explaining the declines in Sahel tree density and species richness (Gonzalez *et al*., 2012). Because the decline in tree cover may contribute to erosion, reduced soil fertility, and other forms of land degradation, it indicates how climate change may exacerbate desertification.

22.3.2.2. Freshwater Ecosystems

Since the 2008 IUCN red list analysis, it is recognized that freshwater ecosystems, particularly in Africa, will be seriously at risk from climate change (Vié *et al*., 2009; Darwall *et al*., 2011), mainly be through changes in water quantity and quality.

The East African River Valley (EARV) is already experiencing high variability in rainfall and river flows and changes in the geographical distribution of water resources, with the arid to semi-arid areas becoming drier and other areas becoming wetter (Kundzewicz *et al*., 2007). Saline Lake Beseka in the arid Ethiopian rift valley, for instance, has quadrupled from 11.1 km^2 in 1973 to 39.5 km^2 in 2002 due to increased discharge from hot springs (Goerner *et al*., 2009). Much of what is happening to freshwater resources across this region is attributable to increased years of drought, particularly in the past two decades (Boko *et al*., 2007; Solomon *et al*., 2007a), which in turn are reducing river inflows (from reduced runoff), and rising temperatures that are causing increased evaporative water loss. However, other factors such as deforestation, soil erosion, and domestic and industrial pollution, among others, are also observed as important drivers in the reduction of water quality and quantity around the region (Hecky *et al*., 2010; Ndebele-Murisa *et al*., 2010; Beck and Bernauer, 2011; Haande *et al*., 2011). Nevertheless, the amount of water inflow for rivers like the Congo, Nile, and Zambezi are determined mainly by the amount of rainfall within their catchments, a process that is influenced by temperature.

In addition to changes in river inflows, declining water levels have been observed in the freshwaters of this region. Water levels are influenced by evaporation rates with low levels corresponding to drought periods (Ndebele-Murisa *et al*., 2011a; Ndebele-Murisa *et al*., 2011b). Reductions in water levels have also reduced habitats of aquatic organisms, particularly shoaling fish, and adversely affect hydroelectricity production for such reservoirs as Kafue (Zambia), Kariba (Zambia/Zimbabwe), Caborra Bassa (Mozambique), and for stations along the Nile and Shire Rivers in Uganda and Malawi respectively (Mukheibir, 2007). Small variations in climate cause wide fluctuations in the thermal dynamics of freshwaters (Odada *et al*., 2006; Stenuite *et al*., 2007; Verburg and Hecky, 2009; Moss, 2010; Olaka *et al*., 2010). Thermal stratification in the regions' lakes, for instance, isolates nutrients from the euphotic zone, and is strongly linked to hydrodynamic and climatic conditions (Sarmento *et al*., 2006; Ndebele-Murisa *et al*., 2010). Elevated water temperatures as a consequence of elevated air temperatures attributed to global warming have been reported in surface waters of lakes Kivu, Victoria, and Malawi (Odada *et al*., 2006; Verburg and Hecky, 2009; Marshall *et al*., 2009; Hecky *et al*., 2010; Magadza, 2010; Tierney *et al*., 2010; Olaka *et al*., 2010; Magadza, 2011; Woltering *et al*., 2011; Osborne, 2012; Ndebele-Murisa *et al*., 2012) (Table 22-1). Moderate warming is reducing lake water inflows and therefore nutrients, destabilizing plankton dynamics and thereby adversely affecting food resources for higher trophic levels of mainly planktivorous fish (Magadza, 2008; Verburg and Hecky, 2009; Magadza, 2010; Ndebele-Murisa *et al*., 2011a).

[INSERT TABLE 22-1 HERE
Table 22-1: Changes and impacts observed in freshwater lakes of Africa.]

In addition to strengthening the thermocline and density stratification, climate warming is leading to declining depths of light transparent epilimnions in a number of the regions' freshwaters, due to upward shifts in thermoclines in response to elevated temperatures. These changes have been observed in lakes Kivu, Kariba, Malawi, Tanganyika, and Victoria, particularly in the past 50 years (Awange *et al*., 2008; McGinley, 2008; Tumbare, 2008; Njaya *et al*., 2011; Ndebele-Murisa, 2011). This has potential cascading effects on aquatic ecosystems by reducing available nutrients in the upper waters, thereby limiting biological production (Bootsma, 2006; Magadza, 2006; Ogutu-Ohwayo and Balirwa, 2006; Magadza, 2008; Verburg and Hecky, 2009; Hecky *et al*., 2010; Ndebele-Murisa *et al*., 2010; Tierney *et al*., 2010; Urama and Ozor, 2010).

22.3.2.3. Coastal and Ocean Systems

Coastal and ocean systems are crucial for the economies and livelihoods of African countries and climate change will increase their existing challenges (overexploitation of resources, habitat degradation, loss of biodiversity, salinization, pollution, and coastal erosion) (Arthurton *et al*., 2006; UNEP and IOC-UNESCO, 2009; Diop *et al*., 2011). Concern is increasing that coastal areas could suffer directly from climate change, not only through sea level rise, but also from a combination of high sea levels and storm swells (extreme events). For example, a conjunction between storm swell up to 14 m, due to winds generated by a cyclone, and high astronomic tide at 2.2 m was experienced along the Durban coast in March 2007, which led to damages estimated at US$ 100 million (Theron and Rossouw, 2008; Mather and Stretch, 2012). Other climate change impacts (such as flooding of river deltas or an increased migration toward coastal towns due to increased drought induced by climate change (Rain *et al*., 2011) will also affect coastal zones.

22.3.2.3.1. Impacts and vulnerability of coastal ecosystems

Different studies assess the vulnerability of the African coast to sea level rise. They all consider that the impacts could be important, especially in coastal towns.

In Kenya, the impacts of climate change on the entire coastal zone were determined (SEI (2009); see Figure 22-6 (Kebede *et al*., 2012). By 2030, the population at risk of inundation in Mombasa, depending on the scenario used, is estimated to be between 226,780 to 299,550 inhabitants, while economic assets at risk are between US$ 0.9 and 1.19 billion.

[INSERT FIGURE 22-6 HERE
Figure 22-6: Population and economic losses in case of climate change for the whole Kenya coastal zone. Source: (SEI, 2009).]

A similar assessment for Dar es Salaam (Kebede and Nicholls, 2011a) estimated that by 2030, the population and economic assets at risk of extreme water levels of 3.07 to 3.23 m are 30,800 to 140,000 inhabitants and US$ 35.6 to 404.1 million US$. The Dynamic Interactive Vulnerability Assessment (DIVA) model was used to assess the monetary and non-monetary impacts of sea level rise on the entire coast (3,461 km) of Tanzania. It estimated that by 2030, 1,924 to 7,624 km^2 would be lost, mainly through inundation; around 234,000 people per year could be potentially affected by inundation, and between 67,000 and 852,000 people living in inundated areas would be forced to migrate. Without adaptation, residual damages have been estimated at between US$ 20 and 42 million per year, of which around US$ 2.7 million could be due to the loss of wetlands (24% of which will be mangroves). Table 22-2 shows the economic impacts of land inundated in Cape Town based on different sea level rise scenarios.

[INSERT TABLE 22-2 HERE
Table 22-2: Land inundated and economic impacts in Cape Town based on a risk assessment (Cartwrigth, 2008a).]

In Durban as well as in the town of Umhlathuze (Zitholele Consulting, 2009), the assessments were mainly qualitative but it was found that the proposed development plans for tourism in Durban could be affected by sea level rise (Naidu *et al.*, 2006). In South Africa, all the authors recognize the fact that a development too close to the shoreline increases its vulnerability. In the southern Africa region, Namibia has coasts vulnerable to sea level rise located around Walvis Bay (with risks of breaching with potential consequences for the harbor and low-lying places in the town). Diamond mining could also be affected. And in Mozambique the risks are almost everywhere, with potential impacts on the two main harbors (Maputo and Beira), but also problems with tourism infrastructure. This could also induce an increase in environmental refugees in South Africa. The risks of salinization, especially for agriculture and on coral reefs are also considered. (Theron and Rossouw, 2008; Cartwright, 2008b):

Assessments for western (Appeaning Addo *et al.*, 2008; Niang *et al.*, 2010) and northern Africa (Snoussi *et al.*, 2009; World Bank, 2011) arrived at the same conclusions as those for eastern and southern Africa.

22.3.2.3.2. Impacts and vulnerability of marine systems

In Africa, fisheries depend on either coral reefs or coastal upwelling. These two ecosystems will be affected by climate change through ocean acidification, a rise in sea surface temperatures, and changes in upwelling. Ocean acidification (OA) is the term used to describe the process whereby increased CO_2 in the atmosphere, upon absorption, causes lowering of the pH of seawater (CC-OA). Projections indicate that severe impairment of reef accretion by organisms such as corals (Hoegh-Guldberg *et al.*, 2007) and coralline algae (Kuffner *et al.*, 2008) will rank amongst the most important consequences of anthropogenic production of CO_2. The combined effects of global warming and OA have been further demonstrated to lower both coral reef productivity (Anthony *et al.*, 2008) and resilience (Anthony *et al.*, 2011). These effects will have serious consequences for reef biodiversity, ecology, and ecosystem services.

OA is nevertheless a serious issue and together with coral bleaching resulting from climate change, will have lasting effects on tropical reefs and other calcifiers. Of the world's coral reefs, 75% occur in developing countries where they support artisanal fisheries in some of the most populous areas (Pauly *et al.*, 2002). While these fisheries only contribute 2 to 5% to global fishery landings, they are an important protein source for coastal communities in developing countries (Pauly *et al.*, 2002). As these fisheries are already deemed unsustainable (McManus, 1997; Pauly *et al.*, 2002; Newton *et al.*, 2007), a further deterioration of coral reefs will have dire consequences for the food security of humans in these areas. In the WIO, the social adaptive capacity to cope with such change varies (Mcclanahan *et al.*, 2009). The fisheries themselves are also likely to be directly affected by OA, as it has been shown to be deleterious to fish larval development, growth, recruitment, and survival (Ferrari *et al.*, 2011; Franke and Clemmesen, 2011; Baumann *et al.*, 2012; Frommel *et al.*, 2012).

22.3.3. Water Resources

Knowledge has advanced since the AR4 regarding current drivers of water resource abundance in Africa, and in understanding of potential future impacts on water resources from climate change and other drivers. Recent long-term studies assessing changes in surface water resources in Africa provide evidence that climate change is currently having a minimal effect on water abundance (*low confidence*). Findings on the availability of freshwater in the region should be taken with caution considering the systemic limitations associated with inadequate observational data in Africa (Neumann *et al*., 2007; Batisani, 2011). As explained in Chapter 3, surface and groundwater hydrology are governed by multiple, interacting drivers and factors, such as land use change, water withdrawals, and natural climate variability, which make detection and attribution exceedingly difficult.

A growing body of literature amassed since the AR4 suggests that climate change in Africa will have an overall modest effect on future water scarcity relative to other drivers, such as population growth, urbanization, agricultural growth, and land use change (Alcamo *et al*., 2007; Carter and Parker, 2009; MacDonald *et al*., 2009; Taylor *et al*., 2009; Calow and MacDonald, 2009; Abouabdillah *et al*., 2010; Beck and Bernauer, 2011; Droogers *et al*., 2012; Notter *et al*., 2012; Tshimanga and Hughes, 2012) (*medium confidence*). However, broad-scale assumptions about drivers of future water shortages can mask significant sub-regional variability of impacts, particularly in water-stressed regions that are projected to become drier, such as southern and northern Africa. For example, rainfed agriculture in northern Africa is highly dependent on winter precipitation and would be negatively impacted if total precipitation and the frequency of wet days declines across North Africa as has been indicated in recent studies (Born *et al*., 2008; Driouech *et al*., 2010; Abouabdillah *et al*., 2010; García-Ruiz *et al*., 2011). Similarly, climate model predictions based on average rainfall years do not adequately capture interannual and interdecadal variability that can positively or negatively influence surface water runoff (Beck and Bernauer, 2011; Notter *et al*., 2012; Wolski *et al*., 2012). Key challenges for estimating future water abundance in Africa lie in a better understanding of the relationships between evapotranspiration, soil moisture, and land use change dynamics in the context of climate change (Goulden *et al*., 2009a) and to understand how compound risks such as heat waves and seasonal rainfall variability might interact under climate change to impact water resources.

Several studies from Africa point to a future decrease in water abundance, particularly in southern and northern Africa (*high confidence*). For example, all countries within the Zambezi River Basin could contend with increasing water shortages (A2 scenario) although non-climate drivers (e.g., population and economic growth, expansion of irrigated agriculture, and water transfers) are expected to have a greater influence on future water availability than climate change (Beck and Bernauer, 2011). In Zimbabwe, climate change could increase water shortages for downstream users dependent on the Rozva dam (Ncube *et al*., 2011). The Okavango Delta could experience increased drying from both climate change and water withdrawals for irrigation (Murray-Hudson *et al*., 2006; Milzow *et al*., 2010; Wolski *et al*., 2012), and the Breede River in South Africa could face decreased runoff (Steynor *et al*., 2009). For North Africa, Droogers et al. (2012) estimated that climate change will account for 22% of future water shortages in the region while 78% of increased future water shortages can be attributed to socioeconomic factors. Abouabdillah et al. (2010) estimated that higher temperatures and declining rainfall (A2 and B1 scenarios) would reduce water resources in Tunisia, though future land use and socioeconomic changes were not considered in the analysis. Reduced snowpack in the Atlas Mountains could reduce supplies of seasonal meltwater for Morocco (García-Ruiz *et al*., 2011).

Potential climate change impacts on the Nile Basin are of particular concern given the basin's geopolitical and socioeconomic importance. Several studies since the AR4 examine potential changes in water resources for the Nile Basin. Reduced flows in the Blue Nile of around 22% at the Ethiopia-Sudan border are possible due to a combination of climate change (higher temperatures and declining precipitation) and upstream water development for irrigation and hydropower by 2100 (A1B) (McCartney and Menker Girma, 2012). Elshamy et al. (2008) also estimated increased moisture constraints in the Blue Nile Basin by late century driven by higher evapotranspiration under temperature rises between 2°C and 5°C. Beyene et al. (2010) estimated that streamflow in the Nile River will increase in the medium term (2010–2039) but will decline in the latter half of this century (A2 and B1 scenarios) as a result of both declining rainfall and increased evaporative demand, with subsequent diminution of water allocation

for irrigated agriculture downstream from the High Aswan Dam. Kingston et al. (2010) reached a similar conclusion about an initial increase followed by a decline in surface water discharge in the Upper Nile Basin in Uganda but caution that limitations inherent in GCMs hamper the robustness of these findings. Also in eastern Africa, Dessu et al. (2012) reported a potential increase in Mara River flow in the second half of this century (A1B, A2, and B1), though under assumptions of current land use patterns. Seasonal runoff volumes in the Lake Tana Basin, Ethiopia, could decrease by the 2080s under the A2 and B2 scenarios (Abdo *et al*., 2009). In West Africa, the Bani River Basin could experience substantial reductions (60–65%) in runoff (A2 scenario) due to reduced rainfall, with catchment discharge potentially decreasing to levels similar to those observed during the severe drought of the 1980s (Ruelland *et al*., 2012). However, high uncertainty about the direction and magnitude of future precipitation in the Sahel (Chapter 14, WG1) warrants caution. The impact of climate change on total runoff in the Congo Basin could be minimal (A2 scenario) (Tshimanga and Hughes, 2012).

Groundwater resources in Africa could be variably affected by climate change. An analysis by MacDonald et al. (2009) indicated that changes in rainfall would not be expected to directly impact the recharge of deep aquifers in areas receiving below 200 mm rainfall per year, where recharge is negligible due to low rainfall. Groundwater recharge may also not be significantly affected by climate change in areas that receive more than 500 mm per year, where sufficient recharge would remain even if rainfall diminished, assuming current groundwater extraction rates. By contrast, areas receiving between 200 to 500 mm per year, including the Sahel, the Horn of Africa, and southern Africa, may experience a decline in groundwater recharge with climate change if prolonged drought becomes more frequent with climate change.

Coastal aquifers are particularly vulnerable to climate change due to high rates of groundwater extraction, which leads to saltwater intrusion in aquifers, coupled with increased saltwater ingression resulting from sea level rise (Moustadraf *et al*., 2008; Bouchaou *et al*., 2008; Al-Gamal and Dodo, 2009; Kerrou *et al*., 2010). Some studies have shown additional impacts of sea level rise on aquifer salinization with salinity potentially reaching very high levels (Carneiro *et al*., 2010; Niang *et al*., 2010; Research Institute for Groundwater, 2011). Although these effects are expected to be localized, in some cases they will occur in densely populated areas (Niang *et al*., 2010). The profitability of irrigated agriculture in Morocco is expected to decline (under both B1 and A1B scenarios) due to increased pumping of groundwater and increased salinization risk for aquifers (Heidecke and Heckelei, 2010).

The capacity of groundwater delivery systems to meet demand may take on increasing importance with climate change (Calow and MacDonald, 2009). For example, where groundwater pumping and delivery infrastructure is poor, and the number of point sources limited, prolonged pumping can lead to periodic drawdowns and increased failure of water delivery systems or increased saline intrusion (Moustadraf *et al*., 2008). Thus if drought conditions become more prevalent in Africa with climate change, stress on groundwater delivery infrastructures could increase.

Future development of groundwater resources to address direct and indirect impacts of climate change, population growth, industrialization, and expansion of irrigated agriculture, will require much more knowledge of groundwater resources and aquifer recharge potentials than currently exists in Africa. Observational data on groundwater resources in Africa are extremely limited and significant effort needs to be expended to assess groundwater recharge potential across the continent (Taylor *et al*., 2009). A preliminary analysis by MacDonald et al. (2012) indicates that total groundwater storage in Africa is 0.66 million km^3, which is "more than 100 times the annual renewable freshwater resources, and 20 times the freshwater stored in African lakes." However, borehole yields are variable and in many places water yields are relatively low. Detailed analysis of groundwater conditions for water resource planning would need to consider these constraints. In this respect, developing organizational frameworks and strengthening institutional capacities for more effectively assessing and managing groundwater resources in Africa are critically important (Nyenje and Batelaan, 2009; Braune and Xu, 2010).

22.3.4. Agriculture and Food Security

Africa's food production systems are among the world's most vulnerable because of extensive reliance on rainfed crop production, high intra- and inter-seasonal climate variability, recurrent droughts and floods, and persistent poverty that limits the capacity to adapt (Boko *et al*., 2007). In the near term, better managing risks associated with

climate variability may help to build adaptive capacities for climate change (Washington *et al.*, 2006; Cooper *et al.*, 2008; Funk *et al.*, 2008). However, agriculture in Africa could face significant challenges in adapting to climate changes projected to occur by mid-century, as negative effects of high temperatures become increasingly prominent (Battisti and Naylor, 2009; Burke *et al.*, 2009a), thus increasing the likelihood that major crops in Africa could experience significant yield losses (Schlenker and Lobell, 2010). Climate change is likely to reduce the growing season length in Africa (Thornton *et al.*, 2011) although not in all sub-regions (Cook and Vizy, 2012). The composition of farming systems from mixed crop-livestock to more livestock dominated food production could occur as a result of reduced growing season length for annual crops and increases in the frequency and prevalence of failed seasons (Jones and Thornton, 2009; Thornton *et al.*, 2010). Transition zones, where livestock keeping is projected to replace crop cultivation by 2050, occur in the West African Sahel and in coastal and mid-altitude areas in eastern and southeastern Africa (Jones and Thornton, 2009), which currently support 35 million people and are chronically food insecure.

22.3.4.1. Crops

Climate change is very likely to have an overall negative effect on yields of major cereal crops in Africa, with strong regional variability in the degree of yield reduction (Lobell *et al.*, 2008; Liu *et al.*, 2008; Walker and Schulze, 2008; Thornton *et al.*, 2009a; Lobell *et al.*, 2011; Roudier *et al.*, 2011; Berg *et al.*, 2013) (*high confidence*). One exception is in eastern Africa where maize production could benefit from warming at sites above roughly 1,500 m in elevation (A1FI scenario) (Thornton *et al.*, 2009a), although the majority of current maize production occurs at lower elevations thereby implying a change in the distribution of maize cropping. Maize-based systems in southern Africa are among the most vulnerable to climate change, with recent yield losses estimated at 18% (Zinyengere *et al.*, submitted) and 30% (Lobell *et al.*, 2008) relative to current yields. In eastern Africa, simulations that combine all regions south of the Sahara suggest consistently negative effects of climate change on five major staples (rice, wheat, maize, millet, and sorghum) by 2050 (A2 scenario) (Nelson *et al.*, 2009). Wheat production in North Africa is vulnerable to projected warming trends in that region (Eid *et al.*, 2007; Hegazy *et al.*, 2008; Drine, 2011; Mougou *et al.*, 2011).

Climate change will likely have differential impacts on non-cereal crops, with both production losses and gains possible (*low confidence*). Cassava yields in eastern Africa could moderately increase up to 2030s assuming CO2 fertilization and under a range of low to high emissions scenarios (Liu *et al.*, 2008), findings that were similar to Lobell et al. (2008). Suitability for growing cassava could increase with the greatest improvement in suitability in eastern and central Africa (A1B scenario) (Jarvis *et al.*, 2012). However, Schlenker and Lobell (2010) estimated negative impacts from climate change on cassava at mid-century, although these impacts are less than those estimated for cereal crops. Given cassava's hardiness to higher temperatures and sporadic rainfall relative to many cereal crops, it may provide a potential option for crop substitution of cereals as an adaptation response to climate change (Rosenthal and Ort, 2011; Jarvis *et al.*, 2012). Bean yields in Eastern Africa could experience yield reductions by the 2030s under an intermediate emissions scenario (A1B) (Jarvis *et al.*, 2012) and by the 2050s under low (B1) and high (A1FI) emissions scenarios (Thornton *et al.*, 2011). For peanuts, some studies indicate a positive effect from climate change (A2 and B2 scenarios) (Tingem and Rivington, 2009) and others a negative one (Lobell *et al.*, 2008; Schlenker and Lobell, 2010). Bambara groundnuts (*Vigna subterranea*) could benefit from moderate climate change (Tingem and Rivington, 2009) (A2 and B2 scenarios) although the effect could be highly variable across varieties (Berchie *et al.*, 2012). Banana and plantain production could decline in West Africa and lowland areas of East Africa, whereas in highland areas of East Africa it could increase (Ramirez *et al.*, 2011).

Suitable agro-climatic zones for growing economically important perennial crops could significantly diminish, largely due to the effects of rising temperatures (Läderach *et al.*, 2010; Eitzinger *et al.*, 2011a; Läderach *et al.*, 2011a; Eitzinger *et al.*, 2011b; Läderach *et al.*, 2011b; Läderach *et al.*, 2011c). With a 2°C or greater temperature rise by mid-century, suitable agro-climatic zones that are currently classified as very good to good for perennial crops could become more marginal, and what are currently marginally suitable zones could become unsuitable; the constriction of crop suitability could be severe in some cases (Table 22-3). Movement of perennial crops to higher altitudes could mitigate the loss of suitability at lower altitudes but this option is limited. Loss of productivity of high-value crops such as tea, coffee and cocoa would have detrimental impacts on export earnings.

[INSERT TABLE 22-3 HERE
Table 22-3. Projected changes in agro-climatic suitability for perennial crops in Africa under an A2 scenario.]

22.3.4.2. Livestock

Livestock systems in Africa face multiple stressors that could potentially interact with climate change and variability to amplify the vulnerability of livestock-keeping communities. These stressors include rangeland degradation, increased variability in access to water, fragmentation of grazing areas, sedentarization, changes in land tenure from communal towards private ownership, in-migration of non-pastoralists into grazing areas, lack of opportunities to diversify livelihoods, conflict and political crisis, weak social safety nets, and insecure access to land, markets, and other resources (Solomon *et al.*, 2007b; Smucker and Wisner, 2008; Galvin, 2009; Thornton *et al.*, 2009b; Dougill *et al.*, 2010; Ifejika Speranza, 2010).

Loss of livestock under prolonged drought conditions is a critical risk given the extensive rangeland in Africa that is prone to drought. Regions that are projected to become drier with climate change, such as northern and southern Africa, are of particular concern (Solomon *et al.*, 2007b; Masike and Urich, 2008; Thornton *et al.*, 2009b; Dougill *et al.*, 2010; Freier *et al.*, 2012; Schilling *et al.*, 2012). Adequate provision of water for livestock production could become more difficult under climate change. For example, Masike and Urich (2009) estimated that the cost of supplying livestock water from boreholes in Botswana could increase 23% by 2050 due to increased hours of groundwater pumping needed to meet livestock water demands under warmer and drier conditions. Although small in comparison to the water needed for feed production, drinking water provision for livestock is critical, and can have a strong impact on overall resource use efficiency in warm environments (Peden *et al.*, 2009; van Breugel *et al.*, 2010; Descheemaeker *et al.*, 2010; Descheemaeker *et al.*, 2011). Livestock production could be indirectly affected by water scarcity through its impact on crop production and subsequently the availability of crop residues for livestock feeding. Thornton et al. (2010) estimated that maize stover availability per head of cattle could decrease in several East African countries by 2050.

The extent to which increased heat stress associated with climate change could affect livestock productivity has not been well established, particularly in the tropics and sub-tropics (Thornton *et al.*, 2009b), although a few studies point to the possibility that keeping heat-tolerant livestock could become more prevalent in response to warming trends. For example, higher temperatures in lowland areas of Africa could result in reduced stocking of dairy cows in favor of cattle (Kabubo-Mariara, 2008), a shift from cattle to sheep and goats (Kabubo-Mariara, 2008; Seo and Mendelsohn, 2008), and decreasing reliance on poultry (Seo and Mendelsohn, 2008). Livestock keeping in highland areas of East Africa, which is currently cold-limited, would presumably benefit from increased temperatures (Thornton *et al.*, 2010).

22.3.4.3. Agricultural Pests and Diseases

Since the AR4, understanding of how climate change could potentially affect crop and livestock pests and diseases and agricultural weeds in Africa is beginning to emerge. In the case of livestock, Olwoch et al. (2008) estimated that the distribution of the main tick vector species (*Rhipicephalus appendiculatus*) of East Coast fever disease in cattle could be altered by a 2°C temperature increase and changes in mean precipitation resulting in the climatically suitable range of the tick shifting southward. However, a number of environmental and socio-economic factors (e.g., habitat destruction, land use and cover change, and host density) in addition to climatic ones influence tick distribution and need to be considered in assigning causality (Rogers and Randolph, 2006).

Warming in highland regions of eastern Africa could lead to range expansion of crop pests into cold-limited areas (*medium confidence*). For example, in highland arabica coffee-producing areas of eastern Africa, warming trends may result in the coffee berry borer (*Hypothenemus hampei*) becoming a serious threat in coffee-growing regions of Ethiopia, Kenya, Uganda, Rwanda, and Burundi (Jaramillo *et al.*, 2011). Temperature increases in highland banana-producing areas of eastern Africa enhance the risk of altitudinal range expansion of the highly destructive burrowing

nematode, *Radopholus similis* (Nicholls *et al*., 2008); however, no detailed studies have assessed this risk. Ramirez et al. (2011) estimated that increasing minimum temperatures by 2020 could expand the suitable range of Black Leaf Streak disease (Mycosphaerella fijiensis M.) of banana in Angola and Guinea.

Climate change may also affect the distribution of economically important pests in lowland and dryland areas of Africa (*low confidence*). Under A2A and B2A for 2020, Cotter et al. (2012) estimated that changes in temperature, rainfall, and seasonality could result in more suitable habitats for *Striga hermonthica* in central Africa, whereas the Sahel region may become less suitable for this weed. Striga weed infestations are a major cause of cereal yield reduction in Sub-Saharan Africa. Climate change could also lead to an overall decrease in the suitable range of major cassava pests – whitefly, cassava brown streak virus, cassava mosaic geminivirus, and cassava mealybug (Jarvis *et al*., 2012), although southeast Africa and Madagascar could experience increased suitability for cassava pests (Bellotti *et al*., 2012).

22.3.4.4. Fisheries

Fisheries are an important source of food security in Africa. Capture fisheries (marine and inland) and aquaculture combined contribute over one-third of Africa's animal protein intake (Cochrane *et al*., 2009), while in some coastal countries fish contribute up to two-thirds of total animal protein intake (Allison *et al*., 2009). Demand for fish is projected to increase substantially in Africa over the next few decades. To meet fish food demand by 2020, De Silva and Soto (2009) estimated that aquaculture production in Africa would have to increase nearly 500%.

Climate change is beginning to affect African lakes, as evident by increasing surface water temperatures in eastern and southern Africa lakes (O'Reilly *et al*., 2003 as cited in; Brander, 2007; Sitoki *et al*., 2010; Ndebele-Murisa *et al*., 2011b; Marshall, 2012). The effect of warming on fisheries in these lakes is uncertain, with some studies indicating that reduced fisheries output is linked to drought conditions and warming that have reduced upwelling of nutrients necessary for stimulating fish production (O'Reilly *et al*., 2003 as cited in; Brander, 2007; Ndebele-Murisa *et al*., 2011b), and other studies urging caution in over-attributing fisheries decline to climate change given the intense pressures on fisheries from overfishing, pollution, and invasive species (Marshall, 2012). Loss of fisheries and tourism livelihoods resulting from coral bleaching is another critical concern in Africa. An analysis by Cinner et al. (2012) indicated that Tanzania, Kenya, Seychelles, and northwest Madagascar are among the most vulnerable to losses from bleaching because of warm seawater temperatures and high ultraviolet exposure. Livelihood dependency on fishing, and thus high sensitivity to fisheries decline linked to coral bleaching, is particularly great in Tanzania (Burke *et al*., 2011; Cinner *et al*., 2012) and parts of Kenya and Madagascar (Cinner *et al*., 2012).

The vulnerability of national economies to climate change impacts on fisheries can be linked to exposure to the physical effects of climate change, the sensitivity of the country to impacts on fisheries, and adaptive capacity within the country (Allison *et al*., 2009). An analysis of 132 countries by Allison et al. (2009) estimated that two-thirds of the most vulnerable countries were in Africa. Among these countries, the most vulnerable were Malawi, Guinea, Senegal, and Uganda, due to the importance of fisheries to the poor and the close link between climate variability and fisheries production. Coastal countries of West Africa could experience a significant negative impact from climate change. Lam et al. (2012) projected that by 2050 (under an A1B scenario) the annual landed value of fish for the region could decline by 21%, resulting in a nearly 50% decline in fisheries-related employment and a total annual loss of US$ 311 million to the region's economy.

22.3.4.5. Food Security

Food security in Africa faces multiple stressors stemming from entrenched poverty, environmental degradation, rapid urbanization, high population growth rates, and climate change and variability. The intertwined issues of markets and food security have emerged as an important issue in Africa and elsewhere in the developing world since the AR4. Price spikes for globally traded food commodities in 2007–2008 and food price volatility and higher overall food prices in subsequent years have undercut recent gains in food security across Africa (Brown *et al*., 2009; Hadley *et al*., 2011; Mason *et al*., 2011; Tawodzera, 2011; Alem and Söderbom, 2012; Levine, 2012). Among

the most affected groups are the urban poor, who typically allocate more than half of their income to food purchases (Cohen and Garrett, 2010; Crush and Frayne, 2010), in addition to the rural poor, especially female-headed households (Kumar and Quisumbing, 2011). Although the recent spike in global food prices can be attributed to a convergence of several factors, the expected intensification of climate change could become more important in the future for exerting upward pressure on food prices of basic cereals (Nelson *et al*., 2009; Hertel *et al*., 2010), which could have serious implications for Africa's food security. As the recent wave of food price crises demonstrates, factors in other regions profoundly impact food security in Africa. Much more research is needed to better understand potential interactions between climate change and other key drivers of food prices that act at national, regional, and global scales.

Africa is undergoing both rapid urbanization and subsequent transformation of its food systems to accommodate changes in food processing and marketing as well as in food consumption patterns. Considering the increasing reliance on purchased food in urban areas, approaches for addressing the impacts of climate change on food security will need to encompass a food systems approach (production as well as processing, transport, storage, and preparation) that moves food from production to consumption (Battersby, 2012). Weaknesses in the food system may be exacerbated by climate change in the region as high temperatures increase spoilage and floods damage transportation infrastructure. In this respect, high post-harvest losses in Africa resulting in a large part from inadequate transport and storage infrastructure (Godfray *et al*., 2010; Parfitt *et al*., 2010) are an important concern.

22.3.4.6. Biofuels and Land Use

The potential for first-generation biofuel production in Africa, derived from bioethanol from starch sources and biodiesel production from oilseeds, is significant given the continent's extensive arable lands, labor availability, and favorable climate for biofuel crop production (Amigun *et al*., 2011; Arndt *et al*., 2011; Hanff *et al*., 2011). While biofuel production could have positive energy security and economic growth implications, the prospect of wide-scale biofuel production in Africa carries with it significant concerns about environmental and social sustainability. Among the concerns are competition for land and water between fuel and food crops, adverse impacts of biofuels on biodiversity and the environment, contractual and regulatory obligations that expose farmers to legal risks, changes in land tenure security, and reduced livelihood opportunities for women, pastoralists, and migrant farmers who depend on access to the land resource base (Unruh, 2008; Amigun *et al*., 2011; German *et al*., 2011; Schoneveld *et al*., 2011).

More research is needed to understand fully the socioeconomic and environmental tradeoffs associated with biofuel production in Africa. One critical knowledge gap concerns the effect of biofuel production, particularly large-scale schemes, on land use change and subsequent food and livelihood security. For example, the conversion of marginal lands to biofuel crop production would impact the ability of users of these lands (pastoralists and in some cases women who are allocated marginal land for food and medicinal production) to participate in land use and food production decisions (Amigun *et al*., 2011; Schoneveld *et al*., 2011). In addition, biofuel production could potentially lead to the extension of agriculture into forested areas, either directly through conversion of fallow vegetation or the opening of mature woodland, or indirectly through use of these lands to offset food crop displacement (German *et al*., 2011). Such land use conversion could result in biofuel production reducing terrestrial carbon storage potential (Vang Rasmussen *et al*., 2012a; Vang Rasmussen *et al*., 2012b).

Better agronomic characterization of biofuel crops is another key knowledge gap. For example, little information exists with respect to the agronomic characteristics of the oilseed crop Jatropha (*Jatropha curcas*) under conditions of intensive cultivation across differing growing environments, despite the fact that Jatropha has been widely touted as an appropriate feedstock for biofuel production in Africa because of its ability to grow in a wide range of climates and soils. Oilseed yields of Jatropha can be highly variable, and even basic information about yield potential and water and fertilizer requirements for producing economically significant oilseed yields is scanty (Achten *et al*., 2008; Peters and Thielmann, 2008; Hanff *et al*., 2011). Such knowledge would not only provide a basis for better crop management but would also help to gain better estimates of the extent of water consumption for biofuel production in the context of non-biofuel water-use needs across landscapes. Assessments of Jatropha's potential as

an invasive species and its potential allelopathic effects on native vegetation are also needed, in light of the fact that some countries have designated Jatropha as an invasive species (Achten *et al.*, 2008).

22.3.5. Health

22.3.5.1. Vulnerability

Africa currently experiences high burdens of health outcomes whose incidence and geographic range could be affected by changing temperature and precipitation patterns, including malnutrition, diarrheal diseases, and malaria and other vector-borne diseases, with most of the impact on women and children. Worldwide in 2010, there were 216 million cases of malaria (malaria (81% of episodes were in Africa) and an estimated 655,000 deaths with most (91% deaths) of the cases in Africa; a child dies every minute from malaria (WHO, 2011). In 2011, malaria accounted for 22% of all childhood deaths (WHO, 2011). Globally, nearly one in five deaths in children is due to diarrhea (1.5 million deaths annually) with 80% of deaths in Africa and Asia (UNICEF and WHO, 2009). Other drivers of these health outcomes include inadequate human and financial resources, inadequate public health and health care systems, insufficient access to water and sanitation, and poor governance. For example, of the more than 1 billion Africans, 341 million lack access to safe drinking water and 589 million lack access to improved sanitation, with sub-Saharan Africa having the lowest coverage (UNICEF and WHO, 2008; UNICEF and WHO, 2012). The health impacts of climate change will arise from the interactions of changing weather patterns with generic and place-specific sources of vulnerability (Cardona *et al.*, 2012).

Further emerging vulnerabilities can arise from adaptations implemented in other sectors through, for example, changing habitats for pathogens and their vectors. Building dams for irrigation could lead to epidemics or the spread of leishmaniasis, a debilitating disease endemic in North Africa that can cause facial scarring and stigmatization, affecting primarily women agricultural workers (M.K.Chahed and al, in preparation, Plos journal).

22.3.5.2. Impacts: Current and Future Projections

Literature on the health effects of climate change in Africa generally lags other sectors. Recent climate change appears to be affecting the incidence and geographic range of certain vector-, food-, and water-borne diseases, with projections suggesting increases in their magnitude and extent with additional climate change.

22.3.5.2.1. Food and water-borne diseases

Cholera is primarily associated with poor sanitation, poor governance, and poverty, and could be exacerbated by climate variability and long-term climate change (Rodó *et al.*, 2002; Koelle *et al.*, 2005; Olago *et al.*, 2007; Murray *et al.*, 2012). The frequency and duration of cholera outbreaks are associated with rainfall variability in Ghana and other African countries (de Magny *et al.*, 2007). The El Niño-Southern Oscillation (ENSO) is a driver of cholera pathogenicity and transmission (de Magny *et al.*, 2007). The worst outbreak of cholera in recent African history occurred in Zimbabwe from August 2008 to June 2009. The epidemic was associated with the rainy season and caused more than 92,000 cases and 4,000 deaths. Contamination of water sources spread the disease (Mason, 2009). Poor governance, poor infrastructure, limited human resources, and underlying population susceptibility (high burden of malnutrition) contributed to the severity and extent of the outbreak (Murray *et al.*, 2012).

Climate change is projected to increase child malnutrition (as measured by severe stunting) in sub-Saharan Africa, even taking economic growth into account; the projected increase in central sub-Saharan Africa is 23% by 2050 (Lloyd *et al.*, 2011). Local economic activity and food accessibility can reduce the incidence of malnutrition (Funk *et al.*, 2008; Rowhani *et al.*, 2011). Prevention of future malnutrition would require, in addition, improved socioeconomic conditions and reductions in greenhouse gas emissions (Lloyd *et al.*, 2011). By 2050, the number of malnourished children in sub-Saharan Africa could increase by 24 million due to climate change (Parry *et al.*, 2009b; ADB and IFPRI, 2009).

22.3.5.2.2. Vector-borne diseases

A wide range of vector-borne diseases contribute to premature morbidity and mortality in Africa. New research has been published since the AR4 on malaria, leishmaniasis, Rift Valley fever, and tick- and rodent-borne diseases.

Malaria: Weather and climate are among the determinants of the geographic range and incidence of malaria. The association between temperature and malaria varies regionally, with some studies concluding it is nonlinear and others quadratic or exponential (Chaves and Koenraadt, 2010; Paaijmans *et al*., 2010a; Alonso *et al*., 2011; Gilioli and Mariani, 2011). Total precipitation, rainfall patterns, and the water temperature of breeding sites will likely alter disease susceptibility (Bomblies and Eltahir, 2010; Paaijmans *et al*., 2010b; Afrane *et al*., 2012). ENSO events also may contribute to malaria epidemics (Mabaso *et al*., 2007; Ototo *et al*., 2011). The complexity of the malaria transmission cycle makes it difficult to determine whether the distribution of the pathogen and vector are already changing due to climate change.

Research continues to support the AR4 finding that climate change could affect the geographic range and incidence of malaria, particularly along the current edges of its distribution, with contractions and expansions, and increasing and decreasing incidence (Yé *et al*., 2007; Peterson, 2009a; Parham and Michael, 2010; Paaijmans *et al*., 2010b; Alonso *et al*., 2011; Chaves *et al*., 2011; Egbendewe-Mondzozo *et al*., 2011; Paaijmans *et al*., 2012; Parham *et al*., 2012; Ermert *et al*., 2012), depending on other drivers, such as public health interventions, factors influencing the geographic range and reproductive potential of malaria vectors, land use change (e.g., deforestation), and drug resistance, as well as the interactions of these drivers with weather and climate patterns (Chaves *et al*., 2008; Kelly-Hope *et al*., 2009; Paaijmans *et al*., 2009; Saugeon *et al*., 2009; Artzy-Randrup *et al*., 2010; Dondorp *et al*., 2010; Gething *et al*., 2010; Jackson *et al*., 2010; Kulkarni *et al*., 2010; Loha and Lindtjørn, 2010; Tonnang *et al*., 2010; Stern *et al*., 2011; Caminade *et al*., 2011; Omumbo *et al*., 2011; Afrane *et al*., 2012; Edlund *et al*., 2012; Gething *et al*., 2012; Githeko *et al*., 2012; Himeidan and Kweka, 2012; Jima *et al*., 2012; Lyons *et al*., 2012; Ermert *et al*., 2012; Mordecai *et al*., 2013). Because various *Anopheles* species are adapted to different climatic conditions, changing weather and climate patterns could affect species composition differentially (Afrane *et al*., 2012).

Consensus is growing that highland areas, especially in East Africa, will experience increased malaria epidemics, with areas above 2,000 m particularly affected (Pascual *et al*., 2006; Peterson, 2009b; Lou and Zhao, 2010; Paaijmans *et al*., 2010a; Ermert *et al*., 2012; Gething *et al*., 2012). Reasons for different projections across models include using GCMs versus regional climate models (Ermert *et al*., 2012); the need for finer-scale and higher-resolution models of the sharp climate variations with altitude (Bouma *et al*., 2011); and the extent to which other drivers of the geographic range and incidence of malaria are included, including how these drivers interact with climate change.

Directly or indirectly, climate change may increase the incidence and geographic range of leishmaniasis. Leishmaniasis, a highly neglected disease, has recently become a significant health problem in northern Africa (Postigo, 2010) with a rising concern in western Africa because of co-infection with HIV (Kimutai *et al*., 2006). The epidemiology of the disease appears to be changing (Dondji, 2001; Yiougo *et al*., 2007; WHO, 2009; Postigo, 2010). Previously an urban disease, leishmaniasis now has a peri-urban distribution linked to changes in the distribution of the rodent host and of the vector over the last 20 years in Algeria (Aoun *et al*., 2008). Cutaneous leishmaniasis has expanded its range from its historical focus at Biskra into the semi-arid steppe, with an associated upward trend in reported cases. In Morocco, epidemic transmission of leishmania major (vector *Phlebotomus papatasi*) occurred in 2009 with occasional outbreaks of up to 2,000 cases, followed by long periods with few or no cases (Rhajaoui, 2011). The disease has spread to areas in West Africa and East Africa (Dondji, 2001; Yiougo *et al*., 2007; WHO, 2009). Outbreaks of zoonotic cutaneous leishmaniasis (ZCL) have become more frequent in Tunisia, Algeria, and Morocco, where the disease is endemic. In Tunisia, weather patterns, including heavy rainfall up to two years prior and warmer than average temperature three to six months prior to an outbreak, are associated with changes in the geographic range and incidence of the disease and/or changes in rodent density and density of sandfly species (Salah *et al*., 2007; Interim Technical Report, 2011). Environmental modifications, such as dam construction, can change

the temperature and humidity of the soil and thus affect vegetation that may result in changes in the composition and density of sandfly species and rodent vectors.

Rift Valley fever (RVF) epidemics in the Horn of Africa are associated with altered rainfall patterns. Additional climate variability and change could further increase its incidence and spread. Rift Valley fever is endemic in numerous African countries, with sporadic repeated epidemics. Epidemics in 2006–2007 in the Horn of Africa (Nguku *et al*., 2007; WHO, 2007; Adam *et al*., 2010; Andriamandimby *et al*., 2010) and southern Africa were associated with heavy rainfall (Chevalier *et al*., 2011), strengthening earlier analyses by Anyamba et al. (2009) showing that RVF epizootics and epidemics are closely linked to the occurrence of the warm phase of ENSO and La Nina events (Linthicum *et al*., 1999; Anyamba *et al*., 2012) and elevated Indian Ocean temperatures. These conditions lead to heavy rainfall and flooding of habitats suitable for the production of the immature *Aedes* and *Culex* mosquitoes that serve as the primary RVF virus vectors in East Africa. Flooding of mosquito habitats also may introduce the virus into domestic animal populations.

Changing weather patterns could expand the distribution of ticks causing animal disease, particularly in East and South Africa. About 300 million Africans depend on livestock for their livelihood. In sub-Saharan Africa, livestock diseases cost an estimated US$ 2 billion, aggravating poverty, hunger, and disease in humans. Globally, six million cattle are exposed to ticks annually, with more than one-third of these in Africa. Theileriosis (East Coast Fever) ticks are vectors and agents of diseases, causing anemia and skin damage that expose cattle to secondary infections. Habitat destruction, land use and cover change, and host density also affect tick distribution (Rogers and Randolph, 2006). Using a climate envelope and a species prediction model, Olwoch et al. (2007) found that East Africa and South Africa are the most vulnerable to climate-induced changes in tick distributions and tick-borne diseases: more than 50% of the 30 *Rhipicephalus* species examined showed significant range expansion and shifts. More than 70% of this range expansion was found in economically important tick species.

Approximately 243 million people are infected with schistosomiasis, of which 90% live in underdeveloped areas of Africa (WHO, 2013). Water resource development, such as irrigation dams recommended for adaptation in agriculture, can amplify the risk of schistosomiasis (Huang and Manderson, 1992; Hunter *et al*., 1993; Jobin, 1999). Migration and sanitation play a significant role in the spread of schistosomiasis from rural areas to urban environments (Babiker *et al*., 1985; WHO, 2013). Temperature and precipitation patterns may play a role in transmission (Odongo-Aginya *et al*., 2008; Mutuku *et al*., 2011; Huang *et al*., 2011). A relation between climate variability and schistosomiasis has been noted elsewhere (Huang *et al*., 2011) and there is the need for further research in Africa to assess the possible climate change impacts on the disease.

Researchers have found a strong relationship between the seasonal pattern of meningococcal meningitis and climate (environmental factors) this includes a relationship between the seasonal pattern of the harmattan dusty winds and the onset of the epidemic and the seasonal cycle of meningitis. Links with other environmental factors affected by climate change like wind and humidity have been noted. Epidemics occur throughout Africa in the dry season and coincide with periods of very low humidity and dusty conditions. The epidemics disappear with the onset of the rains (Molesworth *et al*., 2003). Recently, other researchers have corroborated with earlier hypothized relationships between weather and meningitis, (Yaka *et al*., 2008; Palmgren, 2009; Roberts, 2010; Dukić *et al*., 2012). Further, in the northern region of Ghana, a follow-on study to Hodgson et al. 2001 by Hayden et al. (revision submitted) found that exposure to smoke from cooking fires increased the risk of contracting meningococcal meningitis. This increased risk suggests that exposure to elevated concentrations of air pollutants, such as carbon monoxide (CO) and particulate matter, may be linked to illness. More research is needed to clarify the impact of climate change on air quality and linkages with meningitis. Researchers have quantified the relationship between the environment and the location of the epidemics suggesting that there are connections between epidemics and regional climate variability (Molesworth *et al*., 2003; Sultan *et al*., 2005; Thomson *et al*., 2006). This will be beneficial in predicting location and onset of epidemics in Early Warning Systems.

Novel hantaviruses with unknown pathogenic potential have been identified in some insectivores (shrews and a mole) in Africa (Klempa, 2009). Climate change could alter the natural reservoirs of hantaviruses. Changes in the geographical distribution of the rodent carriers could deliver hantaviruses to new regions, altering species composition in ways that could be epidemiologically important (Klempa, 2009). Exacerbated food insecurity due to

climate change could further compromise the poor nutrition of people living with HIV/AIDs (Drimie and Gillespie, 2010). Laboratory studies suggest that the geographic range of the tsetse fly (Glossina species), the vector of human and animal trypanosomiasis in Africa, may be reduced under future scenarios (Terblanche *et al*., 2008).

Heat waves and heat-related health effects are only beginning to attract attention in Africa. Recent studies in West and southern Africa indicate heat-related health effects may be of concern (Dapi *et al*., 2010; Mathee *et al*., 2010).

Climate change is anticipated to affect the sources of air pollutants as well as the ability of pollutants to be dispersed in the atmosphere (Denman *et al*., 2007). Assessments of the impacts of projected climate change on air quality indicate that changes in surface temperature, land cover, and lightning may alter natural sources of ozone precursor gases and consequently ozone levels over Africa (Stevenson *et al*., 2005; Brasseur *et al*., 2006; Zeng *et al*., 2008). However, insufficient climate and emissions data for Africa prevent a more comprehensive understanding of the nature of the changes to air pollution.

22.3.6. Human Security

Human security of people in Africa is particularly threatened by the impacts of climate variability. Adverse climate events impact all aspects of human security, either directly or indirectly (For more details see Chapter 12). Water stress, land use and food security, health security, violent conflicts, changing migration patterns, and human settlements are interrelating issues between climate change and human with particular relevance on the African continent.

22.3.6.1. Economic Security

The ultimate damages of climate change may significantly affect economic growth and the ability to trade (Lecocq and Shalizi, 2007; Ruppel and Ruppel-Schlichting, 2012). The impacts on the agricultural sector in Africa are probably of the most direct and profound nature. In Tanzania, climate volatility could have severe implications for poverty as agriculture accounts for about half of gross production, and employs about 80% of the labor force (Ahmed *et al*., 2011). For Namibia, general equilibrium model simulations indicate that over 20 years, annual losses to the Namibian economy could be up to 5% of GDP, due to the impact that climate change will have on its natural resources alone (Reid *et al*., 2008). Such losses are detrimental, considering that unemployment, poverty, the HIV/AIDS pandemic, and household food insecurity are among the main problems facing the country (Ruppel, 2011). Ghana's agricultural and economic sector with cocoa being the single most important export product is particularly vulnerable, since cocoa is particularly prone to the effects of a changing climate, which has been central to the country's debates on development and poverty alleviation strategies (WTO Trade Policy Review, 2008; Black *et al*., 2011c). A decline in lake levels in Ghana caused by reduced rainfall over the last 40 years, is another critical aspect with regard to economic development because the demand for power is increasing due to economic growth and hydroelectric power stations generate 80% of Ghana's total national power production (Kuuzegh, 2007; Black *et al*., 2011c).

22.3.6.2. Violent Conflicts

While there seems to be consensus that the environment is only one of several interconnected causes of conflict and is rarely considered to be the most decisive factor (Kolmannskog, 2010), it remains disputed whether the changing climate increases the risk of civil war in Africa. In sub-Saharan Africa, climate variability is a poor predictor of armed conflict. Instead, African civil wars can be explained by generic structural and contextual conditions: prevalent ethno-political exclusion, poor national economies, and the collapse of the Cold War system (Buhaug, 2010). Other research also focusing on sub-Saharan Africa comes to the diametrically opposite result, concluding that warming does increase the risk of civil war in Africa (Burke *et al*., 2009b). Strong historical linkages exist between civil war and temperature in Africa, with warmer years leading to significant increases in the likelihood of war. A roughly 54% increase in armed conflict incidence is predicted by 2030, or an additional 393,000 battle deaths

if future wars are as deadly as recent wars. It has been argued that conflicts are more likely in regions with higher ecosystem productivity (possibly resulting from vegetation recovery after populations are displaced out of conflict zones), and that increased levels of malnutrition are related to armed conflicts (Rowhani *et al.*, 2011). However, with an emphasis on the role of renewable resources such as freshwater and arable land, it is argued that as a long-term trend, population growth and resource scarcities result in violent competition (Raleigh, 2010) while short-term causes may trigger the outbreak of conflict (Hendrix and Glaser, 2007). Distributional conflicts will arise due to the degradation of natural resources as a result of overexploitation and global warming (Kumssa and Jones, 2010). Such distributional conflicts are, for example, occurring in Somalia, and armed conflict may exacerbate the drought. An important part of the war economy in Somalia, namely the commercial production and export of charcoal resulting in deforestation, is one example of environmental degradation contributing to drought (Kolmannskog, 2010).

22.3.6.3 Migration

Human migration in Africa has social, political, demographic, economic, and environmental drivers, which may operate independently or in combination(Perch-Nielsen *et al.*, 2008; Piguet, 2010; Foresight, 2011; Piguet *et al.*, 2011; Black *et al.*, 2011a; Ruppel, 2012). People migrate either temporarily or permanently, within their country or across borders (Warner *et al.*, 2010; Kälin and Schrepfer, 2012). The evidence base in the field of migration in Africa is both varied and patchy. Different assessments of future trends have recently produced contradictory conclusions (e.g., ADB, (2011); Tacoli, (2011)). A global study conducted in 2009 reveals that in 2008, at least 36 million people were newly displaced by sudden-onset natural disasters such as floods and storms, including 697,066 people in Africa. The number of displaced people in Africa has increased from 697,066 in 2008 to 1.1 million in 2009 and 1.7 million in 2010 (IDMC, 2011). It is likely that many more are displaced due to other climate change-related drivers, including slow-onset disasters, such as drought and sea level rise (UN-OCAH and IDMC, 2009). With regard to forced migration in sub-Saharan Africa, it was found that one additional natural disaster per year could lead to an increase in net migration of 0.6 per 1,000 (Naude, 2010). One approach in assessing future migration potentials, with considerable relevance to the African context, focused on capturing the net effect of environmental change on aggregate migration through analysis of both its interactions with other migration drivers and the role of migration within adaptation strategies, rather than identifying specific groups as potential 'environmental migrants' (Foresight, 2011). Even if Africa's population doubles by 2050 to 2 billion (Lutz and Kc, 2010) and the potential for displacement rises as a consequence of the impact of rapid-onset climate events, recent analyses (Foresight, 2011; Black *et al.*, 2011b) show that the picture for future migration is much more complex than previous assessments of a rise in climate refugees suggest, and relates to the intersection of multiple drivers with rates of global growth, levels of governance, and climate change.

Besides low-lying islands and coastal and deltaic regions, sub-Saharan Africa is one of the regions that would particularly be affected by environmentally induced migration (Gemenne, 2011a). Case studies from Somalia and Burundi emphasize the interaction of climate change, disaster, conflict, displacement, and migration (Kolmannskog, 2010). In Ghana for example, an African country with few conflicts caused by political, ethnic, or religious tensions, and thus with migration drivers more likely related to economic and environmental motivators (Tschakert and Tutu, 2010), some different types of migration flows are considered to have different sensitivity to climate change (Black *et al.*, 2011a). The floods of the Zambezi River in Mozambique in 2008 have displaced 90,000 people, and it has been observed that along the Zambezi River Valley, with approximately 1 million people living in the flood-affected areas, temporary mass displacement is taking on permanent characteristics (Jäger *et al.*, 2009; Warner *et al.*, 2010).

The empirical base for major migration consequences is very weak (Lilleør and Van den Broeck, 2011; Black *et al.*, 2011a; Gemenne, 2011b) and non-existent for international migration (Marchiori *et al.*, 2011). Even across the same climate disaster, the response can vary (Findlay, (2011); Gray, (2011) for Kenya and Uganda; Raleigh, (2011) for the African Sahel States). Mobility is indeed a strategy (not a reaction) to high levels of climatic variation that is characteristic of Africa (Tacoli, 2011) and the specifics of the response are determined by the economic context of the specific communities.

22.3.7. Urbanization

Climate change affects the size and characteristics of rural and urban human settlements in Africa. Urbanization through migration is also leading to new vulnerabilities as new migrants face significant ecological issues including floods, etc. (Seto, 2011). The problems associated with voluntary or involuntary environmentally induced migration to Africa's large and intermediate cities will be exacerbated as a result of climate change. Migration flows can be observed away from flood-prone localities, as well as potentially large-scale internal and cross-border mobility away from agricultural zones undermined by changing climatic conditions or declining water availability (UN-Habitat and UNEP, 2010). African inland cities are threatened by the potential risk of water shortages, damage to infrastructure, and desiccating vegetation due to the impacts of climate change.

The urban population in Africa will treble by 2050, increasing by 0.8 billion (UN DESA, 2010). African countries are experiencing some of the world's highest urbanization rates (UN-Habitat, 2008a). Many of Africa's evolving cities are unplanned and have been associated with the uncontrolled growth of informal settlements, inadequate housing and basic services, and increasing urban poverty (Yuen and Kumssa, 2011).[6]

[FOOTNOTE 6: However, community-driven upgrading may contribute to reducing the vulnerability of such informal areas (for more details see Chapter 8).]

Climate change, with its associated erratic rainfall and extreme weather events, is expected to have significant impacts on urbanization in Africa. In particular, the majority of migration flows observed in response to environmental change are internal (Jäger *et al*., 2009; Tacoli, 2009). In particular, extreme climate variations and, more specifically, water shortages, may cause abrupt changes in human settlements and urbanization patterns in sub-Saharan Africa more than anywhere else in the world (Marchiori *et al*., 2012). Rural–urban migration has typically been motivated by livelihood opportunities, and traditionally involves moving into large towns and cities (Barrios *et al*., 2006; Annez *et al*., 2010). Such rapid rates of urbanization represent a burden on the economies of African urban areas, due to the massive investments needed to create job opportunities and provide infrastructure and services. Basic infrastructure services are not keeping up with urban growth, which has resulted in a decline in the coverage of many services, compared to 1990 levels (Banerjee *et al*., 2007).

Thus, African cities and towns represent some of the most vulnerable to the impacts of climate change and climate variability (Boko *et al*., 2007; Diagne, 2007; Dossou and Gléhouenou-Dossou, 2007; Douglas *et al*., 2008; Adelekan, 2010; Kithiia, 2011). The impacts of climate change, which could be seen as one of the key systematic shocks, have the potential to disrupt entire urban systems as well as their sustainability (UN-Habitat, (2010); for further details see Chapter 8).

Furthermore, most of those migrating from rural areas have limited skills and education. This means that they often end up in the informal sector of the urban economy and settle in squatter areas on the peripheries of cities where poverty, overcrowding, unemployment, crime and environmental degradation are common (Yuen and Kumssa, 2011). For instance, despite African cities generating about 55 to 60% of the continent's total GDP, a massive 43% of its urban populations live below the poverty line (Eriksen *et al*., 2010). Moreover, sub-Saharan African countries have the highest levels of urban poverty in the world (Eriksen *et al*., 2010).

Squatter and poor areas typically lack provisions to reduce flood risks or to manage floods when they happen (Douglas *et al*., 2008). Floods are already exerting considerable impacts on cities and smaller urban centers in many African nations – for instance, the heavy rains in East Africa in 2002 that brought floods and mudslides, forcing tens of thousands to leave their homes in Rwanda, Kenya, Burundi, Tanzania, and Uganda and the very serious floods in Port Harcourt and in Addis Ababa in 2006 (Douglas *et al*., 2008).

Another impact of climate change on coastal settlements in Africa is sea level rise along coastal zones, which is likely to disrupt economic activities such as tourism, fisheries, and mining. More than a quarter of Africa's population lives within 100 km of the coast and about 12% of the urban population lives in low-elevation coastal zones. Coastal zones will experience significant impacts arising from storms, floods, and sea level rise. In Africa, coastal cities such as Cape Town, Maputo and Dar es Salaam with large and growing populations will be affected

(Bunce *et al*., 2010). Despite being the most developed of Africa's urban areas, coastal cities are particularly vulnerable to sea level rise. Nearly 60% of Africa's total population living in low-elevation coastal zones is urban, representing 11.5% of the region's total urban population (UN-Habitat, 2008a). Because of their large adaptation deficit, African coastal cities are poorly equipped to deal with sea level rise and will be among the most adversely affected, leading to devastating consequences (UN-Habitat, 2008a). All of these climate change impacts affect the poor and vulnerable most severely (Douglas *et al*., 2008; Kithiia, 2011), making climate change one of the greatest developmental challenges facing the continent's cities.[7]

[FOOTNOTE 7: For more details see Chapter 8.]

African small- and medium-sized cities have "low levels of capacity to adapt to the current range of climate variability, let alone any future climate impacts" (UN-Habitat, 2011). In other words, they have a high adaptation deficit (Satterthwaite et al., (2009); for more details see Chapter 7 and Chapter 8). The shortfall in infrastructure in African cities is a particularly critical concern, as adaptation is often framed in terms of infrastructural changes. It is not possible, however, "to climate-proof infrastructure that is not there" (Satterthwaite *et al*., 2009). It is also important to question the appropriateness of hard infrastructural responses such as seawalls and channelized drainage lines that are costly and often maladaptive (Dossou and Gléhouenou-Dossou, 2007; Douglas *et al*., 2008; Kithiia and Lyth, 2011).

The reason for the high level of vulnerability and low adaptive capacity has less to do with climate change (Kithiia, 2011) and more to do with structural factors, particularly local governments with poor capacities and resources. Weak local government creates and exacerbates a large number of problems, including the lack of appropriate regulatory structures and mandates; poor or no planning; lack of or poor data; lack of disaster risk reduction strategies; poor servicing and infrastructure (particularly waste management and drainage); uncontrolled settlement of high-risk areas such as floodplains, wetlands, and coastlines; ecosystem degradation competing development priorities and timelines; and a lack of coordination among government agencies (AMCEN and UNEP, 2006; Diagne, 2007; Dossou and Gléhouenou-Dossou, 2007; Mukheibir and Ziervogel, 2007; Douglas *et al*., 2008; Roberts, 2008; Adelekan, 2010; Kithiia and Dowling, 2010; Kithiia, 2011).

22.4. Adaptation

22.4.1. Introduction

Since 2007, Africa has gained a wealth of experience in conceptualizing, planning and beginning to implement and support adaptation activities, from local to national levels and across a growing range of sectors (sections 22.4.4 and 22.4.5). However, across the continent, most of the adaptation to climate variability and change is reactive in response to short-term motivations, is occurring autonomously at the individual / household level, and lacks support from government stakeholders and policies (Vermuelen et al., 2008; Ziervogel et al., 2008; Berrang-Ford et al., 2011; Thorn, forthcoming).

22.4.2. Adaptation Needs, Gaps, and Adaptive Capacity

Africa's urgent adaptation needs stem from the continent's foremost vulnerability to climate change and its overall low levels of adaptive capacity (section 22.3). The literature does also highlight a number of inherent adaptation-related strengths in Africa: the continent's wealth in natural resources, well-developed social networks, and longstanding traditional mechanisms of managing variability through, for example, crop and livelihood diversification, migration and small-scale enterprises, all of which are underpinned by local or indigenous knowledge systems for sustainable resource management (Cooper et al., 2008; Nielson, 2010; UNFCCC, 2007; Nyong et al, 2007; Macchi et al., 2008; Castro et al., 2012; Eyong, 2007). However, it is uncertain to what extent these strategies will be capable of dealing with future changes, among them climate change and its interaction with other development processes (van Aalst et al., 2008; Leary et al, 2007; Paavola, 2008; Conway, 2009; Jones, 2011b). Since Africa is extensively exposed to a range of multiple stressors (section 22.3) that interact in complex

ways with longer term climate change, adaptation needs are broad, encompassing institutional, social, physical and infrastructure needs, ecosystem services and environmental needs, and financial and capacity needs. Towards elucidating these needs, least developed countries in Africa have used the National Adaptation Plan of Action (NAPA) process to assess vulnerabilities, explore impacts, and identify adaptation priorities (UNFCCC, 2002), and many African countries have conducted technology needs assessments , including Cote d'Ivoire, Ethiopia, Kenya, Ghana, Mali, Morocco, Mauritius, Rwanda, Senegal, Sudan, and Zambia (GEF Evaluation Office, 2011).

Analyses reveal that making climate change information more reliable and accessible is one of the most pressing and cross-cutting adaptation needs. As noted in the AR4 and emphasised in subsequent literature, monitoring networks in Africa are insufficient and characterised by sparse coverage and short and fragmented records, which makes modelling difficult (Boko et. al., 2007; Goulden et al., 2009b; Ziervogel & Zermoglio, 2009; Jalloh, Sarr et al., 2011). Adding to this is the shortage of relevant information and skills, in particular for downscaling climate models and using scenario outputs for development and adaptation planning, which is exacerbated by under-resourcing of Meteorological Agencies and related organisations; and the capacity of civil society and government organisations' to access, interpret and use climate information for planning and decision making (Ziervogel & Zermoglio, 2009; Brown et al., 2010; Ndegwa et al., 2010; Jalloh, Sarr et al., 2011). Information-related needs include additional vulnerability and impact assessments with greater continuity in countries , country-specific socio-economic scenarios, and greater knowledge on costs and benefits of different adaptation measures (UNFCCC, 2007; AAP, 2012).

Given its dependence on natural-resource based economies, most research on strengthening adaptive capacity in Africa is focused on natural resource-based livelihoods, such as agriculture, forestry or fisheries (Collier et al., 2008; Berrang-Ford et al., 2011). In this regard, many African countries have prioritised the following knowledge needs: comprehensive programmes that promote adaptation through a more holistic development approach, including integrated programmes on desertification, water management and irrigation; promoting sustainable agricultural practices and the use of appropriate technologies and innovations to address shorter growing seasons, extreme temperatures, droughts, and floods; developing alternative sources of energy; and approaches to deal with water shortages, food security and loss of livelihoods (AAP, 2012; Sissoko et al 2011; Jalloh and Roy-Macauley, 2011; Bryan et al., 2009; Chikozho, 2010; Eriksen & Silva, 2009, Gbetibouo et al., 2010). The rural emphasis is now being expanded through a growing focus on requirements for enhancing urban adaptive capacity (Lwasa, 2013). The literature, however, stresses the vast variety of contexts that shape adaptation and adaptive capacity - even when people are faced with the same stimuli, responses vary greatly (Cooper et al., 2008; Vermuelen et al., 2008; Ziervogel et al., 2008; Gbetibou, 2009; Westerhoff & Smit, 2009).

Despite significant data and vulnerability assessment gaps, there is consensus that this should not be used as an excuse to delay action on adaptation (UNFCCC, 2007; Jobbins, 2011). Recent analyses emphasise the significant resources and increased financial, technical and technological support needed to both address Africa's current adaptation deficit and to protect rural and urban livelihoods, societies and economies from climate change impacts at different local scales, with estimates of adaptation costs between US$20-30 billion per annum over the next couple of decades (LDC Expert Group, 2011; Parry et al, 2009a; Fankhauser and Schmidt-Traub, 2010; Watkiss et al, 2010; AfDB, 2011; Dodman and Carmin, 2011; Smith et al, 2011).

22.4.3. Adaptation, Equity, and Sustainable Development

Multiple uncertainties in the African context mean that successful adaptation will depend upon developing resilience in the face of uncertainty (Conway, 2011). The inadequacy of developmental strategies to counter current climate risks reinforces the need for strong inter-linkages between adaptation and development, and for low-regrets adaptation strategies that produce developmental co-benefits (high confidence) (Bauer and Scholz, 2010; Smith et al., 2011). As adaptation and local adaptive capacity are affected by inequalities, an effective adaptation response necessitates differentiated and targeted actions from the local to national levels, given the differentiated social impacts based on gender, age, disability, ethnicity, geographical location, livelihood, and migrant status of climate change (Tanner and Mitchell, 2008; IPCC, 2012). While adaptation efforts in Africa have not sufficiently prioritized equity and social justice, including the differential distribution of adaptation benefits and costs (Burton et al, 2002;

Thomas and Twyman, 2005; Madzwamuse, 2010), some valuable experience has been gained recently on gender equity in adaptation, human rights based-approaches, and involvement of vulnerable or marginalized groups such as indigenous peoples and children, aged and disabled people, internally displaced persons and refugees (Unicef, 2010; Unicef, 2011; Tanner and Seballos, 2012; Romero González et al., 2011; IDS, 2012; African Development Forum, 2010; Levine et al., 2011) (Table 22-4).

[INSERT TABLE 22-4 HERE
Table 22-4: Cross-cutting approaches for equity and social justice in adaptation.]

22.4.4. Experiences in Building the Governance System for Adaptation, and Lessons Learned

22.4.4.1. Introduction

Section 22.4 assesses progress made in developing policy, planning and institutional systems for climate adaptation at regional, national and sub-national levels in Africa. This includes an assessment of community-based adaptation, as an important local level response, and a consideration of adaptation decision making and monitoring.

22.4.4.2. Regional and National Adaptation Planning

While regional policies and strategies for adaptation, as well as transboundary adaptation, are still in their infancy, sub-regional institutions have begun to formulate strategies for climate change. For example, the Southern African Development Community and the Lake Victoria Basin Committee are developing Climate Change Strategies and Action Plans, and efforts are being made by six highly-forested Congo basin countries (Cameroon, Central African Republic, Democratic Republic of Congo, Equatorial Guinea, Gabon, and the Republic of Congo) to coordinate conservation and sustainable forest management of the Central African forest ecosystem, and obtain payments for ecosystem services (Harmeling et al, 2011; African Development Bank, 2012).

At the national level, African countries have initiated comprehensive planning processes for adaptation by developing National Adaptation Programmes of Action (NAPAs) or National Climate Change Response Strategies (NCCRS); implementation is, however, lagging and integration with economic and development planning is limited but growing (high confidence). As of December 2011, 32 Least Developed Countries in Africa had developed NAPAs, with the exception of Equatorial Guinea and Somalia. Prioritized adaptation measures in the NAPAs tend to focus on agriculture, food security, water resources, forestry, and disaster management; and on technical solutions, education and capacity development, although some do include ecosystem response measures (Madzwamuse, 2010; Mamouda, 2011; Pramova et al, 2012). Constraints identified with the NAPAs and some of the NCCRS include a relatively narrow focus on biophysical vulnerabilities and sectoral or project approaches, which limits an integrated cross-sectoral adaptation response; inadequate inclusion of the adaptation needs of vulnerable societal sectors; no or little inclusion of energy adaptation; de-linkage from economic planning and poverty reduction processes; and little facilitation of investment funding - only a small percentage of the NAPA activities have been funded (Romero Gonzalez et al, 2011; Mamouda, 2011; Prowse et al, 2009; Madzwamuse, 2010).

Subsequent to the NAPAs and early experience with the NCCRS, there is some evidence of evolution to a more integrated, multi-level and multi-sector approach to adaptation planning (medium confidence): Ethiopia's Programme of Adaptation to Climate Change deals with adaptation at sectoral, regional, national and local community levels (Hunde, 2012); Lesotho is developing a coordinated policy framework involving all ministries and stakeholders (Corsi et al., 2012); and cross-sectoral adaptation planning and risk management is occurring through mainstreaming initiatives like the twenty country Africa Adaptation Programme (AAP), initiated in 2008 (UNDP, 2009; UNDP, 2010). Examples of the more programmatic approach of national climate resilient development strategies include Rwanda's National Strategy on Climate Change and Low Carbon Development, under development in 2012, and the Pilot Programmes for Climate Resilience in Niger, Zambia and Mozambique (Climate Investment Fund, 2009). Inter-sectoral climate risk management approaches can be detected in integrated

water resources management, disaster risk reduction, and land use planning initiatives, while studies have highlighted the role of integrated coastal zone management in reducing the vulnerability of coastal towns to climate change and particularly coastal flooding (Koch et al, 2007; Boateng, 2006; Cartwright *et al*., 2008; Awuor *et al*., 2008; Kebede *et al*., 2012; Kebede and Nicholls, 2011). Concerning spatial planning, climate change design principles have been incorporated into existing systematic biodiversity planning to guide land use planning in South Africa (Petersen and Holness, 2011).

Adaptation planning is occurring within efforts to construct enabling national policy environments for adaptation in many countries. Examples include Namibia's National Policy on Climate Change (IIED, 2011b); Zambia's National Climate Change Response Strategy and Policy, and South Africa's Draft National Climate Change Response Green Paper in November 2010. Ten countries were developing new climate change laws or formal policies at the end of 2012, including the proposed National Coastal Adaptation Law in Gabon (Corsi et al., 2012).

Despite this progress in mainstreaming climate risk in policy and planning, significant disconnects still exist at the national level, and implementation of a more integrated adaptation response remains tentative (high confidence) (Koch et al, 2007; Madzwamuse, 2010; Fankhauser and Schmidt-Traub, 2010; Oates et al, 2011; UNDP-UNEP Poverty-Environment Initiative, 2011b). Legislative and policy frameworks for adaptation in southern Africa remain fragmented (IIED, 2011b), as is the case for the region as a whole, where adaptation policy approaches seldom take into account realities in the political and institutional spheres (Naess et al, 2011; Lockwood, 2012). While climate resilience is starting to be mainstreamed into economic planning documents - for example, Zambia's Sixth National Development Plan 2011-2015, and the new Economic and Social Investment Plan in Niger (Corsi et al., 2012) - macro-economic development frameworks in Africa have been found to undercut adaptive capacity of poor people through measures to draw foreign direct investment and promote industrial competitiveness (Madzwamuse, 2010),while poor business environments impede both foreign direct investment and adaptation (Collier et al, 2008). National policies are often at odds with autonomous local adaptation strategies, which can act as a barrier to adaptation, especially where cultural, traditional and context-specific factors are ignored (Stringer et al., 2009; Patt and Schroter, 2008; Dube and Sekhwela, 2008; Hisali et al, 2011). National adaptation planning has placed little attention on integrating forests into programmes and strategies compared to mitigation (Bele et al. 2010; Kalame et al. 2011; Sonwa et al. 2012), despite opportunities for enhancing adaptation through forest governance reforms to improve community access to forest resources (Kalame et al. 2008).

22.4.4.3. Institutional Frameworks for Adaptation

The nature of the adaptation institutions at the global level, both within and outside of the UNFCCC, are of critical importance for Africa's ability to move forward on adaptation (Chapter 14). Regional institutions focused on specific ecosystems rather than on political groupings, such as the Commission of Central African Forests (COMIFAC), present an opportunity to strengthen the institutional framework for adaptation. National frameworks include a number of institutions that cover all aspects of climate change, not just adaptation: most countries have inter-ministerial coordinating bodies and inter-sectoral technical working groups, while an increasing number of countries have established multi-stakeholder co-ordinating bodies, including Kenya, South Africa, Senegal and Tanzania (Harmeling et al, 2011). National institutions for climate finance are being established to manage international and domestic funding and encourage mainstreaming into national plans, including the National Implementing Entities in terms of the Adaptation Fund, and national funds to serve as conduits for all sources of climate change funding (Gomez-Echeverri, 2010; Smith et al, 2011).

Under uncertain climatic futures, hierarchical governance systems that operate within siloes will need to be replaced with more adaptive, integrated, multi-level and flexible governance approaches, and inclusive decision making that can operate successfully across multiple scales – or adaptive governance and co-management (Folke et al., 2005; Olsson et al., 2006; Koch et al, 2007; Berkes, 2009; Pahl-Wostl, 2009; Armitage & Plummer, 2010; Bunce et al., 2010a; Plummer, 2012). Despite some progress with developing the institutional framework for governing adaptation, there are significant problems with both transversal and vertical coordination, including institutional duplication with other inter-sectoral platforms, such as those set up for disaster risk reduction; while in fragile states, institutions for reducing climate risk and promoting adaptation may be extremely weak or almost non-existent

(Bettencourt, 2011; Belay Simane et al, 2012; Sietz et al, 2011; Hartmann and Sugulle, 2009). Facilitating institutional linkages and coordinating responses across all boundaries of government, private sector and civil society would enhance adaptive capacity (Brown et al., 2010).

22.4.4.4. Sub-National Adaptation Governance

Since AR4, there has been additional effort on adaptation planning at sub-national and local levels in African countries, but adaptation strategies at provincial and municipal levels are mostly still under development, with many local governments lacking the capacity and resources for the necessary decentralised adaptation response (high confidence). Provinces or states in some countries have developed policies and strategies on climate change: for example, in Nigeria, Delta State developed a Climate Change Policy in 2010, and Lagos State an Adaptation Strategy in 2012 (BNRCC, 2012). Adaptation has been integrated into five district development plans in Ghana, and Morocco's government has approved four communal climate change resilience plans (Corsi et al., 2012). Promising approaches include sub-national strategies that integrate adaptation and mitigation in a low-carbon climate resilient development approach, as is being done in Delta State in Nigeria, Mbale Region in Uganda, and several regions in Senegal, with similar plans for regions of Kenya, South Africa, Burkina Faso, Ivory Coast, Namibia and Egypt (UNDP, 2011b). In response to the identified institutional weaknesses, capacity development has been implemented in many cities and towns, including initiatives in Lagos, Nigeria, Durban and Cape Town in South Africa: notable examples include Maputo's specialized local government unit to implement climate change response, ecosystem-based adaptation and improved city wetlands; and participatory skills development in integrating community-based disaster risk reduction and climate adaptation into local development planning in Ethiopia (Madzwamuse, 2010; ACCRA, 2012; Broto, Vaesa, et al. 2013).

22.4.4.5. Community-Based Adaptation

Since AR4, there has been considerable progress in Africa in implementing and researching community-based adaptation (high confidence), with broad agreement that support to local-level adaptation is best achieved by starting with existing local adaptive capacity, and incorporating and building upon present coping strategies, including indigenous practices (Archer et al, 2008; Dube & Sekhwela, 2007; Huq, 2011). Some relevant initiatives include the Community-based Adaptation in Africa (CBAA) project, which supported three-year climate change adaptation pilot projects at community level in eight African countries (Sudan, Tanzania, Uganda, Zambia, Malawi, Kenya, Zimbabwe, South Africa), implemented as a learning-by-doing approach; and the Adaptation Learning Program, implemented in Ghana, Niger, Kenya and Mozambique (Care International, 2012). The literature includes a wide range of case studies detailing involvement of local communities in adaptation initiatives and projects facilitated by NGOs and researchers (for example, Leary et al, 2008; CCAA, 2011; Care International, 2012); these and other initiatives have generated process-related lessons (section 22.4.5), with positive assessments of effectiveness in improving adaptive capacity of African communities, local organisations and researchers (Lafontaine et al, 2012). Local adaptation planning using participatory scenario development workshops in Mozambique, Ghana, and Ethiopia has revealed the following priorities for pro-poor adaptation: social protection, services and safety nets; better water and land governance; enhanced water storage and harvesting; better post-harvest services; strengthened civil society and greater involvement in planning; and more attention to urban and peri-urban areas heavily affected by migration of poor people (Bizikova et al, 2010).

22.4.4.6. Adaptation Decisionmaking and Monitoring

Emerging patterns regarding adaptation decision-making in Africa include limited inclusive governance at the national level, while some local level initiatives have achieved greater involvement, including of vulnerable and exposed people, in assessing and choosing adaptation responses (high confidence). Civil society institutions and communities have to date played a limited role in formulation of national adaptation policies and strategies, highlighting the need for governments to widen the political space for citizens and institutions to participate in decision-making, for both effectiveness and to ensure rights are met (Madzwamuse, 2010; Castro et al, 2012).

Building African leadership for climate change may assist with this (Climate Change Adaptation in Africa Programme, 2011; Chandani, 2011; Corsi et al., 2012). A critical issue is how planning and decision making for adaptation uses scientific evidence and projections, while also managing the uncertainties within the projections (Dodman and Carmin, 2011; Conway, 2011). The importance of understanding how local knowledge forms the "knowledge frame" through which scientific forecasts are interpreted has been emphasised (Roncoli *et al*. 2009; Ifejika Speranza *et al*., 2010; Newsham and Thomas, 2011).

The range of tools used in adaptation planning in Africa includes vulnerability assessment using various mapping techniques (section 22.4.5), risk assessment, cost-benefit analysis, cost-effectiveness, multi-criteria analysis, and participatory scenario planning. In Ghana, the Akropong Approach was developed to assess inter-relationships between sectoral adaptation options; multi-criteria analysis was used to evaluate and rank the options in the development of the National Climate Change Adaptation Strategy (Kemp-Benedict and Agyemang-Bonsu, 2008). Cost-benefit analysis was used to inform water management decisions for the Berg River basin in South Africa (Callaway et al, 2008) and in uplands of The Gambia to evaluate increased fertilizer use against adoption of irrigation in cereal cultivation (Njie et al, 2008). Adaptation decision making in the coastal zone in South Africa has encompassed cost benefit analysis decision tools, and modeling and mapping the combined effects of sea level rise and coastal storm surge (Cartwright *et al*., 2008; Mather and Stretch, 2012). Innovative approaches include using participatory scenario planning in Ghana and Kenya (CARE, 2012), and developing an online interactive disaster management decision support system as part of the national adaptation response in Mozambique (Corsi et al., 2012).

Monitoring and assessing adaptation is still in its infancy in Africa, with national coordinating systems for collating data and synthesizing lessons not in place. Local-level monitoring of adaptation actions takes place at the project level: a positive community-based adaptation example in the Koue Bokkeveld, South Africa, approaches monitoring through a participatory action research framework, combined with integrating climate projections, local monitoring of climate variables and collaborative assessment of coping/adaptation actions (Archer et al., 2008).

22.4.5. Experiences with Adaptation Measures in Africa and Lessons Learned

22.4.5.1. Overview

Section 22.4.5 provides a cross-cutting assessment of experience gained in Africa with a range of adaptation approaches, encompassing climate risk reduction measures; processes for participatory learning and knowledge development and sharing; communication, education and training; ecosystem-based measures; and technological and infrastructural approaches; concluding with a discussion of maladaptation.

Common priority sectors across countries for implementing adaptation measures since 2008 include agriculture, food security, forestry, energy, water, and education (Corsi et al., 2012), which reflect a broadening of focus since the AR4. While there has been little planning focus on regional adaptation (Sections 22.4.4.2 and 22.4.4.3), the potential has been recognized for regional approaches to adaptation, such as the West African program on coastline change and adaptation (Niang, 2012) and the Congo Basin Forest and Climate Change Adaptation initiative (Sonwa et al., 2009) to catalyze effective collaboration between African countries (UNFCCC, 2007).

Research has highlighted that no single adaptation strategy exists to meet the needs of all communities and contexts in Africa (high confidence). In recognition of the socioeconomic dimensions of vulnerability (Bauer and Scholz, 2010), the previous focus on technological solutions to directly address specific impacts is now evolving toward a broader view that highlights the importance of social, institutional, policy, knowledge, and informational approaches (African Development Forum, 2010; Chambwera and Anderson, 2011), and on linking the diverse range of adaptation options to the multiple livelihood–vulnerability risks faced by many people in Africa (Tschakert and Dietrich, 2010) . 'Soft path' measures are seen as holding promise for adaptation strategies (Martens et al., 2009).

Attention is increasing on identifying opportunities inherent in the continent's adaptation needs, as well as delineating key success factors for adaptation. A number of studies identify the opportunity inherent in implementing relatively low-cost and simple low-regrets adaptation measures that reduce people's vulnerability to

current climate variability, have multiple developmental benefits, and are likely to reduce vulnerability to longer-term climate change as well (UNFCCC, 2007; Conway and Schipper, 2011; see also Section 22.4.3). Responding to climate change provides an opportunity to enhance awareness that maintaining ecosystem functioning underpins human survival and development in a most fundamental way (Shackleton and Shackleton, 2011), and to motivate for new development trajectories (section 22.4.6). While it is difficult to assess adaptation success, given temporal and spatial scale issues, and local specificities, Osbahr et al. (2010) highlight the role of social networks and institutions, social resilience, and innovation as possible key success factors for adaptation in small-scale farming livelihoods in southern Africa.

The following discussion of adaptation approaches under discrete headings does not imply that these are mutually exclusive – adaptation initiatives usually employ a range of approaches simultaneously.

22.4.5.2. Climate Risk Reduction, Risk Transfer, and Livelihood Diversification

African countries have gained experience in a range of approaches to offset the impacts of natural hazards on individual households, communities, and the wider economy, through the following risk reduction strategies: early warning systems, emerging risk transfer schemes, social safety nets, disaster risk contingency funds and budgeting, livelihood diversification, and migration as an adaptive response (World Bank, 2010; UNISDR, 2011). Figure 22-7 shows an assessment of Africa's present and near term risks and risks at the end of the century for 2 temperatures (2°C and 4°C for 2080-2100), and the role of adaptation in reducing those risks.

[INSERT FIGURE 22-7 HERE
Figure 22-7: Risks for the present (blue line), for the near-term (2°C for 2030-2040) and for the end of the century for 2 temperatures (2°C and 4°C for 2080-2100). Risks are depicted for low adaptation and high adaptation.]

Disaster risk reduction (DRR) platforms are being built at national and local levels (Westgate, 2010), with the synergies between DRR and adaptation to climate change being increasingly recognized in Africa (UNISDR, 2011). At the policy level, the shift toward more proactive risk management can be seen in Ethiopia's updated Disaster Risk Management policy, which also emphasizes decentralized and community-based actions (Hunde, 2012), although Conway and Schipper (2011) find that additional effort is needed for a longer-term vulnerability reduction perspective in disaster management institutions.

Early warning systems (EWS) are gaining prominence as multiple stakeholders strengthen capabilities to assess and monitor risks and warn communities of a potential crisis. The operation of regional systems such as the Permanent Inter-States Committee for Drought Control in the Sahel (CILSS) and the Famine Early Warning System Network (FEWS-NET) are seen as crucial for adaptation (Sissoko et al., 2011) . National, local, and community-based EWS on food and agriculture, such as in Niger, Mauritania, Ethiopia, and Burkina Faso, aim to support an effective response to food, nutritional, and pastoral crises (FAO, 2012; Pantuliano and Wekesa 2008). Some of the recent EWS emphasise a gendered approach, and may incorporate local knowledge systems used for making short-, medium-, and long-term decisions about farming and livestock-keeping, as in Kenya (UNDP, 2011). In the health sector, EWS that have employed weather forecasting to predict disease have also been used for adaptation planning and implementation. For example, conditions expected to lead to an outbreak of Rift Valley fever were predicted and a 2 to 6 week warning provided, prior to the occurrence in the Horn of Africa from December 2006 to May 2007(Ayamba, 2006), and progress has been made in prediction of meningitis and in linking climate/weather variability and extremes to the disease, which will be useful in adaptation planning and implementation (Thomson et al., 2006: Cuevas et al., 2007; Irving et al., 2011).

Local projects often use participatory vulnerability assessment methods in the design of adaptation activities (Van Vliet, 2010; GEF Evaluation Office, 2011), but vulnerability assessment at the local government level is often lacking, and assessments to develop national adaptation plans and strategies have not always been conducted in a participatory fashion (Madzwamuse, 2010). Lessons from vulnerability analysis highlight that the highest exposure and risk do not always correlate with vulnerable ecosystems, socially marginalized groups, and areas with at-risk infrastructure, but may also lie in unexpected segments of the population (Moench, 2011).

Various community-level DRR initiatives have focused on resilience-building activities that highlight the links between strengthening food security and household resilience, and delivery of environmental conservation, asset creation, and infrastructure development objectives and co-benefits (Parry et al., 2009b; UNISDR, 2011; Frankenberger et al., 2012). Food security and nutrition-related safety nets and social protection mechanisms can mutually reinforce each other to enhance disaster risk management and climate adaptation, as is being carried out in the Karamoja Productive Assets Programme in Uganda (Government of Uganda and WFP 2010; WFP, 2011). Initiatives in Kenya, South Africa, Swaziland, and Tanzania have also sought to deploy local and traditional knowledge for the purposes of disaster preparedness and risk management (Galloway Mclean, 2010; Mwaura, 2008). Haan et al. (2012) highlight the need for increased donor commitment to the resilience-building agenda within the framework of DRR, based on lessons from the Somalia 2011 famine.

Implementation of effective national and local instruments to offset the impact of natural hazards in Africa, notably concerning social protection and insurance, has been increased. Social protection, a key element of the African Union social policy framework, can include social transfers (cash or food), minimum standards such as for child labor, and social insurance, and is being used in Ethiopia, Rwanda, Malawi, Mozambique, South Africa, and other countries to buffer against the impacts of shocks and disasters by building assets and increasing household resilience of both chronically and transiently poor people (Brown et al., 2007; Heltberg et al. 2009). Examples of social protection systems aimed at moving beyond repeated relief interventions to address *inter alia* slower onset climate shocks are Ethiopia's Productive Safety Net Program (PSNP), the largest social protection program in Africa (Brown et al., 2007), and Rwanda's Vision 2020 Umurenge Program (VUP). There is evidence that social protection is helping with *ex post* and *ex ante* DRR, and that such systems will be increasingly important as a safety net and for securing livelihoods under increasing climate variability, but less evidence exists for the effectiveness of social protection against the most extreme climatic shocks, which requires adaptive strategies that reduce dependence on climate sensitive livelihood activities (Davies et al., 2009; Wiseman et al., 2009; Pelham et al., 2011; Béné et al., 2012). Social protection initiatives could contribute more to building adaptive capacity if based on improved understanding of the structural causes of poverty, including political interests and institutional dimensions (Brown et al., 2007; Davies et al., 2009; Levine et al., 2011).

A number of different mechanisms are used by communities and individuals to spread risk in the African context: kinship networks; community funds; and disaster relief and insurance, which can provide financial security against extreme events such as droughts, floods, and tropical cyclones, and concurrently reduce poverty and enhance adaptive capacity[8] (Leary et al., 2008; Linnerooth-Bayer et al. 2010; Coe and Stern, 2011). Contingency planning at national and local levels, for example for drought, is an important element of risk reduction processes, although this may be hampered by not being linked to sustainable contingency funds (Lesukat, 2012). In Ethiopia, an integrated national risk management framework is being developed through the Livelihoods, Early Assessment and Protection (LEAP) project, an innovative early warning–early action tool that supports the PSNP, including a US$ 160 million contingency fund, which will promote drought risk management. Recent developments in the insurance sector in Africa include the emergence of index-based insurance contracts (Box 22-1), which pay out not with the actual loss, but with a measurable event that causes loss.

[FOOTNOTE 8: Climate (or disaster) risk financing instruments include contingency funds; agricultural and property (private) insurance; sovereign insurance; reallocation of program expenditures; weather derivatives; and bonds.]

_____ START BOX 22-1 HERE _____

Box 22-1. Experience with Index-Based Weather Insurance in Africa

Malawi's initial experience of dealing with drought risk through index-based weather insurance directly to smallholders appears positive: 892 farmers purchased the insurance in the first trial period, which was bundled with a loan for groundnut production inputs (IRI 2009). In the next year, the pilot expanded, with the addition of maize, taking numbers up to 1,710 farmers and stimulating interest among banks, financiers, and supply chain participants such as processing and trading companies and input suppliers. A pilot insurance project in Ethiopia was designed to

pay claims to the government based on a drought index that uses a time window between observed lack of rain and actual materialization of losses. This allows stakeholders to address threats to food security in ways that prevent the depletion of farmers' productive assets, which reduces the future demand for humanitarian aid by enabling households to produce more food during subsequent seasons (Krishnamurty 2011). Another key innovation in Ethiopia is the insurance for work program that allows cash-poor farmers to work for their insurance premiums by engaging in community-identified disaster risk reduction products, such as soil management and improved irrigation (WFP 2011), which makes insurance affordable to the most marginalized and resource-poor sectors of society.

_____ END BOX 22-1 HERE _____

The challenges associated with current risk reduction strategies include communication challenges related to EWS: conveying useful information in local languages; communicating EWS in remote areas; national-level mistrust of locally collected data, which are perceived to be inflated to leverage more relief resources (Hellmuth et al., 2007; Pantuliano and Wekesa, 2008; Cartwright, 2008b; FAO, 2011); the call for improved user-friendliness of early warning information; and the need for better linkages between early warning, response, and prevention (Haan et al., 2012).

Evidence is increasing that livelihood diversification, long used by African households to cope with climate shocks, can also assist with building resilience for longer term climate change by spreading risk. Over the past 20 years, households in the Sahel have reduced their vulnerability and increased their wealth through livelihood diversification, particularly when diversifying out of agriculture (Mertz et al., 2011). Households may employ a range of strategies, including on-farm diversification or specialization (Sissoko et al., 2011; IIED, 2011a). Motsholapheko et al. (2011) show how livelihood diversification is used as an adaptation to flooding in the Okavango Delta, Botswana, and Badjeck et al. (2010) recommend private and public insurance schemes to help fishing communities rebuild after extreme events, and education and skills upgrading to enable broader choices when fishery activities can no longer be sustained..

While livelihood diversification is an important adaptation strategy, it may replace formerly sustainable practices with livelihood activities that have negative environmental impacts (Section 23.4.5.8). Diversification at the national level is also required, especially where there is dependence on a single cash crop, such as cocoa cultivation in Ghana, which is highly vulnerable to the negative effects of climate change (UNFCCC, 2007).

Rural finance and micro-credit are seen as enabling activities for adaptive response, which are also used by women for resilience-building activities (e.g., as documented in Sudan by Osman-Elasha et al., 2006). Credit and storage systems are instrumental to support families during the lean period, to prevent the sale of assets to buy food when market prices are higher (Romero Gonzalez et al., 2011). Long seen as a fundamental process for most African families to incorporate choice into their risk profile and adapt to climate variability (Goldstone, 2002; Urdal, 2005; Reuveny, 2007; Fox and Hoeshler, 2010), there is evidence in some areas of the increased importance of migration and trade for livelihood strategies, as opposed to subsistence agriculture, as shown by Mertz et al. (2011) for the Sudano-Sahelian region of West Africa. Migration involves complex decision making and often supports adaptation to climate change, and may unlock diverse and innovative responses through the role of migrant social institutions (Scheffran et al., 2011; McLeman and Smit, 2006; Scheffran et al., 2012). However, climate-forced migration can exacerbate environmental degradation (e.g., on the Sahel margins) and accelerate land use changes with potential feedbacks to local climate, which can in return increase vulnerability (citations).

22.4.5.3. Adaptation as a Participatory Learning Process

Since AR4, there has been more focus on the importance of flexible and iterative learning approaches for effective adaptation (medium evidence, medium agreement). Learning approaches under investigation in Africa include action research, participatory adaptation planning, and adaptive management. Due to the variety of intersecting social, environmental, and economic factors that affect societal adaptation, governments, communities, and individuals (Jones et al., 2010; Jones 2011), adaptation is increasingly recognized as a complex process involving multiple linked steps at several scales, rather than a series of simple planned technical interventions (Moser and

Ekstrom 2010). Implementing adaptation as a participatory learning process enables people to adopt a proactive or anticipatory stance to avoid 'learning by shock' (Tschakert and Dietrich, 2010).

A number of adaptation initiatives in Africa emphasize the importance of iterative and experiential learning for a flexible adaptation planning, required to deal with the uncertainty inherent in climate projections, compounded by other sources of flux that affect populations in Africa, and the desirability of adjusting approaches based on lessons learned, through a participatory learning-by-doing or experiential learning modality (Suarez et al., 2008; Koelle and Annecke, undated; Dodman and Carmin, 2011; Huq, 2011). Many studies have highlighted the utility of participatory action research, multi-stakeholder dialogue, and experiential learning for managing uncertainty and leading to the social and behavioral change required for adaptation (e.g., Ziervogel and Opere, 2010; Bizikova et al., 2010); CCAA, 2011; Ebi et al., 2011; Faysse et al., 2012; Thorn, forthcoming). Transdisciplinary approaches are also starting to be adopted, as for example in the urban context (Evans, 2011). Learning approaches for adaptation may involve co-production of knowledge – such as combining local and traditional knowledge with science (Section 22.4.5.4).

Recent analyses highlight the importance of social learning and collective action to promote adaptation, and the need to create safe or enabling spaces for multi-stakeholder civic engagement for the adaptation learning process (UNDP/UNEP Poverty-Environment Initiative, 2011a; Tompkins and Adger, 2003). Based on work in Ghana, Tschakert and Dietrich (2010) propose creating learning spaces for iterative learning-by-doing to promote anticipatory adaptation, drawing together learning and principles from both resilience thinking and action research/learning from a dynamic systems perspective. Plummer (2012) points out the potential for adaptive co-management[9] to develop capacity to deal with change, which is relevant for climate change adaptation. Some experience is being gained on the implications of the strategic adaptive management approach for adaptation in aquatic protected areas in South Africa (Kingsford et al., 2011).

[FOOTNOTE 9: Adaptive co-management is understood as "a process by which institutional arrangements and ecological knowledge are tested and revised in a dynamic, ongoing, self-organized process of learning-by-doing" (Folke et al., 2002).]

Caveats and constraints to viewing adaptation as a participatory learning process include the time and resources required from both local actors and external facilitators, the challenges of multidisciplinary research, the politics of stakeholder participation and the effects of power imbalances, and the need to consider not only the consensus approach but also the role of conflicts (Tschakert and Dietrich 2010; Aylett, 2010; Shankland and Chambote, 2011; Jobbins, 2011; Beardon and Newman, 2011). Learning throughout the adaptation process necessitates additional emphasis on ways of sharing experiences between communities and other stakeholders, both horizontally and vertically (Section 22.4.5.4).

The increased emphasis on the importance of innovation for successful adaptation, in both rural and urban contexts, relates to interventions that employ innovative methods, as well as the innovation role of institutions (Tschakert and Dietrich, 2010; Scheffran et al., 2012; Dodman and Carmin, 2011; Rodima-Taylor, 2012). While relevant, high-quality data is important as a basis for adaptation planning, innovative methods are being used to overcome data gaps, particularly local climatic data and analysis capability (Tschakert and Dietrich, 2010; GEF Evaluation Office, 2011). Scheffran et al. (2012) show the role of institutional innovation triggered by migration in response to climate threats in the western Sahel, in which communities and migrants are seen as active social agents, with migrant social organizations initiating innovations across regions by transferring technology and knowledge, as well as remittances and resources. Innovative indigenous adaptation measures on the part of Niger Delta communities are documented by Nzeadibe et al. (2012).

22.4.5.4. Knowledge Development and Sharing

Since AR4, attention to the importance of knowledge development and sharing for enhancing adaptation responses has increased. Key areas investigated include bridging the gap between scientific knowledge and policy; the potential of local and traditional knowledge for informing climate risk management in Africa; and developing multi-

stakeholder platforms for knowledge sharing, including regional collaboration**.** Recent literature has confirmed the positive role of local and traditional knowledge in building resilience and adaptive capacity, and shaping responses to climatic variability and change in Africa. Despite this utility, many argue that local knowledge should not be reduced to a technical input for adaptation planning processes and science frameworks (Berkes, 2002; Harvey, 2009; Kronik and Verner, 2009).

Because adaptation in most African contexts is autonomous, choosing specific adaptation actions needs to be informed by farmer's perceptions and be supported by accurate climate information, relevant to the scale where decisions are made (Vogel and O'Brien, 2006; Ziervogel et al., 2008; Bryan et al., 2009; Godfrey et al., 2010). Key problems regarding how science can inform decisionmaking and policy are how best to match scientific information, for example about uncertainty of change, with decision needs; how to tailor information to different constituencies; what criteria to use to assess whether or not information is legitimate to influence policy and decisionmaking; and how to support scientists to provide information that is accessible by practitioners (Vogel et al., 2007; Hirsch Hadorn et al., 2008). Institutional innovation is one solution: for example, Nigeria established the Science Committee on Climate Change to develop strategies to bridge the gap between increasing scientific knowledge and policy to support Nigeria's goals of economic transformation (Corsi et al., 2012).

Interest is increasing and information is growing on the potential of local and traditional knowledge for informing climate risk management in Africa, particularly at the community scale, where there may be limited access to, quality of, or ability to use scientific information. The recent report on extreme events and disasters (IPCC, 2012) supports this view, finding high agreement and robust evidence of the positive impacts of integrating indigenous and scientific knowledge for adaptation. Local knowledge continues to play an important role in adaptation to climate variability and change in Africa, helping communities to select the most appropriate adaptive or coping mechanisms (Nyong et al., 2007; Osbahr et al., 2007; Ifejika Speranza et al., 2010; Goulden et al., 2009b; Jalloh and Roy-Macauley, 2011; Newsham and Thomas, 2011). Concerns about the future adequacy of local knowledge to respond to climate impacts within the multi-stressor context include the decline in intergenerational transmission; a perceived decline in the reliability of local indicators for variability and change, as a result of socio-cultural, environmental, and climate changes (Hitchcock 2009; Jennings and Magrath 2009); and challenges of the emerging and anticipated climatic changes seeming to overrun indigenous knowledge and coping mechanisms of farmers (Berkes, 2009; Ifejika Speranza et al., 2010; Jalloh and Roy-Macauley, 2011). Based on analysis of the responses to the Sahel droughts during the 1970s and 1980s, Mortimore (2010) argues that local knowledge systems are more dynamic and robust than what is often acknowledged.

Linking indigenous and conventional climate observations can add value to climate change adaptation within different local communities in Africa (Nyong et al., 2007; Chang'a et al., 2010; Roncoli et al., 2002). In Western Kenya, scientists work with local rainmakers to develop consensus forecasts, developed by harmonizing downscaled seasonal forecasts with traditional predictions, which are then disseminated in local languages by radio and at community events (Guthiga and Newsham, 2011). A key question is the extent to which local observations correspond to scientific records, with some literature pointing to strong agreement (West et al. 2008 in Burkina Faso) while other studies find weaker correlation (Rao et al. 2011; Osbahr et al., 2011).

Evidence is growing of the importance of multi-stakeholder platforms for sharing experiences and developing collaborative adaptation responses. Drawing on a transboundary project in the Congo Basin, Tata et al. (2012) highlight the importance of encouraging and monitoring multi-actor negotiation and collaboration processes in order to infer and mitigate future complexities in the process. In Kenya and Ghana, participatory scenario planning has been used as a multi-stakeholder platform for adaptation dialogue, and has been effective in achieving local ownership of flexible adaptation decisionmaking, including through improved relationships between local actors and meteorologists (CARE, 2012).

Knowledge sharing between the many innovative adaptation management programs and projects in Africa is hampered by the lack of platforms to share knowledge on adaptation practices within and between countries. While knowledge management in adaptation interventions has evolved (AAP, 2012), and includes a number of web-based platforms, more comprehensive and proactive systems for knowledge sharing are needed, including institutionalized platforms at the national level (GEF Evaluation Office, 2011).

There is agreement that culture – shaping social norms, values, and rules including those related to ethnicity, class, gender, health, age, social status, cast, and hierarchy – is of crucial importance for adaptive capacity. Culture is important both as a positive attribute but also as a barrier to successful adaptation at the local level, as well as being important in defining who will lose and who will win from adaptation. However, further research is required in this field, not least because culture is highly heterogeneous within a society or locality (Adger et al., 2007, 2009; Ensor and Berger, 2009; Nielsen and Reenberg, 2010; Jones, 2011).

Studies show that integrating cultural components such as stories, myths, and oral history into initiatives to document local and traditional knowledge is a key to better understanding how climate vulnerability and adaptation are framed and experienced (Urquhart, 2009; Ford et al.,.2011; Beardon and Newman, 2011). Nielsen and Reenberg (2010) found that in Northern Burkina Faso, issues of social prestige and cultural identity prevent upper-caste households from engaging in adaptive strategies, such as labor migration, employment with development projects, dry season gardening, and women's income-generation activities. Further, while traditional knowledge may hold significant adaptive and broader social value, it may also be closely guarded or selectively transmitted, limiting women's adaptive capacity in many parts of Africa (Davis, 2010; Roncoli et al., 2009; see also section 22.4.5.9).

Extraction of local and traditional knowledge from the social context that gives it meaning and legitimacy may expose it to the risk of being misunderstood, misused, or misappropriated (McGregor, 2004). To avoid these pitfalls and realize beneficial synergies of local and scientific knowledge, appropriate and equitable processes of participation and communication between scientists and local people are required (Nyong et al., 2007; Orlove et al., 2010; Crane, 2010).

22.4.5.5. Communication, Education, and Training

Enhanced support for communication, education, and training is required to raise awareness and empower people to understand the manifestations of climate change and for behavioral change. Systemic causes of knowledge gaps have been identified in parliamentarian's understanding of climate threats and responses, such as limited access to parliamentary researchers and even to the internet (IIED, 2011b). There has been additional experience with civil society-driven approaches to advocacy and raising awareness about climate change and the need for adaptation (Reid et al., 2010; CCAA, 2011), with examples including youth ambassadors in Lesotho and civil society organizations in Tanzania (Corsi et al., 2012). Some evidence exists of the effectiveness of children as communicators and advocates for behavioral and policy change for adaptation to climate change (Section 22.4.3).

Capacity development to enhance understanding of climate impacts and adaptation measures has been undertaken by a range of institutions, such as regional and national research institutes, international and national programs and non-governmental organizations, and agencies of the United Nations (UNFCCC, 2007; START, 2011). Training and capacity development components are usually included in most adaptation interventions, sometimes within a gender-sensitive approach, and targeting youth (e.g., Figueiredo and Perkins, 2012). However, progress on inclusion of climate change into formal education is mixed. A number of countries have integrated climate change into educational curricula to increase awareness, while in Nigeria, climate change adaptation is becoming an educational priority (UNFCCC, 2007; Corsi et al., 2012), and this has been pursued through project-level approaches. However, integration of climate change into educational curricula occurs within the relatively low priority given to environmental and sustainable development education in most countries, as documented for the SADC (Mukute et al., 2012).

Innovative methods are being used to understand and communicate climate change: photo stories, oral history videos, drama, radio, television, festivals, involvement of youth, the use of participatory video in communicating community-based adaptation within and between communities, and influencing policy decisions. Harvey (2011) showed the usefulness of public education using community radio, video, and participation approaches to provide information about community-level adaptation initiatives, while Chikapa (2012) found that radio, cinema, and vernacular publications were critically important in enhancing community-based adaptation to climate change in Malawi. In Malawi and Mozambique, video and participatory approaches increased the accessibility of health risk

management to local decisionmakers (Suarez et al., 2008). The role of the media in communication and awareness raising has been highlighted, including through a media capacity building project across 20 countries (Corsi et al., 2012).

Considerable effort is still required to raise awareness of the diverse range of stakeholders at all levels on the different aspects of climate change (Niang, 2007; Simane et al., 2012). Better evidence-based communication processes will enhance awareness of climate change and available responses for both policymakers and community-level development workers. This requires bringing together multiple users and producers of both scientific and local knowledgein a trans-disciplinary process (Hirsch Hadorn et al., 2008; Koné et al., 2012; Ziervogel et al., 2008) to achieve a better understanding of the dimensions of the problem, including its multiple causes and political context (Vogel et al., 2007).

22.4.5.6. Ecosystem Services, Biodiversity, and Natural Resource Management

There is increasing evidence that Africa's longstanding experiences with natural resource management and utilization of biodiversity can be harnessed for effective adaptation responses (high confidence). Relevant experiences include using mobile grazing to deal with both spatial and temporal rainfall variability in the Sahel (Djoudi et al., 2012); reducing the negative impacts of drought and floods on agricultural and livestock-based livelihoods through forest goods and services in Mali, Tanzania, and Zambia (Robledo et al., 2011); ensuring food security and improved livelihoods for indigenous and local communities in West and Central Africa through the rich diversity of plant and animal genetic resources (Jalloh and Roy-Macauley, 2011). Different ecosystem-based responses of value for reducing vulnerability include coastal and inland afforestation, rangeland regeneration, catchment rehabilitation, community forestry, and other forms of community-based natural resource management (CBNRM).

The responsibility placed on local stakeholder institutions for CBNRM, which enables a more flexible response to changing climatic conditions, embodies a supportive approach for local adaptation strategies; CBNRM is also a vehicle for for improving links between ecosystem services and poverty reduction, to enable sustainable adaptation approaches (Shackleton et al., 2010; Chishakwe et al, 2012; Girot et al, 2012). Forests provide valuable safety nets for women: when drought affects agriculture, vulnerable women in many African countries assure their livelihoods by using different forest products such as charcoal and non-timber forest products (Brown, 2011; Paavola, 2008). Based on an analysis of lessons learned in Botswana, Malawi, Mozambique, Namibia, Tanzania, Zambia and Zimbabwe, Chishakwe et al (2012) point out the synergies between CBNRM and adaptation at the community level.

Natural resource management practices that address desertification can also serve as adaptation measures by improving the resilience of ecosystems and people to long-term changes in climate. Two dual-benefit practices that have become widespread in Africa are natural regeneration of local trees (Box 22-2) and water harvesting. Water harvesting practices[10] have increased soil organic matter, improved soil structure, and increased agricultural yields at sites in Burkina Faso, Mali, Niger, and elsewhere, and are used by 60% of farmers in one area of Burkina Faso (Fatondji et al., 2009; Vohland and Barry, 2009; Barbier et al., 2009; Larwanou and Saadou, 2011). Although these and other practices serve as adaptations to climate change, revenue generation and other concerns may outweigh climate change as a motivating factor in their adoption (Nielsen and Reenberg, 2010; Mertz et al., 2009). While destocking of livestock during drought periods may also address desertification and adaptation, the lack of individual incentives to destock and other cultural barriers inhibit their widespread adoption in the Sahel (Hein et al., 2009; Nielsen and Reenberg, 2010).

[FOOTNOTE 10: Water harvesting refers to a collection of traditional practices in which farmers use small planting pits, half-moon berms, rock bunds along contours, and other structures to capture runoff from episodic rain events (Kandji et al., 2006).]

_____ START BOX 22-2 HERE _____

Box 22-2. African Success Story: Integrating Trees into Annual Cropping Systems

Recent success stories from smallholder systems in Africa illustrate the potential for transforming degraded agricultural landscapes into more productive, sustainable, and resilient systems through the integration of trees into annual cropping systems. Trees in croplands reduce exposure of crops to wind and heavy rainfall, enhance moisture retention and rainwater capture, increase yields of grain crops, and expand livelihoods through production of fruits, animal fodder, and fuelwood. For example, in Zambia and Malawi, an integrated strategy for replenishing soil fertility on degraded lands, which combines planting of nitrogen-fixing *Faidherbia* trees with small doses of mineral fertilizers, has consistently more than doubled yields of maize leading to increased food security and greater income generation (Garrity et al., 2010). In the Sahel, natural regeneration, or the traditional selection and protection of small trees to maturity by farmers and herders has, perhaps for centuries, produced extensive parks of *Acacia albida* (winter thorn) in Senegal (Lericollais, 1989), *Adansonia digitata* (baobab) in West and southern Africa (Sanchez et al., 2011), and *Butyrospermum parkii* (Shea butter) in Burkina Faso (Gijsbers et al., 1994). Recent natural regeneration efforts have increased tree density and species richness at locations in Burkina Faso (Ræbild et al., in press) and Niger (Larwanou and Saadou, 2011), though adoption and success is somewhat dependent on soil type (Haglund et al., 2011; Larwanou and Saadou, 2011). In southern Niger, farmer-managed natural regeneration of *Faidherbia albida* and other field trees, which began in earnest in the late 1980s, has led to large-scale increase in tree cover across 4.8 million ha, and to decreased sensitivity to drought of the production systems, compared to other regions in Niger (Reij et al., 2009; Tougiani et al., 2009; Sendzimir et al., 2011). Devolvement of tree ownership from the state to the farmer catalysed farmer-managed natural regeneration, which has subsequently spread through community-based efforts, including partnerships between farmers and NGOs, improving food security while reducing exposure to climate risks.

_____ END BOX 22-2 HERE _____

Intact ecosystem services and biodiversity are recognized as critical components of successful human adaptation to climate change that may be more effective and incur lower costs than 'hard' or engineered solutions, and are often the first line of defence for poor people in Africa (Abramovitz et al., 2002; Petersen and Holness, 2011; UNDP/UNEP Poverty-Environment Initiative, 2011a; Girot et al, 2012; Pramova et al, 2012; Box 22-2). This understanding provides a compelling reason for linking biodiversity, developmental, and social goals, which is taken up in some NAPA projects that aim to support local livelihoods through ecosystem services provision that explicitly contributes to adaptation; for instance, Djibouti targets mangrove restoration to reduce salt water intrusion and coastal production losses due to climate hazards (Pramova et al., 2012).

Differentiation in the literature is growing, particularly in the field of integrated water resources management, between 'hard path' and 'soft path' approaches to adaptation (Sovacool, 2011; Kundzewicz, 2011), with 'soft path' approaches – for example, using intact wetlands for flood risk management, sometimes equated with 'low regrets' approaches to adaptation, as contrasted with 'hard path' approaches like embankments and dams for flood control (International Rivers Network, 2007; Kundzewicz, 2011). While ecosystem-based adaptation (EbA) is an emerging global concept, ecosystem-based strategies are not new in many African local contexts (Figure 22-8). There has been additional experience in Africa with flood risk management as an adaptive response, based on the protection of natural infrastructure such as forests in watersheds and on floodplains, more efficient resource use, better power and water sector planning, decentralized technologies such as rainwater harvesting, and power generation from geothermal, wind, solar, and sustainable biomass sources, as well as small and unconventional hydropower technologies (e.g., kinetic 'free-flow' turbines and wave and tidal power) (citations).

[INSERT FIGURE 22-8 HERE
Figure 22-8: Ecosystem-based adaptation - Farmer Managed Natural Regeneration (FMNR): Benefits of ecosystem management for livelihoods and resilience (Garrity et al. 2010; Haglund et al. 2011; Reij et al. 2009; Sendzimir et al. 2011).]

Despite the evidence from studies cited in this section, scaling-up to prioritize ecosystem responses and EbA in plans and policy has been slow. Additional efforts will be required for a broad understanding that EbA is an integral component of the developmental agenda, rather than a competing 'green' agenda. Adaptive environmental governance represents one of the future challenges for the implementation of EbA strategies in Africa, together with sustainable use of resources, secure access to meet needs under climate change, and strong local institutions to enable this (Robledo et al., 2011). Ecosystem-based adaptation could be an important approach to consider for the globally significant Congo Basin forests, particularly given the predominance of REDD+ approaches for this region that risk neglecting adaptation responses (Somorin et al., 2012; Sonwa et al., 2012).

22.4.5.7. Technological and Infrastructural Adaptation Responses

Since AR4, experience has been gained on technological and infrastructural adaptation, with an emphasis on options being used in agricultural and water management responses, and for climate-proofing infrastructure, which has encompassed construction of submersible roads, raising homesteads, retrofitting or designing buildings, and building sea and flood defenses.

Evidence has increased since the AR4 that farmers are changing their production practices in response to increased food security risks linked to climate change and variability. Examples include planting cereal crop varieties that are better suited to shorter and more variable growing seasons (Akullo and Kanzikwera, 2007, Laube et al., 2012; Thomas et al., 2007; Yaro, 2010; Yesuf et al., 2008), constructing bunds to more effectively capture rainwater and reduce soil erosion (Nyssen et al., 2007; Reij et al., 2009; Thomas et al., 2007), reduced tillage practices and crop residue management to more effectively bridge dry spells (Marongwe, 2011; Ngigi et.al., 2006), and adjusting planting dates to match shifts in the timing of rainfall (Abou-Hadid, 2006; Vincent et al., 2011).

Conservation agriculture has good potential to both bolster food production and enable better management of climate risks (Kassam et al., 2012; Syampungani et al., 2010; Thierfelder and Wall, 2010; Thomas, 2008; Verschot et al., 2007). Such practices, which include conservation/zero tillage, soil incorporation of crop residues and green manures, building of stone bunds, agroforestry, and afforestation/reforestation of croplands, reduce runoff and protect soils from erosion, increase rainwater capture and soil water-holding capacity, replenish soil fertility, and increase carbon storage in agricultural landscapes.

Expansion of irrigation in sub-Saharan Africa holds significant potential for spurring growth in the agricultural sector while also better managing water deficiency risks associated with climate change (Dillon, 2011; You et al., 2011). Embedding irrigation expansion within systems-level planning that considers the multi-stressor context in which irrigation expansion is occurring can help to ensure that efforts to promote irrigation can be sustained and do not instead generate a new set of hurdles for producers or engender conflict (Burney and Naylor, 2012; Laube et al., 2012; van de Giesen et al., 2010). Suitable approaches to expand irrigation in Africa include the use of low-pressure drip irrigation technologies, which is becoming more widely available, and construction of small reservoirs, both of which can help to foster diversification toward irrigated high-value horticultural crops (Karlberg et al., 2007; Woltering et al., 2011; Biazin et al., 2011;). Adapting agricultural water management to increased drought risk and changes in rainfall patterns requires a strategic approach that encompasses overall water use efficiency for both rainfed and irrigated production (Weiβet al., 2009), embeds irrigation expansion efforts within a larger rural development context that includes increased access to agricultural inputs and markets (Burney and Naylor, 2012; You et al., 2011), and that involves an integrated suite of options (e.g., plant breeding and improved pest and disease and soil fertility management, and *in situ* rainwater harvesting) to increase water productivity (Biazin et al., 2011; Passioura, 2006).

Experience has been gained since the AR4 on adaptation of infrastructure (transportation, buildings, food storage, coastal), with evidence that this can sometimes be achieved at low cost, and additional implementation of soft measures such as building codes and zone planning. Examples of adaptation actions for road and transportation infrastructure include submersible roads in Madagascar and building dikes to avoid flooding in Djibouti (UNFCCC, 2007; Urquhart, 2009). Infrastructural climate change impact assessments and enhanced construction and infrastructural standards - such as raising foundations of buildings, strengthening roads, and increasing storm water

drainage capacity - are steps to safeguard buildings in vulnerable locations or with inadequate construction (UN-Habitat and UNEP, 2010; Mosha, 2011; Corsi et al., 2012). Mainstreaming adaptation into infrastructure development can be achieved at low cost, as has been shown for flood-prone roads in Mozambique (Halsnæs and and Trarup, 2009). Softer measures, such as building codes and zone planning are being implemented and are needed to complement and/or provide strategic guidance for hard infrastructural climate proofing, for example, the adoption of cyclone-resistant standards for public buildings in Madagascar (AfDB, 2011). Research in Durban (Naidu et al., 2006) and in the city of Umhlathuze (Zitholele Consulting, 2009) proposed the integration of climate change and especially those changes affecting the coastline into urban development plans, and recognized that the best option for adaptation in the coastal zone is not to combat coastal erosion in the long term, but rather to allow progression of the natural processes.

The potential for adaptation to reduce the risks associated with sea level rise is estimated at 10- to 27- fold, with adaptation costs lower than the economic and social damages expected if nothing is done (Kebede et al., 2010). For example, in Tanzania, the total costs of adaptation to sea level rise are estimated to be between US$ 25 and 62 million per year by 2030 (Figure 22-9).

[INSERT FIGURE 22-9 HERE
Figure 22-9: Total costs of adaptation per year from 2000 to 2100 for Tanzania (including beach nourishment and sea and river dikes) Source: Kebede et al., 2010.]

Reducing post-harvest losses through improved food storage, food preservation, greater access to processing facilities, and improved systems of transportation to markets are important means to enhance food security (Brown et al., 2009; Codjoe and Owusu 2011; Godfray et al., 2010). Low cost farm-level storage options, such as metal silos (Tefera et al., 2011), and triple-sealed plastic bags (Baoua et al., 2012) are effective for reducing post-harvest losses from pests and pathogens. Better storage allows farmers greater flexibility in when they sell their grain, with related income benefits (Brown et al., 2009), and reduces post-harvest infection of grain by aflatoxins, which is widespread in Africa and increases with drought stress and high humidity during storage (Shephard, 2008; Cotty and Jaime-Garcia, 2007).

22.4.5.8. Maladaptation Risks

The literature increasingly highlights the need, when designing development or adaptation research, policies and initiatives, to adopt a longer-term view and to consider the multi-stressor context in which people live, in order to avoid maladaptation, or outcomes that may serve short-term goals but come with future costs to society. The short-term nature of policy and other interventions, especially if they favor economic growth and modernization over resilience and human security, may themselves act as stressors or allow people to only react to short-term climate variability (Bryan et al., 2009; Brooks et al., 2009; Bunce et al., 2010a; Levine et al, 2011). The political context can also undermine autonomous adaptation and lead to maladaptation; for instance, Smucker and Wisner (2008) found that political and economic changes in Kenya meant that farmers could no longer use traditional strategies for coping with climatic shocks and stressors, with the poorest increasingly having to resort to coping strategies that undermined their long-term livelihood security, such as more intensive grazing of livestock and shorter crop rotations. In a case from the Simiyu wetlands in Tanzania, Hamisi et al. (2012) find that coping and reactive adaptation strategies may lead to maladaptation – for instance, through negative impacts on natural vegetation because of increased intensity of farming in wetter parts of the floodplain, where farmers have moved to exploit the higher soil water content.

Some diversification strategies, such as charcoal production and artisanal mining, may increase risk through promoting ecological change and the loss of ecosystem services to fall back on (Paavola, 2008; Adger et al, 2011; Shackleton and Shackleton, 2012). Studies also highlight risks that traditional adaptive pastoralism systems may be replaced by maladaptive activities. For example, charcoal burning has become a major source of income for 70% of poor and middle-income pastoralists in some areas of Somaliland, with resultant deforestation (Hartmann and Sugulle, 2009).

Another example of maladaptation provided in the literature is the long-term hydro-dependency risks and threats to ecosystem health and community resilience as a result of increased dam building in Africa, which may be underpinned by policies of multi-lateral donors (add citations; Jones et al, 2012). Additional substantive review of such international development projects is required to ensure that these do not result in maladaptation.

22.4.6. Barriers and Limits to Adaptation in Africa

A complex web of interacting barriers to local-level adaptation exists that manifests from national to local scales to block adaptation, which includes institutional, political, social, cultural, biophysical, cognitive and behavioral, and gender-related (high confidence). While relatively few studies from Africa have focused specifically on barriers and limits to adaptation, perceived and experienced constraints distilled from the literature encompass the resources needed for adaptation, the factors influencing adaptive capacity, the reasons for not employing particular adaptive strategies or not responding to climate change signals, and the reasons why some groups or individuals adapt but not others (Roncoli et al., 2010; Bryan et al.,. 2011; Nyanga et al., 2011; Ludi et al., 2012).

Institutional barriers can hamper adaptation through elite capture and corruption; poor survival of institutions without social roots; and the lack of attention to the institutional requirements of new technological interventions (Ludiet al., 2012). Tenure security over land and vital assets is widely accepted as being crucial for enabling people to make longer-term and forward-looking decisions in the face of uncertainty, such as changing farming practices, farming systems, or even transforming livelihoods altogether (Brown et al., 2010; Bryan et al., 2009; Romero Gonzalez et al., 2011). In addition to unclear land tenure, legislation forbidding ecosystem use is one of the issues strengthening underlying conflicts over resources in Africa, which will have to be resolved if ecosystems are to contribute to adaptation beyond short-term coping (Robledo et al., 2011). There is also evidence that innovation may be suppressed if the dominant culture disapproves of departure from the 'normal way of doing things' (Ludiet et al., 2012; Jones 2011b).

Characteristics such as wealth, gender, ethnicity, religion, class, caste, or profession can act as social barriers for some to adapt successfully or acquire the required adaptive capacities (Ziervogel et al., 2008; Godfrey et al. 2010; Jones and Boyd, 2011). Based on field research conducted in the Borana area of southern Ethiopia, Debsu (2012) highlights the complex way in which external interventions may affect local and indigenous institutions by strengthening some coping and adaptive mechanisms and weakening others. Restrictive institutions can block attempts to enhance local adaptive capacity by maintaining structural inequities related to gender and ethnic minorities (Jones, 2011b). Constraints faced by women, often through customs and legal barriers, include lack of access to land and natural resources,; lack of credit and input in decisionmaking, lack of ability to take financial risk, lack of confidence, limited access to information and new ideas, and lack of value for women's opinions (McFerson, 2008; Jones 2011b; Peach Brown, 2011, Djoudi and Brockhaus 2011; Ludi et al., 2012; Goh, 2012; Codjoe et al. 2012).

Only a portion of small-scale farmers across Africa is able to adapt to perceived climatic changes, while others are restricted by a suite of overlapping barriers (high agreement, robust evidence). Constraints identified in Kenya, South Africa, Ethiopia, Zimbabwe, Zambia, and Ghana included poverty and a lack of cash or credit (financial barriers); lack of access to water and land, poor soil quality, land fragmentation, poor roads, and pests and diseases (biophysical and infrastructural barriers); lack of access to inputs, shortage of labor, poor quality of seed and inputs attributed to a lack of quality controls by government and corrupt business practices by traders, lack of tenure, and poor market access (institutional, technological, and political barriers); and finally a lack of information on agroforestry/afforestation, different crop varieties, climate change predictions and weather, and adaptation strategies (informational barriers) (Nhemachena and Hassan, 2008; Bryan et al. 2009, 2011; Barbier et al., 2009; Clover and Eriksen, 2009; Deressa et al., 2009; Roncoli et al., 2010; Mandeleni and Anim, 2011; Nyanga et al.,2011).

Recognition is increasing that understanding psychological factors such as mindsets and risk perceptions is crucial for supporting adaptation (Jones, 2011b; Patt and Schroter, 2008; Grothman and Patt, 2005). Cognitive barriers to adaptation include alternative explanations of extreme events and weather such as

religion (God's will), the ancestors, and witchcraft, or seeing these changes as out of people's own control (Artur and Hilhorst, 2012; Mubaya et al. 2012, Jones 2011b). Perceptions studies from Africa do show that most rural farmers perceive changes in weather patterns and acknowledge the associated risks, although the cause of the changes are not always known or are attributed to supernatural forces (Mandleni and Anim, 2011; Roncoli et al., 2010; Byran et al., 2009).

Climate uncertainty, high levels of variability, lack of access to appropriate real-time and future climate information, and poor predictive capacity at a local scale are commonly cited barriers to adaptation from the individual to national level (Repetto, 2008; Mather and Stretch, 2012; Jones, 2011b). Despite the cultural and psychological barriers noted above, several studies have shown that farmers with access to weather information are more likely to be aware of changes and to make adjustments accordingly (Mubaya et al., 2012). Dinku et al. (2011) point out that the current monitoring system is not sufficient for supporting sustainable development, being oriented more toward meteorology than climate, and more toward global interests and the presumed needs of government sectoral managers than the needs of local communities.

At a policy level, studies have detected political, institutional, and discursive barriers to adaptation. Adaptation options in southern Africa have been blocked by political and institutional inefficiencies, lack of prioritization of climate change, and the dominance of other discourses, such as the mitigation discourse in South Africa and short-term disaster-focused views of climate variability (Madzwamuse, 2010; Bele et al., 2011; Berrang-Ford et al., 2011; Chevalier, 2011; Conway and Schipper, 2011; Toteng, 2011; Kalame et al., 2011, Toteng, 2011; Leck et al., 2011). Lack of local participation in policy formulation, the neglect of social and cultural context, and the inadvertent undermining of local coping and adaptive strategies have also been identified by several commentators as barriers to appropriate national policies and frameworks that would support local-level adaptation (e.g., Brockhaus and Djoudi, 2008; Bele et al., 2011; Chevalier, 2011).

Many of these constraints to adaptation are well entrenched and will be far from easy to overcome; some may act as limits to adaptation for particular social groups. Biophysical barriers to adaptation in the arid areas could present as limits for more vulnerable groups if current climate change trends continue (Leary et al., 2007; Sallu et al., 2010; Roncoli et al., 2010). Traditional and autonomous adaptation strategies, particularly in the drylands, have been constrained by social-ecological change and drivers such as population growth, land privatization, land degradation, widespread poverty, HIV/AIDS, poorly conceived policies and modernization, and erosion of traditional knowledge to the extent that it is difficult or no longer possible to respond to climate variability and risk in ways that people did in the past (Leary et al., 2007; UNCCD et al., 2009; Dabi et al., 2008; Paavola, 2008; Smucker and Wisner, 2008; Conway, 2009; Clover and Eriksen, 2009; Bunce et al., 2010b; Jones, 2011b; Quinn et al., 2011). As a result of these multiple stressors working together, the number of response options has decreased and traditional coping strategies are no longer sufficient (Dube and Sekhwela, 2008). Increasingly, people are reporting obstacles to mobility, past collective practices, use of indigenous knowledge and diversification activities that hinder their ability to adapt. Studies have shown that most autonomous adaptation usually involves minor adjustments to current practices (e.g., changes in planting decisions); there are simply too many barriers to implementing substantial changes that require investment (e.g., agroforestry and irrigation) (Bryan et al., 2011). Such adaptation strategies require government and private sector/NGO support, without which many poor groups in Africa may face real limits to adaptation.

These findings highlight the need for transformational change in situations where high levels of vulnerability and low adaptive capacity detract from the possibility for systems to adapt sustainably. This is in agreement with the Special Report on Extreme Events, which additionally found high agreement and robust evidence for a needed spectrum of actions ranging from incremental steps to transformational changes in order to reduce climate risks (IPCC, 2012). In support of such solutions, Moench (2011) has called for distilling common principles for building adaptive capacity at different stages, and adaptive management and learning are seen as critical approaches for facilitating transformation (Section 22.4.5.3; IPCC, 2012).

22.5. Case Studies

22.5.1. Climate Change Impacts on Kilimanjaro

Changing weather conditions, large-scale habitat conversion, agricultural intensification, and rapid human population growth have reached a critical stage at Kilimanjaro (Sala *et al*., 2000; Jetz *et al*., 2007; Lovett and Hemp, 2010). Decreasing precipitation is the main driver of increasing forest fires in combination with illegal logging activities affecting, for example, fog water-collecting capacity and with this, the water balance of the whole mountain. This endangers its function as the water tower for northern Tanzania, with potential to affect 10 million people. The problem is exacerbated by an increase in local population density (10 times in 90 years to over 1 million in 2002). Based on current global climate scenarios, Kilimanjaro's ecosystems will be subject to significant further climate warming and shifts in precipitation patterns (McDonald *et al*., 2005; Huntingford *et al*., 2005; Christensen *et al*., 2007), causing a dangerous combination of decreasing adaptive capacity of many of the systems and increasing threats.

Kilimanjaro's glaciers have lost over 80% of their extent since 1912 (Thompson *et al*., 2002; Cullen *et al*., 2006) and annual precipitation has decreased by over 30% (Hemp, 2005). This declining trend in precipitation and humidity rather than increasing temperature is increasingly held responsible for the retreat of glaciers since 1880 (Kaser *et al*., 2004; Mölg *et al*., 2008; Mölg *et al*., 2009a; Mölg *et al*., 2009b; Kaser *et al*., 2010). Since 1848, when Rebmann first drew the world's attention to the presence, so close to the equator, of glaciers on Kilimanjaro, this ice-capped dome in the hot African sun has not only intrigued scientists and writers but also a large number of tourists. Today, the Kilimanjaro National Park (KINAPA) is a major attraction, generating more foreign currency earnings for Tanzania than any other national park (Hemp *et al*., in press). Since the park was established in 1972, the number of visitors to KINAPA has increased five-fold (Hemp *et al*., in press). Most visitors are intent on reaching the summit of Kibo, known as Uhuru Peak, the highest point in Africa. Kilimanjaro will undoubtedly lose part of its beauty once all its glaciers have disappeared, marking the final chapter in an important paleoclimatic archive (Thompson *et al*., 2002; Hemp *et al*., in press).

Changes in local climatic conditions are triggered not only by large-scale effects (such as ocean circulation and dust–aerosol interactions), but also by regional orographic effects (Mölg *et al*., 2009a) and land use feedback effects (e.g., Christensen et al., (2007); Pepin et al., (2010); Mölg et al., (2012)).

Impact

Fires: Loss of natural habitats due to land cover changes and fires is most severe in the foothills of Kilimanjaro. For 10,000 years, fires occurred with various intensities on Kilimanjaro, as suggested by old charcoal horizons in the soil (Hemp and Beck, 2001; Verschuren *et al*., 2009; Zech *et al*., 2011; Schüler *et al*., 2012). However, due to a drier and warmer climate and higher anthropogenic impacts, fires have played an increasingly destructive role in the forests of Kilimanjaro during the last 100 years but in particular over the last three decades. During this period Kilimanjaro has lost about 150 km^2 (nearly 15%) of high-altitude forests, and the upper closed forest line dropped by 900 m (Hemp, 2005; Hemp, 2006a; Hemp, 2009). A high frequency of fires in the upper regions has caused typical alpine *Helichrysum* heath to extend downslope, replacing subalpine forests (Körner, 2003; Pauli *et al*., 2012). In addition, losses due to clear cutting of lower elevation forests amount to 450 km^2 since 1929 (i.e., Kilimanjaro lost about 40% of its forests; Hemp(2006b); Hemp et al., (in press)). An increase in the migration of elephants from the Amboseli ecosystem via the so-called Kitendeni Corridor into the forests of Kilimanjaro due to rising temperatures and other factors like expansion of indigenous communities also have negative consequences on forest cover (impeded forest regeneration and increasing the risk of fire; Hemp et al., (in press)).

The average annual water yield of the entire forest belt is estimated to be about 500 million m^3 (Hemp, 2005). The loss since 1976 of 150 km^2 of cloud forests, which have an important function of fog water collecting in addition to the normal rainwater input, corresponds to an estimated loss of 20 million m^3 of fog water per year (Hemp, 2005). The Pangani River, one of Tanzania's largest rivers, provides water for the hydro plants of Nyumba ya Mungu (8 MW), Hale (17 MW) and Pangani Falls (66 MW), which together generate some 20 % of Tanzania's total electricity output (Hemp *et al*., in press). A water shortage during dry periods would increase the incidence of power cuts, which even now are severely inhibiting economic growth. Fishing in the Nyumba ya Mungu dam yields a catch of

about 4,000 tonnes annually. Water from the Pangani River underpins the large-scale South-East Moshi rice scheme. The southern slopes of Kilimanjaro also provide the water that feeds the Arusha Chini sugarcane plantations of the Tanganyika Planting Company. In Kenya, the Amboseli ecosystem – including the wetlands of Ol Tukai and Kimana, which support Masai pastoralists and abundant wildlife – depends for its survival on Kilimanjaro's water catchments (Hemp *et al*., in press). The traditional Chagga home gardens, covering an area of about 1,000 km^2, represent a special type of coffee–banana agro-forestry that are also dependent on runoff from the montane forest and are now limited to a lowland field where maize, beans, and sunflower are grown to ensure food security (Hemp, 2006c; Liniger *et al*., 2011).

Striking examples for an upward movement of organisms on Kilimanjaro can be found among the grasshopper fauna. In contrast to alpine flora, savanna grasshoppers are spreading from lower elevations to the sub-montane, montane, and even afro-alpine zone due to anthropogenic opening of the closed forest and a warmer microclimate (Figure 22-10; Hemp and Hemp, (2008)).

[INSERT FIGURE 22-10 HERE
Figure 22-10: Upward movement of grasshoppers and bushcrickets at Kilimanjaro. Left circles giving numbers of species which are typical for this zone; right circles giving numbers of species that are additionally found to the typical species of the respective zone, arrows indicating area from which they migrated upwards. Yellow: openland forms, green: forest forms; blue: afroalpine forms. A: colline lowland savanna area, B: submontane and lower montane zone, C: montane zone, D: (sub) alpine zone. 22.5.2. Coastal Zones and Urbanization

Case Studies – Lagos, Dakar, Saint Louis, and Beira

Coastal cities, Africa's most developed urban areas, host 11.5% of the total urban population (UN-Habitat, 2008b). Lagos, Nigeria; Dakar; and Saint Louis, Senegal, all in the low-lying coastal zone of West Africa, as well as Beira, Mozambique, exemplify the state of Africa's coastal cities that are naturally vulnerable to flood hazards from climate change and sea level rise by reason of their location. Moreover, rapid urbanization in these cities has caused migration of large numbers of people into slum or informal communities, often located in flood-prone and risky areas. For instance, between 1984 and 1992, migration resulted in an average increase of 91% in Beira's population, where 75% of the buildings are located in low-lying areas and most immigrants reside in unplanned settlements (Kusangaya, no date). In Saint Louis, the urban poor settle in watersheds and valley bottoms, altering drainage patterns and destabilizing slopes (Diagne, 2007). Similarly, in the Yeumbeul district in the north of Dakar, flood risk is high due to the occupation of depressions by the urban poor that are normally occupied by streams and natural vegetation (Mbow *et al*., 2008). In Lagos, large sections of poor urban coastal communities have been built on land reclaimed by sand infill, which cannot support solid structures (Adelekan, 2010).

Changes in the intensity and pattern of rain storms, land use changes, and subsequent changes in the hydrological fluxes of the urban watershed associated with urban growth, compounded by inadequate or lack of drainage infrastructure, poor urban planning, and poor development control have consequently increased flood risks in these cities (Mbow *et al*., 2008; Adelekan, 2010). In coastal Lagos, significant wetland loss of 38 to 100% was reported in four coastal local government areas between 1986 and 2006 (Taiwo, 2009). Okude and Ademiluyi (2006) showed that developed land comprising residential, industrial, commercial, transportation, and other uses increased from 85.4 km^2 (43.36%) to 111.9 km^2 (56.8%) between 1986 and 2002. Natural vegetation cover, including mangrove and swamp thicket, was also reduced from 59.2 km^2 (30.1%) to 38.3 km^2 (19.4%). In Beira, dryland vegetated areas (3.55 %) were converted to built-up areas followed by alteration of permanently waterlogged areas (1.53%) and finally bare surfaces (0.54%) between 1999 and 2010 (Kusangaya, no date). Urbanization processes and drivers are therefore the strongest cause of floods in Dakar, Lagos, and Saint Louis (Diagne, 2007; Mbow *et al*., 2008; Adelekan, 2010).

Most African coastal cities have limited capacity and infrastructure to cope with the impacts of climate change and sea level rise. Lagos provides a case study of the possible impacts of trends in precipitation behavior in a vulnerable

urban setting. Analyses of rainstorms for Lagos Island from 1971 to 2005 show that in latter years (1996–2005), heavier rainstorms resulting in flooding were recorded. While mean annual rainfall is similar (1,697.8 mm for 1971–1995 and 1,647.3 mm for 1996–2005), fewer rain days were recorded during the latter 10-year period, indicating that rainstorms were much heavier than those of the earlier period and resulted in more flooding (Adelekan, 2010). The range of impacts experienced in affected communities includes damage to roads, flooding of houses, and disruption of movement. Although the severity of impacts varies within communities, the functioning of affected communities and those of its members are affected (Adelekan, 2010). The worsened environmental conditions arising from flood events contribute to the prevalence of waterborne diseases, hepatitis, intestinal diseases, and malaria in poor urban communities. Douglas et al. (2008) also noted the impact of floods on child health in the poor urban communities of Iwaya/Makoko in Lagos. About 91% of households in affected poor urban communities made regular visits to health centers because of ill health, and incurred increased medical expenses and income loss due to inability to work as a result of illness.

Residents of the Makoko community who had benefited from an improved drainage system experienced less flooding than areas where the drainage system was poor (Douglas *et al.*, 2008; Adelekan, 2010). Furthermore, potable water shortages, due to water pollution and damage to water pipes following flood events and cleaning and repair costs, were also experienced by households affected by floods.

At the individual level, flooding of homes and communities deters social interactions as friends and family cannot visit. The nutritional status of members of flood-affected households is also affected as the floods result in loss of food items and scarcity of food. In terms of economic and livelihood activities, over 90% of respondents in the four communities indicated that flood events denied them of job opportunities or hindered their economic activities. Restrictions on economic activities as a result of floods make poor urban dwellers highly vulnerable as the majority depends on wages earned from daily work.

22.5.3. Case Study on Migration

[to be added]

22.6. New Emerging Issues

22.6.1. Integrated Adaptation / Mitigation Approaches

Since AR4, the literature has increasingly recognized that integrated adaptation–mitigation responses need to be implemented within a pro-poor orientation that leverages developmental benefits. Relevant experience gained in Africa on integrated adaptation–mitigation responses encompasses some participation of farmers and local communities in carbon offset systems, increasing the use of technologies that can promote adaptation and mitigation, such as agroforestry and farmer-assisted tree regeneration, emerging policy response within the context of Green Economy discussions and enhanced utilization of renewable energy resources. The recognition that adaptation and mitigation should not be viewed as tradeoffs, but rather as complementary elements of the global response to climate change, is gaining traction in Africa (Nyong *et al.*, 2007; Goklany, 2007; Woodfine, 2009; UNCCD et al., 2009; Milder et al., 2011). Many adaptation activities can contribute significantly to mitigation, provided the expected synergies are capitalized on (Jalloh and Roy-Macauley, 2011).

While the suitability of on- and off-farm techniques for an integrated adaptation-mitigation response depends on local physical conditions as well as political and institutional factors, the literature highlights that sustainable land management techniques particularly beneficial for an integrated response in Africa include agroforestry, including through farmer-managed natural regeneration and conservation agriculture (Woodfine, 2009; Milder *et al.*, 2011; Mutonyi and Fungo, 2011). An emerging area is multiple-benefit initiatives that aim to reduce poverty, promote adaptation through restoring local ecosystems, and deliver benefits from carbon markets. An example is a community-based project in Humbo, Ethiopia, which is facilitating adaptation and generating temporary certified emissions reductions under the Clean Development Mechanism (Brown *et al.*, 2011). Degraded native forests (2,728

ha) are being restored through farmer-managed natural regeneration, which is found to be low-cost and replicable, with benefits to communities of fodder and firewood within a year, and wild fruits and other non-timber forest products within three years. Local cooperatives and establishing user rights were important enabling conditions.

The important role of local communities in carbon offset systems through community forestry entails land use flexibility (Purdon, 2010). Incorporating trees on-farm could expand the opportunity for participation in carbon offset schemes by smallholder farmers (Kung'u *et al*., 2011). Similarly, the local knowledge of communities can support adaptation and mitigation efforts by drawing from locally appropriate options (Nyong *et al*., 2007; Ogden and Innes, 2009). Integrated approaches are constrained by the lack of supportive policy environments – for example, for conservation agriculture (Milder et al., 2011).

The literature has highlighted the need to pursue integrated adaptation–mitigation approaches in the implementation of REDD+ in Africa, and to use spatial planning to find integrated solutions (Bwango *et al*., 2000; Biesbroek *et al*., 2009). Given the significant contribution to food security and livelihoods of communities in Africa, such as the over 30 million indigenous forest people in the Congo Basin Forest of the Central African Region (Nasi *et al*., 2008; Dudley *et al*., 2008; Somorin *et al*., 2012), adaptation and mitigation are inseparable as climate change responses in forest systems (Guariquata et al., 2007; Nkem *et al*., 2007). However, the use of forests for anticipatory adaptation is limited and predominantly serves for reactive coping (Fisher *et al*., 2010). Discourse among forest actors shows separate policy pathways and inclinations for adaptation and mitigation, with a strong government preference for mitigation while the priority of local communities and community-based actors is for adaptation (Somorin *et al*., 2012). Flexible REDD+ models that include agriculture and adaptation may widen the scope for pro-poor participation (Wertz-Kanounnikoff *et al*., 2011), given food security and adaptation priorities (Nkem *et al*., 2008). This is crucial in avoiding the undesirable tradeoffs in the local adaptive capacities of communities, ecosystems, and nations as well as increased vulnerability of some key sectors like agriculture, with the implementation of REDD+ (Richard *et al*., 2011). Harnessing the full potential and cost-effectiveness of REDD+ depends on the opportunity cost (Kremen *et al*., 2000), which in the case of Africa, links to the tradeoffs in social benefits for local communities as well as support for national development efforts in addressing demands for food, fuel, and fiber that underly the decisionmaking process for land use change (Thomson *et al*., 2010). The additional experience being gained on generating co-benefits for poverty reduction through a five-year project launched in 2010 to investigate synergies between adaptation and mitigation in the Congo Basin, with an emphasis on safeguarding local rights, livelihoods, and traditions, is also relevant (CIFOR, 2011).

There have been a number of studies on identifying the most sustainable regional renewable options for Africa owing to the rapid population growth and increase in industrial activities (Sambo, 2008; Chineke et al., 2010; Chineke and Okoro, 2010; Dike et al., 2011). Options explored include solar, wind, small hydro and improved biomass technologies. Insufficient electricity to meet domestic and industrial needs has been the main driver of the increased focus on exploiting Africa's substantial renewable energy sources, rather than reduction in carbon emissions; however, mitigation and broader environmental reasons are seen as increasingly important (Foster-Pedley et al., 2006; Nwofor et al., 2007). An excellent example of integrating renewable energy generation into a national utility service is available from Mauritius (UNIDO, 2007). The three major barriers to the adoption of renewable energy in Africa are policy/legal, technical and financial barriers; other studies have pointed to the need for enhanced political will and continual lobbying for better policy uptake (Legros et al., 2009; Chineke and Ezike, 2010).

Integrated adaptation–mitigation responses are being considered within the context of the emerging Green Economy discussions at both regional and national levels. African leaders agreed in 2011 to develop an African Green Growth Strategy to guide low-carbon growth and climate resilient development. This will build a shared medium and long-term vision to promote sustainable and low-carbon growth in Africa through a linked adaptation–mitigation approach, with adaptation seen as an urgent priority. At the national level, Ethiopia launched its Climate Resilient Green Economy Facility in 2012 (Corsi *et al*., 2012). Given Africa's ongoing development needs, questions to ask include how adaptation programs can be designed to meet the health, education, and employment needs of communities (African Development Forum, 2010). Similarly, for integrated adaptation and mitigation strategies to be effective and sustainable, it is necessary to understand the synergies and tradeoffs between approaches – for

instance, in the agriculture sector, between various practices for food security and for mitigation of greenhouse gas emissions (Chambwera and Anderson, 2011).

22.6.2. Climate Finance and Management

At the UN climate negotiations in Copenhagen (2009), developed countries pledged to mobilize new and additional financial resources for climate change adaptation and mitigation in developing countries, approaching US$ 30 billion for the period 2010 to 2012, and US$ 100 per annum from 2020 onward (UNFCCC, 2009; UNFCCC, 2011). Historically, less than 20% of the global climate finance was directed to adaptation (Buchner *et al*., 2012). However, in line with increasing international impetus for adaptation (Persson *et al*., 2009) the Parties agreed on providing "adequate, predictable and sustainable financial resources" for adaptation in developing countries, and, within this context, paid special attention to Africa which is considered "particularly vulnerable" to the adverse effects of climate change (UNFCCC, 2009; UNFCCC, 2011).

The need for climate finance led to a proliferation of climate funds (Caravani *et al*., 2010). Adaptation funding currently comes from the domestic budgets of developing countries; bilateral and multilateral development assistance; and funds situated under the UNFCCC (Klein, 2010). The Copenhagen Accord states that it should also come from the private sector (UNFCCC, 2009). The UN secretary general's high-level advisory committee considered private finance necessary to meet the US$ 100 billion per annum target (AGF, 2010). However, doubts remain about how private sector financing can be effectively mobilized and channeled toward adaptation in developing countries (Atteridge, 2011; Naidoo *et al*., 2012). The 2012 Landscape of Climate Finance Report (Buchner *et al*., 2012) stated that private climate finance represents 63% of the total climate finance flows, of which close to two- thirds come from developed countries. It also estimates that mitigation activities attracted US$ 350 billion, mostly related to renewable energy and energy efficiency, while adaptation activities attracted US$ 14 billion.

Approximately 30% of the global distributed adaptation finance went to Africa (Nakhooda *et al*., 2011) and seems to prioritize the continent (Naidoo *et al*., 2012). However, there is general consensus that adaptation funding that is currently delivered does not fulfill demonstrated needs, neither globally (Flåm and Skjærseth, 2009; Denton, 2010) nor in sub-Saharan Africa (Nakhooda *et al*., 2011).

Effective adaptation requires more than sufficient levels of funding. It requires developing country 'readiness,' which includes abilities to plan and access finances; the capacity to deliver adaptation projects and programs, and to monitor, report, and evaluate their effectiveness (Vandeweerd *et al*., 2012). Particularly serious challenges are associated with directing finance to the sectors and people most vulnerable to climate change (Denton, 2010; Nakhooda *et al*., 2011; Pauw *et al*., 2012). Mismanagement and misuse of funds eventually puts at risk the rights of those most vulnerable to the negative effects of climate change. (Transparency International 2011:xxvi). The reasons for the high degree of fund mismanagement with regard to climate finance and adaptation funds are rooted in the level of complexity, uncertainty, and novelty that surrounds many climate issues. Solving these problems would, inter alia, require a focus on longer-term and integrated programs rather than isolated projects; building capacity and institutions in African countries (Nakhooda *et al*., 2011; Pauw *et al*., 2012); identifying priorities, processes, and knowledge needs at the local level (Haites, 2011; Pauw, forthcoming); and, accordingly, developing grassroots projects (Fankhauser and Burton, 2011).

22.7. Research Gaps

Research has a key role to play in providing information for informed decisionmaking at local to national levels (Fankhauser, 1997; Ziervogel *et al*., 2008; Arendse and Crane, 2010). While there is significant activity in African research institutions on adaptation, much African research capacity is spent on foreign-led research that may not relate to national knowledge gaps about climate change (Madzwamuse, 2010), and African research may lack merited policy uptake or global recognition as it is often not published in peer-reviewed literature (Denton *et al*., 2011).

The following data and research gaps have been identified:

- A multi-tiered approach to building institutional and community capacity to respond to climate risk
- Developing methods in vulnerability analysis for capturing the complex interactions in systems across scales
- Frameworks for designing adaptation measures to cope with high levels of uncertainty
- Improved analysis of adaptation technologies to build adaptive capacity and resilience
- Development of African capacity and leadership on climate change, including through strengthening and reorienting climate science and policy institutions to harness synergies for translation of new climate change science into policy and/or decisionmaking tools
- Clements et al. (2011) highlight the importance of investigating potential changes in future economic and social systems under different climate scenarios, in order to increase understanding of the implications of adaptation strategy and planning choices.
- Methodologies and "cyclical learning and decision-support tools to explore anticipatory adaptation in high poverty/high vulnerability contexts" (Tschakert and Dietrich, 2010)
- Integrating a differentiated view of poverty into climate change adaptation and disaster risk reduction in order to more effectively address the root causes of poverty and vulnerability, which can be promoted through further integration of climate change adaptation and disaster risk reduction with social protection.
- Approaches to further develop a more equitable approach to adaptation, including gender equity, human rights- based approaches, and involvement of vulnerable or marginalized groups such as indigenous peoples and children
- How to effectively combine social protection measures to mitigate vulnerability to climate change in different contexts
- Frameworks for identifying and eliminating factors that constrain women's ability to adapt at multiple levels
- Understanding and demonstrating how greater integration of women in decisionmaking could address the inequitable distribution of climate impacts, and could improve adaptive decisionmaking more broadly.
- Understanding the factors that determine the effectiveness of adaptation activities in building resilience and increasing adaptive capacity and the effectiveness of community-based adaptation to climate change and variability.
- Monitoring adaptation
- The ethical and political dimensions of engaging with local and traditional knowledge on climate change adaptation are an important but under-examined issue in Africa. While the concept of indigeneity is debated in Africa, the claims for active participation of marginalized groups in global climate deliberations described above are significant for a wide range of communities in Africa.

Frequently Asked Questions

FAQ 22.1: What is the significance of migration in the context of climate change adaptation in Africa?

Migration was considered as a negative impact in the last decade, but a perception of the potential positive role of migration in climate change adaptation now exists. Even if classical literature tends to ignore the environment as a key driver of migration, new theories on African mobility state that migration is a central issue in the adaptation process and one of the most relevant responses to climate change in Africa, regardless of some negative effects on environmental degradation. As in most regions of the world, environmental change will continue to affect African migration during the coming years. In addition to economic, social, and political drivers, environmental change will play a key role in the migration process. Environmental change will affect livelihoods, making migration a primary answer or the only response. Better management of African migration and displacement is a core issue to avoid humanitarian emergencies and the risk of jeopardizing necessary population mobility due to environmental change.

FAQ 22.2: How could climate change impact food security in Africa?

Food security is comprised of food availability, access, quality, utilization, and acceptability. Strong consensus exists that climate change will have a significantly negative impact on food availability in Africa. This could occur through direct climate impacts on crops and livestock, such as through increased incidence of floods, drought, shifts

in the timing and amount of rainfall, and high temperatures, or indirectly through increased soil erosion brought on by an increased incidence of heavy storms and through increased pest and disease pressure on crops and livestock. The link between climate change and food access is less clear, although there is evidence that climate change impacts in important cereal-producing regions of the world could, along with other factors, contribute to increasing food prices, which impede the ability of the poor and middle class in Africa to purchase food, hence their reduced access to food. The impact of climate change on food quality could occur through increased risk of spoilage of fresh food and pest and pathogen damage to stored foods (cereals, pulses, tubers) under warmer and more humid conditions. Climate change could impact food utilization through increased gastro-intestinal diseases, malaria, and other diseases that reduce the ability of the human body to absorb nutrients from food.

FAQ 22.3: What role does climate change play with regard to violent conflict in Africa?

Wide consensus exists that violent conflicts are based on a variety of interconnected causes, of which the environment is considered to be one, but rarely the most decisive factor. Whether or not the changing climate increases the risk of civil war in Africa remains disputed and there exists a lack of robust findings related thereto. A risk of an increase of violent competition over scarce resources exists with a view to the impacts of climate change on renewable resources such as freshwater and arable land on the one side and population growth on the other. Increased distributional conflicts due to the degradation of natural resources as a result of overexploitation and global warming will arise. The outbreak of armed conflict with climate change as one of various interacting reasons, however, depends on country-specific sociopolitical and economic factors among others.
