Section C: Future risks and choices: risks and potential for adaptation
C.i. Sectoral and regional risks
C.ii. Key and emergent risks
Box SPM.5. Consequences of >4°C temperature increase
Box SPM.6. Anthropogenic interference with the climate system

Section D: Building resilience through mitigation, adaptation, and sustainable development
D.i. Climate-resilient pathways and transformation
D.ii. Examples of co-benefits, synergies, and tradeoffs
Box SPM.7. Adaptation limits and transformation

INTRODUCTION

The Working Group II (WGII) contribution to the IPCC's Fifth Assessment Report (AR5) assesses the shifting patterns of risks and opportunities associated with climate change and provides information on how risks can be reduced through mitigation and adaptation.

Box SPM.1 defines central concepts, and Box SPM.2 introduces terms used to convey the degree of certainty in findings. Chapter sections in square brackets indicate the assessment supporting findings in this summary.

_____ START BOX SPM.1 HERE _____

Box SPM.1. Terms Critical for Understanding the Summary

Climate change: A change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external forcings such as modulation of the solar cycles, volcanic eruptions, and persistent anthropogenic changes in the composition of the atmosphere or in land use. In contrast, the Framework Convention on Climate Change (UNFCCC), in its Article 1, defines climate change as: "a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods." The UNFCCC thus makes a distinction between climate change attributable to human activities that alter the atmospheric composition, and climate variability attributable to natural causes.

Exposure: The presence of people, livelihoods, environmental services and resources, infrastructure, or economic, social, or cultural assets in places that could be adversely affected.

Vulnerability: The propensity or predisposition to be adversely affected.

Impacts: Effects on natural and human systems. In this report, the term "impacts" is used to refer to the effects on natural and human systems of physical events, of disasters, and of climate change.

Risk: The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk is often represented as probability of occurrence of a hazardous event(s) multiplied by the consequences if the event(s) occurs. This report assesses climate-related risks.

Adaptation: In human systems, the process of adjustment to actual or expected climate and its effects, which seeks to moderate harm or exploit beneficial opportunities. In natural systems, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate.

Transformation: A change in the fundamental attributes of a system, often based on altered paradigms, goals, or values. Transformations can occur in technological or biological systems, financial structures, and regulatory, legislative, or administrative regimes.

_____ START BOX SPM.2 HERE _____

Box SPM.2. Communication of the Degree of Certainty in Assessment Findings

The WGII AR5 relies on two metrics for communicating the degree of certainty in assessment findings:

- Confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively.
- Quantified measures of uncertainty in a finding expressed probabilistically, based on statistical analysis of observations or model results, or expert judgment.

Each finding has its foundation in an author team's evaluation of associated evidence and agreement. The summary terms to describe available evidence are: *limited*, *medium*, or *robust*; and the degree of agreement: *low*, *medium*, or *high*. Levels of confidence include five qualifiers: *very low*, *low*, *medium*, *high*, and *very high*. When author teams evaluate the likelihood of some well-defined outcome having occurred or occurring in the future, a finding can include likelihood terms: v*irtually certain*, 99–100% probability; *very likely*, 90–100%; *likely*, 66–100%; *about as likely as not*, 33–66%; *unlikely*, 0–33%; *very unlikely*, 0–10%; and *exceptionally unlikely*, 0–1%. Additional terms used: *extremely likely*, 95– 100% probability; *more likely than not*, >50–100%; and *extremely unlikely*, 0–5%.

_____ END BOX SPM.2 HERE _____

A) IMPACTS, VULNERABILITIES, AND ADAPTATION IN A COMPLEX AND CHANGING WORLD

A.i. Observed Impacts and Vulnerabilities

Impacts of recent observed climate change on physical, biological, and human systems have been detected on all continents and in most oceans (*high confidence*). This conclusion is strengthened by observations since the IPCC Fourth Assessment Report (AR4) and through more extensive analyses of earlier observations. Most reported impacts of climate change are attributed to regional atmospheric and oceanic warming, with lower confidence in attribution to shifts in rainfall patterns. For many natural systems on land and in the ocean, new or stronger evidence exists for substantial and wide-ranging climate change impacts. For managed ecosystems and human systems, effects of changing social and economic factors often dominate over direct impacts of climate change. See Table SPM.1 for regional examples. [18.3-18.6]

[INSERT TABLE SPM.1 HERE
Table SPM.1: Observed impacts attributed to climate change with *medium* (*) or *high* (**) confidence, for physical, biological, and human systems across eight major world regions. [Tables 18-6, 18-7, 18-8, 18-9]]

Climatic and biophysical drivers interact with non-climatic drivers of vulnerability and exposure to shape differential risks and impacts (*very high confidence*). See Box SPM.3. Vulnerability and exposure of communities or social-ecological systems to climatic hazards are dynamic and thus varying across temporal and spatial scales. [13.1, 14.1, 14.2, 15.2.4, 19.6.1]

Impacts from recent extreme climatic events show significant vulnerability of some ecosystems and many human systems to current climate variability (*very high confidence*). These experiences are consistent with a significant adaptation deficit in developing and developed countries for some sectors and within some regions. [10.3.1, 10.7.3, 13.2.1, 18.4.4, 18.4.7, 25.8.1, 26.6, 26.7, Tables 18-4, 23-3, 25-1, Boxes 25-5, 25-6, 25-8]

Hydrological systems have changed in many regions due to changing rainfall or melting glaciers, affecting water resources, water quality, and sediment transport (*medium confidence*). The duration of droughts in some regions has been altered by climate change. In many river systems, the frequency of floods has been altered by climate change (*low* to *medium confidence*). Widespread changes and degradation of permafrost in high-latitude and high-elevation mountain regions have been observed over the past years and decades (*high confidence*). [3.2.3, 18.3.1, 18.5]

Terrestrial plant and animal species have shifted their ranges and seasonal activities and altered their abundance, in response to climate change in the past, and they are doing so now in many regions (*high confidence*). Increases in the frequency or intensity of ecosystem disturbances due to fires, pest outbreaks, wind-storms, and droughts have been detected in many parts of the world (*medium confidence*). There is *very low confidence* that most observed species extinctions can be attributed to recent climate warming. However, recent warming has played a role in extinctions of Central American amphibians (*medium confidence*). [4.2-4.4, 18.3.2, 18.5]

Several major terrestrial ecosystems are undergoing broad-scale changes that can be characterized as early warnings for coming regime shifts, in part due to climate change. Climate change is a driver of widespread shrub encroachment in the Arctic tundra (*high confidence*) and of boreal forest tree mortality (*low confidence*). In Central and South America, conversion of natural ecosystems is currently the main cause of biodiversity and

ecosystem loss and a driver of anthropogenic climate change. However, observed recession and degradation of the Amazon forest cannot be attributed to climate change. [18.3.2, 18.5.6, 18.5.7, 27.2.2, 27.3.2]

Warming is causing shifts in marine species' geographical distribution, abundance, migration patterns, and timing of seasonal activities, resulting in altered species interactions (*high confidence*). There are many observations of poleward shifts in the distribution and abundance of fishes and invertebrates and/or of their shifts to deeper and cooler waters. Warming-induced stratification, reduced intensity of ocean circulation, and the breakdown of organic matter by organisms are expanding hypoxic regions that constrain the habitat of oxygen-dependent marine animals, plants, and microbes. In Earth history, natural climate change at rates slower than today's anthropogenic change has led to significant ecosystem shifts in the oceans. [6.1-3, 6.5, 18.3, 30.4-5, Box CC-CR]

Effects of climate change on food production are evident in several regions (*high agreement, medium evidence*). Yields have increased in mid-to-high-latitude regions due to warming and higher CO_2 (*low confidence*) and decreased in other, mainly low-latitude regions due to water shortages and higher temperatures (*medium confidence*). Overall, negative impacts have been more common than positive ones (*high confidence*). Since AR4, there have been several periods of rapid food price increases, demonstrating partial sensitivity of current markets to climate variability. Interactions among production factors (e.g., CO_2 and ozone, mean temperature, extremes, water, nitrogen) can alter primary food production in complex ways (*high agreement, medium evidence*). [7.2, 7.3, 7.4, 18.4.1, Figures 7-2 to 7-7, Tables 7-1, 18-9]

Prevailing rural development constraints, such as low levels of educational attainment, environmental degradation, gender inequality, and remoteness from decisionmakers, create additional vulnerabilities to climate change (*high confidence*). In developing countries, rural people are subject to multiple non-climate stressors, such as under-investment in agriculture and land-policy problems (*high* to *very high confidence*). [9.2, 9.3.1, 9.3.5, 9.4.4, Table 9-1]

In recent decades, climate change has *likely* contributed to levels of ill-health though the present world-wide burden of ill-health from climate change is relatively small compared with other stressors on health and is not well quantified. Changes in temperature, rainfall, and sea-level have altered distribution of some disease vectors, increased heat wave casualties, and reduced food production for vulnerable populations (*medium confidence*). Climate change is a multiplier of existing vulnerabilities affecting health outcomes (*high confidence*). [11.3, 11.4, 18.4.5, 22.3.5, Box 11-4]

People living in places affected by violent conflict are particularly vulnerable to climate change (*high agreement, limited evidence*). A causal effect of climate change and variability on violence is contested, although there is *robust evidence* that shows that low per capita incomes, economic contraction, and inconsistent state institutions, factors sensitive to climate change, are associated with the incidence of civil wars. [12.5, 19.6.1]

Climate change constitutes an additional burden for the rural and urban poor (*very high confidence*). Urban and rural transient poor who face multiple deprivations can slide into chronic poverty as a result of extreme weather events, or a series of events, when they are unable to rebuild their eroded assets (*high agreement, limited evidence*). Preexisting gender inequalities are increased or highlighted by weather events and climate. Often, the more affluent can better take advantage of shocks and crises, given their flexible assets and power status. [13.1, 13.2.1, 13.3]

_____ START BOX SPM.3 HERE _____

Box SPM.3. Multidimensional Vulnerability to Climate Change

People who are socially, economically, culturally, politically, or institutionally marginalized are typically most at risk from adverse impacts of climate change and climate change responses. Such heightened vulnerability is related not only to income and assets but also to gender, class, race, ethnicity, age, and (dis)ability (Box SPM.3 Figure 1). Other dimensions include resource access, location, legal systems, and voice. Understanding differential adaptive capacity for individuals, households, and communities requires attention to multidimensional inequality, deprivation, and power. It also benefits from attention to context-specific interactions in social-ecological systems that contribute to differential vulnerability. [8.1.4, 9.3.5, 9.4.1, 11.4.1, 11.5, 13.2.1, 19.6.1]

[INSERT BOX SPM.3 FIGURE 1 HERE
Box SPM.3 Figure 1: Intersecting, simultaneous, and dynamic axes of privilege and marginalization, shaped by people's multiple identities and embedded in uneven power relations and development pathways. Together, they result in differential vulnerability to the same exposure to climate change and climate responses. [Figure 13-4]]

_____ END BOX SPM.3 HERE _____

A.ii. Adaptation Experience

Human and natural systems respond to climate and its effects. Natural systems have some potential to adapt, and are adapting, through ecological and evolutionary processes, and humans may intervene to promote particular adjustments. Responses in human systems include coping with climate variability and extremes, and managing risks through planned adaptation to climate change impacts. Adaptation can be motivated by broader vulnerability-reduction and development objectives, such as reducing existing adaptation deficits to current climate. [14.1]

Adaptation activity is increasing and becoming more integrated within wider policy frameworks (*high confidence*). Adaptation planning is transitioning from a phase of awareness and promotion to the construction of responses in societies (*high agreement, robust evidence*). [14.3.4, 14.4.2, 15.2, 15.3.1]

Awareness of climate risks and vulnerabilities, and the need for adaptation, does not always lead to action (*high confidence*). Numerous assessments have led to higher awareness among decisionmakers and stakeholders of climate risks and adaptation needs and options. However, in most cases this awareness of changing risks has not been translated into adjustments of ongoing activities or risk management planning. In order to facilitate such integration into decision-making, assessments may need to be linked more directly to particular decisions, with information tailored to support the decisionmaking process. [2.3, 14.5, 14.6]

The diversity of adaptation experience, including corresponding constraints and opportunities, can be seen in specific geographic contexts (see also Table SPM.2):

- **The scale and concentration of urban climate risk and hence the need for adaptation are being acknowledged, but responses are weak except for a handful of cities largely in high-income countries (*medium confidence*).** Examples of approaches to adaptation have included the designation of a unit within city government with responsibility for adaptation, measures to involve key sectors so they understand why they need to engage with adaptation, local champions to initiate measures and ensure continuity, and the importance of dialogue and discussion with all key stakeholders. City-based disaster risk reduction is a strong foundation around which to build urban climate resilience (*high confidence*). [8.2, 8.3, 8.4, 8.5]
- **Gender, the supply of information for decision-making, and the role of social capital in building resilience are all key issues for adaptation in rural areas (*high confidence*).** Constraints to adaptation come from lack of access to credit, land, water, technology, markets, and information, and constraints are particularly pronounced in developing countries. [9.4.1, 9.4.3, 9.4.4]
- **In many African countries, national governments are initiating governance systems for adaptation (*high agreement, medium evidence*).** Efforts such as disaster risk reduction, social protection, climate-resilient infrastructure, ecosystem restoration, and livelihood diversification are reducing vulnerability and enhancing resilience, but this is still largely confined to local scales and isolated initiatives. [22.4.4, 22.4.5, 22.6.2]
- **In Europe, adaptation policy has been developed at international (EU), national, and local government levels, but so far evidence relates to studies of the prioritization of options, and there is limited systematic information on current implementation or effectiveness.** Some adaptation planning has been integrated into coastal and water management, as well as disaster risk management. There is little evidence of adaptation planning in rural development, land-use planning, or conservation. [23.6.4, 23.7, Box 23-2]
- **In Australasia, adaptation is already occurring and adaptation planning is becoming embedded in planning processes, mostly at the conceptual rather than implementation level (*high agreement, robust evidence*).** Planning for sea-level rise and, in Australia, for reduced water availability is becoming widely adopted. Adaptive capacity is generally high in many Australasian human systems, but implementation faces major constraints especially for transformative responses at local and community levels (*high confidence*). Constraints on implementation arise from: uncertainty of projected impacts; limited financial and human resources; limited integration of different levels of governance; and different values and beliefs relating to the existence of climate change and to objects and places at risk. [25.4, 25.10.3, Boxes 25-1, 25-2, and 25-9]

- **In North America, while different tiers of government are assessing their climate vulnerabilities and designing adaptation actions and programs, there has been more leadership in adaptation planning at the local level (*high confidence*).** Important barriers exist to effective adaptation such as path dependency, asymmetries in access to information, top-down decision making, and lack of assets, options, funding, staff, horizontal and vertical coordination, and social capital. The few examples of proactive adaptation anticipating future climate impacts are largely found in sectors with longer-term decision-making, including energy and public infrastructure. [26.7, 26.8, 26.9]
- **In the Arctic, indigenous people have a high adaptive capacity and have begun to develop novel solutions to adapt to climate changes combining traditional and scientific knowledge and co-producing climate studies with scientific partners.** [28.2.4, 28.2.7, 28.4.1]

[INSERT TABLE SPM.2 HERE
Table SPM.2: Illustrative examples of adaptation experience, as well as approaches to reduce vulnerability and enhance resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerabilities, inequalities, and climate change come to the fore. At the same time, place-based examples illustrate how larger-level drivers and stressors shape differential risks and livelihood trajectories, often mediated by institutions.]

B) DECISIONMAKING IN A COMPLEX WORLD: UNDERSTANDING APPROACHES TO MANAGING RISKS THROUGH ADAPTATION

Managing the risks of climate change involves decisions with implications for future society, economies, environment, and climate. Robust decisions can be effective across a range of possible futures (see Box SPM.4). Fundamentally, adaptation to climate change can be considered an iterative process with continuing learning about risks and the effectiveness of risk management actions.

B.i. Determinants and Iterative Management of Risk

Risk in the context of climate change is produced through the interaction of changing physical characteristics of the climate system with evolving characteristics of human, socioeconomic, and biological systems (exposure and vulnerability). See Figure SPM.1. Alternative development paths influence risk both by changing the likelihood of physical impacts (through their effects on greenhouse gas emissions) and by altering vulnerability and exposure. [2.1.1, 19.1, 19.2, Fig.19-1]

Due to the uncertainty, dynamic complexity, and short-to-long timeframes associated with climate change, robust adaptation efforts require iterative risk management strategies (*high agreement, medium evidence*). While no-regret, low-regret, and win-win strategies have attracted attention in the past, there is increasing recognition that adaptive responses will entail acting in the face of continuing uncertainty about the extent of climate change, the nature of its impacts, and adaptation needs. Iterative risk management involves an ongoing process of assessment, action, reassessment, and response that may need to be applied under climate change for decades, if not longer. Monitoring and evaluation are important learning tools in this process. See Figure SPM.2. [2.1.2, 2.2.1, 2.3.1, 14.1, 14.3.4, 15.2.3, 15.3.3, 20.5]

[INSERT FIGURE SPM.1 HERE
Figure SPM.1: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. Vulnerability and exposure are, as the figure shows, largely the result of socioeconomic development pathways and societal conditions. Changes in both the climate system (left) and development processes (right) are key drivers of the different core components (vulnerability, exposure, and physical hazards) that constitute risk. The definition and use of “key” and “emergent” are indicated in Section C.ii. [19.1, Figure 19-1]]

[INSERT FIGURE SPM.2 HERE
Figure SPM.2: Illustration of iterative response to climate change. (A) Four main phases of planned adaptation as a cyclic, iterative process: needs, planning, implementation, and evaluation. Efforts in adaptation can be linked with development or disaster risk management. Adaptation governance at multiple scales underlies capacity. (B) In the

context of iterative risk management, each individual adaptation decision cycle comprises well known aspects of risk assessment and management. (C) A sequence of adaptation decisions creates an adaptation pathway. Some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but there is no single correct adaptation pathway and judgment of outcomes depends strongly on societal values, expectations, and goals. [Figures 15-1, 16-2, 25-6]]

B.ii. Principles for Effective Adaptation

Experience in the practice of adaptation serves to clarify the opportunities for, and the most significant barriers to, adaptation and the synergies and tradeoffs with other societal goals. Types of responses to climate change are overviewed in Table SPM.3.

[INSERT TABLE SPM.3 HERE
Table SPM.3: Entry points, strategies, measures, and options for managing the risks of climate change. These approaches should be considered overlapping rather than discrete, and they are often pursued simultaneously. Examples given can be relevant to more than one category.]

Actors at all geographical and institutional levels and in different development contexts have opportunities to facilitate, initiate, and implement effective adaptation action (*medium agreement, medium evidence*). Because adaptation is a multidimensional issue involving many state and non-state actors functioning at local to global scales, coordination of roles and responsibilities enhances institutional networking for effective implementation (*high agreement, medium evidence*) (Figure SPM.2A). National governments assume a coordinating role of adaptation actions in subnational and local levels of government, including the provision of information and policy frameworks, creation of legal frameworks, actions to protect vulnerable groups, and financial support to other levels of government (*high agreement, robust evidence*). Among the many actors and roles associated with adaptation, those associated with local governance and with the private sector are increasingly recognized as critical to progress (*high confidence*), as these groups bear responsibility for translating the top-down flow of risk information and financing, and for scaling up efforts of communities and households in identifying and implementing selected adaptation actions. [2.3.4, 14.4, 15.2.2, 15.2.3, 15.4, 16.6]

Strategies and actions can be pursued now that increase climate resilience while at the same time helping to improve human livelihoods, social and economic well-being, and responsible environmental management (*high confidence*). Adaptation actions can provide significant co-benefits such as alleviating poverty and enhancing development especially in developing countries. Improving resilience through an emphasis on disaster risk reduction has become increasingly common (*high agreement, medium evidence*). Efforts to improve ecosystem resilience can benefit adaptation. Building climate resilience in cities can involve ecosystem-based adaptation with water and food systems as foci (*medium confidence*). [2.3.4, 2.4.2, 8.3, 8.5, 14.3.4, 14.4.2, 15.2, 15.3.1, 17.2.7, 17.4.4, 20.6.2, 29.6]

Mainstreaming facilitates integration of adaptation into planning and decisionmaking and embeds climate-sensitive thinking in existing and new institutions and organizations (*high confidence*). Mainstreaming promotes synergies with development planning, enables the blending of multiple funding streams, and reduces the possibility of maladaptive actions. [14.3.4, 14.4.2, 16.6, 17.2.7, 17.4.4]

Constraints to adaptation planning and implementation include availability of resources and uncertainties about future climate and disaster risk at national and regional scales (*high agreement, robust evidence*). The manner in which constraints manifest and their implications for capacity to achieve adaptation objectives vary significantly across regions and sectors and across social and temporal scales. [16.2, 16.3, 17.2.6, 17.3, 17.5.4]

Existing and emerging economic instruments can foster adaptation by providing incentives for anticipating and reducing impacts (*high confidence*). Instruments comprise risk sharing and transfer mechanisms, loans including public-private finance partnerships, payment for environmental services, improved resource pricing (water markets), charges and subsidies including land taxes, direct investment, norms and regulations, behavioral approaches, and institutional innovations. Applicable risk financing mechanisms across scales comprise informal and traditional risk sharing, such as relying on kinship networks, as well as market-based instruments including microinsurance, insurance, reinsurance, and national, regional, and global risk pools (*medium confidence*). [8.4, 10.7, 10.9, 17.3.4, 17.3.6, 17.4, 17.5]

Intervention in one location or sector can increase the vulnerability of another location or sector, or increase the vulnerability of the target group to future climate change (*medium confidence*). Such maladaptation can result from decisions where greater emphasis is placed on short-term outcomes ahead of longer-term threats, or from decisions that discount, or fail to consider, the full range of interactions arising from planned actions. See also Figure SPM.2C. [14.7.1, 14.7.2]

_____ START BOX SPM.4 HERE _____

Box SPM.4. Characterizing the Future

While there are many possible scenarios for future climate change and societal development, current decisions narrow future options. New risks will emerge in the coming decades as a result of past emissions and current socioeconomic trends. Societal responses, particularly adaptations, will influence outcomes during this era of climate responsibility. In contrast, benefits of current mitigation efforts will emerge over a longer period. Future risks during this longer-term era of climate options are thus linked to current mitigation and development choices.

Trends in vulnerability, exposure, and climate, as well as weather and seasonal forecasting of climate variability, can inform decisions in the era of climate responsibility. Climate and impact model projections become increasingly relevant for climate-affected decisions playing out over the longer term, recognizing that uncertainties about future vulnerability and exposure also increase over time. [21.3.3, 21.5.1, 21.5.3]

Scenarios are a vital part of managing uncertainty. [2.2.1] Scenarios provide a mechanism for characterizing possible socioeconomic futures and climate change outcomes. Socioeconomic factors influence not only greenhouse gas emissions but also the size and location of populations at risk from various climate change impacts, the differential vulnerability of these populations, and their capacities to adapt.

Modeled future impacts assessed in this report draw on a combination of climate model simulations using SRES scenarios (CMIP3) and new climate model simulations using the Representative Concentration Pathway (RCP) scenarios (CMIP5). The four RCPs reflect different levels of mitigation, leading to 21st century radiative forcing levels of 2.6, 4.5, 6.0, and 8.5 W m^{-2} (see WGI AR5 Chapters 1, 6, 11, and 12). Box SPM.4 Figure 1 illustrates alternative climate futures, under RCPs 4.5 and 8.5, along with observed temperature and precipitation changes. [1.1.3, Box CC-RC]

[INSERT BOX SPM.4 FIGURE 1 HERE
Box SUM.4 Figure 1: Changes in annual average temperature (A) and precipitation (B). For observations (top map, A and B; CRU), differences are shown over land between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For projections (bottom four maps, A and B; CMIP5), four classes of results are displayed. (1) White indicates areas where for >66% of models the annual average change is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Thus in these regions, more than 2/3 of models show no significant change in the annual average using this measure of significance, although this does not imply no significant change at seasonal or shorter time-scales such as months to days. (2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions, more than 2/3 of models show a significant change in annual average, but less than 2/3 agree on whether it will increase or decrease. (3) Colors with white circles indicate the change averaged over all models where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on whether the annual average will increase or decrease. In these regions, more than 2/3 of models show a significant change in annual average and more than 2/3 (but less than 90%) agree on whether it will increase or decrease. (4) Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether the annual average will increase or decrease. For models that have provided multiple realizations for the climate of the recent past and the future, results from each realization were first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-

noise ratios were calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065. See also Annex I of WGI AR5. [Box CC-RC]]

_____ END BOX SPM.4 HERE _____

C) FUTURE RISKS AND CHOICES: RISKS AND POTENTIAL FOR ADAPTATION

Assessment of the full range of potential future impacts, not only the most likely outcomes, provides a basis for understanding future risks. This section covers future risks across sectors and regions, and their sensitivity to the magnitude and rate of climate change, to characteristics of development that affect vulnerability, and to policy choices. It elucidates how and when choices matter in reducing future risks and highlights the differing timeframes for mitigation and adaptation benefits within the eras of climate responsibility and climate options.

C.i. Sectoral and Regional Risks

Freshwater resources

Projected climate changes would change hydrological regimes substantially (*high agreement, robust evidence*). Runoff and groundwater recharge are projected to increase at high latitudes and in the wet tropics, and to decrease in most dry tropical regions, controlled mainly by changes in precipitation. Projected climate changes imply large changes in the frequency of floods. Climate change is projected to reduce renewable water resources in most semi-arid and arid regions, potentially affecting food security. Impacts of climate change on water resources are expected to reduce economic growth, particularly in developing countries (*high agreement, limited evidence*). [3.2.5, 3.4, 3.5, 3.6.5, Table 3-2, WGI AR5 12.4.5]

Adaptive water management techniques, such as scenario planning, learning-based approaches, and flexible solutions, offer an opportunity to address uncertainty due to climate change (*high agreement, limited evidence*). Barriers include lack of technical capacity, financial resources, awareness, and communication. A low-emissions pathway reduces damage costs and costs of adaptation. [3.4, 3.5, 3.6, 3.7.2]

Terrestrial and inland water systems

Direct human impacts such as land-use change, pollution, and water resource development will continue to dominate threats to freshwater ecosystems (*high confidence*) and terrestrial ecosystems (*medium confidence*) with climate change becoming an increasing additional stress through the century, especially for high-warming scenarios (e.g., RCP 6.0 and 8.5). Even for mid-range rates of climate change (i.e., RCP 4.5 and 6.0 scenarios) many species will be unable to move fast enough to track suitable climates (*medium confidence*). See Figure SPM.3. Projected climate changes imply increased extinction risk for a substantial fraction of species during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, and invasive species (*very high confidence*). Forests may be more sensitive to future climate change than reported in AR4, and tree mortality and forest dieback could become a problem in many regions much sooner than previously anticipated (*medium confidence*). [4.2.4, 4.3, 4.4.1, Box CC-RF]

Carbon stored in land and freshwater ecosystems in the form of plant biomass and soil organic matter has increased over the past two decades (*virtually certain*). The terrestrial carbon sink is offset to a large degree by carbon released to the atmosphere through forest conversion to farm and grazing land and through forest degradation (*high confidence*). The carbon stored thus far in terrestrial ecosystems is vulnerable to loss back to the atmosphere as a result of climate change and land-use change (*medium confidence*). [4.2, 4.3, Box 4-4]

Management actions can reduce, but not eliminate, exposure to climate-driven ecosystem impacts and can increase ecosystem adaptability (*high confidence*). Adaptive capacity of ecosystems can be increased by reducing other stresses, maintaining a large pool of genetic diversity and functional evolutionary processes, assisting translocation, and manipulating disturbance regimes. [4.4.1, 4.4.3]

Terrestrial and freshwater ecosystems can, when pushed by climate change, cross "tipping points" and abruptly change in composition, structure, and function (*high confidence*). The crossing of these tipping

points will result in significant increases in carbon emissions to the atmosphere (*medium confidence*). Examples include abrupt transformation of the ecology and albedo of the boreal-arctic system (*low confidence*) and of the Amazon forest to more open, dry-adapted ecosystems (*low confidence*). [4.2, 4.3.3, Box 4-3, 4-4, Figure 4-10]

[INSERT FIGURE SPM.3 HERE
Figure SPM.3: Synthetic overview of projected abilities of some terrestrial and freshwater species to track climate by movement across landscapes. (A) Rates of climate change for global land areas. Black dotted line shows observed rates of climate change. Other rates were calculated from the CMIP5 ensemble for the historical period (black heavy line, with upper and lower bounds as light black lines) and for the future based on the four RCPs. A lower bound is given for RCP 2.6, and an upper bound for RCP 8.5. (B) Corresponding climate velocities, providing indication of the speed at which species' ranges would need to move to track changing climatic conditions. In mountainous areas with low climate velocities, species would only need to move short distances upslope to track a warming climate. In flat areas with high climate velocities, such as the Amazon basin, species would need to move large distances to track a warming climate. (C) Maximum estimated rates of displacement of several terrestrial and freshwater species groups, indicating how fast these groups can move across landscapes. Rates of species displacement are well defined for plants, especially trees, but less well defined for other groups. Displacement rates do not generally account for biotic interactions or human intervention that may speed or hinder dispersal. The thin red arrows give an example of interpretation: a rate of climate change of 0.065 °C/yr (approximately equal to projected rates by mid-century for RCP 8.5) corresponds to ~2.2 km/yr global average climate velocity. This global-average velocity would exceed projected maximum capacity for displacement for most plants, most primates, many rodents, and some less mobile species of other groups. For RCP 2.6, most species would be able to track climate by mid-century. Color gradient in panel A provides overall representation of the ability of species to track climate change. Detailed spatial analyses and maps of species displacement can be found in the references cited in WGII Chapter 4. E.t ungulates = even-toed ungulates; Phyto. insects = phytophagous (herbivorous) insects; Fw. mollusks = freshwater mollusks. [Figure 4-6]]

Coastal systems and low-lying areas

Due to relative sea-level rise, coastal systems and low-lying areas will increasingly experience adverse impacts associated with submergence and flooding from extreme coastal high water levels (*high confidence*). The population and assets exposed to coastal risk as well as human pressures on coastal ecosystems will increase significantly in the coming decades due to population growth, economic development, urbanization, and coastward migration. Under medium population projections, population exposed to the 100-year coastal flood is expected to increase from 271 million in 2010 to 345 million in 2050 due to socioeconomic development only. By 2100, without adaptation, the majority of people projected to be affected by coastal flooding and displaced due to inundation and erosion will be in East, Southeast, and South Asia. In 2100, for medium socioeconomic development assumptions and a 1.26 m sea-level rise, the expected direct global annual cost of coastal flooding may reach 300 US$ billion per year without adaptation and 90 US$ billion per year with adaptation, including costs of adaptation and residual damages. [5.3, 5.4.3, 5.5.3]

Acidification and warming of coastal waters will continue with significant consequences for coastal ecosystems (***high confidence***). The interaction of acidification and warming exacerbates coral bleaching and mortality (*very high confidence*). [5.4.2, 6.2, 6.3, 6.5.2, 30.4, 30.5, Box CC-CR, CC-OA]

Marine systems

Through species gains and losses in response to warming, the diversity of marine animals and plants will increase at mid and high latitudes (*high confidence*) and fall at tropical latitudes (*low confidence*), leading to large-scale redistribution of global catch potential for fishes and invertebrates (*medium confidence*). Animal displacements are projected to lead to a 30–70% increase in the fisheries yield in high-latitude regions but a drop of 40–60% in the tropics by 2055 relative to 2005 under the SRES A1B scenario (*medium confidence* for general trend of shifting fisheries yields, *low confidence* for magnitude of change). See Figure SPM.4. [6.2.5, 6.3, 6.4, 6.5]

Impacts on ocean ecosystems and processes reveal significant regional differences that will benefit from differing policies and adaptation approaches (*medium agreement, medium evidence*). Building dynamic

fisheries management and sustainable aquaculture provides opportunities for adaptation to changes in the distribution and productivity of fish stocks (*high agreement, medium evidence*). [6.5, 7.5.1, 30.5.5, 30.6.3]

Changes to surface winds, sea level, wave height, and storm intensity will increase the risks associated with coastal and ocean based industries such as shipping, oil, gas, and mineral extraction (*medium agreement, medium evidence*). New opportunities as well as international issues over access and vulnerability are expected as waters warm, particularly in high latitude regions. [30.6, 6.5]

[INSERT FIGURE SPM.4 HERE
Figure SPM.4: (A) Multi-model mean changes of projected net primary production. To indicate consistency in the sign of change, regions are stippled where all models (four in total) agree on the sign of change. Changes are annual means under SRES A2 for the period 2080 to 2099 relative to 1870 to 1889. (B) A projection of maximum fisheries catch potential of 1000 species of exploited fishes and invertebrates from 2000 to 2050 under SRES A1B. (C) Example of changes occurring within fisheries across the ocean. [Figures 6-14, 6-15, and 30-15]]

Food production systems and food security

Without adaptation, warming of up to 2°C local temperatures is expected to reduce yields on average for the major cereals (wheat, rice, and maize) in temperate regions, although many individual locations may benefit (*medium confidence*). There is confirmation that warming up to 2°C will decrease yields in low-latitude tropical regions (*medium agreement, robust evidence*). Reductions of more than 5% are *more likely than not* beyond 2050 and *likely* by the end of the century. From the 2070s onwards, all of the positive yield changes are in temperate regions, suggesting that yield reduction in the tropics are *very likely* by this time and substantial, particularly for wheat (*high agreement, robust evidence*). [7.4, Figures 7-5, 7-6, and 7-7]

Adaptation possibilities of food systems to climate change show a very wide range in effectiveness. Net benefits of adaptation will increase with increasing local mean temperature up to ~3°C local warming above preindustrial (*medium confidence*). Generally, adaptation leads to lower reductions in food production than in its absence with an overall crop yield difference in adaptation cases of about 15-20% over non-adaptation cases (*high agreement, medium evidence*), with more effective adaptation at higher latitudes (*medium agreement, limited evidence*), but with some adaptation options more effective than others. Benefits of adaptation are greater for wheat, rice, and maize in temperate rather than tropical regions [7.1, 7.3.2, 7.5, 7.6, Figures 7-5, 7-9]

Urban areas

Increasing concentration of populations, assets, and economic activities in the urban areas of almost all countries, irrespective of income level, will increase the concentration of climate-related risks for a large and growing proportion of the world's population (*medium confidence*, based on *high agreement, medium evidence*). Climate change will shift the comparative advantages of cities and regions and differentially threaten or enhance the resource, asset, and economic base and so lead to significant structural changes and impacts on local, national, and potentially the global economy. [8.1, 8.3, 8.4]

Rural areas

Future impacts on rural areas will be mediated in complex ways by changing patterns of extreme events and/or effects of climate change on agriculture and less-managed ecosystems (*high confidence*). Major impacts will be felt through impacts on water supply, food security, and agricultural incomes, including impacts on major non-food cash crops such as coffee. Adaptation can build on current responses to climate variability, in production of food crops, cash crops, and livestock and in water management, but these may not be sufficient to deal with the range of projected climate change. [9.3.3, 9.4.1, 9.4.3]

Climate change will lead to higher prices and increased volatility in agricultural markets, which may undermine global food supply security while differentially affecting net buyers and net sellers of food (*medium* to *high confidence*). Deepening agricultural markets through reforming trade and making institutional efforts to improve the predictability and reliability of the world trading system, as well as by investing in additional

supply capacity of small-scale farms in developing countries, could help reduce market volatility and manage food supply shortages that might be caused by climate change (*medium agreement*). [9.3.3]

Monetized impacts of climate change will be significant especially for the developing regions, due to their economic dependence on agriculture and natural resources, low adaptive capacities, and geographical locations (*high confidence*). Valuation of non-marketed ecosystem services and limitations of economic valuation models that aggregate across contexts pose challenges for valuing rural impacts. [9.3.4]

Key economic sectors and services

Climate change would reduce energy demand for heating and increase energy demand for cooling in the residential and commercial sectors (*high agreement, robust evidence*). Energy demand will be influenced by changes in demographics, lifestyles, design and insulation of housing, and energy efficiency. [10.2]

Climate change would affect energy sources and technologies differently, depending on resources (water flow, wind, insolation), technological processes, or locations involved (*high agreement, robust evidence*). Changes in the availability and temperature of water for cooling are the main concern for thermal and nuclear power plants, but several options are available to cope with reduced water availability. Climate change would influence the integrity and reliability of pipelines and electricity grids (*medium agreement, medium evidence*). [10.2]

Human health

In the next few decades, climate change impacts on ill-health include the following (*high confidence*): greater incidence of injury, disease, and death due to more intense heat waves, storms, floods, and fires; increased risk of under-nutrition resulting from diminished food production in poor regions; loss of work capacity and reduced labor productivity in vulnerable populations; increased risks of food- and water-borne diseases and vector-borne infections; and modest improvements in some areas due to lower impacts of cold, shifts in food production, and reduction of disease-carrying vectors. The most effective adaptation measures for health in the immediate term are programs that extend basic public health measures and essential health services, increase capacity for disaster preparedness and response, and alleviate poverty (*very high confidence*). [11.4, 11.5, 11.6, 11.7]

For global mean temperature increase of 4°C above 1986-2005, important limits to adaptation for health impacts may have been exceeded in many areas of the world (*high confidence*). These relate to sea-level rise, storms, loss of agricultural productivity, and daily temperature/humidity conditions that exceed coping mechanisms. See Box SPM.5. [11.8]

Human security

Climate change threatens human security, because it a) undermines livelihoods, b) compromises culture and identity, c) increases migration that people would rather have avoided, and d) undermines the ability of states to provide the conditions necessary for human security (*high agreement, robust evidence*). For populations that are already socially marginalized, are resource dependent, and have limited capital assets, human security may be progressively undermined as the climate changes. [12.1.2, 12.2, 12.3, 12.7]

Climate change will have significant impacts on forms of migration that compromise human security (*medium agreement, medium evidence*). Mobility is a widely used and often effective strategy to maintain livelihoods in response to social and environmental changes (*high agreement, medium evidence*). Legitimate and inclusive planning processes can help alleviate the conflict and insecurity that individuals and communities may experience from implementation of planned resettlement. [9.3.3, 12.3.2, 12.4.2, 12.4.3]

Climate change will lead to new challenges to states and will shape both conditions of security and national security policies (*medium agreement, medium evidence*). Some states are experiencing major challenges to their territorial integrity, including Arctic countries, small island states, and other states highly vulnerable to sea-level rise. Some impacts of climate change, such as changes in sea ice, transboundary and shared water resources, and migration of pelagic fish stocks, have the potential to increase rivalry among states. The presence of robust institutions can manage many of these rivalries such that human security is not severely eroded. [12.5.4, 12.6]

Livelihoods and poverty

Future impacts of weather events and climate will slow down economic growth and poverty reduction, further erode food security, and trigger new poverty traps, the latter particularly in urban areas (*medium confidence,* based on *medium agreement, medium evidence*). Climate change will exacerbate multidimensional poverty in low and lower middle-income countries, including high mountain states and countries with indigenous people affected by sea-level rise and relocation, and create new poverty pockets in upper middle- to high-income countries. Urban and wage-labor dependent poor households, as well as regions with high food insecurity (above all in Africa) and high inequality, will be particularly affected due to food price increases. [10.9, 13.2.2, 13.4]

Social protection programs can help the chronically poor reduce risk and protect assets during crises, through transfers of income or assets to the poor, protection against livelihood risks, and enhancement of the social status and rights of the marginalized (*medium confidence*). Existing examples underscore the need to explicitly address livelihood security and resilience in the long-term, rather than focusing on short-term disaster relief. [13.4]

Regional risks

Examples of specific regional risks across sectors are presented in Table SPM.4. Figure SPM.5 provides a synthesis of sectoral risks for several regions, based on the expert judgment of assessment authors. Risks are estimated for the era of climate responsibility (here, for 2030-2040) and for the era of climate options (here, for 2080-2100) under different levels of global average warming (about +2 or +4°C global average warming above preindustrial in 2080-2100). Risks are summarized sector by sector, reflecting the overall structure of the WGII report (Part A).

[INSERT TABLE SPM.4 HERE
Table SPM.4: Examples of regional risks that increase with increasing level of climate change. Examples of potential positive impacts are also given. Risks increasing moderately or severely from now until the 2040s, which can be considered an era of climate responsibility, are described, in addition to risks increasing from ~2050 through the end of the 21st century, which can be considered to represent an era of climate options. For risks increasing in both the era of climate responsibility and the era of climate options, the potential for proactive adaptation to reduce the risks is characterized as low or high, with detail provided on adaptation issues and prospects. Risks increasing in the era of climate options can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options. Increasing risks in the era of climate responsibility are generally difficult to reduce substantially through mitigation, even with globally effective mitigation. They can be managed through vulnerability reduction, adaptation, and transformations that promote climate-resilient development pathways.]

[INSERT FIGURE SPM.5 HERE
Figure SPM.5: Estimated risk from climate change to selected sectors and systems in Africa (A), Europe (B), and North America (C), for different time frames (2030-2040 and 2080-2100), under two levels of global average warming above preindustrial (2°C and 4°C) and different assumptions about adaptation to manage these risks. Levels of risk and of adaptation are differentiated by colored shading, ranging from high adaptation to low adaptation. Estimated risks rely on expert judgments. The risk categories reflect the overall structure of Part A of the WGII AR5. [Figures 22-7 and 26-6]]

C.ii. Key and Emergent Risks

Key risks are potential adverse consequences for humans and social-ecological systems due to the interaction of climate-related physical hazards with vulnerabilities of societies and systems exposed. Risks are considered "key" due to high physical hazard or high vulnerability of societies and systems exposed, or both. [Box 19-2]

Key risks identified with *high confidence* include the following. [19.5.1, 19.6.2]

- Increased food insecurity from local conditions (e.g., adverse changes in rainfall patterns, limited alternative sources of income for some affected households) and regional and national conditions (e.g., breakdown of food distribution and storage processes).

- Dispossession of land, including alteration of rural inhabitants' coping and adaptation processes, from shifts in energy policies and global markets.
- Loss of livelihoods due to changes in climatic conditions and socioeconomic structures affecting people living in low-lying coastal zones and people engaged in rain-fed agriculture in developing and economies-in-transition countries.
- Increasing morbidity, mortality, and infrastructure failure as well as new systemic risks (e.g., risk of heat stress as a result of power shortages during extreme events) affecting urban areas in developed and developing countries.
- Increase in disease burden from the interaction of changes in physical climate conditions (e.g., increasing temperatures) with vulnerability (e.g., due to an aging population).
- Key risks associated with global mean temperature increase >4°C relative to preindustrial include exceedance of human physiological limits in some locations and nonlinear earth system responses. See Box SPM.5.

Interactions among climate change impacts in various sectors and regions, and human vulnerability and adaptation in other sectors and regions, as well as interactions between adaptation and mitigation actions present a variety of emergent risks (*high confidence*). [19.3.2]

- The risk of severe harm and loss due to climate-change-related hazards and various vulnerabilities is particularly high in large urban and rural areas in low-lying coastal zones. These areas, many characterized by increasing populations, are exposed to multiple hazards and potential failures of critical infrastructure.
- The risk of climate change to human systems is increased by loss of ecosystem services (e.g., water and air purification, protection from extreme weather events, preservation of soils, recycling of nutrients, pollination of crops), which are supported by biodiversity.
- In some water-stressed regions, groundwater stores that have historically acted as buffers against climate change impacts are being depleted, with adverse consequences for human systems and ecosystems, whilst at the same time climate change may directly increase or decrease regional groundwater resources.
- Climate change adversely affects human health, increasing exposure and vulnerability to other stresses, for example by altering prevalence and distribution of weather- and climate-sensitive diseases, increasing injuries and fatalities from extreme weather events, and eroding mental health following population displacement.
- Spatial convergence of impacts across sectors creates impact hotspots involving new interactions (Fig. SPM.6).

[INSERT FIGURE SPM.6 HERE
Figure SPM.6: Some salient examples of multi-impacts hotspots identified in this assessment. [Figure 19-2]]

Emergent risks also arise from indirect, trans-boundary, and long-distance impacts of climate change, sometimes mediated by the adaptive responses of human populations (*high confidence*). [19.4.1, 19.4.2]

- Increasing prices of food commodities on the global market due to local climate impacts, sometimes in conjunction with demand for biofuels, decrease food security and exacerbate malnutrition in distant locations.
- Climate change will pose significant consequences for migration flows at particular times and places, creating risks as well as benefits for migrants and for sending and receiving regions and states.
- The possible effect of climate change on conflict and insecurity has the potential to become a key risk because the magnitude of the influence of climate variability on security reported in most studies is large.
- Shifting species ranges in response to climate change adversely affect ecosystem function and services while presenting new challenges to conservation efforts. Where range shifts cannot track climatic changes, species are at risk of eventual extinction.

Under any plausible scenario for mitigation and adaptation, some degree of risk from residual damages is unavoidable (*very high confidence*). Assessments of stringent mitigation scenarios suggest that they can potentially avoid one half of the aggregate economic impacts that would otherwise accrue by 2100, and between 20-60% of the physical impacts, depending on sector and region. [19.7.1, 19.7.2]

Table SPM.5 presents specific examples of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in the report. Box SPM.6 integrates expert judgments about risks under the reasons for concern framework.

[INSERT TABLE SPM.5 HERE

Table SPM.5: A selection of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in the report. The examples underscore the complexity of risks determined by various climatic hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, demographic changes, or tolerance limits of species and ecosystems that often provide important services to vulnerable communities, generate the context in which climate-change-related harm and loss can occur. The examples illustrate that current global megatrends (e.g., climate change, urbanization, demographic changes), in combination and in specific development contexts (e.g., in low-lying coastal zones), can generate new systemic risks that go far beyond existing adaptation and risk management capacities, particularly in highly vulnerable regions. [Table 19-3]]

_____ START BOX SPM.5 HERE _____

Box SPM.5. Consequences of >4°C Temperature Increase

Projections of climate change impacts at 4°C global mean temperature increase above preindustrial indicate large impacts for physical, biological, and human systems and, in turn, large aggregate impacts for society and the global economy (*high confidence*). Global-mean surface temperatures for 2081–2100 (relative to early industrial, 1886–1905) for RCP 6.0 and 8.5 will *likely* be in the 5–95% range of the CMIP5 climate models, i.e., 2.0°C–3.9°C (RCP6.0), 3.3°C–5.5°C (RCP8.5).

For 4°C global mean temperature increase above preindustrial, the effects of climate change on water resources and ecosystems are projected to become dominant over other drivers such as population increases and land use change (*medium confidence*). Widespread coral reef mortality is projected (*high confidence*). Agricultural production is expected to decline in mid to high latitudes once local temperature rise exceeds 3°C (and for lower temperature rise in the tropics), corresponding to a global temperature rise below 4°C (*medium confidence*). Beyond 4°C there is high risk of marked yield loss even at high latitudes (*medium confidence*). Extreme heat waves such as that experienced in Russia in 2010 can become typical of a normal summer for a 4°C increase (*high confidence*). Sea-level rise in a 4°C world could result in the inundation of many small island states (*high confidence*). Emerging risks include exceedance of human physiological limits in some areas for a global temperature rise of 7°C (*medium confidence*).

Sub-Saharan Africa is identified as a multi-impacts hotspot in a 4°C world, with risks of increases in hunger and disease, and of loss of ecosystem function (*high confidence*). A 4°C increase would be expected to result in non-linear earth system responses, such as (1) eventual, irreversible loss of the Greenland Ice Sheet (*high confidence*) and (2) terrestrial carbon loss due to climate-carbon cycle feedback releasing CO_2 or CH_4 (*very likely*), which would accelerate climate change further. There would also be an increased chance of triggering the collapse of the West Antarctic Ice Sheet.

[12.4, 12.5, 19.4.3, 19.5.1, 19.6.3, 19.7.5, 23.4.1, WGI AR5 SPM, 2.4.3, 8.5.3, 12.4.1, Chapter 6, Table 13.5]

_____ END BOX SPM.5 HERE _____

_____ START BOX SPM.6 HERE _____

Box SPM.6. Anthropogenic Interference with the Climate System

Anthropogenic interference with the climate system is occurring. [WGI AR5 SPM, 10.3-10.6] The impacts of climate change[1] are already widespread and consequential. [18.3-18.6] Determining whether anthropogenic interference is dangerous involves judgments about risks.

The IPCC assesses scientific and technical understanding of risks and the range of possible outcomes. It also assesses understanding of how risks are perceived, as well as methods for incorporating different value systems in decisionmaking. The IPCC cannot, however, make a determination of the level of anthropogenic interference that is dangerous.

[INSERT FOOTNOTE 1: See Box SPM.1 for description of differing usage of the term “climate change” in IPCC and UNFCCC.]

Assessment of existing frameworks pertinent to Article 2 of the UNFCCC has led to evaluations of risk being updated in light of the advances since AR4, including SREX and the current report's discussions of vulnerability, human security, and adaptation. The management of key and emergent risks of climate change and reasons for concern includes (i) mitigation that reduces the likelihood of physical impacts and (ii) adaptation that reduces the vulnerability and exposure of societies and ecosystems to those impacts. Many of the key vulnerabilities, key risks, and emergent risks identified in this report reflect differential vulnerability between groups due to, for example, age, wealth, or income status, and deficiencies in governance, which are particularly important in assessing risk from extreme events and risk associated with the distribution of impacts. [19.6.1, 19.6.3, 19.7]

Impacts of climate change have now been documented globally, covering all continents and the ocean (*high confidence*; Table SPM.1). The degree to which projected damages are now manifest, or the detection of stronger early warning signals for expected impacts, can contribute to a more comprehensive risk assessment for dangerous anthropogenic interference with the climate system. [18.6.2]

Updating of the reasons for concern (Box SPM.6 Figure 1) leads to the following assessment:

- Unique human and natural systems tend to have very limited adaptive capacity, and hence climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C over preindustrial levels were exceeded (*high confidence*). [18.6.2, 19.6.3]
- The overall risk from extreme events due to climate change has not changed significantly since AR4, but there is higher confidence in the attribution of some types of extreme events to human activity and in the assessment of the risk from extreme events in the coming decades. In addition, there is a new appreciation for the importance of exposure and vulnerability, in both developed and developing countries, in assessing risk associated with extreme events. [18.6.2, 19.6.1, 19.6.3]
- Risk associated with the distribution of impacts is generally greatest in low-latitude, less developed areas, but because vulnerability is unevenly distributed within countries, some populations in developed countries are highly vulnerable to warming of less than 2°C, as noted in AR4 (*high confidence*). [19.6.3]
- Globally aggregated risk is underestimated because it does not include many non-monetized impacts, such as biodiversity loss, and because it omits many known impacts that have only recently been quantified, such as reduced labor productivity (*high confidence*). In addition, aggregated estimates of costs mask significant differences in impacts across sectors, regions, and populations (*very high confidence*). The overall assessment of aggregate risk and confidence in that assessment has not changed since AR4. [19.6.3]
- The risk associated with large-scale singular events such as at least partial deglaciation of the Greenland ice sheet remains comparable to that assessed in AR4. [19.6.3]

[INSERT BOX SPM.6 FIGURE 1 HERE
Box SPM.6 Figure 1: The dependence of risk associated with reasons for concern (RFCs) about climate change, updated based on expert judgment in this assessment. The color scheme indicates the additional risk due to climate change (with white to purple indicating the lowest to highest level of risk, respectively). Purple color, introduced here for the first time, reflects the assessment that unique human and natural systems tend to have very limited adaptive capacity. [Figure 19-5]]

_____ END BOX SPM.6 HERE _____

D) BUILDING RESILIENCE THROUGH MITIGATION, ADAPTATION, AND SUSTAINABLE DEVELOPMENT

D.i. Climate-resilient Pathways and Transformation

Climate-resilient pathways for development are rooted in iterative processes. These processes identify vulnerabilities to climate change impacts and take appropriate steps to reduce vulnerabilities in the context of development needs and resources and to increase the options available for vulnerability reduction and coping with surprises. They involve monitoring emerging climate parameters and their implications, along with the effectiveness of vulnerability reduction efforts, and revising risk reduction responses on the basis of continuing learning. [20.2.3, 20.6.2]

Climate-resilient pathways include actions across scales (a) to reduce climate change and its impacts and (b) to assure that effective risk management and adaptation can be implemented and sustained (*high confidence* based on *high agreement, medium evidence*). Impacts of climate change avoided under a range of scenarios for mitigation of greenhouse gas emissions are potentially large and increasing over the 21st century. Since mitigation reduces the rate as well as the magnitude of warming, it also delays the need to adapt to a particular level of climate change impacts, potentially by several decades. Prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation. Achieving climate-resilient development pathways benefits from attention to dynamic livelihoods, multidimensional poverty, and multifaceted impacts of climate change and climate change responses. [2.3, 2.4, 13.4, 19.7.1, 20.2, 20.3, 20.4, 20.6.1]

Estimates of global adaptation costs continue to improve but remain inconsistent in methods, sectoral coverage, purposes, and time frames. The most recent estimates suggest a range from 75 to 100 US$ billion per year globally by 2050 (*low confidence*). Important omissions from these estimates suggest the high end of this range could be much higher, and important shortcomings in the data and methods available for costing adaptation suggest the low end of this range could be substantially lower. Existing estimates of global adaptation costs could be higher if sectors such as ecosystems and tourism and socially contingent effects were included, and if developing countries' adaptation deficits were more fully taken into account. [17.3.6, 17.3.10, 17.3.11, 17.6]

Avoiding limits to adaptation will necessitate policy responses and awareness that go beyond greenhouse gas mitigation and adaptation responses alone (*medium agreement, limited evidence*). Climate-resilient pathways will often require transformations in order to assure sustainable development (*high confidence*, based on *high agreement, medium evidence*). See Box SPM.7. [2.2, 16.4, 16.6, 16.7, 20.5]

D.ii. Examples of Co-benefits, Synergies, and Tradeoffs

Responses to the risks of climate change can have implications beyond their primary objectives for the resilience of societies and systems.

Adaptation designed for one sector may interfere with the functioning of another sector, creating new risks (*high confidence*). Table SPM.6 presents potential tradeoffs among adaptation objectives. [4.3, 17.3, 19.3.2]

[INSERT TABLE SPM.6 HERE
Table SPM.6: Examples of potential tradeoffs among adaptation objectives. [Table 16-2]]

Use of the terrestrial biosphere in climate mitigation actions, such as through introduction of fast-growing tree species for carbon sequestration or the conversion of forest to biofuel plantations, may lead to negative impacts on ecosystems and biodiversity (*very high confidence*). Climate policies, such as encouraging cultivation of biofuels and payments under REDD, will result in mixed and potentially detrimental impacts on land-use and on the livelihoods of poor and marginalized people (*medium confidence*). Geoengineering approaches involving manipulation of the ocean to ameliorate climate change (e.g., purposeful nutrient fertilization, direct CO_2 injection into the deep ocean) have very large associated environmental and social consequences (*high confidence*). [3.7.2, 4.2.4, 6.4.2, 9.3.3, 13.3, 13.4, 21.5.3]

Reducing emissions of climate-altering pollutants can help reduce health impacts of climate change and simultaneously have local health co-benefits, for instance by reducing local emissions of health-damaging and climate-altering air pollutants associated with energy production and use in households and communities (*very high confidence*). In Asia as an example, development of sustainable cities with low-emissions vehicles and more trees and greenery would have a number of co-benefits including for public health. [11.9, 24.4-7]

In Europe, there are opportunities for policies that improve adaptive capacity and also help meet mitigation targets (*high confidence*). For example, some agricultural practices can potentially mitigate GHG emissions and at the same time adapt crops to increase resilience to temperature and rainfall variability. [23.8]

For Australasia, significant synergies and tradeoffs exist between mitigation and adaptation responses; interactions occur both within Australasia and between Australasia and the rest of the world (*very high confidence*). Flow-on effects from climate change impacts and responses outside Australasia have the potential to

outweigh some of the direct impacts within the region, particularly economic impacts on trade-intensive sectors such as agriculture (*medium confidence*), but they remain amongst the least explored issues. [25.7.5, 25.9, Box 25-10]

Throughout North America, adaptation actions at the local level have the potential to result in synergies, conflicts, or tradeoffs with mitigation and other development actions and goals (*high confidence*). For example, reductions in emissions of greenhouse gases can yield health co-benefits, while sea walls can protect coastal properties yet may negatively affect the structure and function of coastal ecosystems. [26.8]

For small islands, energy supply and use, tourism infrastructure and activities, and coastal wetlands offer opportunities for adaptation-mitigation synergies (*medium confidence*). [29.6.2, 29.7.2, 29.8, 29.3.3]

_____ START BOX SPM.7 HERE _____

Box SPM.7. Adaptation Limits and Transformation

Limits to adaptation emerge from the interaction between climate change and biophysical and socioeconomic constraints (*high agreement, robust evidence*). See Box SPM.7 Figure 1. Some adaptation limits may be removed over time through changing values or technological advancement.

[INSERT BOX SPM.7 FIGURE 1 HERE
Box SPM.7 Figure 1: Conceptual model of acceptable, tolerable, and intolerable risks and implications for limits to adaptation. [16.2, Figure 16-1]]

Greater adaptation efforts will be required to achieve objectives if mitigation efforts are not successful in avoiding high magnitudes of climate change (*high agreement, limited evidence*). There are, however, limits to the extent to which adaptation could reduce the impacts not avoided by mitigation, and residual loss and damage may occur despite adaptive action. The greater the magnitude of climate change, the greater the likelihood that adaptation will encounter limits.

Transformative changes may be necessary as a response to projected climate changes (*medium confidence*). Transformation in wider political, economic, and social systems can open or close policy spaces for more resilient and sustainable forms of climate responses (*high confidence*). While transformations may be reactive, forced, or induced by random factors, they may also be deliberately created. Deliberate transformations can take place in relation to transformational adaptation, transformation to low-carbon societies, or transformations to global sustainability.

[14.1, 14.3.4, 16.2, 16.3, 16.4, 16.5, 19.6, 19.7, 20.5, 25.3, 25.4, 25.11]

_____ END BOX SPM.7 HERE _____

Table SPM.1: Observed impacts attributed to climate change with *medium* (*) or *high* (**) confidence, for physical, biological, and human systems across eight major world regions. [Tables 18-6, 18-7, 18-8, 18-9]

REGION	Freshwater Resources & Systems	Terrestrial Ecosystems, Drought, & Wildfire	Coastal & Marine Systems	Human Systems
Africa	Retreat of tropical highland glaciers in East Africa* Lake surface warming & water column stratification increases in the Great Lakes & Lake Kariba** [13.2.1, 22.3.2, 22.5.1]	Tree density decreases in Sahel & semi-arid Morocco* Climate-driven range shifts of several southern plants & animals* Increased drought in the Sahel since 1970, partially wetter conditions since 1990* [22.2.2, 22.3.2]		Decline in fruit-bearing trees in Sahel*
Europe	Retreating glaciers in the Alps** Increase in rock slope failures in Western Alps** [18.3.1]	Earlier greening, earlier leaf emergence, & fruiting in temperate & boreal trees** Increased colonization of alien plant species in Europe* Earlier arrival of migratory birds in Europe since 1970* Increasing burnt forest areas during recent decades** [4.2.4, 4.4.1]	Poleward shifts in the distributions of zooplankton, fishes, seabirds, & benthic invertebrates, & conversion of polar into more temperate & temperate into more subtropical system characteristics in Northeast Atlantic** Phenology changes & retreat of colder water plankton to north in the Northeast Atlantic, with mean poleward movement of plankton reaching up to 200–250 km per decade from 1958–2005* Atlantic cod distribution shift due to warming, interacting with regime shift & regional changes in plankton phenology in North Sea.* Decreasing abundance of eelpout in Wadden Sea** [6.3.2, Table 6-8, Figure 6-16, 18.3.3, 30.5.1]	Stagnation of wheat yields in some countries in recent decades, due to warming and/or drought*
Asia	Permafrost degradation in Siberia, Central Asia, & Tibetan Plateau** Shrinking mountain glaciers across Asia.* Increased runoff in many rivers due to shrinking glaciers in the Himalayas & Central Asia** Surface water degradation in parts of Asia partially related to climate change* Earlier timing of maximum spring flood in Russian rivers** [Box 3-1, Box 3-2, 24.4.1, 28.2.1, WGI AR5 Chapter 4.3.2-4.3.3, 10.5.3]	Changes in plant phenology & growth in many parts of Asia, particularly in the north & east* Distribution shifts of many plant & animal species, particularly in the north of Asia, generally upwards in elevation or polewards* Advance of shrubs into the Siberian tundra* [4.2.1, Box 4-1, 24.4.2, 28.2.3]	Decline in coral reefs & large seaweeds in tropical Asian & Japanese waters** Shift from sardines to anchovies in Japanese Sea* [6.3.2, Figure 16-6, 24.4.3]	
Australasia	Significant decline in late-season snow depth at four alpine sites in Australia (1957-2002)*	Climate-related changes in genetics, growth distribution, & phenology of many species (e.g., earlier emergence of butterflies, change in plant flowering dates & bird breeding times, decline in body size of passerine birds)* [Table 25-3]	Mass bleaching of corals in the Great Barrier Reef, changes in coral calcification rates, & changes in coral disease dynamics** Multiple impacts of climate change on marine ecosystems from warming oceans, although other environmental changes may play a role. Examples are growth rate increases in fishes, intertidal-invertebrate range shifts, range shifts in near-shore fishes related to kelp decline, increasing abundance of northern marine species in Tasmania, recruitment declines of rock lobster & abalone, declines in growth rate & biomass of phytoplankton, southward expansion of some tropical seabirds in Australia** [6.3.2, Box 18-3, 25.6.2, Table 25-3]	Wine-grape maturation has advanced in recent decades, partly due to warming*

REGION	Freshwater Resources & Systems	Terrestrial Ecosystems, Drought, & Wildfire	Coastal & Marine Systems	Human Systems
North America	Primarily decreasing trends in amount of water stored in spring snowpack from 1960-2002** Observed shift to earlier peak flow in snow dominated rivers in Western North America** Runoff increases in the Midwestern & Northwestern US, decreases in Southern states* [26.2.2, WGI AR5 Chapter 2.6.2]	Species distribution shifts upward in elevation & northward in latitude across multiple taxa* Phenology changes* Increases in wildfire activity, including fire frequency & duration, length of fire season, & area burned* [26.4.1, 26.4.2, Box 26-2]	Northward range shifts of Northwest Atlantic fishes in response to warming since the 1960s, with some of the shifts being correlated with the Atlantic Multidecadal Oscillation* Earlier onset of Pink Salmon migration (Alaska), collapse of Sockeye Salmon spawning migration (Fraser River, BC), due to warming** Loss of biomass of midwater fishes off California Coast** [6.3.3, 6.6.3, Table 6-8, Figure 6-16]	Direct & indirect economic impacts of climate extremes on industry through reduced supply of raw material, the production process, the transportation of goods, & the demand for certain products* [26.8]
Central & South America	Retreat of tropical Andean glaciers in Venezuela, Colombia, Ecuador, Peru, & Bolivia (1950-2000) & glaciers & ice-fields in the extra tropical Andes** Changes in extreme flows in Amazon River* Changed discharge patterns in rivers in the Western Andes due to retreating glaciers & reduced snowpack; for major river basins in Colombia, decreased discharge during the last 30-40 years** Increased stream flow in sub-basins of the La Plata River, attributed to increasing precipitation, but also to trends in land-use changes that have reduced evapotranspiration** [27.2.1, 27.3.1]		Bleaching of coral reefs in the western Caribbean near the coast of Central America** [27.3.3]	Increase in frequency & extension of malaria* Increase in agricultural yields in Southeastern South America* [27.3.4, 27.3.7]
Polar Regions	Decreasing Arctic sea ice cover in summer & reduction in glacier ice volume, due to warming* Decreasing snow cover duration across the entire Arctic* Widespread permafrost degradation, especially in the southern Arctic** Rising winter minimum flows in most sectors of the Arctic due to enhanced groundwater input due to permafrost thawing* Disappearance of thermokarst lakes due to permafrost degradation in the low Arctic. New lakes being created in areas of formerly frozen peat** [28.2.1, 28.2.3, WGI AR5 Chapter 10.5.1]	Increase in shrub cover in tundra in North America & Eurasia.** Significant advance of Arctic tree-line in latitude & altitude, due to warming, although lower pace than expected due to insect outbreaks & land-use history. Changes in breeding area & population size of subarctic birds, due to warming & shrub encroachment in the tundra* Retreating snow-bed ecosystems & tussock tundra, due to prolonged thawing season & less precipitation in the form of snow.** Increasing occurrence of ice layers in the annual snow pack due to rain-on-snow events, affecting animal populations in the tundra* Increasing plant species in the West Antarctic Peninsula & nearby islands over the past 50 years** Increasing drought in high Arctic polar deserts** Increased frequency of wildfires in conifer forest at Arctic southern fringe, due to increasing summer temperature. Tundra wildfires are increasing in frequency in the Low Arctic, due to increasing summer air temperature & subsequent surface drought* [28.2.1, 28.2.3]	Sea ice loss negatively affecting many arctic & subarctic marine non-migratory mammals (walrus, seals, whales)** Reduced growth rate & body mass, lower survival & reproductive capacity of polar bears, linked to reduced off-shore range & sea-ice loss due to warming** Reduced reproductive success of Arctic seabirds, due to earlier sea-ice break-up* Reduced thickness of foraminifera shells due to acidification of Southern Ocean waters * Declines in Antarctic krill density in the Scotia Sea by ~30% since the 1980s, due to reduced winter sea ice extent & duration* Many Southern Ocean species of seals & seabirds, e.g., penguins & albatross, negatively responding to warmer conditions* Increased coastal erosion in Arctic, due to prolonged ice-free season at shore, increased exposure to wave activity, & degrading permafrost** [6.3.4, 28.2.2, 28.2.4, 28.2.5, 28.3.4]	Impact on livelihoods of Arctic indigenous peoples* [18.4.5, Box 18-5]
Small Islands		Tropical-bird population changes in Mauritius, due to changes in rainfall* [29.3.2]	Coral bleaching near many tropical small islands** [29.3.1]	

Table SPM.2: Illustrative examples of adaptation experience, as well as approaches to reduce vulnerability and enhance resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerabilities, inequalities, and climate change come to the fore. At the same time, place-based examples illustrate how larger-level drivers and stressors shape differential risks and livelihood trajectories, often mediated by institutions.

Mangrove restoration to reduce flood risks and protect shorelines from storm surge
EXPOSURE AND VULNERABILITY: Loss of mangroves increases exposure of coastlines to storm surge, wave erosion, and tropical cyclones. Exposed infrastructure, livelihoods, and people are vulnerable to associated damage. Areas with development in the coastal zone, such as on small islands, are particularly vulnerable. [15.3.4, 29.7.2]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: *Likely* increase in extreme sea levels since 1970, mainly caused by rising mean sea level. *Low confidence* that any reported long-term changes in tropical cyclones are robust. Projected: By the end of the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged. *Likely* increase in both global mean tropical cyclone maximum wind speed and rainfall rates. *More likely than not* substantial increase in the frequency of the most intense tropical cyclones in some basins. [WGI AR5 2.6.3, 3.7.5, 11.3.2, Box 14.2]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: Regional rates of sea level change can vary significantly from the global mean. Mean significant wave height *likely* increased since the mid-1980s over much of the mid-latitude North Atlantic, the North Pacific, and the Southern Ocean. For tropical cyclones observed over the satellite era, increases in the intensity of the strongest storms in the Atlantic appear robust. Projected: For all ocean basins, tropical cyclone frequency is projected to decline or remain the same, the mean lifetime maximum intensity of tropical cyclones is projected to increase or remain the same, and cyclone-associated rainfall rates are projected to increase. In the North Atlantic and the eastern part of the North Pacific, the frequency of category 4/5 tropical cyclones is projected to increase. *Very likely* increase in the occurrence of future extreme sea level and related coastal flooding events with increasing global mean sea level, but *low confidence* in region-specific projections in storminess and storm surges. [WGI AR5 2.6.3, 3.4, 3.7, 13.7.2; Figures 3.6-3.8, 13.19; Box 14.2]
DESCRIPTION: Mangrove restoration and rehabilitation has occurred in a number of locations (Vietnam, Myanmar, Samoa, and Brazil, for example) to reduce coastal flooding risks and protect shorelines from storm surge. In Vietnam, restored mangroves have been shown to attenuate wave height and thus reduce wave damage and erosion. They protect aquaculture industry from storm damage and reduce saltwater intrusion. [8.3.3, 2.3.4, 15.3.4, 27.3.3, 22.4.5]
BROADER CONTEXT: •Considered a low-regrets option benefiting sustainable development, livelihood improvement, and human well-being through improvements for food security and reduced risks from flooding, wave damage, and erosion. •Synergies with mitigation given that mangrove forests are sinks for carbon. •Restoration and rehabilitation can help build local knowledge, capacity, and strategies to institutionalize climate change adaptation and resilience in local planning and development. •Mangrove bioshields created from exotic species can detrimentally impact native ecosystems. [8.4.2, Box 5.4, 29.7.2, 15.3.4]
Farming practices in Africa, such as zai and integration of trees into annual cropping systems
EXPOSURE AND VULNERABILITY: Land degradation and soil infertility have negatively impacted yields in parts of Africa, such as in Zambia, Malawi, the highlands of Ethiopia, Burkina Faso, and the drylands of the Sahel. Soil erosion, soil compaction due to livestock trampling, and low soil water holding capacity reduce plant growth. [7.5.2, Table 9-6, Box 22-4]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: Increase in globally averaged near surface temperatures since 1900, with warming particularly marked since the 1970s. *Very likely* decrease in the overall number of cold days and nights and increase in the overall number of warm days and nights, on the global scale between 1951 and 2010. *Medium confidence* that the length of warm spells, including heat waves, has increased globally since 1950. *Medium confidence* in global precipitation change over land since 1950. *Likely* increase in the number of heavy precipitation events in more regions than the number has decreased since 1950. *Low confidence* in any observed large-scale trends in drought. Projected: For RCP 4.5, 6.0, and 8.5, global mean surface air temperatures are projected to at least *likely* exceed 2°C with respect to preindustrial by 2100. *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global temperature increases, for events defined as extremes on both daily and seasonal timescales. *Virtually certain* increase in global precipitation as global mean surface temperature increases. Regional to global-scale projections of soil moisture and drought remain relatively uncertain. For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 2.4, 2.5.1, 2.6.1, 2.6.2, 12.3.1, 12.4.1, 12.4.3, 12.4.5; Figures 2.28, 12.2, 12.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:

Observed: Increase in frequency of warm days and nights in northern and southern part of continent and decrease in frequency of cold days and nights in southern part of continent.
Overall increase in dryness and modest increases in rainfall over most of equatorial Africa and the Red Sea coast (*medium confidence*).
Projected: *Likely* increase in warm days and decrease in cold days in all regions of Africa (*high confidence*). Increase in warm days largest in summer and fall (*medium confidence*).
Likely more frequent and/or longer heat waves and warm spells in Africa (*high confidence*).
[22.2.2; SREX Tables 3-2, 3-3]

DESCRIPTION:

Zai uses small pits dug manually during the dry season, combined with contour stone bunds to slow runoff. Animal manure or compost is placed in each pit. The pits facilitate water infiltration and concentrate runoff water, and the applied organic matter improves soil nutrient status and attracts termites, which positively affect soil structure. The practice can also improve tree growth amid crop rows, and trees, especially nitrogen-fixing varieties, can be integrated as an independent strategy. Trees reduce crop exposure to wind and heavy rainfall and improve moisture retention and rainwater capture. Factors that have enabled farmer-managed natural regeneration include in southern Niger devolving tree ownership from the state to the farmer, as well as community-based efforts involving partnerships of farmers and NGOs.
[7.5.2, Table 9-6, Box 22-4, 15.3.4]

BROADER CONTEXT:

- Both techniques can improve yields, water retention, food security, and income generation, also reversing land degradation.
- Tree growth, through production of fruit, animal fodder, or fuelwood, can expand livelihood options and allow diversification, thereby enhancing resilience.
- Zai is a very labor-intensive technique, which can be expedited through use of animal-drawn implements.
- Farmer-managed natural regeneration has been paired with other low-cost behavioral actions, for example in Ethiopia, aiming to reverse ecosystem degradation and promote reforestation with benefits for carbon sequestration.

[7.5.2, Table 9-6, Box 22-4, 15.3.4, 17.4.1]

Adaptive approaches to flood defense in Europe

EXPOSURE AND VULNERABILITY:

In some countries, a high percentage of the population is exposed to flooding. Exposed assets and infrastructure represent a substantial fraction of national GDPs.
[Box 5-3]

CLIMATE INFORMATION AT THE GLOBAL SCALE:

Observed: *Likely* increase in extreme sea levels since 1970, mainly caused by rising mean sea level.
Likely increase in the number of heavy precipitation events in more regions than the number has decreased since 1950.
Projected: *Very likely* that the rate of global mean sea level rise during the 21st century will exceed the rate observed during 1971-2010 for all RCP scenarios.
For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms.
[WGI AR5 2.6.2, 3.7.5, 12.4.5, 13.5.1, Table 13.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:

Observed: Increased heavy wintertime precipitation since the 1950s in some areas of Northern Europe (*medium confidence*).
Increased heavy precipitation since the 1950s in some parts of west-central Europe and European Russia, especially in winter (*medium confidence*).
Isostasy and decreasing sea level in Scandinavia.
Projected: Overall precipitation increase in Northern Europe and decrease in Southern Europe (*medium confidence*).
Increased extreme precipitation in Northern and Atlantic regions of Europe during all seasons, and in Central Europe except in summer (*high confidence*). Annual increases of intense precipitation days over the Mediterranean region.
Storm activity over the North Atlantic *likely* to increase and extend farther downstream into Europe, and to decrease on both the north and south flanks, especially over the Mediterranean (*medium confidence*).
Likely reduction in the occurrence of Northern Hemisphere extratropical storms, although the most intense storms reaching Europe *likely* to increase in strength. An increase in the North Atlantic Oscillation *likely* to increase the number of wintertime storms heading into Northern Europe and the average intensity of precipitation per storm.
[23.2.2; WGI AR5 Box 14.3; SREX Table 3-2]

DESCRIPTION:

Several governments have made ambitious efforts to address flood risk over the coming century. In the Netherlands, government recommendations include "soft" measures preserving land from development to accommodate increased river inundation; raising the level of lakes to ensure continuous freshwater supply; restoring natural estuary and tidal regimes; maintaining flood protection through beach nourishment; and ensuring necessary political-administrative, legal, and financial resources. The plan is estimated to cost €2.5 to 3.1 billion a year through 2050, 0.5% of the current Dutch annual GNP. The British government has also developed extensive adaptation plans to adjust and improve flood defenses for the protection of the Thames estuary and the city of London from future storm surges and river flooding. Pathways for different adaptation options and decisions depending on eventual sea level rise have been analyzed.
[Box 5-3, 23.7.1]

BROADER CONTEXT:

- The Dutch plan is considered a paradigm shift, addressing coastal protection by "working with nature" and providing "room for river." The concept of creating space for water and integrating water management approaches with goals of environmental protection is an essential component of integrated water management.
- The British plan incorporates iterative, adaptive decisions depending on the eventual sea level rise.
- The large infrastructure project of the Thames flood defense barrier involved public-private partnerships.
- In cities in Europe and elsewhere, the importance of having strong political leadership or government champions to drive the initial development of climate adaptation plans has been noted.

[Box 5.3, 23.7.1, 17.5.3, 8.5.3, 23.7.4, 23.7.2]

Relocation of agricultural industries in Australia
EXPOSURE AND VULNERABILITY: Crops sensitive to changing patterns of rainfall, water availability, and temperature. [7.5.2]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: Increase in globally averaged near surface temperatures since 1900, with warming particularly marked since the 1970s. *Very likely* decrease in the overall number of cold days and nights and increase in the overall number of warm days and nights, on the global scale between 1951 and 2010. *Medium confidence* that the length of warm spells, including heat waves, has increased globally since 1950. *Medium confidence* in global precipitation change over land since 1950. *Likely* increase in the number of heavy precipitation events in more regions than the number has decreased since 1950. *Low confidence* in any observed large-scale trends in drought. Projected: For RCP 4.5, 6.0, and 8.5, global mean surface air temperatures are projected to at least *likely* exceed 2° C with respect to preindustrial by 2100. *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global temperature increases, for events defined as extremes on both daily and seasonal timescales. *Virtually certain* increase in global precipitation as global mean surface temperature increases. Regional to global-scale projections of soil moisture and drought remain relatively uncertain. For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 2.4, 2.5.1, Figure 2.28, 2.6.1, 2.6.2, 12.3.1, 12.4.1, Figure 12.2, Figure 12.5, 12.4.3, 12.4.5]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: Mean temperature increase of 0.9°C per decade over Australia since 1911 (*very high confidence*). Cool extremes rarer and hot extremes more frequent and intense over Australia and New Zealand (*high confidence*). Late autumn/winter decreases in precipitation in Southwestern Australia since the 1970s and Southeastern Australia since the mid-1990s, and annual increases in precipitation in Northwestern Australia since the 1950s (*very high confidence*). Significant increases in annual intensity of heavy precipitation in recent decades for sub-daily events in Australia (*high confidence*). Projected: Further warming of Australasia this century *virtually certain*, greatest over inland areas and least in coastal areas. Hot days and nights more frequent and cold days and nights less frequent during the 21st century in Australia and New Zealand (*high confidence*). Annual decline in precipitation over southwestern Australia (*high confidence*) and in southern Australia (*medium confidence*). Reductions strongest in the winter half-year (*high confidence*). Increase in intensity of rare daily rainfall extremes (*high confidence*) and of annual daily extremes (*medium confidence*) in Australia and New Zealand. Drought occurrence to increase in Southern Australia (*high confidence*). Snow depth and snow area to decline in Australia (*very high confidence*). Freshwater resources projected to decline in the highly populated southeast and the far southwest of Australia. [25.5.1, Table 25-1]
DESCRIPTION: Industries and individual farmers are relocating parts of their operations, for example for rice, wine, or peanuts in Australia, or are changing land use in situ in response to recent climate change or perceptions of future change. There have been new investments in grapes in Tasmania and switching from grazing to cropping in South Australia. Adaptive movement of crops has also occurred elsewhere, such as in China. [7.5.2, Table 9-6, 25.7.2, Box 25-5]
BROADER CONTEXT: •Considered transformational adaptation in response to impacts of climate change. •Positive or negative implications for communities in origin and destination regions, with substantial changes required in transport chains, inputs, management, or growing contracts. •Some decisions run across scales and include many stakeholders, with comprehensive regional assessments across enterprises and economic and resource outcomes needed. [7.5.2, 25.7.2, Box 25-5]

Table SPM.3: Entry points, strategies, measures, and options for managing the risks of climate change. These approaches should be considered overlapping rather than discrete, and they are often pursued simultaneously. Examples given can be relevant to more than one category.

Entry Point	Category			Examples	Chapter Reference(s)
Vulnerability reduction through development and planning	Forms of sectoral integration	Human development	Specific measures	Low regrets options to reduce structural inequalities: improved access to education, nutrition, health facilities, energy, safe settlement structures, social support structures; reduced gender inequality and marginalization in other forms.	13.1.2, 13.3.1, 13.4.1, 13.4.2, 22.3.1
		Poverty alleviation		Insurance schemes, social protection programs, disaster risk reduction. Improved access to and control of local resources, land tenure, and storage facilities. Low regrets options to reduce structural inequalities.	13.1.2, 13.3.1, 13.3.2, 13.4.1
		Livelihood security		Income and asset diversification. Improved infrastructure. Access to technology and decision-making fora, enhanced agency.	13.1.1, 13.3.1, 13.4.1
		Disaster risk reduction and management		Early warning systems.	11.7.3, 22.4.5, 26.9.1
		Ecosystem management		Maintaining wetlands and urban green spaces, coastal afforestation.	8.3.3, Box 8.1, 15.3.1, Box CC-EA
		Spatial or land-use planning		Provisioning of adequate housing, infrastructure, and services. Managing development in flood prone and other high risk areas.	8.1.4, 8.4.3, 8.5.3
Adaptation	Structural/ concrete	Engineered	Specific options	Sea walls, water storage, improved drainage, beach nourishment, flood shelters. Improved infrastructure.	14.3.1, Table 14-2
		Technological		New crop and animal varieties, efficient irrigation and water use, hazard mapping and monitoring, early warning systems, home insulation.	14.3.1, Table 14-2
		Ecosystem-based		Wetland reestablishment, reestablishment of floodplains, bushfire fuel-reduction actions.	14.3.1, Table 14-2
		Services		Social safety nets, food banks, vaccination programs, municipal services.	14.3.1, Table 14-2
	Institutional	Economic		Financial incentives, insurance and other risk spreading.	13.3.2, 14.3.2, Table 14-2
		Laws and regulations		Land zoning laws, building standards, easements.	14.3.2, Table 14-2
		Government policies and programs		National and local adaptation plans, urban upgrading programs, municipal water conservation programs, disaster planning and preparedness.	14.3.2, Table 14-2
	Social	Educational		Awareness raising, extension services.	14.3.3, Table 14.2
		Informational		Hazard mapping and monitoring, early warning, community support groups.	14.3.3, Table 14-2
		Behavioral		Household preparation, evacuation planning, retreat and migration, water conservation, storm drain clearance.	14.3.3, Table 14-2
Transformation	Spheres of change	Practical	Specific strategies	Social and technical innovations, behavioral shifts, or institutional and managerial changes that produce measurable outcomes.	20.5.2
		Political		Changes in the political, social, cultural, and ecological systems or structures that currently contribute to risk and vulnerability or impede practical transformations.	20.5.2
		Personal		Changes in individual and collective assumptions, beliefs, values, and worldviews that influence climate change responses.	20.5.2
Mitigation	See WGIII AR5.				

Table SPM.4: Examples of regional risks that increase with increasing level of climate change. Examples of potential positive impacts are also given. Risks increasing moderately or severely from now until the 2040s, which can be considered an era of climate responsibility, are described, in addition to risks increasing from ~2050 through the end of the 21st century, which can be considered to represent an era of climate options. For risks increasing in both the era of climate responsibility and the era of climate options, the potential for proactive adaptation to reduce the risks is characterized as low or high, with detail provided on adaptation issues and prospects. Risks increasing in the era of climate options can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options. Increasing risks in the era of climate responsibility are generally difficult to reduce substantially through mitigation, even with globally effective mitigation. They can be managed through vulnerability reduction, adaptation, and transformations that promote climate-resilient development pathways.

---------- LEGEND ----------

ERA & ADAPTATION POTENTIAL	**Risk for current (C) and hypothetical fully adapted (A) state. Color scheme depicts the additional risk due to climate change. White to red indicates lower and higher levels of risk, respectively. The vertical axis of each bar represents the level of climate change (T). The horizontal blue line indicates the level of climate change at the end of the era of climate responsibility.**	
	A risk increasing moderately as early as the era of climate responsibility (now through the 2040s), which can be reduced substantially with proactive adaptation.	 A risk increasing moderately as early as the era of climate responsibility (now through the 2040s), which will be difficult to reduce substantially even with proactive adaptation.
	A risk increasing moderately or severely during the era of climate options (~2050 through the end of the 21st century), which can be reduced substantially with proactive adaptation. The risk can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options.	 A risk increasing moderately or severely during the era of climate options (~2050 through the end of the 21st century), which will be difficult to reduce substantially even with proactive adaptation. The risk can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options.
	A risk increasing moderately as early as the era of climate responsibility (now through the 2040s), for which potential for risk reduction via proactive adaptation was not assessed.	 A risk increasing moderately or severely during the era of climate options (~2050 through the end of the 21st century), for which potential for risk reduction via proactive adaptation was not assessed.

CLIMATE DRIVERS	**Where particular climate driver(s) are especially relevant for an assessed risk, they are indicated via the symbols below.**							
	Average temperature		Extreme temperature		Precipitation		Extreme precipitation
CO_2	CO_2 concentration & ocean acidification		Damaging cyclone		Snow cover		Sea level

REGION	RISKS — FRESHWATER RESOURCES AND SYSTEMS	Climate Driver(s)	Era & Adaptation Potential	Adaptation Issues/Prospects	Chap. Ref.
Europe	Climate change is *likely* to further increase coastal and river flood risk and, if unabated, will substantially increase flood damages (monetary losses and people affected).			Adaptation can prevent most of the projected damages (*high confidence*).	23.3.1, 23.5.1, 23.7.1, 23.8.3
Asia	Shrinking of glaciers in Central Asia and the Himalayas is projected to affect water resources in downstream river catchments. Population growth and increasing demand arising from higher standards of living could worsen water security in many parts of Asia and affect many people in the future.			Water saving technologies and changing to drought tolerant crops have been found to be successful adaptation options in the region.	24.4.1, 24.9.3
Austral-asia	Systematic constraints on water resource use in southern Australia, driven by rising temperatures and reduced cool-season rainfall (*high confidence*).			Integrated responses encompassing management of supply, recycling, water conservation, and increased efficiency across all sectors are available but face implementation constraints.	25.2, 25.5.1, Box 25-2

	Increased frequency and intensity of flood damage to settlements and infrastructure in Australia and New Zealand, driven by increasing extreme rainfall although the amount of change remains uncertain (*high confidence*).			In many locations, continued reliance on increased protection alone would become progressively less feasible.	Table 25-1, 25.4.2, 25.10.3, Box 25-8
North America	Throughout North America, it is *very likely* that the 21st century will witness decreases in water quality, and increases in flooding and droughts under climate change, with these impacts exacerbated by other anthropogenic drivers. It will also witness decreases in water supplies for urban areas and irrigation in some areas of North America, with confounding effects of development.				26.3, 26.8
Central and South America	For regions already vulnerable in terms of water supply, such as the semi-arid zones in Chile-Argentina, North Eastern Brazil, and Central America and the tropical Andes, glacier retreat and a reduction in water availability due to expected precipitation reduction and increased evapotranspiration demands are expected, affecting water supply for large cities, small communities, hydropower generation, and the agriculture sector.			Current practices to reduce the mismatch between water supply and demand could be used to reduce future vulnerability.	27.3.1, 27.6.1

REGION	RISKS — TERRESTRIAL ECOSYSTEMS, DROUGHT, & WILDFIRE	Climate Driver(s)	Era & Adaptation Potential	Adaptation Issues/Prospects	Chap. Ref.
Africa	Many fragile terrestrial and aquatic ecosystems are implicitly or explicitly water dependent. Impacts of climate change will be superimposed onto already water-stressed catchments with complex land uses, engineered water systems, and a strong historical socio-political and economic footprint (*high confidence*).				22.3.2, 22.3.3
Europe	Changes in habitats and species will result in local extinction (*high confidence*) and continental scale shifts (*low/medium confidence*). Increasing local loss of native species and extinction of species across most sub-regions of Europe by 2050 (medium emissions) with economic development and land-use change. Introduction and expansion of invasive species, especially those with high migration rates, from outside Europe will increase with climate change (*medium confidence*).				23.4.4, 23.6.4, 23.6.5, 23.10, Table 23.2
	Climate change will increase damage to forests from pests and diseases in all sub-regions (*high confidence*), from wildfires in Southern Europe (*high confidence*), and from storms (*low confidence*).				23.4.4
Asia	Terrestrial systems are under increasing pressure from both climatic and non-climatic drivers. The projected changes in climate will impact vegetation and increase permafrost degradation during the 21st century (*high confidence*). The largest changes are expected in cold northern and high-altitude areas, where boreal and subalpine trees will *likely* invade treeless arctic and alpine vegetation, and evergreen conifers will *likely* invade deciduous larch forest.				24.2.2, 24.4.2, 24.4.3, 24.9.3
Austral-asia	Loss of montane ecosystems and some endemic species in Australia, driven by rising temperatures, increased fire risk and drying trends (*high confidence*).			Fragmentation of landscapes, limited dispersal, and evolutionary capacity limit adaptation options.	25.6.1
	Increased damages to ecosystems and settlements, economic losses, and risks to human life from wildfires in most of southern Australia and many parts of New Zealand, driven by drying trends and rising temperatures (*high confidence*).			Building codes, design standards, local planning mechanisms, and public education can assist with adaptation and are being implemented in regions that have experienced major events.	25.2, 25.6.1, 25.7.1, Box 25-6
North America	A global increase of 2°C would have widespread adverse impacts on many ecosystems, *likely* reducing biodiversity and ecosystem services (*high confidence*).				26.4
Central and South America	Continued climate change together with land use change and fire activity could cause much of the Amazon forest to transform abruptly to more open, dry-adapted ecosystems, and in doing so, put a large stock of biodiversity at elevated risk and create a large new net greenhouse gas source to the atmosphere (*low confidence*).			Rigorously applied adaptation measures could lower the risk of abrupt change in the Amazon, as well as the impacts of that change (*medium confidence*).	4.2.2, 4.2.4, 4.3.3, Box 4-3, Box 4-4

Polar Regions	Continued climate change could push the boreal-arctic system across a tipping point in this century and cause an abrupt transformation of the ecology and albedo of this region, as well as the release of greenhouse gases from thawing permafrost and burning forests (*low confidence*).			Adaption measures will be unable to prevent substantial change in the boreal-arctic system (*high confidence*).	4.2, 4.3.3, Box 4-3, Box 4-4
REGION	**RISKS — COASTAL & MARINE SYSTEMS**	**Climate Driver(s)**	**Era & Adaptation Potential**	**Adaptation Issues/Prospects**	**Chap. Ref.**
Africa	Impacts of climate change, mainly through sea level rise, combined with other extreme events (such as high tide levels and high storm swells) have the potential to threaten coastal zones, particularly coastal towns (*high confidence*).				22.3.2, 22.3.4, 22.3.7
Europe	Costs of adapting dwellings or upgrading coast defense will increase under all scenarios (*high confidence*).				23.3.2, 23.6.5, 23.7.3
Asia	In the Asian Arctic, rising sea levels will interact with projected changes in permafrost and the length of the ice-free season to cause increased rates of coastal erosion (*high agreement, medium evidence*).				24.4.3
Austral-asia	Significant change in community structure of coral reef systems in Australia, driven by increasing sea-surface temperatures and ocean acidification (*high confidence*).			The natural ability of reefs to adapt to projected changes is limited.	Box CC-CR, 25.6.2, 30.5
	Widespread damages to coastal infrastructure and low-lying ecosystems in Australia and New Zealand if sea level rise exceeds 1m (*high confidence*). Risks from sea level rise *very likely* continue to increase beyond 2100 even if temperatures are stabilized.			Managed retreat is a long-term adaptation strategy for human systems but options for some ecosystems are limited due to rapidity of change & lack of suitable space for inland migration.	WGI AR5 13; Box 25-1, 25.6, 25.4.2
Polar Regions	Shifts in the timing of seasonal biomass production could disrupt matched phenologies in food webs, leading to decreased abundance of high latitude marine organisms (*medium confidence*).				28.2.2, 28.3.2
REGION	**RISKS — HUMAN SYSTEMS**	**Climate Driver(s)**	**Era & Adaptation Potential**	**Adaptation Issues/Prospects**	**Chap. Ref.**
Africa	Spatial convergence of impacts in different sectors creates impact “hotspots” involving new interactions, for example, in Sub-Saharan Africa where global warming at the high end of the range projected for this century, i.e., more than 4°C above preindustrial levels, would be especially disruptive, resulting in high risk of reduced extent of croplands, reduced length of the growing season, increased hunger, and increased malaria transmission.				19.3.2
	Temperature rise and a reduction in growing season length by mid-century are expected to significantly reduce crop productivity with strong adverse effects on food security. New challenges to food security are emerging as a result of strong urbanization trends on the continent and increasingly globalized food chains, which require better understanding of the multi-stressor context of food and livelihood security.				22.3.4
Europe	Increasing heat wave mortality across most sub-regions of Europe by 2050 (medium emissions) with economic development and land-use change. Particularly in Southern Europe, increased frequency and intensity of heat waves (*high confidence*) will have adverse implications for health, agriculture, energy production, transport, tourism, labor productivity, and built environment (*medium confidence*).				23.2.2, 23.5.1, Tables 23-4, 23-5
	Climate warming will decrease space heating demand and increase cooling demand (*high confidence*), with income growth driving the largest part of this increase from 2000-2050 (especially in eastern regions) (*medium confidence*). Climate change will increase problems associated with overheating in domestic housing.			Energy efficient buildings and cooling systems as well as demand-side management will reduce future energy demands.	23.3.2, 23.3.4
	Climate change will increase yields in Northern Europe (*medium confidence*) but decrease cereal yields in Southern Europe (*high confidence*).				23.4.1, 23.4.2, 23.5.1

	Climate change will decrease hydropower production from reductions in rainfall in all sub-regions except Scandinavia (*high confidence*). Climate change will inhibit thermal power production during summer (*medium confidence*).			Plant modifications and operational changes can reduce adverse impacts.	23.3.4
	Increasing damage of cultural buildings and loss of cultural landscapes across most sub-regions by 2050 (medium emissions). Climate change and sea level rise will damage cultural heritage and iconic places such as Venice (*medium confidence*). Some cultural landscapes will be lost forever (*low/medium confidence*).				23.5.4, Table 23-5
Asia	Impacts of climate change on food production and security will vary by region with many regions experiencing productivity decline (*medium confidence*), e.g., in the case of rice production, with lower yields due to shorter growing periods and heat-induced sterility. Some regions are already near the critical temperature threshold. In parts of Asia, increases in flood and drought will exacerbate rural poverty due to negative impacts on rice crops and increases in food prices and costs of living (*high confidence*).			There are many potential adaptation strategies such as crop breeding, but research on their effectiveness is limited.	24.4.4, 24.4.6
	More frequent and intense heat-waves will increase mortality and morbidity in vulnerable groups. Increases in heavy rain and temperature will increase the risk of diarrheal diseases and malaria (*high confidence*).				24.4.6
Austral-asia	Increasing morbidity, mortality, and infrastructure damages during heat waves in Australia, resulting from increased frequency and magnitude of extreme temperatures (*high confidence*). Vulnerable populations include the elderly, children, and those with existing chronic diseases.			Aging trends and prevailing social dynamics constrain effectiveness of adaptation responses.	25.8.1
	Significant reduction in food production in the Murray-Darling Basin, far south-eastern Australia, and some eastern and northern areas of New Zealand if scenarios of severe drying are realized (*high confidence*).			More efficient water use, allocation, and trading would increase the resilience of systems in the near term but cannot prevent significant reductions in agricultural production and severe consequences for ecosystems and some rural communities at the dry end of the projected range.	25.2, 25.5.1, 25.7.2, Box 25-5
North America	Without adaptation, projected changes in temperature, precipitation, and extreme events would result in notable productivity declines in major crops by the end of the 21st century (*very high confidence*). Given that North America is a significant source of global food supplies, there will *likely* be a negative effect on global food security if projected productivity declines are not addressed with substantial investments in adaptation (*medium confidence*).			Adaptation may ameliorate many climate impacts to agriculture, but current institutional support mechanisms are insufficient to ensure effective, equitable, and sustainable adaptation strategies.	26.5
Central and South America	Climate-change-related changes in agricultural productivity are expected to vary greatly spatially. In Southeastern South America, where projections indicate more rainfall, average productivity could be sustained or increased until the mid-century (SRES: A2, B2) (*medium confidence*). In Central America, northeast Brazil, and parts of the Andean region, increases in temperature and decreases in rainfall could decrease productivity in the short-term (before 2025), threatening food security of the poorest populations.				27.3.4
	It is *very likely* that climate variability and change may exacerbate current and future risks to health, given the region's vulnerabilities in existing health, water, sanitation and waste collection systems, nutrition, and pollution.				27.3.7
Polar Regions	Spatial convergence of impacts in different sectors creates impact "hotspots" involving new interactions, for example in the Arctic where sea ice loss and thawing disrupts transportation, buildings, other infrastructure, and potentially disrupts Inuit culture (*high confidence*).				19.3.2
	Significant impacts on the availability of key subsistence marine and terrestrial species are projected as climate continues to change with the ability to maintain economic livelihoods being affected (*high confidence*). Changing sea-ice conditions will result in more difficult access for hunting marine mammals.				28.2.6
Small Islands	Spatial convergence of impacts in different sectors creates impact "hotspots" involving new interactions, for example in the environs of Micronesia, Mariana Island, and Papua New Guinea where coral reefs are highly threatened due to exposure to concomitant sea surface temperature rise and ocean acidification (*high confidence*).				19.3.2

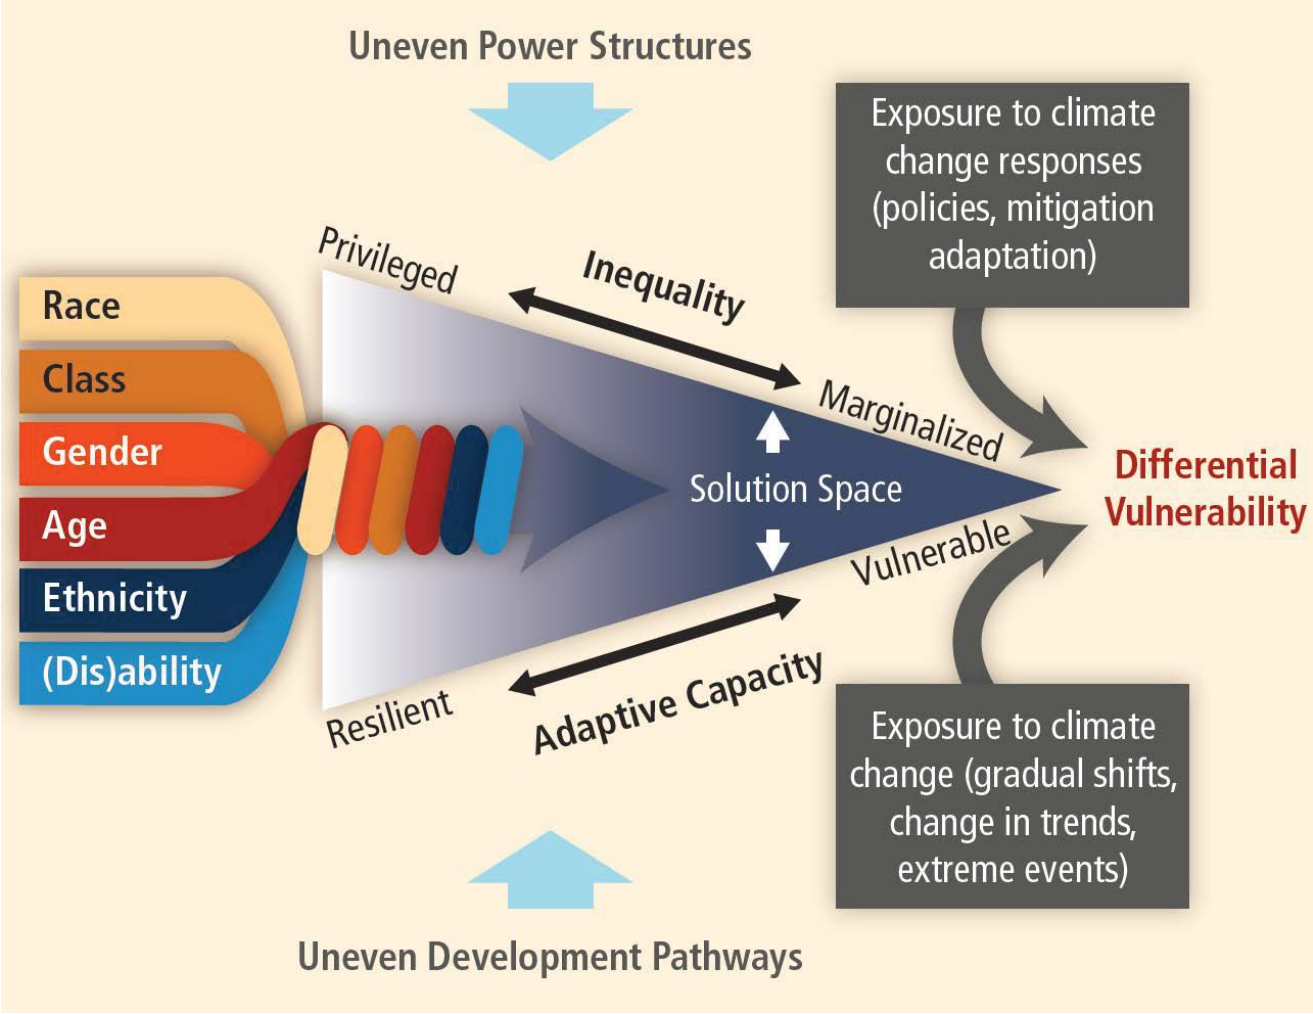
Table SPM.5: A selection of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in the report. The examples underscore the complexity of risks determined by various climatic hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, demographic changes, or tolerance limits of species and ecosystems that often provide important services to vulnerable communities, generate the context in which climate-change-related harm and loss can occur. The examples illustrate that current global megatrends (e.g., climate change, urbanization, demographic changes), in combination and in specific development contexts (e.g., in low-lying coastal zones), can generate new systemic risks that go far beyond existing adaptation and risk management capacities, particularly in highly vulnerable regions. [Table 19-3]

Hazard/Stressor	Key vulnerabilities	Key risks	Emergent risks
Examples from terrestrial and inland water systems			
Rising air, soil, and water temperature.	Exceedence of eco-physiological climate tolerance limits of species, increased viability of alien organisms.	Loss of native biodiversity, increase in alien organism dominance.	Cascades of native species loss due to interdependencies.
	Epidemiological response to spread of temperature-sensitive vectors (insects).	Novel or much more severe pest and pathogen outbreaks.	Interactions between pest, drought, and fire interactions can lead to new risks and large negative impacts on ecosystems.
Examples from ocean systems			
Rising water temperature, increase of (thermal and haline) stratification, and marine acidification. [6.1.1] *(also Chapter 24)*	Tolerance limits of endemic species surpassed, increased abundance of invasive organisms, high vulnerability of warm water coral reefs and respective ecosystem services for coastal communities. [6.2.2, 6.2.5]	Loss of endemic species, mixing of ecosystem types, increased dominance of invasive organisms, loss of coral cover and associated ecosystems with reduction of biodiversity. [6.3.2]	Enhancement of risk due to interactions, e.g., acidification and warming for calcareous organisms. [6.3.5]
Examples from urban areas			
Inland flooding.	Urban areas with large numbers of poor, uninsured people exposed to flood events including low-income informal settlements. Environmental health consequences from overwhelmed, aging, poorly maintained, and inadequate urban drainage infrastructure combined with widespread impermeable surfaces. Inadequate local governance. Increased mosquito and water borne diseases.	Increasing urban flooding with increasing volume and velocity of flood waters on the one hand and increasing vulnerability on the other leads to key risks particularly in urban areas with large numbers of people who are poor and/or exposed to flooding.	Larger and more frequent flooding impacting a much larger population. Impacts reaching the limits of insurance; shift in the burden of risk management from the state to those at risk leading to greater inequality and property blight; abandonment of urban districts and the creation of high risk/high poverty spatial traps.
Changing hazard profile including novel hazards and new multi-hazard complexes.	Newly exposed populations and infrastructure, especially for those with limited capacity for multi-hazard risk forecasting and where risk reduction capacity is limited, e.g., where risk management planning is overly hazard specific including where physical infrastructure is predesigned in anticipation of other risks.	Risks from failures within coupled systems, e.g., reliance of drainage systems on electric pumps, reliance of emergency services on roads and telecommunications, psychological shock from unanticipated risks.	Loss of faith in risk management institutions. Potential for large events that are magnified by a lack of preparation and capacity to respond.
Examples from human health			
Increasing frequency and intensity of extreme heat. *(also chapter 19)*	Older people living in cities are most vulnerable to heat waves, and their population is projected to triple from 2010-2050.	Increased mortality and morbidity during heat waves, particularly in people with pre-existing conditions.	Overloading of health and emergency services. Mortality, morbidity, and productivity loss, particularly for manual workers in hot climates.
Increasing temperatures, increased variability in precipitation.	Food insecurity translates into malnutrition, which is among the largest disease burdens in poorer populations.	Progress in reducing mortality and morbidity from malnutrition may slow or reverse and constitutes a new key risk.	Combined impacts of climate impacts, population growth, plateauing productivity gains, land demand for livestock, biofuels, persistent inequity, and on-going food insecurity for the poor.
Examples from livelihoods and poverty			
Soaring demand (and prices) of biofuels due to climate change policies.	Unclear and/or insecure land tenure arrangements.	Risk of dispossession of land due to "land grabbing" in developing countries.	Creation of large groups of landless farmers unable to support themselves. Social unrest due to disparities between intensive energy production and neglected food production.
Increasing frequency of extreme events (droughts, floods). For example if 1:20 year drought/flood becomes 1:5 year flood/drought.	Livelihoods subject to damage to their productive assets (e.g. in case of droughts – herds of livestock; if floods – dikes, fences, terraces).	Risk of the loss of livelihoods and harm due to shorter time for recovery between extremes. Pastoralists restocking after a drought may take several years; in terraced agriculture, need to rebuild terraces after flood, which may take several years.	Collapse of coping strategies with risk of collapsing livelihoods. Adaptation mechanisms such as insurance fail due to increasing frequency of claims.

Hazard/Stressor	Key vulnerabilities	Key risks	Emergent risks
Examples from Chapter 19			
Warming and drying (degree of precipitation changes uncertain). [WGI AR5 SPM, TS.5.3, 11.3, 12.4]	Limits to coping capacity to deal with reduced water availability; increasing exposure and demand due to population increase; conflicting demands for alternative water uses; socio-cultural constraints on some adaptation options. [19.2.2, 19.3.2, 19.6.1, 19.7.5]	Risk of harm and loss due to livelihood degradation from systematic constraints on water resource use that lead to supply falling far below demand. In addition, limited coping and adaptation options increase the risk of harm and loss. [19.3.2]	Negative outcomes to sending and/or receiving regions from migration of populations due to limits on agricultural productivity and livelihoods. [19.3.2, 19.4.2]
Examples from Africa			
Increasing temperature.	Health of exposed and vulnerable groups (increased exposure to heat, change in the transmission dynamics of vector-borne diseases).	Increase in disease burden – changes in the patterns of infection. Decrease in outdoor worker productivity due to high temperature, increase in heat related morbidity and mortality.	Emerging and re-emerging disease epidemics.
	Vulnerability of aquatic systems and vulnerability of aquatic ecosystem services due to increased water temperatures.	Loss of aquatic ecosystems and risks for people who might depend on these resources.	
Examples from Europe			
Extreme weather events. *(also Chapter 19)*	Limited coping and adaptive capacity as well as high sensitivity of different sectors, e.g., transport, energy, and health.	Stress on multiple sectors can cause systemic risks due to interdependencies among sectors.	Disproportionate intensification of risk due to increasing interdependencies.
Examples from Asia			
Thawing of permafrost due to rising temperature in northern Asia.	Existence of structures and infrastructure on permafrost and high dependence of civil life on them.	Instability of or damage to structures and infrastructures.	Projected exacerbation of instability of residential buildings, pavements, pipelines used to transport petroleum and gas, pump stations, and extraction facilities.
Projected increase in frequency of various extreme events (heat waves, floods, and droughts) and sea level rise. *(also Chapter 19)*	Convergence of livelihoods and properties into coastal megacities, especially into areas not sufficiently protected against natural hazards.	Loss of human life and assets due to coastal floods accompanied by increasing vulnerabilities caused by occurrence of other extreme events like heat waves and droughts.	Projected increase in disruption of basic services such as water supply, sanitation, energy provision, and transportation systems, which themselves could increase vulnerabilities.
Examples from Australasia			
Warming and increased temperature high extremes in Australia. [25.2, Table 25-1, Figure 25-5]	Urbanization, aging of population and vital infrastructure. [25.3, Box 25-9, 25.10.2]	Increase in morbidity, mortality, and infrastructure failure during heat waves. [25.8.1, 25.10.2]	Increasing risk from compound extreme events across time, space and governance scales, and cumulative adaptation needs. [25.10.2, 25.10.3, Box 25-9]
Potential for sea level rise beyond 2100 exceeding 1m [25.2, WGI AR5 Chapter 13]	Long lifetime of coastal infrastructure, concentration and further expansion of coastal population and assets; conflicting priorities and time preferences constraining adaptation options; limited scope for managed retreat in highly developed areas.	Widespread damages to coastal infrastructure and low-lying ecosystems. [Box 25-1, 25.10.2]	
Examples from North America			
Increases in frequency and/or intensity of extreme events, such as hurricanes, river and coastal floods, heat waves, and droughts. [26.2] *(also Chapter 19)*	Declining state of physical infrastructure in urban areas as well as increases in income disparities. [26.7]	Risk of serious harm and losses in urban areas, particularly in coastal environments due to enhanced vulnerabilities of social groups and physical systems combined with increases of extreme weather events. [26.8]	Inability to reduce vulnerability in many areas results in increase in risk greater than change in physical hazard. [26.8]
Higher temperatures, decreases in runoff, and lower soil moisture. [26.2, 26.3]	Increasing vulnerability of small landholders in agriculture. [26.5]	Increased losses and decreases in agricultural production increase food and job insecurity for small landholders and social groups in that region. [26.5]	Increasing risks of social instability and local economic disruption due to internal migration. [26.2, 26.8]

Table SPM.6: Examples of potential tradeoffs among adaptation objectives. [Table 16-2]

Sector	Strategy	Adaptation Objective	Real or Perceived Externality
Agriculture	Biotechnology and genetically modified crops	Enhance drought and pest resistance; enhance yields	Perceived risk to public health and safety; ecological risks associated with introduction of new genetic variants to natural environments
	Subsidized drought assistance; crop insurance	Provide financial safety net for farmers to ensure continuation of farming enterprises	Creates moral hazard and inequality if not appropriately administered
	Increased use of chemical fertilizer and pesticides	Maintain or enhance crop yields; suppress opportunistic agricultural pests and invasive species	Increased discharge of nutrients and chemical pollution to the environment; increased emissions of greenhouse gases; increased human exposure to pollutants
Biodiversity	Migration corridors; expansion of conservation areas	Enable natural adaptation and migration to changing climatic conditions	Unknown efficacy; concerns over property rights regarding land acquisition; governance challenges
	Anticipatory endangerment listings	Enhance regulatory protections for species potentially at-risk due to climate change	Addresses secondary rather than primary pressures on species; concerns over property rights; regulatory barriers to economic development
	Assisted migration	Facilitate conservation of valued species	Potential for externalities for ecological and human systems due to species relocation
Coasts	Sea walls	Protect assets from inundation and/or erosion	High direct and opportunity costs; equity concerns; ecological impacts to coastal wetlands
	Managed retreat	Allow natural coastal and ecological processes; reduce long-term risk to property and assets	Undermines private property rights; significant governance challenges associated with implementation
	Migration out of low-lying areas	Preserve public health and safety; minimize property damage and risk of stranded assets	Loss of sense of place and cultural identity; erosion of kinship and familial ties; impacts to receiving communities
Water resources management	Desalination	Increase water resource reliability and drought resilience	Ecological risk of saline discharge; high energy demand and associated carbon emissions; creates disincentives for conservation
	Water trading	Maximize efficiency of water management and use; increases flexibility	Undermines public good/social aspects of water
	Water recycling/reuse	Enhance efficiency of available water resources	Perceived risk to public health and safety



Box SPM.3 Figure 1: Intersecting, simultaneous, and dynamic axes of privilege and marginalization, shaped by people's multiple identities and embedded in uneven power relations and development pathways. Together, they result in differential vulnerability to the same exposure to climate change and climate responses. [Figure 13-4]

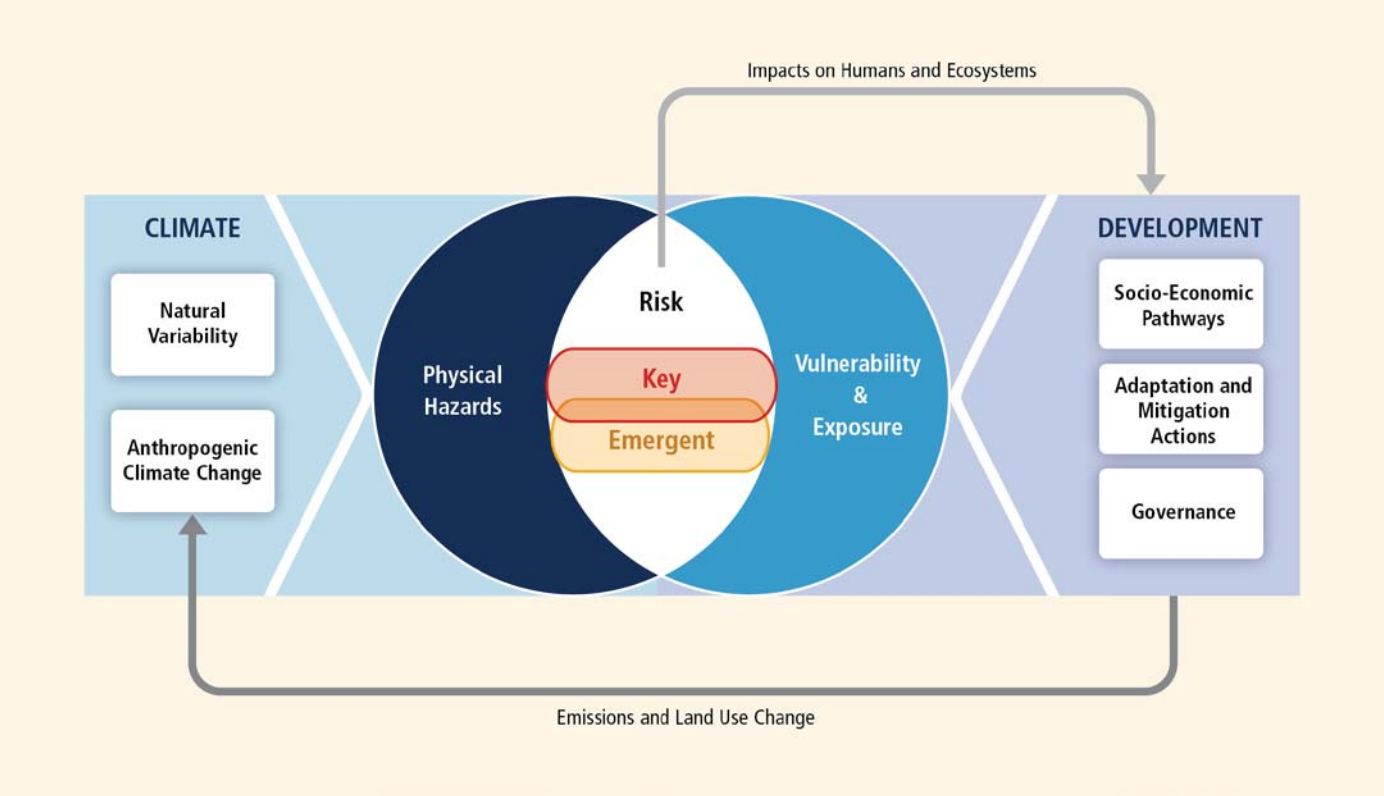


Figure SPM.1: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions. Changes in both the climate system (left) and development processes (right) are key drivers of the different core components (vulnerability, exposure, and physical hazards) that constitute risk. The definition and use of “key” and “emergent” are indicated in Section C.ii. [19.1, Figure 19-1]

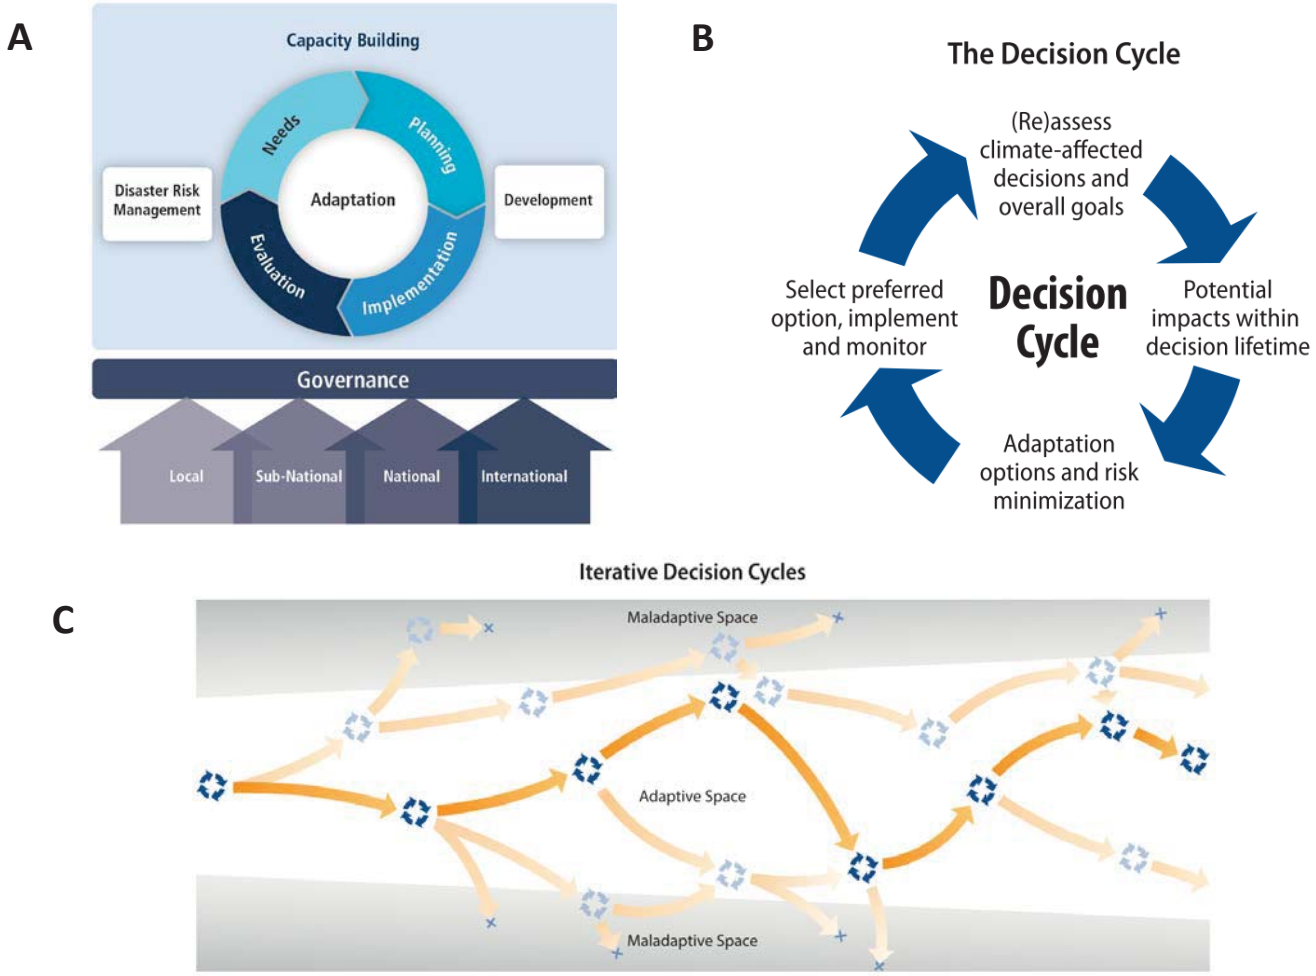

Figure SPM.2: Illustration of iterative response to climate change. (A) Four main phases of planned adaptation as a cyclic, iterative process: needs, planning, implementation, and evaluation. Efforts in adaptation can be linked with development or disaster risk management. Adaptation governance at multiple scales underlies capacity. (B) In the context of iterative risk management, each individual adaptation decision cycle comprises well known aspects of risk assessment and management. (C) A sequence of adaptation decisions creates an adaptation pathway. Some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but there is no single correct adaptation pathway and judgment of outcomes depends strongly on societal values, expectations, and goals. [Figures 15-1, 16-2, 25-6]

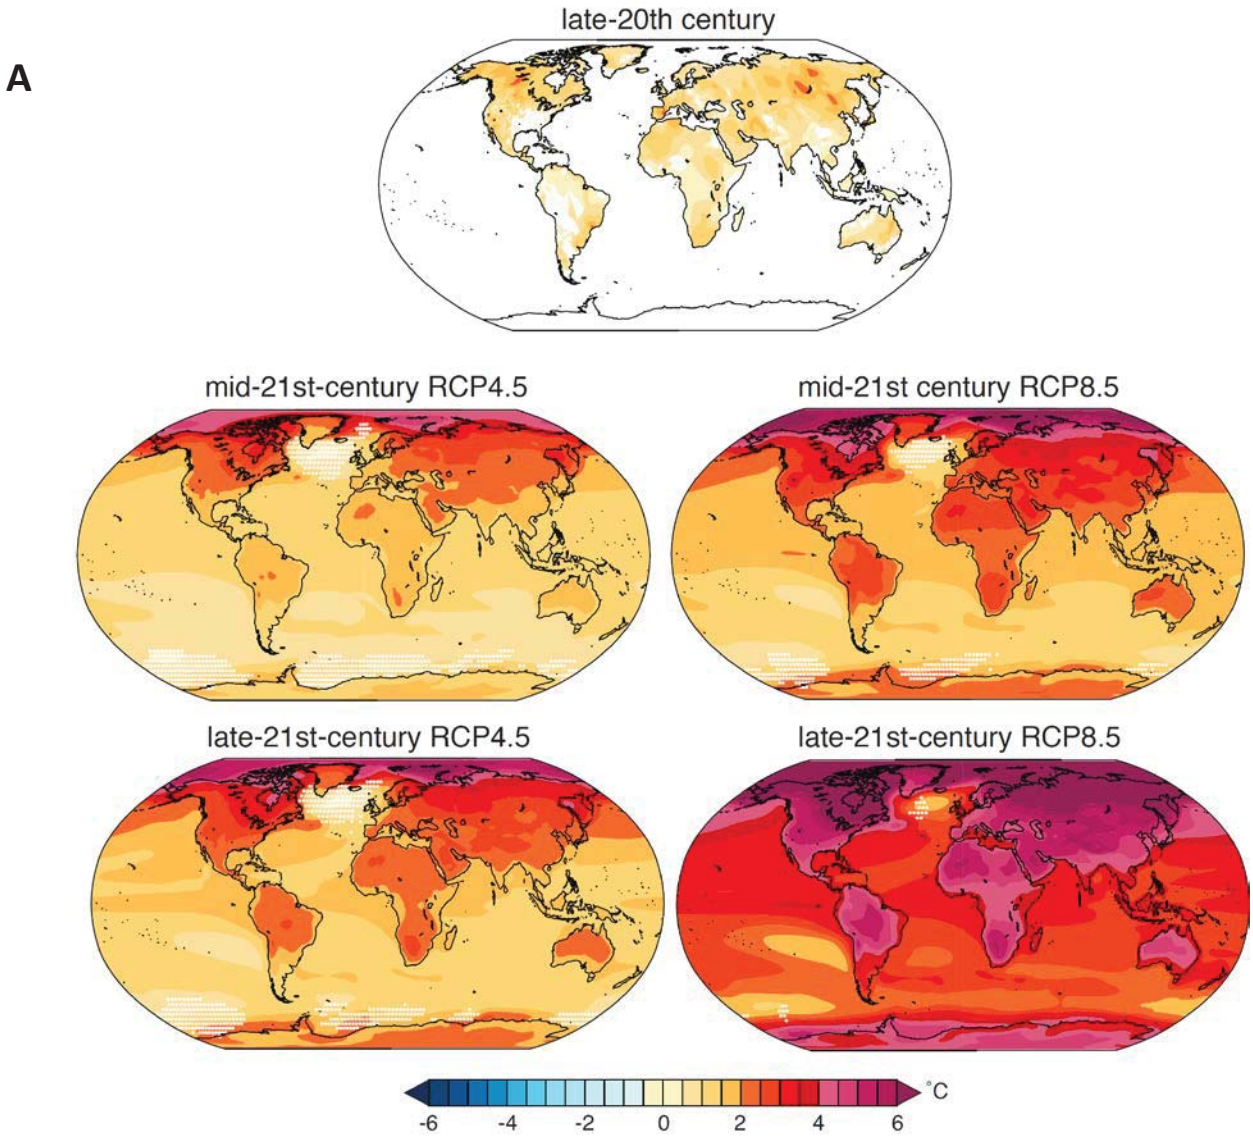
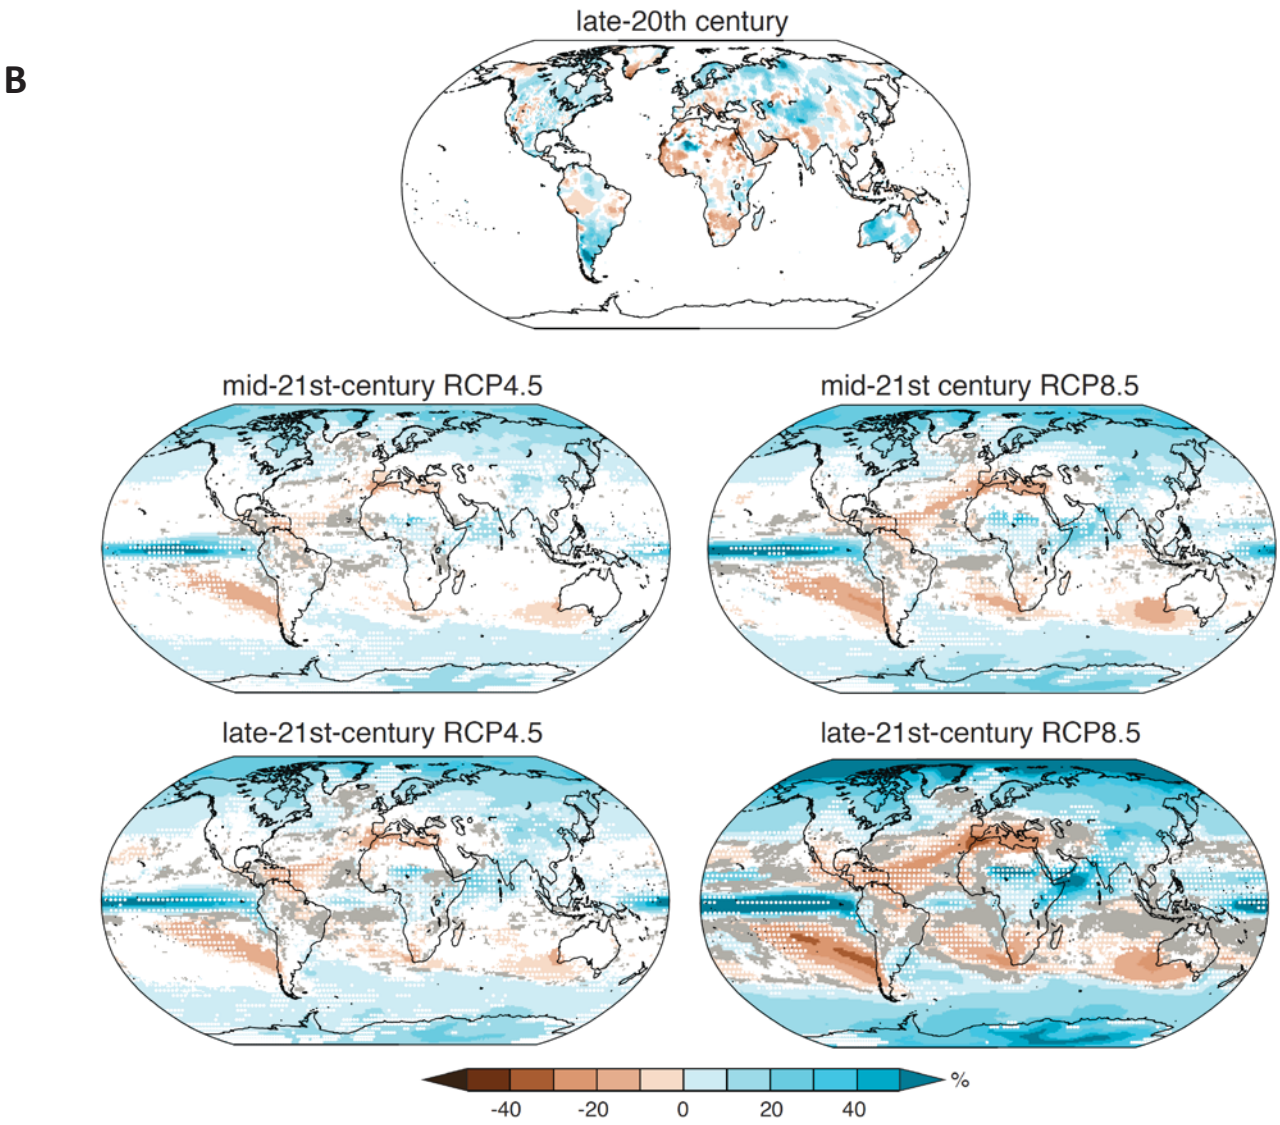


Box SUM.4 Figure 1: Changes in annual average temperature (A) and precipitation (B). For observations (top map, A and B; CRU), differences are shown over land between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For projections (bottom four maps, A and B; CMIP5), four classes of results are displayed. (1) White indicates areas where for >66% of models the annual average change is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Thus in these regions, more than 2/3 of models show no significant change in the annual average using this measure of significance, although this does not imply no significant change at seasonal or shorter time-scales such as months to days. (2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions, more than 2/3 of models show a significant change in annual average, but less than 2/3 agree on whether it will increase or decrease. (3) Colors with white circles indicate the change averaged over all models where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on whether the annual average will increase or decrease. In these regions, more than 2/3 of models show a significant change in annual average and more than 2/3 (but less than 90%) agree on whether it will increase or decrease. (4) Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether the annual average will increase or decrease. For models that have provided multiple realizations for the climate of the recent past and the future, results from each realization were first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios were calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065. See also Annex I of WGI AR5. [Box CC-RC]



Box SUM.4 Figure 1: Changes in annual average temperature (A) and precipitation (B). For observations (top map, A and B; CRU), differences are shown over land between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For projections (bottom four maps, A and B; CMIP5), four classes of results are displayed. (1) White indicates areas where for >66% of models the annual average change is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Thus in these regions, more than 2/3 of models show no significant change in the annual average using this measure of significance, although this does not imply no significant change at seasonal or shorter time-scales such as months to days. (2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions, more than 2/3 of models show a significant change in annual average, but less than 2/3 agree on whether it will increase or decrease. (3) Colors with white circles indicate the change averaged over all models where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on whether the annual average will increase or decrease. In these regions, more than 2/3 of models show a significant change in annual average and more than 2/3 (but less than 90%) agree on whether it will increase or decrease. (4) Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether the annual average will increase or decrease. For models that have provided multiple realizations for the climate of the recent past and the future, results from each realization were first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios were calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065. See also Annex I of WGI AR5. [Box CC-RC]

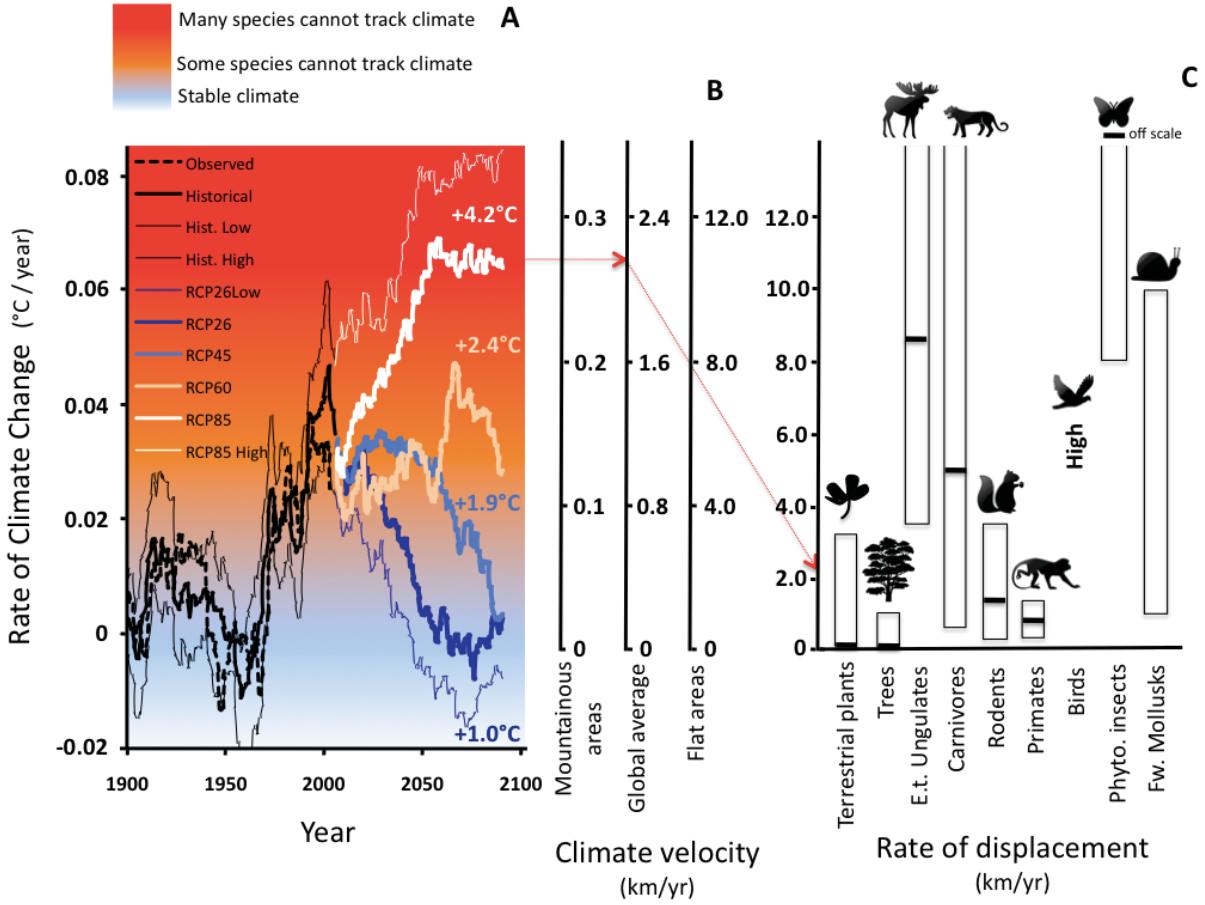


Figure SPM.3: Synthetic overview of projected abilities of some terrestrial and freshwater species to track climate by movement across landscapes. (A) Rates of climate change for global land areas. Black dotted line shows observed rates of climate change. Other rates were calculated from the CMIP5 ensemble for the historical period (black heavy line, with upper and lower bounds as light black lines) and for the future based on the four RCPs. A lower bound is given for RCP 2.6, and an upper bound for RCP 8.5. (B) Corresponding climate velocities, providing indication of the speed at which species' ranges would need to move to track changing climatic conditions. In mountainous areas with low climate velocities, species would only need to move short distances upslope to track a warming climate. In flat areas with high climate velocities, such as the Amazon basin, species would need to move large distances to track a warming climate. (C) Maximum estimated rates of displacement of several terrestrial and freshwater species groups, indicating how fast these groups can move across landscapes. Rates of species displacement are well defined for plants, especially trees, but less well defined for other groups. Displacement rates do not generally account for biotic interactions or human intervention that may speed or hinder dispersal. The thin red arrows give an example of interpretation: a rate of climate change of 0.065 °C/yr (approximately equal to projected rates by mid-century for RCP 8.5) corresponds to ~2.2 km/yr global average climate velocity. This global-average velocity would exceed projected maximum capacity for displacement for most plants, most primates, many rodents, and some less mobile species of other groups. For RCP 2.6, most species would be able to track climate by mid-century. Color gradient in panel A provides overall representation of the ability of species to track climate change. Detailed spatial analyses and maps of species displacement can be found in the references cited in WGII Chapter 4. E.t ungulates = even-toed ungulates; Phyto. insects = phytophagous (herbivorous) insects; Fw. mollusks = freshwater mollusks. [Figure 4-6]

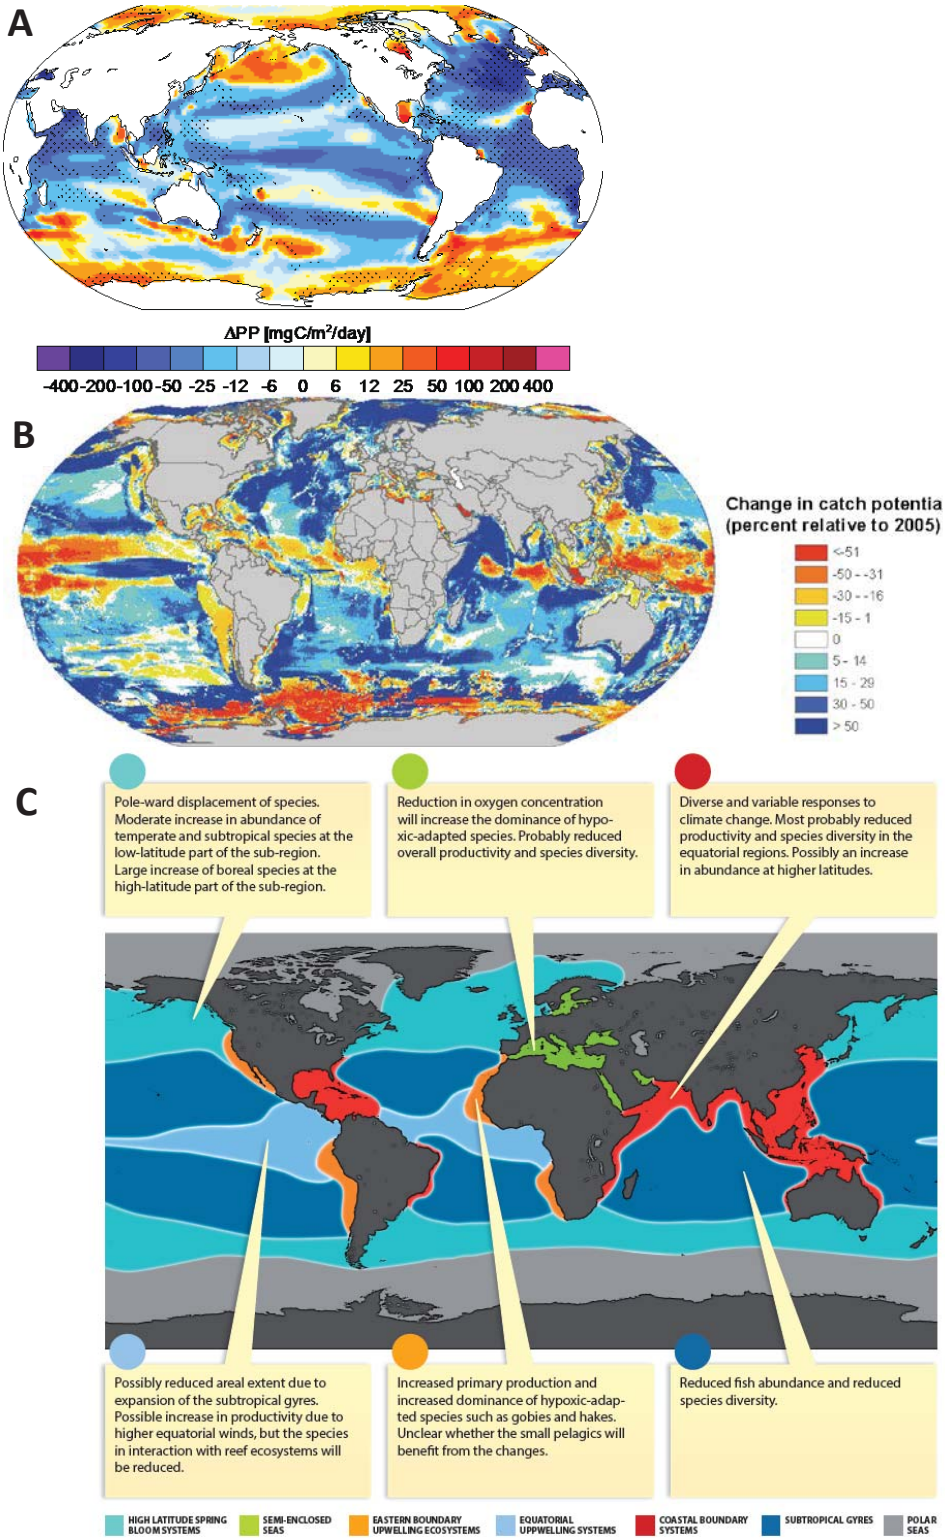

Figure SPM.4: (A) Multi-model mean changes of projected net primary production. To indicate consistency in the sign of change, regions are stippled where all models (four in total) agree on the sign of change. Changes are annual means under SRES A2 for the period 2080 to 2099 relative to 1870 to 1889. (B) A projection of maximum fisheries catch potential of 1000 species of exploited fishes and invertebrates from 2000 to 2050 under SRES A1B. (C) Example of changes occurring within fisheries across the ocean. [Figures 6-14, 6-15, and 30-15]

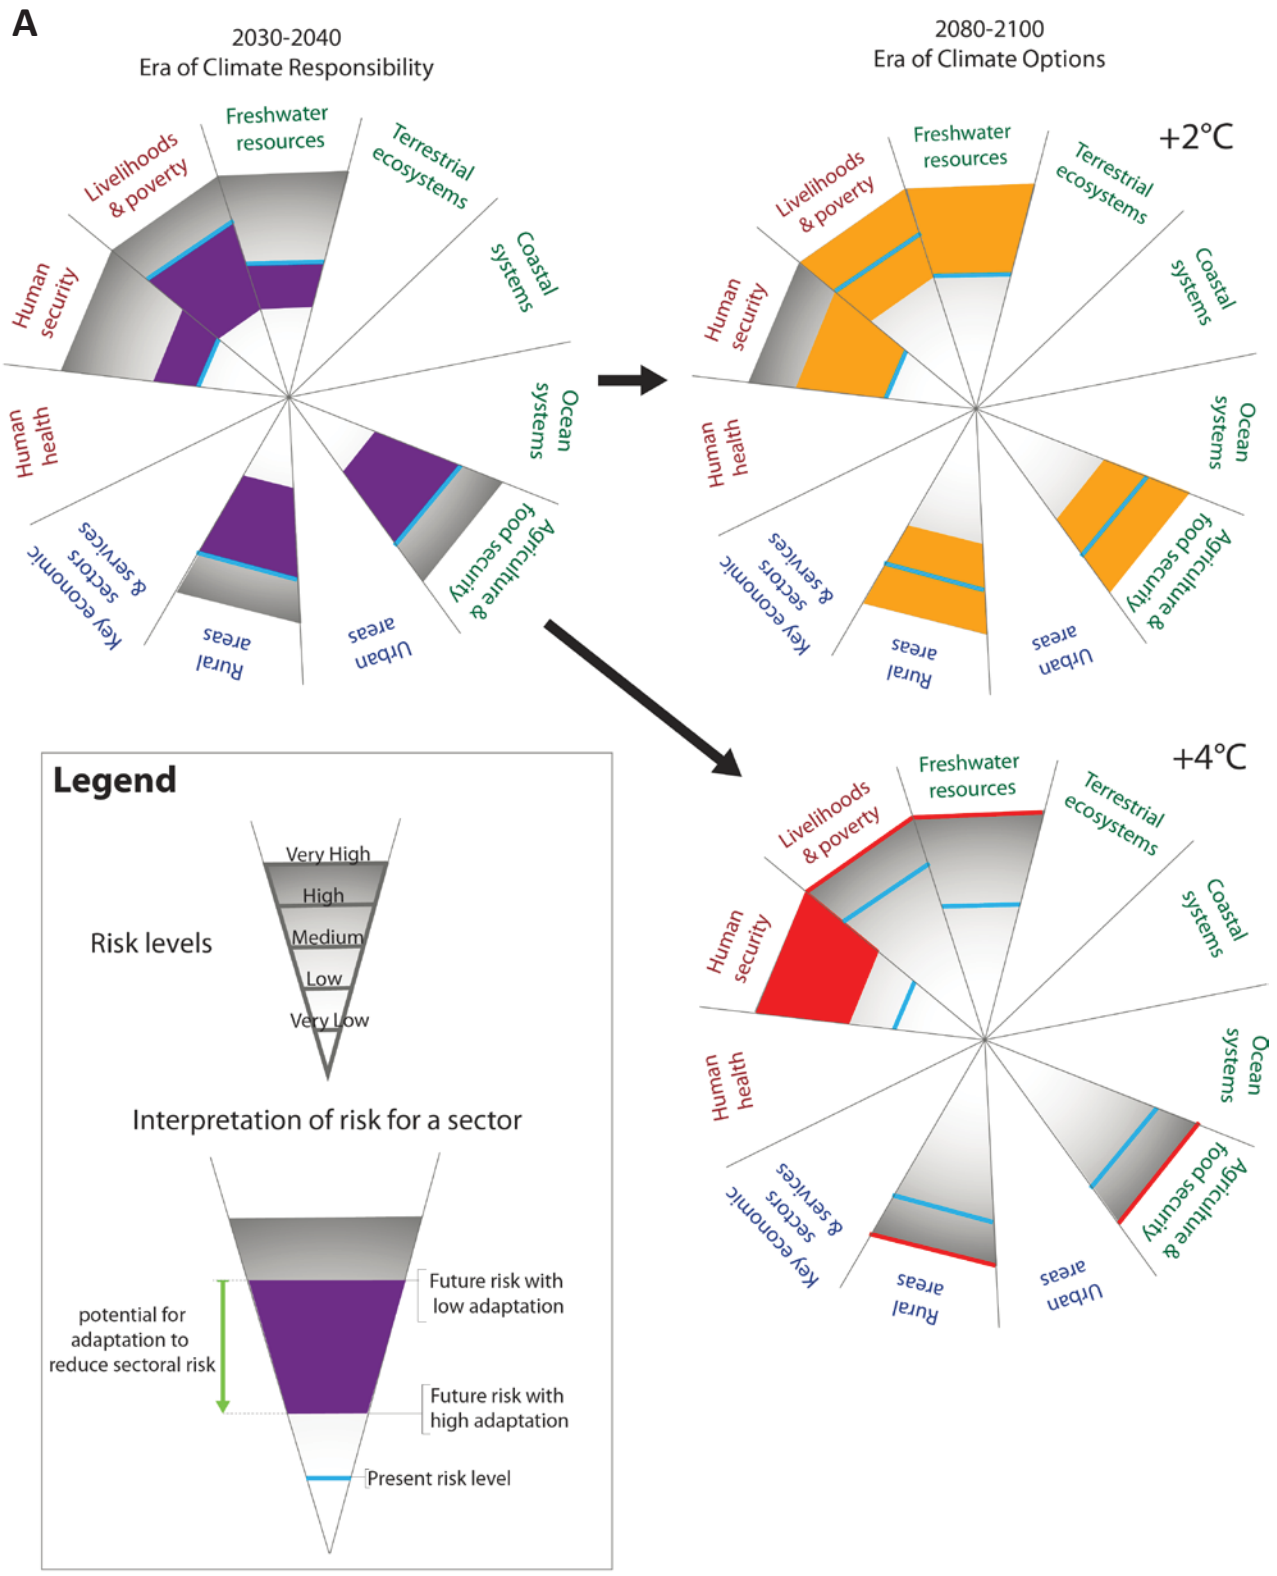

Figure SPM.5: Estimated risk from climate change to selected sectors and systems in Africa (A), Europe (B), and North America (C), for different time frames (2030-2040 and 2080-2100), under two levels of global average warming above preindustrial (2°C and 4°C) and different assumptions about adaptation to manage these risks. Levels of risk and of adaptation are differentiated by colored shading, ranging from high adaptation to low adaptation. Estimated risks rely on expert judgments. The risk categories reflect the overall structure of Part A of the WGII AR5. [Figures 22-7 and 26-6]

INTRODUCTION

Climate change is shifting patterns of risks and opportunities in a complex and changing world. The Working Group II contribution to the IPCC's Fifth Assessment Report (AR5) acknowledges the complexity of climate change and of the world in which it is unfolding. It recognizes that impacts of climate change will vary across regions and populations, through space and time, dependent on myriad factors including the extent of mitigation and adaptation. It provides information on patterns of changing risks and on how they can be managed.

For the past two decades, Working Group II has developed assessments of climate change impacts, adaptation, and vulnerability. The Working Group II contribution to the IPCC's AR5 builds from the Fourth Assessment Report (AR4), published in 2007, and the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX), published in 2012 (Box TS.1). Section A of this summary characterizes observed impacts, vulnerabilities, and responses to date. Section B, building from exposure, vulnerability, and physical hazards as determinants of risk, considers approaches for managing the risks of climate change. Section C examines the range of future risks across sectors and regions, highlighting where choices matter for reducing risks through mitigation and adaptation. Section D explores the broader interactions among mitigation, adaptation, and sustainable development.

Box TS.2 defines concepts central to the Working Group II contribution to the AR5. To accurately convey the degree of certainty in key findings, the report relies on the consistent use of calibrated uncertainty language, introduced in Box TS.3. Chapter sections in square brackets indicate the assessment supporting findings in this summary.

_____ START BOX TS.1 HERE _____

Box TS.1. The Context of the Assessment

The literature available for assessing climate change impacts, adaptation, and vulnerability has more than doubled since 2005 (*very high confidence*). The diversity of the topics and regions covered by the literature has similarly expanded, as well as the geographic distribution of the authors contributing to the knowledge base for climate change assessments (Box TS.1 Figure 1). Production of climate change literature has increased in the developing countries, although their institutions lag those in developed countries regarding access to and production of climate change literature. The unequal distribution of literature, which is influenced by factors such as scientific funding and capacity building, presents a challenge to the development of a comprehensive and balanced assessment of the global impacts of climate change. [1.1.1, Fig. 1-1]

[INSERT BOX TS.1 FIGURE 1 HERE
Box TS.1 Figure 1: Results of English literature search using the Scopus bibliographic database from Reed Elsevier Publishers. (a) Annual global output of publications on climate change and related topics: impacts, adaptation, and costs (1970-2010). (b) Country affiliation of authors of climate change publications summed for IPCC regions for three time periods: 1981-1990, 1991-2000, and 2001-2010, with total number during the period 2001-2010. (c) Results of literature searches for climate change publications with individual countries mentioned in publication title, abstract, or key words, summed for all countries by geographic region. [Figure 1-1]]

The evolution of the IPCC assessments of impacts, adaptation, and vulnerability indicates an increasing emphasis on humans, their role in managing resources and natural systems, and the societal impacts of climate change (*very high confidence*). The expanded focus on societal impacts and responses is evident in the composition of the IPCC author teams, the literature assessed, and the content of the IPCC assessment reports. Three important characteristics in the evolution of the Working Group 2 assessment reports are an increasing attention to: (i) Adaptation limits and transformation in societal and natural systems; (ii) Synergies between multiple variables and factors that affect sustainable development, including risk management; and (iii) Institutional, social, cultural, and value-related issues. [1.1, 1.2]

Adaptation has emerged as a central area of work in climate change research, in country level planning, and in the implementation of climate change strategies (*high confidence*). The body of literature shows an increased

focus on capitalizing upon adaptation opportunities and on the interrelations among adaptation, mitigation, and alternative sustainable pathways. In spite of the uncertainty of future impacts and adaptation, the literature shows an emergence of studies on transformative processes that take advantage of synergies between adaptation planning, development strategies, social protection, and disaster risk reduction and management. [1.1.4]

The treatment and communication of uncertainties in IPCC reports have evolved over time, reflecting iterative learning and more coherent guidance across all Working Groups (*high confidence*). An integral feature of IPCC reports is communicating the strength and uncertainties in the scientific understanding underlying assessment findings. In Working Group II, the use of calibrated language began in the Second Assessment Report, where most chapters used qualitative levels of confidence for their Executive Summary findings. Based on experience, guidance notes were developed for subsequent assessment reports. The AR5 Guidance Note continues to emphasize a theme from all three guidance documents to date: the importance of clearly linking each key finding and corresponding assignment of calibrated uncertainty language to associated chapter text, as part of the traceable account of the author team's evaluation of evidence and agreement supporting that finding (see Box TS.3). [1.1.2.2, Box 1-1]

_____ END BOX TS.1 HERE _____

_____ START BOX TS.2 HERE _____

Box TS.2. Terms Critical for Understanding the Summary

Core concepts defined in the glossary and used throughout the report include:

Climate change: A change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external forcings such as modulation of the solar cycles, volcanic eruptions, and persistent anthropogenic changes in the composition of the atmosphere or in land use. In contrast, the Framework Convention on Climate Change (UNFCCC), in its Article 1, defines climate change as: "a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods." The UNFCCC thus makes a distinction between climate change attributable to human activities that alter the atmospheric composition, and climate variability attributable to natural causes.

Exposure: The presence of people, livelihoods, environmental services and resources, infrastructure, or economic, social, or cultural assets in places that could be adversely affected.

Vulnerability: The propensity or predisposition to be adversely affected.

Impacts: Effects on natural and human systems. In this report, the term 'impacts' is used to refer to the effects on natural and human systems of physical events, of disasters, and of climate change.

Risk: The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk is often represented as probability of occurrence of a hazardous event(s) multiplied by the consequences if the event(s) occurs. This report assesses climate-related risks.

Adaptation: In human systems, the process of adjustment to actual or expected climate and its effects, which seeks to moderate harm or exploit beneficial opportunities. In natural systems, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate.

Incremental adaptation – Adaptation actions where the central aim is to maintain the essence and integrity of an incumbent system or process at a given scale.

Transformational adaptation – Adaptation that changes the fundamental attributes of a system in response to actual or expected climate and its effects.

Resilience: The ability of a social, ecological, or socio-ecological system and its components to anticipate, reduce, accommodate, or recover from the effects of a hazardous event in a timely and efficient manner.

Transformation: A change in the fundamental attributes of a system, often based on altered paradigms, goals, or values. Transformations can occur in technological or biological systems, financial structures, and regulatory, legislative, or administrative regimes.

_____ START BOX TS.3 HERE _____

Box TS.3. Communication of the Degree of Certainty in Assessment Findings

Based on the Guidance Note for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties, the Working Group II contribution to the Fifth Assessment Report relies on two metrics for communicating the degree of certainty in key findings:

- Confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively.
- Quantified measures of uncertainty in a finding expressed probabilistically (based on statistical analysis of observations or model results, or expert judgment).

Each finding has its foundation in an author team's evaluation of associated evidence and agreement. The summary terms to describe available evidence are: *limited*, *medium*, or *robust*; and the degree of agreement: *low*, *medium*, or *high*. These terms are presented with some key findings. In many cases, author teams additionally evaluate their confidence about the validity of a finding, providing a synthesis of the evaluation of evidence and agreement. Levels of confidence include five qualifiers: *very low*, *low*, *medium*, *high*, and *very high*. Box TS.3 Figure 1 illustrates the flexible relationship between the summary terms for evidence and agreement and the confidence metric. For a given evidence and agreement statement, different confidence levels could be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[INSERT BOX TS.3 FIGURE 1 HERE
Box TS.3 Figure 1: Evidence and agreement statements and their relationship to confidence. The shading increasing towards the top right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence. [Figure 1-4]]

When author teams evaluate the likelihood of some well-defined outcome having occurred or occurring in the future, a finding can include likelihood terms (see below) or a more precise presentation of probability. Use of likelihood is not an alternative to use of confidence: an author team will have a level of confidence about the validity of a probabilistic finding. Unless otherwise indicated, findings assigned a likelihood term are associated with *high* or *very high* confidence.

Term*	**Likelihood of the outcome**
Virtually certain	99–100% probability
Very likely	90–100% probability
Likely	66–100% probability
About as likely as not	33–66% probability
Unlikely	0–33% probability
Very unlikely	0–10% probability
Exceptionally unlikely	0–1% probability

* Additional terms used in limited circumstances are *extremely likely:* 95– 100% probability; *more likely than not:* >50–100% probability; and *extremely unlikely:* 0–5% probability.

A) VULNERABILITIES, IMPACTS, AND ADAPTATION IN A COMPLEX AND CHANGING WORLD

This section presents observed effects of climate change, including detection and attribution of impacts on human and natural systems. It evaluates sensitivities to climate, factors determining vulnerability and exposure, and the role of non-climate stressors. It considers that the effects of climate variability, climate extremes, and climate change are determined through the interaction of vulnerability and exposure with physical hazards. The section also examines coping and adaptation responses to climate events and conditions to date. It identifies challenges and options based on adaptation experience, and it looks at what has motivated previous adaptation actions in the context of climate change and broader objectives.

A.i. Vulnerabilities and Observed Impacts across Sectors with Regional Examples

Impacts of recent observed climate change on physical, biological, and human systems have been detected on all continents and in most oceans (*high confidence*). This conclusion is strengthened by observations since the AR4 as well as through more extensive analyses of earlier observations. Most reported impacts of climate change are attributed to regional warming of the atmosphere and the ocean, with lower confidence in attribution of observed impacts to shifts in rainfall patterns. There is emerging evidence of impacts of ocean acidification. For many natural systems, new or stronger evidence for substantial and wide-ranging impacts of climate change exists, including the cryosphere, water resources, coastal systems, and ecosystems on land and in the ocean. For managed ecosystems and human systems, the effects of changing social and economic factors often dominate over any direct impact of climate change. Despite this, numerous impacts of climate change have been detected. See Table TS.1 for examples of observed impacts across regions. [18.3-18.6]

[INSERT TABLE TS.1 HERE
Table TS.1: Observed impacts attributed to climate change with *medium* (*) or *high* (**) confidence. Impacts for physical, biological, and human systems are characterized across eight major world regions. For each observed impact, confidence in detection is equal to or greater than confidence in attribution. [Table 18-6, 18-7, 18-8, 18-9]]

Confidence in attribution is assigned through assessment of the relative contribution to a system's behavior by all known drivers affecting the system's dynamics, using scientific methods and also involving an assessment of confidence in detection. Formal meta-analysis or aggregated assessments of many observations or studies can help to improve confidence. In most studies, the attribution of observed impacts and vulnerabilities is related to all changes in climate that represent deviations from historical means and/or historic variability. Only a smaller number of robust attribution studies link responses in physical and biological systems to *anthropogenic* climate change. Though evidence is improving, there is a persistent gap of knowledge regarding how large parts of the world are being affected by observed climate change. Research to improve the timeliness and knowledge about the detection and attribution is needed in particular for the risk of extreme events. [18.1, 18.2.1, Box 18-1, 18.7]

Factors determining vulnerability and exposure

Climatic and biophysical drivers interact with systemic non-climatic drivers of vulnerability and exposure to shape differential risks and impacts (*very high confidence*). Since AR4 the framing of adaptation has moved further from a focus on biophysical vulnerability to the wider social and economic drivers of vulnerability. Factors affecting vulnerability and exposure involve a complex mix of physical and socio-economic factors, including gender, age, health, social status and ethnicity, environmental degradation, technology gaps, conflict, and institutions, political systems, and governance structures. Uneven socio-economic development pathways at the national and global level create and perpetuate systemic vulnerabilities. This unevenness results from structural conditions of poverty, inequality, and marginalization, as well as differential levels of health and human security. See Box TS.4. [13.1, 14.1, 14.2, 19.6.1]

Vulnerability and exposure of communities or social-ecological systems to climatic hazards are dynamic and thus varying across temporal and spatial scales. Effective risk reduction and adaptation strategies consider these dynamics and the inter-linkages between socio-economic development pathways and the vulnerability and exposure of people. Changes in poverty or socio-economic status, race and ethnicity compositions, age structures, and

governance have had a significant influence on the outcome of past crises associated with climatic hazards. [15.2.4, 19.6.1]

Understanding of future vulnerability of human and social-ecological systems to climate change remains limited due to incomplete consideration of socio-economic dimensions (*very high confidence*). Future vulnerability will depend on factors such as wealth and its distribution across society, patterns of aging, access to technology and information, labor force participation, societal values, and mechanisms and institutions to resolve conflicts (see also Box TS.4). These dimensions have received only limited attention and are rarely included in vulnerability assessments, and frameworks to integrate social and cultural dimensions of vulnerability with biophysical impacts and economic losses are lacking. [25.3, 25.4, 25.11]

Impacts from recent extreme climatic events show significant vulnerability of some ecosystems and many human systems to current climate variability (*very high confidence*). Impacts include the alteration of ecosystems, altered food production, damage to infrastructure and settlements, morbidity and mortality, and consequences for mental health and human well-being. These experiences are consistent with a significant adaptation deficit in developing and developed countries for some sectors and within some regions. See Table TS.2.

- Recent floods in Australia and New Zealand caused severe damage to infrastructure and settlements and 35 deaths in Queensland alone (2011); the Victorian heat wave (2009) increased heat-related morbidity and caused 374 excess deaths, and intense bushfires destroyed over 2,000 buildings and led to 173 deaths; widespread drought in south-east Australia (1997-2009) and many parts of New Zealand (2007-2009) resulted in economic losses (approximately A$7.4b in south-east Australia in 2002-03 and NZ$3.6b in direct and off-farm output in 2007-09) and mental health problems in some areas of Australia. [13.2.1, Table 25-1, 25.8.1, Box 25-5, Box 25-6, Box 25-8]
- The observed impacts of extreme weather events indicate the current vulnerability of Europe across multiple sectors. [Table 23-3]
- In North America, most economic sectors have been affected by and responded to extreme weather, including hurricanes, flooding, and intense rainfall (*high confidence*). Heat extremes currently result in increases in mortality and morbidity, with impacts that vary by age and socioeconomic factors (*very high confidence*). Coastal storm events periodically cause excess mortality and morbidity via a range of direct and indirect pathways in North America, particularly along the east coast of the US, and the gulf coast of both Mexico and the US (*high confidence*). Many infrastructural elements across North America are currently vulnerable to extreme weather events (*medium confidence*). Infrastructures, particularly in water resources and transportation, are in many cases deteriorating, and are thus more vulnerable to extremes than strengthened ones. Extreme events have caused significant damage to infrastructure in many parts of North America. [26.6, 26.7]
- Research to improve the timeliness and knowledge about detection and attribution is needed in particular for the risk of extreme events. [18.7]

[INSERT TABLE TS.2 HERE
Table TS.2: Illustrative selection of some recent extreme impact events for which the role of climate has been assessed in the literature. The table shows confidence assessments as to whether the associated meteorological events made a substantial contribution to the impact event, as well as confidence assessments of a contribution of anthropogenic emissions to the meteorological event. The assessment of confidence in the findings is not necessarily a conclusion of the listed literature but rather results from assessment of the literature. Assessment of the role of anthropogenic emissions in the impact event requires a multi-step evaluation. [Table 18-4]]

_____ START BOX TS.4 HERE _____

Box TS.4. Multidimensional Vulnerability to Climate Change

People who are socially, economically, culturally, politically, or institutionally marginalized are typically most at risk from adverse impacts of climate change and climate change responses. However, such heightened vulnerability does not occur in isolation; rather, it is observed along intersecting and simultaneous axes of marginalization and privilege, including not only income and assets but also gender, class, race, ethnicity, age, and (dis)ability (Box TS.4

Figure 1). Other dimensions include resource access, location, legal systems, and voice. Understanding differential adaptive capacity for individuals, households, and communities requires attention to multidimensional inequality, deprivation, and power, as well as context-specific constellations in which certain dimensions drive differential vulnerability while others play a secondary role or are absent (e.g., class and gender in one case versus race, gender, and age in another case). Few studies depict the full spectrum of these differences and the ways in which they interact to shape resilience or vulnerability, and thus attribution remains a challenge. Since inequality is not just a consequence of climate change, but also a key cause and amplifier of its impacts, inequality-sensitive analyses are needed for effective and efficient adaptation.

[INSERT BOX TS.4 FIGURE 1 HERE

Box TS.4 Figure 1: Intersecting yet simultaneous and dynamic axes of privilege and marginalization, shaped by people's multiple identities and embedded in uneven power relations and development pathways. Together, they result in differential vulnerability to the same exposure to climate change and climate change responses. These intersecting dimensions ("intersectionality") illustrate systemic vulnerability and multidimensional deprivation that determine inequality and adaptive capacity while being transformed as a result of negative climate change impacts and risks as well as consequences of policy responses, often to the detriment of the poor and disadvantaged. [Figure 13-4]]

Example impacts and risks of climate change and climate change responses:

- Differential impacts on men and women arise from distinct roles in society, the way these roles are enhanced or constrained by other dimensions of privilege and marginalization, and the nature of response to hazards. [9.3.5, 13.2.1]
- Both male and female deaths are recorded after flooding, dependent on socio-economic disadvantage and culturally-imposed expectations to save lives. While women are generally more sensitive to heat stress, more male workers are reported to have died largely due to gender roles and responsibilities related to outdoor and indoor work [11.4.1, 13.2.1]
- Women often experience additional duties as laborers and caregivers as a result of weather events, climate, and extreme events, as well as responses (e.g., male outmigration), while facing more psychological and emotional distress, loss in food intake, and in some cases increasing incidences of domestic violence. [9.3.5, 9.4.1, 13.2.1]
- Privileged members of society can benefit from climate change impacts and response strategies, due to their flexibility in mobilizing and accessing resources and positions of power, often to the detriment of others. [13.2.1]
- Populations that presently experience high levels of ill-health are more seriously affected than those currently in relatively good health. [11.3]
- Children and the elderly are often at higher risk, due to narrow mobility, susceptibility to infectious diseases, reduced caloric intake, and social isolation. While adults and older children are more severely affected by some climate-sensitive vector borne diseases such as dengue, young children are more likely to die from or be severely compromised by diarrheal diseases. [11.5, 13.2.1]
- In most urban areas, low-income groups face larger climate change risks and impacts because of poor quality and insecure housing, inadequate infrastructure and lack of provision for health care, emergency services, and measures for disaster risk reduction. [8.1.4]
- Indigenous peoples' livelihoods and lifestyles, often dependent on natural resources, are highly sensitive to climate change and climate change policies, especially those that marginalize their knowledge and perspectives. [12.3]
- Pastoralists and artisanal fisher folk may be becoming more vulnerable to climate change, partly due to neglect, misunderstanding, or inappropriate policy toward them on the part of governments. [9.3.5]
- The ability of migrants to adapt to climate change may be declining in destination areas, particularly in urban centers in developing countries. One primary mechanism is the clustering of low income migrants in flood-prone and landslide-prone high density housing. [12.4.2]
- In areas where violent conflict has destabilized society and damaged natural and social capital people are particularly vulnerable to climate change. [12.5]
- One-dimensional narratives, particularly of women and other marginalized groups, deny agency and portray people's vulnerability as their intrinsic problem. [13.2.1]
- Disadvantaged groups without access to land and labor, including female-headed households, are disproportionately harmed by climate change response mechanisms (e.g., CDM, REDD+, large-scale land acquisition for biofuels, and planned agricultural adaptation projects). [9.3.5, 12.2, 12.5, 13.3.1]

_____ END BOX TS.4 HERE _____

Freshwater resources

Glaciers worldwide continue to shrink (*very high confidence*). New glacier lakes have formed, and existing ones have changed. Seasonal ice in many lakes and rivers forms later and breaks up earlier. A major part of these changes can be attributed to climate change (*high confidence*). [3.2.3, 18.3.1.3, 18.5, Figure 18-3]

Widespread changes and degradation of permafrost of both high-latitude and high-elevation mountain regions have been observed over the past years and decades *(high confidence).* The permafrost boundary has been moving polewards and to higher elevations, and the active layer thickness has increased at many sites (*medium confidence* in attribution to climate change). [18.3.1, 18.5]

Hydrological systems have changed in many regions due to changing rainfall or melting glaciers, affecting water resources, water quality, and sediment transport (*medium confidence*). In many river systems, the frequency of floods has been altered by climate change (*low* to *medium confidence*). The duration of droughts in some regions has been altered by climate change (*medium confidence*). In the last decades, warming has caused a shift towards earlier maximum spring discharge, decreased spring snowpack, and sometimes decreased magnitudes of snowmelt floods in regions with seasonal snow storage (*high confidence*, based on *high agreement, robust evidence*). Where more winter precipitation falls as rain than snow, winter low flows have increased significantly. Where the stream flow is lowest in summer, decreased snow storage has exacerbated summer low flows. [3.2.3, 18.3.1, 18.5]

Specific regional examples include the following. See also Table TS.1.

- In Asia, the Altai-Sayan, Pamir, and Tien Shan glaciers have lost on average 10% of their area and 15% of their ice volume since 1960. Rates of further glacier degradation depend mainly on increases in summer air temperature and changes in precipitation. [24.9.3]
- In North America, changes in climate trends include reductions in spring snowpack along with an earlier peak runoff over many areas (*very high confidence*). Attribution of observed changes to anthropogenic climate change has been established for some physical systems (e.g., snowpack). In most areas, impacts of climate variability such as floods, decreased water availability, and increased salinity of coastal water supplies, which are exacerbated by other anthropogenic drivers, are observed (*high confidence*). Water supply deficits are conducive to adaptive response, with many hard and soft approaches to adaptation currently available. [26.2, 26.3]
- In Central and South America, there have been changes in geophysical variables (cryosphere and runoff) that affect streamflow and ultimately water availability (*high confidence*). Since AR4, there is growing evidence that glaciers (both tropical and extratropical) are retreating and the cryosphere in the Andes is changing according to the warming trends. These changes affect streamflow availability in different seasons of the year. Robust trends are apparent, associated with changes in precipitation such as increasing runoff in the Southeastern South America region (La Plata basin), and decreasing runoff in the Central Andes (Chile, Argentina) and Central America. In contrast to these findings, no robust trend in streamflow in the Amazon Basin has been detected. [27.3.1]
- In the Arctic, the decline of summer sea-ice is occurring at a rate that exceeds most model projections (*high confidence*). In some regions of Antarctica, evidence of similarly rapid rates of change is emerging, particularly for ice shelves. There is some evidence, for example in the reduction of sea-ice extent in the Arctic and in the west Antarctic Peninsula, that the changes are non-linear and may be accelerating. [WGI AR5 Chapter 14]

Terrestrial and inland water systems

The magnitude of future climate change could approach that of many of the largest climatic changes observed in Earth history (*high confidence*). The planet's biota, carbon cycle, and associated feedbacks and services have responded to climate change in Earth history even when the rates of past global climate change were

slower than implied by higher warming scenarios (e.g., RCP 8.5). However, the impacts of climate change on terrestrial and freshwater ecosystems must also be considered in the context of non-climatic influences, both naturally-occurring and directly driven by humans. [4.2.2]

Plant and animal species have moved their ranges, altered their abundance, and shifted their seasonal activities in response to climate change in the past, and they are doing so now in many regions (*high confidence*). The broad patterns of species and biome movement towards the poles and higher in altitude in response to a warming climate are well established for the distant (*very high confidence*) and recent past (*medium confidence*). Seasonal activity of species has responded to warming over the last several decades based on extensive ground and satellite-based measurements (*high confidence*). Species have already started to migrate out of protected areas and towards mountaintops over the last several decades due to a warming climate. Observations and models of the seasonal activities of species indicate that climate warming disrupts species life cycles and interactions between species, as well as altering ecosystem function. At local scales, observed and modeled species responses sometimes differ from qualitative predictions based on global scale indices of warming; this can often be explained by large variation in local scale climate response to global warming, changes in climate factors other than average temperature, non-climatic determinants of species distributions, interactions between climate and other simultaneous global change factors such as nitrogen deposition, and species interactions. No past climate changes are a precise analog to the current and projected climatic changes, so species responses inferred from the past only give indications, especially at the local scale. [4.2.2, 4.3.2, 4.3.3, 4.4.1, 18.3.2, 18.5]

There is *very low confidence* that observed species extinctions can be attributed to recent climate warming given the very low fraction of species for which global extinction has been ascribed to climate change and the tenuous nature of most attributions. However, in the specific case of Central American amphibians, there is *medium confidence* that recent warming has played a role in their extinctions. [4.3.2, 18.3.2, 18.5]

Increases in the frequency or intensity of ecosystem disturbances due to fires, pest outbreaks, wind-storms, and droughts have been detected in many parts of the world (*medium confidence*). Such changes beyond the range of historical natural variability will alter the structure, composition, and functioning of ecosystems (*high confidence*). These changes will often be manifested as relatively abrupt and spatially-patchy transitions following disturbances, rather than gradual and spatially-uniform shifts in location or abundance (*medium confidence*). There is evidence of an increase in tree mortality in many regions over the last decade, but there is *low confidence* in the detection of a global trend in increased mortality or in the attribution of such a global trend to climate change. In some regions, increased tree mortality is sufficiently intense and widespread as to result in forest dieback, which constitutes a major risk because of its large impacts on biodiversity, wood production, water quality, amenity, economic activity, and the climate itself. In detailed regional studies, particularly in western and boreal North America, observed tree mortality is detectable and can be attributed to the direct effects of high temperatures and drought, or to changes in the distribution and abundance of insect pests and pathogens related, in part, to warming (*high confidence*). [4.2.4, 4.3.2, 4.3.3, 4.3.4, Box 4-2, Box 4-3, Box 4-4, Figure 4-12]

Several major terrestrial ecosystems are undergoing broad-scale changes that can be characterized as early warnings for coming regime shifts, in part due to climate change. Climate change is a driver of widespread shrub encroachment in the Arctic tundra (*high confidence*) and of boreal forest tree mortality (*low confidence*). Observed recession and degradation of the Amazon forest cannot be attributed to climate change. [18.3.2, 18.5.6, 18.5.7]

Specific regional examples include the following. See also Table TS.1.

- In Europe, climate change has already affected the distribution and abundance of some animals and plant species in Europe (*high confidence*). Observed climate change is affecting a wide range of flora and fauna in Europe, including plant pests and diseases and the vectors of animal diseases (*medium confidence*). Observed climate warming has increased forest productivity in northern Europe (*medium confidence*) and fire incidence in southern Europe (*high confidence*). [23.4.1, 23.4.3, 23.4.4, Table 23-4, Table 23.6, 23.6.4]
- In North America, climate change is already affecting many ecosystems (*high confidence*). Forests are being affected by fire, drought, pests, and other climate-related stresses. [26.4]
- In Central and South America, land cover change is a key driver of environmental change with significant impacts that may increase potential negative impacts from climate change. Deforestation and land degradation are mainly attributed to increased extensive and intensive agriculture, both from traditional

export activities such as beef and soy production, but more recently from biomass for biofuel production. Agricultural expansion has affected fragile ecosystems such as the edges of the Amazon forest and the tropical Andes, increasing the vulnerability of communities to extreme climate events, particularly floods, landslides, and droughts. Even though deforestation rates in the Amazon have decreased substantially in the last eight years to a current value of 0.29%, the lowest for all forest biomes in Brazil, other regions like the Cerrado and the Chaco forests still present high levels of deforestation with rates as high as 1.33%. [27.2.2]

- In Central and South America, conversion of natural ecosystems is the main proximate cause of biodiversity and ecosystem loss, and in parallel is a driver of anthropogenic climate change. Plant species are rapidly declining in Central and South America; the highest percentage of rapidly declining amphibian species occurs also in Central and South America, with Brazil being among the countries with the most threatened species of birds, mammals, and freshwater fishes. However, the region has still large extensions of natural vegetation cover for which the Amazon is the main example. [27.3.2]
- **Climate change is impacting terrestrial and freshwater ecosystems in some areas of the Arctic and Antarctica.** This is due to ecological effects resulting from reductions in the duration and extent of ice cover and enhanced permafrost thaw (*very high confidence*) and through changes in the precipitation-evaporation balance (*medium confidence*). [28.2] The abundance and biomass of deciduous shrubs and grasses has increased substantially over large – but not all – parts of the Arctic tundra in recent years (*very high confidence*). It is *very likely* that most of this increase in biomass can be attributed to longer growing seasons and higher summer temperatures. The tree line has moved northwards and upwards in many, but not all, Arctic areas, and significant increases in tall shrubs have been observed in many places (*high confidence*). Other factors such as changes in herbivore grazing, anthropogenic disturbances, and changes in precipitation and the snow/water regime also influence the tree line and structural vegetation changes in the northern boreal forest. [28.2]

Coastal systems and low-lying areas

On-going warming and acidification of coastal waters have direct and indirect impacts on natural ecosystems (*very high confidence*). More than 70% of the world's coastlines have significantly warmed during the past 30 years. The increase in the acidity of seawater is much greater in some coastal areas than in the open ocean due to the combined effects of atmospheric CO_2 uptake and eutrophication. Both changes have wide-ranging consequences on coastal organisms and ecosystems, such as species survival and shifts, coral bleaching, and decreased rates of calcification. Reducing regional stressors represents an opportunity to strengthen the ecological resilience of these ecosystems, which may help them survive projected changes in ocean temperature and chemistry. See also Box TS.9. [5.3.4, 6.1.1, 6.2.2, 6.3.2, 6.5.2, 30.4, 30.5, Box CC-CR, CC-OA]

Due to the increased frequency of stress events arising from elevated sea temperatures, coral reefs have experienced increased mass bleaching and mortality (*very high confidence*). These events have contributed to the loss of reef building corals in many parts of the world since the early 1980s. [18.3.3, 18.3.4, Box 18-3, 18.5, Table 18-8, Box CC-CR]

Despite the known sensitivity of coastal systems to sea-level rise, local perturbations from regional variability in the ocean and human activities preclude the confident detection of sea level-related impacts attributable to climate change outside of the Arctic. [18.3.3]

Specific regional examples include the following. See also Table TS.1.

- In North America, coastal zones are being affected by multiple and often interacting climate stresses including higher temperatures, ocean acidification, coral reef bleaching, sea level rise, storm surges, and storms (*high confidence*). [26.4]
- In north-eastern Australia (since the late 1970s) and more recently in western Australia, high sea surface temperatures have repeatedly bleached coral reefs. [25.6.2]
- In Central and South America, coastal and marine ecosystems have been undergoing significant transformations that pose threats to fish stocks, corals, mangroves, places for recreation and tourism, and controls of pests and pathogens. Frequent coral bleaching events have been recently reported for the Mesoamerican Coral Reef. Some of the main drivers of mangrove loss are deforestation and land

conversion, agriculture, and shrimp ponds to an extent that the mangroves of the Atlantic and Pacific coasts of Central America are some of the most endangered on the planet. [27.3.3.1]

- Arctic sea ice has been shrinking in extent, thickness, and composition, with observed impacts on marine biology and the livelihoods of indigenous people (*medium* to *high confidence*). [18.3.1, 18.3.4, 18.4.7, 18.5.7]

Marine systems

Climate change is manifesting itself in the alteration of abiotic and biotic properties of the ocean (*high confidence*). The physical and chemical properties of the ocean have changed significantly over the past 60 years due to anthropogenic climate change, including properties such as circulation intensity, temperature, oxygen (O_2) and nutrient inventories, carbon dioxide, ocean pH, salinity, and light regime. Changes to ocean conditions have resulted in fundamental and extensive changes to organisms and ecosystems in the ocean. [6.1.1, 6.2.2, 6.3.2, 6.5.2, 18.3.3, 18.3.4, 30.4, 30.5, Box CC-CR, CC-OA]

Marine ecosystems have been and are being exposed to and affected by climate changes of different rates, magnitude, and duration (*very high confidence*). In Earth history, natural climate change at rates slower than today's anthropogenic change has led to significant ecosystem shifts (*high confidence*). The fossil record and present field and laboratory observations confirm key environmental drivers and responses of ocean ecosystems to climate change including migration, altered ecosystem composition, changes in abundance, and extinctions. [6.1.2, 6.3]

Understanding of physiology combined with field observations demonstrates that vulnerability of most organisms is defined by their specialization on specific, limited temperature ranges and accordingly by their thermal sensitivity (*high confidence*). See Figure TS.1. Temperature defines the geographical distribution of species and their responses to climate change (*medium confidence*). Temperature extremes act through losses in abundance and habitat (e.g., sea ice and coastal), local extinction, and latitudinal shifts (*very high confidence*). Vulnerability is greatest in polar animals and in species living close to their upper thermal limits, for example in the tropics (*medium confidence*). [6.2.2, 6.2.3, 6.2.4, 6.2.5. 6.3.2, 6.5.2]

Warming is causing shifts in the geographical distribution, abundance, and migration patterns of species, paralleled by a reduction in their body size and a shift in the timing of seasonal activities. This results in altered interactions between species including changes in competition and predator-prey dynamics (*high confidence*). Increased temperatures have significantly altered the phenology or timing of key life-history events such as plankton blooms, migratory patterns, and spawning in fish and invertebrates over recent decades (*medium confidence*). There are many observations of poleward shifts in the distribution and abundance of fishes and invertebrates and/or of their shifts to deeper and cooler waters. Poleward shifts of plankton have occurred up to 250 km per decade, up to 30 times faster than terrestrial species. See Figure TS.1. [6.2.2, 6.2.5, 6.3, 6.5, 30.4, 30.5]

The combination and often amplification of climate change drivers acting globally and additional human-induced local drivers, such as overfishing, pollution, and eutrophication exacerbating hypoxia, result in enhanced vulnerability of natural and human systems to climate related forcings presently and into the future (*high confidence*). Observations include the progressive redistribution of species, changes in species' abundance, and the reduction in marine biodiversity in sensitive regions and habitats, putting the sustained provision of ecosystem services and fisheries productivity at risk. Socio-economic vulnerability is high particularly in tropical developing countries, progressively increasing the risk of reduced food supply, income, and employment. Key uncertainties include the upscaling of climate change effects from organism to ecosystem level, the adaptive capacity of marine organisms and human societies to these impacts, the interactions with other human drivers, the sustenance of biogeochemical functions and productivity in the global ocean, and the effectiveness of climate mitigation and adaptation measures. [6.3.5, 6.4, 6.6]

[INSERT FIGURE TS.1 HERE

Figure TS.1: Thermal specialization of species, sensitive to ocean acidification and hypoxia (A, left) causes warming induced distribution shifts (A, right). An example (B) is the northward expansion of warm-temperate species in the Northeast Atlantic. Differential distribution change across functional groups (C) will be influenced by species-specific impacts of future ocean acidification across phyla (D). Detailed introduction of each panel follows:

A) Mechanisms linking organism to ecosystem response explain the why, how, when, and where of climate sensitivity (blue to red color gradients illustrate transition from cold to warm temperatures). As all biota, animals specialize on limited temperature ranges, within which they grow, behave, reproduce, and defend themselves by immune responses (left). Optimum temperatures (T_{opt}) indicate performance maxima, pejus temperatures (T_p) the limits to long-term tolerance, critical temperatures (T_c) the transition to anaerobic metabolism, and denaturation temperatures (T_d) the onset of cell damage. These thresholds can shift by acclimatization (horizontal arrows). Under elevated CO_2 levels and in hypoxic waters performance levels can decrease and windows of performance be narrowed (dashed green arrows pointing to dashed black curves). Shifts in biogeography result during climate warming (right). The polygon delineates the range in space and time, the level of grey denotes abundance. Species display maximum productivity in southern spring, wide seasonal coverage in the center, and a later productivity maximum in the North. The impact of photoperiod increases with latitude (dashed arrow). During warming, the southern temperature and time window contracts while the northern one dilates (directions and shifts indicated by arrows). Control by water column characteristics or photoperiod may overrule temperature control in some organisms (e.g., diatoms), causing contraction of spatial distribution in the north. B) Long-term changes in the mean number of warm-temperate pseudo-oceanic species in the Northeast Atlantic from 1958 to 2005. C) Rates of change in distribution (km decade^{-1}) for marine taxonomic groups, measured at the leading edges (red), and trailing edges (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward). Means ± standard error are shown, with number of observations and significance (*p<0.1, **p<0.05, ***p<0.01). D) % fraction of studied scleractinian coral, echinoderm, molluscan, crustacean, and fish species affected negatively, positively, or not at all by various levels of ambient CO_2. Effects considered include those on life stages and processes reflecting physiological performance (O_2 consumption, aerobic scope, behaviors, scope for behaviors, calcification, growth, immune response, acid-base balance, gene expression, fertilization, sperm motility, developmental time, production of viable offspring, morphology). Horizontal bars above columns represent frequency distributions significantly different from controls. [Figures 6-7, 6-10, 6-11, and 30-11]]

Rising atmospheric CO_2 not only causes ocean warming but also changes in carbonate chemistry termed ocean acidification. Ocean acidification has ramifications for processes ranging from physiology and behavior to population dynamics (*medium* to *high confidence*). A wide range of sensitivities to projected acidification exists within and across organism phyla (Figure TS.1). Across organisms, sensitivity decreases with increasing capacity to compensate for the elevated internal CO_2 concentration or falling pH (*medium confidence*). Most plants including algae respond positively to elevated CO_2 levels by increasing photosynthesis and growth (*high confidence*). Limits to adaptational capacity remain unexplored. See also Box TS.9. [6.2.2, 6.2.3, 6.2.4, 6.2.5, 6.2.6, 6.3.4, Box CC-OA]

Field observations attributed to anthropogenic ocean acidification are few due to limited changes in water chemistry between preindustrial times and today. Shell thinning in planktonic foraminifera from various regions and Southern Ocean pteropoda has been attributed fully or in part to acidification trends (*medium confidence*). Coastward shifts in upwelling regimes of the Northeast-Pacific and upwelled CO_2-rich waters presently causing larval oyster fatalities in aquacultures (*high confidence*) or shifts from mussels to fleshy algae and barnacles (*medium confidence*) provide an early perspective on future effects of ocean acidification. Ecosystems at risk of ocean acidification are warm and cold water coral reefs (*high* or *medium confidence*). [6.1.2, 6.2.2, 6.2.5, 6.3.4]

Climate change has influenced ocean primary productivity, with positive consequences for some fisheries and negative ones for others (*medium confidence*). The catch potential of fisheries has increased in some regions and decreased in others with consequences for the food and livelihood of involved human communities (*high confidence*). Fisheries at high latitudes are showing increased productivity due to sea ice retreats and increases in net primary productivity. In other regions, stratification of the water column driven by warming has reduced net primary productivity of the ocean. [18.3.4, 18.4.1, 18.5.7]

The ongoing expansion of hypoxic regions termed Oxygen Minimum Zones or anoxic "dead" zones constrains the habitat of oxygen-dependent animals, plants, and microbes while it benefits anaerobic microbial life (*high confidence*). Warming-induced stratification, reduced intensity of ocean circulation, and the decomposition of organic matter by heterotrophic organisms create an expansion of these specialized, microbially dominated ecosystems. The removal of fixed nitrogen (denitrification) via the metabolism of selected bacteria and archaea can

reduce nutrient inventories and alter the nitrogen-phosphorus balance. Hypoxia tolerance varies among species and is influenced by temperature, elevated CO_2, food consumption, and oxygen demand. [6.2.2, 6.2.3, 6.2.4, 6.2.5, 6.2.6, 6.3.3, 6.3.5, 18.3.4]

Specific regional examples include the following. See also Table TS.1.

- In Europe, observed warming has shifted the ranges of marine fishes to higher latitudes (*high confidence*) and reduced body size (*low confidence*). Observed higher water temperatures have adversely affected both wild and farmed freshwater salmon production (*high confidence*). [23.4.6]
- In the Northeastern Atlantic, High Latitude Spring Bloom systems are responding to rapid warming with the greatest changes being observed since the late 1970s in the phenology, distribution, and abundance of plankton assemblages and the reorganization of fish assemblages (*high agreement, medium evidence*). The abundance of boreal species has decreased along the southern fringe and increased along the northern fringe. However, substantial natural variability over the past 30 years has occurred in the entire Northeast Atlantic region as part of the Atlantic Multidecadal Oscillation. These changes have both positive and negative implications for the future of the fisheries within the High Latitude Spring Bloom systems. [6.3.2, 30.5.1, 30.8.3, WGI AR5 Chapter 14]
- The upper layers of the world's Semi-Enclosed Seas show significant warming since 1982, although this warming signal is strongly influenced by long-term variability (e.g., Atlantic Multidecadal Oscillation) (*medium confidence*). Further warming will *very likely* cause greater thermal stratification, reducing oxygen levels at depth and extending hypoxic zones, especially in the Baltic and Black Seas. These changes are *likely* to impact regional ecosystems and fisheries, tourism, and other human activities, although the understanding of the potential impacts is relatively undeveloped. [30.3, 30.5.6]
- An increased nutrient supply through intensified upwelling in some regions (through intensified upwelling) threatens deep sea ecosystems with hypoxia by increasing the rate of metabolism (and hence oxygen use) (*medium agreement, medium evidence*). Similarly, a decrease in primary productivity in some areas (e.g., subtropical gyres) may reduce the availability of organic carbon to deep sea ecosystems. These changes are *virtually certain* to increase due to the amplifying influence of rising deep water temperatures on microbial metabolism. [30.5.7, 6.1.1]

Food production systems and food security

The effects of climate change on food production are already evident in several regions of the world (*high agreement, medium evidence*). Negative impacts of climate trends have been more common than positive ones, although the latter predominate at high latitudes (*high confidence*). Yields have increased in some (mid to high latitude) regions, due to warming and higher CO_2 (*low confidence*), and decreased in other (mainly low latitude) regions due to water shortages and higher temperatures (*medium confidence*). Since AR4, there have been several periods of rapid food price increases, demonstrating the partial sensitivity of current markets to climate variability. These recent price changes cannot presently be attributed to climate change, due to the presence of other drivers. Social and economic issues such as energy policy and changes in household income will remain the main drivers of changes in food security in the near-term, regionally and locally. [7.2, Figures 7-2, 7-3, 7-4, Table 7-1, 18.4.1, Table 18-9]

There is new understanding since AR4 of the sensitivity of crops to extreme heat, which reinforces the importance of temperature changes for determining impacts of climate change on regional crop yields (*medium agreement, medium evidence*). Extreme heat also has a negative effect on food quality in terms of nutrition and processing (*high agreement, robust evidence*). Evidence since AR4 confirms the positive effects of CO_2 and negative effects of elevated tropospheric ozone on crop yields (*high confidence*). There is emerging experimental and modeling evidence that interactions among production factors such as CO_2 and ozone, mean temperature, extremes, water, and nitrogen can alter primary food production in complex ways (*high agreement, medium evidence*). [7.2, 7.3, 7.3.2, 7.4, Figures 7-2, 7-5, 7-6, and 7-7]

Specific regional examples include the following. See also Table TS.1.

- In Africa, livelihood-based approaches for managing risks to food production from multiple stressors, including rainfall variability, have increased substantially since 2007 (*high confidence*). Collaborative, participatory research including scientists and farmers, strengthened communication systems for

anticipating and responding to climate risks, and increased flexibility in livelihood options strengthen agricultural coping strategies for near-term climate variability and provide potential pathways for increasing capacities to adapt to climate change. [22.4.5, 22.4.6, 22.6.1]

- In Europe, yields of some arable crop species such as wheat have been negatively affected by observed warming in some countries since the 1980s (*medium confidence*). [23.4.1]
- Food security of many indigenous and rural residents in the Arctic is being impacted by climate change, for example affecting indigenous people's access to traditional foods that have provided sustenance, cultural, religious, economic, and community well-being for many generations (*high confidence*). [28.2.4, 28.2.7, 28.4.1]

Urban areas

Many urban areas have long been exposed to a range of hazards and disaster risks that could be exacerbated by climate change (*high confidence*). These include water shortages and droughts in urban regions, geo-hydrological hazards, inland and coastal flooding, windstorms and storm surges, high levels of air pollution, extremes in urban heat and cold and urban heat islands, and novel compound and slow onset hazards that impact ecosystem resilience. Reducing basic service deficits and building resilient infrastructure systems could significantly reduce global climate risk (*very high confidence*). [8.2, 8.3]

Around one billion people live in informal settlements in urban areas with inadequate or no provision for infrastructure and services that provides a foundation for adaptation (*high confidence*). Here, poverty and social inequality may be aggravated by climate change and the lack of adaptive capacity. The adaptive capacity of an urban center is much influenced by the quality and coverage of infrastructure (piped water supplies, sewers and drains, all-weather roads, and electricity provision) and services that include solid waste collection, policing, health care, emergency services, and measures to reduce disaster risk. The extent to which urban and higher levels of governments are able to mobilize resources and choose the most appropriate technical and institutional systems for service delivery influences adaptive capacity and deepens climate resilience. The rate and magnitude of urban development in some low- and middle-income countries also bring great challenges that many high-income nations do not have to deal with. [8.2, 8.3]

Specific regional examples include:

- In North America, several social and economic impacts observed in human settlements have been attributed, with different degrees of certainty, to climate-related processes (*high confidence*), including but not limited to sea-level rise, changes in temperature and precipitation, and occurrences of extreme events such as droughts and storms. Differences in the severity of climate impacts on human settlements are strongly influenced by context-specific social and environmental factors and processes, with some (e.g., the legacy of previous and current stresses) common to urban and rural settlements. In cities, concentrations of populations, economic activities, cultural amenities, and built environments in highly-exposed urban locations such as coastal and dry areas create higher hazard risks. For example, Mexico City is vulnerable due to the high density of population combined with several socio-economic and environmental sources of vulnerability. [26.8]

Rural areas

Rural areas still account for almost half the world's population and about 75% of the developing world's poor people. There is a lack of clear definition of what constitutes rural areas, and definitions that do exist depend on definitions of the urban. Across the world, the importance of peri-urban areas and new forms of rural-urban interactions are increasing. However, rural areas, seen as a dynamic spatial category, remain important for assessing the impacts of climate change and the prospects of adaptation. [9.1.1, 9.1.2, 9.1.3]

Cases in the literature of observed impacts on rural areas often suffer from methodological problems of attribution, with regard to the difficulties of attributing extreme events to climate change, the status of local knowledge, and the action of non-climate shocks and trends, but evidence for observed impacts, both of extreme events and other categories, is increasing (*medium confidence*). Impacts attributable to climate change

include declining yields of major crops, extreme events such as droughts and storms, and geographically-specific impacts such as glacier melt in the Andes. [9.3.2]

Climate change in rural areas will take place in the context of many important economic, social, and land-use trends (*very high confidence*). In different regions, rural populations have peaked or will peak in the next few decades. The proportion of the rural population depending on agriculture is extremely varied across regions, but declining everywhere. Poverty rates in rural areas are falling more sharply than overall poverty rates, and proportions of the total poor accounted for by rural people are also falling: in both cases with the exception of sub-Saharan Africa, where these rates are rising. [9.3.1]

In developing countries, rural people are subject to multiple non-climate stressors, including under-investment in agriculture (though there are signs this is improving), problems with land policy, and processes of environmental degradation (*high* to *very high confidence*). Hunger and malnutrition remain prevalent among rural children in South Asia and Sub-Saharan Africa. In developing countries, the levels and distribution of rural poverty are affected in complex and interacting ways by processes of commercialization and diversification, food policies, and policies on land tenure. In industrialized countries, there are important shifts towards multiple uses of rural areas, especially leisure uses, and new rural policies based on the collaboration of multiple stakeholders, the targeting of multiple sectors, and a change from subsidy-based to investment-based policy. [9.3.1, Table 9-1]

Prevailing development constraints, such as low levels of educational attainment, environmental degradation, gender inequality, and remoteness from decisionmakers, create additional vulnerabilities to climate change (*high confidence*). There are low levels of agreement on some of the key factors associated with vulnerability or resilience in rural areas, including rainfed as opposed to irrigated agriculture, small-scale and family-managed farms, and integration into world markets. There is greater agreement on the importance for resilience of access to land and natural resources, flexible local institutions, and knowledge and information, and on the association of gender inequalities with vulnerability. Specific livelihood niches such as pastoralism and artisanal fisheries are vulnerable and at high risk of adverse impacts (*medium* to *high confidence*), partly due to neglect, misunderstanding, or inappropriate policy towards them on the part of governments. Lack of supportive policies in rural areas can reinforce existing vulnerability. [9.2, 9.3.5, 9.4.4]

Specific regional examples include:

- In North America, geographic isolation and institutional deficits are key sources of vulnerability for many small rural areas. [26.8]

Key economic sectors and services

Extreme climate events have impacted natural and physical livelihood assets, incomes, public health, and social institutions. For example, flooding can have major economic costs, both in term of impacts (capital destruction, disruption) and adaptation (construction, defensive investment). Economic losses due to extreme weather events have increased globally, mostly due to increase in wealth and exposure, but with a documented contribution of climate change and variability in some cases. [10.3.1, 10.7.3, 18.4.4, 18.4.7]

Climate change strongly affects insurance systems (*high agreement, robust evidence*). More frequent and/or intensive weather disasters increase losses and loss variability in various regions and challenge insurance systems to offer affordable coverage while raising more risk-based capital, particularly in low- and middle-income countries. Economic-vulnerability reduction through insurance has proven effective. [10.7]

Specific regional examples include the following. See also Tables TS.1 and TS.2.

- In Europe, direct economic river flood damages have increased over recent decades (*high confidence*), but this increase is due to development in flood zones and not observed climate change. Some areas show changes in river flood occurrence related to observed changes in extreme river discharge (*medium confidence*). [23.2.3, 23.3.1, SREX 4.5]
- In North America, slow-onset perils such as sea level rise, drought, and permafrost melt are an emerging concern for some economic sectors, with large regional variation in awareness (*medium confidence*). [26.7]

Human health

The health of human populations is sensitive to shifts in weather patterns and other aspects of climate change (*very high confidence*). These effects occur directly, due to changing incidence in temperature and humidity extremes and occurrence of floods, storms, droughts, and fires. Indirectly, health may be damaged by ecological disruptions brought on by climate change (crop failures, shifting patterns of disease vectors), or social responses to climate change (such as displacement of populations following prolonged drought). Variability is a risk factor in its own right – it is more difficult to protect human health in a highly variable climate than one that is more stable. There is emerging evidence of non-linearities in response (such as greater-than-expected mortality due to heat waves) as climates become more extreme. [11.3, 11.5]

In recent decades, climate change has contributed to levels of ill-health (*likely*) though the present world-wide burden of ill-health from climate change is relatively small compared with other stressors on health and is not well quantified. Changes in temperature, rainfall, and sea-level have altered distribution of some disease vectors, increased heat wave casualties, and reduced food production for vulnerable populations (*medium confidence*). Dengue fever and malaria have increased in several regions of the world over the past few decades, but there is *very low confidence* in attribution of these trends to climate change. Although new infections and other conditions may emerge under climate change (*low confidence*), the largest risks by far will apply in populations already most affected by climate-related diseases. [11.3, 11.4, 18.4.5]

In addition to their implications for climate change, essentially all the important climate altering pollutants aside from CO_2 have other health implications (*very high confidence*). In 2010, more than 7% of the global burden of disease was due to inhalation of these air pollutants (*high confidence*), accounting potentially for an economic impact of 1-2 US$ trillion, depending on the economic valuation method used (*low confidence*). [Box 11.4]

Specific regional examples include the following. See also Table TS.1.

- In Africa, climate change is a multiplier of existing vulnerabilities affecting health outcomes, including water and sanitation coverage, food security, and access to health care and education (*high confidence*). [22.3.5]
- In Europe, climate warming has adversely affected trends in ground level tropospheric ozone (*low confidence*). [23.6.1]
- In Central and South America, climate variability and climate change are negatively affecting human health, either by increasing morbidity, mortality, and disabilities (*very high confidence*), through the emergence of diseases in regions previously non-endemic, or through the re-emergence of diseases in areas where they have previously been eradicated or controlled (*high confidence*). Climate-related drivers have been recognized for respiratory and cardiovascular diseases, vector- and water-borne diseases (malaria, dengue, yellow fever, leishmaniasis, cholera, and other diarrheal diseases), Hantaviruses and Rotaviruses, pregnancy-related outcomes, diabetes, chronic kidney diseases, and psychological trauma. [27.3.7]

Human security

Mobility is a widely used and often effective strategy to maintain livelihoods in response to social and environmental changes (*high agreement, medium evidence*). There is *robust evidence* that migration and mobility are adaptation strategies to climate variability. People who lack the ability to move will face higher exposure to weather-related extremes in both rural and urban areas in the developing world. There is some evidence to suggest that expanding opportunities for mobility reduce vulnerability and enhance human security. Observations of implementation of planned resettlement show that legitimate and inclusive planning processes help alleviate the conflict and insecurity that individuals and communities may experience. [12.4.3]

Some of the factors that increase the risk of violent conflict including civil wars are sensitive to climate change (*medium agreement, medium evidence*). The evidence on the direct effect of climate change and variability on violence is contested. [12.5] Though there is little agreement about causality, there is *robust evidence* that shows that low per capita incomes, economic contraction, and inconsistent state institutions are associated with the

incidence of civil wars. These factors are sensitive to climate change. Climate change policy responses, particularly those associated with changing property rights to land, water, and resources, can increase the risk of violent conflict. A range of policies and institutions at multiple scales has been demonstrated to reduce the effects of environmental change on the risk of violent conflict. Economic growth, high per capita incomes, strong democratic institutions, social protection during economic and climate shocks, and robust institutional structures that protect property rights and manage conflict all reduce the risk that climate variability and extremes will lead to violence. [12.5]

Challenges for vulnerability reduction and adaptation are particularly high in regions that have shown severe difficulties in governance (*high confidence*). People living in places affected by violent conflict are particularly vulnerable to climate change (*high agreement, limited evidence*). Large-scale violent conflict harms infrastructure, institutions, natural capital, social capital, and livelihood opportunities. Since these assets facilitate adaptation to climate change, there are strong grounds to infer that conflict drives vulnerability to climate change impacts. [12.5.2, 19.6.1]

Currently many indigenous peoples are politically and economically marginalized and live in regions or depend on natural resources that are highly sensitive to climate changes (*high agreement, robust evidence*). Indigenous peoples have adapted to highly variable and changing social and ecological conditions. The current rate and magnitude of change will increasingly constrain the efficacy of indigenous and traditional knowledge in adaptive responses. [12.3]

Specific regional examples include the following. See also Table TS.1.

- In Europe, climate change has already affected cultural heritage (*low confidence*). [23.5.4, Table 23.6]
- In both Australia and New Zealand, indigenous peoples have higher than average exposure to climate change due to a heavy reliance on climate-sensitive primary industries and strong income and social connections to the natural environment, and face particular constraints to adaptation (*medium confidence*). Social status and representation, health, infrastructure and economic issues, and engagement with natural resource industries constrain adaptation and are only partly offset by intrinsic adaptive capacity (*high confidence*). Some proposed responses to climate change may provide economic opportunities, particularly in New Zealand related to forestry. Torres Strait communities are vulnerable even to small sea level rises (*high confidence*). [25.3, 25.8.2]
- For North America, indigenous peoples are vulnerable, due to their unique history and relationship to the land (*high confidence*). [26.8]
- Climate impacts on Arctic indigenous groups have been detected and attributed to climate change. These include changes in seasonal migration and hunting patterns, health, and cultural identity (*medium confidence*). [18.4.7, Box 18-5, 18.5.7, Table 18-9]

Livelihoods and poverty

Climate change constitutes an additional burden to the rural and urban poor. It acts as a threat multiplier, often with negative outcomes for livelihoods (*very high confidence,* based on *high agreement, robust evidence*). Weather events and climate, ranging from subtle shifts in trends to extreme events, affect poor people's lives directly through impacts on livelihood assets, such as losses in crop yields, destroyed homes, food insecurity, and loss of sense of place, and indirectly through increased food prices and climate policies. Changing climate trends provoke shifts in rural livelihoods such as from crop-based to mixed livestock- and forest-based livelihoods or to wage-based labor in agricultural and urban employment. Urban and rural transient poor who face multiple deprivations slide into chronic poverty as a result of weather events or extreme events, or a series of events, when they are unable to rebuild their eroded assets (*high agreement, limited evidence*). Many weather events that affect poor people remain unrecognized, such as short periods of extreme temperature or minor changes in the distribution of rainfall, due to short time series and geographically sparse, aggregated, or partial data, inhibiting detection and attribution in many low-income countries. [13.2.1, 13.3]

Climate change worsens existing poverty, exacerbates inequalities, and triggers new vulnerabilities and some opportunities. Poor people are poor for different reasons and thus are not all equally affected, and not all vulnerable people are poor. Climate change interacts with non-climatic stressors and entrenched structural inequalities to shape vulnerabilities (*very high confidence,* based on *high agreement, robust evidence*). Socially

and geographically marginalized people exposed to persistent inequalities at the intersection of gender, age, race, class, caste, indigeneity, and (dis)ability are particularly negatively affected by weather events and climate (see Box TS.4). Context-specific conditions of marginalization shape differential vulnerability. Preexisting gender inequalities are increased or highlighted by weather events and climate. Gendered impacts depend on customary and new roles in society, often entailing higher workloads, occupational hazards indoors and outdoors, psychological and emotional distress, and mortality in climate-induced disasters. Very scarce evidence exists that demonstrates positive impacts of climate change on the poor, including flood preparedness, collective action, institutional change, and social asset accumulation. Often, the more affluent can better take advantage of shocks and crises, given their flexible assets and power status. [13.1.2, 13.1.3, 13.2.1]

Despite known vulnerabilities and increasing exposure to climatic stressors, impacts of climate change on human livelihoods have rarely been detected with confidence. Such detection is complicated by the effects of other economic and social factors. There is emerging literature on the impact of climate on poverty, working conditions, violent conflict, migration, and economic growth, but evidence for detection or attribution remains *limited*. [18.4.3, 18.4.6, 18.4.7]

Information needs and methods

Significant improvements have been made in the amount and quality of climate data available for establishing baseline reference states of climate-sensitive systems. These include new and improved observational datasets, rescue and digitization of historical datasets, and a range of improved global reconstructions of weather sequences. The uncertainties inherent in climate model projections of regional climate changes have not decreased from AR4; in some cases, the addition of regional forcings (e.g., topography) have increased some uncertainties. [21.3.3, 21.5.3]

Specific regional examples include:

- **In Asia, there are regions that are not sufficiently represented in studies of observed climate change, in particular Central and West Asia.** Numerical data on trends in precipitation are hard to find compared to trends in temperature. Furthermore, research data on changes in extreme climate events do not cover most Asian regions. Studies of both observed and projected impacts on biodiversity, boreal forest dynamics, CO_2 fertilization of crops and plants, and urban settlements are limited. More trans-disciplinary research is needed on direct and indirect health effects from climate change impacts on air and water quality and water quantity in different parts of Asia. The vulnerability, impacts, and adaptation of aggregated household welfare, livelihoods, and poverty need to be adequately studied. [24.8]

A.ii. Adaptation Experience

Human and natural systems respond to climate and its effects. Natural systems have some potential to adapt, and are adapting, through ecological and evolutionary processes, and humans may intervene to promote particular adjustments. Responses in human systems include coping with climate variability and extremes and managing risks through planned adaptation to climate change impacts. Adaptation can be motivated by broader vulnerability-reduction and development objectives, such as reducing existing adaptation deficits to current climate. [14.1]

Adaptation activity is increasing and becoming more integrated within wider policy frameworks (*high confidence*). Adaptation planning is transitioning from a phase of awareness and promotion to the construction of concrete responses in societies (*high agreement, robust evidence*). National-level plans and adaptation strategies for developed countries are mentioned in the literature more than for developing countries, whereas more implementation cases are documented at the local level in developing countries. [14.3.4, 14.4.2, 15.2, 15.3.1]

The social dimensions of adaptation have attracted more attention, including the relationship between adaptation, development, and disaster risk management (*high agreement, robust evidence*). Attention to climate change impacts and disaster risk management, which are key elements of adaptation planning, appears to have a more prominent role in developed countries. Risk reduction, especially for developed countries, has been planned by a top-down approach including engineered infrastructure-based solutions such as dikes to prevent flooding and

coastal inundation and dams to improve water supplies. In contrast, there is a trend to link adaptation planning to development needs and stresses in developing countries. Strategies adopted in developing countries, e.g., those in NAPAs, are almost identical with standard development projects. [15.2, 15.3.1]

Adaptation assessments continue to evolve, and most include both top-down assessments of biophysical climate change risks and bottom-up assessments of what makes people vulnerable to those risks (*high confidence*). Most of the assessments of adaptation done so far have been restricted to impacts, vulnerability, and adaptation planning, with very few assessing the processes of implementation and evaluation of actual adaptation actions. The numerous assessments have led to a general awareness among decisionmakers and stakeholders of climate risks and adaptation needs and options, but this is often not translated into the implementation of even simple adaptation measures within ongoing activities or risk management planning. To overcome this "adaptation bottleneck," assessments may need to be linked more directly to particular decisions and the information tailored to facilitate the decision making process. [14.5.3, 14.5.4]

Evaluation of adaptation effectiveness is still in its infancy (*high confidence*). The demand for metrics to measure adaptation needs and effectiveness is increasing as more resources are directed to adaptation. But the search for metrics for adaptation will remain contentious with multiple alternatives competing for attention as governments, institutions, communities, and individuals value needs and outcomes differently and many of those values cannot be captured in a comparable way by metrics. These indicators need to track not just process and implementation, but also the extent to which targeted changes are occurring. [14.6.2, 14.6.3, 14.6.4]

A variety of tools are being employed in adaptation planning and implementation depending on social and management context (*high agreement, robust evidence*). Multidisciplinary efforts have been engaged to develop, assess, and communicate climate information and risk assessments across timescales. These efforts use a mixed portfolio of products from simple agroclimate calendars to computerized decision-support tools. Monitoring and early warning systems play an important role in helping to adjust adaptation implementation, especially on the local scale. [15.2.4]

The national level plays a key role in adaptation planning and implementation, while adaptation responses have diverse processes and outcomes at national, subnational, and local levels (*high agreement, robust evidence*). National governments assume a coordinating role of adaptation actions in subnational and local levels of government, including the provision of information and policy frameworks, creating legal frameworks, actions to protect vulnerable groups, and financial support to other levels of government. The number of adaptation responses has increased at the local level in developed and developing countries. However, there is a common trend that local governments are hindered by the absence of applicable guides to adaptation decision-making. Local councils and planners are often confronted by the complexity of adaptation, and even when information is available, they are left with a portfolio of options to prepare for future climatic changes and the potential unanticipated consequences of their decisions. Therefore, linkages with national and subnational levels of government, as well as the collaboration and participation of a broad range of stakeholders, are important. [15.2.2]

The diversity of adaptation experience, including corresponding constraints and opportunities, can be seen in specific geographic contexts:

- **The scale and concentration of urban climate risk and hence the imperative for adaptation are being acknowledged, but responses are weak except for a handful of cities largely in high-income countries (*medium confidence*, based on *high agreement, medium evidence*).** City governments are slowly learning from adaptation implementation experience. Most current adaptation action focuses on low-cost interventions such as infrastructure and asset-creation as a co-benefit of existing development interventions. Examples of adaptation actions have often included the designation of a unit within city government with responsibility for adaptation, measures to involve key sectors so they understand why they need to engage with adaptation, the importance of local champions to initiate measures and ensure continuity, and the importance of dialogue and discussion with all key stakeholders. [8.3, 8.4, 8.5]
- **There is also recognition of the need to review building codes, infrastructure standards, and land-use management thereby developing scalable approaches to local adaptation planning (*medium confidence*, based on *high agreement, medium evidence*).** The weak emphasis on human, institutional, and ecological adaptation with long-term resilience building potential is a matter of concern. [8.3, 8.4, 8.5]

- **City-based disaster risk reduction is a strong foundation around which to build urban climate resilience (*high confidence*, based on *high agreement, medium evidence*).** The capacity to integrate climate risk, disaster risk reduction, and urban infrastructure and planning is being slowly built in some parts of the world. Locally-relevant adaptation plans, data, and feedback mechanisms are important for building urban resilience (*high agreement, medium evidence*). Improved feedback, monitoring, and reporting capacity supported by new generation risk screening, vulnerability mapping, and integrated urban climate assessment tools are helping catalyze social-learning to help mainstreaming. [8.2, 8.3, 8.4]
- **There is a growing body of literature on successful adaptation in rural areas, including documentation of practical experience (*high confidence*).** Gender, the supply of information for decision-making, and the role of social capital in building resilience are all key issues. Constraints to adaptation come from lack of access to credit, land, water, technology, markets, and information, and constraints are particularly pronounced in developing countries. [9.4.1, 9.4.3, 9.4.4]
- **In all regions of Africa, national governments are initiating governance systems for adaptation and responding to climate change (*high agreement, medium evidence*).** While a wide range of adaptation options, approaches, and decision tools are being tested and implemented at different scales across Africa, these have not yet been taken to a scale that would address the complex vulnerabilities and needs identified. Institutional frameworks cannot yet effectively coordinate the range of adaptation initiatives being implemented, resulting in a largely ad hoc and project-level approach, which is often donor-driven and may not result in local or national ownership (*medium agreement, medium evidence*). Efforts such as disaster risk reduction, social protection, adaptation technologies, climate-resilient infrastructure, ecosystem restoration, and livelihood diversification are reducing vulnerability and enhancing resilience, but this is still largely confined to local scales and isolated initiatives (*high agreement, medium evidence*). Institutional capacities and governance mechanisms need to be strengthened with respect to the ability of national governments and scientific institutions in Africa to absorb and effectively manage funds allocated for adaptation (*medium confidence*). [22.4.4, 22.4.5, 22.6.2]
- **In Europe, adaptation policy has been developed at international (EU), national, and local government level, but so far evidence relates to studies of the prioritization of options, and there is limited systematic information on current implementation (or effectiveness).** Some adaptation planning has been integrated into coastal and water management, as well as disaster risk management. There is little evidence of adaptation planning in rural development or land-use planning. Conservation policies and selection of protected areas have not considered so far impact of climate changes. [23.6.4, 23.7, Box 23-2]
- **In Australasia, adaptation is already occurring and adaptation planning is becoming embedded in planning processes, albeit mostly at the conceptual rather than implementation level (*high agreement, robust evidence*).** Many solutions for reducing energy and water consumption in urban areas with co-benefits for climate change adaptation (e.g., greening cities and recycling water) are already being implemented. Planning for sea-level rise and, in Australia, for reduced water availability is becoming widely adopted, although implementation of specific policies remains piecemeal, subject to political changes, and open to legal challenges. Adaptive capacity is generally high in many human systems, but implementation faces major constraints especially for transformative responses at local and community levels (*high confidence*). Constraints on implementation arise from: uncertainty of projected impacts; limited financial and human resources to develop and implement effective policies and rules; limited integration of different levels of governance; lack of binding guidance on principles and priorities; different values and beliefs relating to the existence of climate change and to objects and places at risk; and attitudes towards risk. [25.4, 25.10.3, Boxes 25-1, 25-2, and 25-9]
- **In North America, while different tiers of government are assessing their climate vulnerabilities and designing adaptation actions and programs, there has been more leadership in adaptation planning at the local level (*high confidence*).** Many governmental responses are in the diagnosis and planning stage and have not yet moved into implementation. Important barriers exist to effective adaptation such as path dependency, lack of assets and options, lack of funding and staff, lack of horizontal and vertical coordination, asymmetries in access to information, lack of social capital, and top-down decision making. There are few examples of proactive adaptation anticipating future climate impacts, and these are largely found in sectors with longer-term decision-making, including energy and public infrastructure. [26.7, 26.8, 26.9]

- **In the Arctic, indigenous people have a high adaptive capacity and have begun to develop novel solutions to adapt to climate changes combining traditional and scientific knowledge and co-producing climate studies with scientific partners.** [28.2.4, 28.2.7, 28.4.1]
- **Since AR4, the analysis and implementation of coastal adaptation has progressed significantly, but much more effort is needed for a transition towards climate resilient and sustainable coasts (*very high confidence*).** The analysis of adaptation has progressed towards novel approaches such as robust decision making and adaptation pathways that recognize that deep uncertainty in projections of drivers does not have to be a barrier to adaptation (*high confidence*). Adaptation analysis and implementation have also progressed towards considering the institutional context and governance of adaptation, albeit many governance challenges related to vertical and horizontal policy integration, political will, and power relations remain (*very high confidence*). Many countries, states/provinces, cities, and communities are now carrying out adaptation activities including the mainstreaming of coastal adaptation into relevant strategies and management plans. [5.5.2, 5.5.4]

Adaptation actions and approaches to reducing vulnerability and enhancing resilience can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management (see Table TS.3).

[INSERT TABLE TS.3 HERE
Table TS.3: Illustrative examples of adaptation experience, as well as approaches to reduce vulnerability and enhance resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerabilities, inequalities, and climate change come to the fore. At the same time, place-based examples illustrate how larger-level drivers and stressors shape differential risks and livelihood trajectories, often mediated by institutions.]

B) DECISIONMAKING IN A COMPLEX WORLD: UNDERSTANDING APPROACHES TO MANAGING RISKS THROUGH ADAPTATION

Managing the risks of climate change involves decisions with implications for future society, economies, environment, and climate. Some risks will emerge in the next few decades before substantial mitigation benefits can emerge, an era of climate responsibility. Other risks will emerge over a longer-term era of climate options; these risks vary across alternative climate change and development futures and depend on mitigation choices. The state of the future world cannot be known or projected with certainty (see Box TS.5), but robust decisions can be effective across a range of possible futures, especially if they build on existing knowledge. Fundamentally, responding to climate change can be considered an iterative process with continuing learning about risks and the effectiveness of risk management actions. Societies may need to transform in response to limits, for example by shifting goals or paradigms.

B.i. Determinants of risk

All decisions involving uncertainty and valued outcomes are risk assessments. Risk in the context of climate change is produced through the interaction of changing physical characteristics of the climate system with evolving characteristics of human, socioeconomic, and biological systems (exposure and vulnerability). See Figure TS.2. Alternative development paths influence risk both by changing the likelihood of physical impacts (through their effects on greenhouse gas emissions) and by altering vulnerability and exposure. [2.1.1, 19.1, 19.2, 19.2.4, Fig.19-1]

[INSERT FIGURE TS.2 HERE
Figure TS.2: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. Risks are a product of a complex interaction between physical hazards associated with climate change and climate variability on the one hand, and the vulnerability of a society or a social-ecological system and its exposure to climate-related hazards on the other. The definition and use of "key" and "emergent" are indicated in Section C.ii. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions. Changes in both the climate system (left side) and development processes (right side) are key drivers of the different core components (vulnerability, exposure, and physical hazards) that constitute risk. [19.1, Figure 19-1]]

B.ii. Principles for Effective Adaptation

Experience in the practice of adaptation serves to clarify the opportunities for, and the most significant barriers to, adaptation and the synergies and tradeoffs with other societal goals.

Among the many actors and roles associated with adaptation, those associated with local governance and with the private sector are increasingly recognized as critical to progress (*high confidence*). These two groups will bear the main responsibility for translating the top-down flow of risk information and financing, and for scaling up the efforts of communities and households in identifying and implementing their selected adaptation actions. Local institutions, including local governments, NGOs, and civil society organizations, are often limited by lack of resources and capacity. Private entities, from individual farmers and small to medium enterprises (SMEs) to large corporations, will seek to protect their production systems, supply lines, and markets, by pursuing adaptation-related opportunities. These goals will help expand adaptation activities, but they may not align with government or community priorities without coordination and incentives. [14.4.2, 14.4.3, 14.4.8]

In the presence of limited resources and a range of goals, adaptation implies trade-offs between alternative policy goals (*high confidence*). Economics provides important inputs to the evaluation and ranking of adaptation options in the face of uncertainty. Approximate approaches are often necessary because of the lack of data or because of uncertainties about the nature of climate change or the efficacy of adaptation actions. A range of economic tools helps to address these uncertainties and helps design policies that are acceptable with a range of preferences and robust to existing uncertainties. There are methodologies that are able to capture non-monetary

effects and distributional impacts, and to reflect ethical considerations. The resulting ranking depends on the "value system," i.e. on the weights attributed to different objectives. [17.2.6, 17.3, 17.5.4]

A range of factors constrains the planning and implementation of adaptation actions and potentially reduces their effectiveness (*high agreement, robust evidence*). The availability of resources for adaptation continues to feature strongly in the adaptation literature as a significant constraint on adaptation, as does uncertainty regarding future climate and disaster risk at national and regional scales. However, there is increasing awareness within the literature of the dynamics of social processes and governance that mediate the entitlements of actors to resources and promote social learning regarding adaptation. The manner in which these constraints manifest and their implications for the capacity of an actor to achieve adaptation objectives vary significantly across different regions and sectors as well as across different social and temporal scales. Some constraints to adaptation are a consequence of inherent trade-offs among different perceptions of risk and the allocation of finite resources, and therefore, adaptation efficiency and effectiveness may often be less than optimal. See Figure TS.3. Climate change policy at regional scales is constrained by the dual challenge in achieving integration at multiple administrative scales from global through national to local (multi-level governance), and across different sectors (policy coherence). The scales at which political decisions about climate change need to be made are frequently at odds with the definitions of regions. Climate change transcends political boundaries and is highly variable from region to region in terms of impacts and vulnerability. Likewise adaptation policies, options, and mitigation strategies are strongly region dependent and tied to local and regional development issues. [16.2, 16.3, 21.3]

[INSERT FIGURE TS.3 HERE
Figure TS.3: Key adaptation constraints assessed, categorized into two groups. One group reflects constantly evolving biophysical and socio-economic processes that influence the societal context for adaptation. These processes subsequently influence the second group of constraints affecting the implementation of specific adaptation policies and measures that could be deployed to achieve a particular objective. [Figure 16-2]]

Maladaptation is a cause of increasing concern to adaptation planners, where intervention in one location or sector could increase the vulnerability of another location or sector, or increase the vulnerability of the target group to future climate change (*medium confidence*). Such maladaptation can result from decisions where greater emphasis is placed on short-term outcomes ahead of longer-term threats, or from decisions that discount, or fail to consider, the full range of interactions arising from planned actions. [14.7.1, 14.7.2]

Cities are complex inter-dependent systems with potential synergies that could be leveraged to support adaptation (*high agreement, limited evidence*). Urban enterprises developed within globalized systems of production depend on reliable supply chains that may face particular difficulties. There are potential urban agglomeration economies around cost-effective adaptation and resilience building via improved built and ecological infrastructure and services and bringing together people, communities, and institutions to respond collectively (*medium confidence*, based on *medium agreement, limited evidence*). Thus, raising urban adaptive capacity requires effective multi-level governance with institutions that facilitate coordination across multiple, nested, and poly-centric authorities and have the capacity to mainstream adaptation measures. This is yet to be built in most parts of the world. [8.3, 8.4, 8.5]

Building human and institutional capacity for urban climate resilience will accelerate implementation and improve outcomes (*high confidence*). A binding constraint to effective and timely urban adaptation and building resilience is effective institutions and leadership across government, communities, civil society, knowledge institutions, and the media. There is evidence of expanding urban adaptation leadership, but building a wide support base for adaptation across many sectors, in and outside of government, to de-risk the impact of slow institutional development and leadership change is an important priority. This can be addressed by a number of structural interventions to enable city-wide alliances and frameworks to be built, institutionalization of processes, building a culture of exchange between learning organizations, and a strong emphasis on capacity building. Networking and sharing experiences among adaptation practitioners and between cities is also an important vehicle to improve city-level outcomes. [8.4, 8.5]

B.iii. Approaches for Managing Risks and Building Resilience in a Complex and Changing World

The report assesses a wide variety of approaches for managing risks and building resilience. Mitigation is assessed in WGIII AR5. Strategies and approaches to climate change adaptation include efforts to decrease vulnerability or exposure and/or increase resilience or adaptive capacity. Types of responses are given in Table TS.4.

[INSERT TABLE TS.4 HERE
Table TS.4: Entry points, strategies, measures, and options for managing the risks of climate change. These approaches should be considered overlapping rather than discrete, and they are often pursued simultaneously. Examples given can be relevant to more than one category.]

Low-regrets actions to increase resilience

Strategies and actions can be pursued now that increase climate resilience while at the same time helping to improve human livelihoods, social and economic well-being, and responsible environmental management (*high confidence*). Adaptation actions can provide significant co-benefits such as alleviating poverty and enhancing development especially in developing countries. Climate change adaptation efforts can improve ecosystem resilience by implementing sustainable forestry quotas, expanding floodplain setbacks, implementing coastal afforestation and coral reef propagation, restoring degraded lands, maintaining healthy vegetation on slopes, incentivizing development away from coastal areas and bluffs, and removing barriers to the migration of plants and animals. [15.3.1, 17.2.7, 17.4.4, 20.6.2, 29.6.1, 29.6.2, Figure 29-5]

A low-regrets co-benefits approach of improving resilience through an emphasis on disaster risk reduction has become increasingly common (*high agreement, medium evidence*). Climate change adaptation and disaster risk reduction share similar objectives and challenges, although disaster risk management strategies by themselves often fail to account for a wide spectrum of threats and scales needed for climate change adaptation. There are many synergies between adaptation, development, and disaster risk reduction, and steps are being taken to achieve better integration (*high confidence*). [14.3.4, 14.4.2, 15.2.1, 15.2.3]

Building climate resilience in cities can be well-served by ecosystem-based adaptation with water and food systems as foci (*medium confidence*). Ecosystem-based adaptation is regarded as one of the more cost effective and sustainable approaches to urban adaptation, although the costs of needed land acquisition can be high. This is even though climate change will impact ecosystem services by altering ecosystem functions such as temperature and precipitation regimes, evaporation, humidity, and soil moisture levels. Ecosystem-based adaptation is closely linked to sustainable water management that ensures sufficient supplies, increases capacities to manage reduced freshwater availability, enables flood risk reduction and mitigation, manages waste water flows, and ensures water quality. [8.3, 8.5]

Integration and mainstreaming

Integration streamlines the planning and decisionmaking process and embeds climate sensitive thinking in existing and new institutions and organizations (*high confidence*). Integration helps avoid mismatches with development planning, facilitates the blending of multiple funding streams, and reduces the possibility of maladaptive actions. Development and adaptation can be complementary or competitive and development can yield adaptation co-benefits, provided it takes into account climate change in its design. Many aspects of economic development also facilitate adaptation to a changing climate, such as better education and health, and there are adaptation strategies that can yield welfare benefits even in the event of a constant climate, such as more efficient use of water and more robust crop varieties. Maximizing these synergies requires a close integration of adaptation actions with existing policies, referred to as mainstreaming. Mainstreaming adaptation into planning and decision-making, including official development assistance, is an opportunity for enhancing the effectiveness and efficiency of adaptation investments. [14.3.4, 14.4.2, 16.6, 17.2.7, 17.4.4]

Iterative approaches and learning

Due to the uncertainty, dynamic complexity, and short-to-long timeframes associated with climate change, robust adaptation efforts require iterative risk management strategies (*high agreement, medium evidence*). See Figure TS.4. Iterative risk management involves an ongoing process of assessment, action, reassessment, and response that may need to be applied under climate change, for decades, if not longer. [2.1.2, 2.2.1, 2.3.1, 15.2.3]

Adaptation planning and implementation is considered as a social learning process to formulate efficient plans, which allows periodical adjustments in order to reduce the uncertainty of the impacts of climate change and societal needs to cope with them (*high agreement, medium evidence*). Social learning is a relevant but under-investigated feature of planning and a critical part in the innovations for adaptation. Understanding of why and how learning takes place is needed to improve the impact and efficiency of plans, improve the transferability of best practices, increase public support, and translate learning into new plans. Monitoring and evaluation are two important learning tools in promoting this process. Although the importance of evaluation in adaptation is recognized, this topic is under-researched and requires significant work. [15.3.3]

[INSERT FIGURE TS.4 HERE
Figure TS.4: Schematic illustration of adaptation as an iterative risk management process. Each individual adaptation decision comprises well known aspects of risk assessment and management (top left panel). Each such decision occurs within and exerts its own sphere of influence, determined by the lead and consequence time of the decision, and the broader regulatory and societal influences on the decision (top right panel). A sequence of adaptation decisions creates an adaptation pathway (bottom panel). There is no single correct adaptation pathway, although some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but the judgment of outcomes depends strongly on societal values, expectations, and goals. [Figure 25-6]]

Working across scales

Opportunities exist for actors at all geographical and institutional levels and in different development contexts to facilitate, initiate, and implement effective adaptation action (*medium agreement, medium evidence*). Adaptation action at all levels—from households, firms, or municipalities to national government agencies and regional economic integration organizations—is influenced by resources made available by third parties, including the sharing of knowledge and information, the transfer of technologies, and the provision of financial resources. In addition, national and international public policy can encourage the preparation and implementation of national adaptation strategies. [16.6]

Adaptation governance plays a key role in promoting the transition from planning to implementation of adaptation (*high agreement, medium evidence*). The role of governance is highlighted in building adaptive capacity to climate change, in providing the connections among individuals, communities, organizations, agencies, and institutions at multiple levels, and in articulating top-down or bottom-up perspectives. Bottom-up approaches are particularly useful in efforts seeking to reduce social vulnerability and addressing adaptation to climate change as a process. However, adaptation to climate change also requires complementary top-down strategies through different levels of governments to realize mainstreaming adaptation. Adaptation planning also highlights the importance of intergovernmental and multidisciplinary approaches integrating science and planning. Because adaptation is a multidimensional issue involving many state and non-state actors functioning on varying scales of global, national, and local levels, a coordination of roles and responsibilities enhances institutional networking for effective implementation. Multilevel governance offers the chance to identify options for switching from reactive to proactive adaptation processes that are essential in safeguarding investments and infrastructures especially in urban adaptation. See Figure TS.5. [15.2.3, 15.4]

[INSERT FIGURE TS.5 HERE
Figure TS.5: Four main phases of adaptation planning and implementation: needs, planning, implementation, and evaluation. This is a cyclic, iterative process. Building capacity to respond to change, whether expected or unexpected, creates resilience in societies to cope in the face of uncertainties in climate change projections. Efforts in adaptation can be linked with development or disaster risk management. Adaptation governance underlies

capacity, and governance takes place at multiple scales: international, national, sub-national, and local. [Figure 15-1]]

Knowledge transfer

Information and knowledge on climate change risks from various stakeholders and organizations are essential resources for adaptation planning (*high agreement, robust evidence*). Although a wide range of adaptations are possible with current technologies and management practices, development and diffusion of technologies can expand the range of adaptation possibilities by expanding opportunities or reducing costs. [15.2.4]

Decision support situated at the intersection of data provision, expert knowledge and human decision-making across scales is most effective when it is context-sensitive, taking account of the diversity of different types of decisions, decision processes, and constituencies. [2.2, 2.3]

Traditional and indigenous forms of knowledge are a major resource for adapting to climate change except when the changes exceed the knowledge repertoire (*high agreement, robust evidence*). Culture and local and traditional forms of knowledge are highly dynamic and context dependent, reflecting and reasserting values and shaping both adaptive and maladaptive responses. Local and traditional knowledge is often neglected in policy and research, and mutual recognition and integration of local and traditional knowledge with scientific knowledge will increase the effectiveness of adaptation responses. [12.3]

Risk sharing mechanisms and economic instruments

Economic instruments have high potential in fostering adaptation as they directly and indirectly provide incentives for anticipating and reducing impacts (*high confidence*). Instruments comprise risk sharing and transfer mechanisms (insurance), loans including public private finance partnerships, payment for environmental services, improved resource pricing (water markets), charges and subsidies including land taxes, direct investment, norms and regulations, behavioral approaches, and institutional innovations. Innovative fiscal instruments, measures to attract "climate-proof" public and private investment and micro-insurance coverage of poorer households, risk transfer mechanisms, and innovative market-based insurance coverage will be necessary to address the large climate adaptation finance needs. Markets provide an additional mechanism for adaptation (*high agreement, medium evidence*). [8.4, 10.7.4, 10.7.5, 10.7.6, 10.9, 17.4, 17.5]

Risk financing mechanisms at local, national, regional, and global scales contribute to increasing resilience to climate extremes (*medium confidence*). Applicable mechanisms comprise informal and traditional risk sharing, such as relying on kinship networks, as well as market-based instruments including microinsurance, insurance, reinsurance, and national, regional, and global risk pools. Large-scale public-private risk prevention initiatives and government insurance of the non-diversifiable portion of risk offer example mechanisms for adaptation. Commercial reinsurance and risk-linked securitization markets also have a role in ensuring financially resilient insurance systems. With considerable disaster insurance market failure, public-private partnerships are the norm rather than the exception with the public sector acting as regulator, provider, or insurer of last resort (*high confidence*). Price signals associated with risk financing can provide incentives for reducing risk, yet the evidence of effectiveness is *limited* and the presence of many counteracting factors actually often leads to disincentives, also known as moral hazard. [10.7, 17.3.4, 17.3.6, 17.4, 17.5.1]

Transformation, including transformational adaptation

Adaptation options have focused mostly on cautious, incremental changes, but there is increasing recognition that transformative changes may be necessary as a response to projected climate changes (*medium confidence*). While no-regret, low-regret, and win-win strategies have attracted most attention in the past, there is increasing recognition that an adequate adaptive response will mean acting in the face of continuing uncertainty about the extent of climate change and the nature of its impacts and, thus, of adaptation needs. A focus on flexibility and adaptive management is becoming more common in selecting adaptation options. However, many see the need

for more transformative changes in perception and paradigms about the nature of climate change, adaptation, and their relationship to other natural and human systems. [14.1, 14.3.4]

Transformation in wider political, economic, and social systems can either open up or close policy spaces for more resilient and sustainable forms of climate responses, particularly where contemporary development pathways are identified and addressed as part of the root causes of vulnerability. While transformations may be reactive, forced, or induced by random, stochastic factors, they may also be deliberately created. Deliberate transformations can take place across interacting spheres, the practical, political, and personal spheres of transformation (See Figure TS.6). Whether in relation to transformational adaptation, transformation to low-carbon societies, or transformations to global sustainability, attention to all three spheres is relevant in responding to the observed and anticipated impacts of climate change. Climate-resilient pathways may involve conflicting goals and visions for the future, and not every transformation is considered equally ethical, equitable, or sustainable. [20.5.2]

[INSERT FIGURE TS.6 HERE
Figure TS.6: The practical, political, and personal spheres of transformation. [20.5.2, Figure 20-2]]

B.iv. Understanding of Limits to Adaptation

Limits to adaptation emerge as a result of the interaction between climate change and other biophysical and socioeconomic constraints (*high agreement, robust evidence*). While biophysical thresholds represent an important determinant of limits to adaptation, particularly for natural systems, socioeconomic conditions and trends also contribute to the definition of limits in social systems. In particular, demographic change as well as economic development will influence future human vulnerability and adaptive capacity, but the externalities of these processes may reduce the resilience of natural systems to adapt to a changing climate. [16.2, 16.3, 16.4]

Evidence from both natural and human-managed systems demonstrates the existence of limits to adaptation to climatic and other related environmental and socio-economic risks (*high agreement, robust evidence*). Archeological and historical evidence is providing growing insights into periods of societal change, including catastrophic societal failures, in which climate change or variability may have been a contributory factor. Such evidence indicates that socioeconomic and cultural factors mediate societal responses to emergent risks such as changes in climate and influence the likelihood of limits to adaptation being reached and exceeded. [16.3, 16.5, 16.5.1, 16.5.2, 16.8, Box 16-3]

Social limits to adaptation are dynamic over space and time due to normative judgments and values of actors, technological change, and emergent properties of complex systems (*high agreement, limited evidence*). Limits to adaptation are expected to be exceeded locally before being exceeded regionally and at larger spatial scales. This should provide regional, national, and international actors with an early warning of possible future adaptation constraints and limits. Some adaptation limits may be removed over time either due to changing normative judgments and values of actors that lead to the abandonment of previously held objectives, or through technological advancement. However, some actors may find that transformational changes are required that necessitate trade-offs in some values in order to preserve others. [16.4.1, 16.4.2]

The greater the magnitude of climate change, the greater the likelihood that adaptation will encounter limits (*high agreement, limited evidence*). Mitigation and adaptation are complementary strategies. Greater adaptation efforts will be required to achieve the objectives of actors if mitigation efforts are not successful in avoiding high magnitudes of climate change. There are, however, limits to the extent to which adaptation could reduce the impacts not avoided by mitigation, and residual loss and damage may occur despite adaptive action. Knowledge about limits to adaptation could therefore inform the level and timing of mitigation and might justify early mitigation action. However, as the future capacity of actors in different sectoral and regional contexts to adapt to climate change remains uncertain, the implications of adaptation for mitigation demand will be contingent upon economic development pathways and investments made to enhance the adaptive capacity of vulnerable actors. [16.3.1, 16.5, 19.6, 19.7, 20.5.3]

Much of the literature identifying limits to adaptation for specific systems and/or management objectives is associated with biophysical systems, particularly ecosystems and/or individual species that are dependent

upon specific biophysical regimes (*high agreement, robust evidence*). Those species that already persist at the edge of their thermal and/or hydrological limits may be most vulnerable to a changing climate. Species do have capacity to adapt through phenotypic and genetic responses. The physiological and/or ecological thresholds imposed by climate effectively represent "hard" limits in that no adaptation options can be implemented to enable sustainability once thresholds are exceeded. As a broad range of human values and managed systems are dependent upon ecosystems goods and services, "hard" limits in ecological systems have the potential to constrain or limit adaptation in socioeconomic systems. [16.4.1]

The capacity to describe and predict limits to adaptation is significantly impaired by the complexity of socio-ecological systems (*high agreement, limited evidence*). While there is *high agreement* that limits to adaptation exist, detailed understanding of the level at which climate change impacts may impose an intolerable risk to social objectives (the definition of adaptation limits adopted here) is available only for a small number of ecosystems and crop species. Any assessment of limits to adaptation in human systems is preliminary because of uncertainty about the existence and level of adaptation limits, and whether these limits are hard or soft. Furthermore, social, economic, and cultural trends and conditions, including uncertainty regarding actors' objectives and values and how they evolve over time, further confound explicit definitions of limits. Thus, while climate change raises "reasons for concern" regarding the sustainability of various natural and human systems, there is little evidence to support climate thresholds, such as a 2°C increase in global mean temperature, as being robust definitions of limits to adaptation. [16.4.2]

Specific regional examples of limits to adaptation have been assessed:

- In Africa, growing understanding of the multiple inter-linked constraints on increasing adaptive capacity is beginning to indicate potential limits to adaptation (*high agreement, limited evidence*). Climate change combined with other external changes (environmental, social, political, technological) may overwhelm the ability of people to cope and adapt, especially if the root causes of poverty and vulnerability are not addressed. Risks of maladaptation are increased by development interventions that often fail to consider how different types of change interact and undermine the ability of people to cope with multiple stressors. Evidence is growing for the effectiveness of flexible and diverse development systems designed for reducing vulnerability, spreading risk, and building adaptive capacity, and for the benefits of new development trajectories that place climate resilience, ecosystem stability, equity, and justice at the center of development efforts. [22.4.6]
- For Europe, synthesis of evidence across sectors and subregions confirms that there are limits to adaptation from social, economic, and technological factors. Adaptation is further impeded because climate change affects multiple sectors. [23.5, 23.10]

_____ START BOX TS.5 HERE _____

Box TS.5: Characterizing the Future

While there are many possible scenarios for future climate change and societal development, current decisions narrow future options. New risks will emerge in the coming decades as a result of past emissions and current socioeconomic trends. Societal responses, particularly adaptations, will influence outcomes during this era of climate responsibility. In contrast, benefits of current mitigation efforts will emerge over a longer period. Future risks during this longer-term era of climate options are thus linked to current mitigation and development choices.

Trends in vulnerability, exposure, and climate, as well as weather and seasonal forecasting of climate variability, can inform decisions in the era of climate responsibility. Climate and impact model projections become increasingly relevant for climate-affected decisions playing out over the longer term, recognizing that uncertainties about future vulnerability and exposure also increase over time. [21.3.3, 21.5.1, 21.5.3]

Scenarios are a vital part of managing uncertainty. [2.2.1] Scenarios provide a mechanism for characterizing possible socioeconomic futures and climate change outcomes. Socioeconomic factors influence not only greenhouse gas emissions but also the size and location of populations at risk from various climate change impacts, the differential vulnerability of these populations, and their capacities to adapt.

Modeled future impacts assessed in this report draw on a combination of climate model simulations (CMIP3) using SRES scenarios and new climate model simulations (CMIP5, completed in 2011-12) using the new Representative Concentration Pathway (RCP) scenarios. The RCPs span the range of SRES scenarios for long-lived greenhouse gases, but they have a narrow range and fall at or below the lowest SRES in terms of emissions of ozone and aerosol precursors and related pollutants (*high confidence*). The IPCC has created and used emission scenarios to project future climate since the First Assessment Report, and most recently the SRES scenarios were used in the Third Assessment Report, AR4, and SREX. With AR5, the new RCP scenarios present both emissions and greenhouse gas concentration pathways, and corresponding socio-economic pathways have also been developed. The 4 RCPs assume different levels of mitigation, leading to 21st century radiative forcing levels of 2.6, 4.5, 6.0, and 8.5 W m^{-2} (see WGI AR5 Chapters 1, 6, 11, and 12). All RCPs project a rapid decline in short-lived pollutants and land-use change by 2050, almost independent of fossil-fuel use and population, while other published scenarios indicate a less rapid decline in aerosol precursors**.** A process (shared socioeconomic pathways, SSP's) has been initiated to identify shared assumptions and global scenarios for use in both mitigation and adaptation research. But although progress has been made, the vast majority of the impacts, adaptation, and vulnerability literature since AR4 continues to be based on the SRES. [1.1.3, 21.5.3]

Future climate depends on future climate forcing from emissions and concentrations, the climate system response to forcing, and the natural internal variability of the climate system (see Box TS.5 Figure 1). Climate models continue to produce a range of projected futures where for some variables and locations the sign of projected change may differ from one model to another. However, in many instances this indicates a lack of significant change compared to the natural variability for that region. The degree to which the model uncertainty can be reduced remains an open question. [21.5.3]

Box TS.5 Figure 1 illustrates alternative climate futures, under RCPs 4.5 and 8.5, along with observed temperature and precipitation changes. Future climate change interacts with vulnerability and exposure to determine future risks.

[INSERT BOX TS.5 FIGURE 1 HERE
Box TS.5 Figure 1: Changes in annual average temperature (A) and precipitation (B). For observations (top map, A and B; CRU), differences are shown over land between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For projections (bottom four maps, A and B; CMIP5), four classes of results are displayed. (1) White indicates areas where for >66% of models the annual average change is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Thus in these regions, more than 2/3 of models show no significant change in the annual average using this measure of significance, although this does not imply no significant change at seasonal or shorter time-scales such as months to days. (2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions, more than 2/3 of models show a significant change in annual average, but less than 2/3 agree on whether it will increase or decrease. (3) Colors with white circles indicate the change averaged over all models where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on whether the annual average will increase or decrease. In these regions, more than 2/3 of models show a significant change in annual average and more than 2/3 (but less than 90%) agree on whether it will increase or decrease. (4) Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether the annual average will increase or decrease. For models that have provided multiple realizations for the climate of the recent past and the future, results from each realization were first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios were calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065. See also Annex I of WGI AR5. [Box CC-RC]]

_____ END BOX TS.5 HERE _____

C) FUTURE RISKS AND CHOICES: RISKS AND POTENTIAL FOR ADAPTATION

Assessment of the full range of potential future impacts, not only the most likely outcomes, provides a basis for understanding future risks. In some cases, the probability of an impact occurring may be relatively low, but consideration is warranted because the potential consequences are significant. This section covers future risks across sectors and regions, and their sensitivity to the magnitude and rate of climate change, to the characteristics of development that affect vulnerability, and to policy choices. It emphasizes the importance of societal development in determining impacts at a given magnitude of climate change. It also recognizes that individuals vary in what they hold most dear, in how they value assets that are not typically monetized, and in how much they discount the future. The section examines the distribution of risks across populations with contrasting vulnerability and adaptive capacity, across sectors where metrics for quantifying impacts may be quite different, and across regions with widely varying traditions and resources. The assessment features interactions across sectors and regions and among climate change and other stressors. It elucidates how and when choices matter in reducing future risks and highlights the differing eras for mitigation and adaptation benefits.

C.i. Sectoral Risks with Regional Examples

For the era of climate responsibility (the next few decades) and the era of climate options (the longer term), risks will emerge across sectors and regions, dependent on the magnitude and rate of climate change and on the vulnerability of exposed social and natural systems.

Freshwater resources

Projected climate changes would change hydrological regimes substantially (*high agreement, robust evidence*). Runoff and groundwater recharge are projected to increase at high latitudes and in the wet tropics, and to decrease in most dry tropical regions, controlled mainly by changes in precipitation. Changes in runoff are typically one to three times greater than changes in precipitation. Except in very cold regions, warming brings forward the snowmelt season, altering the seasonal regime. Figure TS.7 depicts projected decreases in groundwater resources and associated vulnerability. [3.4.5, 3.4.6]

Hydrological impacts of climate change increase with increasing greenhouse-gas emissions (*high agreement, robust evidence*). A low-emissions pathway reduces damage costs and costs of adaptation. Impacts of climate change on water resources are expected to reduce economic growth, particularly in developing countries (*high agreement, limited evidence*). [Table 3-2, 3.4, 3.5, 3.6.5]

Glaciers will continue to lose mass, with meltwater yields from stored glacier ice eventually diminishing as the glaciers shrink (*high agreement, robust evidence*). The rate of loss per unit of glacierized area will accelerate. The accumulation season will become shorter and the melting season longer, and in almost all regions total accumulation will decrease. In many regions meltwater production will increase during the next several decades but decrease thereafter. Glaciers have long response times and would continue to lose mass even if the climate were to cease to change. [3.4.4]

[INSERT FIGURE TS.7 HERE
Figure TS.7: Human vulnerability to climate-change-induced decreases of renewable groundwater resources by the 2050s for lower (B2) and higher (A2) emissions pathways and two global climate models. The higher the vulnerability index (percent decrease of groundwater recharge multiplied by a sensitivity index), the higher the vulnerability. The index is computed for areas where groundwater recharge is projected to decrease by at least 10%, as compared to the reference period 1961-90. [Figure 3-9]]

Climate change is projected to reduce renewable water resources in most semi-arid and arid regions, potentially affecting food security (*high agreement, robust evidence*). Drying of soils is projected in most dry regions (*medium confidence*). Projected changes in droughts depend partly on the definition of drought. [3.4.9, 3.5, WGI AR5 12.4.5]

Projected climate changes imply large changes in the frequency of floods (*high agreement, robust evidence*). More frequent intense rainfall events [WGI AR5 12.4.5] would increase the frequency of flooding in small catchments, but the implications for larger catchments are more uncertain because of the limited extent of the intense events. In some areas, reduced snowfall will reduce spring flood peaks. More people will be exposed to floods, notably in Asia, Africa, and Central and South America, and economic losses will increase due to both increased exposure and anthropogenic climate change (*high confidence*, based on *high agreement, limited evidence*). Vulnerability can be reduced by adaptation. [3.4.9]

Water quality changes are linked to warming, changes in rainfall, and climate-related erosion and deforestation (*high agreement, limited evidence*). Projections under climate change scenarios show a risk of deteriorating water quality for municipal supply, even with conventional treatment. Possible positive impacts include reduced risks of eutrophication and algal blooms when nutrients are flushed from lakes and estuaries by more frequent storms and hurricanes (*high agreement, limited evidence*). [3.2.5, 3.5.2]

Climate change increases investment costs for water and wastewater treatment, while operating costs could rise or fall. Improved or even new water-treatment infrastructure may be needed to address variations in the quantity and quality of water (*high agreement, medium evidence*), but under warmer conditions water and wastewater treatment processes may perform better (*low* to *medium agreement, limited evidence*). [3.5.2, 3.6]

Adaptive water management techniques offer an opportunity to address uncertainty due to climate change (*high agreement, limited evidence*). Such techniques include scenario planning, employing experimental approaches that involve learning from experience, and developing flexible solutions that are resilient to uncertainty. However, there are barriers such as lack of technical capacity, financial resources, awareness, and communication. [3.6.2, 3.6.6]

Adaptation to climate change in the water sector provides many opportunities for low-regrets improvements (*high agreement, limited evidence*). Of the global cost of adaptation, 85% is required in developing countries (*medium agreement, medium evidence*), in amounts similar to those estimated for the Millennium Development Goals. Annual global adaptation costs to maintain baseline levels of water-supply and sanitation services will be 50 to 70% of baseline investment in the sector (*high agreement, limited evidence*). Some adaptive water-management measures also mitigate climate change (*medium agreement, limited evidence*). For example, wetland conservation increases carbon storage. [3.6.1, 3.6.5, 3.7.2]

Specific regional examples include:

- In Africa, the impact of climate change on water availability is uncertain (*high confidence*). Water resources are subject to high hydro-climatic variability over space and time, and are a key constraint on the continent's continued economic development. Water is the primary medium through which early and subsequent climate change impacts will be felt by people, ecosystems, and economies. Many of the fragile terrestrial and aquatic ecosystems in Africa are implicitly or explicitly water dependent. Impacts of climate change will be superimposed onto already water-stressed catchments with complex land uses, engineered water systems, and a strong historical socio-political and economic footprint. Strategies and plans of action to adapt to climate change through an integrated approach to land and water management benefit establishment of effective resilience to the projected impacts of climate change. [22.3.2, 22.3.3]
- In Europe, climate change will decrease surface water quality due to higher temperatures (*medium confidence*). [23.6.3]
- In Asia, water scarcity is expected to be a major challenge for most of the region due to increased water demand and lack of good management (*medium confidence*). Water resources are important in Asia given the massive population. However, there is *low confidence* in future precipitation projections at a regional scale and thus in freshwater availability in most parts of Asia. Shrinking of glaciers in Central Asia and the Himalayas is projected to affect water resources in downstream river catchments. Population growth and increasing demand arising from higher standards of living could worsen water security in many parts of Asia and affect many people in the future. Better water management strategies are needed to ease water scarcity. Water saving technologies and changing to drought tolerant crops have been found to be successful adaptation options in the region. [24.4.3, Box 3-1]
- In Australasia, freshwater resources are projected to decline in far south-west and far south-east mainland Australia (*high confidence*) and for rivers originating in the eastern and northern parts of New Zealand

(*medium confidence*). Systematic constraints on water resource use in southern Australia, driven by rising temperatures and reduced cool-season rainfall, have the potential to be severe but can be moderated or delayed significantly by globally effective mitigation combined with adaptation, with an increasing need for transformative adaptation for greater rates and magnitude of change (*high confidence*). Integrated responses encompassing management of supply, recycling, water conservation, and increased efficiency across all sectors are available but face implementation constraints. [25.2, 25.5.1, Box 25-2]

- Throughout North America, it is *very likely* that the 21st century will witness decreases in water quality, and increases in flooding and droughts under climate change, with these impacts exacerbated by other anthropogenic drivers. It will also witness decreases in water supplies for urban areas and irrigation in some areas of North America, with confounding effects of development, except in general for southern Mexico, the northwest and northeast coastal USA, and west and east Canada. [26.3, 26.8]
- In Central and South America, although there is high uncertainty in terms of climate change projections for regions with high vulnerability in terms of current water availability, this vulnerability is expected to increase in the future due to climate change impacts (*high confidence*). Already vulnerable regions in terms of water supply, like the semi-arid zones in Chile-Argentina, North Eastern Brazil, and Central America and the tropical Andes, are expected to increase even further their vulnerability due to climate change. Glacier retreat is expected to continue, and a reduction in water availability due to expected precipitation reduction and increased evapotranspiration demands is expected in the semi-arid regions of Central and South America. These scenarios would affect water supply for large cities, small communities, hydropower generation, and the agriculture sector. Current practices to reduce the mismatch between water supply and demand could be used to reduce future vulnerability. Constitutional and legal reforms towards more efficient and effective water resources management and coordination among relevant actors in many countries in the region (e.g., Honduras, Nicaragua, Ecuador, Peru, Uruguay, Bolivia, and Mexico) also represent an adaptation strategy to climate variability and change. [27.3.1, 27.6.1]

Terrestrial and inland water systems

There is *high confidence* for freshwater ecosystems and *medium confidence* for terrestrial ecosystems that direct human impacts such as land-use change, pollution, and water resource development will continue to dominate the threats to ecosystems, with climate change becoming an increasing additional stress through the century, especially for high-warming scenarios such as RCP 6.0 and 8.5. Model-based projections imply that direct land cover change will continue to dominate over climate-induced change for low to moderate warming scenarios at global scales (e.g., RCP2.6 to RCP6.0). However, in many areas not subject to intensive human disturbance, even lower levels of projected future climate changes will result in changes in large-scale ecosystem character depending on the nature of regional climate changes (*high confidence*). Such changes may not be fully apparent for several decades after reaching the critical regional climate state, due to long response times in ecological systems (*medium confidence*). For higher warming scenarios, some model projections imply climate-driven large-scale ecosystem changes that become comparable with direct human impacts at the global scale. [Box CC-RF, 4.3.3]

Significant feedbacks exist between terrestrial ecosystems and the climate (*medium confidence*). Thus local, regional, and global climate may be affected as ecosystems are altered, through climate change itself or other mechanisms, such as conversion to agriculture or human settlement. These climate feedbacks are driven by changes in surface albedo, evapotranspiration, and greenhouse gas emissions. The regions where the climate is affected may be different from the location of the ecosystem change. [4.3.3]

The capacity of many species to respond to climate change will continue to be constrained by non-climate factors (*high confidence*), including but not limited to the simultaneous presence of land-use changes, habitat fragmentation and loss, competition with alien species, exposure to novel pests and diseases, nitrogen loading, and increasing carbon dioxide and tropospheric ozone. [Figure 4-1, 4.2.4, 4.3.3]

A changing climate exacerbates other threats to biodiversity (*high confidence*). In some systems, such as high altitude and latitude freshwater and terrestrial ecosystems, climate changes exceeding those projected under RCP2.6 will lead to major changes in species distributions and ecosystem function. Since the specific changes in individual regions depend on the nature of the projected regional climate change, the confidence in specific future

ecosystem changes is limited by the confidence assigned to regional climate change projections by Working Group I. [4.3.2, 4.3.3, 4.4.1]

Terrestrial plant and animal species will continue to move their ranges, alter their abundance, and shift their seasonal activities in response to projected future climate change (*high confidence*). *High confidence* in past responses, coupled with projections from a diversity of models and studies, provides *high confidence* that such responses will be the norm with continued warming. These shifts in species ranges will cause large changes in local abundance under all climate change scenarios: abundance declining in areas where climate becomes unfavorable and potentially increasing in areas where climate becomes more favorable. Such changes in species abundance lead to changes in community composition and ecosystem function. [4.2.1, 4.2.2, 4.3.2, 4.3.3]

Climate change is increasing the likelihood of the establishment, growth, spread, and survival of some invasive alien species populations in some regions (*high confidence*). Invasive species are more likely than native species to have traits that favor their survival and reproduction under changing climates. Species movement into areas where they were not present historically will be driven both by climate change and by increased dispersal opportunities associated with human activities. [4.2.4]

Even for mid-range rates of climate change (i.e., RCP 4.5 and 6.0 scenarios) many species will be unable to move fast enough to track suitable climates (*medium confidence*). See Figure TS.8. Over the last several decades many, but not all, species have tracked changes in climate. Populations of species that cannot track future climate change by migrating will find themselves in unfavorable climates and are unable to expand into newly climatically suitable areas. Species in large flat areas are particularly vulnerable because they must migrate over longer distances to keep up with climate change than will species in mountainous regions. Species with low migration capacity will also be especially vulnerable: examples include most trees, many plants, and some small mammals. Combinations of low migration capacity and large flat areas are projected to pose the most serious problems for tracking climate; for example, even the maximum observed and modeled migration rates for mid- and late-successional tree species will be insufficient to track climate change in flat areas even at moderate rates of climate change (*medium confidence*). Barriers to migration such as mountain ranges, dams, habitat fragmentation, and occupation of habitat by competing species substantially reduce the ability of species to migrate to more suitable climates (*high confidence*). Outlier populations (e.g., collections in botanical gardens or parks), as well as intentional and accidental anthropogenic transport, will speed migration (*high confidence*). [4.3.2, 4.3.3]

[INSERT FIGURE TS.8 HERE
Figure TS.8: Rate of climate change (A), corresponding climate velocities (B), and rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention (C). The thin red arrows give an example of interpretation. Rates of climate change of 0.03 °C/yr correspond to ca. 1.1 km/yr global average climate velocity. When compared to rates of displacement, this would exceed rates for most plants, many primates, and some rodents. (A) Observed rates of climate change for global land areas are derived from CRUTEM4 climate data reanalysis; all other rates are calculated based on the average of the CMIP5 climate model ensembles for the historical period and for the future based on the four RCP emissions scenarios. The lower bound (17% of model projections are outside this bound) is given for the lowest emissions scenario and the upper bound for the highest emissions scenario. Data were smoothed using a 20-year sliding window, and rates are based on means of between 17 and 30 models using one member per model. Global average temperatures at the end of the 21st century are given for each RCP scenario. Colors in the background synthesize the ability of species to track climate through displacement. (B) Estimates of climate velocity were semi-quantitatively synthesized from seven studies using a diversity of analytical approaches and spatial resolutions. The three axes represent estimated climate velocities for mountainous areas (left), for global land area (center), and for regions that are flat or have high rates of climate change (right). (C) Rates of displacement for terrestrial plants, trees, mammals, birds, phytophagous insects, and freshwater mollusks. Each box represents ~95% of the estimates, and the bar is a qualitative estimate of the median. [Figure 4-6]]

Large magnitudes of climate change will negatively impact species with populations that are primarily restricted to protected areas, mountaintops, or mountain streams, even those that potentially migrate fast enough to track suitable climates (*high confidence*). Climate change is projected to either create unsuitable climates for species that remain in these areas, or force species out of protected areas and off mountaintops. These effects are foreseen to be modest for low magnitudes of climate change (e.g., RCP 2.6) and very high for the highest

magnitudes of projected climate change (e.g., RCP 8.5). Species have already started to migrate out of protected areas and towards mountaintops over the last several decades due to a warming climate. [4.3.2, 4.3.4]

Projected climate changes imply increased extinction risk for a substantial fraction of species during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, and invasive species (*very high confidence*). Uncertainties in regional climate projections, highly variable estimates from comparisons of paleontological extinctions in response to past climate changes, different methods of estimating present and future extinction risk, and the variable adaptive capacity of wild species all contribute to an extremely broad range of estimates of future extinction risk due to climate change. There is *low confidence* that global extinction risks due to climate change can be accurately quantified. There is, however, a strong consensus that current climate change pressures and their interactions with other global changes will increase extinction risk for many terrestrial and freshwater species. [4.3.2]

It is *virtually certain* that the carbon stored in land and freshwater ecosystems in the form of plant biomass and soil organic matter has increased over the past two decades in what is known as the terrestrial carbon sink. There is *low confidence* that the transfer of carbon dioxide from the atmosphere to the land will continue at a similar rate for the remainder of the century. The terrestrial carbon sink is offset to a large degree by carbon released to the atmosphere through forest conversion to farm and grazing land and through forest degradation (*high confidence*). The carbon stored thus far in terrestrial ecosystems is vulnerable to loss back to the atmosphere as a result of climate change (including indirect effects such as increased risk of fires and pest outbreaks) and land-use change (*medium confidence*). Terrestrial and freshwater ecosystems have been responsible for the uptake of about a quarter of all anthropogenic CO_2 emissions in the past half century. The net fluxes out of the atmosphere and into plant biomass and soils show large year-to-year variability. As a result there is *low confidence* in the ability to determine whether the net fluxes into or out of terrestrial ecosystems at the global scale have increased or decreased over the past two decades. The factors causing the current increase in land carbon include the positive effects of rising CO_2 on plant productivity, a warming climate, and recovery from past disturbances (*high confidence*), but there is *low confidence* in the relative contribution by each of these and other factors. Experiments and modeling studies provide *medium confidence* that increases in CO_2 up to about 600 ppm will continue to enhance photosynthesis and plant water-use efficiency, but at a diminishing rate. Other factors associated with global change, including high temperatures, rising ozone concentrations, and in some places drought, decrease plant productivity by comparable amounts (*medium confidence*). Models provide *high confidence* that nitrogen availability will limit the response of many natural ecosystems to rising CO_2. There are few field-scale experiments on ecosystems at the highest CO_2 concentrations projected by RCP 8.5 for late in the century, and none of these includes the effects of other potential confounding factors. [4.2.2, 4.2.4, 4.3.2, 4.3.3, Box 4-4]

Recent experimental, observational, and modeling studies provide *medium confidence* that forests may be more sensitive to future climate change than reported in the IPCC AR4, and that tree mortality and forest dieback could become a problem in many regions much sooner than previously anticipated. Future climate change impacts on tree mortality and tree ranges could be large (*high confidence*), but experimental, observational, and modeling studies also indicate that there is *low confidence* associated with model-based projections of the details of these impacts. As such, projections of increased tree growth and enhanced forest carbon sequestration mediated by increasing growing season length, rising CO_2 concentrations, and atmospheric nitrogen deposition are being viewed with increasingly greater caution due to the counter-balancing effects of mortality and dieback. The consequences for the provision of timber and other wood products are projected to be highly variable between regions and products depending on the balance of the positive vs. negative effects of global change. [4.3.3, 4.3.4]

Terrestrial and freshwater ecosystems can, when pushed by climate change, cross "tipping points" and abruptly change in composition, structure, and function (*high confidence*). The crossing of these tipping points will result in significant increases in carbon emissions to the atmosphere (*medium confidence*). This has happened many times in Earth history. There are plausible mechanisms, supported by experimental evidence and model results, for the existence of ecosystem tipping points in both boreal-arctic systems and the rainforests of the Amazon basin; others may exist. Continued climate change could push the boreal-arctic system across such a tipping point in this century, and cause an abrupt transformation of the ecology and albedo of this region, as well as the release of greenhouse gases from the thawing permafrost and burning forests (*low confidence*). Adaption measures will be unable to prevent substantial change in the boreal-arctic system (*high confidence*). Continued climate change together with land use change and fire activity could also cause much of the Amazon forest to transform abruptly to

more open, dry-adapted ecosystems, and in doing so, put a large stock of biodiversity at elevated risk and create a large new net greenhouse gas source to the atmosphere (*low confidence*). The combination of climate change and land-use change in the Amazon will cause accelerated drying and drought frequency in the region (*medium confidence*), and there is *low confidence* that these Amazon changes will affect rainfall in agricultural regions elsewhere on the planet. Rigorously applied adaptation measures could lower the risk of abrupt change in the Amazon, as well as the impacts of that change (*medium confidence*). Policy and market-driven interventions have caused a steep decline in deforestation in the Amazon since 2005 that has decreased anthropogenic carbon emissions to the atmosphere by 1.5% (*very high confidence*). [4.2.2, 4.2.4, 4.3.3, Box 4-3, Box 4-4, Figure 4-10]

Management actions can reduce, but not eliminate, exposure to climate-driven ecosystem impacts, and can increase ecosystem adaptability (*high confidence*). The capacity for natural adaptation by ecosystems and their constituent organisms is substantial, but for many ecosystems and species this is insufficient to cope without substantial loss of species and ecosystem services, given the rate and magnitude of climate change projected under medium-range warming (e.g., RCP 6.0) or high–range warming scenarios (e.g., RCP 8.5) (*medium confidence*). The capacity for ecosystems to adapt to climate change can be increased by reducing the other stresses operating on them; reducing the rate and magnitude of change; reducing habitat fragmentation and increasing connectivity; maintaining a large pool of genetic diversity and functional evolutionary processes; assisted translocation of slow moving organisms or those whose migration is impeded, along with the species on which they depend; and manipulation of disturbance regimes to keep them within the ranges necessary for species persistence and sustained ecosystem functioning. [4.4.1, 4.4.3]

Specific regional examples include:

- In Europe, climate change will cause changes in habitats and species, with local extinction (*high confidence*) and continental scale shifts (*low/medium confidence*). The habitat of alpine plants will be significantly reduced (*high confidence*). Phenological mismatch will constrain both terrestrial and marine ecosystem functioning under climate change (*high confidence*), with a reduction in some ecosystem services (*low confidence*). The introduction and expansion of invasive species, especially those with high migration rates, from outside Europe will increase with climate change (*medium confidence*). Biodiversity is affected in unprotected areas more than in protected areas, but Natura 2000 areas retain climate suitability for species no better and sometimes less effectively than unprotected areas (*low confidence*). All ecosystem services, particularly provisioning, regulating, and cultural services, will be degraded by climate change in at least one European sub-region. [23.6.4, 23.6.5, 23.10, Table 23.2]
- In Europe, climate change will increase damage to forests from pests and diseases in all sub-regions (*high confidence*), from wildfires in Southern Europe (*high confidence*), and from storms (*low confidence*). Climate change will cause ecological and socio-economic damages from shifts in forest tree species range, with a general trend of south-west to north-east (*medium confidence*), and in pest species distributions (*low confidence*). Short-term and long-term strategies in forest management may be an adequate measure to enhance ecosystem resistance and resilience (*medium confidence*). [23.4.4]
- In Asia, terrestrial systems are under increasing pressure from both climatic and non-climatic drivers. The projected changes in climate will impact vegetation and increase permafrost degradation during the 21st Century (*high confidence*). The largest changes are expected in cold northern and high-altitude areas, where boreal and subalpine trees will *likely* invade treeless arctic and alpine vegetation, and evergreen conifers will *likely* invade deciduous larch forest. Large changes may also occur in arid and semi-arid areas, but uncertainties in precipitation projections make these difficult to predict. Vegetation change in the more densely populated parts of Asia will be constrained by the impact of vegetation fragmentation on seed dispersal. The impacts of projected climate changes on the vegetation of the lowland tropics are currently poorly understood. Trends in phenological timing consistent with the impacts of regional warming are widespread in eastern Asia, particularly for plants. Permafrost degradation will spread during the 21st century from the southern and low-altitude margins, advancing northwards and upwards. Many models agree on the direction of change, but rates of change vary greatly between different projections. [24.2.2, 24.4.2, 24.4.3, 24.9.3]
- In Australia, loss of montane ecosystems and some endemic species, driven by rising temperatures, increased fire risk, and drying trends, can be delayed but now appears very difficult to avoid entirely, even with combined globally effective mitigation and planned adaptation (*high confidence*). Fragmentation of landscapes, limited dispersal, and evolutionary capacity limit adaptation options. Many endemic species will suffer from range contractions, and some may face local or even global extinction. [25.6.1]

- In Australasia, projected changes in climate and increasing atmospheric CO_2 have the potential to benefit forest growth in cooler regions except where soil nutrients or rainfall are limiting (*high confidence*). Spring pasture growth in cooler regions would also increase and be beneficial for animal production if it can be utilized. [25.7.1, 25.7.2]
- In North America, a global increase of 2°C would have widespread adverse impacts on many ecosystems, *likely* reducing biodiversity and ecosystem services (*high confidence*). [26.4]
- In Antarctica, warming in combination with increased water availability is expected to lead to increased productivity and biomass, and the development of community complexity in native terrestrial biota (*high confidence*). However, these responses are potentially confounded by multiple stressors, including human activities (research stations, tourism, etc.). Climate change will increase the vulnerability of terrestrial ecosystems to invasions by non-indigenous taxa, the majority expected to arrive through direct human assistance, which poses the greatest threat to terrestrial plant and animal communities in the future (*high confidence*). [28.3.3]

Coastal systems and low-lying areas

Coastal systems and low-lying areas will increasingly experience adverse impacts associated with submergence and extreme sea level flooding due to relative sea level rise (*high confidence*). Large spatial variations in the projected sea level rise, together with local factors such as subsidence, suggest that relative sea level rise can be considerably larger than projected global mean sea level rise and therefore is an important consideration in impact assessments (*very high confidence*). Changes in storms and associated storm surges may further contribute to changes in sea level extremes, but the small number of regional storm surge studies, limited spatial coverage, and different modeling approaches used means that there is *low confidence* in projections of storm surge. [5.3.1, 5.3.3]

Acidification and warming of coastal waters will continue with significant consequences for coastal ecosystems (***high confidence***). The increase in acidity will be higher in areas where eutrophication is an issue, with negative consequences for many calcifying organisms. The interaction of acidification and warming exacerbates coral bleaching and mortality (*very high confidence*). Some warm water corals and their reefs will continue to respond to warming with species replacement, bleaching from loss of associated algae, and a decreased coral cover resulting in habitat loss. Warming will cause a decline of vegetated coastal habitats across the temperate zone. Temperate seagrass and kelp ecosystems will decline with increased frequency of heat waves and sea temperature extremes as well as through the impact of invasive subtropical species (*high confidence*).The decline of seagrass and kelp habitats will affect food webs, biodiversity, and biogeochemical cycling in these ecosystems (*very high confidence*). The projected degradation of some marine ecosystems such as coral reefs and Mediterranean intertidal communities is *very likely* to pose substantial challenges for coastal societies where livelihoods and food security may depend on ecosystem health. In the absence of adaptation, beaches, sand dunes, and cliffs currently eroding will continue to do so under increasing sea levels (*high confidence*). Increased human-induced drivers have been the primary drivers of change in coastal aquifers, lagoons, estuaries, deltas, and wetlands (*very high confidence*). Climate-change-related drivers will exacerbate currently existing problems in these natural systems. [5.4.2, 6.2, 6.3.2, 6.3.5, 6.5.2, 30.4, 30.5.3, 30.5.6, Box CC-CR, Box CC-OA]

The population and assets exposed to coastal risk as well as human pressures on coastal ecosystems will increase significantly in the coming decades due to population growth, economic development, urbanization, and coastward migration of people (*high confidence*). Under medium population projections, the population exposed to the 1 in 100 year coastal flood is expected to increase from 271 million in 2010 to 345 million in 2050 due to socio-economic development only. This increase in coastal population is expected to further exacerbate human pressures on coastal systems resulting from excess nutrient input, reduced run-off, and sediment delivery. [5.3.4]

The costs of inaction are larger than the sum of adaptation and residual damage costs for the 21st century at the global scale (*high agreement*). Without adaptation, hundreds of millions of people will be affected by coastal flooding and be displaced due to land loss through submergence and erosion by 2100; the majority of those affected are from East, Southeast, and South Asia (*high confidence*). Even with global mean sea-level rise of 1.3m by 2100, protection is considered economically rational for most developed coastlines in most countries (*high agreement*).

Under medium socio-economic development assumptions, the expected direct global annual cost of coastal flooding (adaptation and residual damage costs) may reach 300 US$ billion per year in 2100 without adaptation and 90 US$ billion per year with adaptation under a 1.26 m sea-level rise scenario. [5.4.3, 5.5.3]

The impacts of climate change on coasts and the required level of adaptation vary strongly between regions and countries (*high confidence*). While developed countries are expected to be able to adapt to even high levels of sea-level rise, small island states and some low-lying developing countries are expected to face very high impacts and associated annual damage and adaptation costs of several percentage points of GDP (*high agreement*). Developing countries and small island states within the tropics relying on coastal tourism are impacted not only directly by future sea-level rise and associated extremes but also by the impacts of coral bleaching and ocean acidification and reductions in tourist flows from other-regions **(***very high confidence*). [5.4.3, 5.5.3]

Specific regional examples include:

- In Africa, the impacts of climate change, mainly through sea level rise, combined with other extreme events (such as high tide levels and high storm swells) have the potential to threaten coastal zones, particularly coastal towns (*high confidence*). The example of the Kwa Zulu Natal coast (South Africa), where Durban is located, which was affected by a combination of high water level and high storm swell in March 2007, is indicative of what could happen. There is growing evidence that the costs of these impacts will increase for economic sectors and people living in these zones (*medium confidence*). [22.3.2, 22.3.7]
- In Africa, ocean ecosystems, in particular coral reefs, will be affected by climate-change-induced ocean acidification. Ocean ecosystems are also affected by changes in upwelling, with ramifications for crucial economic activities, mainly fisheries (*medium confidence*). [22.3.2, 22.3.4]
- In Europe, the costs of adapting dwellings or upgrading coast defence will increase under all scenarios (*high confidence*). Climate change will entail the loss or movement of coastal wetlands. [23.3.2, 23.6.5, 23.7.6]
- In Asia, coastal and marine systems are under increasing pressure from both climatic and non-climatic drivers (*high confidence*). Mean sea level rise will *very likely* contribute to upward trends in extreme coastal high water levels, and in the Asian Arctic, rising sea levels will interact with projected changes in permafrost and the length of the ice-free season to cause increased rates of coastal erosion (*high agreement, medium evidence*). Coastal freshwater swamps and marshes will be vulnerable to saltwater intrusion with rising sea levels. Widespread damage to coral reefs correlated with episodes of high sea-surface temperature has been reported in recent decades, and such damage will increase during the 21st century as a result of both warming and ocean acidification (*high confidence*). [24.4.3]
- In Australia, significant change in community structure of coral reef systems, driven by increasing sea-surface temperatures and ocean acidification, can be delayed but now appears very difficult to avoid entirely, even with combined globally effective mitigation and planned adaptation (*high confidence*). The natural ability of reefs to adapt to projected changes is limited. [Box CC-CR, 25.6.2, 30.5]
- In Australia and New Zealand, rising sea levels and increasing heavy rainfall are projected to increase erosion and inundation, with consequent damages to many low-lying ecosystems, infrastructure, and housing (*high confidence*). Widespread damages to coastal infrastructure and low-lying ecosystems would present major challenges if sea level rise exceeds 1m. Managed retreat is a long-term adaptation strategy for human systems, but options for some natural ecosystems are limited due to the rapidity of change and lack of suitable space for inland migration. Risks from sea level rise are *very likely* continue to increase beyond 2100 even if temperatures are stabilized. [WGI AR5 13.ES, Box 25-1, Table 25-1, 25.4.2, 25.6.1-2]
- In Brazil, fisheries' co-management—a participatory process involving local fishermen communities, government, academia, and NGOs—favors a balance between conservation of marine fisheries, coral reefs, and mangroves, and the improvement of livelihoods, as well as the cultural survival of traditional populations. [27.3.3]
- In the Arctic, the primary conservation concern for polar bears over the foreseeable future is the recent and projected loss of annual ice over continental shelves and decreased ice duration and thickness (*high confidence*). [28.2.2]

Marine systems

Physical effects of climate change on marine ecosystems may act, under some circumstances, as an additional pressure that cannot be ameliorated by local conservation measures or a reduction in human activities like fishing (*high confidence*). Effects of climate change will thus complicate management regimes, e.g. presenting direct challenges to the objectives of spatial management once species undergo large-scale distributional shifts. This increases the vulnerabilities of marine ecosystems and fisheries. [6.4]

Ocean acidification resulting from the increased flux of atmospheric CO_2 into the ocean represents a fundamental challenge to marine organisms and ecosystems, although the extent of its influence varies with the taxa and process involved (*high confidence*). Evidence from controlled laboratory experiments and mesocosm studies indicate that ocean acidification significantly impacts a large range of organisms (e.g., corals, fish, pteropods, coccolithophores, and macroalgae), physiological (e.g., skeleton formation, gas exchange, reproduction, growth, and neural function), and ecosystem processes (e.g., productivity, reef building, and erosion), but there are fewer field studies that have shown (or not shown) direct ecosystem changes. Ocean acidification and its effects are characterized in Box TS.9. [30.3.1, 30.3.2, 30.4, Box CC-OA, 6.2, 6.3, 6.5, Box 5-1, Box 6-2]

Several environmental drivers act simultaneously on ocean biota, often leading to interactive effects and complex responses (*high confidence*). Ocean acidification and hypoxia narrow thermal ranges and enhance sensitivity to temperature extremes in organisms such as corals, coralline algae, molluscs, crustaceans, and fishes. Genetic adaptation may occur; the capacity to compensate for or keep up with the rate of ongoing thermal change is limited (*low confidence*). [6.2, 6.3.2, 6.3.5, 6.5.2, 30.4, 30.5.3, 30.5.6, Box CC-CR]

The oceans currently provide about half of global net primary production (NPP). Environmental controls on NPP include temperature, CO_2, nutrient supply, and irradiance, all of which are projected to be altered (WGI AR5). The direction, magnitude, and regional differences of a change of NPP in the open ocean as well as in coastal waters have *limited evidence* and *low agreement* for a global decrease projected by 2100. At high (polar) latitude an increase in NPP is also projected with *low confidence*. [6.3.1, 6.5.1]

Modeling projects that, through species gains and losses in response to warming, the diversity of marine animals and plants will increase at mid and high latitudes (*high confidence*) and fall at tropical latitudes (*low confidence*), leading to a large-scale redistribution of global catch potential for fishes and invertebrates (*medium confidence*). If a decrease in global ocean net primary production or a shift downwards in the size spectrum of primary producers occurs, the overall fisheries catch potential will decrease. Animal displacements are projected to lead to a 30–70% increase in the fisheries yield of high-latitude regions but a drop of 40–60% in the tropics by 2055 relative to 2005 under the SRES A1B scenario (*medium confidence* for the general trend of shifting fisheries yields, *low confidence* for the magnitude of change). See Figure TS.9. Climate change impacts on the abundance and distribution of harvested aquatic species, both freshwater and marine, and aquaculture production systems in different parts of the world, are expected to continue with negative impacts on nutrition and food security for especially vulnerable people in some regions but with benefits in other regions that become more favorable for aquatic food production (*high agreement, medium evidence*). [6.2.5, 6.3.2, 6.4, 6.5, 6.5.2, 7.2.1, 7.3.2, 7.4.2, 7.5.1]

[INSERT FIGURE TS.9 HERE
Figure TS.9: A) Multi-model mean changes of projected vertically-integrated net primary production (small and large phytoplankton). To indicate consistency in the sign of change, regions are stippled where all models (four in total) agree on the sign of change. Changes are annual means under the SRES A2 scenario (between RCP 6.0 and 8.5) for the period 2080 to 2099 relative to 1870 to 1889. B) A projection of maximum fisheries catch potential of 1000 species of exploited fishes and invertebrates from 2000 to 2050 under the SRES A1B scenario. C) Example of changes occurring within fisheries across the ocean. [Figures 6-14, 6-15, and 30-15]]

The observed and projected impacts on ocean ecosystems and processes reveal significant regional differences that will benefit from differing policy responses and adaptation approaches (*medium agreement, medium evidence*). Changing distribution and abundance of fish species as waters warm and acidify suggest the need for flexible and informed decision-making. For example, tuna, a key fisheries species, are highly sensitive to changes in sea temperature, and changes in their distribution and abundance will provoke new technological and policy

challenges. The cross-boundary migration of fish stocks (from the waters of one nation to another) will benefit from international cooperation and evidence-based decision making. [30.5.5, 30.6.3]

Building dynamic fisheries management and sustainable aquaculture represent opportunities for adaptation to changes in the distribution and productivity of fish stocks (*high agreement, medium evidence*). The application of ecosystem-based management that includes climate change to manage the development and maintenance of fish stocks represents a key tool for adapting to changes resulting from climate change. Reducing non-sustainable fishing (e.g., bottom trawling, "ghost" fishing) provides an avenue for adapting to climate impacts by reducing the impact of additional stressors. Changes to coastal fishing due to the loss of coastal ecosystems will require adaptation strategies such as marine protected areas, alternative livelihoods, and/or the movement of people and industry sectors. Key adaptations for fisheries are for policy and management to maintain ecosystems in a state that is resilient to change, to enable occupational flexibility, and to develop early warning systems for extreme events (*high agreement, medium evidence*). Industries such as nature-based tourism will require similar strategies for decision-making. [30.6.3, 6.5, 7.5.1]

Projected change to ocean ecosystems as a result of ocean warming and acidification will reduce access to food, and increase poverty and disease in many countries (*medium agreement, limited evidence*). Reduced access to food in some coastal regions as a result of declining fisheries will affect an increasing number of already vulnerable people and will result in associated health impacts. [30.6.3, 30.6.5, 6.4]

Climate change, by increasing temperatures and altering surface winds, has influenced ocean mixing, nutrient levels, and primary productivity. These changes are *very likely* to have positive consequences for some fisheries and negative ones for others through the de-oxygenation of deep water environments and associated spread of hypoxic zones (*medium agreement, medium evidence*). In regions where primary production has increased (or is predicted to increase), such as in the High Latitude Spring Bloom Systems, Eastern Boundary Upwelling Ecosystems, and Equatorial Upwelling, energy transfer to higher trophic levels is *likely* to increase along with microbial activity. Increased primary productivity is *likely* to lead to an increased transfer of organic carbon to deep sea habitats stimulating respiration and drawing down oxygen levels in some areas. These changes are further influenced by the contribution of nutrients from coastal pollution, leading to the expansion of hypoxic (low in oxygen) zones in areas such as the Gulf of Mexico, North Sea, Arabian Sea, and coastal areas of many countries. Increasing temperatures will also reduce the solubility of oxygen, adding to oxygen stress (*very high confidence*). [30.5.2, 30.5.4, 30.5.6, 6.2, 6.3, 6.5]

Changes to surface winds, sea level, wave height, and storm intensity will increase the risks associated with coastal and ocean based industries such as shipping, oil, gas, and mineral extraction (*medium agreement, medium evidence*). Storm impacts on coastal areas will increase with sea level rise through greater storm surge impacts. [WGI AR5 3.7.4] Strategies will require consideration of these changes in the design and use of ocean-based infrastructure together with the evolution of policy for reducing risks to equipment and people. New opportunities for shipping, oil, gas, and mineral extraction, as well as international issues over access and vulnerability, are expected to evolve as waters warm, particular in high latitude regions. [30.6, 6.5]

Ocean ecosystems and associated sub-regions offer a large potential for carbon dioxide mitigation strategies (*medium agreement, limited evidence*). Ecosystems such as mangroves, seagrass, and salt marsh represent potentially significant carbon sequestration strategies (e.g., "blue carbon"). Reducing highly anoxic habitats through coastal restoration (and hence the emission of methane) also represents significant mitigation opportunities, although an understanding of these opportunities is limited. Sequestration of anthropogenic CO_2 into deep ocean areas has been explored, although studies indicate significant hurdles with respect to expense and to the vulnerability of deep water marine ecosystems. [30.7]

Geoengineering approaches involving manipulation of the ocean to ameliorate climate change (e.g., purposeful nutrient fertilization, binding of CO_2 by enhanced alkalinity, and direct CO_2 injection into the deep ocean) have very large associated environmental footprints (*high confidence*), with some requiring purposeful alteration of ocean ecosystems for implementation. Alternative methods focusing on solar radiation management leave ocean acidification unabated. [6.4.2]

Specific regional examples include:

- In Europe, climate change will not decrease net fisheries economic turnover in some parts of Europe (e.g. Bay of Biscay) (*low confidence*) due to introduction of new (high temperature tolerant) species. Climate change will not entail relocation of fishing fleets (*high confidence*). High temperatures will increase frequency of harmful algal blooms (*medium confidence*). [23.4.6]
- In the polar regions, shifts in the timing of seasonal biomass production could disrupt matched phenologies in food webs, leading to decreased abundance of high latitude marine organisms (*medium confidence*). Ocean acidification has the potential to inhibit egg development and shell formation of some zooplankton and krill with potentially far-reaching consequences to food webs. Loss of sea ice in summer is expected to enhance secondary pelagic production in the Arctic with associated changes in the energy pathways within the marine ecosystem. [28.2.2, 28.3.2]

Food production systems and food security

Without adaptation, moderate warming of up to 2°C local temperatures is expected to reduce yields on average for the major cereals (wheat, rice, and maize) in temperate regions, although many individual locations may benefit (*medium confidence*). There is confirmation that even modest warming up to 2°C will decrease yields in low-latitude tropical regions (*medium agreement, robust evidence*). Reductions of more than 5% are *more likely than not* beyond 2050 and *likely* by the end of the century. From the 2070s onwards, all of the positive yield changes are in temperate regions, suggesting that yield reduction in the tropics are *very likely* by this time and substantial, particularly for wheat (*high agreement, robust evidence*). [7.4, Figures 7-5, 7-6, and 7-7]

Changes in climate and CO_2 levels will enhance the distribution and increase the competiveness of agronomically important and invasive weeds (*high agreement, robust evidence*). Rising CO_2 reduces the effectiveness of herbicides (*high agreement, medium evidence*). The effects of climate change on disease pressure on food crops is uncertain, with evidence pointing to changed geographical ranges of diseases but less certain changes in disease intensity (*low agreement, medium evidence*). [7.3.2]

Impacts of increased heat stress and more frequent extreme events will be negative in all regions for livestock (*high agreement, robust evidence*). Changes in animal diseases and vectors are less certain (*medium agreement, medium evidence*). Livestock systems' adaptations center around adjusting management to the available resources, using breeds better adapted to the prevailing climate, and removing barriers to adaptation such as improving credit access (*medium evidence, medium agreement*). [7.3.2, 7.5]

Adaptation possibilities of food systems to climate change show a very wide range in effectiveness, with *medium confidence* that adaptation will increase in effectiveness with increasing local mean temperature up to ca. 3°C local warming above pre-industrial, after which the net benefits no longer increase (*medium agreement, medium evidence*). Most studies, however, have focused on food production rather than on adapting food systems. Generally, adaptation leads to lower reductions in food production than in its absence with an overall crop yield difference in adaptation cases of about 15-20% over non-adaptation cases (*high agreement, medium evidence*), with more effective adaptation at higher latitudes (*medium agreement, limited evidence*), but with some adaptation options more effective than others. Thus, benefits of adaptation are greater for wheat, rice, and maize in temperate rather than tropical regions (see Figure TS.10). A range of potential adaptation options exists across all food system activities, not just in food production, but benefits from potential innovations in food processing, packaging, transport, storage, and trade are insufficiently researched. [7.1, 7.3.2, 7.5, 7.6, Figure 7-5, Figure 7-9] Urban food-adaptation is linked to progressive public policy on food security and livelihood development, addressing constraints in agricultural production and food supply chains, and limiting the impact of food price shocks caused by extreme events on the food and nutrition security of the poor. [8.3]

[INSERT FIGURE TS.10 HERE
Figure TS.10: Projected changes in crop yield as a function of time. The y-axis indicates degree of consensus and the colors denote percentage change in crop yield. Data are plotted according to the 20-year period in which the center point of the projection period falls. [Figure 7-6]]

Specific regional examples include:

- In Africa, recent evidence further strengthens a key finding from the AR4 that "agricultural production and food security (including access to food) in many African countries and regions are *likely* to be severely compromised by climate change and climate variability" (*high confidence*). Temperature rise and a reduction in growing season length by mid-century are expected to significantly reduce crop productivity with strong adverse effects on food security. New evidence is also emerging that fisheries and high-value perennial crops could also be adversely affected by temperature rise, and that the pressure of pest and diseases on crops and livestock is expected to increase as a result of climate change and other factors. Moreover, new challenges to food security are emerging as a result of strong urbanization trends on the continent and increasingly globalized food chains, which require better understanding of the multi-stressor context of food and livelihood security in Africa. [22.3.4]
- In Europe, climate change will increase yields in Northern Europe (*medium confidence*) but decrease cereal yields in Southern Europe (*high confidence*). Compared to AR4, new evidence regarding future yields in Northern Europe is less consistent regarding the magnitude and sign of change. In Northern Europe, climate change will increase the seasonal activity of pests and plant diseases (*high confidence*). Climate change will adversely affect dairy production in Southern Europe because of heat stress in lactating cows (*medium confidence*). Climate warming has caused the spread of blue tongue disease in ruminants in Europe (*high confidence*) and northward expansion of tick vectors (*medium confidence*). [23.4.1, 23.4.2, 23.5.1]
- In Europe, climate change will increase irrigation needs (*high confidence*), but future irrigation will be constrained by reduced runoff, demand from other sectors, and economic costs. By 2050s, irrigation will not be sufficient to prevent damage from heat waves to crops (*medium confidence*). System costs will increase under all climate scenarios (*high confidence*). Integrated management of water can address future competing demands among agriculture, conservation, and human settlements. [23.4.1, 23.4.3, 23.7.2]
- In Europe, shifts in agriculture production across sub-regions will occur (*medium confidence*). Climate change will alter the productivity of bioenergy crops by shifting their distribution northward (*high confidence*). Elevated atmospheric CO_2 can improve drought tolerance of bioenergy crop species due to improved plant water use, maintaining high yields in future climate scenarios (*medium confidence*). [23.4.5] Climate change will change the geographic distribution of wine grape varieties (*high confidence*). This will reduce the economic value of wine products and the livelihoods of local wine communities in Southern and Continental Europe (*medium/low confidence*). Some adaptation is possible through technologies and good practice. [23.3.5, 23.4.1, 23.4.5, 23.5.4, Box 23-1]
- In Asia, the impacts of climate change on food production and food security will vary by region with many regions experiencing a decline in productivity (*medium confidence*). This is evident in the case of rice production. Most models using a range of GCMs and SRES scenarios show that higher temperatures will lead to lower rice yields as a result of shorter growing periods and heat-induced sterility. There are a number of regions that are already near the critical temperature threshold. However, CO_2 fertilization may at least in part offset yield losses in rice and other crops. In Central Asia, some areas could be winners (cereal production in northern and eastern Kazakhstan could benefit from the longer growing season, warmer winters, and slight increase in winter precipitation), while others could be losers (western Turkmenistan and Uzbekistan, where frequent droughts could negatively affect cotton production, increase water demands for irrigation, and exacerbate desertification). In the Indo-Gangetic Plains of South Asia, there could be up to 50% decrease in the most favorable and high yielding wheat area due to heat stress at 2x CO_2. There are many potential adaptation strategies such as crop breeding, but research on their effectiveness is limited. [24.4.4]
- In Australia and New Zealand, rainfall changes and rising temperatures will shift agricultural production zones (*high confidence*). Significant reduction in food production in the Murray-Darling Basin, far south-eastern Australia, and some eastern and northern areas of New Zealand would present major challenges if scenarios of severe drying are realized. More efficient water use, allocation, and trading would increase the resilience of systems in the near term but cannot prevent significant reductions in agricultural production and severe consequences for ecosystems and some rural communities at the dry end of the projected range. [25.2, 25.5.1, 25.7.2, Box 25-5]
- In North America, without adaptation, projected changes in temperature, precipitation, and extreme events would result in notable productivity declines in major crops by the end of the 21st Century (*very high confidence*). Given that North America is a significant source of global food supplies, there will *likely* be a

negative effect on global food security if projected productivity declines are not addressed with substantial investments in adaptation (*medium confidence*). Adaptation may ameliorate many climate impacts to North American agriculture, but the institutional support mechanisms currently in place are insufficient to ensure effective, equitable, and sustainable adaptation strategies. [26.5]

- In Central and South America, changes in agricultural productivity in response to climate change are expected to have a great spatial variability. In Southeastern South America, where projections indicate more rainfall, average productivity could be sustained or increased until the mid-century (SRES: A2, B2) (*medium confidence*). In Central America, northeast of Brazil, and parts of the Andean region, increases in temperature and decreases in rainfall could decrease the productivity in the short-term (before 2025), threatening the food security of the poorest population (*medium confidence*). The great challenge for Central and South America will be to increase food and bioenergy production and at the same time sustain environmental quality in a scenario of climate change. [27.3.4]
- In the Arctic, significant impacts on the availability of key subsistence marine and terrestrial species are projected as climate continues to change with the ability to maintain economic livelihoods being affected (*high confidence*). Changing sea-ice conditions will result in more difficult access for hunting marine mammals. [28.2.6]

Urban areas

Increasing concentration of populations, assets, and economic activities in the urban areas of almost all countries, irrespective of income level, will increase the concentration of climate-related risks for a large and growing proportion of the world's population (*medium confidence*, based on *high agreement, medium evidence*). This could threaten economic and development processes, poverty reduction, and ecological sustainability. Furthermore, projections for the next few decades suggest that it is in and around urban areas that almost all the increase in the world's population and much of the increment in capital formation, economic activity, infrastructure development, ecosystem degradation, and emissions will take place. [8.1, 8.3, 8.4]

Adapting urban centers' economic base can enhance comparative advantage, deepen climate resilience, and limit disadvantage (*high agreement, medium evidence*). Climate change will shift the comparative advantages of cities and regions and differentially threaten or enhance the resource, asset, and economic base and so lead to significant structural changes and impacts on local, national, and potentially the global economy. Effective adaptation can protect a city's economic base via a mix of strategies. These include extreme weather exposure reduction via effective land-use planning, selective relocation and structural measures, reduction in the vulnerability of lifeline infrastructure and services, and measures to assist vulnerable sectors and households, mitigation of business interruption and capital stock losses, and support to the "waste economy" and the "green economy." These adaptation actions may be easier and cheaper to implement in new and peri-urban development. [8.3]

Good quality, affordable, and well-located housing provides one of the bases for city-wide adaptation (*high confidence*), by conforming to appropriate health and safety and climate-resilient building standards and having sufficient residual structural integrity over its service life to protect its occupants against extreme weather, especially heat waves and storms. It is particularly important for vulnerable groups, especially children and older residents with chronic health conditions. This can be enabled via a range of structural interventions, interventions that reduce risks to housing and support access to quality housing for low-income groups, non-structural interventions (like insurance), and disaster risk reduction measures. Well-coordinated strategies are required to address a multiplicity of agencies working at various levels, overlapping regulations, and lack of committed resources. [8.3]

Rural areas

Future impacts of climate change on the rural economic base and livelihoods, land-use, and regional interconnections are at the latter stages of complex causal chains (*high confidence*). These flow through changing patterns of extreme events and/or effects of climate change on biophysical processes in agriculture and less-managed ecosystems. This increases the uncertainty associated with any particular projected impact. [9.3.3]

Major impacts of climate change in rural areas will be felt through impacts on water supply, food security, and agricultural incomes (*high confidence*). In certain countries shifts in agricultural production, of food and non-food crops, could take place. Areas suitable for cultivation of coffee, tea and cocoa, which support millions of smallholders in over 60 countries, will be significantly reduced. Price rises, which may be induced by extreme weather events apart from other factors, have a disproportionate impact on the welfare of the poor in rural areas, such as female-headed households and those with limited access to modern agricultural inputs, infrastructure, and education. Adaptation can build on current responses to climate variability, in production of food crops, cash crops and livestock and in water management, but these may not be sufficient to deal with the range of projected climate change. [9.3.3, 9.3.4, 9.4.1, 9.4.3]

Climate change will lead to higher prices and increased volatility in agricultural markets, which might undermine global food supply security while affecting rural households depending on whether they are net buyers or net sellers of food (*medium* to *high confidence*). Deepening agricultural markets through reforming trade and making institutional efforts to improve the predictability and the reliability of the world trading system, as well as by investing in additional supply capacity of small-scale farms in developing countries, could help reduce market volatility and manage food supply shortages that might be caused by climate change (*medium agreement*). [9.3.3]

Most studies on valuation highlight that climate change impacts will be significant especially for the developing regions, due to their economic dependence on agriculture and natural resources, low adaptive capacities, and geographical locations (*high confidence*). Valuation of climate impacts needs to draw upon both monetary and non-monetary indicators. The valuation of non-marketed ecosystem services and the limitations of economic valuation models which aggregate across multiple contexts pose challenges for valuing impacts in rural areas. [9.3.4]

Specific regional examples include:

- In parts of Asia, increases in flood and drought will exacerbate rural poverty due to negative impacts on rice crops and increases in food prices and the cost of living (*high confidence*). [24.4.6]

Key economic sectors and services

Climate change would reduce energy demand for heating and increase energy demand for cooling in the residential and commercial sectors (*high agreement, robust evidence*). The balance of the two depends on the geographic, socioeconomic, and technological conditions. Increasing income will allow people to regulate indoor temperatures to a comfort level that leads to fast growing energy demand for air conditioning even in the absence of climate change in warm regions with low income levels at present. Energy demand will be influenced by changes in demographics (upwards by increasing population and decreasing average household size), lifestyles (upwards by larger floor area of dwellings), the design and heat insulation properties of the housing stock, the energy efficiency of heating/cooling devices, and the abundance and energy efficiency of other electric household appliances. The relative importance of these drivers varies across regions and will change over time. [10.2]

Climate change would affect different energy sources and technologies differently, depending on the resources (water flow, wind, insolation), the technological processes (cooling), or the locations (coastal regions, floodplains) involved (*high agreement, robust evidence*). Gradual changes in various climate attributes (temperature, precipitation, windiness, cloudiness, etc.) and possible changes in the frequency and intensity of extreme weather events will progressively affect operation over time. Climate-induced changes in the availability and temperature of water for cooling are the main concern for thermal and nuclear power plants, but several options are available to cope with reduced water availability. Similarly, already available or newly developed technological solutions allow firms to reduce the vulnerability of new structures and enhance the climate suitability of existing energy installations. [10.2]

Climate change would influence the integrity and reliability of pipelines and electricity grids (*medium agreement, medium evidence*). Pipelines and electric transmission lines have been operated for over a century in diverse climatic conditions on land from hot deserts to permafrost areas and increasingly at sea. Climate change is *about as likely as not* to require the adoption of technological solutions for the construction and operation of

pipelines and power transmission and distribution lines from other geographical and climatic conditions, adjustments in existing pipelines, and improvements in the design and deployment of new ones in response to the changing climate and weather conditions. [10.2]

Climate change would negatively affect transport infrastructure (*high agreement, limited evidence*). Transport infrastructure malfunctions if the weather is outside the design range, which would happen more frequently should climate change. All transportation infrastructure is vulnerable to freeze-thaw cycles; paved roads are particularly vulnerable to temperature extremes and unpaved roads to precipitation extremes. Transport infrastructure on ice or permafrost is especially vulnerable. [10.4]

Climate change would affect tourism resorts, particularly ski resorts, beach resorts, and nature resorts (*high agreement, robust evidence*), and tourists would be inclined to spend their holidays at higher altitudes and latitudes (*high agreement, medium evidence*). The economic implications of climate-change-induced changes in tourism demand and supply may be substantial, with gains for countries closer to the poles and higher up the mountains and losses for other countries. The demand for outdoor recreation is affected by weather and climate, and impacts will vary geographically and seasonally. [10.6]

Climate change would affect the health sector (*high agreement, medium evidence*) through increases in the frequency, intensity, and extent of extreme weather events adversely affecting infrastructure and increase the demands for services due to the human health impacts of climate change, placing additional burdens on public health, disease burden, and health care personnel and supplies; these have economic consequences. [10.8]

Climate change would have impacts, heterogeneous in both sign and size, on water resources and water use (*high agreement, robust evidence*), but the economic implications are not well understood. Economic impacts include flooding, scarcity, and cross-sectoral competition. Water scarcity and competition for water, driven by institutional, economic, or social factors, may mean that water assumed to be available for a sector is not. [10.3]

The impacts of climate change would decrease productivity and economic growth, but the magnitude of this effect is not well understood (*high agreement, limited evidence*). Climate could be one of the causes why some countries are trapped in poverty, and climate change may make it harder to escape poverty traps. [10.9]

Not all key sectors have been subject to detailed research based on a comprehensive assessment across economic sectors. Few studies have evaluated the possible impacts of climate change on mining, manufacturing, or services (apart from health, insurance, and tourism). Further research, collection, and access to more detailed economic data and the advancement of analytic methods and tools will be required to further assess the potential impacts of climate on key economic systems and sectors. [10.5, 10.8, 10.10]

Specific regional examples include:

- In Europe, climate warming will decrease space heating demand and increase cooling demand (*high confidence*), with income growth driving the largest part of this increase from 2000-2050 (especially in eastern regions) (*medium confidence*). Energy efficient buildings and cooling systems as well as demand-side management will reduce future energy demands. Climate change will increase the problems associated with overheating in domestic housing. [23.3.2, 23.3.4]
- In Europe, climate change will decrease hydropower production from reductions in rainfall in all sub-regions except Scandinavia (*high confidence*). Climate change will have no impact on wind energy production before 2050 (*medium confidence*) and only a small impact after 2050 (*low confidence*). Climate change will inhibit thermal power production during summer (*medium confidence*). Plant modifications and operational changes can reduce adverse impacts. [23.3.4]
- In Europe, climate change is *likely* to further increase coastal and river flood risk and, if unabated, will substantially increase flood damages (monetary losses and people affected). Adaptation can prevent most of the projected damages (*high confidence*, based on *high agreement, medium evidence*). [23.3.1, 23.5.1, 23.7.1, 23.8.3]
- In Europe, climate change will affect the impacts of hot and cold weather extremes on transport leading to economic damage and/or adaptation costs, as well as some benefits during winter (e.g., reduction of maintenance costs) (*medium confidence*). Climate change will reduce severe accidents in road transport and adversely affect inland water transport particularly the Rhine in summer after 2050. Damages to rail

infrastructure from high temperatures will increase. Adaptation through maintenance and operational measures can reduce adverse impacts to some extent. [23.3.3]

- In Europe, no significant impacts are projected before 2050 in winter or summer tourism except for ski tourism in low altitude and mid altitude sites and under limited adaptation (*medium confidence*). After 2050, tourism activity will decrease in southern Europe (*low confidence*) and increase in northern/continental Europe (*medium confidence*). Artificial snowmaking will prolong the activity of some ski resorts (*medium confidence*). [23.3.6]
- In Europe, the capacity to adapt will be higher than for other world regions, but there are important differences in impacts and the capacity to respond within the European sub-regions. Climate change will affect economic activity in southern Europe more than other sub-regions (*medium confidence*), [Table 23.4, 23.9.1] and increase future intra-regional disparity (*low confidence*). [23.9] The Mediterranean (part of Southern region) is particularly vulnerable to climate change as multiple sectors will be adversely affected (tourism, agriculture, forestry, infrastructure, energy, population health) (*high confidence*). [23.9, 23.9.1, Box 23-3, Table 23.4]
- In Australia and New Zealand, increased frequency and intensity of flood damage to settlements and infrastructure are projected, driven by increasing extreme rainfall although the amount of change remains uncertain (*high confidence*). In many locations, continued reliance on increased protection alone would become progressively less feasible. Increased damages to ecosystems and settlements, economic losses, and risks to human life from wildfires in most of southern Australia and many parts of New Zealand are projected, driven by drying trends and rising temperatures (*high confidence*). Building codes, design standards, local planning mechanisms, and public education can assist with adaptation and are being implemented in regions that have experienced major events. These impacts have the potential to be severe but can be moderated or delayed significantly by globally effective mitigation combined with adaptation, with an increasing need for transformative adaptation for greater rates and magnitude of change. [25.2, Table 25-1, 25.4.2, 25.6.1, 25.7.1, Box 25-6, 25.10.3, Box 25-8]
- In New Zealand and southern parts of Australia, projected changes in climate have the potential to reduce energy demand for winter heating (*high confidence*). [25.7.4]
- In North America, there is an emerging concern that dislocation in one sector of the economy may have an adverse impact on other sectors due to supply chain interdependency (*medium confidence*). [26.7]
- In the Arctic, climatic and other large-scale changes can have potentially large effects on communities where relatively small and narrowly based economies leave a narrower range of adaptive choices (*high confidence*). Increased economic opportunities and challenges for culture, security, and environment are expected with the increased navigability of Arctic marine waters and the expansion of land- and fresh water-based transportation networks. Rising temperatures, leading to the further thawing of permafrost and changing precipitation patterns, have the potential to affect all infrastructure types and related services in the Arctic. [28.2.6, 28.4.2]

Human health

If climate change continues as projected in scenarios in the next few decades, the major increases of ill-health compared to no climate change will occur with *high confidence* through:

- Greater incidence of injury, disease, and death due to more intense heat waves, storms, floods, and fires.
- Increased risk of under-nutrition resulting from diminished food production in poor regions.
- Loss of work capacity and reduced labor productivity in vulnerable populations.
- Increased risks of food- and water-borne diseases and vector-borne infections.
- Modest improvements in some areas due to lower impacts of cold, shifts in food production, and reduction of disease-carrying vectors. These positive effects will be out-weighed, world-wide, by the magnitude and severity of the negative effects of climate change.

Impacts on health will be reduced, but not eliminated, in populations that benefit from rapid social and economic development, particularly among the poorest and least healthy groups. [11.4, 11.5, 11.6, 11.7]

For RCP 8.5 by 2100, most of the world land area will be experiencing annual mean temperatures at least 4°C above those of 1986-2005. This means that important limits to adaptation for health impacts may have been exceeded in many areas of the world during this century (*high confidence*). These relate to sea level rise,

storms, loss of agricultural productivity, and daily temperature/humidity conditions that exceed coping mechanisms, making potentially large areas seasonally unsuitable for normal human activities, including growing food or working outdoors. [11.8]

Climate change is expected to substantially affect regional air quality, for example near surface ozone concentrations; however, this effect also depends strongly on future emissions. [21.3.3, 21.5.3]

The most effective adaptation measures for health in the immediate term are programs that extend basic public health measures and essential health services, increase capacity for disaster preparedness and response, and alleviate poverty (*very high confidence*). [11.6]

Specific regional examples include:

- In Africa, climate change is expected to increase the burden of a wider range of health outcomes (*medium confidence*). Findings on malaria are similar to AR4, emphasizing the spatial and temporal spread of malaria in the East Africa Highlands and increased transmission intensity in South Africa. Indirectly, climate change could increase the burden of malnutrition, which will have the highest toll on children and women. Adaptation in the health sector will build on existing public health interventions as well as specific adaptation measures such as early warning systems. [22.3.5, 22.4.5]
- In Europe, climate change will increase the frequency tropospheric ozone events (exceedences) in the future (*low confidence*), even assuming future emissions reductions. [23.6.1]
- In Europe, particularly in Southern Europe, climate change will increase the frequency and intensity of heat waves (*high confidence*) with adverse implications for health, agriculture, energy production, transport, tourism, labour productivity, and built environment, and heat-related deaths and injuries will increase (*medium confidence*). Climate change will change the distribution and seasonal pattern of some human infections, including those transmitted by arthropods. [23.2.2, 23.5.1, Table 23.4]
- In Asia, more frequent and intense heat-waves will increase mortality and morbidity in vulnerable groups. Increases in heavy rain and temperature will increase the risk of diarrheal diseases and malaria (*high confidence*). [24.4.6]
- In Australia, increasing morbidity, mortality, and infrastructure damages during heat waves, resulting from increased frequency and magnitude of extreme temperatures, have the potential to be severe but can be moderated or delayed significantly by globally effective mitigation combined with adaptation (*high confidence*). Vulnerable populations include the elderly, children, and those with existing chronic diseases; aging trends and prevailing social dynamics constrain effectiveness of adaptation responses, with an increasing need for transformative adaptation for greater rates and magnitude of change. [25.8.1]
- In New Zealand and southern parts of Australia, projected changes in climate have the potential to reduce morbidity from winter illnesses (*high confidence*). [25.8.1]
- In North America, the effect of increasing heat extremes on health will depend on the pace of adaptation (*high confidence*). Given current levels of adaptation, there are *likely* to be increased health impacts from heat extremes among vulnerable communities, populations, and individuals. Conditional on an increase in storm severity under a changing climate, there are *likely* to be continued human health risks in the absence of specific adaptation planning. [26.6]
- In Central and South America, climate variability and change may exacerbate current and future risks to health, given the region's vulnerabilities in existing health, water, sanitation and waste collection systems, nutrition, and pollution. [27.3.7]

Human security

Climate change threatens human security, because it a) undermines livelihoods, b) compromises culture and identity, c) increases migration that people would rather have avoided, and d) undermines the ability of states to provide the conditions necessary for human security (*high agreement, robust evidence*). Human security breakdowns almost never have single causes, but instead emerge from the interaction of multiple factors. For populations that are already socially marginalized, are resource dependent, and have limited capital assets, human security will be progressively undermined as the climate changes. Increases in the rate and magnitude of climate

change increase the risk to human security by exacerbating negative feedbacks between cultural processes, migration, and violent conflict. See Figure TS.11. [12.1.2, 12.2, 12.7]

[INSERT FIGURE TS.11 HERE
Figure TS.11: Synthesis of evidence on the impacts of climate change on elements of human security and the interactions between elements. Examples of positive and negative changes in security associated with interventions indicated by arrows. [Figure 12-3]]

Climate change will have significant impacts on forms of migration that compromise human security (*medium agreement, medium evidence*). Some migration flows are sensitive to changes in resource availability and ecosystem services. Major extreme weather events have in the past led to significant population displacement, and changes in the incidence of extreme events will amplify the challenges and risks of such displacement. There is evidence that many vulnerable groups do not have the resources to be able to migrate to avoid the impacts of floods, storms, and droughts. There is evidence from models, scenarios, and observations that coastal inundation and loss of permafrost can lead to migration and resettlement. Migrants themselves may be vulnerable to climate change impacts in destination areas, particularly in urban centers in developing countries. [9.3.3, 12.3.2, 12.4.2]

Climate change will lead to new challenges to states and will shape both conditions of security and national security policies (*medium agreement, medium evidence*). Physical aspects of climate change, such as sea level rise, extreme events, and hydrologic disruptions, pose major challenges to vital transportation, water, and energy infrastructure. Some states are experiencing major challenges to their territorial integrity, including Arctic countries, small island states, and other states highly vulnerable to sea level rise. Some impacts of climate change, such as changes in sea ice, transboundary and shared water resources, and the migration of pelagic fish stocks, have the potential to increase rivalry among states. There is evidence that the presence of robust institutions can manage many of these rivalries such that human security is not severely eroded. These threats to national security will affect the capacity of states and communities to provide human security. [12.5.4, 12.6]

Climate change affects cultures and the cultural expressions important for maintaining identity and traditional and local forms of knowledge (*high agreement, medium evidence*). Climate change impacts will lead to significant changes in environmental and societal conditions throughout the natural world, and in human settlements. These changes will compromise dimensions of the cultural core and assets that are highly valued by societies. The magnitude of the perceived loss depends on the robustness of cultural identity and the mechanisms for maintaining and transferring knowledge. [12.3]

Specific regional examples include:

- In Europe, climate change and sea level rise will damage European cultural heritage, including buildings, local industries, landscapes, and iconic places such as Venice (*medium confidence*), and some cultural landscapes will be lost forever (*low/medium confidence*). [23.5.4, Table 23-5]
- In the Arctic, impacts on human health and well-being from climate change are significant and projected to increase, especially for many indigenous peoples (*high confidence*). Impacts include injury and risk from changes in extreme weather and ice and snow conditions; decreased access to local foods and compromised freshwater sources; permafrost and erosion damage to infrastructure; and loss of traditional livelihood, language, culture, and relocation of communities. These impacts are expected to vary among diverse settlements, and are often related to the large percentage of northern settlements along coastlines or beside rivers and lakes. [28.2.4]

Livelihoods and poverty

Climate change will create new poor, in low-income countries and middle- to high-income countries, and will jeopardize sustainable development. Most severe impacts are projected for urban areas and some regions in sub-Saharan Africa and Southeast Asia (*medium confidence,* based on *medium agreement, medium evidence*). Future impacts of weather events and climate will slow down economic growth and poverty reduction, further erode food security, and trigger new poverty traps, the latter particularly in urban areas. Climate change will exacerbate multidimensional poverty in low and lower middle-income countries, including high mountain states and countries with indigenous people threatened by sea level rise and relocation, and create new poverty pockets in upper middle-

to high-income countries. Urban and wage-labor dependent poor households, as well as regions with high food insecurity, above all in Africa, and high inequality, will be particularly affected due to food price increases. [13.2.2, 13.4]

Social protection programs can help the chronically poor reduce risk and protect assets during crises, through transfers of income or assets to the poor, protection against livelihood risks, and enhancement of the social status and rights of the marginalized (*medium confidence*). However, existing projects have offered few concrete suggestions on how to address underlying social and political vulnerabilities and inequalities that inhibit adaptation. Also, there is *limited evidence* that such programs strengthen local collective capacity to act, for instance to install or modify risk-reducing infrastructure and services, or address the incapacity in local governments in provision for water, sanitation, drainage, health care, and emergency services. Existing examples underscore the need to explicitly address livelihood security and resilience in the long-term, rather than focusing on short-term disaster relief. [13.4]

Specific regional examples include:

- In North America, climate change impacts can hamper progress towards sustainability and have the potential to exacerbate existing challenges such as deficits in infrastructure or in institutional capacity to promote the health and wellbeing of human populations (*high confidence*). [26.7, 26.9]

Regional risks

Figure TS.12 provides a synthesis of sectoral risks for several regions, based on the expert judgment of assessment authors. Risks are estimated for the era of climate responsibility (here, for 2030-2040) and for the era of climate options (here, for 2080-2100) under different levels of global average warming dependent on mitigation outcomes (about +2 or +4°C global average warming above preindustrial in 2080-2100). Risks are summarized sector by sector, reflecting the overall structure of the WGII report (Part A). Risks, indicated by colored shading, are estimated for low to high adaptation to indicate opportunities for reducing risks through adaptation. Distance of this shading from the center of each diagram indicates the level of risk, with greater distance corresponding to higher risk. Examples of specific risks are presented in Table TS.5.

Assessed impacts across Europe are summarized in Table TS.6. Key regional risks for Australia and New Zealand are presented for the era of climate options in Table TS.7. Observed changes in climate and other environmental factors are shown for Central and South America in Figure TS.13. Key risks and vulnerabilities for the ocean's regions are depicted in Figure TS.14.

[INSERT FIGURE TS.12 HERE
Figure TS.12: Estimated risk from climate change to selected sectors and systems in Africa (A), Europe (B), and North America (C), for different time frames (2030-2040 and 2080-2100), under two levels of global average warming above preindustrial (2°C and 4°C) and different assumptions about adaptation to manage these risks. Levels of risk and of adaptation are differentiated by colored shading, ranging from high adaptation to low adaptation. Estimated risks rely on expert judgments. The risk categories reflect the overall structure of Part A of the WGII AR5. [Figures 22-7 and 26-6]]

[INSERT TABLE TS.5 HERE
Table TS.5: Examples of risks that increase with increasing level of climate change. Examples of potential positive impacts are also given. Risks increasing moderately or severely from now until the 2040s, which can be considered an era of climate responsibility, are described, in addition to risks increasing from ~2050 through the end of the 21st century, which can be considered to represent an era of climate options. For risks increasing in both the era of climate responsibility and the era of climate options, the potential for proactive adaptation to reduce the risks is characterized as low or high, with detail provided on adaptation issues and prospects. Risks increasing in the era of climate options can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options. Increasing risks in the era of climate responsibility are generally difficult to reduce substantially through mitigation, even with globally effective mitigation. They can be managed through vulnerability reduction, adaptation, and transformations that promote climate-resilient development pathways.]

[INSERT TABLE TS.6 HERE
Table TS.6: Assessment of climate change impacts by European sub-region and sector (by 2050, medium emissions) With economic development, with land use change. No further planned adaptation. [Table 23-4]]

[INSERT TABLE TS.7 HERE
Table TS.7: Key regional risks during the 21st century from climate change for Australia and New Zealand. Color bars indicate risk as a function of global mean temperature relative to pre-industrial, based on the studies assessed and expert judgement, for the current (top bar) and a hypothetical fully adapted state (bottom bar). For each risk, relevant climate variables and trends are indicated by symbols, in approximate order of priority. Where relevant climate projections span a particularly wide range even for a given amount of global mean temperature change, risks are shown in two pairs for high and low end projections, each without and with effective adaptation. [Table 25-8]]

[INSERT FIGURE TS.13 HERE

[INSERT FIGURE TS.14 HERE
Figure TS.14: Summary of key risks and vulnerabilities associated with climate change on the world's ocean regions. [Figure 30-15]]

C.ii. Key and Emergent Risks

Key risks are potential adverse consequences for humans and social-ecological systems due to the interaction of climate-related physical hazards with vulnerabilities of societies and systems exposed. Risks are considered "key" due to high physical hazard or high vulnerability of societies and systems exposed, or both. [Box 19-2]

Key risks resulting from the interaction of hazardous climate changes and physical impacts with the vulnerability of societies and exposed systems, identified with *high confidence* [19.6.2], include the following:

- The risk for increased food insecurity can result from both local conditions like adverse changes in rainfall patterns and a lack of alternative sources of income for some affected households, as well as regional and national conditions like a breakdown of food distribution and storage processes.
- The risks of dispossession of land—including the alteration of rural inhabitants' coping and adaptation processes—result from shifts in energy policies and global markets.
- The risk of loss of livelihoods due to changes in climatic conditions and socioeconomic structures affects people living in low-lying coastal zones and people engaged in rain-fed agriculture in developing countries and countries with economies in transition.
- The risks of increasing morbidity, mortality, and infrastructure failure as well as new systemic risks (such as the risk of heat stress as a result of power shortages during extreme events) affect urban areas in both developed and developing countries.
- The risk of increase in disease burden results from the interaction of changes in physical climate conditions like increasing temperatures with the vulnerability of people due to, for example, an aging population.

Consequences of global temperature rise in excess of 4°C relative to preindustrial levels can now be assessed. See Box TS.6. Key risks associated with large temperature rise include exceedance of human physiological limits in some locations and nonlinear earth system responses (*high confidence*). There may also be key risks in other sectors and regions that have not been studied in this context. [19.5.1]

Interactions among climate change impacts in various sectors and regions, and human vulnerability and adaptation in other sectors and regions, as well as interactions between adaptation and mitigation actions, are generally not included, or not well integrated, into projections of climate change impacts. Their consideration leads to the identification of a variety of emergent risks (*high confidence*). [19.3] Several such complex-system interactions that increase vulnerability and risk are identified with *high confidence*, for example:

- The risk of severe harm and loss due to climate change-related hazards and various vulnerabilities is particularly high in large urban and rural areas in low-lying coastal zones. These areas, many characterized by increasing populations, are exposed to multiple hazards and potential failures of critical infrastructure, generating new systemic risk. [19.3.2]
- The risk of climate change to human systems is increased by the loss of ecosystem services (e.g., water and air purification, protection from extreme weather events, preservation of soils, recycling of nutrients, and pollination of crops), which are supported by biodiversity. [19.3.2]
- In some water stressed regions, groundwater stores that have historically acted as buffers against climate change impacts are being depleted, with adverse consequences for human systems and ecosystems, whilst at the same time climate change may directly increase or decrease regional groundwater resources. [19.3.2]
- Climate change adversely affects human health, increasing exposure and vulnerability to a variety of other stresses, for example by altering the prevalence and distribution of diseases that are weather and climate sensitive, increasing injuries and fatalities resulting from extreme weather events, and eroding mental health in response to population displacement. [19.3.2]
- Spatial convergence of impacts in different sectors creates impact "hotspots" involving new interactions (Figure TS.15). Examples include the Arctic (where sea ice loss and thawing disrupts transportation, buildings, other infrastructure, and potentially disrupts Inuit culture); the environs of Micronesia, Mariana Island, and Papua New Guinea (where coral reefs are highly threatened due to exposure to concomitant sea surface temperature rise and ocean acidification); and Sub-Saharan Africa (where global warming at the high end of the range projected for this century, i.e., more than 4°C above preindustrial levels, would be especially disruptive, resulting in high risk of reduced extent of croplands, reduced length of the growing season, increased hunger, and increased malaria transmission). [19.3.2]

[INSERT FIGURE TS.15 HERE
Figure TS.15: Some salient examples of multi-impacts hotspots identified in this assessment. [Figure 19-2]]

Emergent risks also arise from indirect, trans-boundary, and long-distance impacts of climate change, sometimes mediated by the adaptive responses of human populations (*high confidence*). Responses to climate change can result from localized impacts that generate distant harm via responses transmitted through human or ecological systems. [19.4] Several such emergent risks are identified with *high confidence*, for example:

- Increasing prices of food commodities on the global market due to local climate impacts, sometimes in conjunction with demand for biofuels, decrease food security and exacerbate malnutrition at distant locations. [19.4.1]
- Climate change will bear significant consequences for migration flows at particular times and places, creating risks as well as benefits for migrants and for sending and receiving regions and states. [19.4.2]
- The possibility that climate change will alter patterns of violence is a risk emerging in the literature. The effect of climate change on conflict and insecurity has the potential to become a key risk because the reported magnitude of the influence of the climate's variability on security is large. [19.4.2]
- Shifting species ranges in response to climate change adversely affect ecosystem function and services while presenting new challenges to conservation efforts. Where range shifts cannot track climatic changes, species are at risk of eventual extinction. [19.4.2]

Additional risks have emerged recently in the literature related to particular biophysical impacts of climate change (*high confidence*). These include decreasing viability of marine calcifying organisms due to ocean acidification; increasing production and allergenicity of pollen and allergenic compounds as well as decreasing nutritional quality of key food crops due to high ambient concentrations of CO_2; and adverse regional impacts arising from Solar Radiation Management implemented for the purposes of limiting global warming. [19.5, 19.5.2, 19.5.3, 19.5.4]

The risk of crossing tipping points in socio-ecological systems may be reduced by preserving ecosystem services (*medium confidence*). Tipping points are thresholds beyond which adverse impacts increase non-linearly. Some tipping points may be avoided by limiting the level of climate change and/or removing concomitant stresses such as overgrazing, overfishing, and pollution, but there is *low confidence* in location of such tipping points and measures to avoid them. [19.7.4]

Impacts of climate change avoided under a range of scenarios for mitigation of greenhouse gas emissions are potentially large and increasing over the 21st century (*high confidence*). Advances in the assessment and implementation of mitigation measures and adaptation strategies include for the first time evaluation of avoided damages from a range of strategies. Among the impacts assessed, benefits from mitigation are most immediate for ocean acidification and least immediate for impacts related to sea level rise. Since mitigation reduces the rate as well as the magnitude of warming, it also delays the need to adapt to a particular level of climate change impacts, potentially by several decades. [19.7.1]

Under any plausible scenario for mitigation and adaptation, some degree of risk from residual damages is unavoidable (*very high confidence*). For example, no model-based scenarios in the literature demonstrate the feasibility of limiting warming to a maximum of 1.5°C with at least 50% likelihood, and recent findings suggest that comprehensive adaptation to current climate risk is prohibitively expensive, indicating that adaptions to future changes are similarly constrained. Assessments of stringent mitigation scenarios suggest that they can potentially avoid one half of the aggregate economic impacts that would otherwise accrue by 2100, and between 20-60% of the physical impacts, depending on sector and region. [19.7.1, 19.7.2]

The design of risk-management strategies could be informed by observation and projection systems that provide an actionable early warning signal of an approaching threshold response. However, there is *low confidence* in the feasibility and requirements for such systems, since studies to date are highly simplified and limited in number. [19.7.3]

Table TS.8 presents specific examples of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in the report. Box TS.7 integrates expert judgments about risks under the reasons for concern framework. Box TS.8 summarizes understanding of adaptation costs.

[INSERT TABLE TS.8 HERE
Table TS.8: A selection of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in the report. The examples underscore the complexity of risks determined by various climatic hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, demographic changes, or tolerance limits of species and ecosystems that often provide important services to vulnerable communities, generate the context in which climate-change-related harm and loss can occur. The examples illustrate that current global megatrends (e.g., climate change, urbanization, demographic changes), in combination and in specific development contexts (e.g., in low-lying coastal zones), can generate new systemic risks that go far beyond existing adaptation and risk management capacities, particularly in highly vulnerable regions. [Table 19-3]]

Many impacts on small islands are generated from processes well beyond the borders of an individual nation or island, and generally they have negative effects (*high confidence)*. Trans-boundary impacts on small islands may originate in distant regions including continental countries and high latitudes. Examples of the former include airborne dust from the Sahara and Asia reaching small islands far down-drift from the desert source; examples of the latter include large ocean swells generated by extra tropical cyclones and high latitude low pressure systems. [29.5.1, 29.5.2] Other trans-boundary impacts result from invasive plant and animal species that reach the warmth of tropical small islands and the spread of aquatic pathogens that may have implications for human health. For island communities the trans-boundary implications of existing and future “invasions” and human health challenges are projected to increase in a changing climate. [29.3.3.2, 29.5.3, 29.5.5]

_____ START BOX TS.6 HERE _____

Box TS.6. Consequences of Large Temperature Increase (e.g., >4°C)

Projections of climate change impacts at 4°C global mean temperature increase above preindustrial indicate large impacts for physical, biological, and human systems and, in turn, large aggregate impacts for society and the global economy (*high confidence*). Global-mean surface temperatures for 2081–2100 (relative to early industrial, 1886–1905) for RCP 6.0 and 8.5 will *likely* be in the 5–95% range of the CMIP5 climate models, i.e., 2.0°C–3.9°C (RCP6.0), 3.3°C–5.5°C (RCP8.5).

For 4°C global mean temperature increase above preindustrial, the effects of climate change on water resources and ecosystems are projected to become dominant over other drivers such as population increases and land use change (*medium confidence*). Widespread coral reef mortality is projected (*high confidence*). Agricultural production is expected to decline in mid-high latitudes once local temperature rise exceeds 3°C (and for lower temperature rise in the tropics), corresponding to a global temperature rise below 4°C (*medium confidence*). Beyond 4°C there is high risk of marked yield loss even at high latitudes (*medium confidence*). Extreme heat waves such as that experienced in Russia in 2010 can become typical of a normal summer for a 4°C increase (*high confidence*). Sea level rise in a 4°C world could result in the inundation of many small island states (*high confidence*). Emerging risks include exceedance of human physiological limits in some areas for a global temperature rise of 7°C (*medium confidence*).

Sub-Saharan Africa is identified as a multi-impacts hotspot in a 4°C world, with risks of increases in hunger and disease, and of loss of ecosystem function (*high confidence*). A 4°C increase would be expected to result in non-linear earth system responses: Amazon dieback (*medium confidence*); eventual, irreversible loss of the Greenland Ice Sheet (*high confidence*); and terrestrial carbon loss due to climate-carbon cycle feedback releasing CO_2 or CH_4 (*very likely*), which would accelerate climate change further. There would also be an increased chance of triggering the collapse of the West Antarctic Ice Sheet.

Box TS.7. Anthropogenic Interference with the Climate System

Anthropogenic interference with the climate system is occurring. [WGI AR5 SPM, 10.3-10.6] The impacts of climate change[1] are already widespread and consequential. [18.3-18.6] Determining whether anthropogenic interference is dangerous involves judgments about risks.

Science can quantify risks in a technical sense, based on the probability, magnitude, and scope of potential consequences of climate change. Interpreting risks and their potential danger, however, also requires value judgments, made across scales by people with differing goals and worldviews and without full certainty of what the future will hold. Judgments about the risks of climate change depend on the relative importance ascribed to economic vs. ecosystem assets, to the present vs. the future, and to the distribution vs. aggregation of impacts. From some perspectives, isolated or infrequent damages from climate change may not rise to the level of dangerous anthropogenic interference, but accumulation of the same kinds of damages could, as they become more widespread, more frequent, or more severe. The rate of climate change can also influence risks of damages, as reflected in Article 2.

The IPCC assesses scientific and technical understanding of risks and the range of possible outcomes. It also assesses understanding of how risks are perceived, as well as methods for incorporating different value systems in decisionmaking. The IPCC cannot, however, make a determination of the level of anthropogenic interference that is dangerous.

[INSERT FOOTNOTE 1: See Box TS.2 for description of differing usage of the term “climate change” in the IPCC and UNFCCC.]

Assessment of existing frameworks pertinent to Article 2 of the UNFCCC has led to evaluations of risk being updated in light of the advances since AR4, including SREX and the current report’s discussions of vulnerability, human security, and adaptation. The management of key and emergent risks of climate change and reasons for concern includes (i) mitigation that reduces the likelihood of physical impacts and (ii) adaptation that reduces the vulnerability and exposure of societies and ecosystems to those impacts. Many of the key vulnerabilities, key risks, and emergent risks identified in this report reflect differential vulnerability between groups due to, for example, age, wealth, or income status, and deficiencies in governance, which are particularly important in assessing

risk from extreme events and risk associated with the distribution of impacts. [19.6.1, 19.6.3, 19.7]

Impacts of climate change have now been documented globally, covering all continents and the ocean (*high confidence*; Table TS.1). Detection and attribution of observed impacts of climate change supports assessments of current conditions with respect to the reasons for concern. The degree to which projected damages are now manifest, or the detection of stronger early warning signals for expected impacts, can contribute to a more comprehensive risk assessment for dangerous anthropogenic interference with the climate system. [18.6.2]

Updating of the reasons for concern (Box TS.7 Figure 1) leads to the following assessment:

- Unique human and natural systems tend to have very limited adaptive capacity, and hence we have *high confidence* that climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C over preindustrial levels were exceeded. In addition, there is new and stronger evidence to support the previous judgment of *high confidence* that a warming of up to 2°C above 1990-2000 levels would result in significant impacts on many unique and vulnerable systems, and would likely increase the endangered status of many threatened species, with increasing adverse impacts and increasing risk of extinctions (and increasing confidence in this conclusion) at higher temperatures. There is higher confidence in observed impacts on Arctic marine and terrestrial ecosystems and indigenous livelihoods (*medium to high confidence*), tropical coral reefs (*high confidence*) and glaciers in most mountain regions (*high confidence*). [18.6.2, 19.6.3]
- The overall risk from extreme events due to climate change has not changed significantly since AR4, but there is higher confidence in the attribution of some types of extreme events to human activity and in the assessment of the risk from extreme events in the coming decades. In addition, there is a new appreciation for the importance of exposure and vulnerability, in both developed and developing countries, in assessing risk associated with extreme events. [19.6.1, 19.6.3]
- Risk associated with the distribution of impacts is generally greatest in low-latitude, less developed areas, but because vulnerability is unevenly distributed within countries, some populations in developed countries are highly vulnerable to warming of less than 2°C, as noted in AR4 (*high confidence*). [19.6.3]
- Globally aggregated risk is underestimated because it does not include many non-monetized impacts, such as biodiversity loss, and because it omits many known impacts that have only recently been quantified, such as reduced labor productivity (*high confidence*). In addition, aggregated estimates of costs mask significant differences in impacts across sectors, regions, countries, and populations (*very high confidence*). The overall assessment of aggregate risk and confidence in that assessment has not changed since AR4. [19.6.3]
- The risk associated with large-scale singular events such as the at least partial deglaciation of the Greenland ice sheet remains comparable to that assessed in AR4. [19.6.3]

[INSERT BOX TS.7 FIGURE 1 HERE
Box TS.7 Figure 1: The dependence of risk associated with reasons for concern (RFCs) on the level of climate change, updated based on expert judgment in this assessment. The color scheme indicates the additional risk due to climate change (with white to purple indicating the lowest to highest level of risk, respectively). Purple color, introduced here for the first time, reflects the assessment that unique human and natural systems tend to have very limited adaptive capacity. [Figure 19-5]]

The determination of key risks as reflected, for example, in the reasons for concern in the Third and Fourth Assessment Reports did not distinguish between alternative development pathways. The development of risk profiles from Shared Socioeconomic Pathways and Representative Concentration Pathways is an important area of research that can lead to improvement in the framework developed in this report. [19.6.3]

_____ END BOX TS.7 HERE _____

_____ START BOX TS.8 HERE _____

Box TS.8. Adaptation Costs

Estimates of the global costs of adaptation continue to improve, but remain inconsistent in methods, sectoral coverage, purposes, and time frames. The most recent estimates suggest a range from 75 to 100 US$ billion per year globally by 2050 (*low confidence*), but important omissions from these estimates suggest the high end of this range could be much higher, and important shortcomings in the data and methods available for costing adaptation suggest the low end of this range could be substantially lower.

- Defining the benefits and cost of adaptation is difficult, is limited by data, and depends on value judgments. Estimating adaptation costs poses methodological, practical, and moral difficulties, with consequences for how adaptation can be funded. [17.3.6, 17.3.10, 17.3.11, 17.6]
- The existing estimates of global adaptation costs could be higher if sectors such as ecosystems and tourism and socially contingent effects are included, and if the adaptation deficits of developing countries are more fully taken into account. The global figures are based on only a few lines of evidence and cover a selected number of sectors. [17.6]
- Some evidence suggests that incremental adaptation costs increase over time as climate change unfolds (*low confidence*), but consideration of current adaptation deficits suggests that costs could be high in the short-term as well, and inconsistencies in the effect of economic development on adaptation capacity also confound the reliability of estimates of the trend over time. [17.6.3]

Adaptation costing studies suffer from the absence of a robust community of practice, with great inconsistencies in the purposes, methods, data quality, and sectoral coverage of these analyses, limiting attempts to aggregate the finer-scale study results across regions and time. Among these regional and local-scale analyses desirable characteristics include: a broad representation of relevant climate stressors to ensure robust economic evaluation; consideration of multiple alternative and/or conditional groupings of adaptation options; rigorous economic analysis of costs and benefits across the broadest possible market and nonmarket scope; and a strong focus on support of practical decision-making that incorporates consideration of sources of uncertainty. Few current studies manage to achieve all of these objectives. [17.6.3]

_____ END BOX TS.8 HERE _____

_____ START BOX TS.9 HERE _____

Box TS.9. Ocean Acidification

Anthropogenic ocean acidification (Box TS.9 Figure 1A) and climate change share the same primary cause at the global level, the increase of atmospheric carbon dioxide. [WGI AR5 2.2.1] The fundamental chemistry is well understood: the uptake of CO_2 into mildly alkaline ocean results in an increase in dissolved CO_2 and reductions in pH, dissolved carbonate ion, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of surface seawater can be projected with high accuracy from projections of atmospheric CO_2 levels in the open ocean, but not in coastal waters where eutrophication and upwelling contribute to local ocean acidification. [5.3.3.6, 30.5.4]

Ocean acidification occurs on a backdrop of other environmental changes, both global (e.g. warming, decreasing oxygen levels) and local (e.g. pollution, eutrophication), yet their combined impacts remain poorly understood. A pattern of impacts—some positive, others negative—emerges for some processes and organisms (*high confidence*; Box TS.9 Figure 1B), but key uncertainties remain from organismal to ecosystem levels. A wide range of sensitivities exists within and across organisms, with higher sensitivity in early life stages. [6.2.4] Lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers, reducing their competitiveness with non-calcifiers (*high confidence*; Chapters 5, 6, and 30). Growth and primary production are stimulated in seagrasses and some phytoplankton (*high confidence*), and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Adult fish remain relatively undisturbed by elevated CO_2, although serious behavioral disturbances have been reported in larval and juvenile reef fishes. [6.2.4] Natural analogues at CO_2 vents indicate decreased species diversity, biomass, and trophic complexity of communities living on the sea floor. Shifts in

organisms' performance and distribution will change both predator-prey and competitive interactions, which could impact food webs and higher trophic levels (*limited evidence, high agreement*). [6.3]

A few studies provide *limited evidence* for adaptation in phytoplankton and mollusks. However, mass extinctions during times in Earth history with much slower rates of ocean acidification suggest that evolutionary rates are too slow for sensitive species to adapt to the projected rates of change (*high confidence*). [6.1.2]

The biological, ecological, and biogeochemical changes driven by ocean acidification will affect key ecosystem services. The oceans will become less efficient at absorbing CO_2 and hence moderating climate (*very high confidence*). The impacts of ocean acidification on coral reefs, together with those of bleaching and sea level rise, will diminish their role in shoreline protection as well as their direct and indirect benefits on the tourism industry (*limited evidence, high agreement*). [Box CC-CR] The global cost of production loss of mollusks could be over 100 billion USD by 2100. The largest uncertainty is how the impacts on prey will propagate through marine food webs. Models suggest that ocean acidification will generally reduce fish biomass and catch (*limited evidence, high agreement*) and that complex additive, antagonistic, and/or synergistic interactions will occur with other environmental and human factors.

[INSERT BOX TS.9 FIGURE 1 HERE
Box TS.9 Figure 1: A) Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options. B) Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival, which is not weighted. The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect. [Box CC-OA]]

_____ END BOX TS.9 HERE _____

D) BUILDING RESILIENCE THROUGH MITIGATION, ADAPTATION, AND SUSTAINABLE DEVELOPMENT

This section evaluates the ways that human and social-ecological systems can build resilience through mitigation, adaptation, and sustainable development. It assesses understanding of climate-resilient pathways and of incremental versus transformational changes, and it considers co-benefits, synergies, and tradeoffs among mitigation, adaptation, and development.

D.i. Climate-resilient Pathways and Transformation

Climate change calls for new approaches to sustainable development that take into account complex interactions between climate and social-ecological systems (see Figure TS.16). Climate-resilient pathways for development are rooted in iterative processes of identifying vulnerabilities to climate change impacts; taking appropriate steps to reduce vulnerabilities in the context of development needs and resources and to increase the options available for vulnerability reduction and coping with surprises; monitoring emerging climate parameters and their implications, along with monitoring the effectiveness of vulnerability reduction efforts; and revising risk reduction responses on the basis of continuing learning. This process may involve a combination of incremental changes and, as necessary, significant transformations. [20.2.3.1, 20.6.2]

[INSERT FIGURE TS.16 HERE
Figure TS.16: Conceptual framework for assessing interactions between biophysical and societal stressors that impact the resilience of natural and human systems today and in the future. Actions, including climate change adaptation and mitigation, taken in the opportunity space lead to a diverse range of pathways and outcomes—toward a future of high risk, high vulnerability, and low resilience space or toward a future of low risk, low vulnerability, and high resilience space. [Figure 1-7]]

Assessment findings integrate a variety of complex issues in assessing climate-resilient pathways in a variety of regions at a variety of scales: sustainable development as the ultimate aim, mitigation as the way to keep climate change impacts moderate rather than severe, adaptation as a response strategy to cope with impacts that cannot be (or are not) avoided, and elements of sustainable development pathways that contribute to climate-resilience. In most cases, vulnerability reduction and appropriate risk management approaches will differ from situation to situation, calling for a multi-scale perspective. But most situations share at least one fundamental characteristic: threats to sustainable development are greater if climate change is substantial than if it is moderate.

The findings are based on a high level of consensus in source materials and in the expert communities, although the amount of supporting evidence is usually limited by the fact that so many aspects of sustainable development and climate change mitigation and adaptation, considered together over periods many decades into the future, are surrounded by issues that are beyond past and current observation and experience. The task of this part of the assessment is to move out into uncharted territory.

Because climate change is a growing threat to development, it is a high priority to identify and pursue climate-resilient pathways for sustainable development (*high confidence* based on *high agreement, medium evidence*). Added to other stresses on sustainable development, effects of climate change will make sustainability more difficult to achieve for many locations, systems, and affected populations, related to such objectives as poverty reduction, health, and livelihood security; but climate-resilient pathways can improve prospects for sustainable development. [20.2]

Climate-resilient pathways include (a) actions to reduce climate change and its impacts and (b) actions to assure that effective risk management and adaptation can be implemented and sustained (*high confidence*, based on *high agreement, medium evidence*). Adaptation and mitigation have the potential to both contribute to and impede sustainable development, and sustainable development strategies and choices have the potential to both contribute to and impede climate change responses. Both kinds of responses are needed, working together to reduce risks of disruptions from climate change. [20.3, 20.4]

In some cases, each of the two categories of responses can benefit the other as well, offering potentials for co-benefits from integration (*medium* to *high confidence,* based on *medium* to *high agreement, medium evidence*). Development pathways that are resilient with respect to a wide range of challenges and threats are more likely to be climate-resilient, while climate change risk reduction can contribute to strengthening capacities for risk management in other regards as well. Strategies to achieve each goal have the potential to reinforce the other, but windows of opportunity may narrow with time. [20.2.1, 20.3.3]

Paying attention to dynamic livelihoods and multidimensional poverty and the multifaceted impacts of climate change and climate change responses is central to achieving climate-resilient development pathways (*high confidence*). Business-as-usual development and climate policies will bring the poor and the marginalized precariously close to the two most undesirable future scenarios as conceptualized in the shared socio-economic pathways (SSPs): social fragmentation (fragmented world) and inequality (unequal world). Global inequality has been increasing, with new poverty pockets emerging in middle- and high-income countries and shifts from transient to chronic poverty, while at the level of communities, elite capture and unsupportive policy structures often propel less affluent households into deeper poverty. [13.4]

Avoiding limits to adaptation is a complex management challenge necessitating new integrative forms of risk governance (*medium agreement, limited evidence*). Limits to adaptation are influenced by cultural, institutional, and socio-economic factors. Consequently, avoiding limits will necessitate policy responses and awareness that goes beyond greenhouse gas mitigation and adaptation responses alone. Driving forces such as inequality and the disproportionate vulnerability of marginalized actors to climate-related disasters and catastrophic losses will need to be addressed. Hence, a portfolio of local, national, and international strategies will be needed to facilitate sustainable development that expands the range of climate to which socio-ecological systems can adapt. [16.4, 16.6, 16.7]

Prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation (*high confidence,* based on *high agreement, medium evidence*). As the magnitude of climate change grows, the challenges to climate resilience grow; and above some high level of climate change, the impacts on most systems would be great enough that climate-resilience is no longer possible for many systems and locations (see Box TS.10). [20.6.1]

Because climate change vulnerabilities are significant for many areas, systems, and populations, climate-resilient pathways will often require transformations in order to assure sustainable development (*high confidence,* based on *high agreement, medium evidence*). Significantly large and/or rapid increases in extreme weather and climate events are less amenable to incremental adaptations to climate change and will often require more transformational change if development is to be sustained without major disruptions (see Box TS.10). [20.5]

At a global scale, climate-resilient pathways will include both climate change adaptation and mitigation. At sub-global scales, climate-resilient pathways will involve a range of actions appropriate to potentials for vulnerability/risk reduction at those scales (*high confidence,* based on *high agreement, medium evidence*). Although at a global scale both mitigation and adaptation are essential, relatively local scales in many developing regions have limited capacities to include mitigation in their climate-resilience strategies because they contribute very little to the causes of climate change. At all scales, however, actions are important to assure that effective risk management can be implemented and sustained. [20.2.3, 20.6.1]

D.ii. Examples of Co-benefits, Synergies, and Tradeoffs

Responses to the risks of climate change can have implications beyond their primary objectives for the resilience of societies and systems.

Example interactions among impacts and adaptation responses

Adaptation designed for one sector may interfere with the functioning of another sector, creating new risks (*high confidence*). For example, increasing crop irrigation in response to a drying climate can exacerbate water stress in downstream wetlands, where the latter otherwise provide important water cleaning services (*high*

confidence). Examples of potential trade-offs among adaptation objectives are provided in Table TS.9. [4.3.3, 4.3.4, 19.3.2]

[INSERT TABLE TS.9 HERE
Table TS.9: Examples of potential trade-offs among adaptation objectives. [Table 16-2]]

Example interactions among impacts and mitigation responses

Certain approaches to reduce greenhouse-gas emissions imply greater risks for freshwater systems than others (*high agreement, limited evidence*). Bioenergy crops can require larger amounts of water for irrigation than the amount of water for other mitigation measures. Hydropower has negative effects on freshwater ecosystems that can be reduced by appropriate management. Carbon capture and storage can decrease groundwater quality. In some regions, afforestation can reduce renewable water resources but also flood risk. [3.7.2]

Use of the terrestrial biosphere in climate mitigation actions, such as through introduction of fast-growing tree species for carbon sequestration or the conversion of forest to biofuel plantations, may lead to negative impacts on ecosystems and biodiversity (*very high confidence*). The land use scenario accompanying the mitigation scenario RCP2.6, intended to avoid 2°C global warming, features large expansion of biofuel production displacing natural forest cover. [4.2.4]

Achieving emission targets without putting a price on carbon emissions from land-use has the potential to lead to very large reductions in forested area, and much higher overall costs for mitigation, compared to meeting the same targets while putting a price on all carbon emissions. Similarly, substantial regional variation in the availability of technologies exists, but the differences in how these are represented regionally are largely unexplored. [21.5.3]

There are opportunities to both reduce emissions of climate altering pollutants and at the same time improve local health in the communities that take action, as well as protecting health for populations worldwide through climate change abatement. Among others, mitigation-related actions with health co-benefits include:

- Reducing local emissions of health-damaging and climate-altering air pollutants from energy production and use in households and communities, through better combustion, energy efficiency, and a shift to cleaner renewable energy sources (*very high confidence*). [11.9]
- Providing access to reproductive health services and thus improving child and maternal health through increased birth spacing, while reducing population growth and consequent climate altering pollutant emissions over time (*high confidence*). [11.9]

Example interactions among mitigation, adaptation, and development

Climate policies, such as encouraging cultivation of biofuels and payments under REDD, will result in mixed and potentially detrimental impacts on land-use and on the livelihoods of poor and marginalized people (*medium confidence*). Mitigation efforts such as CDM and REDD+, as well as land acquisition for food and biofuel production, show preliminary negative impacts on the poor, particularly indigenous people and (women) smallholders. In rural areas, secondary impacts and trade-offs between mitigation and adaptation have implications for governance. Insurance schemes, social protection programs, and disaster risk reduction may enhance long-term livelihood resilience among poor and marginalized people, if policies address multidimensional poverty. Climate-resilient development pathways will have only marginal effects on poverty reduction, unless structural inequalities are removed and needs for equity among the poor and non-poor met. [9.3.3, 13.3.1, 13.3.2, 13.4.1, 13.4.2]

In Europe, there are opportunities for policies that improve adaptive capacity and also help meet mitigation targets (*high confidence*). Some agricultural practices can potentially mitigate GHG emissions and at the same time adapt crops to increase resilience to temperature and rainfall variability. Climate policy in transport and energy sectors to reduce emissions can improve population health. However there is also potential for unintended consequences of mitigation policies in the built environment (especially housing) and energy sectors. [23.8]

In Asia, multiple stresses caused by rapid urbanization, industrialization, and economic development will be compounded by climate change (*high confidence*). Climate change is expected to adversely affect sustainable development capabilities of most Asian developing countries by aggravating pressures on natural resources and the environment. Development of sustainable cities in Asia with fewer fossil fuel driven vehicles and with more trees and greenery would have a number of co-benefits including for public health. [24.4, 24.5, 24.6, 24.7]

For Australasia, significant synergies and trade-offs exist between alternative adaptation responses, and between mitigation and adaptation responses; interactions occur both within Australasia and between Australasia and the rest of the world (*very high confidence*). Increasing efforts to mitigate and adapt to climate change imply an increasing complexity of interactions, particularly at the intersections among water, energy, and biodiversity, but tools to understand and manage these interactions remain limited. Flow-on effects from climate change impacts and responses outside Australasia have the potential to outweigh some of the direct impacts within the region, particularly economic impacts on trade-intensive sectors such as agriculture (*medium confidence*), but they remain amongst the least explored issues. [25.7.5, 25.9.1, 25.9.2, Box 25-10]

Throughout North America, adaptation actions at the local level have the potential to result in synergies, conflicts, or tradeoffs with mitigation and other development actions and goals (*high confidence*). For example, reductions in emissions of greenhouse gases will in many cases bring proximal benefits for human health by reducing health-damaging air pollution concentrations. Conversely, sea walls can protect coastal properties, yet may negatively affect the structure and function of coastal ecosystems. [26.8]

In Central and South America, long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the population. Such conditions weaken the importance of adaptation planning to climate change on the political agenda. Various examples demonstrate possible synergies between development, adaptation, and mitigation planning, which can help local communities and governments to allocate efficiently available resources in the design of strategies to reduce vulnerability. [27.3.4, 27.4.1, 27.4.2, 27.4.3, 27.4.4, 27.5].

In Central and South America, renewable energy has a potential impact on land use change and deforestation, but at the same time will be an important means of adaptation, particularly in Southeastern South America. Hydropower is currently the main source of renewable energy in Central and South America, followed by biofuels, notably bioethanol from sugarcane and biodiesel from soy. Southeastern South America is one of the main sources of production of the feedstocks for biofuels' production. Sugarcane and soy are *likely* to respond to the elevation of CO_2 and temperature with an increase in growth, which might lead to an increase in productivity and production. However, the drought effects expected for some regions in Central and South America will be critical, and scientific knowledge has to advance in this area. Advances in second generation bioethanol from sugarcane and other feedstocks will be important as a measure of adaptation, as they have the potential to increase biofuels productivity in the region. In spite of the large amount of arable land available in the region, the expansion of sugarcane and soy, related to biofuels production, might have some indirect land use change effects, producing teleconnections that could lead to deforestation in the Amazon and loss of employment in some countries. This is especially derived from the expansion of soy, which is used for biodiesel production inclusively. [27.3.6]

For small islands, adaptation and mitigation are not trade-offs, but can be regarded as complementary components in the response to climate change (*medium confidence*). For most small islands climate change is just one of a series of multiple stresses that must be coped with, and often it is not the most important one. Three key areas for adaptation-mitigation inter-linkages in small islands are identified: energy supply and use, tourism infrastructure and activities, and coastal wetlands. The alignment of these sectors for potential emission reductions together with adaptation needs offers co-benefits and opportunities in small islands. Lessons learned from adaptation and mitigation experiences in one island may offer some guidance to other small island states, though we have *low confidence* in the wholesale transfer of adaptation and mitigation options when the lenses through which they are viewed differ from one island state to the next, based on cultural, socio-economic, ecological, and political values. [29.6.2.1, 29.7.2, 29.8, 29.3.3]

For small islands, assistance from the international community is vital for supporting adaptation and mitigation programs, though there is increasing concern that some types of interventions may be maladaptive (*high agreement, medium evidence*). Caution is needed to ensure that donors are not driving the climate change

agenda in small islands, as there is a risk that donor-driven adaptation and mitigation aid may not address the critical challenges confronting island governments and communities, and may not be aligned with the sustainable development goals of small islands. This may lead to inadequate adaptation or a waste of scarce resources and may unintentionally cause enhanced vulnerability by supporting inappropriate adaptation strategies that are externally derived, rather than optimizing the benefits of local practices that have proven to be efficacious through time. [29.8, Box 29-1, 29.6.2.3, 29.6.3]

Table TS.10 provides further specific examples of interactions to complement the assessment findings above.

[INSERT TABLE TS.10 HERE
Table TS.10: Illustrative examples of intra-regional interactions among adaptation, mitigation, and sustainable development.]

Box TS.10. Adaptation Limits and Transformation

Adaptation can expand the capacity of natural and human systems to cope with a changing climate. However, there are limits to adaptation that, when exceeded, prevent the achievement of management goals or the maintenance of societal values. Such limits are context-specific and subject to uncertainty. Therefore, they are best considered in a risk management context that focuses on the values and objectives of actors. This allows limits to be defined as the point at which an actor's objectives (or biophysical system needs) cannot be secured from intolerable risks through adaptive actions (see Box TS.10 Figure 1). [16.2, Box 16-2] The determination of what constitutes an intolerable risk is made by actors at different scales of governance through processes of deliberation and social learning. Beyond a limit, there must be a change in objectives or needs, else actors will experience an escalating risk of loss and damage. [16.2, 16.4.3, 20.5, 20.6.1]

Limits to adaptation can arise from a diverse array of factors. The rate and magnitude of climate and socioeconomic changes are key determinants of adaptation limits, as they influence the vulnerability of natural systems as well as their capacity to respond. [16.3.1] The Representative Concentration Pathways and Shared Socioeconomic Pathways, for example, represent a broad range of greenhouse gas emissions futures and socioeconomic development storylines. [Box 20-3] The greater the rate and magnitude of climate change, the more likely limits to adaptation will be exceeded. [16.4.2, 20.5.1] Limits also arise from the subjective values of societal actors, which influence both the demand for adaptation and the perceived appropriateness of specific policies and measures. [16.2, 16.3.1, 16.3.4, 16.4.1] While limits fundamentally imply that adaptation can no longer avoid intolerable impacts, they can be viewed as "soft" if there are opportunities for impacts to be reduced over time through, for example, changes in laws, institutions, or values or the emergence of new technologies. [16.4.1] In contrast, "hard" limits are those which cannot be reduced through human agency and tend to be associated with biophysical processes, such as climate thresholds in natural systems. [16.4.1]

The Earth System is committed to some climate change in the future, and some degree of loss and damage may be inevitable. [20.5.1] Considering that climate change can include large-scale discontinuities and irreversible adverse consequences, the existence of limits to adaptation suggests greater attention to deliberate transformational change is needed. Such transformations, defined as fundamental changes in the attributes of a system, can occur through social and technological innovations or changes in behavior or institutions, but often they involve changes in political, economic, social, cultural or legal systems, as well as changes in individual and collective beliefs, values, and worldviews. [20.5.2] As such, transformational change may trigger societal debate over the acceptability of risk, mitigation, and adaptation strategies in order to reconcile conflicting goals and visions of the future while placing new and increased demands on governance structures at multiple levels.

_____ END BOX TS.10 HERE _____

WGII Frequently Asked Questions

Chapters of the report supporting each FAQ are provided in square brackets.

1. Are we seeing impacts of climate change?

Yes, many climate-change impacts are already apparent. Impacts of recent observed climate change on physical, biological, and human systems have been detected on all continents and in most oceans. We have *medium* to *very high confidence* that several regions have experienced warming trends and more frequent high-temperature extremes. We have *high* to *very high confidence* that, due to rising temperatures, hydrological cycles have been disrupted by decreased snowpack, degradation of permafrost regions, and diminishing glaciers. Moreover, many ecosystems are experiencing climate-induced shifts in the activity, range, or abundance of the species that inhabit them, leading to changes in ecosystem function. There is emerging evidence that oceans are also displaying changes in physical and chemical properties that, in turn, are affecting coastal and marine ecosystems such as coral reefs, and other oceanic organisms such as crustaceans and zooplankton. Crops and other managed ecosystems are seeing changes as well. While crop yields and fishery stocks are sensitive to changes in temperature; only *limited evidence* confirms a role of climate change in crop and fish production.

[Chapters 3, 4, 5, 6, 7, 18, 22, 24, 25, 27, and 30; SPM]

2. Has climate change already affected food production?

Changes in crop and aquaculture production are sensitive to both climatic drivers and non-climatic socioeconomic drivers, making it difficult to isolate the changes caused by climate change. However, there is emerging evidence that agricultural crop yields are changing in many regions in response to climate. For example, there is *medium confidence* that declines attributable to climate change have been observed in the yields of wheat crops of some European countries. Moreover, there is *high confidence* that extreme heat has a negative effect on food nutritional quality. There is emerging evidence that other parts of the Earth system altered by climate change, (e.g. atmospheric CO_2, tropospheric ozone, and water and nitrogen cycles) can alter food production in complex ways. Hence, climate change will continue to affect food systems, with impacts that are widespread, complex, and varying over space and time.

[Chapters 6, 7, 18, 19, 22, and 23]

3. Is climate change bad news for everyone or will there be winners and losers?

Of the many climate-change impacts assessed in this report, only a few are positive. They will not be felt equally around the world. There is *very high confidence* that climate changes interact with vulnerability and exposure to shape differential risks and impacts. Climate change can act as a threat multiplier for those at the social or economic margins or in unfavorable locations. Climate change will have different implications for people across the world, with impacts that vary over time and depend on the rate and magnitude of climate change. For example, there is *medium* to *high confidence* that some countries will have increased opportunities for economic development, reduced instances of some diseases, or expanded areas of productive land. Other countries will face increased challenges for economic development, increased risks of some diseases, or degraded ecosystems. There is *medium confidence* that crop yields will vary by latitude, with yield losses in the tropics. In temperate regions, climate change could stimulate yield increases over the next few decades but decrease them after that. There is *high confidence* that the potential global catch for fisheries will change, with both positive and negative consequences from climate-induced impacts on ocean mixing and shifts in species range.

[Chapters 4, 6, 7, 10, 11, 13, 22, 25, and 30]

4. What aspects of ecosystems will change due to climate change, and how will that affect communities?

There is *high confidence* that many ecosystems are sensitive to climate change, interacting with other human activities. Changes in ecosystems influence society through diverse effects on available natural resources and ecosystem services. For example, there is emerging evidence that reductions in fish stocks will affect the livelihoods

of fishing communities, as well as food security for those that rely on fish. There is *medium* to *high confidence* that ecosystem impacts can include losses of carbon, increased likelihood of the establishment and spread of invasive alien species, and loss of valuable biodiversity, disrupting ecosystem services that contribute towards the quality of human life.

[Chapters 4, 19, and 30]

5. What are key vulnerabilities, and what kinds of factors contribute to them?

Key vulnerabilities are those that have the potential to combine with climate-change impacts to result in severe consequences for society or social-ecological systems. Seven factors contribute to a key vulnerability. These are:

- the exposure of societies, communities, or social-ecological systems to climatic stressors
- the probability that these would experience major harm, loss, and damages
- the importance of the vulnerable systems
- the limited ability of societies or communities to cope with the climate-related hazards within existing capacities
- the limited ability of societies or communities to build adaptive capacities to reduce or limit vulnerability as environmental and climatic conditions change
- the persistence of vulnerable conditions and degree of irreversibility of consequences
- the presence of conditions that make societies highly susceptible or sensitive to cumulative stressors in complex, interacting systems

[Chapter 19]

6. Does climate change cause violent conflicts?

There is *medium confidence* that some factors that increase the risk of violent conflicts and civil wars are sensitive to climate change. *Robust evidence* demonstrates that low per capita incomes, economic contraction, and inconsistent state institutions, all of which are sensitive to climate change, are associated with the incidence of civil wars. There is little agreement about whether these factors cause violent conflicts. Climate-change policies, particularly those associated with changing property rights, can increase the risk of violent conflict. Policies and institutions at multiple scales that encourage economic growth, high per capita incomes, strong democratic institutions, social protection during economic and climate shocks, and robust institutional structures that protect property rights and manage conflicts reduce the risk that climate variability and extremes will lead to violence.

[Chapter 19]

7. How is ocean acidification related to climate change and how does it affect marine and coastal areas?

Ocean acidification is a consequence of increased atmospheric CO_2. This leads to a net transfer of CO_2 from the atmosphere to the oceans, resulting in an increase in dissolved CO_2 and a reduction in pH. Seawater with higher dissolved CO_2 has lower concentrations of dissolved carbonate ion, the building block for shells and skeletons of many marine organisms. There is *high confidence* that seawater acidity (pH) has numerous implications for ocean and coastal processes and organisms, including rates of primary production, the deposition of calcium carbonate in shells and skeletons, and the degradation of limestone.

[Chapter 5; Cross-chapter Box, Ocean Acidification]

8. What communities are most vulnerable to impacts of climate change?

Every society is vulnerable to the threats from climate change, although the nature of that vulnerability varies across regions and communities, and over time. Poorer communities tend to be more vulnerable to loss of life, while wealthier communities have more economic assets at risk. There is *high confidence* that differences among communities in age, race and ethnicity, socio-economic status, and governance have had significant influence on the outcome of past weather and climate extremes. Regions affected by violence or governance failure are particularly

vulnerable. Other development challenges, such as gender inequality and low levels of educational attainment, also make communities vulnerable to climate change.

[Chapters 9, 10, 19, 26, and 27]

9. How are adaptation, mitigation, and sustainable development connected?

Adaptation, mitigation, and sustainable development are intrinsically related to each other in the context of climate change. Mitigation reduces the likelihood of physical impacts. Adaptation reduces the vulnerability and exposure of societies and ecosystems to those impacts. Together, both responses help define climate-resilient pathways that contribute to long-term sustainable development. There is *very high confidence* that interactions between adaptation and mitigation responses have both potential synergies and tradeoffs that vary according to context. There are many examples of the potential for co-benefits, but there are also examples of competitive relationships between adaptation and development, which, when poorly implemented, can aggravate the condition of vulnerable communities. Integrating adaptation, mitigation, and sustainable development simultaneously in long-term planning has the potential to amplify the benefits of each.

[Chapters 9, 13, 17, 19, 20, 25, and 29]

10. Why is it difficult to attribute observed changes to climate change?

Attribution addresses the question of whether observed changes were caused by climate change. The main challenge in attribution is separating the role of climate change from the roles of other factors. For example, widespread flooding in Australia and other parts of the western Pacific during 2010 and 2011 was caused by unusually heavy rainfall. This was related to La Niña conditions. La Niña is part of the naturally occurring ENSO variation, making it impossible, based on the available evidence, to attribute the flooding to climate change. In human systems, attributing observed changes to climate change is complicated by interactions with the effects of economic and social factors. The emerging literature discussing the relationship between climate change and poverty, working conditions, violent conflict, migration, and economic growth has many examples, but unequivocal attribution remains a challenge.

[Chapter 18]

11. Are risks of climate change mostly due to changes in extremes, changes in average climate, or both?

People and ecosystems across the world experience climate in many different ways. Average climate conditions are important. They provide a starting point for understanding how far ecosystems extend north and south, and for informing decisions about tourist destinations, other business opportunities, and crops to plant. But weather and climate extremes strongly influence losses and dislocations. Crops can fail following flood or drought. Buildings constructed to stricter codes are more likely to weather the waves or winds of a storm. And forests burn when high winds combine with low humidity. In a changing climate, many impacts for people, ecosystems, activities, and infrastructure will occur due to changes in the intensity, frequency, or duration of weather and climate extremes.

[Chapters 2, 4, 7, 8, 9, 10, 12, 13, 20, and 25; TS]

12. How much do we know about the world in 2100?

People can often guess what tomorrow might bring. But anticipating the future 5, 10, or 50 years out is increasingly difficult. On the scale of decades, technological revolutions, political movements, or singular events can shape the course of history in unpredictable ways. To understand potential impacts of climate change for societies and ecosystems at the end of this century, scientists use a variety of approaches. One is recognizing consequences of some intrinsic limits. The total amount of land or the number of species of mammals will not increase, for example. Another opportunity builds on simple relationships that have been robust over long periods. Scenarios are internally consistent descriptions of possible futures, reflecting factors like possible population growth, investments in technology, and commitments to protecting the environment. Over timeframes of a few years to as much as a century, they provide powerful means of exploring the implications of decisions that affect people, ecosystems, and

economies. Scenarios can also link patterns of greenhouse gas emissions to underlying societal and economic trends, bridging from decisions to their consequences for climate.

[Chapters 1, 2, 4, 6, 17, 20, and 21; TS]

13. Why is climate change a challenge of managing risks?

For individuals, enterprises, or nations, success can hinge on making good decisions under uncertainty. Effective decisionmaking under uncertainty considers outcomes that are highly likely, but it also considers less probable outcomes that would have big consequences. As the WGII AR5 demonstrates, we know a great deal about impacts of climate change that have already occurred, and we understand many aspects of impacts projected for the future. But impacts of climate change also involve uncertainties, including some that are persistent. Future emissions of greenhouse gases will depend on societal decisions not yet made. Modeling future climate change and impacts entails uncertainties due to variability in Earth's physical systems and ecosystems and due to limits of current scientific understanding. We also have limited ability to characterize fully the resilience of people and ecosystems experiencing impacts. Good decisions about avoiding or managing the consequences of climate change build on available information, recognizing the value of timely investments and actions, even with consequential uncertainty. Managing risks positions societies, economies, and ecosystems to capitalize on the upside outcomes of climate change, while preparing for the full range of possible downside outcomes.

[Chapters 1, 2, 17, 19, 20, 21, and 25; TS]

14. What are the timeframes for mitigation and adaptation benefits?

Adaptation can reduce the damage from impacts that cannot be avoided. Mitigation strategies can decrease the amount of climate change that occurs, as summarized in the WGIII AR5. But the consequences of investments in mitigation emerge incrementally, not immediately. Over the next few decades, the climate change we experience will be determined primarily by the combination of past actions and current trends in greenhouse gas emissions. The next few decades are, in essence, an era of climate responsibility, where short-term risk reduction comes from adapting to the changes already underway, while we also take responsibility for the leverage of mitigation on the potential for climate change in the latter decades of the century, the era of climate options.

[Chapters 1, 2, 16, 19, 20, and 21; TS]

15. Can science identify thresholds beyond which climate change is dangerous?

Anthropogenic interference with the climate system is occurring. The impacts of climate change are already widespread and consequential. Determining whether anthropogenic interference is dangerous involves judgments about risks. Science can quantify risks in a technical sense, based on the probability, magnitude, and scope of potential consequences of climate change. Interpreting risks and the scale at which they become dangerous, requires value judgments, made by people with differing goals and worldviews and without full certainty of what the future will hold. Judgments about the risks of climate change depend on the relative importance ascribed to the present vs. the future, to economic vs. cultural, natural, and aesthetic assets, and to global GDP versus the interests of the most vulnerable. Isolated or infrequent damages from climate change may not rise to the level of dangerous anthropogenic interference, but accumulation of the same kinds of damages could, as they become more widespread, more frequent, or more severe. The IPCC assesses scientific and technical understanding of risks and the range of possible outcomes. It also assesses understanding of how risks are perceived, as well as methods for incorporating different value systems in decisionmaking. The IPCC cannot, however, make a determination of the level of anthropogenic interference that is dangerous.

[Chapters 1, 2, 4, 5, 6, 17, 18, 19, and 25; TS]

WGII CROSS-CHAPTER BOXES

Box CC-EA. Ecosystem Based Approaches to Adaptation - Emerging Opportunities

[Rebecca Shaw (USA), Jonathan Overpeck (USA), Guy Midgley (South Africa)]

Ecosystem-based approaches to adaptation (also termed Ecosystem-based Adaptation, EBA) integrate the use of biodiversity and ecosystem services into climate change adaptation strategies (e.g., CBD, 2009; Munroe *et al.*, 2011; Munroe *et al.*, 2011). EBA is implemented through the sustainable management of natural resources, as well as conservation and restoration of ecosystems, to provide and sustain services that facilitate adaptation both to climate variability and change (Colls *et al.*, 2009). The CBD COP 10 Decision X/33 on Climate Change and Biodiversity states further that effective EBA also "takes into account the multiple social, economic and cultural co-benefits for local communities".

The potential for EBA is increasingly being realized (e.g., Munroe *et al.*, 2011), offering opportunities that integrate with or even substitute for the use of engineered infrastructure or other technological approaches. Engineered defenses such as dams, sea walls and levees, may adversely affect biodiversity, resulting in maladaptation due to damage to ecosystem regulating services (Campbell *et al.*, 2009, Munroe *et al.*, 2011). There is some evidence that the restoration and use of ecosystem services may reduce or delay the need for these engineering solutions (CBD, 2009). Well-integrated EBA is also more cost effective and sustainable than non-integrated physical engineering approaches, and may contribute to achieving sustainable development goals (e.g., poverty reduction, sustainable environmental management, and even mitigation objectives), especially when they are integrated with sound ecosystem management approaches. EBA also offers lower risk of maladaptation than engineering solutions in that their application is more flexible and responsive to unanticipated environmental changes.

EBA provides opportunities particularly in developing countries where economies depend more directly on the provision of ecosystem services (Vignola *et al.*, 2009), to reduce risks to climate change impacts and ensure that development proceeds on a pathways that are resilient to climate change (Munang *et al.*,). In these settings, ecosystem-based adaptation projects may be readily developed by enhancing existing initiatives, such as community-based adaptation and natural resource management approaches (e.g., Khan *et al.*, 2012, Midgley *et al.*, 2012; Roberts *et al.*, 2012)

Examples of ecosystem based approaches to adaptation include:

- Sustainable water management, where river basins, aquifers, flood plains, and their associated vegetation are managed or restored to provide resilient water storage and enhanced baseflows, flood regulation services, reduction of erosion/siltation rates, and more ecosystem goods (e.g., Midgley *et al.*, 2012, Opperman *et al.*, 2009).
- Disaster risk reduction through the restoration of coastal habitats (e.g., mangroves, wetlands and deltas) to provide effective measure against storm-surges, saline intrusion and coastal erosion;
- Sustainable management of grasslands and rangelands to enhance pastoral livelihoods and increase resilience to drought and flooding;
- Establishment of diverse and resilient agricultural systems, and adapting crop and livestock variety mixes to secure food provision. Traditional knowledge may contribute in this area through, for example, identifying indigenous crop and livestock genetic diversity, and water conservation techniques;
- Management of fire-prone ecosystems to achieve safer fire regimes while ensuring the maintenance of natural processes.

It is important to assess the appropriate and effective application of EBA as a developing concept through learning from work underway, and to build understanding of the social and physical conditions that may limit its effectiveness. Application of EBA, like other approaches, is not without risk, and risk/benefit assessments will allow better assessment of opportunities offered by the approach.

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water structures made of calcium carbonate mostly secreted by reef-building (scleractinian) corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics. About 275 million people live within 30 km of a coral reef (Burke et al., 2011) and are likely to derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including those from provisioning (food, construction material, medicine), regulating (shoreline protection, water quality), supporting services (oxygen supply) and cultural (religion, tourism). This is especially true in small islands (29.3.3.1).

Most human-induced disturbances to coral reefs were local (e.g., coastal development, pollution, nutrient enrichment and overfishing) until the early 1980s when global and climate-related disturbances (ocean warming and acidification) began to occur. Temperature and seawater acidity are two of the most important environmental variables determining the distribution of coral reefs (Kleypas et al., 2001). As corals are centrally important as ecosystem engineers (Wild et al., 2011), the impacts on corals have led to widespread degradation of coral reefs.

A wide range of climatic and non-climatic stressors affect corals and coral reefs and negative impacts are already observed (5.4.2.4, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae (genus *Symbiodinium*), which live in the coral tissues and play a key role in supplying the coral host with energy and nutrients (Baker et al., 2008) (see 6.2.5 for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies, is the most widespread and conspicuous impact (Fig. 5X; see Sections, 5.4.2.4, 6.2.5, 25.6.2, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Elevated temperature along with ocean acidification reduces the calcification rate of corals (*high confidence*; 5.4.2.4), and may tip the calcium carbonate balance of reef frameworks towards dissolution (*medium evidence and agreement*; 5.4.2.4). These changes will erode fish habitats with cascading effects reaching fish community structure and associated fisheries (*robust evidence, high agreement*, 30.5).

Around 50% of all coral reefs have experienced medium-high to very high impact of human activities (30-50% to 50-70% degraded; Halpern et al., 2008), which has been a significant stressor for over 50 years in many cases. As a result, the abundance of reef building corals is in rapid decline (1 to 2% per year, 1997-2003) in many Pacific and SE Asian regions (Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner et al., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and coral bleaching have led to a decline in coral cover on the Great Barrier Reef (about 51% between 1985 and 2012; De'ath et al., 2012).

One third of all coral species exhibit a high risk of extinction, based on recent patterns of decline and other factors such as reproductive strategy (Carpenter et al., 2008). Although less well documented, non-coral benthic invertebrates are also at risk (Przeslawski et al., 2008). Fish biodiversity is threatened by the permanent degradation coral reefs, including in a marine reserve (Jones et al., 2004). While many factors, such as overfishing and local pollution, are involved in the decline of coral reefs, climate change through its pervasive influence on sea temperature, ocean acidity, and storm strength plays a very significant role.

There is *robust evidence* and *high agreement* that coral reefs are one of the most vulnerable marine ecosystems (Chapters 5, 6, 25, and 30). Globally, more than half of the world's reefs are under medium or high risk of degradation (Burke et al., 2011) even in the absence of climatic factors. Future impacts of climate stressors (ocean warming, acidification and sea level rise) will exacerbate the impacts of non-climatic stressors (*high agreement, robust evidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9–60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation under the RCP3-PD scenario (Frieler et al., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30–88%, 68% uncertainty range). If present day corals have residual capacity to acclimatize and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited*

agreement; Logan et al., sbm). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs produce 10-12% of the fish caught in tropical countries, and 20-25% of the fish caught by developing nations (Garcia & Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton et al. (2012) are already exploiting their coral reef fisheries in an unsustainable way (13.X.X).
- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke et al., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).
- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard et al., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4, 30.5).

Coral reefs make a modest contribution to the global domestic product but their economic importance can be high at the country and regional scales (Pratchett et al., 2008). For example, tourism and fisheries represent on average 5% of the GDP of South Pacific islands (Laurans et al., 2013). At the local scale, these two services provide at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans et al., 2013).

Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod et al., 2009). Although they are key conservation and management tools, they are less effective in reducing coral loss from thermal stress (Selig et al., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau et al., 2012). Controlling the input of nutrients and sediment from land is an important complementary management strategy because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann et al., 2012). There is also high confidence that, in the long term, limiting the amount of warming and acidity is central to ensuring the viability of coral reef systems and dependent communities (5.X.X and 30.5).

[INSERT FIGURE CR-1 HERE

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

Box CC-RF. Impact of Climate-Change on Freshwater Ecosystems due to Altered River Flow Regimes
[Petra Döll (Germany), Stuart E. Bunn (Australia)]

It is widely acknowledged that the flow regime is a primary determinant of the structure and function of rivers and their associated floodplain wetlands, and flow alteration is considered to be a serious and continuing threat to freshwater ecosystems (Bunn and Arthington, 2002; Poff and Zimmerman, 2010; Poff *et al.*, 2010). Most species distribution models do not consider the effect of changing flow regimes (i.e. changes to the frequency, magnitude, duration and/or timing of key flow parameters) or they use precipitation as proxy for river flow (Heino *et al.*, 2009).

There is growing evidence that climate change will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (Aldous *et al.*, 2011; Xenopoulos *et al.*, 2005). By the 2050s, climate change is projected to impact river flow characteristics like long-term average discharge, seasonality and statistical high flows (but not statistical low flows) more strongly than dam construction and water withdrawals have done up to the year 2000 (Figure RF-1; Döll and Zhang, 2010). For one climate scenario, 15% of the global land area may suffer, by the 2050s, from a decrease of fish species in the upstream basin of more than 10%, as compared to only 10% of the land area that has already suffered from such decreases due to water withdrawals and dams (Döll and Zhang, 2010). Climate change may exacerbate the negative impacts of dams for freshwater ecosystems but may also provide opportunities for operating dams and power stations to the benefit of riverine ecosystems. This is the case if total runoff increases and, like in Sweden, the annual hydrograph becomes more similar to variation in electricity demand, i.e. with a lower spring flood and increased run-off during winter months (Renofalt *et al.*, 2010).

[INSERT FIGURE RF-1 HERE
Figure RF-1: Impact of climate change on the ecologically relevant river flow characteristics mean annual river flow and monthly low flow Q_{90} as compared to the impact of water withdrawals and dams on natural flows, as computed by a global water model (Döll and Zhang, 2010). Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002.]

Because biota are often adapted to a certain level of river flow variability, the larger variability of river flows that is due to increased climate variability is *likely* to select for generalist or invasive species (Ficke *et al.*, 2007). The relatively stable habitats of groundwater-fed streams in snow-dominated or glacierized basins may be altered by reduced recharge by meltwater and as a result experience more variable (possibly intermittent) flows (Hannah *et al.*, 2007). A high-impact change of flow variability is a flow regime shift from intermittent to perennial or vice versa. It is projected that until the 2050s, river flow regime shifts may occur on 5-7% of the global land area, mainly in semi-arid areas (Döll and Müller Schmied, 2012; see Chapter 3, Table 3-2).

In Africa, one third of fish species and one fifth of the endemic fish species occur in eco-regions that may experience a change in discharge or runoff of more than 40% by the 2050s (Thieme *et al.*, 2010). Eco-regions containing over 80% of Africa's freshwater fish species and several outstanding ecological and evolutionary phenomena are *likely* to experience hydrologic conditions substantially different from the present, with alterations in long-term average annual river discharge or runoff of more than 10% due to climate change and water use (Thieme *et al.*, 2010).

Due to increased winter temperatures, freshwater ecosystems in basins with significant snow storage are affected by higher river flows in winter, earlier spring peak flows and possibly reduced summer low flows (chapter 3.2.3). Strongly increased winter peak flows may lead to a decline in salmonid populations in the Pacific Northwest of the USA of 20-40% by the 2050s (depending on the climate model) due to scouring of the streambed during egg incubation, the relatively pristine high-elevation areas being affected most (Battin *et al.*, 2007). Reductions in summer low flows will increase the competition for water between ecosystems and irrigation water users (Stewart *et al.*, 2005). Ensuring environmental flows through purchasing or leasing water rights and altering reservoir release patterns will be an important adaptation strategy (Palmer *et al.*, 2009).

Observations and models suggest that global warming impacts on glacier and snow-fed streams and rivers will pass through two contrasting phases (Burkett *et al.*, 2005; Vuille *et al.*, 2008; Jacobsen *et al.*, 2012). In the first phase,

when river discharge is increased due to intensified melting, the overall diversity and abundance of species may increase. However, changes in water temperature and stream-flow may have negative impacts on narrow range endemics (Jacobsen *et al.*, 2012). In the second phase, when snowfields melt early and glaciers have shrunken to the point that late-summer stream flow is reduced, broad negative impacts are foreseen, with species diversity rapidly declining once a critical threshold of roughly 50% glacial cover is crossed (Figure RF-2).

[INSERT FIGURE RF-2 HERE
Figure RF-2: Accumulated loss of regional species richness (gamma diversity) as a function of glacial cover GCC. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%. Each data point represents a river site and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.]

River discharge also influences the response of river temperatures to increases of air temperature. Globally averaged, air temperature increases of 2°C, 4°C and 6°C are estimated to lead to increases of annual mean river temperatures of 1.3°C, 2.6°C and 3.8°, respectively (van Vliet *et al.*, 2011). Discharge decreases of 20% and 40% are computed to result in additional increases of river water temperature of 0.3° C and 0.8°C on average (van Vliet *et al.*, 2011). Therefore, where rivers will experience drought more frequently in the future, freshwater-dependent biota will suffer not only directly by changed flow conditions but also by drought-induced river temperature increases, as well as by related decreased oxygen and increased pollutant concentrations.

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Introduction

Anthropogenic ocean acidification and climate change share the same primary cause at the global level, the increase of atmospheric carbon dioxide (WGI, 2.2.1). Eutrophication and upwelling contribute to local ocean acidification (5.3.3.6, 30.5.4). Past and futures changes in chemistry are well known in the surface open ocean (WGI, 3.8.2 and 6.4.4) but are more difficult to project in the more complex coastal systems (5.3.3.6 and 30.5.2).

Chemistry and Projections

The fundamental chemistry of ocean acidification has long been understood: the uptake of CO_2 into mildly alkaline ocean results in an increase in dissolved CO_2 and reductions in pH, dissolved carbonate ion, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of surface seawater can be projected at the global scale with high accuracy from projections of atmospheric CO_2 levels. Time series observations of changing upper ocean CO_2 chemistry support this linkage (WGI Table 3.2 and Figure 3.17; WGII Figure 30.5). Projections of regional changes, especially in coastal waters (5.3.3.6), and at depth are more difficult; observations and models show with high certainty that fossil fuel CO_2 has penetrated at depths of 1 km and more. Importantly, the natural buffering of increased CO_2 is less in deep than in surface water and thus a greater chemical impact is projected. Additional significant CO_2 increases and pH decreases at mid-depths are expected to result from increases in microbial respiration induced by warming. Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGII, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration).

Biological, Ecological, and Biogeochemical Impacts

The effects of ocean acidification on marine organisms and ecosystems have only recently been investigated. A wide range of sensitivities to projected rates of ocean acidification exists within and across organism groups and phyla with a trend for higher sensitivity in early life stages (*high confidence*; Kroeker et al., in press; 6.2.3-5, 6.3.4). A pattern of impacts, some positive, others negative, emerges for some processes and organisms (*high confidence*; Fig. X.C) but key uncertainties remain from organismal to ecosystem levels (Chap. 5, 6, 30). Responses to ocean acidification are exacerbated at high temperature extremes (*medium confidence*) and can be influenced by other drivers, such as oxygen concentration, nutrients, and light availability (*medium confidence*).

Experimental evidence shows that lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers such as reef-building corals (Box CC-CR, coralline algae (Raven, in press), bivalves and snails (Gazeau et al., in press) reducing their competitiveness compared to, e.g. seaweeds (Chap. 5, 6, 30). A reduced performance of these ecosystem builders would affect the other components of the ecosystem dependent on the habitats they create.

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*) and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may significantly stimulate nitrogen fixation in the oceans (*limited evidence, low agreement*; 6.2.3, 6.3.4). There are few known direct effects on early stages of fish and adult fish remain relatively undisturbed by elevated CO_2. Serious behavioral disturbances were reported, mostly on larval and juvenile coral reef fishes (6.2.4).

Projections of ocean acidification effects at the ecosystem level are limited by the diversity of species-level responses. Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities living on the sea-floor. Shifts in community structure have been documented in rocky shore environments (e.g., Wootton et al., 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012). Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.2-3), which could impact food webs and higher trophic levels (*limited evidence, high agreement*).

There is *limited evidence* and *medium agreement* that some phytoplankton and mollusks can adapt to ocean acidification, indicating that the long-term responses of these organisms to ocean acidification could be less than responses obtained in short-term experiments. However, mass extinctions during much slower rates of ocean

acidification in Earth history (6.1.2) suggest that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of change (*high confidence*).

The effect of ocean acidification on global biogeochemical cycles is difficult to predict due to the species-specific responses to ocean acidification, lack of understanding of the effects on trophic interactions, and largely unexplored combined responses to ocean acidification and other climatic and non-climatic drivers, such as temperature, concentrations of oxygen and nutrients, and light availability.

Risks

Climate risk is defined as the probability that climate change will cause specific physical hazards and that those hazards will cause impacts (19.5.2). The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, includes both the probability that ocean acidification will affect key processes, and the magnitude of the resulting impacts. The changes in key processes mentioned above present significant ramifications on ecosystems and ecosystem services (Fig. 19.3). For example, ocean acidification will cause a decrease of calcification of corals, which will cause not only a reduction in the coral's ability to grow its skeleton, but also in its contribution to reef building (*high confidence*; 5.4.2.4). These changes will have consequences for the entire coral reef community and on the ecosystem services that coral reefs provide such as fisheries habitat (*medium confidence*; 19.5.2) and coastal protection (*medium confidence*; Box CC-CR). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Socioeconomic Impacts and Costs

The biological, ecological and biogeochemical changes driven by ocean acidification will affect several key ecosystem services. The oceans will become less efficient at absorbing CO_2, hence less efficient at moderating climate change, as their CO_2 content will increase (*very high confidence*). The impacts of ocean acidification on coral reefs, together with those of bleaching and sea level rise, will in turn diminish their role of shoreline protection in atolls and small island nations as well as their direct and indirect benefits on the tourism industry (*limited evidence, high agreement*; Box CC-CR).

There is no global estimate of the observed or projected economic costs of ocean acidification. The production of commercially-exploited shelled mollusks may decrease (Barton et al., 2012) resulting in an up to 13% reduction of US production (limited evidence, low agreement; Cooley and Doney, 2009). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (Narita et al., 2012). The largest uncertainty is how the impacts on prey will propagate through the marine food webs and to top predators. Models suggest that ocean acidification will generally reduce fish biomass and catch (*limited evidence, high agreement*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (Branch et al., 2012; Griffith et al., 2012). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 500 billion USD, respectively for A1 and B2 SRES emission scenarios (Brander et al. 2012). Although this number is small compared to global GDP, it represents a large proportion of the GDP of some regions or small island states which rely economically on coral reefs.

Adaptation and Mitigation

The management of ocean acidification comes down to mitigation of the source of the problem and adaptation to the consequences (Rau et al., 2012; Billé et al., sbm). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts. Climate geoengineering techniques based on solar radiation management would have no direct effect on ocean acidification because atmospheric CO_2 would continue to rise (6.4.2). Techniques based on carbon dioxide removal could directly address the problem but their effectiveness at the scale required to ameliorate ocean acidification has yet to be demonstrated. Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep water oxygen levels (Williamson and Turley, 2012; 6.4.2; 30.3.2.3 and 30.5.7). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Specific activities, such as aquaculture, could adapt to ocean acidification within limits, for example by altering the production process, selecting less sensitive species or strains, or relocating elsewhere. A low-regret approach is to limit the number and the magnitude of drivers other than CO_2. There is evidence, for example, that reducing a

locally determined driver (i.e. nutrient pollution) may substantially reduce its synergistic effects with a globally determined driver such as ocean acidification (Falkenberg et al., 2013).

[INSERT FIGURE OA-1 HERE
Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.]

Box CC-RC. Regional Climate Summary Figures

[Noah S. Diffenbaugh (USA), Daithi Stone (Canada), Filippo Giorgi (Italy), Bruce Hewitson (South Africa), Richard Jones (UK), Geert Jan van Oldenborg (Netherlands)]

The WGII regional climate summary figures draw on climate model simulations archived in Phase 5 of the Coupled Model Intercomparison Project (CMIP5) (Taylor et al. 2012). The CMIP5 simulations are also the basis for the figures presented in Annex I of the WGI contribution (*Atlas of Global and Regional Climate Projections*). The CMIP5 archive includes output from approximately three dozen climate models, including atmosphere-ocean general circulation models (AOGCMs), AOGCMs with coupled vegetation and/or carbon cycle components, and AOGCMs with coupled atmospheric chemistry components. The number of models from which output is available, and the number of realizations of each model, varies between the different CMIP5 experiments.

In contrast to CMIP3 (which used the IPCC SRES scenarios), CMIP5 uses the Representative Concentration Pathways (RCPs) (van Vuuren et al. 2011) to simulate the climate response to possible changes in forcing over the 21st century. The WGI Atlas focuses on RCP4.5, with supplemental analysis of RCP2.6, RCP6.0, and RCP8.5. The WGII regional climate figures compare RCP4.5 and RCP8.5, using the same baseline, mid-21st-century, and late-21st-century time periods as the WGI Atlas (1986-2005, 2046-2065, 2081-2100). The RCPs exhibit overlapping likelihood of global warming in the mid-21st-century period (including median warming of 1.4˚C and 2.1˚C above the late-20th-century baseline in RCP4.5 and RCP8.5, respectively) (Rogelj et al. 2012), but divergent likelihood of global warming in the late-21st-century period (including median warming of 1.8˚C and 3.8˚C above the late-20st-century baseline in RCP4.5 and RCP8.5, respectively) (Rogelj et al. 2012). Given that real emissions have tracked on or above RCP8.5 in recent years (Peters et al. 2013), the regional climate figures are focused on the middle (RCP4.5) and upper end (RCP8.5) of the range of RCPs available in CMIP5.

The regional climate figures show the mean annual temperature and precipitation, categorizing differences in the CMIP5 simulation of the baseline and future periods into four classes. The classes are constructed based on the IPCC uncertainty guidance, which provides a quantitative basis for assigning likelihood statements (Mastrandrea et al. 2011). The classifications in the figures are constructed to parallel the 66-100% ("likely") and 90-100% ("very likely") probability ranges identified in the IPCC uncertainty guidance.

However, there are a number of plausible assignments of likelihood in a multi-model ensemble (e.g., (Knutti et al. 2010)). The classifications in the regional climate figures are based on two interpretations of likelihood reflected in the literature. The first interpretation is the likelihood that the climate in the future period is different than the climate in the baseline period (e.g., (Tebaldi et al. 2011). The regional climate figures use the percentage of models for which the simulated change exceeds two standard deviations of the simulated baseline variability as the measure of probability that the simulated future climate is statistically different than the simulated baseline climate. The second interpretation is the likelihood of the sign of change (e.g., (Christensen et al. 2007; Field et al. 2012). The regional climate figures use the percentage of models that exhibit the same sign of change as the measure of probability of increase or decrease in a given quantity.

The four classifications depicted in the regional climate figures are:

1) White indicates areas where less than 66% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability.
2) Gray indicates areas where greater than 66% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability, and less than 66% of the models agree on the sign of difference.
3) Colors with circles indicate areas where greater than 66% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability, and greater than 66% of the models agree on the sign of the difference. The color contour shows the magnitude of the multi-model mean difference between the future and baseline periods.
4) Colors without circles indicate areas where greater than 90% of the models exhibit difference between the future and baseline periods that exceeds twice the baseline variability, and greater than 90% of the models agree on the sign of the difference. The color contour shows the magnitude of the multi-model mean difference between the future and baseline periods.

Only those models that have archived output from the historical, RCP4.5 and RCP8.5 experiments are included. For each of the included models, all realizations are used. For a given model, the mean and variability of each realization is first calculated for each period. The mean of the individual-realization mean and variability values are then calculated across the realizations of that model in each period, yielding model-mean mean and variability values derived from the timeseries of each realization (rather than from the mean of the timeseries). The difference between the model-mean in the future and baseline periods is then calculated for each model, and compared with each model's model-mean baseline variability. (Prior to analysis, each realization of each model is first interpolated to a common 1˚ geographical grid using linear interpolation.)

Because the regional climate figures quantify differences between 20-year periods, the measure of baseline variability is chosen to reflect the variability between 20-year periods in the baseline climate forcing. Given that the baseline period is selected as 1986-2005, the baseline variability is calculated as the standard deviation between the 20 20-year periods ending in the years 1986 through 2005 (1967-1986, 1968-1987, … , 1986-2005). Although the 20 20-year periods are not independent, they reflect the population of 20-year periods within the recent climate forcing regime, and a 20-year period that is more than two standard deviations removed is considered to be reflective of a different climate.

In addition to maps of the CMIP5 simulations, the regional climate figures also include maps of observed temperature and precipitation differences between the baseline period (1986-2005) and the early 20th century (1906-1925). The observational analyses use the CRU TS3.10.01 gridded station-based temperature and precipitation data (CRU 2012). On the observational panel, white indicates areas where the difference between the baseline and early-20th-century periods does not exceed two standard deviations of the early-20th-century variability. Colors indicate areas where the difference between the baseline and early-20th-century periods exceeds two standard deviations of the early-20th-century variability, with the color contours showing the magnitude of the difference. For the observational analyses, the early-20th-century variability is calculated as the standard deviation between the 20 20-year periods beginning in the years 1906 through 1925 (1906-1925, 1907-1926, … , 1925-1944).

[INSERT FIGURE RC-1 HERE
Figure RC-1: Change in annual temperature. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

[INSERT FIGURE RC-2 HERE
Figure RC-2: Change in annual precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a

change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

Box CC-TC. Case Study Building Long Term Resilience from Tropical Cyclone Disasters
[Yoshiki Saito (Japan), Kathleen McInnes (Australia)]

Tropical cyclones (also referred to as hurricanes and typhoons in some regions) cause powerful winds, torrential rains, high waves and storm surge, all of which can have major impacts on society and ecosystems. For example, Bangladesh and India account for 86% of mortality from tropical cyclones (Murray *et al.*, 2012), which is mainly due to the rarest and most severe storm categories (i.e. Categories 3, 4, and 5).

About 90 tropical cyclones occur globally each year (Seneviratne et al, 2012) although interannual variability is large. Changes in observing techniques particularly after the introduction of satellites in the late 1970s, confounds the assessment of trends in tropical cyclone frequencies and intensities. Therefore, SREX concluded that there is *low confidence* that any observed long-term (i.e. 40 years or more) increases in tropical cyclone activity are robust, after accounting for past changes in observing capability (Seneviratne, *et al.*, 2012; Chapter 2). There is also *low confidence* in the detection and attribution of century scale trends in tropical cyclones. Future changes to tropical cyclones arising from climate change are *likely* to vary by region. This is because there is *medium confidence* that for certain regions, shorter-term forcing by natural and anthropogenic aerosols has had a measurable effect on tropical cyclones. Tropical cyclone frequency is *likely* to decrease or remain unchanged over the 21st century, while intensity (i.e. maximum wind speed and rainfall rates) is *likely* to increase. Regionally specific projections have *lower confidencelower confidence* (see WG1 Box 14.2).

Longer term impacts from tropical cyclones includes salinisation of coastal soils and water supplies and subsequent food and water security issues from the associated storm surge and waves (Terry and Chui, 2012). However, preparation for extreme tropical cyclone events through improved governance and development to reduce their impacts provides an avenue for building resilience to longer term changes associated with climate change.

Densely populated Asian deltas are particularly vulnerable to tropical cyclones due to their large population density in expanding urban areas (Nicholls *et al.*, 2007). Extreme cyclones in Asia since 1970 caused over 0.5 million fatalities (Murray *et al.*, 2012) e.g., cyclones Bhola in 1970, Gorky in 1991, Thelma in 1998, Gujarat in 1998, Orissa in 1999, Sidr in 2007, and Nargis in 2008. Tropical cyclone Nargis hit Myanmar on 2 May 2008 and caused over 138,000 fatalities. Several-meter high storm surges widely flooded densely populated coastal areas of the Irrawaddy Delta and surrounding areas (Revenga *et al.*, 2003; Brakenridge *et al.*, 2012). The flooded areas were captured by a NASA MODIS image on 5 May 2008 (Figure TC-1).

[INSERT FIGURE TC-1 HERE
Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. (From Brakenridge *et al.*, 2012).]

Murray *et al.* (2012) compared the response to cyclone Sidr in Bangladesh in 2007 and Nargs in Myanmar in 2008 and demonstrated how disaster risk reduction methods could be successfully applied to climate change adaptation (Murray et al, 2012). Sidr, despite being of similar strength to Nargis, caused far fewer fatalities (3,400 compared to over 138000) and this was attributed to advancement in preparedness and response in Bangladesh through experience in previous cyclones such as Bhola and Gorky. The responses included the construction of multi-storied cyclone shelters, improvement of forecasting and warning capacity, establishing a coastal volunteer network, and coastal reforestation of mangroves. Birkmann and Teichman, (2010) caution that while the combination of risk reduction and climate change adaptation strategies may be desirable, different spatial and temporal scales, norm systems, and knowledge types and sources between the two goals can confound their effective combination.

Box CC-WE. The Water-Energy-Food Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Ken Strzepek (UNU/USA), FerencToth (IAEA/Hungary), Blanca Elena Jimenez Cisneros (Mexico), Taikan Oki (Japan)]

Water, energy, and food are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure CC-WE-1. The depth and intensity of those linkages vary enormously between regions and production systems. Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Chapter 3.7.2, 7.3.2, 10.2,10.3.4, McMahon and Price, 2011, Macknick et al, 2012a, Cary and Weber 2008). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Kahn and Hajra 2009, Gertenet al. 2011). While food production and transport require large amounts of energy (Pelletier et al 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (7.3.2, Diffenbaugh et al 2012, Skaggs et al, 2012).

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change.]

Most energy production methods require significant amounts of water, either directly (e.g. crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Chapter 10.2.2 and 10.3.4, and Davies et al 2013, van Vliet et al 2012). Water is also required for mining, processing, and residue disposal of fossil fuels. Water for biofuels, for example, has been reported by Gerbens-Leenes et al. 2012 who computed a scenario of water use for biofuels for transport in 2030 based on the Alternative Policy Scenario of the IEA. Under this scenario, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water for energy currently ranges from a few percent to more than 50% of freshwater withdrawals, depending on the region and future water requirements will depend on electric demand growth, the portfolio of generation technologies and water management options employed (WEC 2010, Sattler et al., 2012). Future water availability for energy production will change due to climate change (Chapter 3.5.2.2).

Water may require significant amounts of energy for lifting, transport and distribution, treatment or desalination. Non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced or reclaimed wastewater vs. desalinated seawater (Plappally and Lienhard 2012, Macknick et al, 2012b). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user, Döll et al. 2012) is generally more energy intensive than surface water – in some countries, 40% of total energy use is for pumping groundwater. Pumping from greater depth (following falling groundwater tables) increases energy demand significantly– electricity use ($kWhr/m^3$) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard 2012). A lack of water security can lead to increasing energy demand and vice versa, e.g. over-irrigation in response to electricity or water supply gaps.

Other linkages through land use and management, e.g. afforestation, can affect water as well as other ecosystem services, climate and water cycles (4.4.4, Box 25-10). Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security (3.7.2, 4.4.4). Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water (McCornick *et al.*, 2008, Bazilian *et al.*, 2011, Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy demand, bioproductivity and other factors (see Figure WE-1 and Wise et al, 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this Assessment Report.

Box CC-VW. Active Role of Vegetation in Altering Water Flows Under Climate Change

[Richard Betts (UK), Dieter Gerten (Germany), Petra Döll (Germany)]

Terrestrial vegetation dynamics, carbon and water cycles are closely coupled, for example by the simultaneous transpiration and CO_2 uptake through plant stomata in the process of photosynthesis, and by feedbacks of land cover and land use change on water cycling.Numerous experimental studies have demonstrated that elevated atmospheric CO_2 concentration leads to reduced opening of stomatal apertures, associated with a decrease in leaf-level transpiration (de Boer *et al.*, 2011; Reddy *et al.*, 2011). This physiological effect of CO_2 is associated with an increased intrinsic water use efficiency (iWUE) of plants, as less water is transpired per unit of carbon assimilated. Records of stable carbon isotopes in woody plants (Peñuelas *et al.*, 2011) corroborate this finding, suggesting an increase in iWUE of mature trees by 20.5% between the 1970s and 2000s. Increases since pre-industrial times have also been found for several forest sites (Andreu-Hayles *et al.*, 2011; Gagen *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and in a temperate semi-natural grassland (Koehler *et al.*, 2010), although in one boreal tree species iWUE ceased to increase after 1970 (Gagen *et al.*, 2011). However, the physiological CO_2 effect is accompanied by structural changes to C3 plants (including all tree species), i.e. increased biomass production, spatial encroachment and, thus, higher transpiration, as confirmed by Free Air CO_2 Enrichment (FACE) techniques (Leakey *et al.*, 2009).

There are conflicting views on whether the direct CO_2 effects on plants already have a significant influence on evapotranspiration and runoff at global scale. AR4 reported work by Gedney *et al.*, (2006) which suggested that physiological CO_2effects (lower transpiration) contributed to a supposed global increase in runoff seen in reconstructions by (Labat *et al.*, 2004). However, a more recent dataset (Dai *et al.*, 2009) showed different runoff trends in some areas. Detection of ecosystem influences on terrestrial water flows, hence, critically depends on the availability and quality of hydrometeorological observations (Haddeland *et al.*, 2011; Lorenz and Kunstmann, 2012).

A key influence on the significance of increased iWUE for large-scale transpiration is whether overall leaf area of primary vegetation has remained approximately constant (Gedney *et al.*, 2006) or has increased in some regions due to structural CO_2effects (as assumed in models by Piao *et al.*, 2007; Gerten *et al.*, 2008). While field-based results vary considerably between sites, tree ring studies suggest that tree growth did not increase globally since the 1970s in response to climate and CO_2change (Peñuelas *et al.*, 2011; Andreu-Hayles *et al.*, 2011). However, basal area measurements at over 200 plots across the tropics suggest that biomass and growth rates in intact tropical forests have increased in recent decades (Lewis *et al.*, 2009), which is also confirmed for 55 temperate forest plots, with a suspected contribution of CO_2 rise (McMahon *et al.*, 2010). The net impact of CO_2 on global-scale transpiration and runoff therefore remains poorly constrained.

Moreover, model results differ in terms of the importance of CO_2 effects for historical runoff relative to other drivers such as climate, land use change and irrigation water withdrawal. Other than Gedney *et al.*, (2006), Piao *et al.*, (2007) and Gerten *et al.*, (2008) found that CO_2 effects on global runoff were small relative to effects of precipitation, and that land use change (which often acts to decrease evapotranspiration and to increase runoff) was of second-most importance, as also supported by Sterling *et al.*, (2012) data and model analysis. By contrast, using a shorter time period and a smaller selection of river basins, Alkama *et al.*, 2011(2011) suggested that global effects of land use change on runoff have been negligible. Oliveira *et al.*, 2011(2011) furthermore point to the importance of changes in incident solar radiation and the mediating role of vegetation; their global simulations demonstrate, for example, that a higher diffuse radiation fraction during 1960–1990 increased evapotranspiration in the tropics by 3% due to increased photosynthesis from shaded leaves. Since the anthropogenic component of the precipitation and temperature contributions(i.e. of the radiative CO_2 effect) to runoff trends is not yet established, a full attribution of anthropogenic emissions of CO_2 (and other greenhouse gases)is still missing.

Analogously, there is uncertainty about how vegetation responses to future increases in CO_2 will modulate effects of climate change on the terrestrial water balance.21st-century continental- and basin-scale runoff is projected by some models to either increase more or decrease less when CO_2-induced increases in iWUE are included in addition to climate change (Betts *et al.*, 2007; Murray *et al.*, 2012), potentially reducing an increase in water stress due to rising population or climate change (Wiltshire *et al.*, submitted) – although other models project a smaller response (Cao *et al.*, 2009). Direct effects of CO_2 on plants have been modelled to increase future global runoff by 4–5% (Gerten *et al.*, 2008) up to 13% (Nugent and Matthews, 2012), depending on the assumed CO_2 trajectory and whether feedbacks of changes in vegetation structure and distribution to the climate are accounted for. The model analysis by

Alkama *et al.*, (2010) suggests that although the physiological CO_2 effect will be the second-most important factor for 21st-centuryglobal runoff and although both physiological and structural effects will amplify compared to historic conditions, runoff changes will still primarily follow the projected climatic changes. Using a large ensemble of climate change projections, Konzmann *et al.*, (2013) put hydrological changes into an agricultural perspective and suggest that direct CO_2 effects on crops reduce their irrigation requirements (Fig. CC-VW-1). Thus, adverse climate change impacts on crop yields might be partly buffered as iWUE improves (Fader *et al.*, 2010), but only if proper management abates limitation of plant growth by nutrient availability or other factors. Lower transpiration under rising CO_2 may also affect future regional climate change itself (Boucher *et al.*, 2009) and may enhance the contrast between land and ocean surface warming (Joshi *et al.*, 2008).

Application of a soil-vegetation-atmosphere-transfer model indicates complex responses of groundwater recharge to changes in different climatic variables mediated by vegetation,with computed groundwater recharge being always larger than would be expected from just accounting for changes in rainfall (McCallum *et al.*, 2010). In a warmer climate with increased atmospheric CO_2 concentration, iWUE of plants increases and leaf area may either increase or decrease, and even though precipitation may slightly decrease, groundwater recharge may increase as a net effect of these interactions (Crosbie *et al.*, 2010). Depending on the type of grass in Australia, the same change in climate is suggested to lead to either increasing or decreasing groundwater recharge in this location (Green *et al.*, 2007). For a location in the Netherlands, a biomass decrease was computed for each of eight climate scenarios indicating drier summers and wetter winters (A2 emissions scenario), using a fully coupled vegetation and variably saturated hydrological model. The resulting increase in groundwater recharge up-slope was simulated to lead to higher water tables and an extended habitat for down-slope moisture-adapted vegetation (Brolsma *et al.*, 2010).

Future anthropogenic and climate-driven land cover and land use changes will also affect regional evapotranspiration, surface and subsurface water flows, with the direction and magnitude of these changes depending on the direction and intensity of the changes in vegetation coverage,as shown e.g. for a river basin in Iowa (Schilling *et al.*, 2008) or for the Elbe river basin (Conradt *et al.*, 2012).Removal of vegetation acting as source of atmospheric moisture can change regional water cycling and decrease potential crop yields by up to 17%in regions otherwise receiving this moisture in the form of precipitation (Bagley *et al.*, 2012).Changes in vegetation coverage and structure due to long-term climate change or shorter-term extreme events such as droughts (Anderegg *et al.*, 2013) also affect the partitioning of precipitation into evapotranspiration and runoff, sometimes involving complex feedbacks with the climate system such as in the Amazon region (Port *et al.*, 2012; Saatchi *et al.*, 2013). As water, carbon and vegetation dynamics evolve synchronously and interactively under climate change (Heyder *et al.*, 2011) in that e.g. vegetation structure and composition can dynamically adapt to changing climatic and hydrologic conditions (Gerten *et al.*, 2007), it remains a challenge to disentangle the effects of future land cover changes on the water cycle.

Table TS.1: Observed impacts attributed to climate change with *medium* (*) or *high* (**) confidence. Impacts for physical, biological, and human systems are characterized across eight major world regions. For each observed impact, confidence in detection is equal to or greater than confidence in attribution. [Table 18-6, 18-7, 18-8, and 18-9]

REGION	Freshwater Resources & Systems	Terrestrial Ecosystems, Drought, & Wildfire	Coastal & Marine Systems	Human Systems
Africa	Retreat of tropical highland glaciers in East Africa* Lake surface warming & water column stratification increases in the Great Lakes & Lake Kariba** [13.2.1, 22.3.2, 22.5.1]	Tree density decreases in Sahel & semi-arid Morocco* Climate-driven range shifts of several southern plants & animals* Increased drought in the Sahel since 1970, partially wetter conditions since 1990* [22.2.2, 22.3.2]		Decline in fruit-bearing trees in Sahel*
Europe	Retreating glaciers in the Alps** Increase in rock slope failures in Western Alps** [18.3.1]	Earlier greening, earlier leaf emergence, & fruiting in temperate & boreal trees** Increased colonization of alien plant species in Europe* Earlier arrival of migratory birds in Europe since 1970* Increasing burnt forest areas during recent decades** [4.2.4, 4.4.1]	Poleward shifts in the distributions of zooplankton, fishes, seabirds, & benthic invertebrates, & conversion of polar into more temperate & temperate into more subtropical system characteristics in Northeast Atlantic** Phenology changes & retreat of colder water plankton to north in the Northeast Atlantic, with mean poleward movement of plankton reaching up to 200–250 km per decade from 1958–2005* Atlantic cod distribution shift due to warming, interacting with regime shift & regional changes in plankton phenology in North Sea.* Decreasing abundance of eelpout in Wadden Sea** [6.3.2, Table 6-8, Figure 6-16, 18.3.3, 30.5.1]	Stagnation of wheat yields in some countries in recent decades, due to warming and/or drought*
Asia	Permafrost degradation in Siberia, Central Asia, & Tibetan Plateau** Shrinking mountain glaciers across Asia.* Increased runoff in many rivers due to shrinking glaciers in the Himalayas & Central Asia** Surface water degradation in parts of Asia partially related to climate change* Earlier timing of maximum spring flood in Russian rivers** [Box 3-1, Box 3-2, 24.4.1, 28.2.1, WGI AR5 Chapter 4.3.2-4.3.3, 10.5.3]	Changes in plant phenology & growth in many parts of Asia, particularly in the north & east* Distribution shifts of many plant & animal species, particularly in the north of Asia, generally upwards in elevation or polewards* Advance of shrubs into the Siberian tundra* [4.2.1, Box 4-1, 24.4.2, 28.2.3]	Decline in coral reefs & large seaweeds in tropical Asian & Japanese waters** Shift from sardines to anchovies in Japanese Sea* [6.3.2, Figure 16-6, 24.4.3]	
Australasia	Significant decline in late-season snow depth at four alpine sites in Australia (1957-2002)*	Climate-related changes in genetics, growth distribution, & phenology of many species (e.g., earlier emergence of butterflies, change in plant flowering dates & bird breeding times, decline in body size of passerine birds)* [Table 25-3]	Mass bleaching of corals in the Great Barrier Reef, changes in coral calcification rates, & changes in coral disease dynamics** Multiple impacts of climate change on marine ecosystems from warming oceans, although other environmental changes may play a role. Examples are growth rate increases in fishes, intertidal-invertebrate range shifts, range shifts in near-shore fishes related to kelp decline, increasing abundance of northern marine species in Tasmania, recruitment declines of rock lobster & abalone, declines in growth rate & biomass of phytoplankton, southward expansion of some tropical seabirds in Australia** [6.3.2, Box 18-3, 25.6.2, Table 25-3]	Wine-grape maturation has advanced in recent decades, partly due to warming*

REGION	Freshwater Resources & Systems	Terrestrial Ecosystems, Drought, & Wildfire	Coastal & Marine Systems	Human Systems
North America	Primarily decreasing trends in amount of water stored in spring snowpack from 1960-2002** Observed shift to earlier peak flow in snow dominated rivers in Western North America** Runoff increases in the Midwestern & Northwestern US, decreases in Southern states* [26.2.2, WGI AR5 Chapter 2.6.2]	Species distribution shifts upward in elevation & northward in latitude across multiple taxa* Phenology changes* Increases in wildfire activity, including fire frequency & duration, length of fire season, & area burned* [26.4.1, 26.4.2, Box 26-2]	Northward range shifts of Northwest Atlantic fishes in response to warming since the 1960s, with some of the shifts being correlated with the Atlantic Multidecadal Oscillation* Earlier onset of Pink Salmon migration (Alaska), collapse of Sockeye Salmon spawning migration (Fraser River, BC), due to warming** Loss of biomass of midwater fishes off California Coast** [6.3.3, 6.6.3, Table 6-8, Figure 6-16]	Direct & indirect economic impacts of climate extremes on industry through reduced supply of raw material, the production process, the transportation of goods, & the demand for certain products* [26.8]
Central & South America	Retreat of tropical Andean glaciers in Venezuela, Colombia, Ecuador, Peru, & Bolivia (1950-2000) & glaciers & ice-fields in the extra tropical Andes** Changes in extreme flows in Amazon River* Changed discharge patterns in rivers in the Western Andes due to retreating glaciers & reduced snowpack; for major river basins in Colombia, decreased discharge during the last 30-40 years** Increased stream flow in sub-basins of the La Plata River, attributed to increasing precipitation, but also to trends in land-use changes that have reduced evapotranspiration** [27.2.1, 27.3.1]		Bleaching of coral reefs in the western Caribbean near the coast of Central America** [27.3.3]	Increase in frequency & extension of malaria* Increase in agricultural yields in Southeastern South America* [27.3.4, 27.3.7]
Polar Regions	Decreasing Arctic sea ice cover in summer & reduction in glacier ice volume, due to warming* Decreasing snow cover duration across the entire Arctic* Widespread permafrost degradation, especially in the southern Arctic** Rising winter minimum flows in most sectors of the Arctic due to enhanced groundwater input due to permafrost thawing* Disappearance of thermokarst lakes due to permafrost degradation in the low Arctic. New lakes being created in areas of formerly frozen peat** [28.2.1, 28.2.3, WGI AR5 Chapter 10.5.1]	Increase in shrub cover in tundra in North America & Eurasia.** Significant advance of Arctic tree-line in latitude & altitude, due to warming, although lower pace than expected due to insect outbreaks & land-use history. Changes in breeding area & population size of subarctic birds, due to warming & shrub encroachment in the tundra* Retreating snow-bed ecosystems & tussock tundra, due to prolonged thawing season & less precipitation in the form of snow.** Increasing occurrence of ice layers in the annual snow pack due to rain-on-snow events, affecting animal populations in the tundra* Increasing plant species in the West Antarctic Peninsula & nearby islands over the past 50 years** Increasing drought in high Arctic polar deserts** Increased frequency of wildfires in conifer forest at Arctic southern fringe, due to increasing summer temperature. Tundra wildfires are increasing in frequency in the Low Arctic, due to increasing summer air temperature & subsequent surface drought* [28.2.1, 28.2.3]	Sea ice loss negatively affecting many arctic & subarctic marine non-migratory mammals (walrus, seals, whales)** Reduced growth rate & body mass, lower survival & reproductive capacity of polar bears, linked to reduced off-shore range & sea-ice loss due to warming** Reduced reproductive success of Arctic seabirds, due to earlier sea-ice break-up* Reduced thickness of foraminifera shells due to acidification of Southern Ocean waters * Declines in Antarctic krill density in the Scotia Sea by ~30% since the 1980s, due to reduced winter sea ice extent & duration* Many Southern Ocean species of seals & seabirds, e.g., penguins & albatross, negatively responding to warmer conditions* Increased coastal erosion in Arctic, due to prolonged ice-free season at shore, increased exposure to wave activity, & degrading permafrost** [6.3.4, 28.2.2, 28.2.4, 28.2.5, 28.3.4]	Impact on livelihoods of Arctic indigenous peoples* [18.4.5, Box 18-5]
Small Islands		Tropical-bird population changes in Mauritius, due to changes in rainfall* [29.3.2]	Coral bleaching near many tropical small islands** [29.3.1]	

Table TS.2: Illustrative selection of some recent extreme impact events for which the role of climate has been assessed in the literature. The table shows confidence assessments as to whether the associated meteorological events made a substantial contribution to the impact event, as well as confidence assessments of a contribution of anthropogenic emissions to the meteorological event. The assessment of confidence in the findings is not necessarily a conclusion of the listed literature but rather results from assessment of the literature. Assessment of the role of anthropogenic emissions in the impact event requires a multi-step evaluation. [Table 18-4]

YEAR	REGION	EXTREME IMPACT EVENT		METEOROLOGICAL EVENT	
		Impact / damage	Confidence in contribution of extreme weather event to observed damage	Meteorological event	Confidence in contribution of anthropogenic emissions to extreme weather event
2003	Europe	excess death toll exceeding 70,000	*very high*	hottest summer in at least 500 years	*high*
2005	North Atlantic / USA	1,700 deaths and over 100 US$ Bn in damage	*very high*	record number of tropical storms, hurricanes, and category 5 hurricanes since 1970	*very low*
2006-2007	Europe	partial second flowering or extended flowering in 2006, early flowering in 2007	*high*	hottest record fall and winter in at least 500 years	*medium*
2010	Western Russia	burned area > 12,500km	*low*	hottest summer since 1500	*medium*
2011	Thailand	prolonged (up to 2 month) inundation of urban and industrialized areas, insured loss 8-11 US$ Bn, total loss ca. 45 US$ Bn	*very high*	wettest monsoon on record in middle and upper Chao Phraya Basin	*very low*
2010	Colombia	exceptionally heavy rainfall and floods, 4 M people affected, 7.8 US$ Bn total damage	*very high*	ENSO-related second and third highest SST in Caribbean on record in late 2010; second most active storm and hurricane season	*low*
2010	Pakistan	worst ever known floods in the region, 2000 people killed, 20 M affected, total loss 40 US$ Bn	*very high*	exceptionally high rainfall amounts over northern Pakistan with unusual atmospheric circulation patterns	*very low*
2011	Queensland, Australia	>200,000 people affected, >30,000 homes flooded, damages and cost to economy 2.5 – 10 US$ Bn	*very high*	2010 wettest year on record for Queensland, with extreme precipitation in January 2011 on saturated ground; record high Southern Oscillation Index in 2010	*low*

Table TS.3: Illustrative examples of adaptation experience, as well as approaches to reduce vulnerability and enhance resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerabilities, inequalities, and climate change come to the fore. At the same time, place-based examples illustrate how larger-level drivers and stressors shape differential risks and livelihood trajectories, often mediated by institutions.

Early warning systems for heat
EXPOSURE AND VULNERABILITY : Factors affecting exposure and vulnerability include age, pre-existing health status, level of outdoor activity, socio-economic factors including poverty and social isolation, access to and use of cooling, physiological and behavioral adaptation of the population, urban heat island effects, and urban infrastructure. [11.7,SREX Table SPM.1]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: *Very likely* decrease in the overall number of cold days and nights and increase in the overall number of warm days and nights, on the global scale between 1951 and 2010. *Medium confidence* that the length of warm spells, including heat waves, has increased globally since 1950. Projected: *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global temperature increases, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 2.6.1, 12.4.3]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: *Medium confidence* in an increase in heat waves or warm spells over North America and Central America, Europe and the Mediterranean region, parts of Asia and Australia/New Zealand, and Southern Africa. Insufficient evidence for assessment or spatially varying trends in heat waves or warm spells for South America and most of Africa. Warming since 1901 generally greater in mid-to-high latitude regions. Projected: *Likely* that, under RCP8.5 in most regions, a 20-year maximum temperature event will at least double its frequency and in many regions occur every two years or annually, while 20-year minimum temperature events will become exceedingly rare by the end of the 21st century. *Likely* more frequent, longer, and/or more intense heat waves or warm spells in most regions of the world. [WGI AR5 2.4.3, 12.4.3; SREX Tables 3-2, 3-3]
DESCRIPTION: Heat-health early warning systems are instruments to prevent negative health impacts during heat waves. Weather forecasts are used to predict situations associated with increased mortality or morbidity. Essential and common components include identifying weather situations that adversely affect human health, monitoring weather forecasts, activating mechanisms for issuing warnings, targeting notifications of adaptation actions to the most vulnerable populations, and providing heat avoidance advice to the general population. Warning systems for heat waves have been used in Europe, the United States, Canada, and Australia. [11.7.3, 25.8.1, 26.9.1]
BROADER CONTEXT: •Heat warning systems appear effective in raising awareness of the risks associated with heat waves, although it is less certain whether this extends to behavioral changes. •Heat health warning systems can be combined with other elements of a health protection plan as has been done in France and Victoria, Australia, for example building capacity to support communities most at risk, supporting and funding health services, and distributing public health information. •In Africa, Asia, and elsewhere, early warning systems have been used to provide warning of and reduce a variety of risks, related to famine and food insecurity; cyclones, flooding, and other weather-related hazards; exposure to air pollution from fire; and vector-borne and food-borne disease outbreaks. [11.7.3, 25.8.1, 22.4.5, 11.7, , 15.3.2, box 21-3, 24.4.1, 24.4.6, Box 25-6]
Mangrove restoration to reduce flood risks and protect shorelines from storm surge
EXPOSURE AND VULNERABILITY : Loss of mangroves increases exposure of coastlines to storm surge, wave erosion, and tropical cyclones. Exposed infrastructure, livelihoods, and people are vulnerable to associated damage. Areas with development in the coastal zone, such as on small islands, are particularly vulnerable. [15.3.4, 29.7.2]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: *Likely* increase in extreme sea levels since 1970, mainly caused by rising mean sea level. *Low confidence* that any reported long-term changes in tropical cyclones are robust. Projected: By the end of the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged. *Likely* increase in both global mean tropical cyclone maximum wind speed and rainfall rates. *More likely than not* substantial increase in the frequency of the most intense tropical cyclones in some basins. [WGI AR5 2.6.3, 3.7.5, 11.3.2, Box 14.2]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: Regional rates of sea level change can vary significantly from the global mean. Mean significant wave height *likely* increased since the mid-1980s over much of the mid-latitude North Atlantic, the North Pacific, and the Southern Ocean. For tropical cyclones observed over the satellite era, increases in the intensity of the strongest storms in the Atlantic appear robust. Projected: For all ocean basins, tropical cyclone frequency is projected to decline or remain the same, the mean lifetime maximum intensity of tropical cyclones is

projected to increase or remain the same, and cyclone-associated rainfall rates are projected to increase. In the North Atlantic and the eastern part of the North Pacific, the frequency of category 4/5 tropical cyclones is projected to increase.
Very likely increase in the occurrence of future extreme sea level and related coastal flooding events with increasing global mean sea level, but *low confidence* in region-specific projections in storminess and storm surges.
[WGI AR5 2.6.3, 3.4, 3.7, 13.7.2; Figures 3.6-3.8, 13.19; Box 14.2]

DESCRIPTION:
Mangrove restoration and rehabilitation has occurred in a number of locations (Vietnam, Myanmar, Samoa, and Brazil, for example) to reduce coastal flooding risks and protect shorelines from storm surge. In Vietnam, restored mangroves have been shown to attenuate wave height and thus reduce wave damage and erosion. They protect aquaculture industry from storm damage and reduce saltwater intrusion.
[8.3.3.7, 2.3.4, 15.3.4, 27.3.3, 22.4.5]

BROADER CONTEXT:
•Considered a low-regrets option benefiting sustainable development, livelihood improvement, and human well-being through improvements for food security and reduced risks from flooding, wave damage, and erosion.
•Synergies with mitigation given that mangrove forests are sinks for carbon.
•Restoration and rehabilitation can help build local knowledge, capacity, and strategies to institutionalize climate change adaptation and resilience in local planning and development.
•Mangrove bioshields created from exotic species can detrimentally impact native ecosystems.
[8.4.2.4, Box 5.4, 29.7.2, 15.3.4]

Community-based adaptation and traditional practices in small island contexts

EXPOSURE AND VULNERABILITY:
With small land area, often low elevation coasts, and concentration of human communities and infrastructure in coastal zones with limited resettlement opportunities, small islands are particularly vulnerable to rising sea levels and impacts such as inundation, saltwater intrusion, and shoreline change. Island vulnerability to climate change may be related to the experience and perceptions of islanders to both climate and non-climate stressors.
[29.3.3, 29.6.1, 29.6.2]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Likely* increase in extreme sea levels since 1970, mainly caused by rising mean sea level.
Low confidence that any reported long-term changes in tropical cyclones are robust.
Likely increase in the number of heavy precipitation events in more regions than the number has decreased since 1950.
Projected: *Very likely* that the rate of global mean sea level rise during the 21st century will exceed the rate observed during 1971-2010 for all RCP scenarios.
By the end of the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged.
Likely increase in both global mean tropical cyclone maximum wind speed and rainfall rates.
More likely than not substantial increase in the frequency of the most intense tropical cyclones in some basins.
For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms.
[WGI AR5 2.6.2, 2.6.3, 3.7.5, 11.3.2, Box 14.2, 13.5.1, table 13.5, 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: Regional rates of sea level change can vary significantly from the global mean.
Mean significant wave height *likely* increased since the mid-1980s over much of the mid-latitude North Atlantic, the North Pacific, and the Southern Ocean.
For tropical cyclones observed over the satellite era, increases in the intensity of the strongest storms in the Atlantic appear robust.
Projected: For all ocean basins, tropical cyclone frequency is projected to decline or remain the same, the mean lifetime maximum intensity of tropical cyclones is projected to increase or remain the same, and cyclone-associated rainfall rates are projected to increase. In the North Atlantic and the eastern part of the North Pacific, the frequency of category 4/5 tropical cyclones is projected to increase.
Very likely increase in the occurrence of future extreme sea level and related coastal flooding events with increasing global mean sea level, but *low confidence* in region-specific projections in storminess and storm surges.
[WGI AR5 2.6.3, 3.4, 3.7, 13.7.2; Figures 3.6-3.8, 13.19; Box 14.2]

DESCRIPTION:
There is growing awareness of the role of traditional technologies and skills in adapting to climate change in small island contexts. In the Solomon Islands, relevant traditional practices include elevating concrete floors to keep them dry during heavy precipitation events and building low aerodynamic houses with palm leaves as roofing to avoid hazards from flying debris during cyclones, supported by perceptions that traditional construction methods are more resilient to extreme weather. In Fiji after cyclone Ami, mutual support and risk sharing formed a central pillar for community-based adaptation, with unaffected households fishing to support those with damaged homes. Intensive participatory consultations across stakeholders and sectors within communities and capacity building taking into account traditional practices have been shown to be vital to the success of adaptation initiatives in island communities, such as in Fiji or Samoa.
[29.6.2]

BROADER CONTEXT:
• Perceptions of self-efficacy in addressing climate stress can be an important pre-condition for anticipatory adaptation in islands. For example, individuals' belief in their own ability to cope with water scarcity based on past experience is a key driver of attitudes to and choice of adaptation strategy in Kiribati.
•The relevance of community-based adaptation principles to island communities, as a facilitating factor in adaptation planning and implementation, has been highlighted, for example with empowerment that helps people help themselves while addressing local priorities and building on local knowledge and capacity.
[29.6.2]

Farming practices in Africa, such as zai and integration of trees into annual cropping systems
EXPOSURE AND VULNERABILITY: Land degradation and soil infertility have negatively impacted yields in parts of Africa, such as in Zambia, Malawi, the highlands of Ethiopia, Burkina Faso, and the drylands of the Sahel. Soil erosion, soil compaction due to livestock trampling, and low soil water holding capacity reduce plant growth. [7.5.2, Table 9-6, Box 22-4]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: Increase in globally averaged near surface temperatures since 1900, with warming particularly marked since the 1970s. *Very likely* decrease in the overall number of cold days and nights and increase in the overall number of warm days and nights, on the global scale between 1951 and 2010. *Medium confidence* that the length of warm spells, including heat waves, has increased globally since 1950. *Medium confidence* in global precipitation change over land since 1950. *Likely* increase in the number of heavy precipitation events in more regions than the number has decreased since 1950. *Low confidence* in any observed large-scale trends in drought. Projected: For RCP 4.5, 6.0, and 8.5, global mean surface air temperatures are projected to at least *likely* exceed 2° C with respect to preindustrial by 2100. *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global temperature increases, for events defined as extremes on both daily and seasonal timescales. *Virtually certain* increase in global precipitation as global mean surface temperature increases. Regional to global-scale projections of soil moisture and drought remain relatively uncertain. For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 2.4, 2.5.1, 2.6.1, 2.6.2, 12.3.1, 12.4.1, 12.4.3, 12.4.5; Figures 2.28, 12.2, 12.5]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: Increase in frequency of warm days and nights in northern and southern part of continent and decrease in frequency of cold days and nights in southern part of continent. Overall increase in dryness and modest increases in rainfall over most of equatorial Africa and the Red Sea coast (*medium confidence*). Projected: *Likely* increase in warm days and decrease in cold days in all regions of Africa (*high confidence*). Increase in warm days largest in summer and fall (*medium confidence*). *Likely* more frequent and/or longer heat waves and warm spells in Africa (*high confidence*). [22.2.2; SREX Tables 3-2, 3-3]
DESCRIPTION: Zai uses small pits dug manually during the dry season, combined with contour stone bunds to slow runoff. Animal manure or compost is placed in each pit. The pits facilitate water infiltration and concentrate runoff water, and the applied organic matter improves soil nutrient status and attracts termites, which positively affect soil structure. The practice can also improve tree growth amid crop rows, and trees, especially nitrogen-fixing varieties, can be integrated as an independent strategy. Trees reduce crop exposure to wind and heavy rainfall and improve moisture retention and rainwater capture. Factors that have enabled farmer-managed natural regeneration include in southern Niger devolving tree ownership from the state to the farmer, as well as community-based efforts involving partnerships of farmers and NGOs. [7.5.2, Table 9-6, Box 22-4, 15.3.4]
BROADER CONTEXT: •Both techniques can improve yields, water retention, food security, and income generation, also reversing land degradation. •Tree growth, through production of fruit, animal fodder, or fuelwood, can expand livelihood options and allow diversification, thereby enhancing resilience. •Zai is a very labor-intensive technique, which can be expedited through use of animal-drawn implements. • Farmer-managed natural regeneration has been paired with other low-cost behavioral actions, for example in Ethiopia, aiming to reverse ecosystem degradation and promote reforestation with benefits for carbon sequestration. [7.5.2, Table 9-6, Box 22-4, 15.3.4, 17.4.1]
Adaptive approaches to flood defense in Europe
EXPOSURE AND VULNERABILITY : In some countries, a high percentage of the population is exposed to flooding. Exposed assets and infrastructure represent a substantial fraction of national GDPs. [Box 5-3]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: *Likely* increase in extreme sea levels since 1970, mainly caused by rising mean sea level. *Likely* increase in the number of heavy precipitation events in more regions than the number has decreased since 1950. Projected: *Very likely* that the rate of global mean sea level rise during the 21st century will exceed the rate observed during 1971-2010 for all RCP scenarios. For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 2.6.2, 3.7.5, 12.4.5, 13.5.1, Table 13.5]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: Increased heavy wintertime precipitation since the 1950s in some areas of Northern Europe (*medium confidence*). Increased heavy precipitation since the 1950s in some parts of west-central Europe and European Russia, especially in winter (*medium confidence*). Isostasy and decreasing sea level in Scandinavia. Projected: Overall precipitation increase in Northern Europe and decrease in Southern Europe (*medium confidence*). Increased extreme precipitation in Northern and Atlantic regions of Europe during all seasons, and in Central Europe except in summer (*high confidence*). Annual increases of intense precipitation days over the Mediterranean region. Storm activity over the North Atlantic *likely* to increase and extend farther downstream into Europe, and to decrease on both the north and south flanks, especially

over the Mediterranean (*medium confidence*).
Likely reduction in the occurrence of Northern Hemisphere extratropical storms, although the most intense storms reaching Europe *likely* to increase in strength. An increase in the North Atlantic Oscillation *likely* to increase the number of wintertime storms heading into Northern Europe and the average intensity of precipitation per storm.
[23.2.2; WGI AR5 Box 14.3; SREX Table 3-2]

DESCRIPTION:
Several governments have made ambitious efforts to address flood risk over the coming century. In the Netherlands, government recommendations include "soft" measures preserving land from development to accommodate increased river inundation; raising the level of lakes to ensure continuous freshwater supply; restoring natural estuary and tidal regimes; maintaining flood protection through beach nourishment; and ensuring necessary political-administrative, legal, and financial resources. The plan is estimated to cost €2.5 to 3.1 billion a year through 2050, 0.5% of the current Dutch annual GNP. The British government has also developed extensive adaptation plans to adjust and improve flood defenses for the protection of the Thames estuary and the city of London from future storm surges and river flooding. Pathways for different adaptation options and decisions depending on eventual sea level rise have been analyzed.
[Box 5-3, 23.7.1]

BROADER CONTEXT:
•The Dutch plan is considered a paradigm shift, addressing coastal protection by "working with nature" and providing "room for river." The concept of creating space for water and integrating water management approaches with goals of environmental protection is an essential component of integrated water management.
•The British plan incorporates iterative, adaptive decisions depending on the eventual sea level rise.
•The large infrastructure project of the Thames flood defense barrier involved public-private partnerships.
• In cities in Europe and elsewhere, the importance of having strong political leadership or government champions to drive the initial development of climate adaptation plans has been noted.
[Box 5.3, 23.7.1, 17.5.3, 8.5.3, 23.7.4, 23.7.2]

Index-based insurance for agriculture in Africa

EXPOSURE AND VULNERABILITY:
Susceptibility to food insecurity and depletion of farmers' productive assets following crop failure. Low prevalence of insurance due to absent or poorly developed insurance markets or to amount and timing of premium payments. The most marginalized and resource-poor especially may have limited ability to afford insurance premiums.
[Box 22-3, 13.3.2, 10.7.6]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Very likely* decrease in the overall number of cold days and nights and increase in the overall number of warm days and nights, on the global scale between 1951 and 2010.
Medium confidence that the length of warm spells, including heat waves, has increased globally since 1950.
Likely increase in the number of heavy precipitation events in more regions than the number has decreased since 1950.
Low confidence in any observed large-scale trends in drought.
Projected: *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global temperature increases, for events defined as extremes on both daily and seasonal timescales.
Regional to global-scale projections of soil moisture and drought remain relatively uncertain.
For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms.
[WGI AR5 2.6.1, 2.6.2, 12.4.3, 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: Increase in frequency of warm days and nights in northern and southern part of continent and decrease in frequency of cold days and nights in southern part of continent.
Overall increase in dryness and modest increases in rainfall over most of equatorial Africa and the Red Sea coast (*medium confidence*).
Projected: *Likely* increase in warm days and decrease in cold days in all regions of Africa (*high confidence*). Increase in warm days largest in summer and fall (*medium confidence*).
Likely more frequent and/or longer heat waves and warm spells in Africa (*high confidence*).
[22.2.2; SREX Tables 3-2, 3-3]

DESCRIPTION:
A recently introduced mechanism that has been piloted in a number of rural locations, including in Malawi, Ghana, and Ethiopia. When conditions reach a particular predetermined threshold where significant losses are likely to occur--weather conditions such as excessively high or low cumulative rainfall or temperature peaks affecting average crop yields or revenues--the insurance pays out. Where understanding of insurance is low, participation rates can be improved by using simulation games, as piloted in Ethiopia and Malawi, or by more conventional training methods.
[9.4.2, 15.2.4, 13.3.2, Box 22-3]

BROADER CONTEXT:
•Can be considered a low-regrets climate change adaptation option.
•The mechanism allows risk to be shared across communities, with costs spread over time, while overcoming obstacles to traditional agricultural and disaster insurance markets. It can be integrated with other strategies such as micro-finance and social protection programs.
•Risk-based premiums foster risk awareness and risk reduction by providing financial incentives to policyholders to reduce their risk profile.
•Challenges can be associated with limited availability of accurate weather data, difficulties in establishing which weather conditions cause losses, and varying weather conditions between adjacent areas and meteorological stations. Basis risk (i.e., farmers suffer damage but no payout is triggered based on weather data) can promote distrust. There can also be difficulty in scaling up successful pilot schemes.
•Insurance for work programs can enable cash-poor farmers to work for insurance premiums by engaging in community-identified disaster risk reduction projects.
[15.2.4, 13.3.2, Box 22-3, 15.2.2, Box 25-7, 10.7.6, 10.7.5]

Relocation of agricultural industries in Australia
EXPOSURE AND VULNERABILITY : Crops sensitive to changing patterns of rainfall, water availability, and temperature. [7.5.2]
CLIMATE INFORMATION AT THE GLOBAL SCALE: Observed: Increase in globally averaged near surface temperatures since 1900, with warming particularly marked since the 1970s. *Very likely* decrease in the overall number of cold days and nights and increase in the overall number of warm days and nights, on the global scale between 1951 and 2010. *Medium confidence* that the length of warm spells, including heat waves, has increased globally since 1950. *Medium confidence* in global precipitation change over land since 1950. *Likely* increase in the number of heavy precipitation events in more regions than the number has decreased since 1950. *Low confidence* in any observed large-scale trends in drought. Projected: For RCP 4.5, 6.0, and 8.5, global mean surface air temperatures are projected to at least *likely* exceed 2° C with respect to preindustrial by 2100. *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global temperature increases, for events defined as extremes on both daily and seasonal timescales. *Virtually certain* increase in global precipitation as global mean surface temperature increases. Regional to global-scale projections of soil moisture and drought remain relatively uncertain. For short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 2.4, 2.5.1, figure 2.28, 2.6.1, 2.6.2, 12.3.1, 12.4.1, figure 12.2, figure 12.5, 12.4.3, 12.4.5]
CLIMATE INFORMATION AT THE REGIONAL SCALE: Observed: Mean temperature increase of 0.9°C per decade over Australia since 1911 (*very high confidence*). Cool extremes rarer and hot extremes more frequent and intense over Australia and New Zealand (*high confidence*). Late autumn/winter decreases in precipitation in Southwestern Australia since the 1970s and Southeastern Australia since the mid-1990s, and annual increases in precipitation in Northwestern Australia since the 1950s (*very high confidence*). Significant increases in annual intensity of heavy precipitation in recent decades for sub-daily events in Australia (*high confidence*). Projected: Further warming of Australasia this century *virtually certain*, greatest over inland areas and least in coastal areas. Hot days and nights more frequent and cold days and nights less frequent during the 21st century in Australia and New Zealand (*high confidence*). Annual decline in precipitation over southwestern Australia (*high confidence*) and in southern Australia (*medium confidence*). Reductions strongest in the winter half-year (*high confidence*). Increase in intensity of rare daily rainfall extremes (*high confidence*) and of annual daily extremes (*medium confidence*) in Australia and New Zealand. Drought occurrence to increase in Southern Australia (*high confidence*). Snow depth and snow area to decline in Australia (*very high confidence*). Freshwater resources projected to decline in the highly populated southeast and the far southwest of Australia. [25.5.1, Table 25-1]
DESCRIPTION: Industries and individual farmers are relocating parts of their operations, for example for rice, wine, or peanuts in Australia, or are changing land use in situ in response to recent climate change or perceptions of future change. There have been new investments in grapes in Tasmania and switching from grazing to cropping in South Australia. Adaptive movement of crops has also occurred elsewhere, such as in China. [7.5.2, Table 9-6, 25.7.2, Box 25-5]
BROADER CONTEXT: •Considered transformational adaptation in response to impacts of climate change. •Positive or negative implications for communities in origin and destination regions, with substantial changes required in transport chains, inputs, management, or growing contracts. •Some decisions run across scales and include many stakeholders, with comprehensive regional assessments across enterprises and economic and resource outcomes needed. [7.5.2, 25.7.2, Box 25-5]

Table TS.4: Entry points, strategies, measures, and options for managing the risks of climate change. These approaches should be considered overlapping rather than discrete, and they are often pursued simultaneously. Examples given can be relevant to more than one category.

Entry Point	Category			Examples	Chapter Reference(s)
Vulnerability reduction through development and planning	Forms of sectoral integration	Human development	Specific measures	Low regrets options to reduce structural inequalities: improved access to education, nutrition, health facilities, energy, safe settlement structures, social support structures; reduced gender inequality and marginalization in other forms.	13.1.2, 13.3.1, 13.4.1, 13.4.2, 22.3.1
		Poverty alleviation		Insurance schemes, social protection programs, disaster risk reduction. Improved access to and control of local resources, land tenure, and storage facilities. Low regrets options to reduce structural inequalities.	13.1.2, 13.3.1, 13.3.2, 13.4.1
		Livelihood security		Income and asset diversification. Improved infrastructure. Access to technology and decision-making fora, enhanced agency.	13.1.1, 13.3.1, 13.4.1
		Disaster risk reduction and management		Early warning systems.	11.7.3, 22.4.5, 26.9.1
		Ecosystem management		Maintaining wetlands and urban green spaces, coastal afforestation.	8.3.3, Box 8.1, 15.3.1, Box CC-EA
		Spatial or land-use planning		Provisioning of adequate housing, infrastructure, and services. Managing development in flood prone and other high risk areas.	8.1.4, 8.4.3, 8.5.3
Adaptation	Structural/ concrete	Engineered	Specific options	Sea walls, water storage, improved drainage, beach nourishment, flood shelters. Improved infrastructure.	14.3.1, Table 14-2
		Technological		New crop and animal varieties, efficient irrigation and water use, hazard mapping and monitoring, early warning systems, home insulation.	14.3.1, Table 14-2
		Ecosystem-based		Wetland reestablishment, reestablishment of floodplains, bushfire fuel-reduction actions.	14.3.1, Table 14-2
		Services		Social safety nets, food banks, vaccination programs, municipal services.	14.3.1, Table 14-2
	Institutional	Economic	Specific options	Financial incentives, insurance and other risk spreading.	13.3.2, 14.3.2, Table 14-2
		Laws and regulations		Land zoning laws, building standards, easements.	14.3.2, Table 14-2
		Government policies and programs		National and local adaptation plans, urban upgrading programs, municipal water conservation programs, disaster planning and preparedness.	14.3.2, Table 14-2
	Social	Educational	Specific options	Awareness raising, extension services.	14.3.3, Table 14.2
		Informational		Hazard mapping and monitoring, early warning, community support groups.	14.3.3, Table 14-2
		Behavioral		Household preparation, evacuation planning, retreat and migration, water conservation, storm drain clearance.	14.3.3, Table 14-2
Transformation	Spheres of change	Practical	Specific strategies	Social and technical innovations, behavioral shifts, or institutional and managerial changes that produce measurable outcomes.	20.5.2
		Political		Changes in the political, social, cultural and ecological systems or structures that currently contribute to risk and vulnerability or impede practical transformations.	20.5.2
		Personal		Changes in individual and collective assumptions, beliefs, values, and worldviews that influence climate change responses.	20.5.2
Mitigation	See WGIII AR5.				

Table TS.5: Examples of risks that increase with increasing level of climate change. Examples of potential positive impacts are also given. Risks increasing moderately or severely from now until the 2040s, which can be considered an era of climate responsibility, are described, in addition to risks increasing from ~2050 through the end of the 21st century, which can be considered to represent an era of climate options. For risks increasing in both the era of climate responsibility and the era of climate options, the potential for proactive adaptation to reduce the risks is characterized as low or high, with detail provided on adaptation issues and prospects. Risks increasing in the era of climate options can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options. Increasing risks in the era of climate responsibility are generally difficult to reduce substantially through mitigation, even with globally effective mitigation. They can be managed through vulnerability reduction, adaptation, and transformations that promote climate-resilient development pathways.

---------- LEGEND ----------

ERA & ADAPTATION POTENTIAL	Risk for current (C) and hypothetical fully adapted (A) state. Color scheme depicts the additional risk due to climate change. White to red indicates lower and higher levels of risk, respectively. The vertical axis of each bar represents the level of climate change (T). The horizontal blue line indicates the level of climate change at the end of the era of climate responsibility.	
	A risk increasing moderately as early as the era of climate responsibility (now through the 2040s), which can be reduced substantially with proactive adaptation.	 A risk increasing moderately as early as the era of climate responsibility (now through the 2040s), which will be difficult to reduce substantially even with proactive adaptation.
	A risk increasing moderately or severely during the era of climate options (~2050 through the end of the 21st century), which can be reduced substantially with proactive adaptation. The risk can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options.	 A risk increasing moderately or severely during the era of climate options (~2050 through the end of the 21st century), which will be difficult to reduce substantially even with proactive adaptation. The risk can generally be reduced through globally effective mitigation occurring during the era of climate responsibility and the era of climate options.
	A risk increasing moderately as early as the era of climate responsibility (now through the 2040s), for which potential for risk reduction via proactive adaptation was not assessed.	 A risk increasing moderately or severely during the era of climate options (~2050 through the end of the 21st century), for which potential for risk reduction via proactive adaptation was not assessed.

CLIMATE DRIVERS	Where particular climate driver(s) are especially relevant for an assessed risk, they are indicated via the symbols below.							
	Average temperature		Extreme temperature		Precipitation		Extreme precipitation
CO_2	CO_2 concentration & ocean acidification		Damaging cyclone		Snow cover		Sea level

REGION	CROSS-SECTORAL RISKS			
	Risk	Era & Adaptation Potential	Adaptation Issues/Prospects	Chap. Ref.
Global	Stringent mitigation scenarios can potentially avoid one half of the aggregate economic impacts that would otherwise accrue by 2100, and between 20-60% of the physical impacts, depending on sector and region.			19.7.1, 19.7.2
	Key risks associated with global temperature rise in excess of 4°C relative to preindustrial levels include exceedance of human physiological limits in some locations and nonlinear earth system responses (*high confidence*).			19.5.1, 19.6.3, Box TS.6
	Warming of up to 2°C above 1990-2000 levels would result in significant impacts on many unique and vulnerable systems, and would likely increase the endangered status of many threatened species (*high confidence*), with increasing adverse impacts and increasing risk of extinctions (and increasing confidence in this conclusion) at higher temperatures.		Unique human and natural systems tend to have very limited adaptive capacity. Climate change impacts would outpace adaptation for many species and systems if a global temperature rise of 2°C over preindustrial levels were exceeded (*high confidence*).	19.6.3

	Since AR4, the assessment of overall risk from extreme events due to climate change has not changed significantly, but there is higher confidence in the attribution of some types of extreme events to human activity and in the assessment of the risk from extreme events in the coming decades.			There is a new appreciation for the importance of exposure and vulnerability, in both developed and developing countries, in assessing risk associated with extreme events.	19.6.1, 19.6.3
REGION	**FRESHWATER RESOURCES AND SYSTEMS**				
	Risk	**Climate Driver(s)**	**Era & Adaptation Potential**	**Adaptation Issues/Prospects**	**Chap. Ref.**
Global	Hydrological impacts of climate change increase with increasing greenhouse-gas emissions (*high agreement, robust evidence*).			A low-emissions pathway reduces damage costs and costs of adaptation.	Table 3-2, 3.4, 3.5, 3.6.5
	Glaciers will continue to lose mass, with meltwater yields from stored glacier ice eventually diminishing as the glaciers shrink (*high agreement, robust evidence*).				3.4.4
Europe	Climate change is *likely* to further increase coastal and river flood risk and, if unabated, will substantially increase flood damages (monetary losses and people affected).			Adaptation can prevent most of the projected damages (*high confidence*).	23.3.1, 23.5.1, 23.7.1, 23.8.3
Asia	Shrinking of glaciers in Central Asia and the Himalayas is projected to affect water resources in downstream river catchments. Population growth and increasing demand arising from higher standards of living could worsen water security in many parts of Asia and affect many people in the future.			Water saving technologies and changing to drought tolerant crops have been found to be successful adaptation options in the region.	24.4.1, 24.9.3
Australasia	Systematic constraints on water resource use in southern Australia, driven by rising temperatures and reduced cool-season rainfall (*high confidence*).			Integrated responses encompassing management of supply, recycling, water conservation, and increased efficiency across all sectors are available but face implementation constraints.	25.2, 25.5.1, Box 25-2
	Increased frequency and intensity of flood damage to settlements and infrastructure in Australia and New Zealand, driven by increasing extreme rainfall although the amount of change remains uncertain (*high confidence*).			In many locations, continued reliance on increased protection alone would become progressively less feasible.	Table 25-1, 25.4.2, 25.10.3, Box 25-8
North America	Throughout North America, it is *very likely* that the 21st century will witness decreases in water quality, and increases in flooding and droughts under climate change, with these impacts exacerbated by other anthropogenic drivers. It will also witness decreases in water supplies for urban areas and irrigation in some areas of North America, with confounding effects of development.				26.3, 26.8
Central and South America	For regions already vulnerable in terms of water supply, such as the semi-arid zones in Chile-Argentina, North Eastern Brazil, and Central America and the tropical Andes, glacier retreat and a reduction in water availability due to expected precipitation reduction and increased evapotranspiration demands are expected, affecting water supply for large cities, small communities, hydropower generation, and the agriculture sector.			Current practices to reduce the mismatch between water supply and demand could be used to reduce future vulnerability.	27.3.1, 27.6.1
REGION	**TERRESTRIAL ECOSYSTEMS, DROUGHT, & WILDFIRE**				
	Risk	**Climate Driver(s)**	**Era & Adaptation Potential**	**Adaptation Issues/Prospects**	**Chap. Ref.**
Global	Drying of soils is projected in most dry regions (*medium confidence*).				3.4.9, 3.5, WGI AR5 12.4.5
	For freshwater ecosystems (*high confidence*) and terrestrial ecosystems (*medium confidence*), direct human impacts such as land-use change, pollution, and water resource development will continue to dominate threats to ecosystems, with climate change becoming an increasing additional stress through the century, especially for high-warming scenarios such as RCP 6.0 and 8.5.			Management actions can reduce, but not eliminate, exposure to climate-driven ecosystem impacts, and can increase ecosystem adaptability (*high confidence*).	Box CC-RF, 4.3.3, 4.4.1, 4.4.3

	For high altitude and latitude freshwater and terrestrial ecosystems, climate changes exceeding those projected under RCP 2.6 will lead to major changes in species distributions and ecosystem function.				4.3.2, 4.3.3, 4.4.1
	Even for mid-range rates of climate change (i.e., RCP 4.5 and 6.0), many species will be unable to move fast enough to track suitable climates (*medium confidence*). Era of relevance depends on species and habitat type.			Low migration capacity and large flat areas pose the most serious problems for tracking climate. Capacity for natural adaptation is substantial but, for many ecosystems and species, insufficient to cope with the rate and magnitude of climate change projected under RCP 6.0 or 8.5.	4.3.2, 4.3.3, 4.4.1, 4.4.3
	Large magnitudes of climate change will negatively impact species with populations primarily restricted to protected areas, mountaintops, or mountain streams, even those that potentially migrate fast enough to track suitable climates (*high confidence*).			Capacity for ecosystems to adapt to climate change can be increased by, for example, assisted translocation.	4.3.2, 4.3.4, 4.4.1, 4.4.3
	Increased extinction risk for a substantial fraction of species during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, and invasive species (*very high confidence*).			Capacity for ecosystems to adapt to climate change can be increased by reducing other stresses; reducing habitat fragmentation and increasing connectivity; maintaining a large pool of genetic diversity and functional evolutionary processes; and manipulation of disturbance regimes.	4.3.2, 4.4.1, 4.4.3
Africa	Many fragile terrestrial and aquatic ecosystems are implicitly or explicitly water dependent. Impacts of climate change will be superimposed onto already water-stressed catchments with complex land uses, engineered water systems, and a strong historical socio-political and economic footprint (*high confidence*).				22.3.2, 22.3.3
Europe	Changes in habitats and species will result in local extinction (*high confidence*) and continental scale shifts (*low/medium confidence*). Increasing local loss of native species and extinction of species across most sub-regions of Europe by 2050 (medium emissions) with economic development and land-use change. Introduction and expansion of invasive species, especially those with high migration rates, from outside Europe will increase with climate change (*medium confidence*).				23.4.4, 23.6.4, 23.6.5, 23.10, Table 23.2
	Climate change will increase damage to forests from pests and diseases in all sub-regions (*high confidence*), from wildfires in Southern Europe (*high confidence*), and from storms (*low confidence*).				23.4.4
Asia	Terrestrial systems are under increasing pressure from both climatic and non-climatic drivers. The projected changes in climate will impact vegetation and increase permafrost degradation during the 21st century (*high confidence*). The largest changes are expected in cold northern and high-altitude areas, where boreal and subalpine trees will *likely* invade treeless arctic and alpine vegetation, and evergreen conifers will *likely* invade deciduous larch forest.				24.2.2, 24.4.2, 24.4.3, 24.9.3
Australasia	Loss of montane ecosystems and some endemic species in Australia, driven by rising temperatures, increased fire risk and drying trends (*high confidence*).			Fragmentation of landscapes, limited dispersal and evolutionary capacity limit adaptation options.	25.6.1
	Projected changes in climate and increasing atmospheric CO_2 have the potential to benefit forest growth in cooler regions except where soil nutrients or rainfall are limiting (*high confidence*).				25.7.1, 25.7.2
	Increased damages to ecosystems and settlements, economic losses, and risks to human life from wildfires in most of southern Australia and many parts of New Zealand, driven by drying trends and rising temperatures (*high confidence*).			Building codes, design standards, local planning mechanisms, and public education can assist with adaptation and are being implemented in regions that have experienced major events.	25.2, Table 25-1, 25.6.1, 25.7.1, Box 25-6
North America	A global increase of 2°C would have widespread adverse impacts on many ecosystems, *likely* reducing biodiversity and ecosystem services (*high confidence*).				26.4

Central and South America	Continued climate change together with land use change and fire activity could cause much of the Amazon forest to transform abruptly to more open, dry-adapted ecosystems, and in doing so, put a large stock of biodiversity at elevated risk and create a large new net greenhouse gas source to the atmosphere (*low confidence*). The combination of climate change and land-use change in the Amazon will cause accelerated drying and drought frequency in the region (*medium confidence*), and there is *low confidence* that these Amazon changes will affect rainfall in agricultural regions elsewhere on the planet.			Rigorously applied adaptation measures could lower the risk of abrupt change in the Amazon, as well as the impacts of that change (*medium confidence*).	4.2.2, 4.2.4, 4.3.3, Box 4-3, Box 4-4, Figure 4-10
Polar Regions	Continued climate change could push the boreal-arctic system across a tipping point in this century and cause an abrupt transformation of the ecology and albedo of this region, as well as the release of greenhouse gases from thawing permafrost and burning forests (*low confidence*).			Adaption measures will be unable to prevent substantial change in the boreal-arctic system (*high confidence*).	4.2.2, 4.2.4, 4.3.3, Box 4-3, Box 4-4, Figure 4-10

REGION	COASTAL & MARINE SYSTEMS Risk	Climate Driver(s)	Era & Adaptation Potential	Adaptation Issues/Prospects	Chap. Ref.
Global	Under medium socio-economic development assumptions, the expected direct global annual cost of coastal flooding (adaptation and residual damage costs) may reach 300 US$ billion per year in 2100 without adaptation and 90 US$ billion per year with adaptation under a 1.26 m sea-level rise scenario.				5.4.3, 5.5.3
	While developed countries are expected to be able to adapt to even high levels of sea-level rise, small island states and some low-lying developing countries are expected to face very high impacts and associated annual damage and adaptation costs of several percentage points of GDP (*high agreement*). Developing countries and small island states within the tropics relying on coastal tourism are impacted not only directly by future sea-level rise and associated extremes but also by the impacts of coral bleaching and ocean acidification and reductions in tourist flows from other regions (*very high confidence*).				5.4.3, 5.5.3
	Physical effects of climate change on marine ecosystems may act, under some circumstances, as an additional pressure that cannot be ameliorated by local conservation measures or a reduction in human activities like fishing (*high confidence*).				6.4
	Some warm water corals and their reefs will continue to respond to warming with species replacement, bleaching, and decreased coral cover. The projected degradation of some marine ecosystems such as coral reefs and Mediterranean intertidal communities is *very likely* to pose substantial challenges for coastal societies where livelihoods and food security may depend on ecosystem health.			Genetic adaptation may occur; the capacity to compensate for or keep up with the rate of ongoing thermal change is limited (*low confidence*).	6.2, 6.3, 6.5.2, 30.4, 30.5.3, 30.5.6, Box CC-CR
	Through species gains and losses correlated with warming, the diversity of animals and plants will increase at mid and high latitudes (*high confidence*) and fall at tropical latitudes (*low confidence*), leading to a large-scale redistribution of global catch potential for fishes and invertebrates (*medium confidence*). Animal displacements are projected to lead to a 30–70% increase in the fisheries yield of high-latitude regions but a drop of 40–60% in the tropics by 2055 relative to 2005 under the SRES A1B scenario (*medium confidence* for the general trend of shifting fisheries yields, *low confidence* for the magnitude of change).				6.2.5, 6.3.2, 6.4, 6.5, 6.5.2
	Changes in ocean mixing, nutrient levels, and primary productivity are *very likely* to have positive consequences for some fisheries and negative ones for others through the de-oxygenation of deep water environments and associated spread of hypoxic zones (*medium agreement, medium evidence*).				30.5, 6.2, 6.3, 6.5
	Changes to surface winds, sea level, wave height, and storm intensity will increase the risks associated with coastal and ocean based industries such as shipping, oil, gas, and mineral extraction (*medium agreement, medium evidence*).				30.6, 6.5
Africa	Impacts of climate change, mainly through sea level rise, combined with other extreme events (such as high tide levels and high storm swells) have the potential to threaten coastal zones, particularly coastal towns (*high confidence*).				22.3.2, 22.3.4, 22.3.7
Europe	Costs of adapting dwellings or upgrading coast defence will increase under all scenarios (*high confidence*).				23.3.2, 23.6.5, 23.7.3

	Climate change will not decrease net fisheries economic turnover in some parts of Europe (e.g., Bay of Biscay) (*low confidence*) due to introduction of new (high temperature tolerant) species. Climate change will not entail relocation of fishing fleets (*high confidence*).				23.4.6
Asia	In the Asian Arctic, rising sea levels will interact with projected changes in permafrost and the length of the ice-free season to cause increased rates of coastal erosion (*high agreement, medium evidence*).				24.4.3
Australasia	Significant change in community structure of coral reef systems in Australia, driven by increasing sea-surface temperatures and ocean acidification (*high confidence*).			The natural ability of reefs to adapt to projected changes is limited.	Box CC-CR, 25.6.2, 30.5
	Widespread damages to coastal infrastructure and low-lying ecosystems in Australia and New Zealand if sea level rise exceeds 1m (*high confidence*). Risks from sea level rise *very likely* continue to increase beyond 2100 even if temperatures are stabilized.			Managed retreat is a long-term adaptation strategy for human systems but options for some natural ecosystems are limited due to the rapidity of change and lack of suitable space for inland migration.	WGI AR5 13.ES; Box 25-1, Table 25-1, 25.4.2, 25.6.1-2
Polar Regions	Shifts in the timing of seasonal biomass production could disrupt matched phenologies in food webs, leading to decreased abundance of high latitude marine organisms (*medium confidence*).				28.2.2, 28.3.2

REGION	HUMAN SYSTEMS Risk	Climate Driver(s)	Era & Adaptation Potential	Adaptation Issues/Prospects	Chap. Ref.
Global	Global arable area is *likely* to increase from 2007 to 2050 (*high agreement, medium evidence*), with projected increases over this period of between 9% and 25% (*medium agreement, medium evidence*). From the mid-21st century onwards, the human food system at scales from the local to global and particularly in low-latitude lands will be seriously and negatively affected by projected climate change (*high agreement, robust evidence*). For 4-6 °C global mean temperature above pre-industrial levels, global risks to food production and security may become very severe (*high agreement, medium evidence*).			Adaptation possibilities for food systems vary widely in effectiveness. Adaptation will increase in effectiveness up to ca. 3°C local mean warming above pre-industrial, after which the net benefits no longer increase (*medium confidence*).	7.1, 7.2, 7.3, 7.4, 7.5, 7.6, Figures 7-5, 7-9
	Without adaptation, moderate warming of up to 2°C local temperatures is expected to reduce yields on average for the major cereals (wheat, rice, and maize) in temperate regions, although many individual locations may benefit (*medium confidence*). There is confirmation that even modest warming up to 2°C will decrease yields in low-latitude tropical regions (*medium agreement, robust evidence*).			Benefits of adaptation are greater for wheat, rice, and maize in temperate rather than tropical regions.	7.1, 7.3.2, 7.4-6, Figs 7-5, 7-6, 7-7, 7-9
	Yield reductions of more than 5% are *more likely than not* beyond 2050 and *likely* by the end of the century. From the 2070s, all positive yield changes are in temperate regions, suggesting yield reductions in the tropics are *very likely* by this time and substantial, particularly for wheat (*high agreement, robust evidence*).				7.4, Figures 7-5, 7-6, and 7-7
	Climate change will lead to higher prices and increased volatility in agricultural markets, which might undermine global food supply security while affecting rural households depending on whether they are net buyers or net sellers of food (*medium* to *high confidence*).			Deepening agricultural markets through reforming trade and institutional efforts to improve the predictability and reliability of the world trading system, as well as investing in supply capacity of small-scale farms in developing countries, could help reduce market volatility and manage food supply shortages (*medium agreement*).	9.3.3
	In the next few decades, climate change will increase incidence of injury, disease, and death due to more intense heat waves, storms, floods, and fires; increase risk of under-nutrition in some developing regions; reduce work capacity and labor productivity in vulnerable populations; increase risks of food- and water-borne diseases and vector-borne infections; and modestly improve health outcomes in some areas due to lower impacts of cold, shifts in food production, and reduction of disease-carrying vectors. Positive health effects will be out-weighed, world-wide, by the magnitude and severity of negative impacts.			Impacts on health will be reduced, but not eliminated, in populations that benefit from rapid social and economic development, particularly among the poorest and least healthy groups.	11.4, 11.5, 11.6, 11.7

	For RCP 8.5 by 2100, limits to adaptation for health impacts may be exceeded in many areas of the world (*high confidence*), related to sea level rise, storms, loss of agricultural productivity, and daily temperature/humidity conditions that exceed coping mechanisms.				11.8
	Climate change threatens human security, because it a) undermines livelihoods, b) compromises culture and identity, c) increases migration that people would rather have avoided, and d) undermines the ability of states to provide the conditions necessary for human security (*high agreement, robust evidence*). Increases in the rate and magnitude of climate change increase the risk to human security by exacerbating negative feedbacks between cultural processes, migration, and violent conflict.			Human security breakdowns almost never have single causes, but instead emerge from the interaction of multiple factors. For populations already socially marginalized and resource dependent with limited capital assets, human security will be progressively undermined as the climate changes.	12.1.2, 12.2, 12.7
Africa	Spatial convergence of impacts in different sectors creates impact "hotspots" involving new interactions, for example, in Sub-Saharan Africa where global warming at the high end of the range projected for this century, i.e., more than 4°C above preindustrial levels, would be especially disruptive, resulting in high risk of reduced extent of croplands, reduced length of the growing season, increased hunger, and increased malaria transmission.				19.3.2
	Temperature rise and a reduction in growing season length by mid-century are expected to significantly reduce crop productivity with strong adverse effects on food security. New challenges to food security are emerging as a result of strong urbanization trends on the continent and increasingly globalized food chains, which require better understanding of the multi-stressor context of food and livelihood security.				22.3.4
	Climate change is expected to increase the burden of a wider range of health outcomes (*medium confidence*).				22.3.5
Europe	Increasing heat wave mortality across most sub-regions of Europe by 2050 (medium emissions) with economic development and land-use change. Particularly in Southern Europe, increased frequency and intensity of heat waves (*high confidence*) will have adverse implications for health, agriculture, energy production, transport, tourism, labour productivity, and built environment (*medium confidence*).				23.2.2, 23.5.1, Tables 23-4, 23-5
	Climate warming will decrease space heating demand and increase cooling demand (*high confidence*), with income growth driving the largest part of this increase from 2000-2050 (especially in eastern regions) (*medium confidence*). Climate change will increase problems associated with overheating in domestic housing.			Energy efficient buildings and cooling systems as well as demand-side management will reduce future energy demands.	23.3.2, 23.3.4
	Climate change will increase yields in Northern Europe (*medium confidence*) but decrease cereal yields in Southern Europe (*high confidence*).				23.4.1, 23.4.2, 23.5.1
	Climate change will increase irrigation needs (*high confidence*), but future irrigation will be constrained by reduced runoff, demand from other sectors, and economic costs. By 2050s, irrigation will not be sufficient to prevent damage from heat waves to crops (*medium confidence*).				23.4.1, 23.4.3, 23.7.2
	Climate change will decrease hydropower production from reductions in rainfall in all sub-regions except Scandinavia (*high confidence*). Climate change will inhibit thermal power production during summer (*medium confidence*).			Plant modifications and operational changes can reduce adverse impacts.	23.3.4
	No significant impacts are projected before 2050 in winter or summer tourism except for ski tourism in low- and mid-altitude sites and under limited adaptation (*medium confidence*). After 2050, tourism activity will decrease in southern Europe (*low confidence*) and increase in northern/continental Europe (*medium confidence*).				23.3.6
	Increasing damage of cultural buildings and loss of cultural landscapes across most sub-regions by 2050 (medium emissions). Climate change and sea level rise will damage cultural heritage and iconic places such as Venice (*medium confidence*), and some cultural landscapes will be lost forever (*low/medium confidence*).				23.5.4, Table 23-5
Asia	The impacts of climate change on food production and food security will vary by region with many regions experiencing a decline in productivity (*medium confidence*). This is evident in the case of rice production, with lower yields as a result of shorter growing periods and heat-induced sterility. There are a number of regions that are already near the critical temperature threshold. In parts of Asia, increases in flood and drought will exacerbate rural poverty due to negative impacts on rice crops and increases in food prices and the cost of living (*high confidence*).			There are many potential adaptation strategies such as crop breeding, but research on their effectiveness is limited.	24.4.4, 24.4.6

	More frequent and intense heat-waves will increase mortality and morbidity in vulnerable groups. Increases in heavy rain and temperature will increase the risk of diarrheal diseases and malaria (*high confidence*).				24.4.6
Australasia	Increasing morbidity, mortality, and infrastructure damages during heat waves in Australia, resulting from increased frequency and magnitude of extreme temperatures (*high confidence*). Vulnerable populations include the elderly, children, and those with existing chronic diseases.			Aging trends and prevailing social dynamics constrain effectiveness of adaptation responses.	25.8.1
	Significant reduction in food production in the Murray-Darling Basin, far south-eastern Australia, and some eastern and northern areas of New Zealand if scenarios of severe drying are realized (*high confidence*).			More efficient water use, allocation, and trading would increase the resilience of systems in the near term but cannot prevent significant reductions in agricultural production and severe consequences for ecosystems and some rural communities at the dry end of the projected range.	25.2, 25.5.1, 25.7.2, Box 25-5
North America	Without adaptation, projected changes in temperature, precipitation, and extreme events would result in notable productivity declines in major crops by the end of the 21st century (*very high confidence*). Given that North America is a significant source of global food supplies, there will *likely* be a negative effect on global food security if projected productivity declines are not addressed with substantial investments in adaptation (*medium confidence*).			Adaptation may ameliorate many climate impacts to agriculture, but the institutional support mechanisms currently in place are insufficient to ensure effective, equitable, and sustainable adaptation strategies.	26.5
	Given current levels of adaptation, there are *likely* to be increased health impacts from heat extremes among vulnerable communities, populations, and individuals.			Health impacts from increasing heat extremes will depend on the pace of adaptation (*high confidence*).	26.6
Central and South America	Climate-change-related changes in agricultural productivity are expected to vary greatly spatially. In Southeastern South America, where projections indicate more rainfall, average productivity could be sustained or increased until the mid-century (SRES: A2, B2) (*medium confidence*). In Central America, northeast Brazil, and parts of the Andean region, increases in temperature and decreases in rainfall could decrease productivity in the short-term (before 2025), threatening food security of the poorest populations.				27.3.4
	It is *very likely* that climate variability and change may exacerbate current and future risks to health, given the region's vulnerabilities in existing health, water, sanitation and waste collection systems, nutrition, and pollution.				27.3.7
Polar Regions	Spatial convergence of impacts in different sectors creates impact "hotspots" involving new interactions, for example in the Arctic where sea ice loss and thawing disrupts transportation, buildings, other infrastructure, and potentially disrupts Inuit culture (*high confidence*).				19.3.2
	Significant impacts on the availability of key subsistence marine and terrestrial species are projected as climate continues to change with the ability to maintain economic livelihoods being affected (*high confidence*). Changing sea-ice conditions will result in more difficult access for hunting marine mammals.				28.2.6
	Increased economic opportunities and challenges for culture, security, and environment are expected with the increased navigability of Arctic marine waters and the expansion of land- and fresh water-based transportation networks (*high confidence*).				28.2.6, 28.4.2
Small Islands	Spatial convergence of impacts in different sectors creates impact "hotspots" involving new interactions, for example in the environs of Micronesia, Mariana Island, and Papua New Guinea where coral reefs are highly threatened due to exposure to concomitant sea surface temperature rise and ocean acidification (*high confidence*).				19.3.2

Table TS.6: Assessment of climate change impacts by European sub-region and sector (by 2050, medium emissions) With economic development, with land use change. No further planned adaptation. [Table 23-4]

FOOTNOTES

[1] Simulations have been performed, but mostly for the period after 2070.

[2] The increasing trend is for Norway.

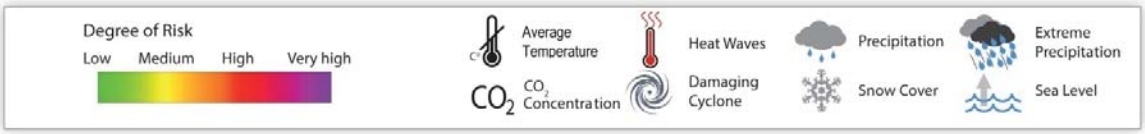
[3] The decreasing trend refers mainly to the number of severe accidents.

[4] Impacts have been studied and quantified for UK only. The increasing trend stands for summer delays and the decreasing trend for winter delays.

[5] In both seasons, no significant impacts are expected by 2020, while more substantial changes are expected by 2080. For 2050 impacts are assumed to vary linearly (although this may not be the case).

[6] The constant trend stands for the Mediterranean, where some studies estimate no changes due to climate change at least until 2030 or even 2060.

Table TS.7: Key regional risks during the 21st century from climate change for Australia and New Zealand. Color bars indicate risk as a function of global mean temperature relative to pre-industrial, based on the studies assessed and expert judgement, for the current (top bar) and a hypothetical fully adapted state (bottom bar). For each risk, relevant climate variables and trends are indicated by symbols, in approximate order of priority. Where relevant climate projections span a particularly wide range even for a given amount of global mean temperature change, risks are shown in two pairs for high and low end projections, each without and with effective adaptation*. [Table 25-8]



Arrows show projected future changes in key drivers under a range of climate and mitigation scenarios. Arrows pointing in both directions indicate that the direction of change (indicated by red and blue colours) is uncertain. Narrow horizontal bars indicate the range of potential changes, with more bars indicating greater uncertainty. Thick bars are used where the direction of change is highly certain and some amount of further change over the 21st century is virtually unavoidable even under mitigation scenarios.

Key Regional Risk		Risk for current and hypothetical fully adapted state	Key Climate Drivers and Trends	Key adaptation issues / prospects
Impacts that can be delayed but now appear very difficult to avoid entirely, even with globally effective mitigation and proactive adaptation	Significant change in community structure of coral reef systems in Australia [25.6.2, 30.5, Box CC-CR]	current / adapted; 0 °C 2 °C 4 °C 6 °C	CO_2	Limited evidence for autonomous genetic adaptation of corals; other adaptation options are limited to reducing other stresses, mainly enhancing water quality and limiting pressures from tourism and fishing
	Loss of montane ecosystems and some endemic species in Australia [25.6.1]	current / adapted; 0 °C 2 °C 4 °C 6 °C		Direct adaptation options are limited, but reducing other stresses such as pests, diseases and predator control and enhancing connectivity of habitats provides immediate co-benefits; need to consider translocation and migration
Impacts that have the potential to be severe but can be moderated or delayed significantly by globally effective mitigation and a portfolio of available adaptation measures	Wild fire damages to ecosystems and settlements and risks to human life in southern Australia and many parts of New Zealand [Table 25-1, Box 25-6]	current / adapted; 0 °C 2 °C 4 °C 6 °C		Part of integrated landscape management; trade-offs exist between different management objectives and settlement patterns and goals
	Systematic constraints on water resource use in southern Australia [25.5.1, Box 25-2, 25-9]	current / adapted; 0 °C 2 °C 4 °C 6 °C		Water resources already struggling to meet unlimited demand in many locations and exacerbated by projected population growth; effective adaptation relies on combination of demand and supply mechanisms
	Increase in morbidity and mortality and infrastructure failure during heat waves in Australia [25.7.4, 25.8.1]	current / adapted; 0 °C 2 °C 4 °C 6 °C		Linked to social dynamics and ageing population in cities; transport and power infrastructure already at coping limit in many regions, with significant financial costs from future upgrades
	Increased frequency and intensity of flood damage to infrastructure and settlements in Australia and New Zealand [25.2, Table 25-1, Box 25-8, 25-9]	current / adapted; 0 °C 2 °C 4 °C 6 °C		Significant adaptation deficit in some regions to current flood risk; effective adaptation includes land-use controls and relocation as well as protection and accommodation of increased risk to ensure flexibility
Impacts that have a low or currently unknown probability but cannot be ruled out even with globally effective mitigation, and would present major challenges if realized	Significant reduction in food production in the Murray-Darling Basin, far south-east Australia and eastern and northern parts of New Zealand [25.2, Table 25-1, 25.6.1, 25.7.2, Box 25-2, 25-5]	current / adapted Wet; current / adapted Dry; 0 °C 2 °C 4 °C 6 °C		Immediate co-benefits from improved management of over-allocated water resources and balancing competing demands, but the extreme dry end would threaten agricultural production as well as ecosystems and some rural communities
	Widespread damages to coastal infrastructure and low-lying ecosystems in Australia and New Zealand [Table 25-1, 25.6.1, 25.6.2, Box 25-2, 25-9]	current / adapted Low; current / adapted High; 0 °C 2 °C 4 °C 6 °C		Adaptation deficit in some locations to current coastal erosion and flood risk; successive building and protection cycles constrain flexible responses; effective adaptation includes land-use controls and ultimately relocation as well as protection and accommodation

* For rainfall and its impact on food production, wet and dry scenarios represent approximately the 10 and 90 percentile range of current model projections and RCP emissions scenarios. For sea level, the low scenario is a 0.39 m rise by 2100 (mid-range model projections, RCP 2.6); the high scenario is a 1.5 m rise by 2100 (semi-empirical models, RCP 8.5). See AR5 WGI Chap 13 for more details. Under either scenario, sea level would continue to rise beyond 2100, but the focus of the risk assessment here is for risks that could be realised during the 21st century.

Table TS.8: A selection of the hazards/stressors, key vulnerabilities, key risks, and emergent risks identified in the report. The examples underscore the complexity of risks determined by various climatic hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, demographic changes, or tolerance limits of species and ecosystems that often provide important services to vulnerable communities, generate the context in which climate-change-related harm and loss can occur. The examples illustrate that current global megatrends (e.g., climate change, urbanization, demographic changes), in combination and in specific development contexts (e.g., in low-lying coastal zones), can generate new systemic risks that go far beyond existing adaptation and risk management capacities, particularly in highly vulnerable regions. [Table 19-3]

Hazard/Stressor	Key vulnerabilities	Key risks	Emergent risks
Examples from terrestrial and inland water systems			
Rising air, soil, and water temperature.	Exceedence of eco-physiological climate tolerance limits of species, increased viability of alien organisms.	Loss of native biodiversity, increase in alien organism dominance.	Cascades of native species loss due to interdependencies.
	Epidemiological response to spread of temperature-sensitive vectors (insects).	Novel or much more severe pest and pathogen outbreaks.	Interactions between pest, drought, and fire interactions can lead to new risks and large negative impacts on ecosystems.
Examples from ocean systems			
Rising water temperature, increase of (thermal and haline) stratification, and marine acidification. [6.1.1] *(also Chapter 24)*	Tolerance limits of endemic species surpassed, increased abundance of invasive organisms, high vulnerability of warm water coral reefs and respective ecosystem services for coastal communities. [6.2.2, 6.2.5]	Loss of endemic species, mixing of ecosystem types, increased dominance of invasive organisms, loss of coral cover and associated ecosystems with reduction of biodiversity. [6.3.2]	Enhancement of risk due to interactions, e.g., acidification and warming for calcareous organisms. [6.3.5]
Examples from urban areas			
Inland flooding.	Urban areas with large numbers of poor, uninsured people exposed to flood events including low-income informal settlements. Environmental health consequences from overwhelmed, aging, poorly maintained, and inadequate urban drainage infrastructure combined with widespread impermeable surfaces. Inadequate local governance. Increased mosquito and water borne diseases.	Increasing urban flooding with increasing volume and velocity of flood waters on the one hand and increasing vulnerability on the other leads to key risks particularly in urban areas with large numbers of people who are poor and/or exposed to flooding.	Larger and more frequent flooding impacting a much larger population. Impacts reaching the limits of insurance; shift in the burden of risk management from the state to those at risk leading to greater inequality and property blight; abandonment of urban districts and the creation of high risk/high poverty spatial traps.
Changing hazard profile including novel hazards and new multi-hazard complexes.	Newly exposed populations and infrastructure, especially for those with limited capacity for multi-hazard risk forecasting and where risk reduction capacity is limited, e.g., where risk management planning is overly hazard specific including where physical infrastructure is predesigned in anticipation of other risks.	Risks from failures within coupled systems, e.g., reliance of drainage systems on electric pumps, reliance of emergency services on roads and telecommunications, psychological shock from unanticipated risks.	Loss of faith in risk management institutions. Potential for large events that are magnified by a lack of preparation and capacity to respond.
Examples from human health			
Increasing frequency and intensity of extreme heat. *(also chapter 19)*	Older people living in cities are most vulnerable to heat waves, and their population is projected to triple from 2010-2050.	Increased mortality and morbidity during heat waves, particularly in people with pre-existing conditions.	Overloading of health and emergency services. Mortality, morbidity, and productivity loss, particularly for manual workers in hot climates.
Increasing temperatures, increased variability in precipitation.	Food insecurity translates into malnutrition, which is among the largest disease burdens in poorer populations.	Progress in reducing mortality and morbidity from malnutrition may slow or reverse and constitutes a new key risk.	Combined impacts of climate impacts, population growth, plateauing productivity gains, land demand for livestock, biofuels, persistent inequity, and on-going food insecurity for the poor.
Examples from livelihoods and poverty			
Soaring demand (and prices) of biofuels due to climate change policies.	Unclear and/or insecure land tenure arrangements.	Risk of dispossession of land due to "land grabbing" in developing countries.	Creation of large groups of landless farmers unable to support themselves. Social unrest due to disparities between intensive energy production and neglected food production.
Increasing frequency of extreme events (droughts, floods). For example if 1:20 year drought/flood becomes 1:5 year flood/drought.	Livelihoods subject to damage to their productive assets (e.g. in case of droughts – herds of livestock; if floods – dikes, fences, terraces).	Risk of the loss of livelihoods and harm due to shorter time for recovery between extremes. Pastoralists restocking after a drought may take several years; in terraced agriculture, need to rebuild terraces after flood, which may take several years.	Collapse of coping strategies with risk of collapsing livelihoods. Adaptation mechanisms such as insurance fail due to increasing frequency of claims.

Hazard/Stressor	Key vulnerabilities	Key risks	Emergent risks
Examples from Chapter 19			
Warming and drying (degree of precipitation changes uncertain). [WGI AR5 SPM, TS.5.3, 11.3, 12.4]	Limits to coping capacity to deal with reduced water availability; increasing exposure and demand due to population increase; conflicting demands for alternative water uses; socio-cultural constraints on some adaptation options. [19.2.2, 19.3.2, 19.6.1, 19.7.5]	Risk of harm and loss due to livelihood degradation from systematic constraints on water resource use that lead to supply falling far below demand. In addition, limited coping and adaptation options increase the risk of harm and loss. [19.3.2]	Negative outcomes to sending and/or receiving regions from migration of populations due to limits on agricultural productivity and livelihoods. [19.3.2, 19.4.2]
Examples from Africa			
Increasing temperature.	Health of exposed and vulnerable groups (increased exposure to heat, change in the transmission dynamics of vector-borne diseases).	Increase in disease burden – changes in the patterns of infection. Decrease in outdoor worker productivity due to high temperature, increase in heat related morbidity and mortality.	Emerging and re-emerging disease epidemics.
	Vulnerability of aquatic systems and vulnerability of aquatic ecosystem services due to increased water temperatures.	Loss of aquatic ecosystems and risks for people who might depend on these resources.	
Examples from Europe			
Extreme weather events. *(also Chapter 19)*	Limited coping and adaptive capacity as well as high sensitivity of different sectors, e.g., transport, energy, and health.	Stress on multiple sectors can cause systemic risks due to interdependencies among sectors.	Disproportionate intensification of risk due to increasing interdependencies.
Examples from Asia			
Thawing of permafrost due to rising temperature in northern Asia.	Existence of structures and infrastructure on permafrost and high dependence of civil life on them.	Instability of or damage to structures and infrastructures.	Projected exacerbation of instability of residential buildings, pavements, pipelines used to transport petroleum and gas, pump stations, and extraction facilities.
Projected increase in frequency of various extreme events (heat waves, floods, and droughts) and sea level rise. *(also Chapter 19)*	Convergence of livelihoods and properties into coastal megacities, especially into areas not sufficiently protected against natural hazards.	Loss of human life and assets due to coastal floods accompanied by increasing vulnerabilities caused by occurrence of other extreme events like heat waves and droughts.	Projected increase in disruption of basic services such as water supply, sanitation, energy provision, and transportation systems, which themselves could increase vulnerabilities.
Examples from Australasia			
Warming and increased temperature high extremes in Australia. [25.2, Table 25-1, Figure 25-5]	Urbanization, aging of population and vital infrastructure. [25.3, Box 25-9, 25.10.2]	Increase in morbidity, mortality, and infrastructure failure during heat waves. [25.8.1, 25.10.2]	Increasing risk from compound extreme events across time, space and governance scales, and cumulative adaptation needs. [25.10.2, 25.10.3, Box 25-9]
Potential for sea level rise beyond 2100 exceeding 1m [25.2, WGI AR5 Chapter 13]	Long lifetime of coastal infrastructure, concentration and further expansion of coastal population and assets; conflicting priorities and time preferences constraining adaptation options; limited scope for managed retreat in highly developed areas.	Widespread damages to coastal infrastructure and low-lying ecosystems. [Box 25-1, 25.10.2]	
Examples from North America			
Increases in frequency and/or intensity of extreme events, such as hurricanes, river and coastal floods, heat waves, and droughts. [26.2] *(also Chapter 19)*	Declining state of physical infrastructure in urban areas as well as increases in income disparities. [26.7]	Risk of serious harm and losses in urban areas, particularly in coastal environments due to enhanced vulnerabilities of social groups and physical systems combined with increases of extreme weather events. [26.8]	Inability to reduce vulnerability in many areas results in increase in risk greater than change in physical hazard. [26.8]
Higher temperatures, decreases in runoff, and lower soil moisture. [26.2, 26.3]	Increasing vulnerability of small landholders in agriculture. [26.5]	Increased losses and decreases in agricultural production increase food and job insecurity for small landholders and social groups in that region. [26.5]	Increasing risks of social instability and local economic disruption due to internal migration. [26.2, 26.8]

Table TS.9: Examples of potential trade-offs among adaptation objectives. [Table 16-2]

Sector	Strategy	Adaptation Objective	Real or Perceived Externality
Agriculture	Biotechnology and genetically modified crops	Enhance drought and pest resistance; enhance yields	Perceived risk to public health and safety; ecological risks associated with introduction of new genetic variants to natural environments
	Subsidized drought assistance; crop insurance	Provide financial safety net for farmers to ensure continuation of farming enterprises	Creates moral hazard and inequality if not appropriately administered
	Increased use of chemical fertilizer and pesticides	Maintain or enhance crop yields; suppress opportunistic agricultural pests and invasive species	Increased discharge of nutrients and chemical pollution to the environment; increased emissions of greenhouse gases; increased human exposure to pollutants
Biodiversity	Migration corridors; expansion of conservation areas	Enable natural adaptation and migration to changing climatic conditions	Unknown efficacy; concerns over property rights regarding land acquisition; governance challenges
	Anticipatory endangerment listings	Enhance regulatory protections for species potentially at-risk due to climate change	Addresses secondary rather than primary pressures on species; concerns over property rights; regulatory barriers to economic development
	Assisted migration	Facilitate conservation of valued species	Potential for externalities for ecological and human systems due to species relocation
Coasts	Sea walls	Protect assets from inundation and/or erosion	High direct and opportunity costs; equity concerns; ecological impacts to coastal wetlands
	Managed retreat	Allow natural coastal and ecological processes; reduce long-term risk to property and assets	Undermines private property rights; significant governance challenges associated with implementation
	Migration out of low-lying areas	Preserve public health and safety; minimize property damage and risk of stranded assets	Loss of sense of place and cultural identify; erosion of kinship and familial ties; impacts to receiving communities
Water resources management	Desalination	Increase water resource reliability and drought resilience	Ecological risk of saline discharge; high energy demand and associated carbon emissions; creates disincentives for conservation
	Water trading	Maximize efficiency of water management and use; increases flexibility	Undermines public good/social aspects of water
	Water recycling/reuse	Enhance efficiency of available water resources	Perceived risk to public health and safety

Table TS.10: Illustrative examples of intra-regional interactions among adaptation, mitigation, and sustainable development.

Green infrastructure and green roofs	
Objectives: *Storm water management, adaptation to increasing temperatures, reduced energy use, urban regeneration*	
Relevant Sectors: *Infrastructure, energy use, water management*	
Overview: Benefits of green infrastructure and roofs can include reduction of storm water runoff and the urban heat island effect, improved energy performance of buildings, reduced noise and air pollution, health improvements, better amenity value, increased property values, improved biodiversity or species migration, and inward investment. Trade-offs can result between higher urban density to improve energy efficiency and open space for green infrastructure. [8.3.3.7, 14.2.2.1, 17.4.1, 23.7.4, table 25-6]	
Location	**Example, with interactions**
London	The Green Grid for East London seeks to create interlinked and multi-purpose open spaces to support regeneration of the area. It aims to connect people and places, to absorb and store water, to cool the vicinity, and to provide a diverse mosaic of habitats for wildlife. [8.3.3]
New York	In preparation for more intense storms, New York is using green infrastructure to capture rainwater before it can flood the combined sewer system; implementing green roofs, blue roofs, and porous pavements for streets; and elevating boilers and other equipment above ground. [26.4.3]
Singapore	Singapore has used several anticipatory plans and projects to enhance green infrastructure including its Streetscape Greenery Master Plan, constructed wetlands or drains, and community gardens. Under its Skyrise Greenery project, Singapore has provided subsidies and handbooks for rooftop and wall greening initiatives. [8.3.3]
Durban	In Durban, ecosystem-based adaptation is part of its climate change adaptation strategy, seeking a more detailed understanding of the ecology of indigenous ecosystems and ways in which biodiversity and ecosystem services can reduce vulnerability of ecosystems and people. Examples include a pilot green roof project and its Community Reforestation Programme in which communities produce indigenous seedlings used in the planting and managing of restored forest areas. Needs for knowledge, new data collection, expertise, and resources, along with direct and immediate developmental co-benefits, have been identified in developing a network of bio-infrastructure. [8.3.3]

Water management	
Primary Objective: *Water resource management given multiple stressors in a changing climate*	
Relevant Sectors: *Water use, energy use, biodiversity*	
Location	**Example, with interactions**
New York	New York has a well-established program to protect and enhance its water supply through watershed protection. The Watershed Protection Program includes city ownership of land that remains undeveloped and coordination with landowners and communities to balance water-quality protection, local economic development, and improved wastewater treatment. The city government indicates it is the most cost-effective choice for New York given the costs and environmental impacts of a filtration plant. [8.3.3]
Africa	Water stress has encouraged dam construction to ensure water resource resiliency, but in some parts of Africa this has resulted in deleterious health impacts. Dam building can stimulate the reproduction of parasites in lakes nearby human settlements, amplifying the risk of schistosomiasis and leishmaniasis. [22.3.5]
Capital cities in Australia	Many Australian capital cities are reducing reliance on catchment runoff and groundwater—water resources most sensitive to climate change and drought—and are diversifying supplies through desalination plants, water reuse including sewage and storm water recycling, and integrated water cycle management that considers climate change impacts. Demand is being reduced through water conservation and water sensitive urban design and, during severe shortfalls, through implementation of restrictions. The water augmentation program in Melbourne includes a desalinization plant. Trade-offs beyond energy intensiveness have been noted, such as damage to sites significant to aboriginal communities and higher water costs that will disproportionately affect poorer households. [Box 25-2, 14.7.2]

Payment for environmental services and green fiscal policies	
Primary Objective: *Management incorporating the costs of environmental externalities and the benefits of ecosystem services*	
Relevant Sectors: *Biodiversity, ecosystem services*	
Location	**Example, with interactions**
Central and South America	A variety of payment for environmental services (PES) schemes have been implemented in Latin America. For example, national-level programs have operated in Costa Rica and Guatemala since 1997 and in Ecuador since 2008. Examples to date have shown that PES can finance conservation, ecosystem restoration and reforestation, and better land-use practices. Uniform payments for beneficiaries can be inefficient if, for example, recipients that promote greater environmental gains receive only the prevailing payment. [27.3.2, 27.6.2, table 27-8, 17.5.2, 17.5.4]
Brazil	Municipal funding in Brazil tied to ecosystem-management quality is a form of revenue transfer important to funding local adaptation actions. State governments collect a value-added tax redistributed among municipalities, and some states allocate revenues in part based on municipality area set aside for protection. This mechanism has helped improve environmental management and increased creation of protected areas. It benefits relations between protected areas and surrounding inhabitants, as the areas can be perceived as opportunities for revenue generation rather than as obstacles to development. The approach builds on existing institutions and administrative procedures and thus has low transaction costs. [8.4.3, Box 8-3]
Renewable energy	
Primary Objective: *Renewable energy production and reduction of emissions*	
Relevant Sectors: *Biodiversity, agriculture, food security*	
Location	**Example, with interactions**
Central and South America	Renewable resources, especially hydroelectric power and biofuels, account for substantial fractions of energy production in countries such as Brazil. Where bioenergy crops compete for land with food crops, substantial trade-offs can exist. Land-use change to produce bioenergy can affect food crops, biodiversity, and ecosystem services. Lignocellulosic feedstocks, such as sugarcane second-generation technologies, do not compete with food. [27.3.6, Table 27-6]
Australia and New Zealand	Mandatory renewable energy targets and incentives to increase carbon storage support both increased biofuel production and increased biological carbon sequestration, with impacts on biodiversity depending on implementation. Benefits can include reduced erosion, additional habitat, and enhanced connectivity, with risks or lost opportunities associated with large-scale monocultures especially if replacing more diverse systems. Large-scale land-cover changes can affect catchment yields and regional climate in complex ways. New crops such as oil mallees or other eucalypts may provide multiple benefits, especially in marginal areas, displacing fossil fuels or sequestering carbon, generating income for landholders (essential oils, charcoal, bio-char, biofuels), and providing ecosystem services. [Box 25-10, Table 25-6]

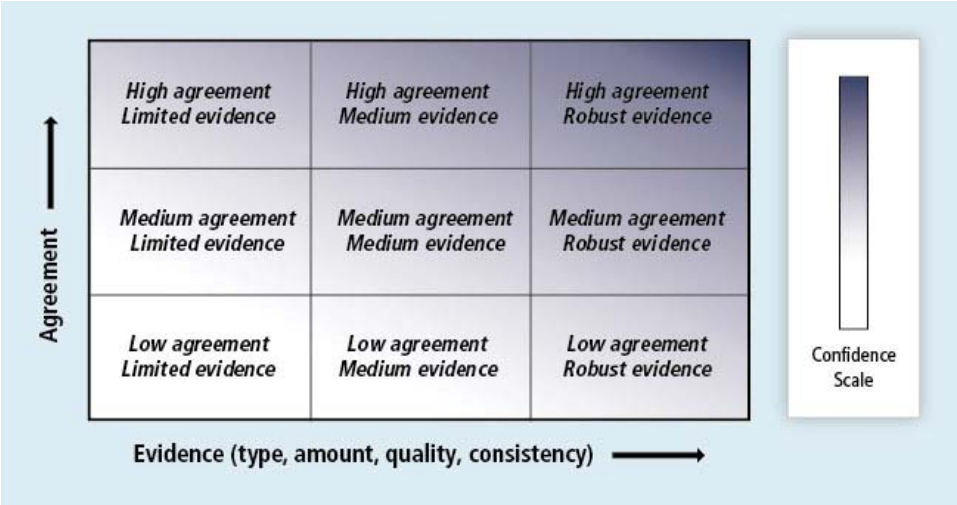
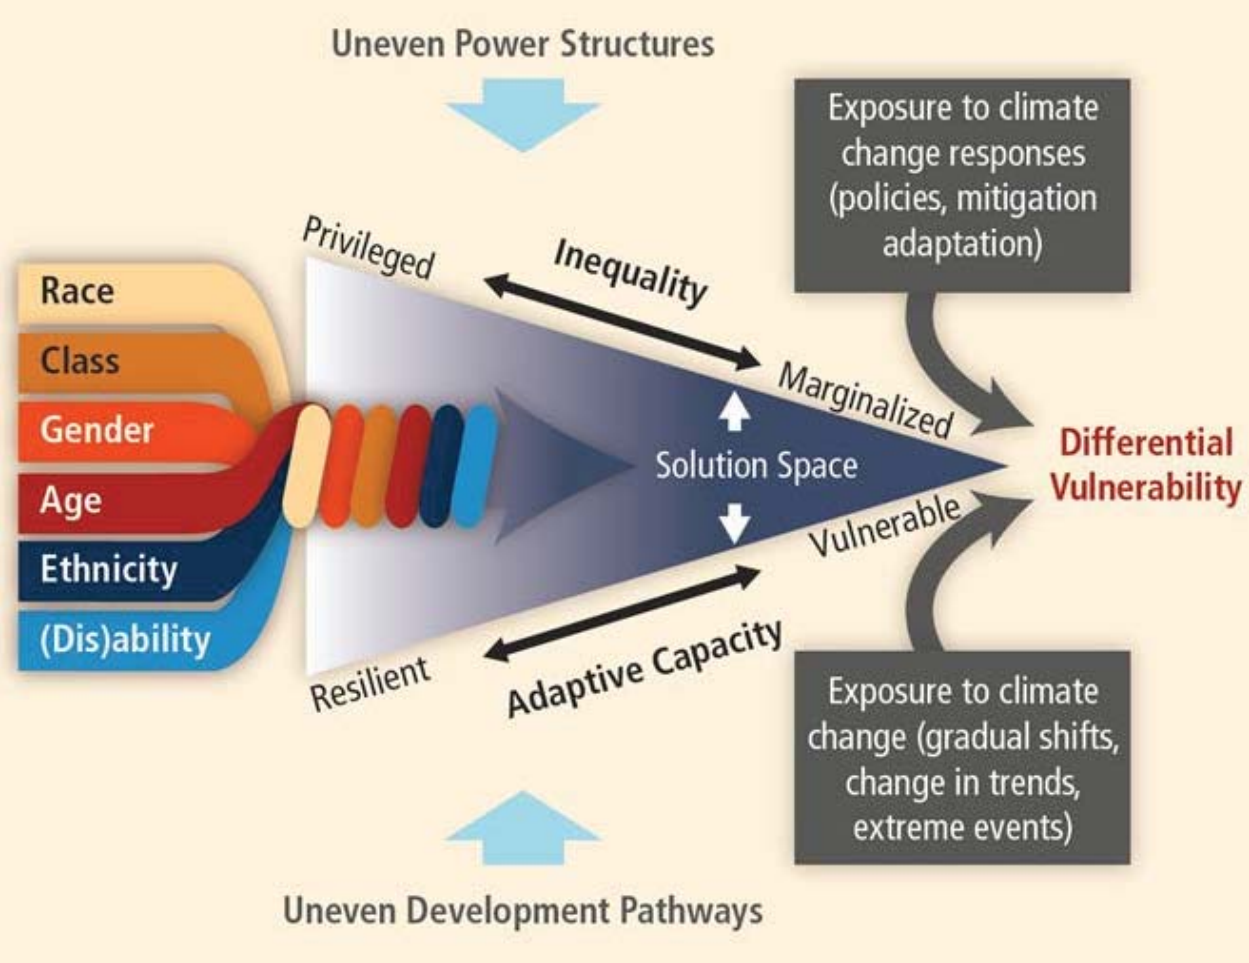
Central and South America	2	677	7142
Australia and New Zealand	7	1654	13515

Box TS.1 Figure 1: Results of English literature search using the Scopus bibliographic database from Reed Elsevier Publishers. (a) Annual global output of publications on climate change and related topics: impacts, adaptation, and costs (1970-2010). (b) Country affiliation of authors of climate change publications summed for IPCC regions for three time periods: 1981-1990, 1991-2000, and 2001-2010, with total number during the period 2001-2010. (c) Results of literature searches for climate change publications with individual countries mentioned in publication title, abstract, or key words, summed for all countries by geographic region. [Figure 1-1]



Box TS.3 Figure 1: Evidence and agreement statements and their relationship to confidence. The shading increasing towards the top right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence. [Figure 1-4]



Box TS.4 Figure 1: Intersecting yet simultaneous and dynamic axes of privilege and marginalization, shaped by people's multiple identities and embedded in uneven power relations and development pathways. Together, they result in differential vulnerability to the same exposure to climate change and climate change responses. These intersecting dimensions ("intersectionality") illustrate systemic vulnerability and multidimensional deprivation that determine inequality and adaptive capacity while being transformed as a result of negative climate change impacts and risks as well as consequences of policy responses, often to the detriment of the poor and disadvantaged. [Figure 13-4]

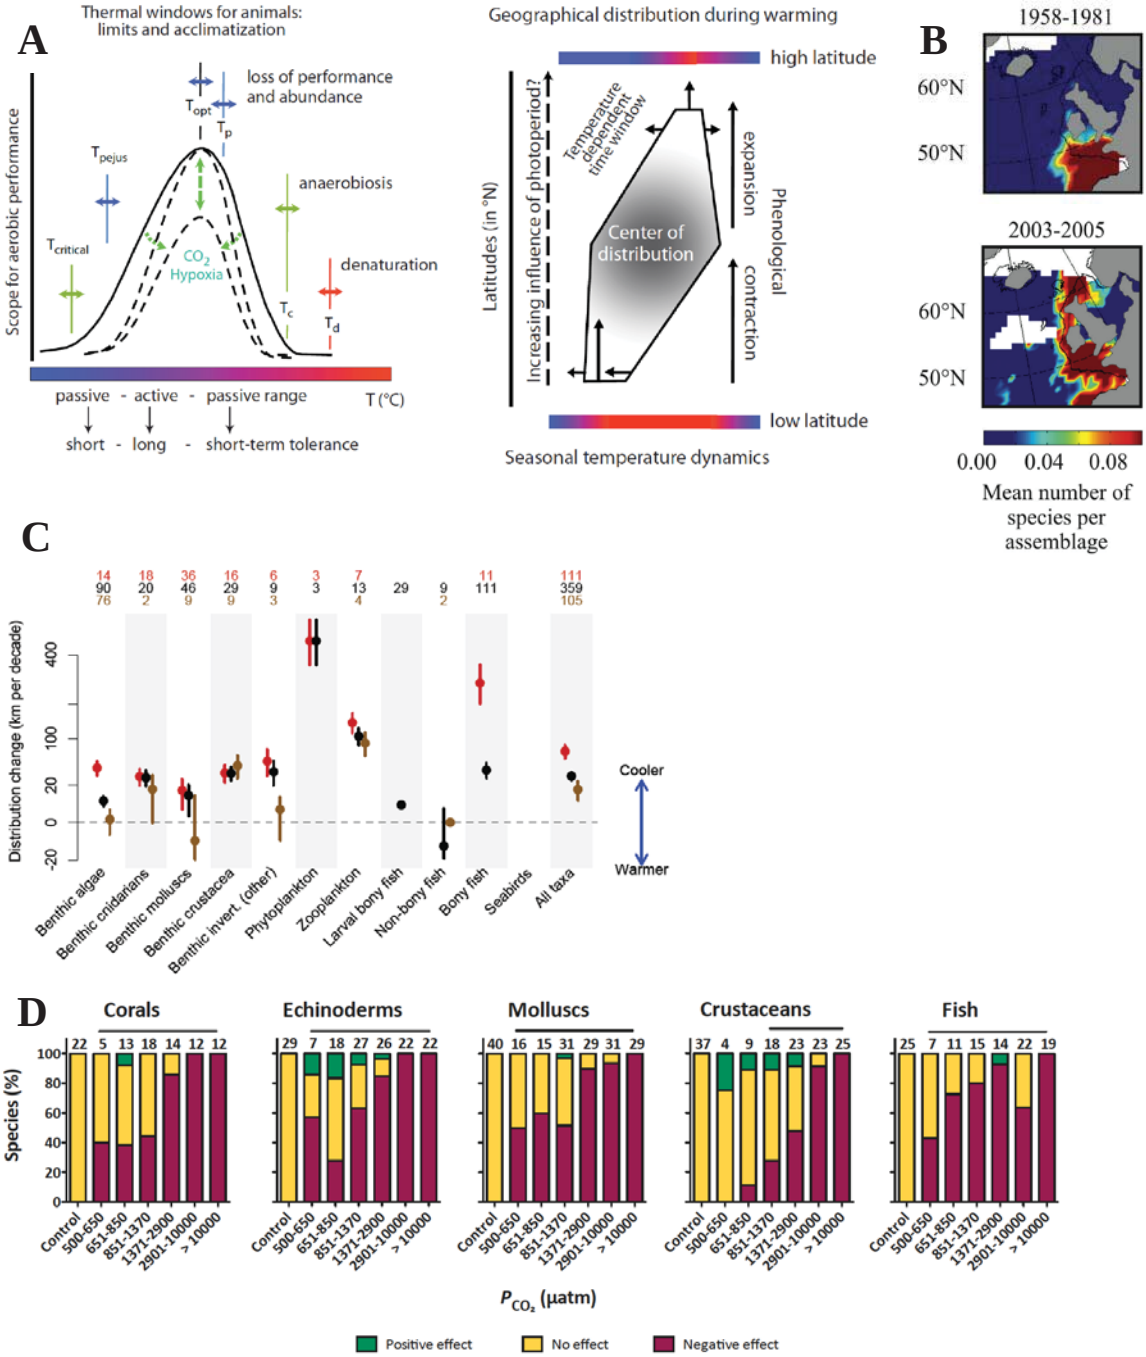


Figure TS.1: Thermal specialization of species, sensitive to ocean acidification and hypoxia (A, left) causes warming induced distribution shifts (A, right). An example (B) is the northward expansion of warm-temperate species in the Northeast Atlantic. Differential distribution change across functional groups (C) will be influenced by species-specific impacts of future ocean acidification across phyla (D). Detailed introduction of each panel follows: A) Mechanisms linking organism to ecosystem response explain the why, how, when, and where of climate sensitivity (blue to red color gradients illustrate transition from cold to warm temperatures). As all biota, animals specialize on limited temperature ranges, within which they grow, behave, reproduce, and defend themselves by immune responses (left). Optimum temperatures (T_{opt}) indicate performance maxima, pejus temperatures (T_p) the limits to long-term tolerance, critical temperatures (T_c) the transition to anaerobic metabolism, and denaturation temperatures (T_d) the onset of cell damage. These thresholds can shift by acclimatization (horizontal arrows). Under elevated CO_2 levels and in hypoxic waters

performance levels can decrease and windows of performance be narrowed (dashed green arrows pointing to dashed black curves). Shifts in biogeography result during climate warming (right). The polygon delineates the range in space and time, the level of grey denotes abundance. Species display maximum productivity in southern spring, wide seasonal coverage in the center, and a later productivity maximum in the North. The impact of photoperiod increases with latitude (dashed arrow). During warming, the southern temperature and time window contracts while the northern one dilates (directions and shifts indicated by arrows). Control by water column characteristics or photoperiod may overrule temperature control in some organisms (e.g., diatoms), causing contraction of spatial distribution in the north. B) Long-term changes in the mean number of warm-temperate pseudo-oceanic species in the Northeast Atlantic from 1958 to 2005. C) Rates of change in distribution (km decade^{-1}) for marine taxonomic groups, measured at the leading edges (red), and trailing edges (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward). Means ± standard error are shown, with number of observations and significance (*p<0.1, **p<0.05, ***p<0.01). D) % fraction of studied scleractinian coral, echinoderm, molluscan, crustacean, and fish species affected negatively, positively, or not at all by various levels of ambient CO_2. Effects considered include those on life stages and processes reflecting physiological performance (O_2 consumption, aerobic scope, behaviors, scope for behaviors, calcification, growth, immune response, acid-base balance, gene expression, fertilization, sperm motility, developmental time, production of viable offspring, morphology). Horizontal bars above columns represent frequency distributions significantly different from controls. [Figures 6-7, 6-10, 6-11, and 30-11]

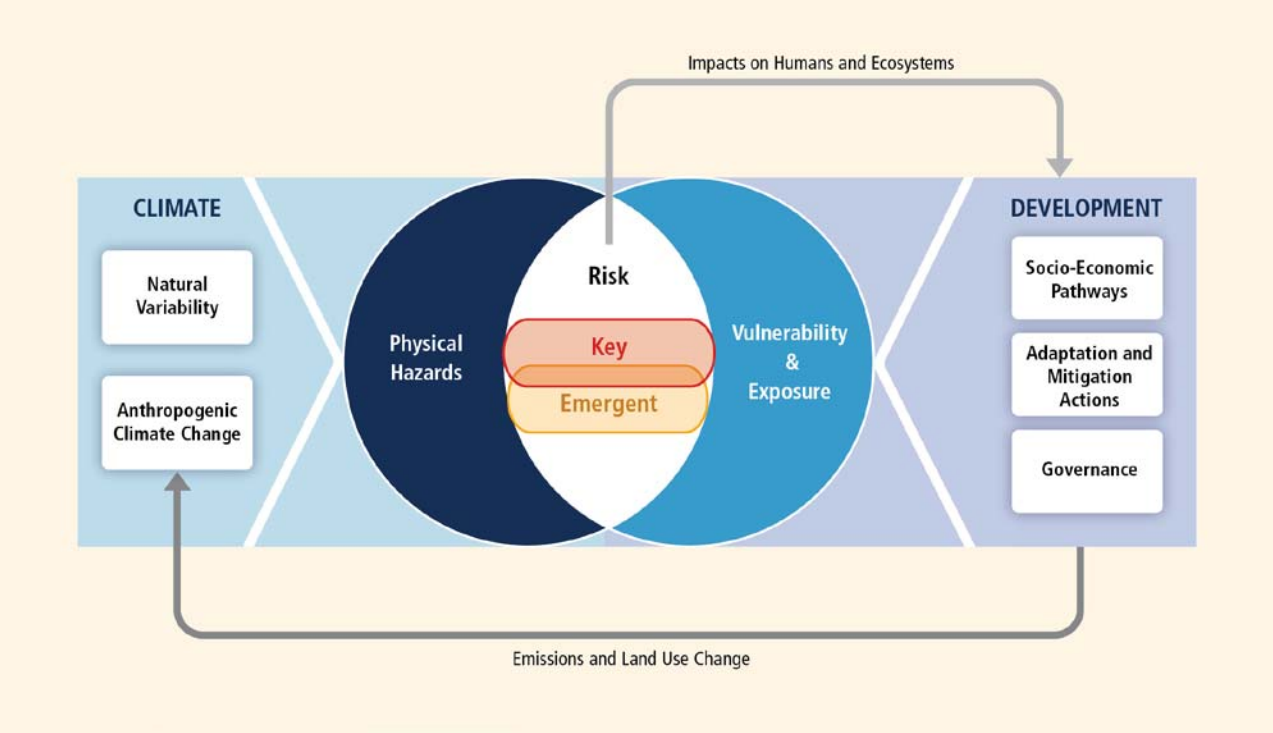

Figure TS.2: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. Risks are a product of a complex interaction between physical hazards associated with climate change and climate variability on the one hand, and the vulnerability of a society or a social-ecological system and its exposure to climate-related hazards on the other. The definition and use of “key” and “emergent” are indicated in Section C.ii. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions. Changes in both the climate system (left side) and development processes (right side) are key drivers of the different core components (vulnerability, exposure, and physical hazards) that constitute risk. [19.1, Figure 19-1]

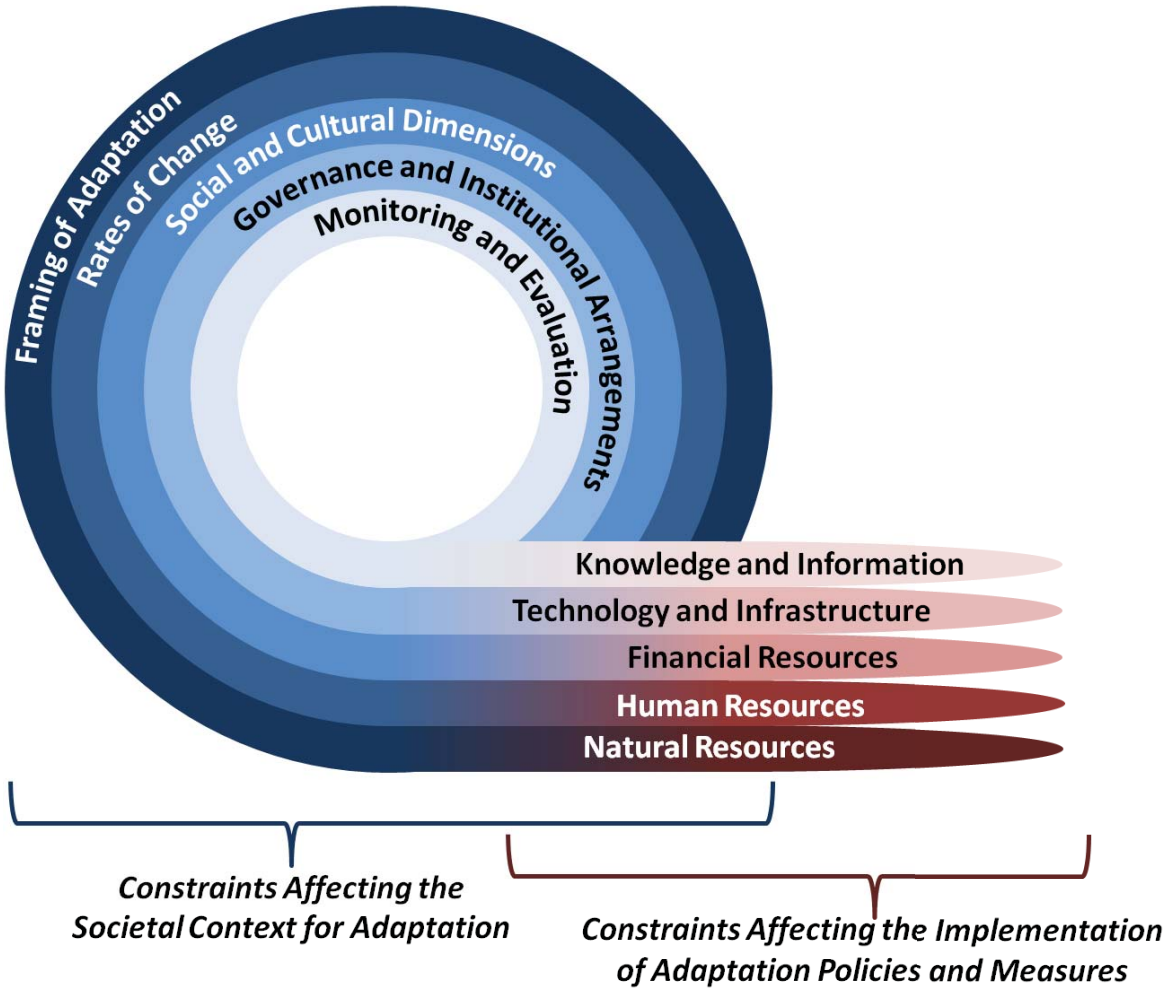

Figure TS.3: Key adaptation constraints assessed, categorized into two groups. One group reflects constantly evolving biophysical and socio-economic processes that influence the societal context for adaptation. These processes subsequently influence the second group of constraints affecting the implementation of specific adaptation policies and measures that could be deployed to achieve a particular objective. [Figure 16-2]

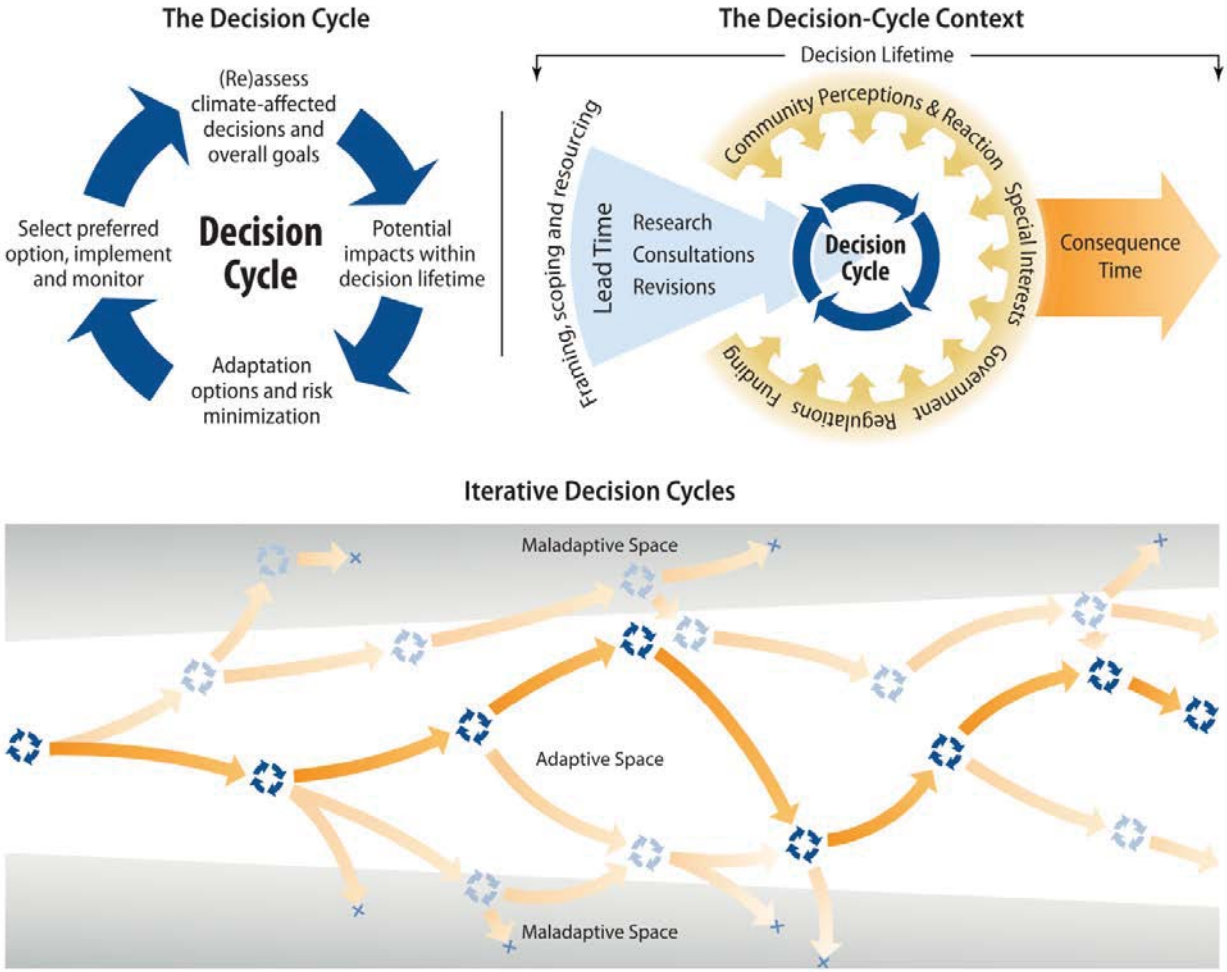

Figure TS.4: Schematic illustration of adaptation as an iterative risk management process. Each individual adaptation decision comprises well known aspects of risk assessment and management (top left panel). Each such decision occurs within and exerts its own sphere of influence, determined by the lead and consequence time of the decision, and the broader regulatory and societal influences on the decision (top right panel). A sequence of adaptation decisions creates an adaptation pathway (bottom panel). There is no single correct adaptation pathway, although some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but the judgment of outcomes depends strongly on societal values, expectations, and goals. [Figure 25-6]

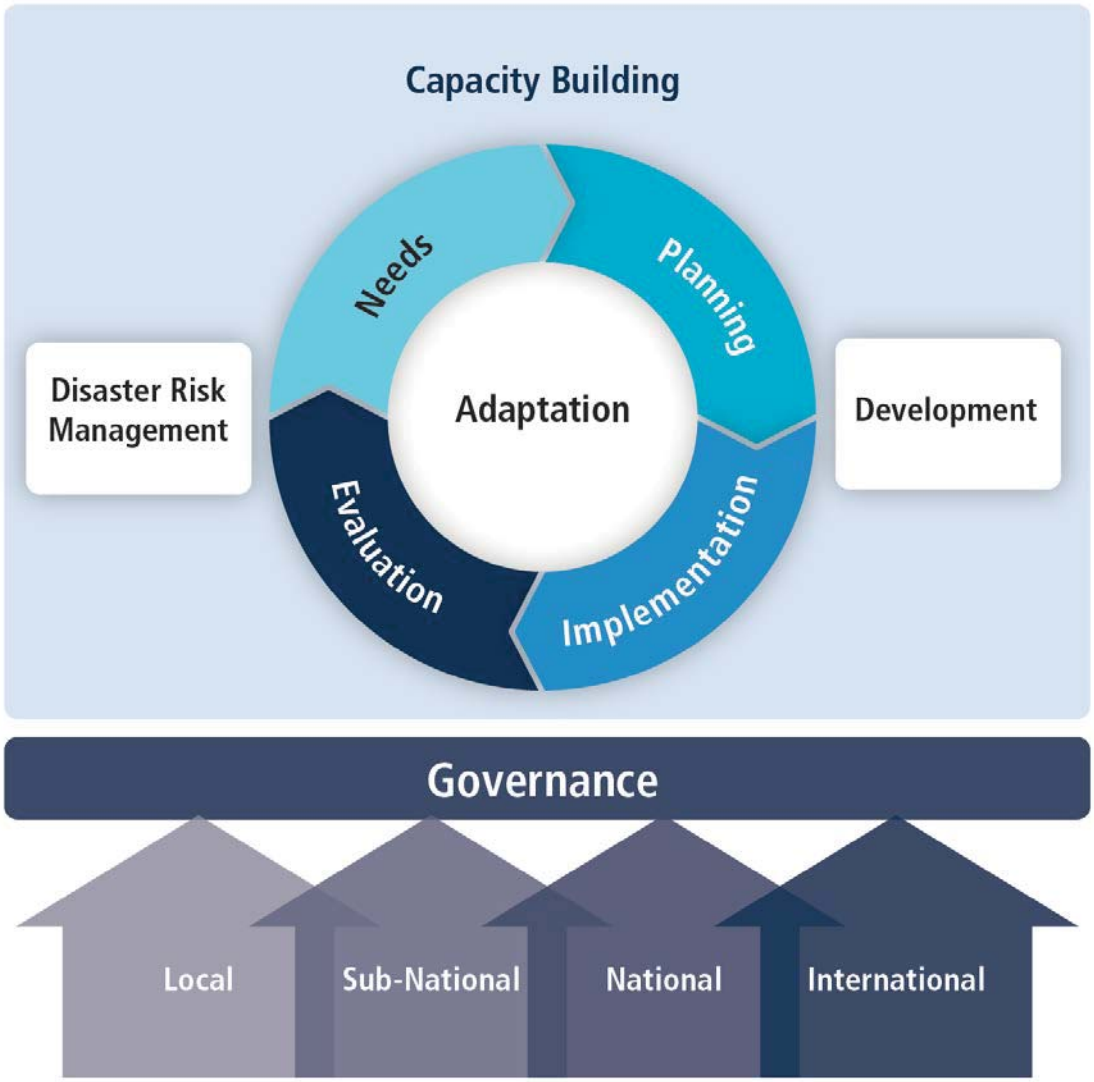

Figure TS.5: Four main phases of adaptation planning and implementation: needs, planning, implementation, and evaluation. This is a cyclic, iterative process. Building capacity to respond to change, whether expected or unexpected, creates resilience in societies to cope in the face of uncertainties in climate change projections. Efforts in adaptation can be linked with development or disaster risk management. Adaptation governance underlies capacity, and governance takes place at multiple scales: international, national, sub-national, and local. [Figure 15-1]

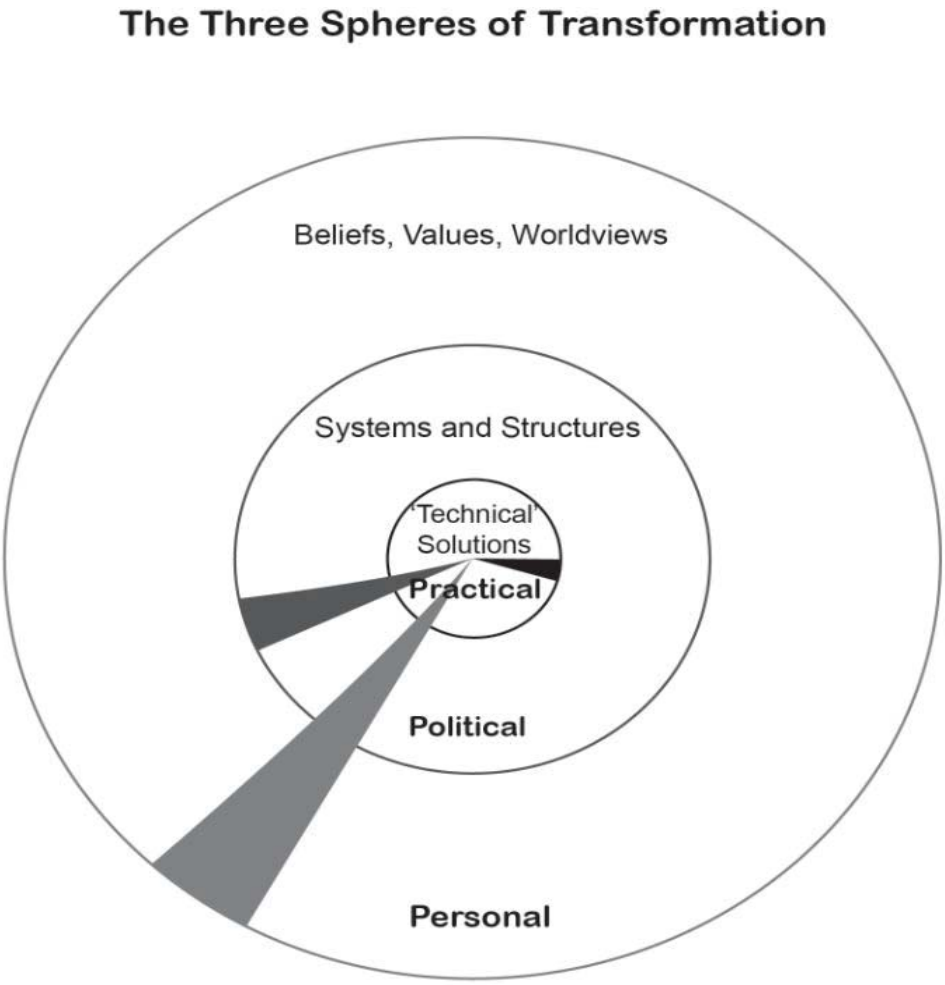

Figure TS.6: The practical, political, and personal spheres of transformation. [20.5.2, Figure 20-2]

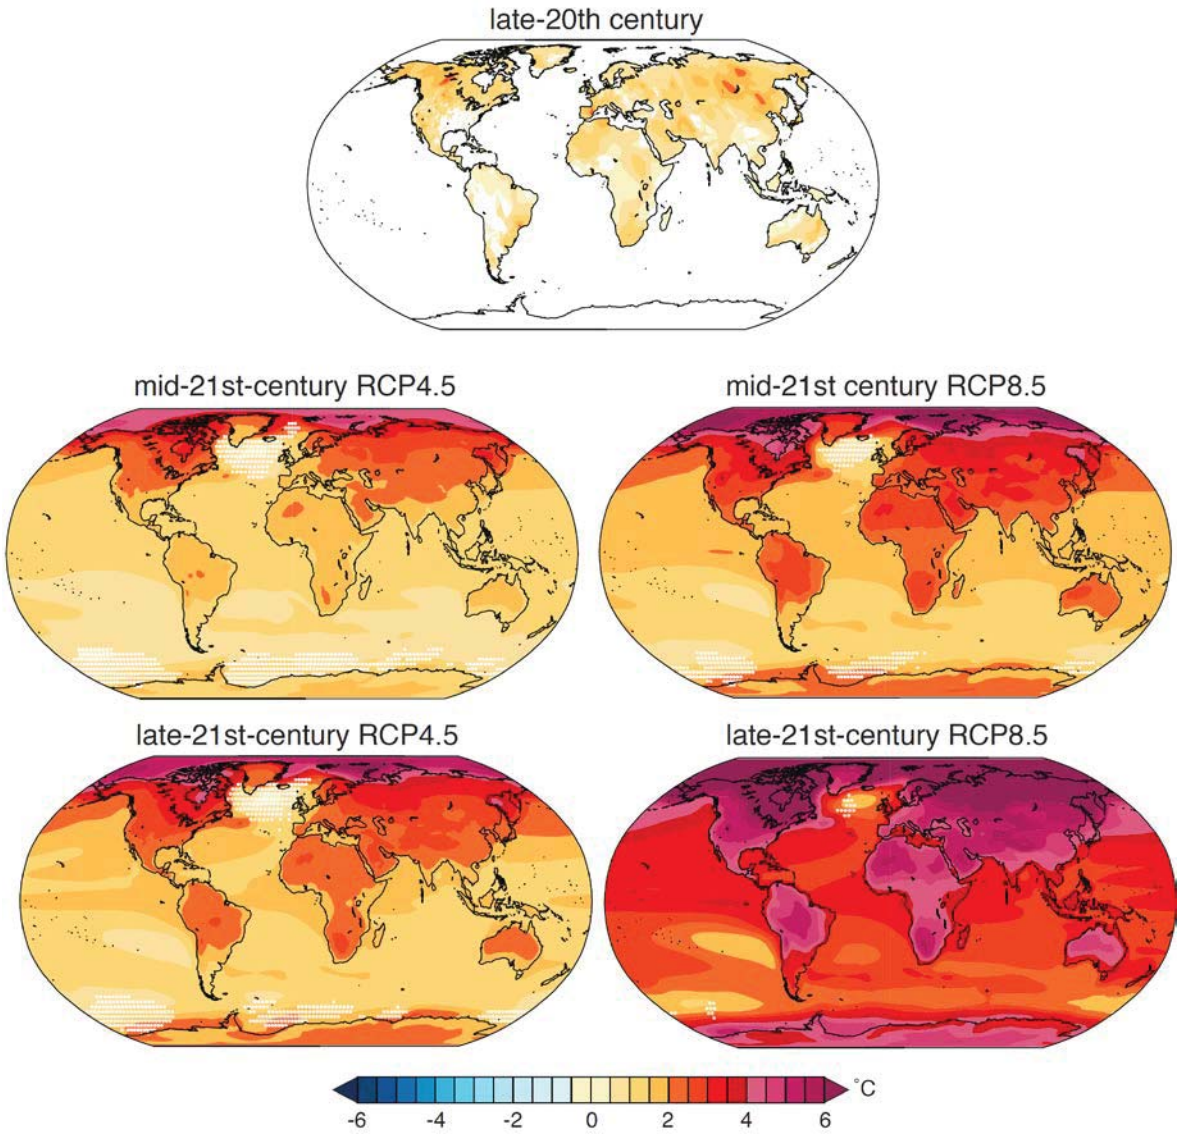
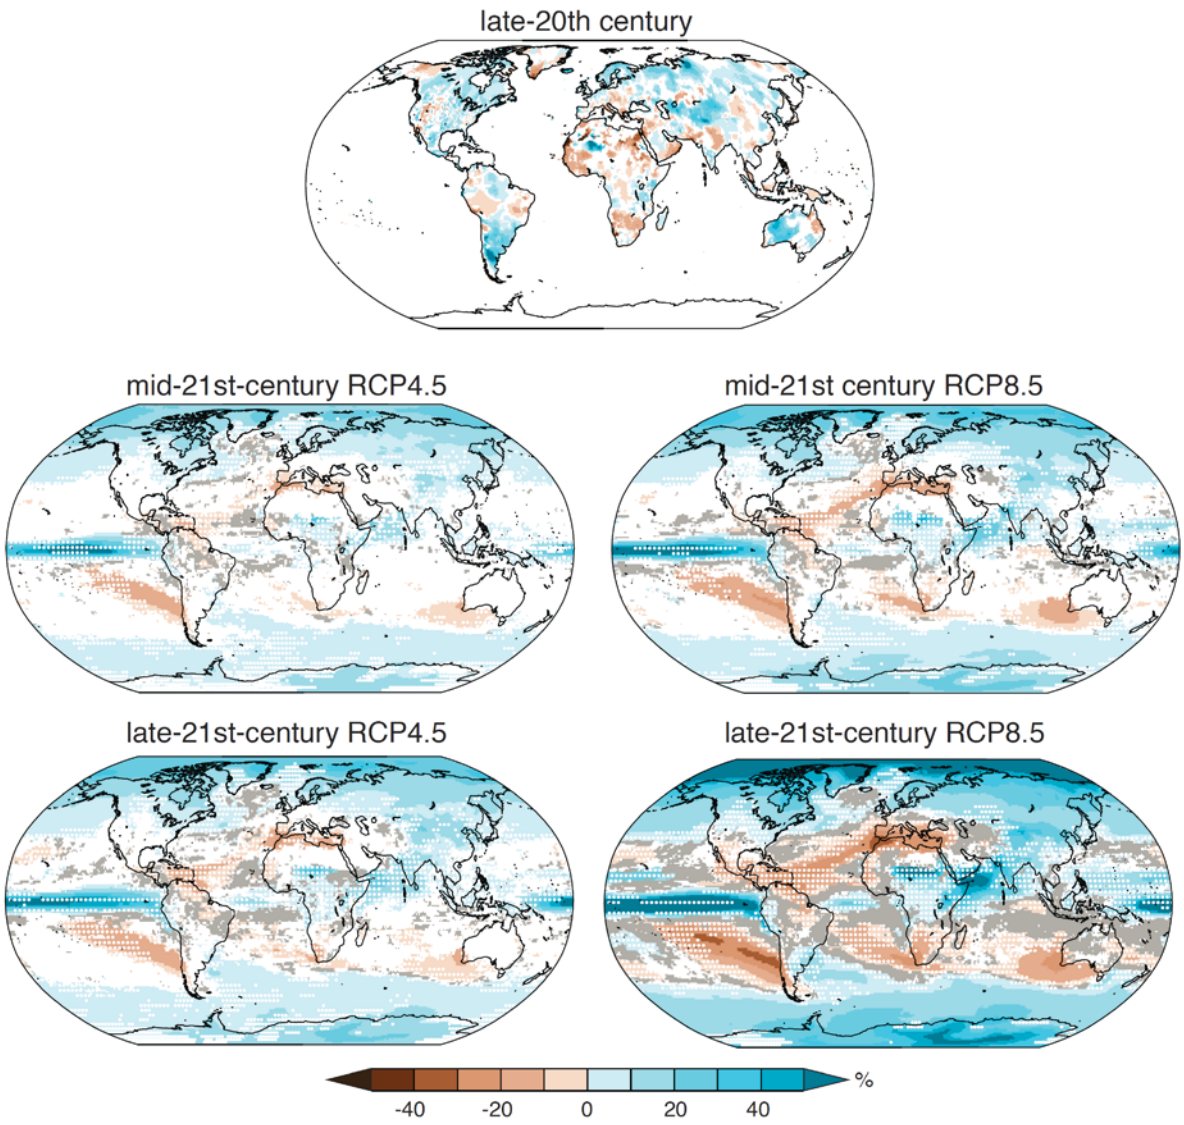


Box TS.5 Figure 1: Change in annual average temperature (A) and precipitation (B). For observations (top map, A and B; CRU), differences are shown over land between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For projections (bottom four maps, A and B; CMIP5), four classes of results are displayed. (1) White indicates areas where for >66% of models the annual average change is less than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Thus in these regions, more than 2/3 of models show no significant change, using this measure of significance, in the annual average, although this does not imply no significant change at seasonal or shorter time-scales such as months to days. (2) Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. In these regions, more than 2/3 of models show a significant change in annual average, but less than 2/3 agree on whether it will increase or decrease. (3) Colors with circles indicate the change averaged over all models where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on whether the annual average will increase or decrease. In these regions, more than 2/3 of models show a significant change in annual average and more than 2/3 (but less than 90%) agree on whether it will increase or decrease. (4) Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on whether the annual average will increase or decrease. For models that have provided multiple realizations for the climate of the recent past and the future, results from each realization were first averaged to create the baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios were calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065. See also Annex I of WGI AR5. [Box CC-RC]



Box TS.5 Figure 1: Change in annual average temperature (A) and precipitation (B). For observations (top map, A and B; CRU), differences are shown over land between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For projections (bottom four maps, A and B; CMIP5), four classes of results are displayed. Figure TS.7: Human vulnerability to climate-change-induced decreases of renewable groundwater resources by the 2050s for lower (B2) and higher (A2) emissions pathways and two global climate models. The higher the vulnerability index (percent decrease of groundwater recharge multiplied by a sensitivity index), the higher the vulnerability. The index is computed for areas where groundwater recharge is projected to decrease by at least 10%, as compared to the reference period 1961-90. [Figure 3-9]

Figure TS.8: Rate of climate change (A), corresponding climate velocities (B), and rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention (C). The thin dotted red arrows give an example of interpretation. Rates of climate change of 0.03 °C/yr correspond to ca. 1.1 km/yr global average climate velocity. When compared to rates of displacement, this would exceed rates for most plants, many primates, and some rodents. (A) Observed rates of climate change for global land areas are derived from CRUTEM4 climate data reanalysis; all other rates are calculated based on the average of the CMIP5 climate model ensembles for the historical period and for the future based on the four RCP emissions scenarios. The lower bound (17% of model projections are outside this bound) is given for the lowest emissions scenario and the upper bound for the highest emissions scenario. Data were smoothed using a 20-year sliding window, and rates are based on means of between 17 and 30 models using one member per model. Global average temperatures at the end of the 21st century are given for each RCP scenario. Colors in the background synthesize the ability of species to track climate through displacement. (B) Estimates of climate velocity were semi-quantitatively synthesized from seven studies using a diversity of analytical approaches and spatial resolutions. The three axes represent estimated climate velocities for mountainous areas (left), for global land area (center), and for regions that are flat or have high rates of climate change (right). (C) Rates of displacement for terrestrial plants, trees, mammals, birds, phytophagous insects, and freshwater mollusks. Each box represents ~95% of the estimates, and the bar is a qualitative estimate of the median. [Figure 4-6]

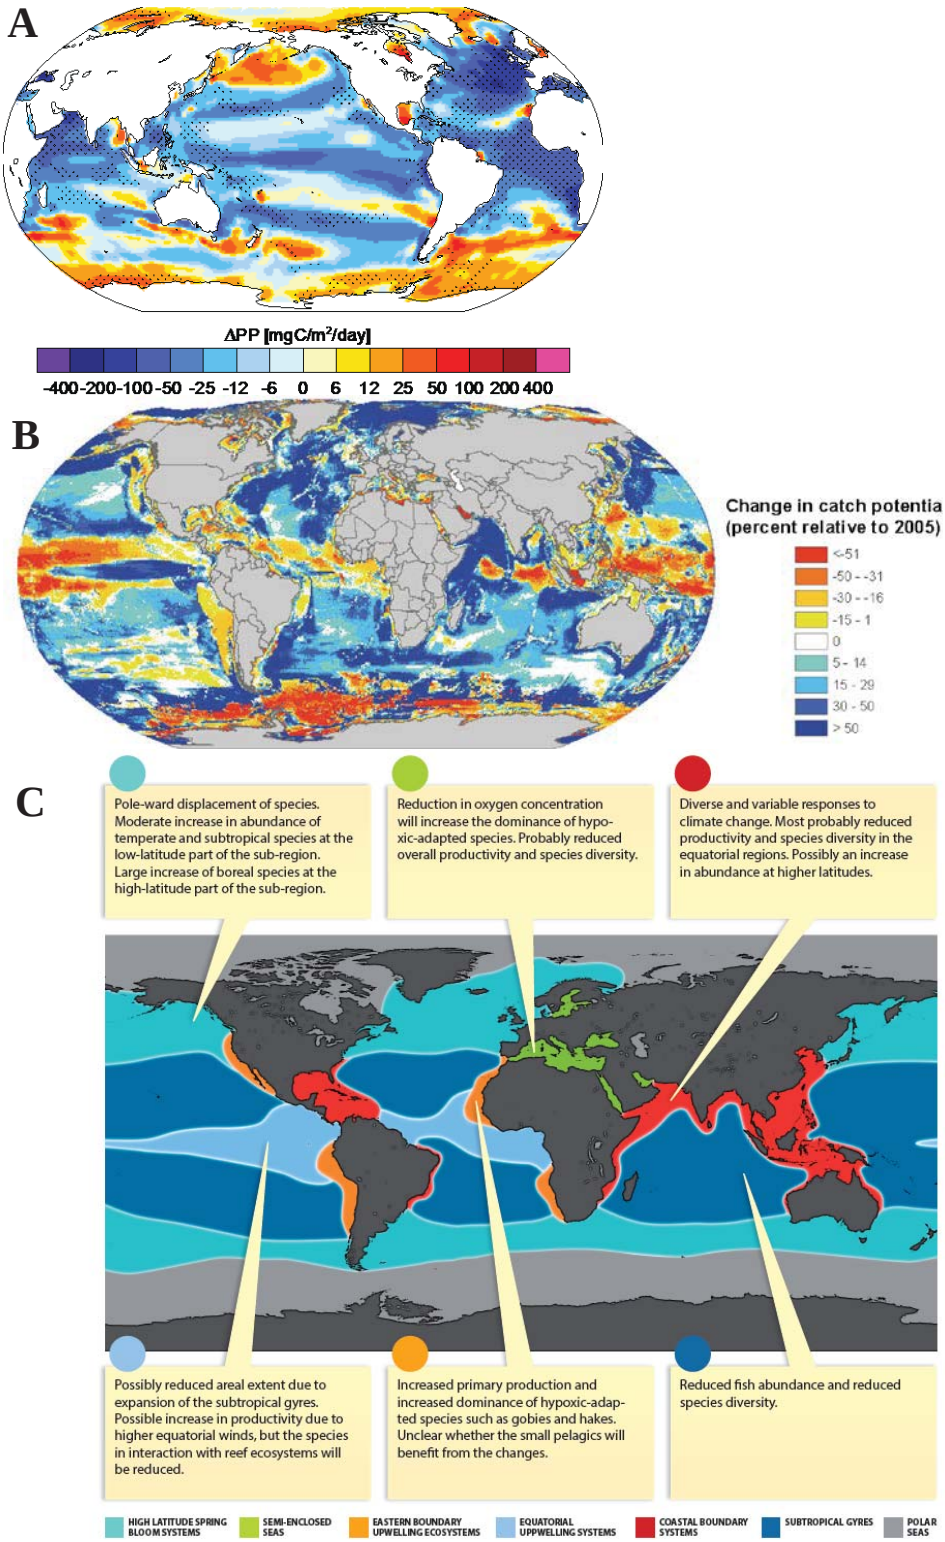

Figure TS.9: A) Multi-model mean changes of projected vertically-integrated net primary production (small and large phytoplankton). To indicate consistency in the sign of change, regions are stippled where all models (four in total) agree on the sign of change. Changes are annual means under the SRES A2 scenario (between RCP 6.0 and 8.5) for the period 2080 to 2099 relative to 1870 to 1889. B) A projection of maximum fisheries catch potential of 1000 species of exploited fishes and invertebrates from 2000 to 2050 under the SRES A1B scenario. C) Example of changes occurring within fisheries across the ocean. [Figures 6-14, 6-15, and 30-15]

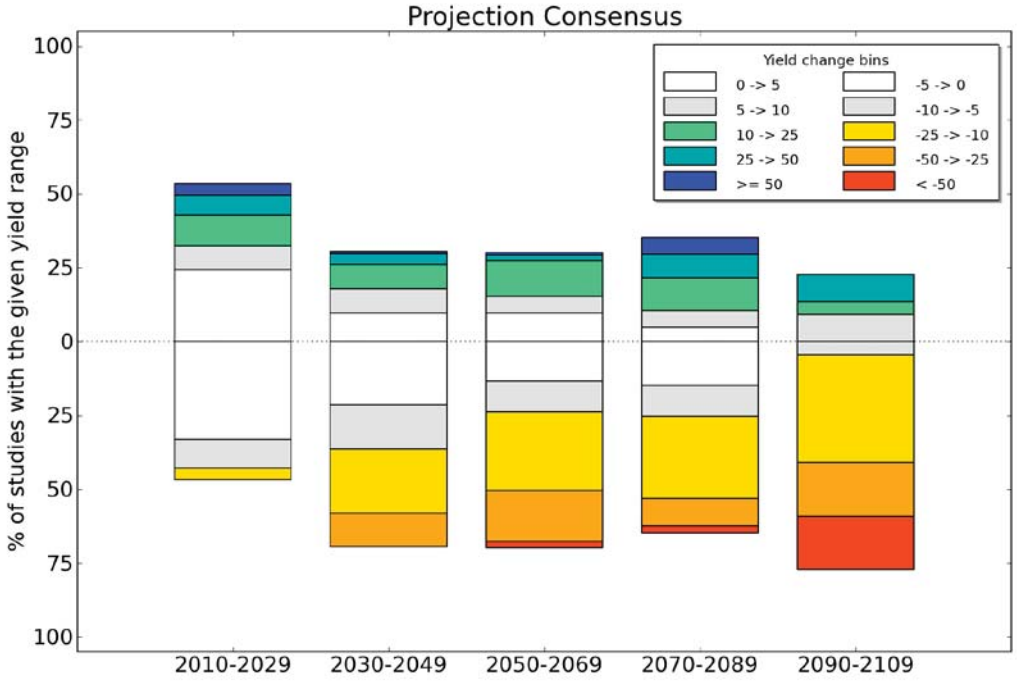

Figure TS.10: Projected changes in crop yield as a function of time. The y-axis indicates degree of consensus and the colors denote percentage change in crop yield. Data are plotted according to the 20-year period in which the center point of the projection period falls. [Figure 7-6]

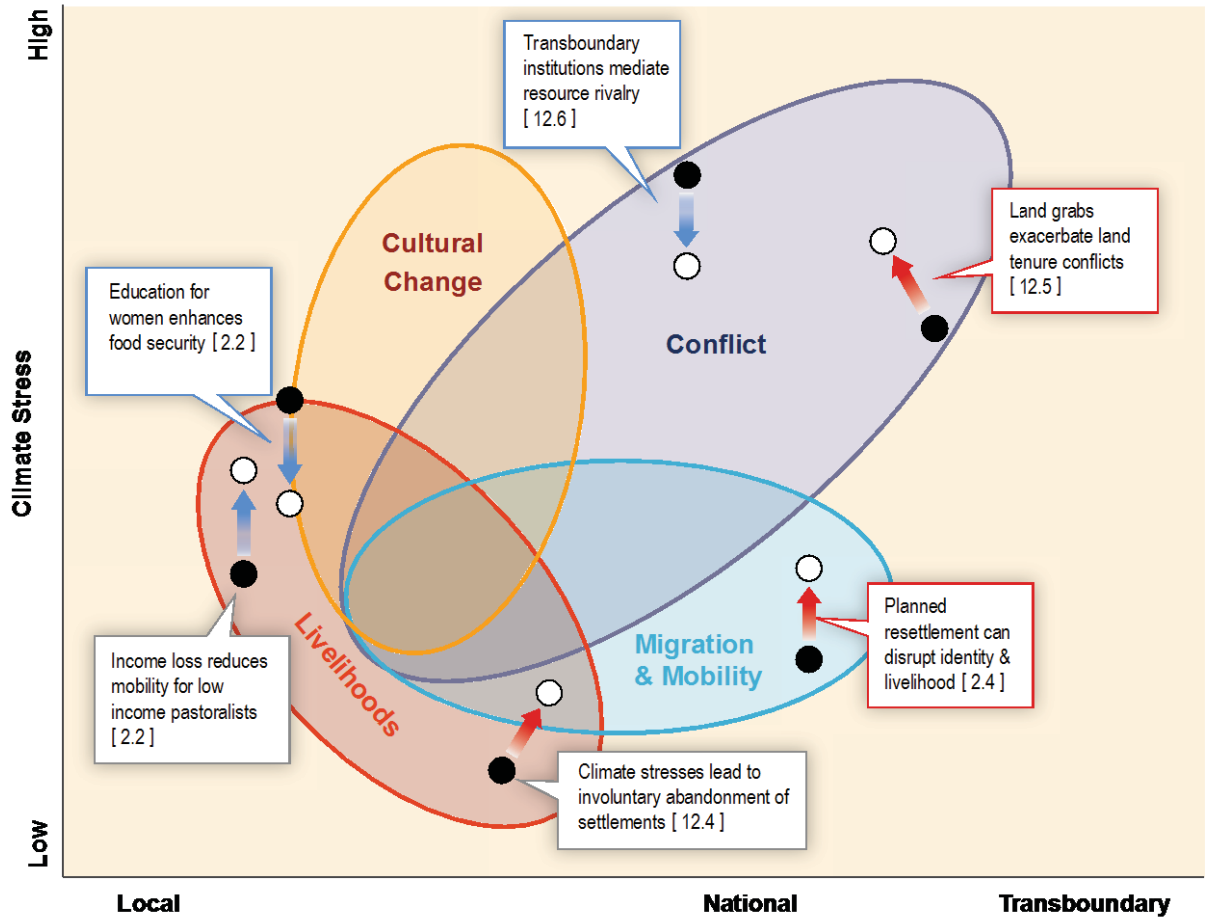

Figure TS.11: Synthesis of evidence on the impacts of climate change on elements of human security and the interactions between elements. Examples of positive and negative changes in security associated with interventions indicated by arrows. [Figure 12-3]

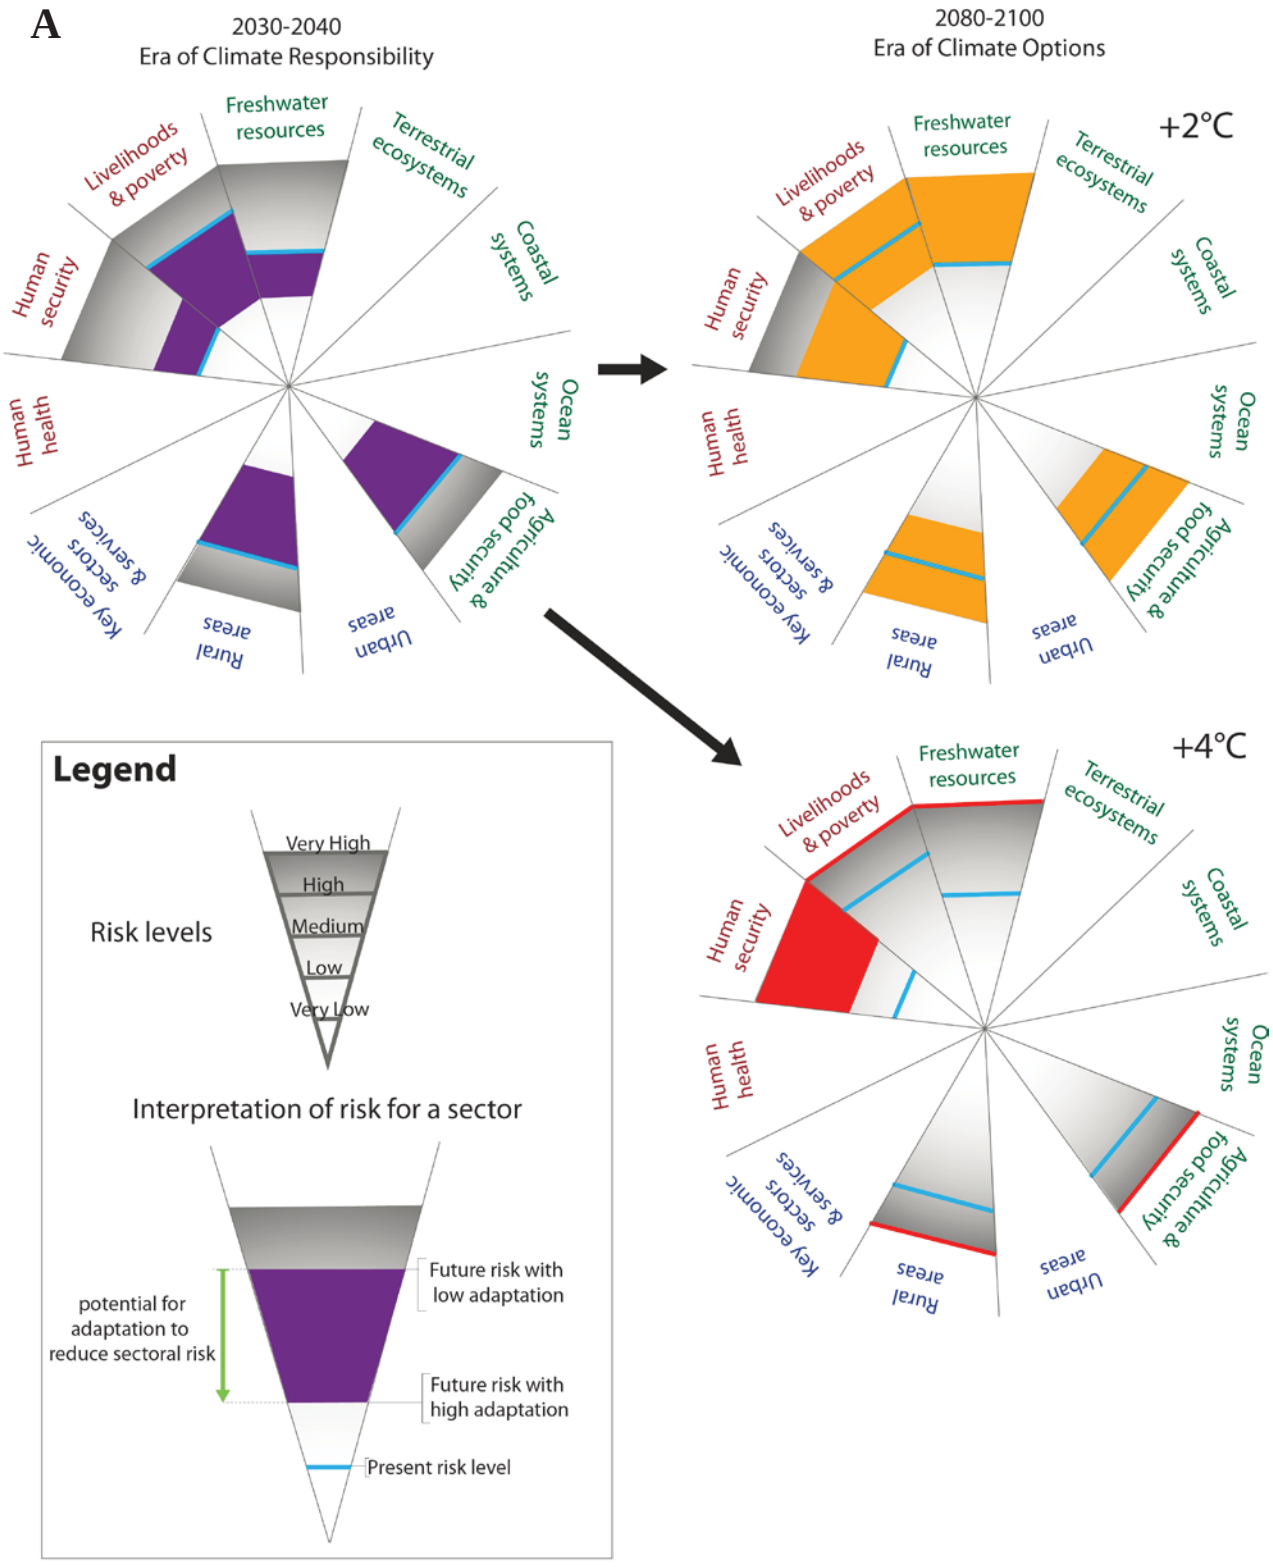

Figure TS.12: Estimated risk from climate change to selected sectors and systems in Africa (A), Europe (B), and North America (C), for different time frames (2030-2040 and 2080-2100), under two levels of global average warming above preindustrial (2°C and 4°C) and different assumptions about adaptation to manage these risks. Levels of risk and of adaptation are differentiated by colored shading, ranging from high adaptation to low adaptation. Estimated risks rely on expert judgments. The risk categories reflect the overall structure of Part A of the WGII AR5. [Figures 22-7 and 26-6]

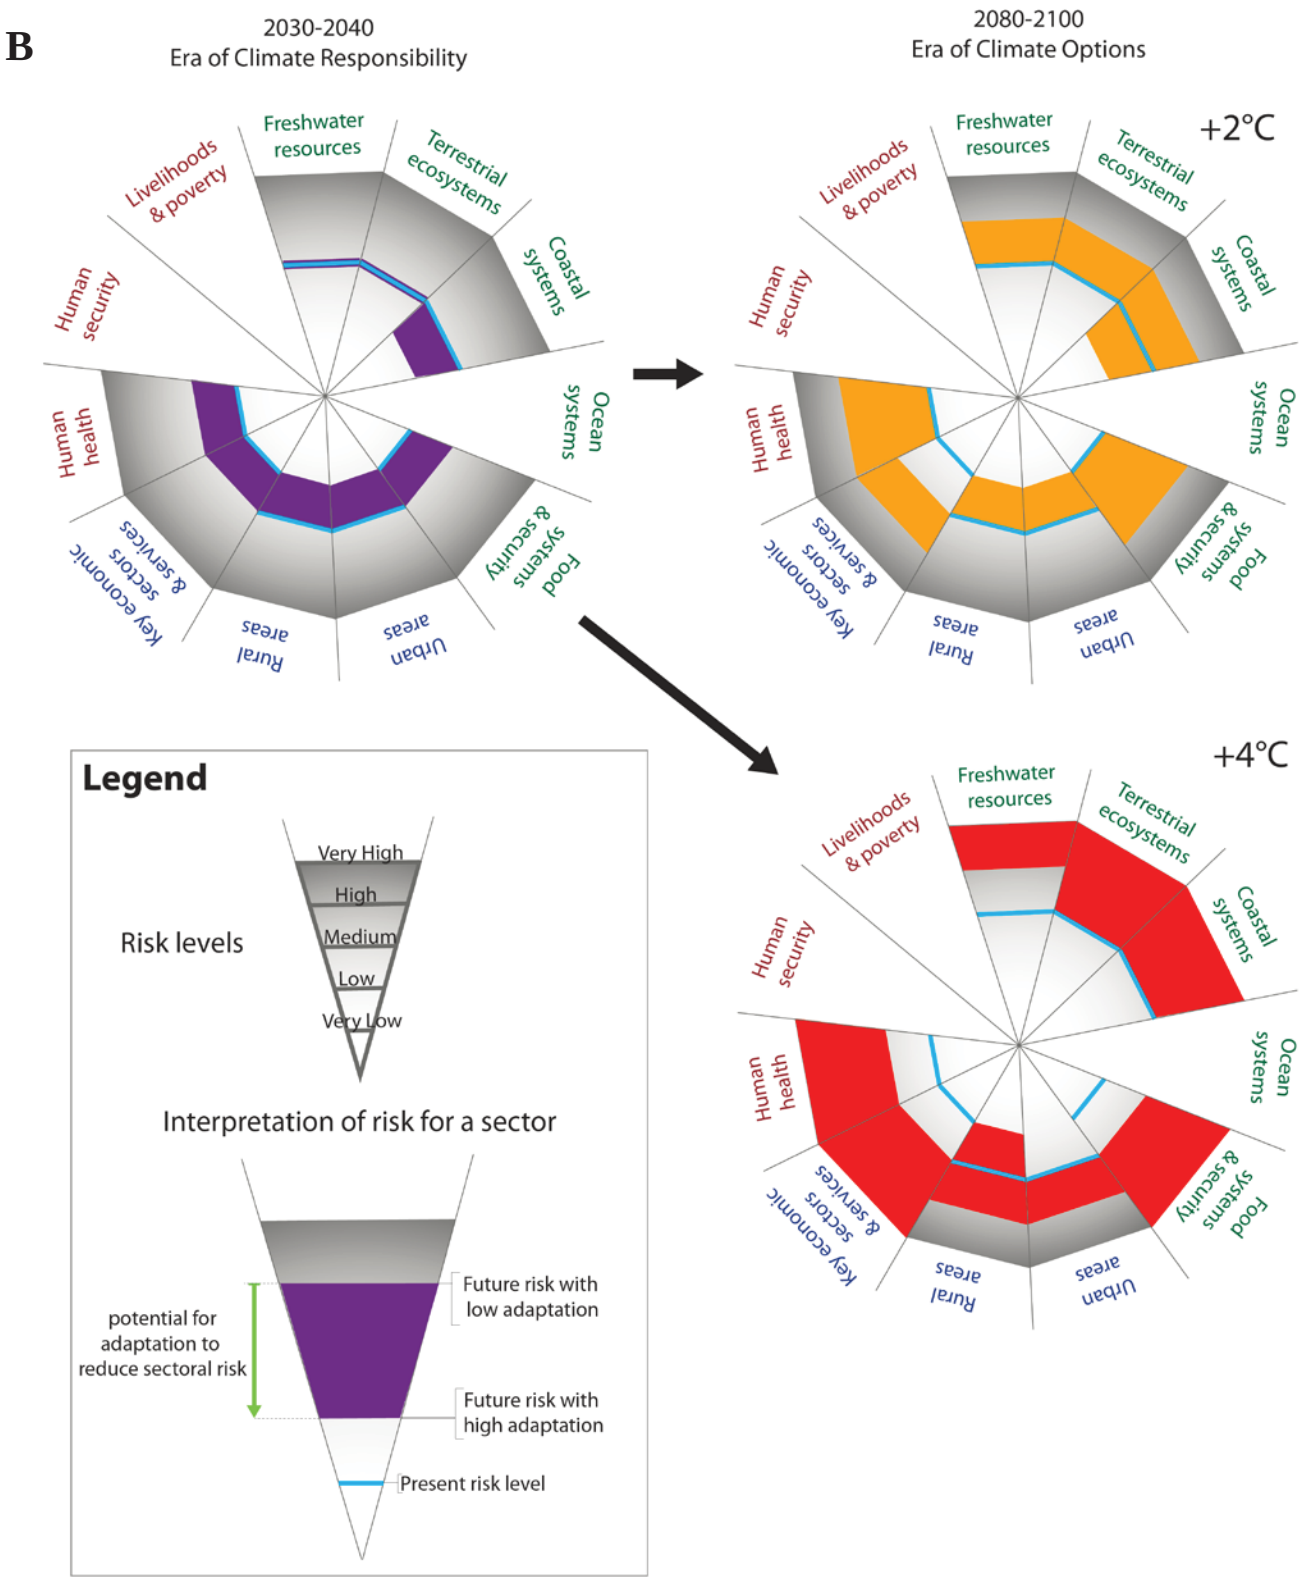

Figure TS.12: Estimated risk from climate change to selected sectors and systems in Africa (A), Europe (B), and North America (C), for different time frames (2030-2040 and 2080-2100), under two levels of global average warming above preindustrial (2°C and 4°C) and different assumptions about adaptation to manage these risks. Figure TS.13: Summary of observed changes in climate and other environmental factors in representative regions of Central and South America. The boundaries of the regions in the map are conceptual (not precise geographic nor political) and follow those developed in SREX Figure 3-1. [Figure 27-7]

Figure TS.14: Summary of key risks and vulnerabilities associated with climate change on the world's ocean regions. [Figure 30-15]

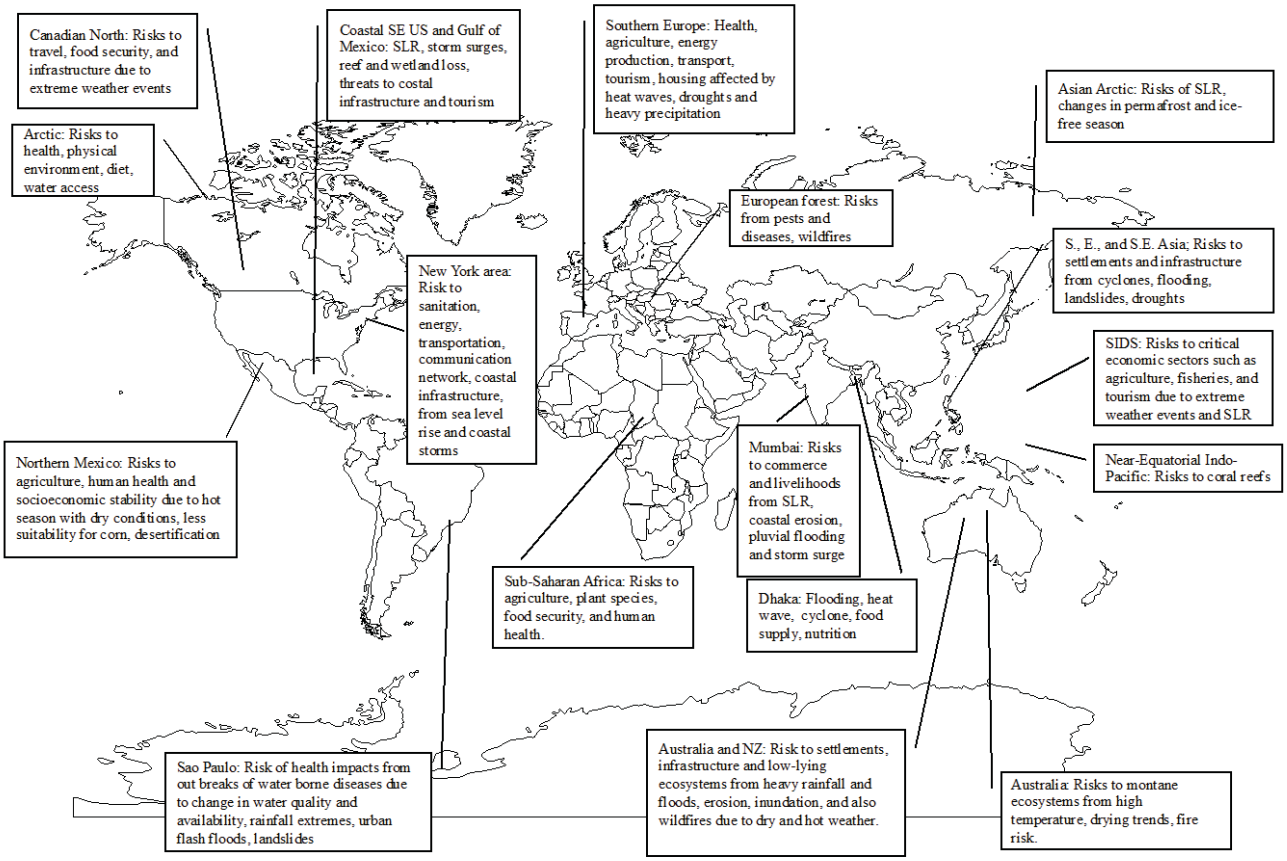

Figure TS.15: Some salient examples of multi-impacts hotspots identified in this assessment. [Figure 19-2]

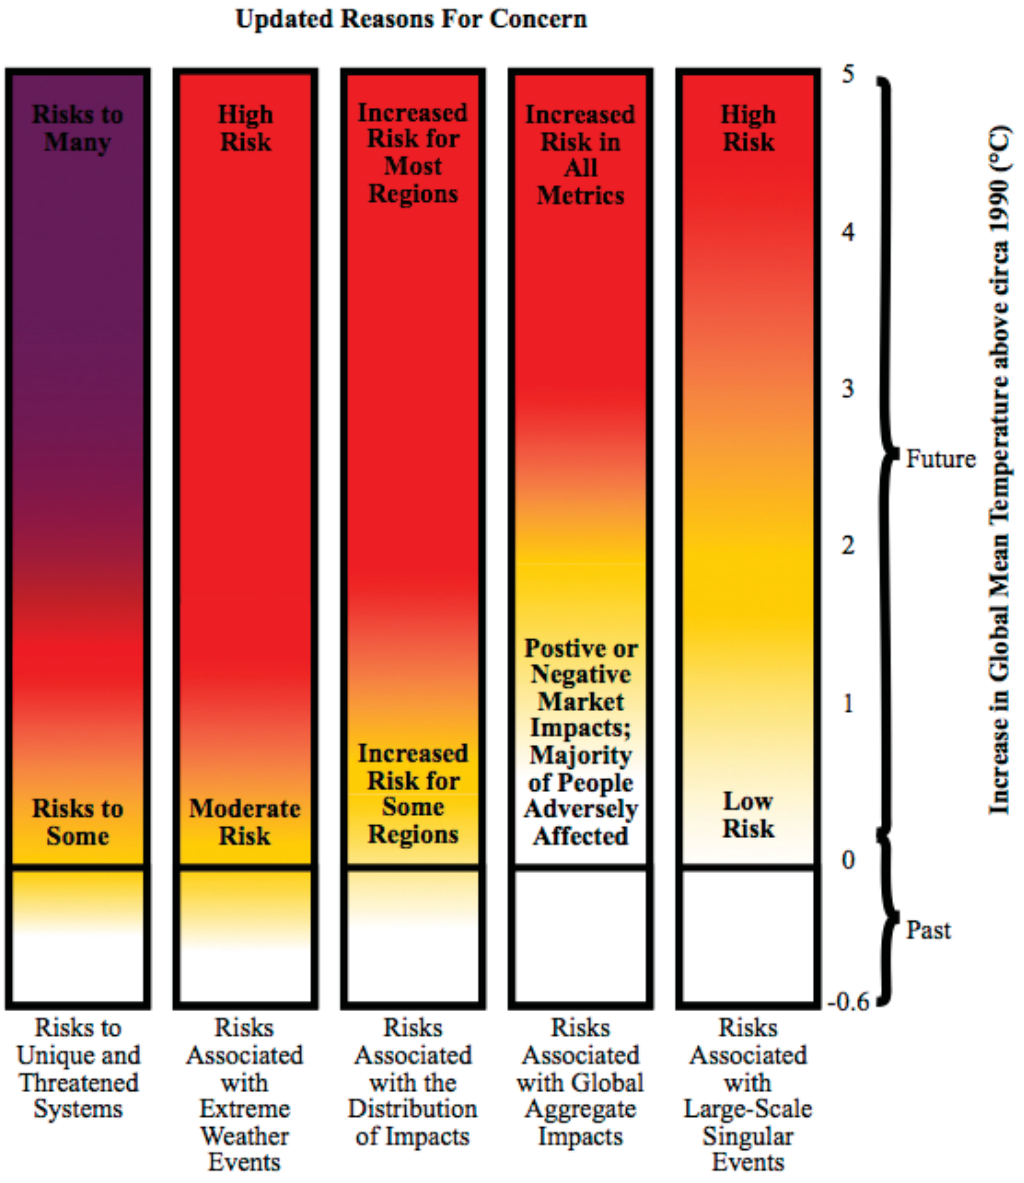
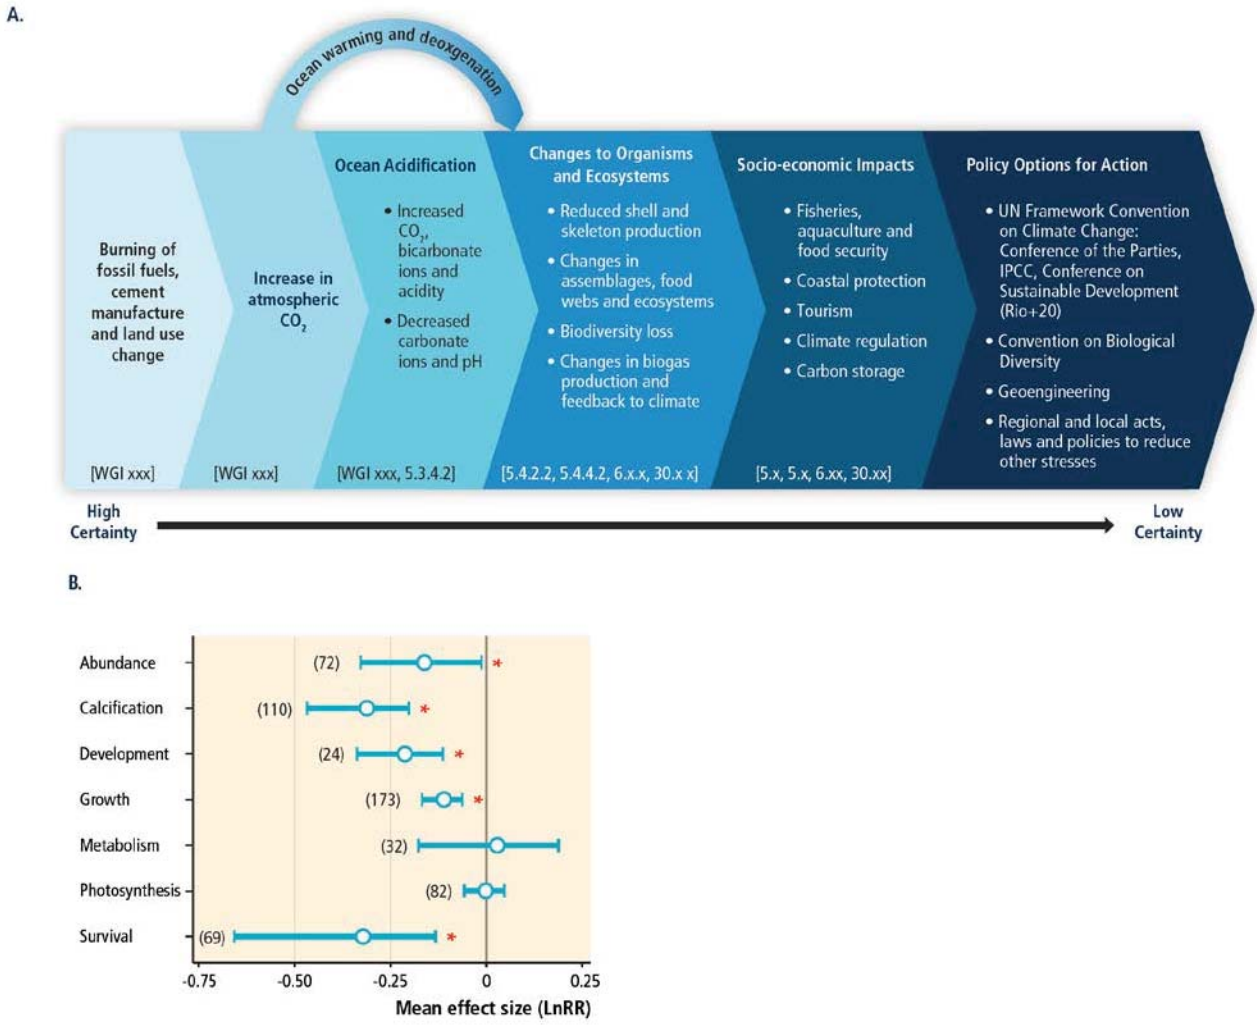


Box TS.7 Figure 1: The dependence of risk associated with reasons for concern (RFCs) on the level of climate change, updated based on expert judgment in this assessment. The color scheme indicates the additional risk due to climate change (with white to purple indicating the lowest to highest level of risk, respectively). Purple color, introduced here for the first time, reflects the assessment that unique human and natural systems tend to have very limited adaptive capacity. [Figure 19-5]



Box TS.9 Figure 1: A) Overview of the chemical, biological, and socio-economic impacts of ocean acidification and of policy options. B) Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival, which is not weighted. The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect. [Box CC-OA]

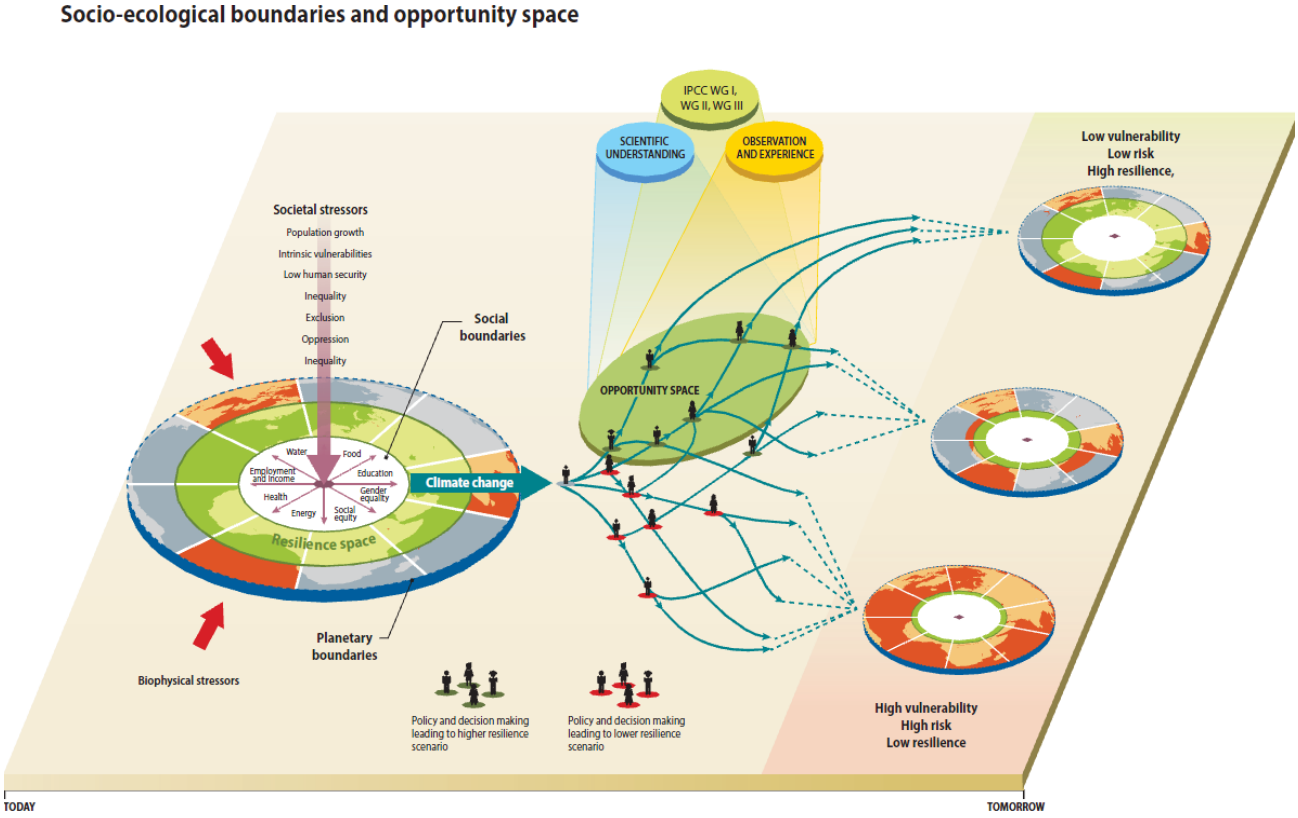


Figure TS.16: Conceptual framework for assessing interactions between biophysical and societal stressors that impact the resilience of natural and human systems today and in the future. Actions, including climate change adaptation and mitigation, taken in the opportunity space lead to a diverse range of pathways and outcomes—toward a future of high risk, high vulnerability, and low resilience space or toward a future of low risk, low vulnerability, and high resilience space. [Figure 1-7]

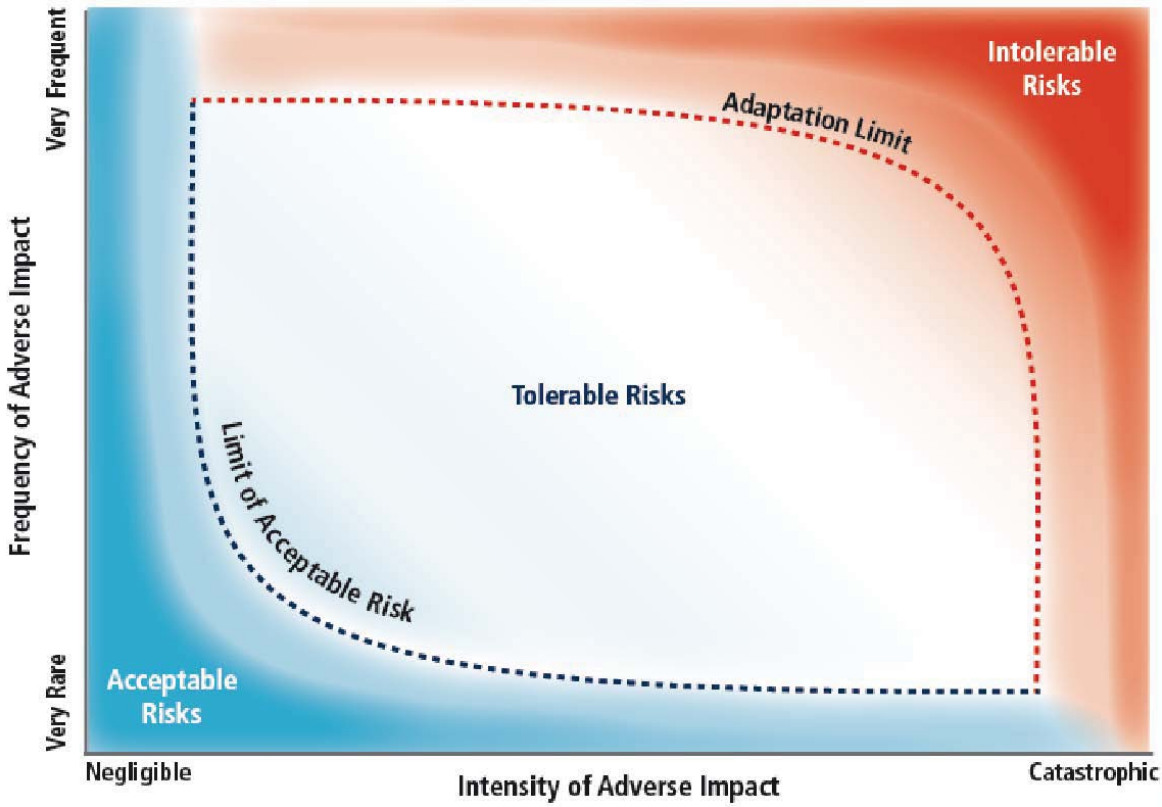

Box TS.10 Figure 1: Conceptual model of the determinants of acceptable, tolerable, and intolerable risks and their implications for limits to adaptation. [16.2, Figure 16-1]

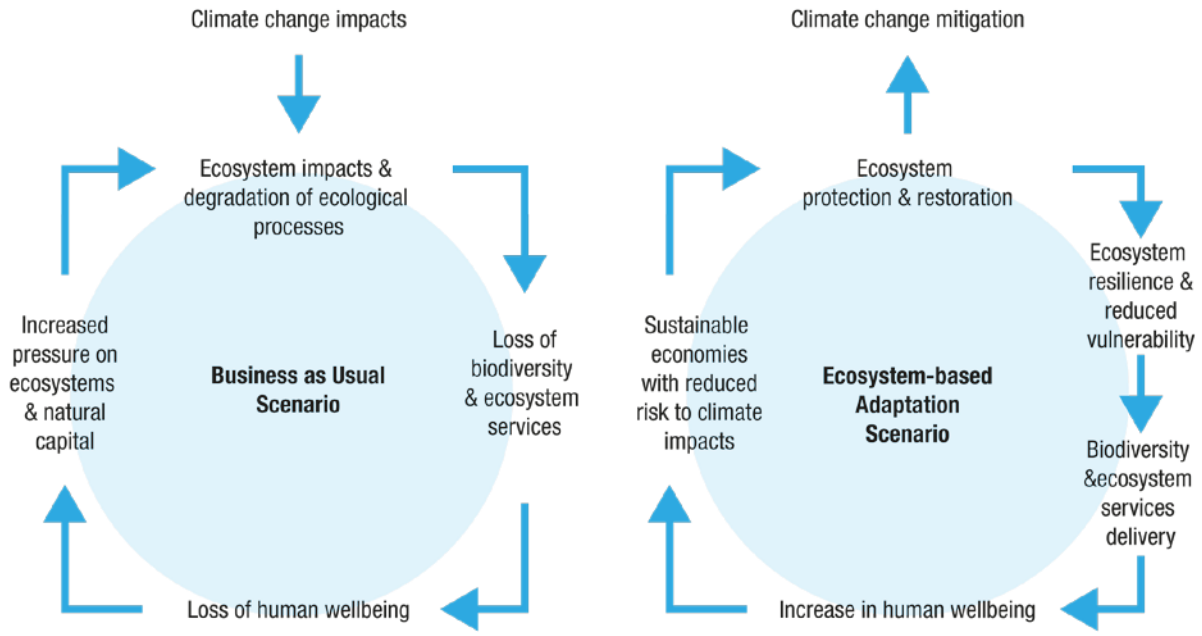

Figure EA-1: Adapted from Munang *et al.* (2013). Ecosystem based adaptation approaches to adaptation can utilize the capacity of nature to buffer human systems from the adverse impacts of climate change through sustainable delivery of ecosystems services. A) Business as Usual Scenario in which climate impacts degrade ecosystems, ecosystem service delivery and human well-being B) Ecosystem-based Adaptation Scenario which utilizes natural capital and ecosystem services to reduce climate-related risks to human communities.

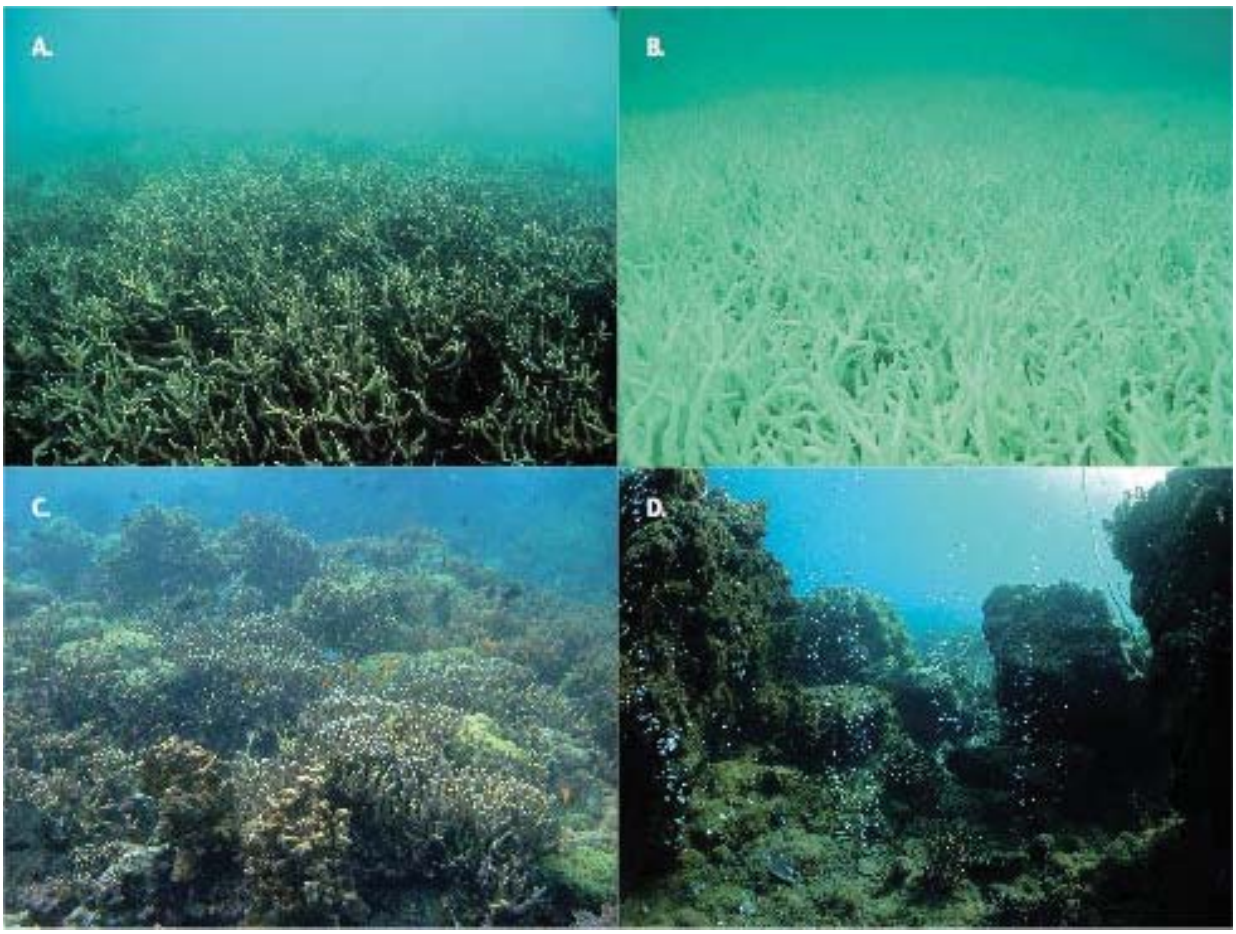

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

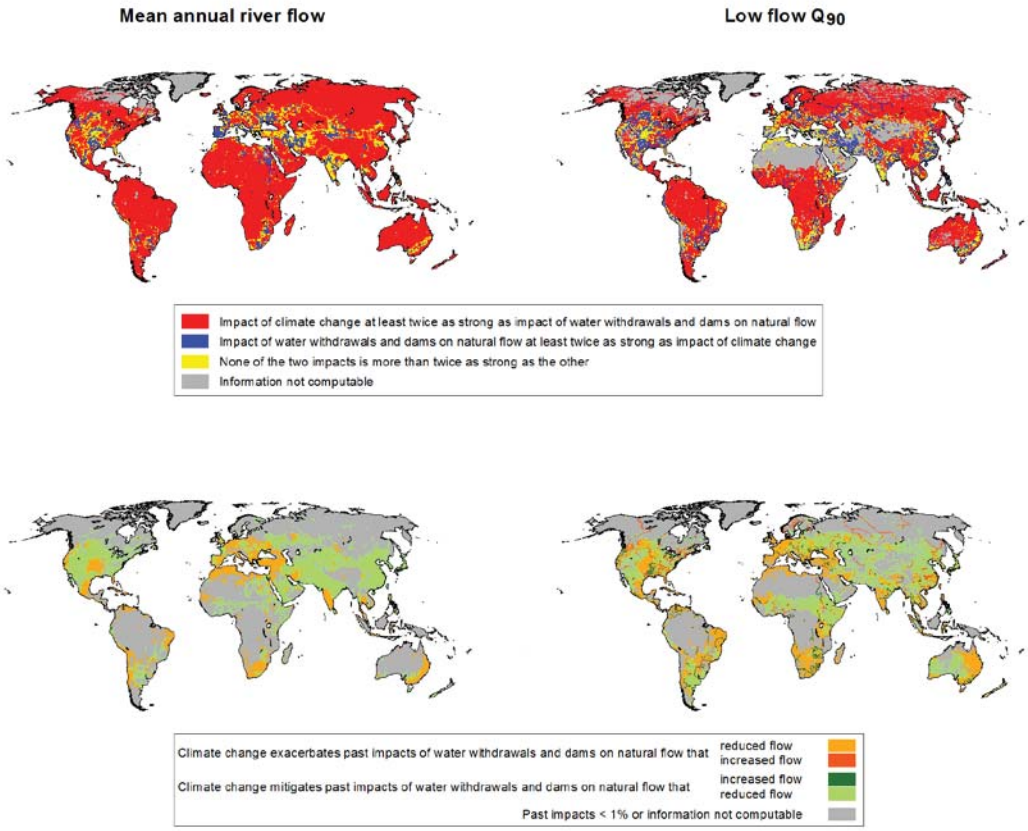

Figure RF-1: Impact of climate change on the ecologically relevant river flow characteristics mean annual river flow and monthly low flow Q_{90} as compared to the impact of water withdrawals and dams on natural flows, as computed by a global water model (Döll and Zhang, 2010). Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002.

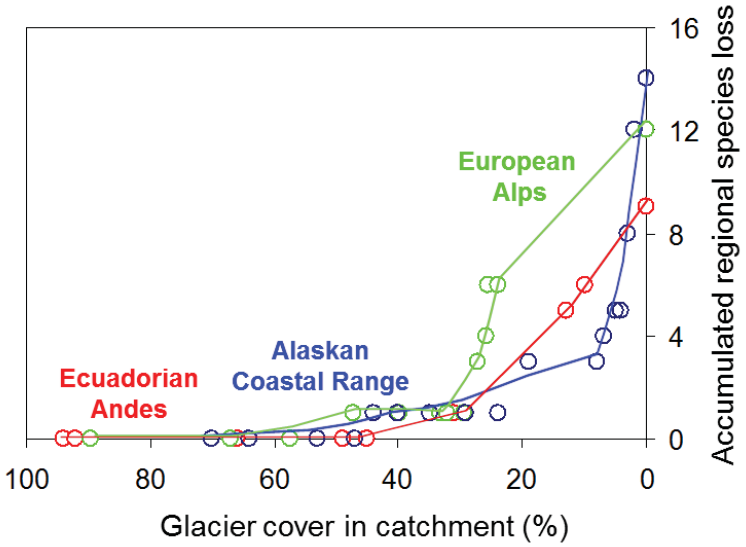

Figure RF-2: Accumulated loss of regional species richness (gamma diversity) as a function of glacial cover GCC. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%. Each data point represents a river site and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.

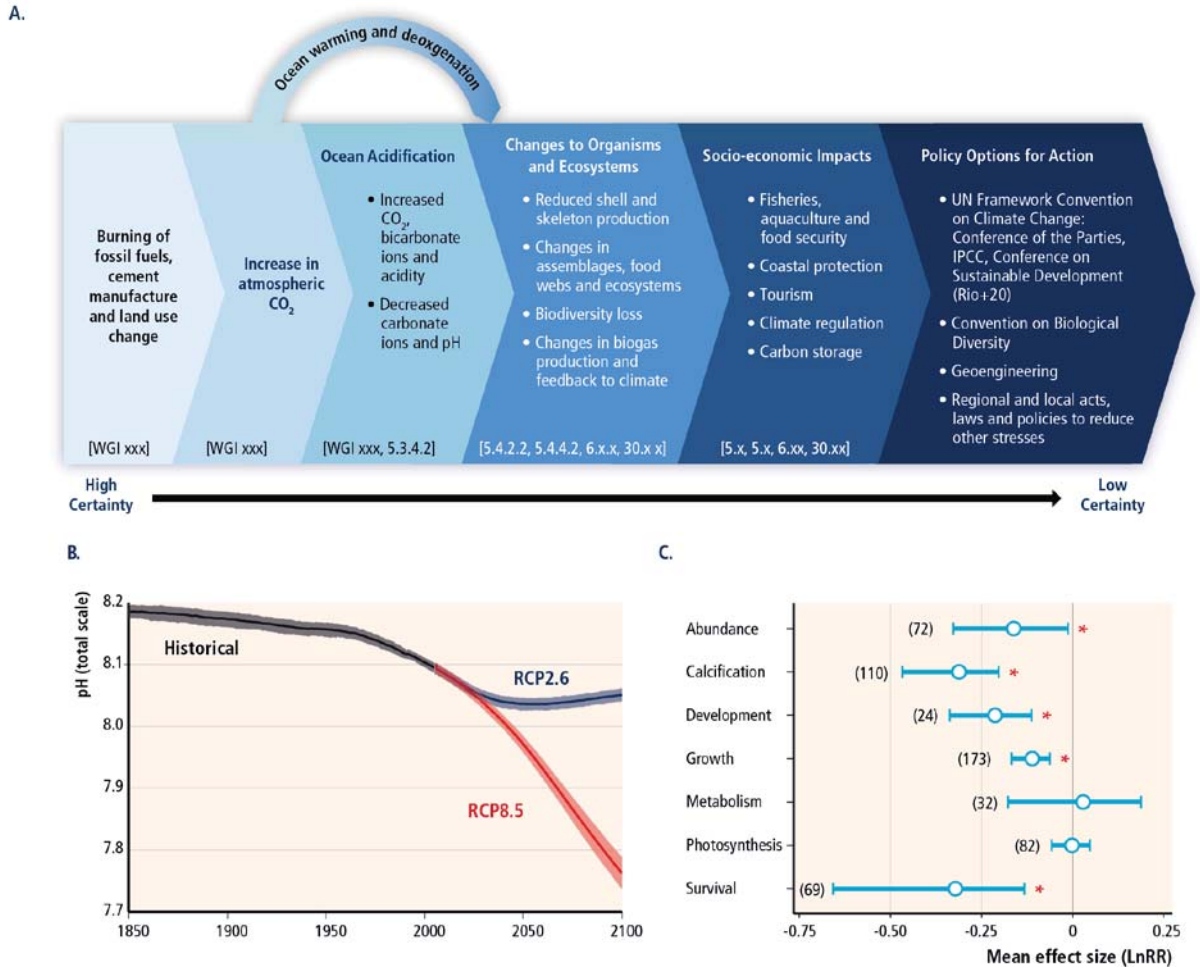

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.

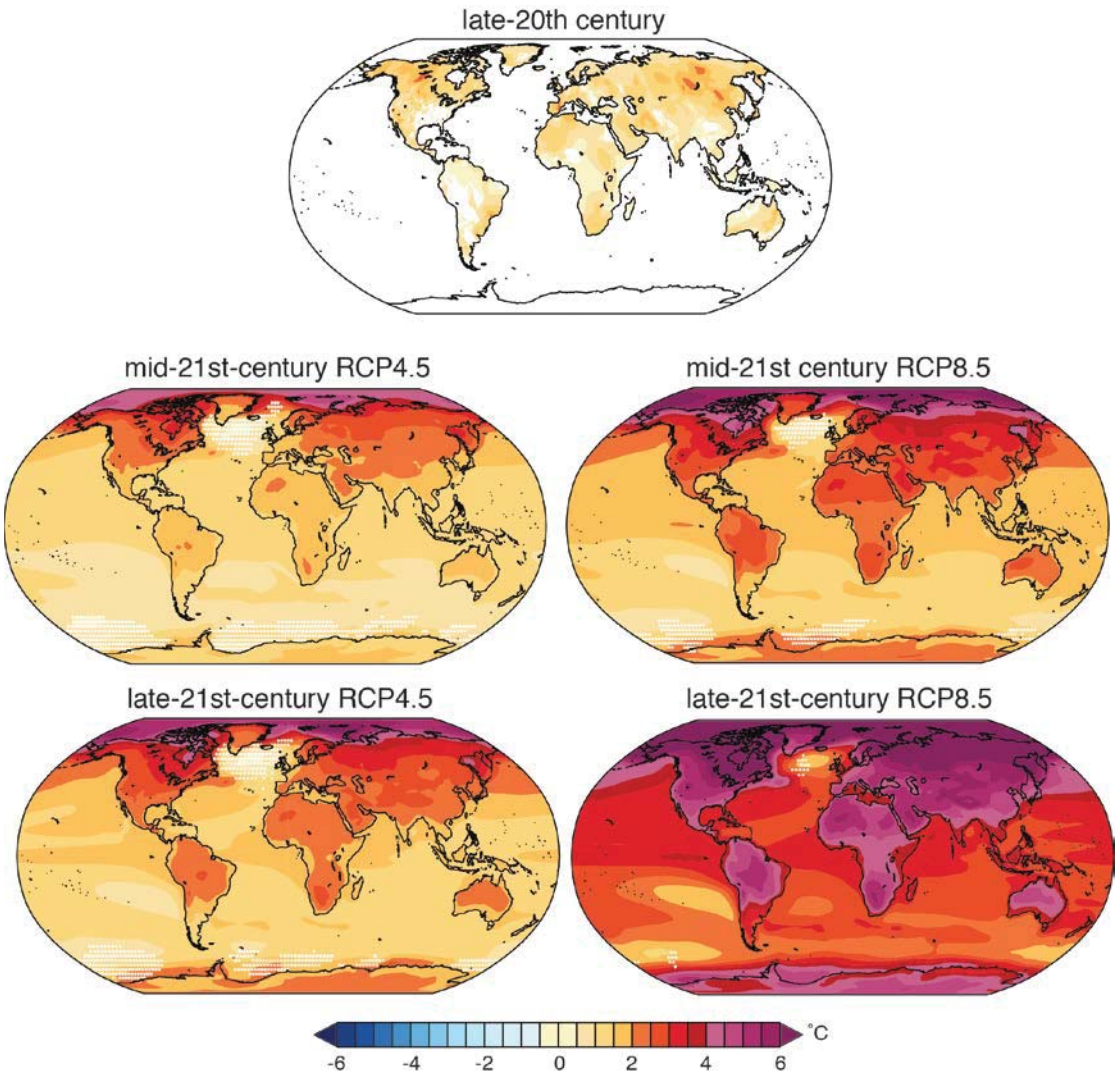

Figure RC-1: Change in annual temperature. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

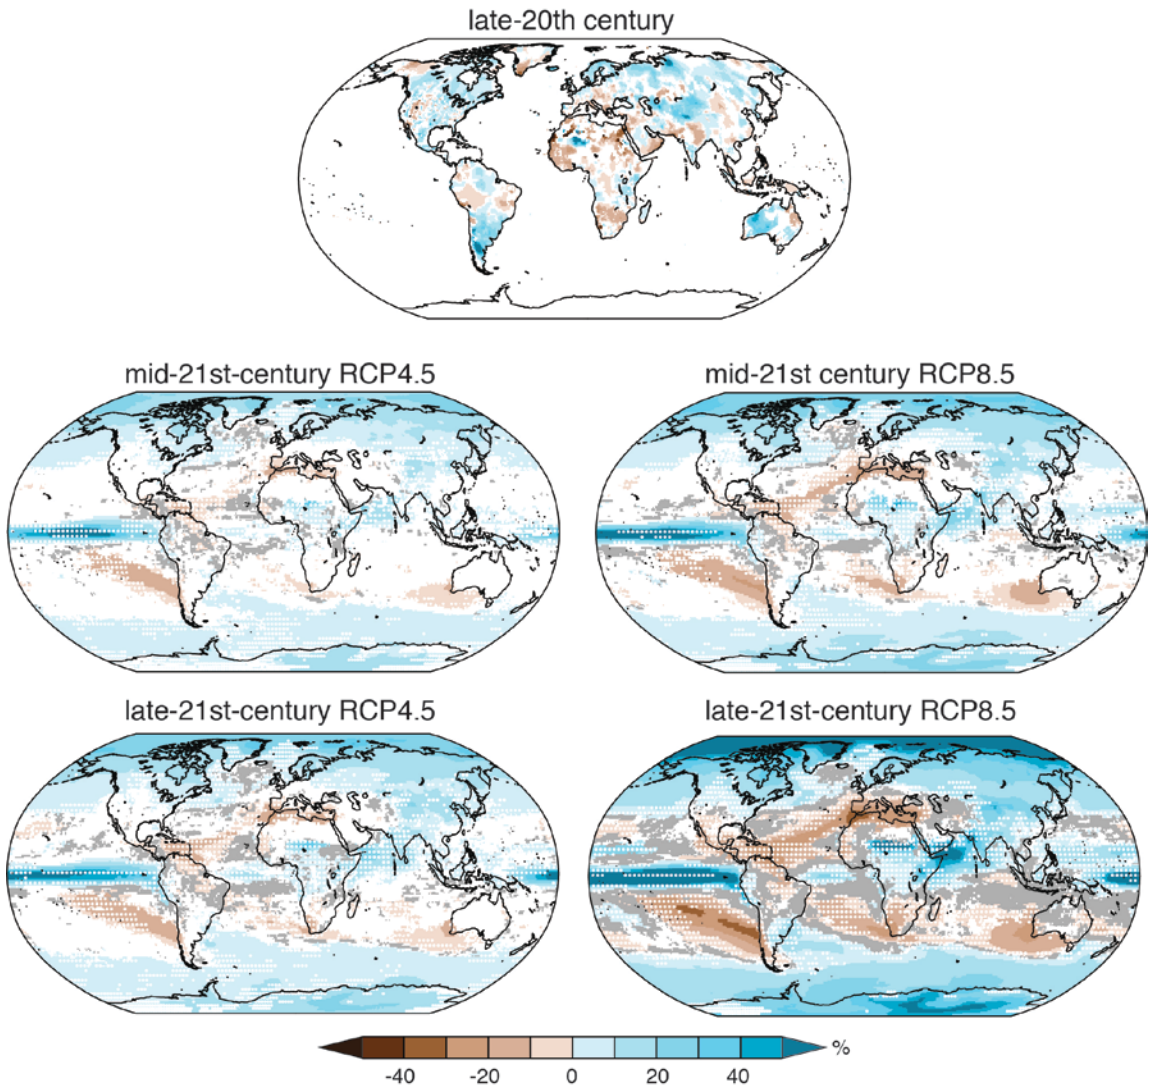

Figure RC-2: Change in annual precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

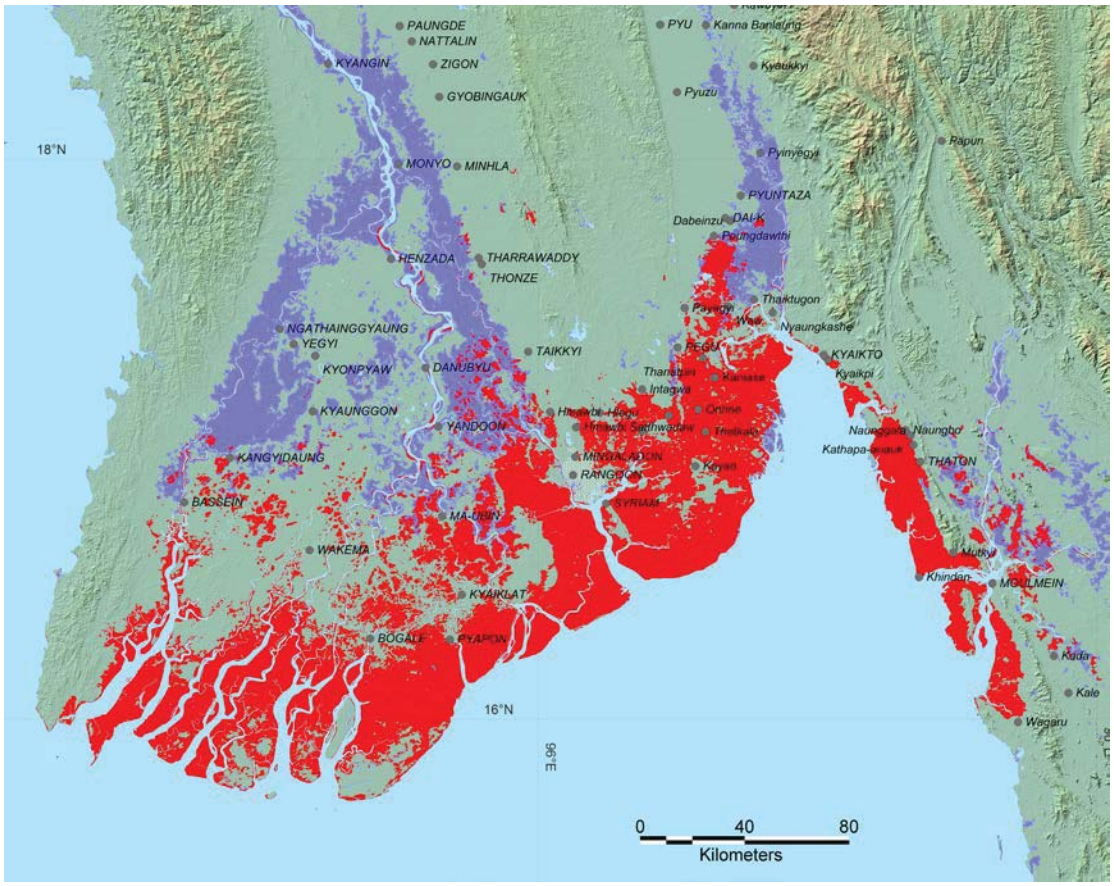

Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. (From Brakenridge *et al.*, 2012).

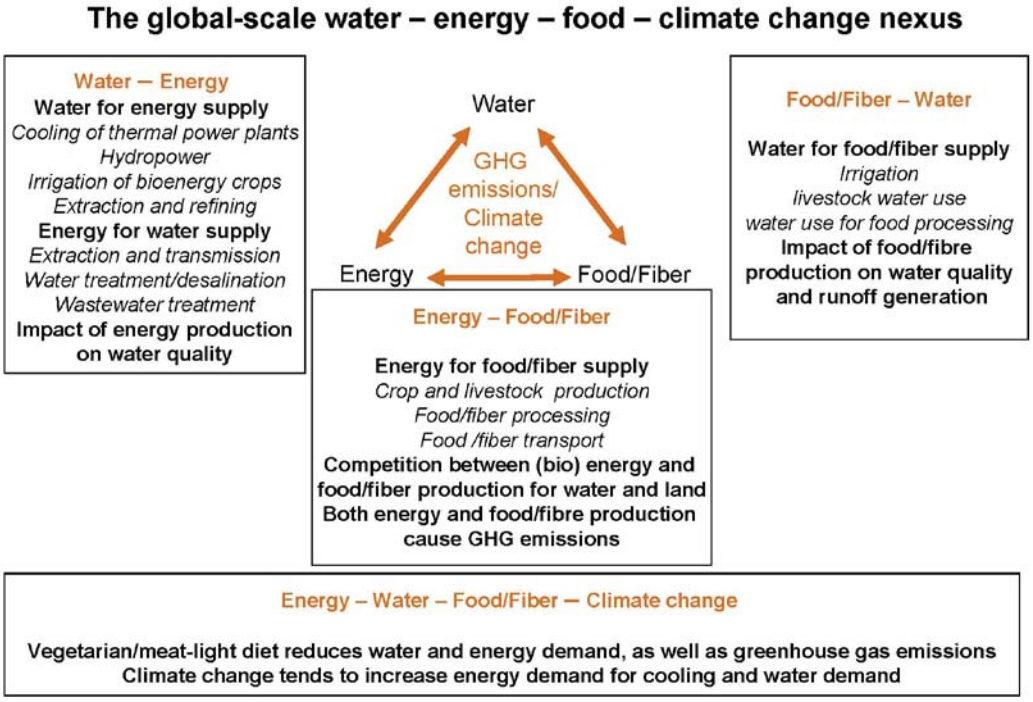

Figure WE-1: The water-energy-food nexus as related to climate change.

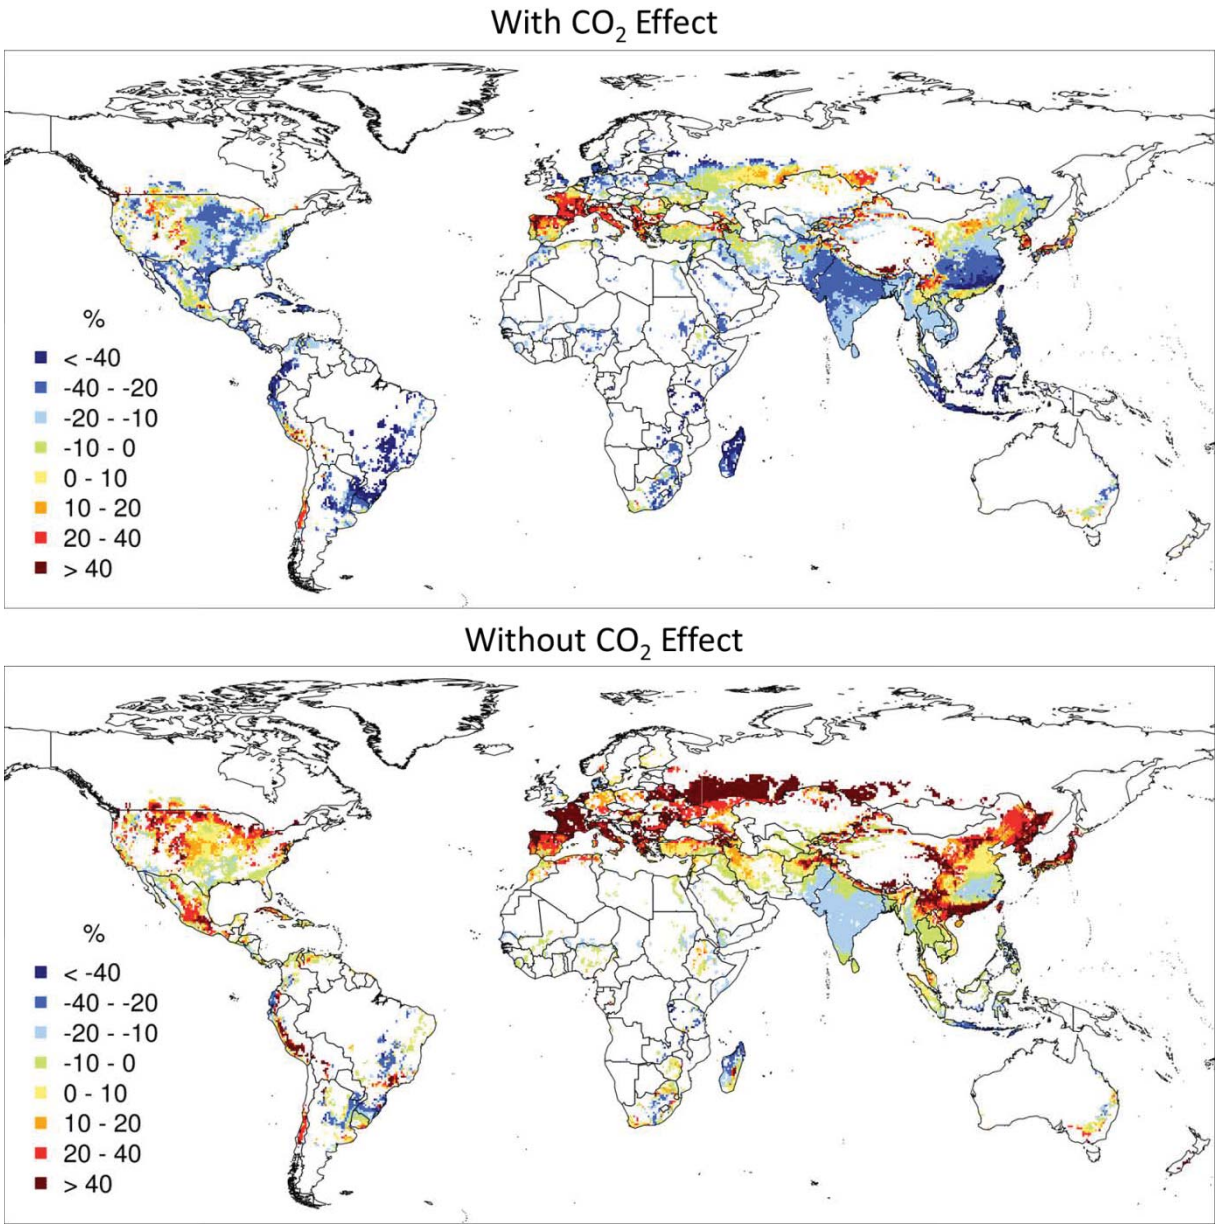

Figure VW-1: Percentage change (ensemble median across 19 GCMs used to force a vegetation and hydrology model) in net irrigation requirements of 12 major crops by the 2080s, assuming current extent of irrigation areas and current management practices. Top: impacts of climate change only; bottom: additionally considering physiological and structural crop responses to increased atmospheric CO_2 concentration. Taken from Konzmann *et al.* (2013).

Executive Summary

The literature available for assessing climate change impacts, adaptation, and vulnerability has more than doubled since 2005 (*very high confidence*). The diversity of the topics and regions covered by the literature has similarly expanded, as well as the geographic distribution of the authors contributing to the knowledge base for climate change assessments. Production of climate change literature has increased in the developing countries, although their institutions lag those in developed countries regarding access to and production of climate change literature. The unequal distribution of literature, which is influenced by factors such as scientific funding and capacity building, presents a challenge to the development of a comprehensive and balanced assessment of the global impacts of climate change. [1.1.1, Figure 1-1]

The evolution of the IPCC assessments of impacts, adaptation, and vulnerability indicates an increasing emphasis on humans, their role in managing resources and natural systems, and the societal impacts of climate change (*very high confidence*). The expanded focus on societal impacts and responses is evident in the composition of the IPCC author teams, the literature assessed, and the content of the IPCC assessment reports. Three important characteristics in the evolution of the Working Group 2 assessment reports are an increasing attention to: (i) Adaptation limits and transformation in societal and natural systems; (ii) Synergies between multiple variables and factors that affect sustainable development, including risk management, and (iii) Institutional, social, cultural, and value-related issues. [1.1, 1.2]

Adaptation has emerged as a central area of work in climate change research, in country level planning and in the implementation of climate change strategies *(high confidence).* The body of literature shows an increased focus on the capitalizing on adaptation opportunities and the interrelations between adaptation, mitigation and alternative sustainable pathways. In spite of the uncertainty of future impacts and adaptation, the literature shows an emergence of studies on transformative processes that take advantage of synergies between adaptation planning, development strategies, social protection and disaster risk reduction and management. [1.1.4]

The treatment and communication of uncertainties in IPCC reports have evolved over time, reflecting iterative learning and more coherent guidance across all Working Groups *(high confidence).* An integral feature of IPCC reports is communicating the strength and uncertainties in the scientific understanding underlying assessment findings. In Working Group II, the use of calibrated language began in the SAR, where most chapters used qualitative levels of confidence for their Executive Summary findings. Based on experience, guidance notes were developed for subsequent AR. The AR5 Guidance Note continues to emphasize a theme from all three guidance documents to date: the importance of clearly linking each key finding and corresponding assignment of calibrated uncertainty language to associated chapter text, as part of the traceable account of the author team's evaluation of evidence and agreement supporting that finding. [1.1.2.2, Box 1-1]

Impacts assessed in this report are based on a combination of AR4 climate models (CMIP3) using SRES scenarios and new AR5 climate models (CMIP5, completed in 2011-12) using the new Representative Concentration Pathway (RCP) scenarios. The RCPs span the range of SRES scenarios for long-lived greenhouse gases, but they have a narrow range and fall at or below the lowest SRES in terms of emissions of ozone and aerosol precursors and related pollutants *(high confidence).* The IPCC has created and used emission scenarios to project future climate since the FAR, and most recently the SRES scenarios were used in the TAR and AR4. With AR5, the new RCP scenarios present both emissions and greenhouse gas concentration pathways, and

corresponding shared socio-economic pathways have also been developed. The 4 RCPs assume different levels of mitigation, leading to 21st century radiative forcing levels of 2.6, 4.5, 6.0 and 8.5 W m^{-2} (See WGI Chapters 1, 6, 11, 12). All RCPs project a rapid decline in short-lived pollutants and land-use change by 2050, almost independent of fossil-fuel use and population, while other published scenarios indicate a less rapid decline in aerosol precursors**.** [1.1.3]

1.1. The Setting

This chapter describes the information basis for the Fifth Assessment Report (AR5) of IPCC Working Group II and the rationale for its organization. As the initial point of departure from the prior IPCC WGII assessments, the chapter begins with an analysis of how the literature for the assessment has developed through time and proceeds with an overview of how the framing and content of the Working Group II reports have changed since the first IPCC report was published in 1990. The future climate scenarios that have been used by the scientific community to explore the potential consequences of climate change have marked important transitions over the past five years; this chapter describes the evolution of these scenarios and the methods used to communicate scientific uncertainty in IPCC assessments. The chapter provides a summary of the most relevant key findings from the IPCC *Special Report on Renewable Energy Sources and Climate Change Mitigation* (IPCC, 2011a), the IPCC *Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation* (IPCC, 2012), and the IPCC Working Group I (*The Physical Science Basis*) and Working Group III (*Mitigation of Climate Change*) contributions to AR5. Collectively these recent reports, new scenarios, and other advancements in climate change science set the stage for an assessment of impacts, adaptation and vulnerability that could potentially overcome many of the limitations identified in the IPCC Fourth Assessment Report (AR4), particularly with respect to the human dimensions of climate change.

The IPCC has published four impact assessment reports (WGII) of the state of knowledge of climate change in 1990, 1995, 2001 and 2007. The critical review and synthesis of the scientific literature published since 2007 has required an expanded multidisciplinary approach that, in general, has more focused more heavily on societal impacts and responses. This includes analysis on how aggregate impacts are the result of coupled socio-ecological systems, and the rapid emergence of research on adaptation and vulnerability. The chapter shows an increased concern with how societal change evolves and the role of transformative thinking and action to achieve sustainability, a dynamic process that helps guarantee the persistence of natural and human systems.

In addition to the knowledge gaps in earlier Reports, point of departure in this chapter refers to a combination of the status of the biophysical planetary boundaries and the existing social boundaries on which climate impacts occur. These social boundaries include poverty and inequality, low levels of human development, and lack of access to basic needs and energy by a large part of an increasing global population interacting creating and reaction to climate change (see 1.1.4 and Figure 1-7).

The IPCC WGII Fifth Assessment Report (AR5) differs from the prior assessments primarily in the expanded outline and diversity of content that stems directly from the growth of the scientific basis for the assessment. The publication of the WGII contribution to AR5 in two volumes (Part A. Global and Sectoral Aspects and Part B. Regional Aspects) has permitted the presentation of more detailed regional analyses and an expanded coverage of the human dimensions (such as adaption) described above. For the IPCC Fifth Assessment, the contributions of Working Group I (Climate Change 2013: The Physical Science Basis) were finalized approximately six months in advance of the Working Group II contributions, allowing the authors of the latter more time to evaluate and include where possible the findings of Working Group I AR5 in the context of impacts, adaptation and vulnerability.

1.1.1. Development of the Science Basis for the Assessment

The volume of literature available for assessing climate change impacts, adaptation and vulnerability (CCIAV) has grown significantly over the past two decades (Figure 1-1a). A bibliometric analysis of reports produced with two bibliographic search tools (Scopus and ISI Web of Knowledge) indicates that fewer than 800 articles in journals,

books, and conference proceedings were published in English on the topic of "climate change" between 1970 and 1990. Since then, the literature published on the topic has increased almost 100-fold, with a total of 73,039 articles published from 1990 through 2010. Since 1990 the international distribution of scientists contributing to the climate change literature has expanded from Europe and North America to Asia and Australasia. Literature from scientists affiliated with institutions in Africa and Central and South America comprised approximately 6% of the literature published on the topic of climate change during 2001-2010 (Figure 1-1b). The proportion of literature focusing on individual countries within IPCC regions has also broadened, particularly for Asia, over the past 3 decades (Figure 1-1c). This brief chronicle does not differentiate across the various "sub-categories" of the climate literature or claim to be comprehensive in terms of literature produced in languages other than English. For example, disparities of the geographic coverage of the climate change literature on the capacity for adaptation or the assessment of impacts and vulnerability have not been assessed.

[INSERT FIGURE 1-1 HERE
Figure 1-1: Results of English literature search using the Scopus bibliographic database from Reed Elsevier Publishers. (a) Annual global output of publications on climate change and related topics: impacts, adaptation, human health, and costs (1970-2010). (b) Country affiliation of authors of climate change publications summed for IPCC regions for three time periods: 1981-1990, 1991-2000, and 2001-2010, with total number during the period 2001-2010. (c) Results of literature searches for climate change publications with individual countries mentioned in publication title, abstract or key words, summed for all countries by geographic region. The following individuals conducted the literature searches: Valentin Przyluski (French), Huang Huanping (Chinese), and Peter Zavialov and Vasily Kokore (Russian), and Saúl Armendáriz Sánchez (Spanish). (d) Number of publications in five languages that include the words "climate change" and "climate change" plus "adaptation", "impacts" and "cost" (translated) in the title, abstract or key words during the three time periods.]

Growth in both the total volume of literature about climate change and the percentage of that literature devoted to impacts and adaptation has influenced the depth and scope of assessment reports produced by Working Group II of the IPCC. A doubling of the total number of publications on the topic of climate change impacts between 2005 and 2010 and on the topic climate change adaptation between 2008 and 2010 has enabled substantial advances in the assessment of the full range of impacts, adaptation and vulnerability (Figure 1-1a). The unequal distribution of literature, however, presents a challenge to the development of a comprehensive and balanced assessment of the global impacts of climate change. The geographical and topical distribution of literature is influenced by factors such as the availability of funding for scientific research, level of capacity building, regional experience with climate-related disasters, and the availability of long-term observational records.

Literature published on the topic of climate change during 1970-1990 focused primarily on changes in the physical climate system and how these changes affected other aspects of the Earth's physical environment. The Scopus database indicates that literature began to surface at the rate of more than 100 articles per year on the topic of climate change "impacts" in 1991. The rate of publication of at least 100 articles per year on the topics of climate change "adaptation" and societal "cost" began in 2003. The proportion of the literature on the topic of "climate change" published in social science journals increased from 6% to 9% from the 1970s-1980s to the 1990s-2000s. The proportion of the literature on the topic of "climate change" appearing in engineering journals has not changed appreciably over the past four decades, but there was a significant increase in the proportion of literature relating to climate change in the biological and agricultural science literature. The themes covered by literature on vulnerability to climate change have also expanded to issues of ethics, equity, and sustainable development.

While authors continue to publish primarily in English, literature published on the topic of "climate change" in other languages have also expanded. Literature searches in Chinese, French, Russian and Spanish revealed roughly a 4-fold or greater increase in literature published on the topic of "climate change" in each language during the past two decades (Figure 1-1d). Scientists from many countries tend to publish their work in English, as indicated by comparing the regional analysis and country affiliation of authors in Figure 1-1 with the results of the literature searches in the other 5 languages. This process of "scientific internationalism", which primarily means a shift to English as a language of scientific communication, has been described as a growing trend among Russian (Kirchik, Gingras, and Ladviere, 2012), Spanish (Alcaide, Zurián, and Benavent, 2012), and French (Gingras and Mosbah-Natanson, 2010) researchers.

1.1.2. Evolution of the WGII Assessment Reports and Treatment of Uncertainty

1.1.2.1. Framing and Outlines of WGII Assessment Reports

The framing and contents of the IPCC WGII assessments have evolved since the First Assessment Report (FAR, 1990) as summarized in Figure 1-2. Three important characteristics of this evolution are: (i) extended range and coupling of variables that impact a sustainable future; (ii) an increasing focus on human beings (managing resources and natural systems, the societal impacts of climate change); and (iii) participation of more social and human dimensions scholars as authors and reviewers. The continuing focus of WGII on impacts, adaptation and vulnerability extends the assessment challenges from the physical, ecological and economic systems to institutional, social and cultural issues. Effectively, WGII now focuses on understanding the interactions between the natural climate system and human society, adding to the emphasis of earlier assessments on sectoral and regional biogeophysical impacts of climate change. This assessment contributes to a better understanding of the likelihood of certain development paths, a key uncertainty in climate projections.

[INSERT FIGURE 1-2 HERE
Figure 1-2: Tables of Contents for the Working Group II contributions to the IPCC Assessments since 1990. The First Assessment Report (FAR, 1990) of IPCC Working Group II (WGII) focused on the impacts of climate change, but for the Second Assessment Report (SAR, 1996) the WGII contribution included mitigation and adaptation with the impact assessment. With the TAR (2001) and subsequent assessments, IPCC Working Group III has assessed the options and potential for climate change mitigation. Since the TAR, WG II has focused on impacts, adaptation and vulnerability with an expanded effort on the regional scale.]

The WGII FAR (296 pages) was organized into six major sectors: agriculture & forestry, terrestrial ecosystems, water resources, human settlements, and oceans & coastal zones. The report focused on the anticipated climate changes for a doubling of CO_2. The FAR SPM highlights the coupling of anthropogenic non-climate stresses with climate variability and greenhouse-gas-driven climate change. Given the state of the science in 1990, it is understandably qualitative on some topics (e.g., global agricultural potential may either increase or decrease; major health impacts are possible), but more quantitative on large-scale climate impacts (e.g., climatic zones shift poleward by 100s km; alpine and montane regions are most at risk for habitat and species loss). Health impacts were vague, emphasizing ozone depletion and UV-B damage. The IPCC WGII 1992 Supplementary Report followed with four assigned topics (regional climate change; energy; agriculture and forestry; sea-level rise) and was primarily a strategy report, focusing on guidelines for studies, e.g., urging that studies of change in tropical cyclones and storm surges are of highest priority (IPCC, 1992).

For the IPCC Second Assessment Report (SAR, 1996) WGII reviewed climate change impacts and vulnerability plus mitigation options for greenhouse gases (GHG). In addition to two introductory primers, there were eighteen chapters on impacts and adaptation sorted primarily by land use (e.g., forests, rangelands, deserts, human settlements, agriculture, fisheries, financial services, human health) and seven chapters on mitigation sorted by sector (energy, industry, forests, other). The SAR made use of the new IPCC IS92 scenarios. Projections of 2100 sea level rise (15-95 cm) and temperature increase (1.0-3.5°C) were similar to the FAR's doubled-CO_2 scenario. The SAR notes "Impacts are difficult to quantify, and existing studies are limited in scope; Detection [of climate-induced changes] will be difficult," but some specifics are given (e.g., the number of people at risk of flooding from storm surges from sea level rise; the increase in malaria incidence). Vegetation models are used to map out projected changes in major biomes (see SAR WGII SPM Fig. 2) – the first such predictive figure in a WGII SPM. On mitigation, the SAR analyzed historical GHG emissions by sector and discussed technological options, but cost analysis was left to WGIII.

The Third Assessment Report of WGII (TAR, 2001) returned to impacts, adaptation, and vulnerability, returning mitigation to WGIII. It included five core chapters on sectors (water resources, ecosystems, coastal and marine, human settlements and energy, and financial services), eight regional chapters, plus two focus chapters on (i) adaptation, sustainable development, and equity, and (ii) vulnerability and reasons for concern. The TAR made the

first strong conclusion on attributing impacts: "recent regional climate changes, particularly temperature increases, have already affected many physical and biological systems." Recent increases in floods and droughts, while affecting some human systems, could not be tied to GHG-driven climate change. The TAR introduced the "burning embers" diagram (TAR Fig. 2, updated in Chapter 18 of this report) as a way to represent "reasons for concern." The adaptive capacity, vulnerability and key concerns for each region were laid out in detail (TAR, 2001, Table 2).

The Fourth Assessment Report of WGII (AR4, 2007) retained the basic structure of the TAR with core chapters on sectors and regions. With the large increase in regional studies, AR4 concluded: "it is likely that anthropogenic warming has had a discernible influence on many physical and biological systems." Many, more specific examples of attributed and projected impacts are reported with confidence levels, but many still remain qualitative. Two major graphics in the AR4 SPM (Figure 1-2 and Table 1-1) give many examples of projected impacts of climate change, but the state of the science – both of WGI climate projections and WGII impacts – remained too uncertain at the time to give more quantitative estimates of the impacts or necessary adaptation.

This Fifth Assessment Report of WGII (AR5) continues and expands the sector and regional parts. The AR5 considers a wide and complex range of multiple stresses that threaten the sustainability of human and ecological systems. Figure 1-3 gives examples of the wide range of stressors directly coupled to climate change (e.g., population, land-use change, projected temperature, heat waves, water availability), demonstrating the geographic heterogeneity. The focus on climate change and related stressors, and the resulting vulnerability, occurs throughout this report, including the expanded “reasons for concern” (Chapters 2 and 19, see also Section 1.1.4).

[INSERT FIGURE 1-3 HERE

(http://sedac.ciesin.columbia.edu/data/collection/gpw-v3/maps); (b) Croplands and pasture/rangeland coverage from Foley *et al*. (2005); (c) Industrial sector energy/electricity-related CO_2 emissions ($GtCO_2$) for 1971-2000 (historical) and 2001-2030 (SRES B2) (AR4 WGIII TS.18 and Table 7.1, 7.2). EECCA = Countries of Eastern Europe, the Caucasus and Central Asia; (d) Surface temperature change projected for Dec-Jan-Feb, years 2046-2065 minus 1986-2005 under RCP8.5 from CMIP5 median (AR5 WGI Annex I); (e) Heat extremes based on Warm Spell Duration Index increase from 1980-1999 to 2081-2100 under SRES A2 normalized by standard deviation (SD) (SREX; after Fig.5 of Orlowsky and Seneviratne, 2011); (f) Water availability based on projected change of annual runoff (%) from 1981-2000 to 2081-2100 for SRES A1B (AR4 WGII Fig. 3.8, based on CMIP3); (g) Vulnerability to climate change in year 2050 (SRES A2, climate sensitivity 5.5°C, adapted from AR4 WGII Fig TS.19, 20.6).]

1.1.2.2. Treatment of Uncertainties in IPCC Assessment Reports: a Brief History and Terms Used in AR5

An integral feature of IPCC reports is communication of the strength of and uncertainties in scientific understanding underlying assessment findings. Treatment of uncertainties and corresponding use of calibrated uncertainty language in IPCC reports have evolved across IPCC assessment cycles (Swart et al., 2009; Mastrandrea and Mach, 2011). In Working Group II, the use of calibrated language began in the contribution to the Second Assessment Report, in which most chapters used qualitative levels of confidence in findings presented in their Executive Summaries (IPCC, 1996). Starting with the Third Assessment Report (TAR), formal guidance across the Working Groups has been developed in each assessment cycle (Moss and Schneider, 2000; IPCC, 2005; Mastrandrea et al., 2010). The TAR guidance paper (Moss and Schneider, 2000) stated that “guidelines such as these will never truly be completed,” and an iterative process of learning and improvement of guidance has ensued, informed by experience in each assessment cycle. Each subsequent guidance paper has presented related but distinct approaches for evaluating and communicating the degree of certainty in findings of the assessment process.

The AR5 Guidance Note (summarized in Box 1-1) continues to emphasize a theme from all three guidance documents to date: the importance of clearly linking each key finding and corresponding assignment of calibrated

uncertainty language to associated chapter text, as part of the traceable account of the author team's evaluation of evidence and agreement supporting that finding

_____ START BOX 1-1 HERE _____

Box 1-1. Communication of Uncertainty in the Working Group II Fifth Assessment

Based on the Guidance Note for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties (Mastrandrea et al., 2010), the Working Group II contribution to the Fifth Assessment Report relies on two metrics for communicating the degree of certainty in key findings:

- Confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively.
- Quantified measures of uncertainty in a finding expressed probabilistically (based on statistical analysis of observations or model results, or expert judgment).

Each finding has its foundation in an author team's evaluation of associated evidence and agreement. The type and amount of evidence available varies for different topics, and that evidence can vary in quality. The consistency of different lines of evidence can also vary. Beyond consistency of evidence, the degree of agreement indicates the consensus within the scientific community on a topic and the degree to which established, competing, or speculative scientific explanations exist. Consistent evidence does not necessarily imply a high degree of agreement, if, for example, evidence is consistent but judged to be low in quality.

The Guidance Note provides summary terms to describe the available evidence: *limited*, *medium*, or *robust*; and the degree of agreement: *low*, *medium*, or *high*. These terms are presented with some key findings. In many cases, author teams additionally evaluate their confidence about the validity of a finding, providing a synthesis of the evaluation of evidence and agreement. Levels of confidence include five qualifiers: *very low*, *low*, *medium*, *high*, and *very high*. Figure 1-4 illustrates the relationship between the summary terms for evidence and agreement and the confidence metric. There is flexibility in this relationship; increasing confidence is associated with increasing evidence and agreement, but different levels of confidence can be assigned for a given evidence and agreement statement.

[INSERT FIGURE 1-4 HERE
Figure 1-4: Evidence and agreement statements and their relationship to confidence. The shading increasing towards the top-right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence.]

In some cases, available evidence incorporates quantitative analyses, based on which uncertainties can be expressed probabilistically. In such cases, a finding can include calibrated likelihood language or a more precise presentation of probability. The likelihood terms and their corresponding probability ranges are presented below. Use of likelihood is not an alternative to use of confidence: an author team will have a level of confidence about the validity of a probabilistic finding. Unless otherwise indicated, findings assigned a likelihood term are associated with *high* or *very high* confidence. When authors evaluate the likelihood of some well-defined outcome having occurred or occurring in the future, the terms and associated meanings are:

Term*	**Likelihood of the outcome**
Virtually certain	99–100% probability
Very likely	90–100% probability
Likely	66–100% probability
About as likely as not	33–66% probability
Unlikely	0–33% probability
Very unlikely	0–10% probability
Exceptionally unlikely	0–1% probability

* Additional terms that were used in limited circumstances in the Fourth Assessment Report (*extremely likely:* 95–100% probability, *more likely than not:* >50–100% probability, and *extremely unlikely:* 0–5% probability) are also be used if appropriate.

_____ END BOX 1-1 HERE _____

1.1.3. Scenarios used as Inputs to Working Group II Assessments

A scenario is a story or image that describes a potential future, developed to inform decision-making under uncertainty (Parson et al. 2007). Historical uses of storylines for planning and analysis can be traced back to the first formalized war games that were developed for military officer training in 19th century Prussia (Brewer and Shubik, 1979). Scenarios are commonly used in the analysis of global climate change policy and assessment and have been part IPCC future climate projections since the FAR (1990), where WGIII generated four scenarios (Bau = business-as-usual, B, C, and D) that were used by WGI to project climate change. In the IPCC Supplementary Report (IPCC, 1992), a joint WGI-WGIII effort defined six new scenarios (IS92a-f) that were used in the SAR (1996). For the TAR (2001), the IPCC Special Report on Emissions Scenarios (SRES: Nakicenkovic et al., 2000) created many scenarios from four Integrated Assessment Models (IAMs), out of which a representative range of marker scenarios were selected (A1B, A1T, A1FI, A2, B1, B2). In the SRES, IPCC explicitly forbade climate-mitigation options. The SRES scenarios carried over into the AR4 (2007) and formed the basis for the large number of ensemble climate simulations (CMIP3), both historical and 21st century, which are in use for climate-change studies relevant to AR5 WGII.[1]

INSERT FOOTNOTE 1 HERE: The Coupled Model Intercomparison Project is an activity of the World Climate Research Programme's Working Group on Coupled Modelling. Climate model output from simulations of the past, present and future climate archived mainly in 2005-2006 constituted phase 3 of the Coupled Model Intercomparison Project (CMIP3). Similar climate simulations by an expanded set of models in 2011-2013 is being used in AR5 and constitutes phase 5 of the project (CMIP5). CMIP3 used the SRES scenarios, and CMIP5 used the RCP scenarios.]

With the AR5, the scenarios fundamentally changed: an ad hoc community of experts, anticipating AR5, built a new structure for scenarios called Representative Concentration Pathways (RCPs) (Moss et al., 2010; van Vuuren et al., 2011) that defined the scenario from socio-economic path to emissions to greenhouse gas abundances and to global mean climate change using updated IAMs. These are primarily stabilization scenarios and labeled by their radiative forcing at the end of the century in W m^{-2} (RCP2.6, RCP4.5, RCP6.0, RCP8.5). The RCPs provide a flexible, interactive, and iterative approach to climate change scenarios without the governmental approval process. The connection between the anthropogenic emissions and climate forcing is weaker with the RCPs, which rely on a single parametric model (Meinshausen et al., 2011) than in previous assessments, which let the lead authors of the assessment report develop a best estimate. This aspect is assessed in AR5 WGI. The RCPs were used to drive multi-model ensembles of simulated climate change, historical and projected, designated CMIP5.

1.1.3.1. Comparison of RCP and SRES Scenarios

The WGI AR5 deals primarily with results from the RCP CMIP5, but this WGII assessment also uses results from the SRES CMIP3, and thus we identify similar or parallel scenarios from each set. The radiative forcing (RF in W m^{-2}) from the SRES and RCP scenarios are compared in Figure 1-5a. SRES A2 has a similar trajectory to RCP8.5, while SRES B1 matches RCP4.5. RCP6.0 has no simple analog: up to 2060, it is similar to both RCP4.5 and SRES B1; but after 2070, it lies between SRES B1 and B2. The RCP2.6 scenario, a strong mitigation scenario with net CO_2 uptake by 2100, falls well outside the SRES range, falling 2 W m^{-2} below SRES B2.

Total RF does not adequately describe the differences in climate change between SRES and RCPs. The RCPs universally adopt stringent mitigation policies for local air pollution and thus have much lower aerosol abundances than the SRES scenarios, which for the most part incorrectly ignored air quality regulations (AR5 WGI Tables AII.2.16-22). In terms of ozone and particulate matter precursor emissions, there is almost no overlap between

SRES and RCPs. In terms of surface ozone at the continental scale, after 2060 the RCPs are similar to low-end SRES B1 (AR5 WGI Tables AII.7.1-2).

Global mean surface temperature change for the scenarios (Figure 1-5b) shows bounding cases but no simple analogs. The AR5 RCP data is taken directly from the CMIP5 runs, whereas the AR4 data is based on a simple model, parameterized to match the different CMIP3 models (see figure caption). In terms of temperature change, RCP8.5 lies slightly above SRES A2, but below SRES A1FI. RCP4.5 follows SRES B2 up to 2060, but then drops to track SRES B1; whereas RCP6.0 has lower temperature change to start, following SRES B1 but then increasing towards SRES B2 by 2100. In general, scenarios SRES A1B, A1T and even B2 lie in the large gap between RCP8.5 and RCP4.5/6.0. The RCP2.6 temperature change stabilizes at about 1°C above the reference period (1986-2005), while for the 2090s, all SRES and the other RCPs span the range 1.8 – 4.1 °C.

[INSERT FIGURE 1-5 HERE
Figure 1-5: (a) Projected RF (W m^{-2}) and (b) global mean surface temperature change (°C) over the 21st century from the SRES and RCP scenarios. RF for the RCPs are taken from their published CO_2-eq (Meinshausen et al., 2011), and RF for SRES are from the TAR Appendix II (Table II.3.11). Comparable models are used in both RF calculations. The SRES RF are shifted upward by 0.12 W m^{-2} to match at year 2000. Temperature changes are decadal means based on the model ensemble mean CMIP5 data for the RCPs (see AR5 WGI Chapters 11, 12, Annex II tables). The same analysis applied to CMIP3 SRES A1B is also shown (yellow circles). The SRES temperatures (colored squares, AR4 WGI Figure 10.26) are based on a simple climate model tuned to the CMIP3 models. Thus the yellow circles and yellow squares differ by a few tenths °C.]

1.1.3.2. Shared Socio-economic Pathways

Complementing the development of the RCPs that represent radiative forcing, efforts are also currently underway to provide a linkage between them and a range of human development pathways. For that purpose, Shared Socioeconomic Pathways (SSPs) are being generated (Arnell et al., 2011) considering socioeconomic challenges to mitigation and socioeconomic challenges to adaptation. The SSPs include storylines, which are descriptions of the state of the world, Integrated Assessment Models (IAM) quantitative variables (such as population, GDP, technology availability), and other variables, not included in the IAMs, such as ecosystem productivity and sensitivity or the governance index. It is expected that they would facilitate comparison across research results of the Climate Models, the IAMs, and Impacts, Adaptation and Vulnerability (IAV) communities, and facilitate use of new climate modeling results in conjunction with IAV research. Several chapters of this report refer to the SSPs in their discussion of analysis of future impacts and vulnerability; Chapter 21 (21.3.3.1.3) addresses how the time lags in producing the RCPs and SSPs have limited the use of these scenarios in AR5.

1.1.4. Evolution of Understanding the Interaction between Climate Change Impacts, Adaptation, and Vulnerability with Human and Sustainable Development

The lack of progress in reducing greenhouse gas emissions at a global scale has fostered concern about unavoidable climate change impacts and has contributed to an increasing emphasis on vulnerability, adaptation, and development pathways. The possible range of socio-economic trajectories in developed and developing countries is among the largest sources of uncertainty in scenario building and climate predictions (Hawkins and Sutton, 2009). A deeper understanding of patterns of global development and the possibilities for the transformation of all countries towards sustainability is therefore a fundamental aspect of addressing climate change and its impacts.

The IPCC's first three Assessment Reports focused primarily on characterizing the biophysical impacts of climate change, with a progressively more elaborated understanding of the economic and social impacts. The last decade has seen major advances in the conceptual integration of the physical and social impacts of climate change. The Fourth Assessment Report asserted that "climate change impacts depend on the characteristics of natural and human systems, their development pathways and their specific locations" (IPCC 2007a, page 64). It offered a catalogue of

multiple stresses jointly impacting people and communities, and also highlighted questions of justice and equity in shaping development pathways in the context of climate change (IPCC 2007a, pages 811-841).

Vulnerability was defined in the TAR as a "function of the character, magnitude, and rate of climate variation to which a system is exposed, its sensitivity, and its adaptive capacity" (IPCC, TAR, 2001b, page 388). Since then, the concept of vulnerability has acquired increased complexity as a multi-dimensional concept, also referring to structural conditions of poverty and inequality. This Report reveals substantive risks for socio-ecological systems in all regions, particularly in low-income economies. Literature reviewed in many chapters suggests that climate impacts could reverse past development achievements and hinder global efforts on poverty reduction, lead to human insecurity, displacement and conflict, maladaptation and negative synergies (for example, Barnett and O'Neill, 2010; Boyd and Juhola, 2009; Jerneck and Olsson, 2008; Klein et al., 2007; Ogallo, 2010; see also 13.2.1.; 12.2.1; 12.4.1; 12.5.1).

The importance of the social context in determining both resilience and vulnerability is encompassed by the notions of sensitivity and adaptive capacity and can be tracked using human development indicators. For example, adaptive capacity in many urban centers of the African continent is constrained by widespread poverty, lack of access to employment, inappropriate housing, or lack of access to water, sanitation and drainage, health care and education (8.2.4; 11.6.2, 22.4.4). Adaptation options and limits to high end warming in all countries are often contextualized in relation to socio-economic vulnerabilities and other stressors (Brown, 2012; New, Liverman, Schroeder and Anderson, 2010; Stafford Smith et al., 2011; World Bank, 2012; see 16.4.2.4). But concerted action to mitigate and address climate change along with increased adaptation practice creates an opportunity space for transformed pathways leading to increased resilience, low risk and low vulnerabilities. Sustainability, assuring and protecting the endurance of natural systems and equitable distribution in human systems, in the present and for the future, is thus a dynamic process and the context for climate resilience (see 20.2 and 20.3.3). The pathways identified in this report point to two eras. The era of climate responsibility, addressing the interconnectedness of multiple vulnerabilities for unavoidable impacts; and the era of climate options, the opportunity space to transform our actions toward a low risk and high resilient future.

A survey of the literature published since the last IPCC Report shows several key areas of emerging theoretical and methodological scholarship. Attention is being focused on devising and refining research methodologies to address the complexity of juxtaposing biophysical and social factors. This requires new approaches to transdisciplinarity, and the co-production of knowledge among stakeholders to enhance synergies between academic merit, policy relevance, and salience for users at the community level (Hegger et al., 2012; Pohl, 2011). A substantial amount of literature has emerged linking perspectives and methods, in particular resilience thinking, adaptive learning, anticipatory adaptation, sustainability science, welfare and social science research, vulnerability assessments, risk assessment and studies addressing the crucial role of mitigation in relation to development achievements (see for example, Beddoe et al., 2009; Cannon and Müller-Mahn, 2010; Folke et al., 2010; Reid et al., 2010). All point to the co-production of knowledge as a way to increase the saliency, legitimacy and credibility of the research process.

There is increased attention to questions of ethics, justice and responsibilities (for example, Arnold, 2011; Caney, 2012; Gardiner, 2011; Marino and Ribot, 2012; O'Brien et al., 2010; Pelling, 2010; Timmons and Parks, 2007). As basic needs such as energy, land, food or water become threatened, inequalities and unfairness may deepen leading to maladaptation and new forms of vulnerability. Responses to climate change may have unfair outcomes. For example, there are increasing cases of land-grabbing, large acquisitions of land or water rights for industrial agriculture, mitigation projects, or biofuels that have negative consequences on local and marginalized communities (Borras, McMichael, and Scoones, 2011, see also 14.7). Ethical perspectives are also important in relation to adaptation constraints and limits (see 16.7) and mitigation (see 1.3.4 and the Working Group III contribution to AR5). Addressing climate change vulnerabilities has become closely linked to addressing other injustices and reclaiming the role of democratic processes of social contestation against a perceived unfair distribution of wealth and resources and attention to underlying values, cultures and belief systems (Bond, 2011; Martinez-Alier et al., 2011; Shiva, 2005).

The relations with development are complex and contested. There is disagreement about some fundamental issues, in particular whether ideas of modernization, quality of life and increasing living standards based on consumption

patterns of western countries and exported to the global south through development aid are part of the problem (Brooks, Grist, and Brown, 2009; Grist, 2008; Schipper, 2007). The literature points to how inequalities, trade imbalances, intellectual property rights, gender injustice, or agricultural systems, for example, cannot be corrected with "development as usual", even if climate concerns are mainstreamed (Alston, 2011; Büscher et al., 2012; McMichael, 2009; OECD, 2009; Pogge, 2008; UNDP, 2007, 2011).

Practitioners link adaptation planning and policy instruments with ongoing development efforts. Climate change impacts are increasingly becoming a central issue in the work of United Nations development cooperation and specialized agencies, bilateral donor institutions, and international development Non Governmental Organizations (NGOs). At the same time, environmental institutions are increasingly paying attention to socio-economic contexts, institutions, culture and behaviors as key drivers for addressing environmental crises. The concept of "green" growth, for example, framed the 2012 Rio + 20 Earth Summit and has led to an academic debate on the opportunities and limits of this concept. However, concern about the incompatibility of growth with environmental goals remains (see 20.4.3), and proposals for alternative conceptions of growth (and growth reversal) have been proposed (Jackson, 2010).

The increase in adaptation literature and experience has led to the development of adaptation policy in many parts of the world, as reflected in all of the regional chapters of this report. The need for improved decision analysis has also led to a rapid increase in many approaches to climate change impact, adaptation and vulnerability assessments. At the policy level, individual country National Adaptation Programmes of Action and National Communication reports to the United Nations Framework Convention on Climate Change (UNFCCC) have focused primarily on physical climate change drivers and impacts. An analysis of National Communications documents submitted through 2004 by many of the developed countries (members of the Organisation for Economic Co-operation and Development) showed that climate change impacts and adaptation receive very limited attention relative to the discussion of greenhouse gas emissions and mitigation policies (Gagnon-Lebrun and Agrawala, 2006). The National Communications documents from 17 Latin American and Caribbean countries National Communications submitted through 2010 showed a similar pattern, with roughly 3% of the space (in pages) in these documents explicitly focused on adaptation (Figure 1-6). Progress towards adaptation is evident in some recent National Communications, however, such as the most recent National Communications from India and Iran, which devoted 28.8% (58 pages in a volume of 203) and 27.4% (52 pages in a volume of 190) respectively, to the topic of adaptation in their most recent National Communication.

[INSERT FIGURE 1-6 HERE
Figure 1-6: Distribution of topics related to impacts and vulnerability, adaptation, mitigation and greenhouse gas inventories (GHG inventories) in the First (1), Second (2) or Third (3) National Communications (NC) of several Latin American and Caribbean countries (Argentina, Belize, Bolivia, Brazil, Chile, Costa Rica, Cuba, Dominica, Ecuador, El Salvador, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Uruguay and Venezuela). Documents source: http://unfccc.int/national_reports/non-annex_i_natcom/items/2979.phpUNFCCC.]

Some market theorists have sought to identify an appropriate and synergistic continuum between development and adaptation strategies and financing (Heltberg, Siegel and Jorgensen, 2009; Mearns and Norton, 2010; Richardson et al., 2011; OECD, 2009; USAID, 2008; World Bank, 2010). "Greener" versions of economic growth-driven development and revisited ideas of sustainable development have been proposed. Key instruments in this area are market-based mechanisms aiming to achieve synergies between mitigation and adaptation efforts, development financing and planning, the development of appropriate measurement and monitoring tools and links to energy needs, such as the "Clean Development Mechanism". But discussions are underway about the preconditions for market mechanisms, such as offsets, to work as intended (Liverman, 2010), the problems of carbon leakage, and the potential negative effects of mitigation strategies. An in-depth discussion of these interactions is given in Chapter 13, and Chapters 8, 11 and 12 identify central topics with particular relevance for poor communities. All regional chapters also assess this literature.

A concept emerging in the past years to avoid dichotomies between adaptation and mitigation is the term transformation. Within adaptation, we can distinguish between incremental and transformative adaptation, the later referring to changes in the fundamental attributes of a system in response to actual or expected climate and its

effects (Park et al., 2012). The IPCC Special Report on *Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation* (IPCC, 2012) put forward a conception of transformation as a change in the fundamental attributes of a system, including technological, financial, regulatory, legislative and administrative (see 1.1.3; 20.5.4).

Emergent literature points to transformation of values, norms, belief systems, culture, and conceptions of progress and wellbeing in facilitating or preventing transformation (Kates et al., 2012; O'Brien, 2011; Pelling, 2011). Societal innovation and conditions for transformation of this nature requires a particular understanding of risk assessment, adaptive management, learning, innovation, and leadership and may lead to resilient development pathways (see also section 1.2.3 and Chapter 20). We see a focus on global transformation in the recent strategic reframing of global environmental change research (Rockström et al., 2009). But there are large gaps especially drawing from mainstream social and human sciences (Hackmann and St. Clair, 2012).

Climate science is advancing rapidly, with a wide range of new knowledge concerning diverse aspects of impacts, adaptation, and vulnerability, along with the knowledge assessed in other working groups of the IPCC. This provides an "opportunity space" for policy relevant information to support policy decisions leading to high resilience, low risk and low vulnerability and climate change is just one of many stressors that influence resilience. A conceptual approach that summarizes central issues presented in this Report emerges from describing existing planetary boundaries created by the interactions of biophysical and societal stressors within the context of a changing climate has been developed by Rockström et al. (2009) and Raworth (2012). This approach focuses on multi-sector risks today and in the future, with the concept of sustainability as a dynamic process that guarantees the resilience and persistence of natural and human systems. In this conceptual framework of existing stressors and the boundaries they create, actions to reduce climate change impacts can be envisioned as a double edged sword: entailing both an era of responsibility and an era of climate options. On the one hand there is an option for responsible action to protect those vulnerable to unavoidable impacts. This era of responsibility requires increasing the resilience space by reducing both societal and biophysical stressors and, thus, an increased emphasis on adaptation. On the other hand, there is an opportunity space, the era of climate options, which through mitigation can reduce the rate of planetary warming and its impacts. The decisions and pathways that societies choose in the opportunity space, informed by science, observation and experience, will affect the degree of resilience in human and natural systems of the future (Figure 1-7).

[INSERT FIGURE 1-7 HERE
Figure 1-7: Conceptual framework for assessing interactions between biophysical and societal stressors that impact the resilience of natural and human systems today and in the future. Actions, including climate change adaptation and mitigation, taken in the opportunity space lead to a diverse range of pathways and outcomes – toward a future of high risk, high vulnerability and low resilience space or toward a future of low risk, low vulnerability and high resilience space.]

1.2. Major Conclusions of the WGII Fourth Assessment Report

1.2.1. Observed Impacts

Evidence presented in Chapter 1 of the WGII Fourth Assessment Report (AR4) (Rosenzweig *et al*., 2007, page 81) indicated that "Physical and biological systems on all continents and in most oceans are already being affected by recent climate changes, particularly regional temperature increases (*very high confidence*)". In terrestrial ecosystems, warming trends were consistent with observed change in the timing of spring events and poleward and upward shifts in plant and animal ranges. Other examples of observed change presented in Chapter 1 of AR4 included changes in the phenology of 542 plant species in Europe and 145 species of wild animals and plants in the Northern Hemisphere. The authors of Chapter 1 also concluded that the geographical locations of observed changes during the period 1970-2004 are consistent with spatial patterns of atmospheric warming. The types of hydrologic changes reported ranged from effects on snow, ice and frozen ground; the number and size of glacial lakes; increased runoff and earlier spring peak discharge in many glacier- and snow-fed rivers; effects on thermal structure and water quality of rivers and lakes; and changes associated with more intense drought and heavy rains in some

regions. The authors of AR4 concluded from a synthesis of studies "**that the spatial agreement between regions of significant warming and the locations of significant observed changes is *very unlikely* to be due solely to natural variability of temperatures or natural variability of the systems**" (IPCC, 2007d, page 9).

Observed regional impacts to human systems were less obviously attributed to anthropogenic climate change. The authors of AR4 concluded that "**There is *medium confidence* that other effects of regional climate change on natural and human environments are emerging, although many are difficult to discern due to adaptation and non-climatic drivers"** (IPCC, 2007c, page 3)**.** They presented evidence on the effects of temperature increases on agricultural and forestry management at Northern Hemisphere higher latitudes (e.g. earlier spring planting of crops, alterations in disturbance regimes of forests due to fires and pests); on some aspects of human health (e.g. heat-related mortality in Europe, changes in infectious disease vectors in some areas, and allergenic pollen in Northern Hemisphere high and mid-latitudes); and some human activities in the Arctic (e.g. hunting and travel over snow and ice) and in lower-elevation alpine areas (such as mountain sports)".

The authors of AR4 concluded that "**Recent climate changes and climate variations are beginning to have effects on many other natural and human systems, but the impacts have not yet become established trends**" (IPCC, 2007d, page 9). In mountain regions melting glaciers enhanced risk of glacier lake outburst floods on settlements; in the Sahelian region of Africa warmer and drier conditions had detrimental effects on some crops; and in coastal areas sea-level rise and human development contributed to losses of coastal wetlands and mangroves and to increases in damage from coastal flooding (Chapter 1 of WGII-AR4).

1.2.2. Advances in the Assessment Process

The authors of the Working Group II contribution to AR4 noted that the demand for assessments had grown significantly since the release of the IPCC Third Assessment Report (TAR), thereby motivating researchers to expand the ranges of approaches and methods in use and to develop characterizations of future conditions (scenarios and related products) required by those methods. In particular, they indicated that major advancements in CCCIAV assessment were related to the need for improved decision analysis, the inputs from stakeholders, the role of non-climate factors, the increase in spatial and temporal resolution of scenario information, the characterization of the future including mitigation scenarios, large-scale singularities and probabilistic futures (Chapter 2 WGII-AR4, page 135).

1.2.3. Key Vulnerabilities and Reasons for Concern

In an effort to provide some insights into the seriousness of the impacts of climate change, the authors of the IPCC Third Assessment Report (IPCC, 2001b) identified five ''Reasons for Concern'' (RfC's). Considering new evidence of observed changes on every continent, coupled with a more thorough understanding of the concept of vulnerability, the authors of AR4 concluded that: "The five 'reasons for concern' identified in the TAR remained a viable framework to consider key vulnerabilities. These 'reasons' are assessed here to be stronger than in the TAR. Many risks are identified with higher confidence. Some risks are projected to be larger or to occur at lower increases in temperature. Understanding about the relationship between impacts (the basis for 'reasons for concern' in the TAR) and vulnerability (that includes the ability to adapt to impacts) has improved. This is due to more precise identification of the circumstances that make systems, sectors and regions especially vulnerable and growing evidence of the risks of very large impacts on multiple-century time scales" (IPCC 2007c, page 19).

Plenary-approved language in the SPM of Synthesis Report of the AR4 (page 19) summarized the RfCs as follows:

- *Risk to Unique and Threatened Systems*: There is new and stronger evidence of observed impacts of climate change on unique and vulnerable systems (such as polar and high mountain communities and ecosystems), with increasing levels of adverse impacts as temperatures increase.
- *Risks of Extreme Weather Events*: Responses to some recent extreme events reveal higher levels of vulnerability than the TAR. There is now higher confidence in the projected increases in droughts, heat waves and floods, as well as their adverse impacts.

- *Distribution of Impacts*: There are sharp differences across regions and those in the weakest economic position are often the most vulnerable to climate change. There is increasing evidence of greater vulnerability of specific groups such as the poor and elderly not only in developing but also in developed countries. Moreover, there is increased evidence that low-latitude and less developed areas generally face greater risk, for example, in dry areas and megadeltas.
- *Aggregate Impacts*: Compared to the TAR, initial net market-based benefits from climate change are projected to peak at a lower magnitude of warming, while damages would be higher for larger magnitudes of warming. The net costs of impacts of increased warming are projected to increase over time.
- *Risks of Large Scale Discontinuities*: There is high confidence that global warming over many centuries would lead to a sea level rise contribution from thermal expansion alone that is projected to be much larger than observed over the 20th century, with loss of coastal area and associated impacts. There is better understanding than in the TAR that the risk of additional contributions to sea level rise from both the Greenland and possibly Antarctic ice sheets may be larger than projected by ice sheet models and could occur on century time scales.

Perhaps more importantly for the AR5, careful reading of the AR4 reveals that authors also added some increased texture to each RfC by moving from impacts to vulnerabilities and their expanding scope – health metrics were added to the "Aggregate Impacts" RfC, for example; and widespread extinctions of species were added to the "Risks of Large Scale Discontinuities" (which had been called "Singularities" in the TAR). This is evidence that the RfC's evolve over time as knowledge and nuance expands with new knowledge.

Chapter 18 of this report uses RfC's to organize much of its synthesis of detection and attribution confidence conclusions across the volume; the point there is to expand our understanding of how observed and attributed impacts and vulnerabilities support the significance of each of the five reasons. Chapter 19 of this report will return to the RfC's as a unifying construction, expanding the scope to reflect risks and vulnerabilities – a continuation of the evolutionary process of their applicability.

The authors throughout the AR4 concluded that the evidence of vulnerability to observed climate change is most prevalent in places where warming has been the greatest and in systems that are more sensitive to temperature. Marine, freshwater and terrestrial biological systems are particular sensitive to observed temperature warming (e.g. changes in morphology, physiology, phenology, reproduction, species distribution, community structure, ecosystem processes and species evolutionary processes, etc.). Agricultural ecosystems have shown changes in phenology, management practices and yields. Human diseases linked with temperature sensitive vectors have shown spreader distribution. Natural systems are generally considered more affected than managed systems. Physical and biological systems appear to be more vulnerability to extreme events or exceptional episodes than to mean climate change (e.g. agricultural response and mortality occurring in the 2003 heat waves in Europe). Some regions, such as heavily populated deltas and low-lying islands, were identified as hotspots of societal vulnerability.

1.2.4. Risk Assessment as a Response to Climate Change

A fundamental point of departure to be drawn from the AR4 for the entire AR5 is that: "**Responding to climate change involves an iterative risk management process that includes both adaptation and mitigation and takes into account climate change damages, co-benefits, sustainability, equity and attitudes to risk"** (IPCC, 2007c). This plenary approved language from the AR4 Synthesis Report SPM elevates the concept of risk in the assessment process. As indicated in the elaboration of this conclusion recorded in Topic 5 of IPCC AR4: "Risk management techniques can explicitly accommodate sectoral, regional and temporal diversity, but their application requires information about not only impacts resulting from the most likely climate scenarios, but also impacts arising from lower-probability but higher-consequence events and the consequences of proposed policies and measures. Risk is generally understood to be the product of the likelihood of an event and its consequences. Climate change impacts depend on the characteristics of natural and human systems, their development pathways and their specific locations (IPCC 2007c, page 64)".

IPCC (2007a) offered several summary glimpses at the risks from climate change and changes in climate variability that could be expected as global mean temperatures rise in Chapter 20 and its own SPM. These risks were calibrated by the various author teams in the most appropriate metric (i.e., not converted universally to economic indicators) and various levels of warming that could be experienced over the coming century. While they were also cast against ranges of warming at the end of the century for various manifestations of the SRES storylines, most of the indicated risks were drawn from the A2 alternative scenario for which specific trajectories of driving variables (like population), associated rates of change (in climate and socio-economic development), and corresponding levels of adaptive capacity were implied. They offered an alternative portrait for regional impacts so that the distributional implications of climate change might be inferred.

Transferring these insights into other scenarios from the SRES suite and/or the new RCP scenarios must be done with care, and is a task that has been picked up by the authors of the AR5. As the AR5 takes a risk-based perspective in response to governments' recognition that decision makers must adopt an "iterative risk-management approach", authors will have to add conclusions to which lower confidence has been assigned if they relate to "key vulnerabilities" with large consequences. The criteria identified in Chapter 19 of IPCC AR4 (2007b) can be applied in sorting through the literature of sectoral and regional impacts.

1.2.5. Interaction of Adaptation and Mitigation in a Policy Portfolio

The climate community in general and decision-makers in particular have begun to understand that coping with risks of climate change will involve a portfolio of initiatives that will evolve iteratively over time as new information about the workings of the climate system and new insights into how various responses are actually working and penetrating the global socio-economic structure. The suite of assessments offered under the rubric of "America's Climate Choices" by the U.S. National Academy of Sciences as well as the report of the New York (City) Panel on Climate Change provide ample evidence to these points. The authors of the IPCC AR4 made these points and thereby offered guidance to the AR5 process when it reported that: "**There is high confidence that neither adaptation nor mitigation alone can avoid all climate change impacts; however, they can complement each other and together can significantly reduce the risks of climate change.** Adaptation is necessary in the short and longer term to address impacts resulting from the warming that would occur even for the lowest stabilization scenarios assessed. There are barriers, limits and costs, but these are not fully understood. Unmitigated climate change would, in the long term, be *likely* to exceed the capacity of natural, managed and human systems to adapt. The time at which such limits could be reached will vary between sectors and regions. Early mitigation actions would avoid further locking in carbon intensive infrastructure and reduce climate change and associated adaptation needs" (IPCC 2007c, page 19).

IPCC (2007c, page 19) also conveyed a sense of urgency by concluding that "**Many impacts can be reduced, delayed or avoided by mitigation. Mitigation efforts and investments over the next two to three decades will have a large impact on opportunities to achieve lower stabilization levels. Delayed emission reductions significantly constrain the opportunities to achieve lower stabilization levels and increase the risk of more severe climate change impacts**."

WGII AR5 devotes considerable attention to this interface and the mechanisms for iterating as new information emerges in a collection of chapters designed explicitly for this purpose. Meanwhile, author teams for the sectoral and regional chapters will work to bring insights on adaptation to bear on the risk summaries that they will produce. In these efforts, we begin with the recognition from the Synthesis Report of IPCC Working Groups II, II and III (2007c, page 14) that: "**A wide array of adaptation options is available, but more extensive adaptation than is currently occurring is required to reduce vulnerability to climate change. There are barriers, limits and costs, which are not fully understood.** Societies have a long record of managing the impacts of weather- and climate-related events. Nevertheless, additional adaptation measures will be required to reduce the adverse impacts of projected climate change and variability, regardless of the scale of mitigation undertaken over the next two to three decades. Moreover, vulnerability to climate change can be exacerbated by other stresses. These arise from, for example, current climate hazards, poverty and unequal access to resources, food insecurity, trends in economic globalization, conflict and incidence of diseases such as HIV/AIDS. Some planned adaptation to climate change is

already occurring on a limited basis. Adaptation can reduce vulnerability, especially when it is embedded within broader sectoral initiatives. There is *high confidence* that there are viable adaptation options that can be implemented in some sectors at low cost, and/or with high benefit-cost ratios. However, comprehensive estimates of global costs and benefits of adaptation are limited."

In addition, the AR4 authors concluded in IPCC (2007c, page 14) that **"Adaptive capacity is intimately connected to social and economic development but is unevenly distributed across and within societies.** A range of barriers limits both the implementation and effectiveness of adaptation measures. The capacity to adapt is dynamic and is influenced by a society's productive base, including natural and man-made capital assets, social networks and entitlements, human capital and institutions, governance, national income, health and technology. Even societies with high adaptive capacity remain vulnerable to climate change, variability and extremes." The challenge in extending this list and expanding understanding about adaptation and sustainable development at the time of the AR4 was attributed to the diversity of context, the paucity of actual adaptation to climate change that had been analyzed in the peer review literature, and the broader context within which multiple sources of stress are recognized.

1.2.6. Gaps in the Assessment of Impacts, Adaptation, and Vulnerability Identified in AR4

While the scope and complexity of climate change impact assessments have expanded with each IPCC synthesis report since 1990, several information gaps and shortcomings were identified in the Working Group II contribution to IPCC Fourth Assessment Report (AR4) (IPCC 2007a). Examples of some of the gaps cited in the Summary for Policymakers (SPM), the Technical Summary (TS) and individual chapters of AR4 are indentified below in categories that reflect apparent levels of progress that can be gauged by the contents of AR5.

Gaps and limitations for which significant progress is evident in the literature since AR4

- A lack in geographic balance in data and literature on observed changes [SPM, page 8]
- Difficulty discerning effect of regional climate changes due to adaptation and non-climatic drivers [SPM, page 9] and proximity to thresholds and tipping points [TS 6.1]
- Impacts under different assumptions about how the world will evolve in future – societies, governance, technology and economic development [TS 6.1]
- Lack of understanding regional sea level rise trends since 1950 and lack of information concerning the persistence of regional trends through the 21st century; lack of sea level rise scenarios for beyond 2100 [Ch. 6 and TS 6.2]
- Most AR4 studies of future climate change were based on a small number of studies using SRES scenarios, especially the A2 and B2 families. This allowed some limited, but incomplete, characterisation of the potential range of futures and their impacts [TS 6.2 and Ch. 2.3]
- Inadequacies of climate models to simulate changes in patterns of extreme events, particularly with respect to precipitation changes, at a scale that is useful for assessing future climate-related impacts on water resources [TS 6.2, Ch 5.8.2].
- Understanding of the likely future impacts of climate change was hampered by lack of knowledge regarding the nature of future changes, particularly at the regional scale and particularly with respect to precipitation changes and their hydrological consequences on water resources, and changes in extreme events, due in part to the inadequacies of existing climate models at the required spatial scales [TS 6.2 and Ch. 2.5, 3.3.1, 3.4.1, 4.3].
- Only a small amount of literature on the costs of climate change impacts could be found for the WGII Fourth Assessment Report [TS and Ch. 5.6, 6.5.3, 7.5]. Debate still surrounded the topic of how to measure impacts, and which metrics should be used to ensure comparability [TS and Ch. 2.2.3, 19.3.2.3, 20.9].
- Impact of climate change on utilization of biofuels and how the use of biofuels affects competition for land [Ch. 5.8.2]; high uncertainty about vulnerabilities and adaptation potentials in human systems [Ch. 7.8]; and the availability of few national health impact assessments [Ch. 8.8]
- Literature on adaptation costs and benefits was limited and fragmented [TS and Ch. 17.2.3]. It focused on sea-level rise and agriculture, with more limited assessments for energy demand, water resources and transport. There was an emphasis on the USA and other OECD countries, with a few assessments having

been conducted in developing countries [Ch. 17.2.3]. There was growing evidence, however, that adaptation measures are being implemented on a limited basis in developing and developed countries [TS 5.1].

- AR4 recognized that synergies exist between adaptive capacity and sustainable development, but further research was required to determine factors that contribute to this synergy [TS 6.2 and Ch. 20.9].

Gaps and limitations for which more modest or little progress is evident in the literature since AR4

- Inadequate understanding of the impacts of abrupt change events, such as collapse of the North Atlantic Meridional Overturning Circulation. However, without a better understanding of the likelihood that such events will be manifested at the regional scale, it will not be possible to carry out impact assessments of such events [TS and Ch. 6.8, 7.6, 8.8, 10.8.3].
- Wide range in future sea level rise estimates and high uncertainty about timing of sea level rise (lack of time slices for sea level rise due to uncertainties concerning ice sheet dynamics, only given end of century estimates)[Ch.10]
- Poor understanding of trends and future changes in wave regime – important particularly to small island nations [Ch. 6 and Ch. 16]
- Lack of high-quality observations that are essential for full understanding of causes and for unequivocal attribution of present-day trends to climate change [TS 4.8 and 6.2].

Understanding of abrupt climate change and the impacts of such events as the Progress towards resolving some of the shortcomings in data and reporting cited above were addressed in the IPCC Special Report on *Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation* (IPCC, 2012) that was produced jointly by Working Groups I and II (see Section 1.3.1 in this chapter). The WGI contribution to AR5 has advanced our understanding of the drivers of ice sheet decline and contains new estimates of sea level rise that are updated with mass balance trends and models of ice sheet at time scales that are relevant to decision making. Though not reflected due to scale limitations in IPCC AR5 assessment, progress with high resolution downscaling of climate information has helped address the needs of natural resource managers operating at a sub-regional scale in many parts of the world.

1.3. Major Conclusions of More Recent IPCC Reports

Since the publication of the Fourth Assessment Report (AR4) in 2007 the IPCC has produced two Special Reports: the Special Report on Renewable Energy Sources and Climate Change Mitigation (SRREN), produced by Working Group III and published in 2011, and a Special Report on "Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX), published in 2012. In addition, the AR5 has staggered the assessment work for its three working groups. The Report of Working Group I was published in 2013 and the Report of Working Group III will be published later in 2014. In this section we summarize the major conclusions of the SREX, the SSREN and the Working Group I and III contributions to the AR5. We focus on the key findings and the fundamental framings and conceptual innovations these Assessment Reports bring to the development of the chapters that form the Working Group II contribution to AR5.

One aspect that cuts across the Working Groups is the detection of climate change or its impacts observed to date (2011 for WGI), the attribution of that climate change to the observed increases in greenhouse gases (a measure of the human forcing of climate change), the attribution of local climate impacts to the observed warming of that region, and the projection of these impacts and climate change into the 21st century. Table 1-1 gives a summary of phenomena for which such detection, attribution, or projection has been made across the Working Groups. A schematic presentation of this detection-attribution-projection sequence from preceding reports is given in Figure 1-8. For AR5 WGII attribution, see Chapter 18, and for projections, see the other chapters.

[INSERT TABLE 1-1 HERE
Table 1-1: Observed, attributed, and projected changes in the climate system, including impacts, adaptation, mitigation and vulnerability to climate change.]

[INSERT FIGURE 1-8 HERE
Figure 1-8: Climate change and its impacts detected to date (horizontal axis) is plotted against (left panel) attribution of those changes to greenhouse gases and (right panel) projection of those changes into the 21st century for a global warming exceeding 2°C. Only phenomena with a detection, attribution or projection at high confidence levels or with quantifiable uncertainty are shown. All phenomena are defined in Table 1-1 where the color coded symbols and likelihood are defined. Results are taken from the AR4, SREX, and AR5 WGI, but primarily from WGI because the attribution is to the observed increase in greenhouse gases that has driven anthropogenic climate change, rather than as in WGII to the regional/local observed warming. For AR5 WGII results, see inter alia Chapters 18 and 19.]

1.3.1. IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)

The SREX (IPCC, 2012) is the first IPCC Special Report produced jointly by Working Groups I and II and is the first IPCC report to focus on risk management. The report integrates perspectives from historically distinct research communities studying climate science, climate impacts, climate adaptation and disaster risk management. The SREX assesses relationships between climate change and the characteristics of extreme weather and climate events. The report and its Summary for Policymakers provide information on existing societal exposure and vulnerability to climate-related extreme events and disasters; observed trends in weather- and climate-related disasters and disaster risk management; projected changes in weather and climate extremes and projected disaster losses during the 21st century; approaches for managing the increasing risks of climate extremes and disasters; and implications for sustainable development. One chapter of the SREX is devoted to fourteen case studies that illustrate the impacts of extreme climate events and options for risk management and adaptation, such as early-warning systems, new forms of insurance coverage, and expansion of social safety nets.

1.3.1.1. Themes and Findings of SREX

The most relevant results of the assessment carried out by the SREX author team can be synthesized along the three major themes: changing weather and climate-related extreme events, trends in disaster losses, and managing the risks of extreme events and disasters. Some of the findings presented in the SREX concerning the type, magnitude and frequency of extreme weather and climate events are presented in Table1-1. Examples of findings from the SREX report concerning trends in disaster-related losses and challenges in managing risks are presented below:

- Economic losses from weather- and climate-related disasters have increased, but with large spatial and interannual variability (*high confidence*, based on *high agreement, medium evidence*). [SPM, 4.5.1, 4.5.3, 4.5.4]. Trends in losses have been heavily influenced by increasing exposure of people and economic assets *(high confidence)*. [SPM, 4.5.3]
- Economic, including insured, disaster losses associated with weather, climate, and geophysical events are higher in developed countries. Fatality rates and economic losses expressed as a proportion of gross domestic product (GDP) are higher in developing countries (*high confidence*). [SPM, 4.5.2, 4.5.4]
- Deaths from natural disasters occur much more in developing countries (*high confidence)*. From 1970 to 2008 for example, more than 95% of deaths from natural disasters were in developing countries. [SPM, 4.5.2, 4.5.4]
- Development practice, policy and outcomes contribute to shaping disaster risks (*high confidence):* skewed development that may lead to environmental degradation, unplanned urbanization, failure of governance or reduction of livelihood options result in increased exposure and vulnerability to disasters. [SREX 1.1.2, 1.1.3 and 2.2.2, 2.5]
- Managing risks is an iterative process involving monitoring, research, evaluation, learning and innovation can reduce disaster risk in the context of climate extremes (*robust evidence, high agreement)* [SPM, 8.63, 8.7]
- Risk management works best when tailored to local circumstances. Combining local knowledge with additional scientific and technical expertise helps communities reduce their risk and adapt to climate change (*robust evidence, high agreement*). [SPM, 5.4.4].

- Actions ranging from incremental improvements in governance and technology to more transformational changes are essential for reducing risk from climate extremes (*robust evidence, high agreement)*. [SPM, 8.6, 8.6.3, 8.7]
- Effective risk management generally involves a portfolio of actions to reduce and transfer risks and to respond to events and disasters, rather than a singular focus on any one type of action (high confidence)., Successful strategies include both hardware measures and soft solutions such as from improving infrastructure to building individual and institutional capacity building., in order to reduce risk and respond to disasters (*high confidence*). [SPM, 1.1.2, 1.1.4, 1.3.3]
- Post-disaster recovery and reconstruction provide an opportunity for reducing the risks posed by future weather- and climate-related disasters (*robust evidence, high agreement*). [SPM, 5.2.3, 8.4.1, 8.5.2] However, short-term measures to protect people from immediate risks can increase future risks, such as improvements in levees encouraging further development in flood plains (*medium evidence, high agreement*).
- Socio economic, demographic, health related differences, access to livelihoods, good governance and entitlements are some of the factors that lead to inequalities between people and countries. Inequalities influence local coping and adaptive capacity and pose challenges for risk management systems from local to national levels (*high agreement, robust evidence*) [SREX 5.5.1, 6.2, 6.3.2, 6.6].
- Many measures for managing current and future risks have additional benefits, such as improving peoples' livelihoods, conserving biodiversity, and improving human well-being (*medium evidence, high agreement*). [SPM, 6.3.1, Table 6-1].
- Many measures, when implemented effectively, make sense under a range of future climates (*medium evidence, high agreement*). These "low regrets" measures include systems that warn people of impending disasters; changes in land use planning; sustainable land management; ecosystem management; improvements in health surveillance, water supplies, and drainage systems; development and enforcement of building codes; and better education and awareness. [SPM, 5.3,1, 5.3.43, 6.3.1, 6.5.1, 6.5.2, 7.4.3 and Case Studies 9.2.11, 9.2.14]
- Post-disaster recovery and reconstruction provide an opportunity for reducing the risks posed by future weather- and climate-related disasters (*robust evidence, high agreement*). [SPM, 5.2.3, 8.4.1, 8.5.2] However, short-term measures to protect people from immediate risks can increase future risks, such as improvements in levees encouraging further development in flood plains (*medium evidence, high agreement*).

1.3.1.2. Advances in Conceptualizing Climate Change Vulnerability, Adaptation, and Risk Management in the Context of Human Development

The conceptual framing of the SREX reflects the diversity of expert communities involved in this assessment. It links exposure and vulnerability with socio-economic development pathways as determinants of the impacts and the likelihood of disaster risk for both human society and natural ecosystems. It is important to note that the SREX acknowledges the fundamental role that values and aspirations play in people's perception of risk, change and causality, and on imagining present and future situations. This value-based approach is put to work as a tool for managing the risks of extreme events and disasters enabling the recognition that socio-economic systems are in constant flux, and that there are many conflicting and contradictory values at play. The conceptual framing of the problem space offered by the SREX (illustrated in figure 1-1 of the SREX SPM) serves as a point of departure for many chapters in this AR5. Equally important for the AR5 is the conceptualization of a feasible solution space offered in the SREX. As stated in the summary of key findings, there is robust evidence and high agreement that addressing the risks calls for "actions ranging from incremental improvements in governance and technology to more transformational changes are essential for reducing risk from climate extremes" (SREX Fact Sheet, IPCC, 2011b).

1.3.2. Special Report on Renewable Energy Sources and Climate Change Mitigation (SRREN)

The SRREN (IPCC, 2011a) assesses existing literature on the relationship between renewable energy sources and the mitigation of climate change. It examines six renewable energy sources: bioenergy, direct solar energy, geothermal energy, hydropower, ocean and wind energy in terms of available technologies, technical potential and associated costs. It examines the challenges of integrating renewable energy sources into existing electrical power systems, heating and cooling networks, gas grids and liquid fuel systems and provides an in-depth assessment of the relationship of renewable energies to goals of sustainable development. In a review of 164 scenarios, the role of renewable energy sources in climate change mitigation is compared within a portfolio of mitigation options that include end-use energy efficiency, nuclear energy and fossil-fuel based energy with carbon capture and storage (CCS). Finally, for policy-makers interested in scaling up renewable energy for climate change mitigation goals, supporting policies for the development and deployment of these technologies are assessed.

Though renewable energy accounted for only 12.9% of the total primary energy supply in 2008, the SRREN shows that the deployment of renewable energy technologies has been increasing rapidly in recent years, often associated with cost reductions that are expected to continue with further technical advances. Biomass accounted for the majority of this total (10.2% out of 12.9%), much of which is traditional biomass in developing countries. Despite the small contribution of renewable energy to current energy supplies, in its assessment the SRREN shows the global technical potential of renewable energy to be substantially higher than the global energy demand. It is therefore not the technical potential of renewable energy that constrains its development, but rather economic factors, system integration and infrastructure constraints, public acceptance and sustainability concerns. The assessment of lifecycle assessment studies in the SRREN showed that GHG emissions associated with the generation of electricity from renewable energy technologies are, in general, significantly lower than those associated with fossil fuels, and under a range of conditions, also less than fossil fuels employing CCS. The percent increase of renewable energy in future primary energy supplies varies widely across scenarios, though a majority indicate a significant increase – from 64 EJ/yr total RE production in 2008 to more than 173 EJ/yr in 2050. Even under baseline scenarios the deployment of renewable energies is expected to increase, many showing to levels more than 100 EJ/yr. The growth of renewable energy is typically expected to be widespread across the world, though in the long-term (2050) most development is expected in non-Annex I countries (IPCC, 2011a).

Several SRREN findings have clear linkages with this assessment of climate change impacts, adaptation and vulnerability, as captured in Table 1-2.

[INSERT TABLE 1-2 HERE
Table 1-2: Links between SRREN and the Working Group II contribution to the Fifth Assessment Report.]

1.3.3. Relevant Findings from IPCC Working Group I Fifth Assessment Report First-Order Draft

[PROVISIONAL - This WGII SOD version is shortened, but not yet updated to reflect the WGI SOD/FGD.]

Key findings from the WGI FOD Executive Summaries relevant to WGII are summarized here. All summary statements below have *high confidence* attached to them in the WGI AR5 and are likely or higher if quantified uncertainty is given.

Climate Models. For AR5, a range of "climate" models are considered, including: coupled Atmosphere-Ocean General Circulation Models (AOGCMs) used in both climate reconstructions and future projections; their extension to 'Earth System' Models (ESMs) that include biogeochemical cycles; higher resolution, limited-area Regional Climate Models (RCMs) used to downscale global climate results; Earth System Models of Intermediate Complexity (EMICs) used primarily for exploring parameter uncertainty [WGI-9]. Datasets of multi-model ensembles for both past and future climate are available from Coupled Model Intercomparison Projects (CMIP3 and CMIP5[1]) and the Coordinated Regional Downscaling Experiment (CORDEX) [WGI-9]. The ability of climate models to simulate historical climate, its change, and its variability, has improved in many important respects since the AR4 [WGI-9]. RCMs are able to add value to coarser-resolution global model results, providing realistic spatial detail and improved representation of climate extremes [WGI-9]. Errors and biases in models tend to be related to

smaller-scale features [WGI-9]. Lack of agreement across models on local trends is often a result of natural variability, rather than models actually disagreeing on their forced response [WGI-12].

Climate change comparison with AR4. The new CMIP5 results are similar to the AR4 CMIP3 results for the near term [WGI-11] but differ in the long term (see 1.1.3.1 and WGI-12). Multi-model average patterns of change in temperature and precipitation from CMIP3 and CMIP5 ensembles, once normalized per 1ºC of global temperature change, present a high degree of pattern correlation, with values larger than 0.9 for temperature change patterns and larger than 0.8 for precipitation patterns [WGI-12]. The characteristic stability of robust geographical patterns of temperature change (less so for precipitation) during a transient experiment remains valid in the new generation of models participating in CMIP5 [WGI-12]. Agreement and thus confidence in projections is higher for temperature related quantities than for those related to the water cycle or circulation [WGI-12]. In cumulative terms, the 2°C temperature target implies cumulative carbon emissions of about 1000–1300 GtC, of which about 520 GtC were already emitted by 2011 [WGI-12].

Temperatures. The global combined land and ocean temperature data show a temperature increase of about 0.8°C for the period 1901–2010 and about 0.5 °C for 1979–2010 when estimated by a linear trend [WGI-2]. Over every continent except Antarctica, anthropogenic influence (GHG increases) has made a substantial contribution to surface temperature increases [WGI-10]. Across all RCP scenarios, the multi-model global mean warming over the period 2016–2035 relative to the reference period 1986–2005 lies in a narrow range about 0.7°C [WGI-11]. Globally and regionally, the surface temperature response is fairly independent of scenario until after 2040 [WGI-11]. For RCP4.5, 6.0 and 8.5, global temperatures exceed 2ºC warming (over pre-industrial) by 2100 [WGI-12]. Based on model results and other studies, RCP2.6 pathway may or may not achieve the policy-relevant objective of no more than 2°C global warming relative to pre-industrial [WGI-12].

Precipitation. Precipitation in the tropics has increased over the last decade reversing the drying trend that occurred from the mid-1970s to mid-1990s reported in the AR4 [WGI-2]. New evidence has emerged for the detection of anthropogenic influence on aspects of the water cycle: on zonal patterns of global precipitation changes, including reductions in low latitudes and increases in northern hemisphere mid to high latitudes [WGI-10]. There is limited, if any, evidence and no agreement that the small-scale impact of aerosols on cloud microphysical structure translates into a significant regional impact in terms of precipitation amount (beyond orographic locations) [WGI-7]. Precipitation in the near-term is projected to increase in regions of tropical precipitation maxima and at high latitudes, with general decreases in drier regions of the tropics and sub-tropics, but projections vary considerably from model to model [WGI-11]. For the near term, CMIP5 projections confirm a clear tendency for increases in heavy precipitation events in the global mean as in AR4, but there are significant variations across regions [WGI-11]. Global-scale precipitation is projected to gradually increase in the 21st century, approximately 2% K^{-1} [WGI-12]. Average precipitation in a much warmer world will not be uniform, with regions experiencing increases, or decreases or no much change at all, but many mid-latitude arid and semi-arid regions will likely experience less precipitation [WGI-12]. Largest precipitation changes over northern Eurasia and North America are projected to occur during the winter [WGI-12].

Hydrology, Flooding and Droughts. Extended intervals of drought associated with weak Indian Summer Monsoon in the last 2000 years may have been synchronous across a large region of southeastern Asia [WGI-5]. The most recent and most comprehensive analyses of river runoff do not support the AR4 conclusion that global runoff has increased during the 20th Century [WGI-2]. Projections of soil moisture and drought remain relatively uncertain [WGI-12]. Decreases in runoff are projected in southern Europe, the Middle East, and southwestern United States, but increases in high latitude runoff, as with AR4 [WGI-12]. A shift to more intense individual storms and fewer weak storms is projected, with possibly more frequent/intense periods of agricultural drought (from intervening dry spells between intense individual storms) [WGI-12].

Sea Level. Under all the RCP scenarios, the time-mean rate of global mean sea level rise during the 21st century is very likely to exceed the rate observed during 1971–2010 [WGI-13]. For the period 2081 to 2100 compared to 1986 to 2005, GMSL rise is projected to lie in the range 0.27–0.50 m for RCP2.6, 0.32–0.56 m for RCP4.5 and RCP6.0, and 0.41–0.71 m for RCP8.5 [WGI-13]. Under RCP 8.5, the likely range reaches 0.84 m in 2100, but larger values than these ranges cannot be excluded [WGI-13]. The contribution from rapid changes in ice-sheet dynamics – 0.12

m from the two ice sheets combined – is the main reason why these ranges are higher than those given in the AR4 [WGI-13]. Regional patterns of projected sea level change, while overall positive, deviate significantly from the global mean [WGI-13]. Extreme wave heights have likely increased over the past 60 years, in keeping with increases in extreme winds [WGI-3]. A rise in mean sea level is largely responsible for an increase in extreme sea level events and stronger storm surges in coastal areas [WGI-3].

Ocean Acidification and Oxygen. The uptake of CO_2 by the ocean has resulted in a gradual acidification of seawater. Long time series from several ocean sites show declines in pH in the mixed layer between -0.0015 and -0.0024 yr^{-1} [WGI-3]. Projections show large 21st century decreases in pH and carbonate ion concentrations (CO_3^{2-}) throughout the world oceans for high-emissions scenarios [WGI-6]. Projections show large 21st century decreases in oceanic dissolved oxygen caused by enhanced stratification and warming, and mainly located in the sub-surface mid-latitude oceans. There is however no consensus on the future evolution of the volume of hypoxic and suboxic waters [WGI-6].

Sea Ice and the Cryosphere. The significant retreat in the extent of Arctic sea ice in all seasons that was documented by AR4 has continued. Since 1979, the end-of-summer extent of Arctic sea ice has decreased by 12% per decade [WGI-4]. In contrast, the total extent of Antarctic sea ice has increased slightly over the same 30-year period, but there are strong regional differences in the changes around the Antarctic [WGI-4]. Overall, CMIP5 models better capture the rapid decline in summer Arctic sea ice observed during the last decades than CMIP3 models, but spread across Arctic sea ice projections remains wide. More than 90% of the CMIP5 models analyzed reach nearly ice-free September conditions in the Arctic by 2100 under RCP8.5 [WGI-12]. In the Southern Hemisphere future changes in sea ice remain highly uncertain [WGI-12]. Reductions in northern hemisphere snow cover extent, permafrost degradation, glacier retreat, and increased surface melt of Greenland are evidence of systematic changes in the cryosphere linked to anthropogenic climate change [WGI-10]. The Arctic region warms most under all scenarios, as in AR4, with a polar amplification factor ranging from 1.8 to 3.3 [WGI-12]. Northern Hemisphere spring snow covered area is projected by 2100 to decrease between 9% (RCP2.6) and 24% (RCP8.5) [WGI-12].

Greenhouse Gases, Pollution, & Radiative Forcing. Land-use, land-use change and land management is emerging as a key driver of the future terrestrial carbon cycle, modulating both emissions and sinks, but this human induced process is not consistently represented in coupled carbon cycle climate models, causing a significant source of uncertainty in future projections of atmospheric CO_2 and climate [WGI-6]. Warming alone will likely increase O_3 in polluted regions, but decrease baseline O_3 levels in surface air [WGI-11]. The sign of the PM response to climate change is uncertain, depending on regional precipitation changes and shifting aerosol components [WGI-11]. The RCPs project much lower emissions of pollutants than do the SRES [WGI-11].

Atmospheric Circulation and Patterns. As the climate warms, the Hadley and Walker circulations are projected to slow down, and the Hadley cell widens giving broader tropical regions and a poleward encroachment of subtropical dry zones [WGI-12]. Changing mean sea level pressure is projected to shift the mid-latitude storm tracks poleward in both hemispheres along with reducing the overall frequency of storms [WGI-12]. Global monsoon precipitation is projected to strengthen in the 21st century with increase in its area affected and its intensity, while the monsoon circulation weakens [WGI-14].

Extreme Weather & Climate. Globally, there is confidence that the length or number of warm spells, including heat waves, has increased since the middle of the 20th century, and this is clearly the case for large parts of Europe [WGI-2]. Consistent with AR4 conclusions, the number of heavy precipitation events (e.g., 95th percentile) has increased significantly in more regions than it has decreased, with strongest evidence in North America [WGI-2]. There continues to be a lack of evidence regarding the sign of trend in the magnitude and/or frequency of floods on a global scale [WGI-2]. New results no longer support the AR4 conclusions regarding global increasing trends in droughts since the 1970s [WGI-2]. There is little confidence in basin-scale projections of trends in tropical cyclone frequency and intensity to the mid-21st century [WGI-11]. The magnitude of both high and low temperature extremes is projected to increase faster than the mean, and in most regions a one-in-20 year maximum temperature event will become a one-in-2 year event by the end of the 21st Century under RCP8.5 [WGI-12]. Twenty-first century projections of extreme water levels and waves are based on future storminess in a warming climate using

both dynamical and statistical approaches, but it is difficult to specify regional changes in atmospheric, storm-driven extremes [WGI-13].

Regional Climate Change. Projected climate change in North America will be characterized by a loss of snowpack at high elevations, mid-continental summertime drying, and increasing precipitation over the northern third of the continent [WGI-14]. Projected climate change in South America will be characterized by precipitation increase over southeastern South America, with an increase in extreme precipitation over La Plata basin region and decrease in central Amazonia and northern coast, and an increase in the number of consecutive dry days in northeastern South America [WGI-14]. A significant rainfall decrease across the entire Mediterranean region is projected [WGI-14]. Termination of the rainy season over Japan (Baiu) will be delayed [WGI-14]. Indian Monson circulation is projected to weaken while the total seasonal precipitation increases and the number of rainy days decreases [WGI-14]. A drying trend is projected to continue over southern Australia through the 21st century, and become evident over the north and east of New Zealand [WGI-14]. Precipitation is *likely* to increase in the west of New Zealand in winter and spring [WGI-14].

1.3.4. Working Group III Contribution to the IPCC Fifth Assessment Report

Working Group III of the IPCC is charged with assessing scientific research related to the mitigation of climate change. "Mitigation" is any human intervention to reduce the sources or enhance the sinks of greenhouse gases. Because mitigation lowers the likely effects of climate change as well as the risks of extreme impacts, it is part of a broader policy strategy that includes adaptation to climate impacts—a topic addressed in more detail in this report of WGII. Responding to climate change is ultimately an exercise of risk management that includes both mitigation and adaptation, taking into account actual and avoided climate change damages, co-benefits, sustainability, and attitudes about risk. The literature assessed in AR5 also emphasizes the ethics of climate policy, as well as equity considerations, in considerably more detail than AR4.

Since the AR4 (2004 data), global anthropogenic greenhouse gas (GHG) emissions have continued to grow and reached an all-time high of 50.1 Gt CO_2eq in 2010. Despite existing mitigation policies, GHG emissions have grown more quickly between 2000 and 2010 than in previous decades. While CO_2 emission growth from increases in population and per capita income continue to outgrow savings from efficiency improvements, a growing carbon intensity of energy inputs contributed to emission increases for the first time since 1970. At 2010 levels, every 12 years an amount of fossil-fuel related CO_2 is emitted comparable to the total cumulative emissions before 1970 [WGIII-1, WGIII-5].

Regionally, the large majority of CO_2 emission growth over the last decade (2000-2010) has taken place in Asia. Roughly 83% of the CO_2 emission growth between 2000 and 2010 can be attributed to Asia from a territorial and 72% from a consumption perspective. Developing countries (non-Annex B) have overtaken developed countries (Annex B) in terms of their territorial as well as consumption based CO_2 emissions. Average per capita CO_2 emissions of developed countries remain roughly four times higher than of developing countries, even though a growing number of developing countries show per capita GHG emissions in the range of developed countries [WGIII-1, WGIII-5, WGIII-14].

Baseline emission trajectories for fossil and industrial sources from the scenarios literature are inconsistent with a 1.5^{0} or 2^{0} C target as discussed in the international climate change negotiations. The majority of baseline scenarios will exceed atmospheric GHG concentrations of 1000 ppm in 2100 with a likely temperature increase larger than 4^{0}C compared to pre-industrial levels [WGIII-6].

Scenarios meeting a stringent concentration goal of 450 ppm CO_2eq by 2100 with a 60% probability of not exceeding a temperature increase of 2^{0}C are becoming increasingly challenging. The vast majority of scenarios include temporary overshoot of this concentration goal [WGIII-6]. If ambitious stabilization targets such as 450 ppm CO_2eq are to be met, delays in international cooperation on climate change mitigation increasingly require net negative emission in the second half of the 21st century and the large-scale application of carbon dioxide removal technologies (CDR). Most CDR technologies are not mature and attended by a large set of risks. Pathways that are

dependent on the large-scale application of CDR technologies are characterized by increasingly risky profiles through a loss in the ability of policymakers to hedge risks freely across the mitigation technology portfolio [WGIII-6]. The cost of mitigation can affect the ability of society to adapt to climate change. Delays in mitigation not only increase the cost of mitigation, but also they reduce the capacity for adaptation. Some mitigation strategies could substantially increase stressors on water and other natural resources that are also being directly affected by changes in the physical climate system.

A broad body of literature has emerged analysing mitigation choices and societal objectives and non-climate policies that may affect mitigation efforts. Initial evidence from comprehensive models shows that if stringent climate policies are in place, synergistic relationships between societal objectives tend to be stronger and the added costs of any supplementary policies to reach other objectives (energy security/air pollution) at stringent levels can be significantly reduced – particularly in the near term [WGIII-6]. Demand side mitigation options tend to be associated with fewer risks and a larger number of co-benefits than mitigation options on the supply side. Energy efficiency options may therefore provide opportunities to manage risks across the mitigation portfolio and achieve other societal objectives beyond their potential to limit GHG emissions [WGIII-7, WGIII-8, WGIII-9, WGIII-10].

Human decision making is directly affected by the type of uncertainties that prevail. While previous reports have emphasised the uncertainties in the natural system, WGIII AR5 highlights social system uncertainties and suggests that these may be at least of similar magnitude [WGIII-2].

Approaches to international cooperation in climate policies have increased and become more diverse ranging from strong multi-lateralism to harmonized national and regional policies to decentralised architectures that may arise out of heterogeneous regional, national, and sub-national policies [WGIII-13]. Linkages among regional, national, and sub-national programs may complement international cooperation. While policy linkage can take several forms, linkage through carbon markets has been the primary means of regional policy linkage due to the greater opportunities for trade as carbon markets expand. Such forms of regional agreements could then, in principle, form building blocks for greater global cooperation by linking these efforts across regions [WGIII-13, WGIII-14].

The WGIII report further suggests that there is no best policy for mitigation. Different policies play different roles, typically to 1) provide a price signal; 2) remove barriers; or 3) promote long-term investments. A combination of policies that addresses all three roles could be most effective. It may be advantageous to design and adjust policies so as to complement rather than substitute for other policies in the same and other jurisdictions. Appropriate designs depend on national and local circumstances and institutional capacity. These categories are complementary when policy packages are designed to take advantage of synergies and avoid negative interactions. If there is no coordination within an integrated perspective then results in one area may be undone by results in another area for instance through leakage and rebound effects [WGIII-15].

Frequently Asked Questions

FAQ 1.1: What is the information basis for the assessment and how has it changed since the last IPCC report?
IPCC assessment reports are based on the most recent scientific, technical and socio-economic literature produced worldwide relevant to the understanding of climate change. IPCC report authors critically assess the literature and develop a synthesis of current understanding based on that literature. While the majority of the literature they assess is contained in peer-reviewed journal articles and books, IPCC authors can also consider non-published or non peer-reviewed literature sources. The volume of literature available for assessing climate change impacts, adaptation and vulnerability has grown dramatically since the last IPCC assessment report (AR4, 2007) was prepared. The total number of publications on the topic of climate change impacts roughly doubled between 2005 and 2010. The proportion of literature focusing on individual countries within IPCC regions has broadened, particularly for Asia.

FAQ 1.2: How has our understanding of the interface between human, natural and climate systems expanded since the 2007 IPCC Assessment?
Fundamental advances in scientific methods that integrate physical climate science with knowledge about impacts in human and natural systems have enabled a more robust assessment across a greater number of sectors with finer-

scale regional details. Many of the challenging regional impacts of climate change emerge from interacting stresses on people, societies, infrastructure, industry, and ecosystems. These complexities can now be quantitatively described for some systems. A more comprehensive, diverse overview of regional vulnerabilities, impacts and adaptation is made possible with the growth in the assessment-relevant scientific literature for all IPCC regions, including *Open Oceans* [Chapter 30], and by improved coordination with WG I and WG III. This report as a whole reflects substantial expansion of relevant knowledge from the social sciences and increased collaboration among experts on the human dimensions of climate change.

FAQ 1.3: How is the state of scientific understanding communicated in this report?

The body of science on climate change and its impacts has increased greatly over time. Future climate change and its impacts, however, cannot be known exactly. Some uncertainties stem from the possible future paths of socioeconomic development, resulting emissions of greenhouse gases, and associated changes in the exposure and vulnerability of society. Others follow from incomplete understanding of changes in the climate system and also of the societal capacities and challenges for potential responses. Because impacts for human and natural systems depend on how changes in climate and development choices interact, evaluating and implementing response strategies is an exercise in risk management. Importantly, decisionmaking requires judgments beyond the realm of science about what society and stakeholders value. Scientific understanding informs decisionmaking that anticipates, prepares for, and responds to climate change, by providing information about the full range of possible consequences and associated probabilities. In some cases, the probability of an impact occurring may be relatively low, but the consequences of the impact are so important that it warrants consideration. To clearly communicate the state of scientific understanding related to climate change and its impacts, the scientists developing this assessment report use specific terms, methods, and guidance for characterizing their degree of certainty in conclusions.

Table 1-2: Links between SRREN and the Working Group II contribution to the Fifth Assessment Report.

SRREN findings	WGII-AR5 findings
The sustainability of bioenergy, in particular in terms of lifecycle GHG emissions, is influenced by land and biomass resource management practices (Ch. 9)	Land cover (including forests and agriculture) may be affected by future climate change, which has inferences implications for the potential of these lands to produce biofuels and sequester carbon from the atmosphere (Ch. 19)
The water availability is a critical factor that limits the development of water cooled thermal power and hydropower (Ch. 9)	Climate change is likely to affect future surface and groundwater supplies and the stresses that the development of water-dependent energy resources can have on freshwater ecosystems (Ch. 4)
A wide range of technologies are already available (e.g. wind turbines) or however possible (e.g. barrages for tidal range, submarine turbines for tidal and ocean currents, heat exchangers for ocean thermal energy conversion, etc.) to produce energy from oceans and wind (Ch. 6 and 7)	Ocean currents and wind action could be affected by climate change. Thus, the capacity of these energy technologies should be revised on the basis of future climate conditions (Ch. 6).
Higher energy prices associated with transitions from fossil fuels to renewable energy sources may have adverse effects on local and regional economic and social development (Ch. 9)	The challenge for climate-resilient pathways is to identify and implement mixes of technological options that reduce net carbon emissions and at the same time support sustained economic and social growth (Ch. 20)
Latin America is second to Africa in terms of technical potential for bioenergy production from rain-fed lignocellulosic feedstocks on unprotected grassland and woodlands (Ch. 9)	In large countries of Latin America the production of bioenergy requires large areas for agriculture determining environmental degradation and strong economic teleconnections (e.g. economic growth of giant consumers as China) (Ch. 27)
Central and South America are second to Asia in terms energy generation in the world, displaying a 20% share of total annual generation. The quality of water resources availability is the largest in the world with an average regional capacity factor of over 50%. As a result, the region has by far the largest proportion of electricity generated through hydropower facilities (Ch. 5)	Hydropower is the main source of renewable energy available in Central and South America, but it is also affected from potential impacts of climate change (Ch. 27)

Figure 1-1: Results of English literature search using the Scopus bibliographic database from Reed Elsevier Publishers. (a) Annual global output of publications on climate change and related topics: impacts, adaptation,

human health, and costs (1970-2010). (b) Country affiliation of authors of climate change publications summed for IPCC regions for three time periods: 1981-1990, 1991-2000, and 2001-2010, with total number during the period 2001-2010. (c) Results of literature searches for climate change publications with individual countries mentioned in publication title, abstract or key words, summed for all countries by geographic region. The following individuals conducted the literature searches: Valentin Przyluski (French), Huang Huanping (Chinese), and Peter Zavialov and Vasily Kokore (Russian), and Saúl Armendáriz Sánchez (Spanish). (d) Number of publications in five languages that include the words "climate change" and "climate change" plus "adaptation", "impacts" and "cost" (translated) in the title, abstract or key words during the three time periods.]

Figure 1-2: Tables of Contents for the Working Group II contributions to the IPCC Assessments since 1990. The First Assessment Report (FAR, 1990) of IPCC Working Group II (WGII) focused on the impacts of climate change, but for the Second Assessment Report (SAR 1996) the WGII contribution included mitigation and adaptation with the impact assessment. With the TAR (2001) and subsequent assessments, mitigation was addressed by IPCC Working Group III. Since the TAR, WG II has focused on impacts, adaptation and vulnerability with an expanded effort on the regional scale.

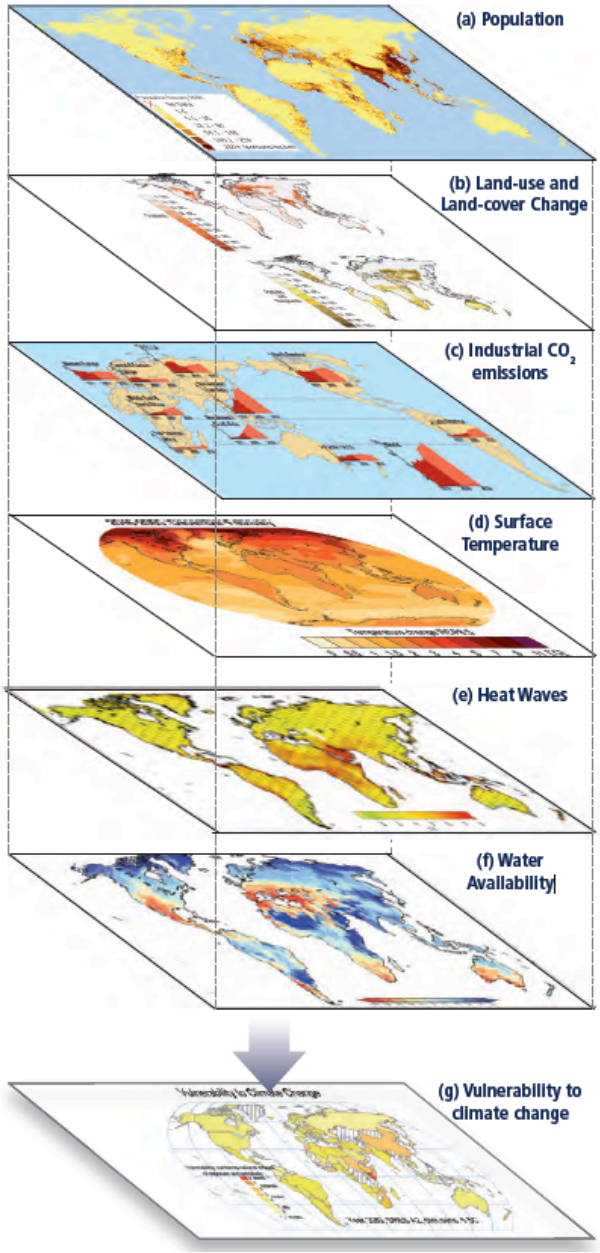

Figure 1-3. Examples of the diversity and global heterogeneity of the many stressors related to climate change impacts, adaptation, and vulnerability: (a) Population, (b) Land-use and land-cover change, (c) Industrial CO_2 emissions, (d) Surface temperature change, (e) Heat waves, (f) Water availability, and (g) Vulnerability to climate change. Sources: (a) Global population density for year 2000 from the LandScan project at Oak Ridge National Laboratory and CIESIN, Columbia U. (http://sedac.ciesin.columbia.edu/data/collection/gpw-v3/maps); (b) Croplands and pasture/rangeland coverage from Foley *et al.* (2005); (c) Industrial sector energy/electricity-related CO_2 emissions ($GtCO_2$) for 1971-2000 (historical) and 2001-2030 (SRES B2) (AR4 WGIII TS.18 and Table 7.1, 7.2). EECCA = Countries of Eastern Europe, the Caucasus and Central Asia; (d) Surface temperature change projected for Dec-Jan-Feb, years 2046-2065 minus 1986-2005 under RCP8.5 from CMIP5 median (AR5 WGI Annex I); (e) Heat extremes based on Warm Spell Duration Index increase from 1980-1999 to 2081-2100 under SRES A2 normalized by standard deviation (SD) (SREX; after Fig.5 of Orlowsky and Seneviratne, 2011); (f) Water availability based on projected change of annual runoff (%) from 1981-2000 to 2081-2100 for SRES A1B (AR4 WGII Fig. 3.8, based on CMIP3); (g) Vulnerability to climate change in year 2050 (SRES A2, climate sensitivity 5.5°C, adapted from AR4 WGII Fig TS.19, 20.6).

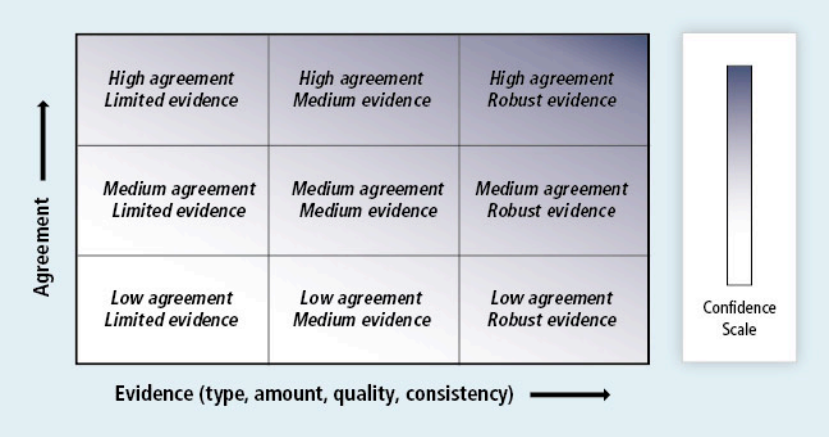

Figure 1-4: Evidence and agreement statements and their relationship to confidence. The shading increasing towards the top-right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence.

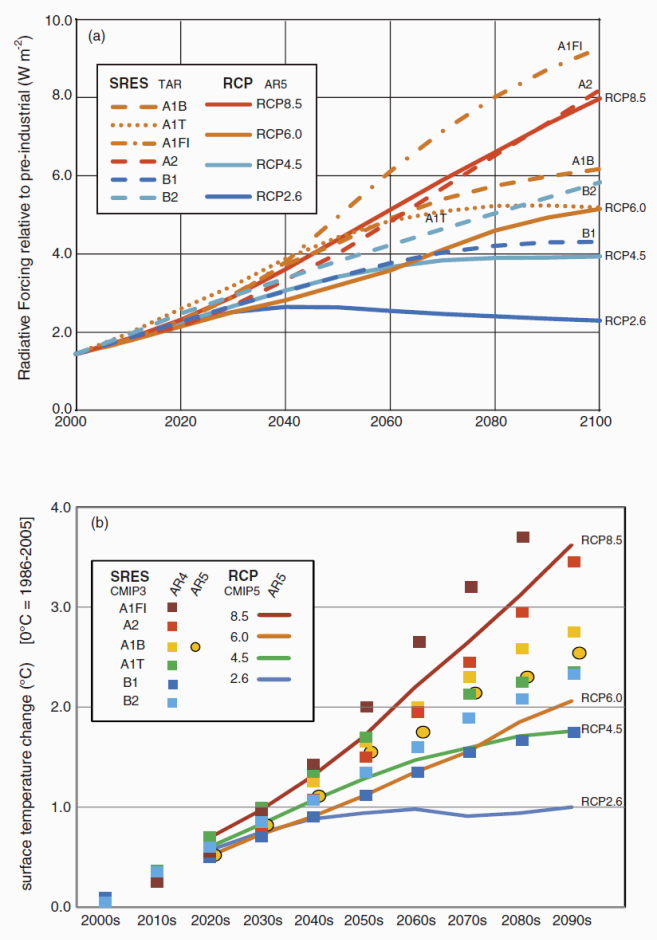

Figure 1-5: (a) Projected RF (W m-2) and (b) global mean surface temperature change (°C) over the 21st century from the SRES and RCP scenarios. RF for the RCPs are taken from their published CO2-eq (Meinshausen et al., 2011), and RF for SRES are from the TAR Appendix II (Table II.3.11). Comparable models are used in both RF calculations. The SRES RF are shifted upward by 0.12 W m-2 to match at year 2000. Temperature changes are

decadal means based on the model ensemble mean CMIP5 data for the RCPs (see AR5 WGI Chapters 11, 12, Annex II tables). The same analysis applied to CMIP3 SRES A1B is also shown (yellow circles). The SRES temperatures (colored squares, AR4 WGI Figure 10.26) are based on a simple climate model tuned to the CMIP3 models. Thus the yellow circles and yellow squares differ by a few tenths °C.

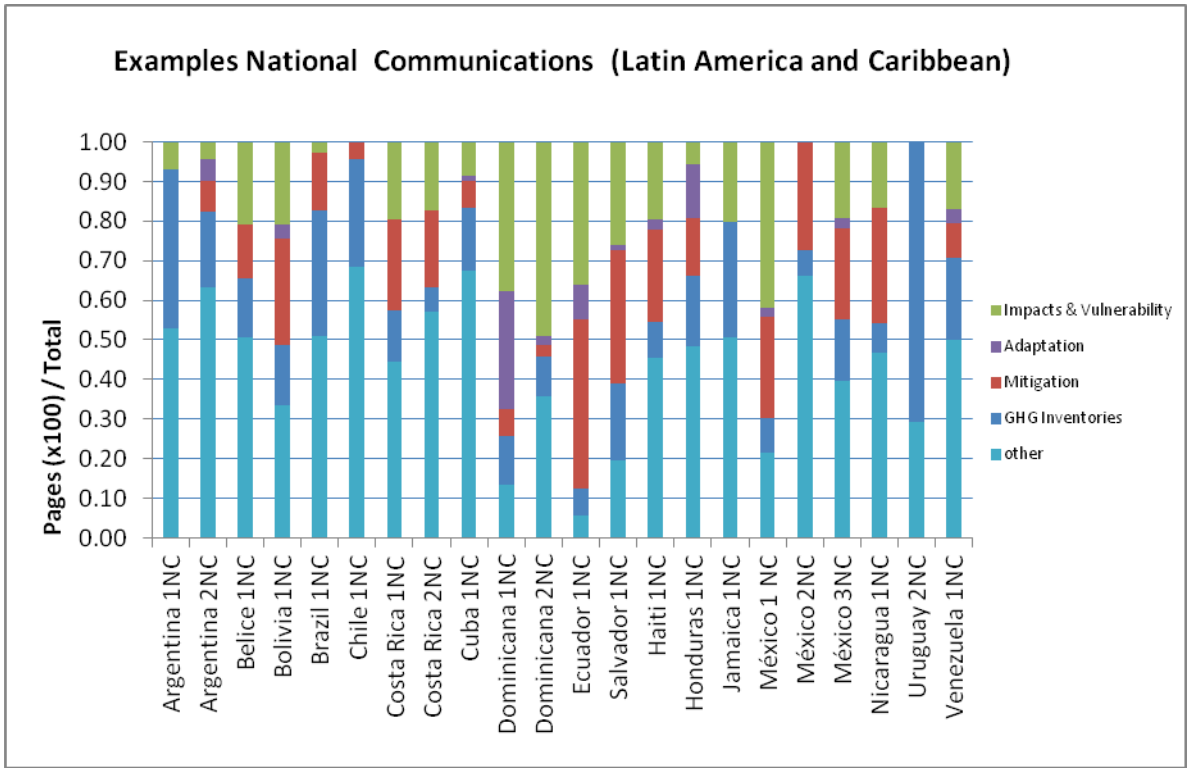

Figure 1-6: Distribution of topics related to impacts and vulnerability, adaptation, mitigation and greenhouse gas inventories (GHG Inventories) in the First (1), Second (2) or Third (3) National Communications (NC) of several Latin American and Caribbean countries (Argentina, Belize, Bolivia, Brazil, Chile, Costa Rica, Cuba, Dominica, Ecuador, El Salvador, Haiti, Honduras, Jamaica, Mexico, Nicaragua, Uruguay and Venezuela). Documents source: http://unfccc.int/national_reports/non-annex_i_natcom/items/2979.phpUNFCCC.

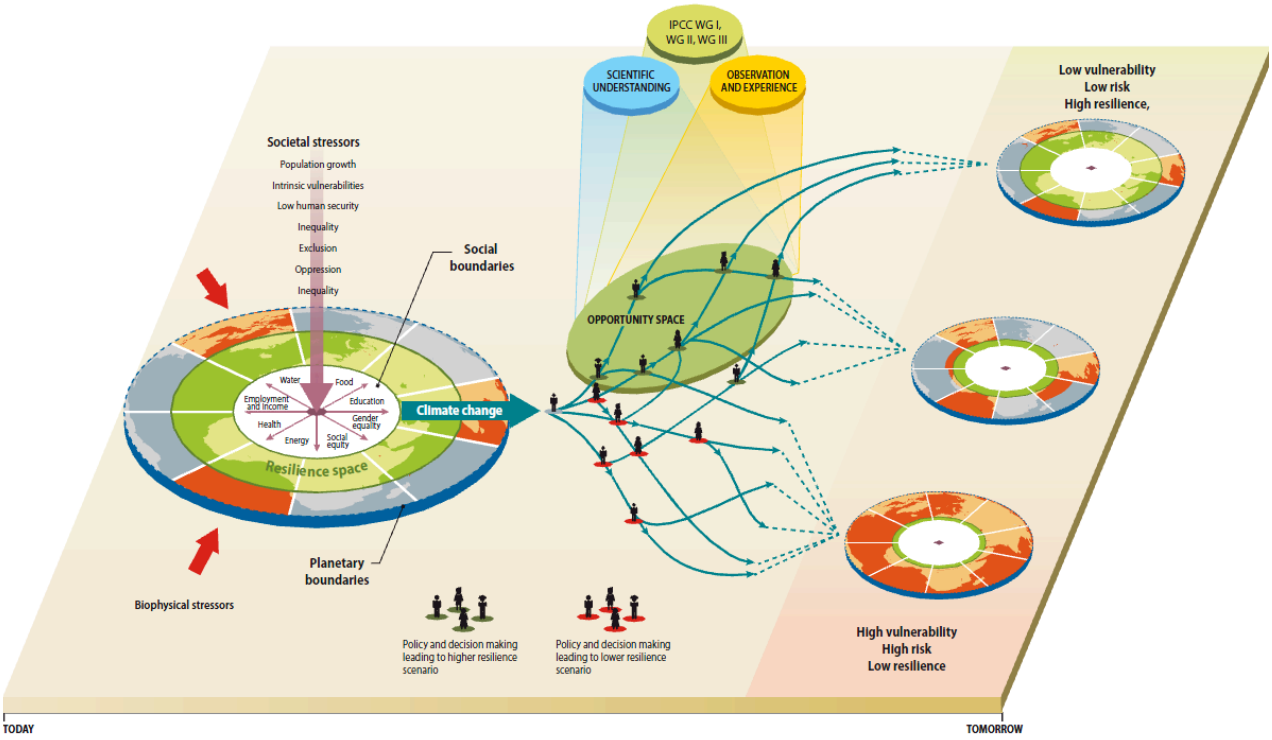

Figure 1-7: Conceptual framework for assessing interactions between biophysical and societal stressors that impact the resilience of natural and human systems today and in the future. Actions, including climate change adaptation and mitigation, taken in the opportunity space lead to a diverse range of pathways and outcomes – toward a future of high risk, high vulnerability and low resilience space or toward a future of low risk, low vulnerability and high resilience space.

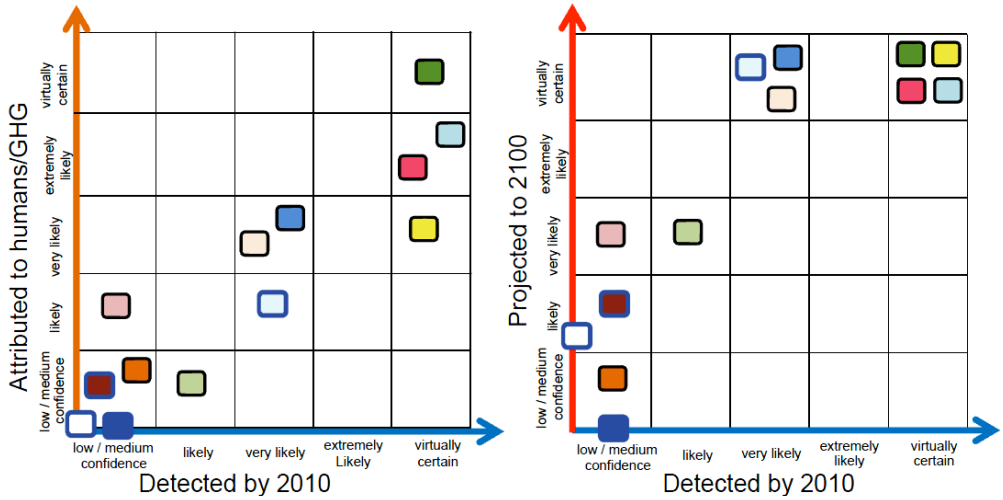

Figure 1-8: Climate change and its impacts detected to date (horizontal axis) is plotted against (left panel) attribution of those changes to greenhouse gases and (right panel) projection of those changes into the 21st century for a global warming exceeding 2°C. Only phenomena with a detection, attribution or projection at high confidence levels or with quantifiable uncertainty are shown. All phenomena are defined in Table 1-1 where the color coded symbols and likelihood are defined. Results are taken from the AR4, SREX, and AR5 WGI, but primarily from WGI because the attribution is to the observed increase in greenhouse gases that has driven anthropogenic climate change, rather than as in WGII to the regional/local observed warming. For AR5 WGII results, see inter alia Chapters 18 and 19.

Chapter 2. Foundations for Decision-Making

Executive Summary

The purpose of this chapter is to offer foundational knowledge and important perspectives on how better decisions can be made in response to assessments of climate impacts, adaptation and vulnerability. [2.1.1] It introduces new material from a range of disciplines, broadening the decision-making methods used to date. In the past, IPCC-sponsored assessment methods and policy advice have been framed by the assumption that better science will lead to better decisions. [2.1.2] While better science is necessary, it is not sufficient, requiring additional decision-support processes and tools. [2.1.2, 2.2] The decision-sciences applied on scales from the individual to organizations to institutions provide a great deal of decision-making theory and practice that can inform process and methods. [2.2, 2.3]

All decisions involving uncertainty and valued outcomes involve risk management. [2.1.1] The international risk management standard defines risk as *the effect of uncertainty on objectives*. Risk management provides a useful framework for most CCIA decision-making. [2.1] A broad operational definition of risk is *a situation or an event where something of human value (including humans themselves) is at stake and where the outcome is uncertain*. [2.1.1]

Iterative risk management involves an ongoing process of assessment, action, reassessment, and response that may need to be applied under climate change, for decades, if not longer. [2.1.2, 2.3.1] Both the objective and subjective aspects of risk: 1) calculated risks derived through formal processes and 2) perceived risk, the subjective view of risk held by a stakeholder, need to be incorporated into the decision-making process. [2.1.2] In simple systems, calculated and perceived risks are more likely to be closely aligned. Complex decision-making contexts will require both the risks of various future outcomes and the risks of alternative actions to be assessed. [2.3.1] This places significant demands on people and organisations to manage that process within the context of their own aims. [2.3.1]

Scenarios are a vital part of managing uncertainty. They can be divided into those that explore how futures may unfold under various drivers (problem exploration) and those that test how various interventions may play out (solution exploration). [2.2.1.1] Historically, most scenarios used for CCIAV assessments have involved the former type. The new RCP scenario process is being constructed to cater for both problem and solution framing. [2.2.1.1]

Most social-ecological systems where adaptation takes place are reflexive, requiring the development of adaptive management techniques such as iterative risk assessment. In reflexive systems, decisions that are implemented will change the system itself, demanding ongoing monitoring and assessment in order to track those changes, as they are rarely predictable. [2.2.1.1] Formal processes of monitoring and periodic review, including revisiting ongoing aims and objectives, are required to support adaptive management. [2.2.1.3]

Decision-making on CCIAV has a very strong ethical basis that is expressed at a range of institutional scales and is strongly embedded into elements of risk governance on those scales. [2.2.2.1, 2.2.2.2, 2.2.3.4]

Decision support is situated at the intersection of data provision, expert knowledge and human decision-making at a range of scales from the individual to the organization and institution. Decision support is defined as a set of processes intended to create the conditions for the production of decision-relevant information and its appropriate use. [2.2.1, 2.2, 2.3] Such support is most effective when it is context-sensitive, taking account of the diversity of different types of decisions, decision processes, and constituencies. [2.3.1, 2.3.3, 2.3.4] Institutionally, boundary organisations are important in translating and transferring these messages. [2.3.1, 2.3.2]

Climate services aim to make knowledge about climate regionally accessible to a wide range of decision makers. [2.3.3] In doing so they have to consider information supply, knowledge competition and user demand.

Knowledge transfer is a negotiated process that can take a variety of cultural values, orientations and alternative forms of knowledge into account. [2.3.1, 2.3.3]

Climate change response can be linked with sustainable development through actions that enhance resilience, which is the capacity to absorb shocks and to change in order to maintain the same identity. Sustainable adaptation, disaster risk management, and new types of governance and institutional arrangements are being studied for their potential to support the goal of enhanced resilience. [2.4.2]

Transformation can be managed through transitional arrangements but these are notoriously difficult to control and are best managed through adaptive management or similar process. [2.4.3]

2.1. Introduction and Key Concepts

2.1.1. Decision-Making Approaches in this Report

This chapter addresses the foundations of decision-making with respect to climate change impact, adaptation and vulnerability (CCIAV) assessment. The Fourth Assessment Report (AR4) summarized methods for CCIAV (Carter et al., 2007), which we build on by surveying the broader academic literature to obtain knowledge on decision-making suitable for CCIAV. This expanded focus reflects the evolution of CCIAV assessments from the straightforward linear scenario-driven approaches described in the early literature to the wide range of decision-making approaches active today.

The overarching theme of the chapter is risk management. The International Standard ISO:31000 defines risk as *the effect of uncertainty on objectives* (ISO, 2009) and Rosa (2003) defines it as *a situation or an event where something of human value (including humans themselves) is at stake and where the outcome is uncertain*. Because all decisions on CCIAV are affected by uncertainty and involve valued objectives, all are decisions of risk (e.g., Giddens, 2009). To encompass both this broad theme and the specific nature of many kinds of decision-support, a three-tier hierarchy for decision-making is presented: approach, methodology and method (Figure 2-1). Approach describes the broad framing and scoping of an issue; methodology comprises the principles and rules governing the decision-making process; and that process is applied using methods and tools.

[INSERT FIGURE 2-1 HERE
Figure 2-1: Risk portrayed as an approach, methodology and method using definitions relevant to this report.]

Risk management frames the overall chapter approach, but at the methodological scale can be applied in many ways: e.g., financial, disaster, engineering, environmental and health risk. A range of different tools and methods can be applied to each methodology. Many other methodologies such as vulnerability, resilience and livelihood assessments may at first seem to be unconnected with traditional risk assessment, but may in fact be analysing, evaluating or managing risks within a larger risk management process. For example, developing resilience can be seen as managing a range of potential risks; sustainable development aims to developing a system robust to risks informed by values-based processes and outcomes.

The Fourth Assessment Report endorsed risk management as a suitable decision-support framework for CCIAV assessment because it offers formalized methods for addressing uncertainty, involving stakeholder participation, identifying potential policy responses, and evaluating those responses (Carter et al., 2007; Yohe et al., 2007). A risk management framework also facilitates the mainstreaming of climate-centric decision-making into broader decision-making processes. The AR4 report also summarized advances in many CCIAV assessment approaches and described how they can fit into a risk management framework. The literature shows significant advances on all these topics since AR4 greatly expanding methodologies for assessing impacts, adaptation and vulnerability in a risk context (Agrawala and van Aalst, 2008; Hinkel, 2011; Jones and Preston, 2011; Preston et al., 2011).

A major aim of risk management is to make better decisions. There are many definitions of decision in the literature but all involve choosing amongst alternatives, and some involve a course of action to enact that decision. **But what**

constitutes a "better" decision? *A better decision is one where the process of decision-making is judged to produce more acceptable outcomes within a given set of circumstances than previous decisions*. It may be highly precautionary, designed to avoid the worst possible outcomes (Hansson, 2006; Malik et al., 2010). Elwyn and Miron-Shatz (2010) argue that process be given more weight than outcomes under uncertain futures where many outcomes are possible. Many factors that influence how a decision can be assessed include: who is making the decision, its context and purpose, what information is used, who implements its actions, the resources invested in the decision-making process, the choice of method, who is affected by its outcomes, how those outcomes are valued and assessed over a given time horizon, and the extent to which the objectives being pursued are regarded as appropriate. Section 2.2.3.4 shows that ethics are an important aspect of such choices.

Two aspects of decision-making that distinguish climate change from most other contexts are the long time scales involved and pervasive uncertainties (Kandlikar et al., 2005; Ogden and Innes, 2009; Lempert and McKay, 2011). These uncertainties include not only future climate but also socio-economic change and potential changes in norms and values across generations. Process uncertainties also affect the choice of the most suitable decision-support applications for managing specific problems or seeking uncertain solutions within a given context.

Decision-makers range from individuals, to organizations to institutions, at the largest scale comprising systems of systems. Decision-makers are influenced by both individual and group factors, such as internal psychological and cognitive factors, their physical and socio-cultural environments, and the institutions within which they operate. They draw from a knowledge base and utilize a variety of methods and tools that they know and accept. Decisions are framed by aspirations and goals and informed by scenarios of how the future may play out.

The study of human reasoning has a long history, in eastern and western traditions and in widespread indigenous cultures. In recent decades, research describing the actual processes of human decision-making, note that the normative (the decision one should arrive at) and descriptive/positive (what people actually do) aspects often diverge (e.g., Raïffa et al., 2002). For example, people often fail to take simple preparations for disasters such as earthquakes or floods even when they have sufficient resources to do so and would, upon more careful reflection, come to believe that they should (McClure et al., 1999; McIvor and Paton, 2007). People may also act inconsistently with a particular formal analysis because they have values and goals not well represented in that analysis (Davies and Walters, 1998; Helsloot and Ruitenberg, 2004).

Previous assessments have described the methods and tools used for decision support, giving less regard to decision-making processes (Carter et al., 1994; Parry and Carter, 1998; Carter et al., 2001; Hulme and Mearns, 2001; Carter et al., 2007; IPCC-TGICA, 2007). Much method development has aimed for objectivity, often assuming that rational knowledge will induce 'rational' behavior. However, the decision sciences literature makes clear that people make decisions based on a whole variety of criteria (Karvetski et al., 2009; Tryhorn and Lynch, 2010); for example, stakeholder groups in a single region show multiple preferences for coastal protection leading to very different solutions for the same hazard (Mustelin et al., 2010). To date, the socio-cultural and cognitive-behavioural aspects of CCIAV decision-making have largely been restricted to descriptions of social learning processes; e.g., Section 2.3.2 on stakeholders in Carter et al. (2007). However, we see these factors as being just as important as specific knowledge brought into the decision-making process.

The next section (2.2) describes diverse aspects important to a full understanding of CCIAV decision making, including methods, tools, and processes (Sect 2.3.1); institutional (2.3.2); and social (2.3.3) contexts. Section 2.3 describes how understanding of these aspects can be used to improve decision making. Section 2.4 addresses the interaction between adaptation and mitigation, sustainable development and transformation.

2.1.2. Iterative Risk Management

Complexity is an important attribute for framing and implementing decision-making processes *[High confidence]*. Simple, well-bounded contexts involving cause and effect can be addressed by straightforward linear methods. When complex contexts interact with human values they become associated with wicked problems. Wicked problems are not well bounded, they are framed differently by various actors and groups, they harbour large

scientific to existential uncertainties and have unclear solutions and pathways to those solutions (Rittel and Webber, 1973; Australian Public Service Commission, 2007). Such 'deep uncertainty' cannot easily be quantified (Dupuy and Grinbaum, 2005; Kandlikar et al., 2005). One important attribute of complex systems is reflexivity, where cause and effect feed back into each other. For example, actions taken to manage a risk will affect the outcomes, requiring iterative processes of decision-making. Under climate change, risks will also change with time (Ranger et al., 2010)

The CCIAV literature has increasingly adopted an iterative risk management framework (Carter et al., 2007; Yohe et al., 2007; Jones and Preston, 2011), which is also consistent with risk governance (Renn, 2008) and a wide range of approaches for structured decision-making involving process uncertainty (Ohlson et al., 2005; Wilson and McDaniels, 2007; Ogden and Innes, 2009; Martin et al., 2011). Iterative risk management involves an ongoing process of assessment, action, reassessment, and response (Kambhu et al., 2007; IRGC, 2010) that will continue – in the case of many climate-related decisions – for decades if not longer (Committee on America's Climate Choices National Research Council, 2011).

Two levels of iteration can be recognised within the iterative risk management process, two internal and one external (Figure 2-2). One internal iteration occurs during the assessment stage and addresses the interactions between the problem, proposed solutions and system feedbacks where managing risk feeds back into the risk itself. A second internal iteration occurs during the management stage following implementation when formal monitoring and review tracks how the system responds and reacts accordingly. The third iteration covers the entire process when an assessment has finished and the decision process returns to the scoping phase.

[INSERT FIGURE 2-2 HERE

Idealised, Calculated, Perceived Risks

In complex situations, socio-cultural and cognitive-behavioural contexts become central to decision-making. This requires combining the scientific understanding of risk with how risks are framed and perceived by actors and institutions (e.g., Hansson, 2010). For that reason, formal risk assessment is moving from a largely technocratic exercise carried out by experts to a more participatory process of decision support (Fiorino, 1990; Pereira and Quintana, 2002; Renn, 2008), although this process is proceeding slowly (Christoplos et al., 2001; Pereira and Quintana, 2002; Bradbury, 2006; Mercer et al., 2008).

Earlier applications of risk involved the calculation of hazard × likelihood or probability and consequence, and communicated the results to decision-makers, similar to the way that early CCIAV assessments were carried out. More recent applications have moved from the objective analysis of risk to addressing values at risk and the governance of risk (Power, 2007; Renn, 2008), although hazard-based methodologies remain important when the hazard is the primary concern. Likewise CCIAV methods are expanding from a direct focus on specific climate risks to more mainstream settings where the management of climate risks is integrated with other areas of risk management (Hellmuth et al., 2011). For example, climate risks affecting a local government area will have planning, legal, financial, health and community aspects (Measham et al., 2011). Mainstreaming may require trade-offs between climate and other risks (Kok and de Coninck, 2007; Eakin et al., 2009).

Different epistemologies, or 'ways of knowing' exist for risk (Hansson, 2004; Althaus, 2005; Hansson, 2010), vulnerability (Weichselgartner, 2001; O'Brien et al., 2007) and adaptation assessments (Adger et al., 2009) affecting the way they are framed by various disciplines and are also understood by the public (Garvin, 2001; Adger, 2006; Burch and Robinson, 2007). These differences have been nominated as a source of widespread misunderstanding and disagreement. They are also used as evidence to warn against a uniform epistemic approach (Hulme, 2009; Beck, 2010), a critique that has been levelled against previous IPCC assessments (Hulme and Mahony, 2010).

The following five types of risk have been nominated as important epistemological constructs (based on Thompson, 1986; Althaus, 2005; Jones, 2012):

1) Idealized risk: the conceptual framing of the problem at hand. For example, dangerous anthropogenic interference with the climate system is how climate change risk is idealized within the UNFCCC.
2) Calculated risk: the product of a model based on a mixture of historical (observed) and theoretical information. Frequentist or recurrent risks often utilize historical information whereas single-event risks may be unprecedented, requiring a more theoretical approach.
3) Subjective risk: the mental state of an individual who experiences uncertainty or doubt or worry as to the outcome of a given event. Gives rise to:
4) Perceived risk: the rough estimate of an idealized risk derived informally by individuals and groups.
5) Observed risk: the risk observed once an event is realized. This will update to conceptualization of future risks.

These different types show risk to be partly an objective threat of harm and partly a product of social and cultural experience (Kasperson, 1992; Rosa, 2008). The aim of calculating risk is to be as objective as possible, but the subjective nature of idealized and perceived risk reflects the division between positivist (imposed norms) and constructivist (derived norms) approaches to risk from the natural and social sciences respectively (Demeritt, 2001; Hansson, 2010). Idealized risk will follow both formal and informal pathways through the assessment process. Acceptance of the science behind controversial risks is strongly influence by social and cultural influences (Leiserowitz, 2006; Kahan et al., 2007; Brewer and Pease, 2008); Figure 2-3). Risk perceptions can be amplified socially where events pertaining to hazards interact with psychological, social, institutional, and cultural processes in ways that heighten or attenuate individual and social perceptions of risk and shape risk behaviour (Kasperson et al., 1988; Renn et al., 1992; Pidgeon et al., 2003; Rosa, 2003; Renn, 2011).

[INSERT FIGURE 2-3 HERE
Figure 2-3: Schema for the chapter, showing a hierarchy of decision-makers in the centre and broad groupings of subjects addressed in the chapter. The decision-making environment is described by adaptation, mitigation and sustainable development, the methods and tools utilised include scenarios, decisions are made in the human context of individuals to groups and decisions can be assessed to measure varying degrees of success.]

Understanding of how these perceptions resonate at an individual and collective level can help overcome constraints to action (Renn, 2011). Science is most suited to calculating risk in areas where it has predictive skill and will provide better estimates than may be obtained through more arbitrary methods (Beck, 2000), but an assessment of what is at risk needs to be generally accepted by stakeholders. Therefore, the science always sits within a broader social setting, often requiring a systems approach where science and policy are investigated in tandem, rather than separately (Pahl-Wostl, 2007; Ison, 2010).

Despite there being a literature on the sociology of science relevant to climate change risks (Jasanoff, 1996; Demeritt, 2001; Wynne, 2002; Demeritt, 2006) only recently are these approaches being built into CCIAV assessments. The different types of risk listed above give rise to complex interactions between formal and informal knowledge that cannot be bridged by better science or better predictions but require socially mediated processes of engagement *[medium confidence]*, as discussed in later sections. Idealised risk is important for framing and conceptualising risk. Calculated risk covers the analytic side of risk that concentrates on quantitative decision analysis. Perceived risk is closely aligned with socially constructed risk that emerges from the psychological and behavioural sciences and from social sciences literatures such as anthropology, geography, ethics, sociology, political science, and other.

A large literature describes best practice methods for incorporating and communicating information about risk and uncertainties into decisions about climate change (Climate Change Science Program, 2009; Pidgeon and Fischhoff, 2011). This literature suggestions that effective communication of uncertainty requires products and processes that: i) closes psychological distance, explaining why is this information is important to the recipient; ii) establishes self-agency, explaining what the recipient can do with the information; iii) recognizes that each person's view of risks and opportunities depends on their values; iv) recognizes that emotion is a critical part of judgment; and v) provides mental models that help recipients to understand the connection between cause and effect. In addition, this literature

emphasizes that information providers need to test their messages, since they may not be communicating what they think they are.

2.2. Aspects of Decision-Making

This section surveys aspects of decision-making important to understanding and improving CCIAV decisions. It begins (Section 2.2.1) with a survey of methods, tools, and processes potentially useful for improving such decisions. This literature emphasizes the importance of the organizational and cultural/psychological contexts of decision-making, which are addressed in Sections 2.2.2 and 2.2.3.

2.2.1. Methods, Tools, and Processes for Climate-Related Decisions

Since the AR4, the level of adaptation activity among organizations worldwide has increased substantially (Preston et al., 2009). This activity has delivered substantial experience on which practitioners can draw, as well as expanded needs and opportunities for research. This experience suggests that those faced with CCIAV decisions often require systematic methods, tools, and processes for effective risk management because the challenges they face are complex, complicated, and novel (whether or not the challenges had such attributes before climate change, they certainly do with climate change).

The heterogeneous field of decision sciences integrates 'abstract' decision theory with economic applications, cognitive psychology, and philosophy of action, theoretical computer science or neuroscience. It represents complementary links between cognitive psychology and economics and, more generally, cognitive sciences and social sciences (Kleindorfer et al., 1993; Buchanan and O'Connell, 2006).

Extensive evidence from the decision sciences shows that good scientific and technical information alone is rarely sufficient to result in better decisions *[high confidence]*. Better decisions result from effective decision-making processes that include access to appropriate scientific and technical information but also pay attention to institutional and organizational contexts. Based on the limited experience to date, there may now exist a sufficiently rich set of available methods, tools, and processes to support effective CCIAV decisions in a wide range of contexts *[medium confidence]*.

The concept of *decision support* provides a useful framework for understanding how risk-based concepts and information can help enhance decision-making (see McNie, 2007; National Research Council (US) Panel on Design Issues for the NOAA Sectoral Applications Research Program et al., 2007; Moser, 2009; Romsdahl and Pyke, 2009; Kandlikar et al., 2011; Pidgeon and Fischhoff, 2011). The concept also helps situate methods, tools, and processes intended to improve decision-making within appropriate institutional and cultural contexts.

Decision support is defined as "a set of processes intended to create the conditions for the production of decision-relevant information and its appropriate use" (National Academy of Sciences, 2009). Information is decision relevant if it yields deeper understanding or a choice or, if incorporated into making a choice, yields better results for decision makers and their constituents. These definitions, and criteria that can be used to judge the effectiveness of decision processes and decision support, are drawn from surveys of scientific communication and decision-making in many literatures, including public health, hazards management, natural resource management, environmental management and policy-making, land use planning, environmental risk communication, sustainability science, local air quality, as well as climate change mitigation and adaptation (National Academy of Sciences, 2009).

2.2.1.1. Treatment of Uncertainties (including Scenarios)

Methods and tools for addressing uncertainty are often central to risk management and effective CCIAV decision-making. Whether embodied in formal analyses or in the training and habits of decision makers, appropriate uncertainty frameworks are often needed because unaided human reasoning can produce mismatches between

actions and goals under conditions of uncertainty (Kahneman, 2011). The literature also emphasizes the importance of quantifying uncertainty, because merely verbal descriptions can prove ambiguous and often fail to provide the information necessary to adjudicate trade-offs. Adopting frameworks for considering and quantifying uncertainty raises both technical challenges as well as those of organizing uncertain information so that it proves useful within a specific decision support process.

As one key aspect of these challenges, the literature recognizes a wide range of different types of uncertainty. Knight (1921) first contrasted as the difference between well-characterized risks and more poorly-understood, unquantifiable uncertainties. AR4 (Box 2-1) provides a taxonomy of characterizations of the future that distinguishes comprehensiveness, the degree to which a representation captures the full range of socio-economic and biophysical factors, and plausibility, the extent to which a future is possible and to which a probabilistic description can be ascribed (Carter et al., 2007). Recent taxonomies focus on both the level and location of uncertainty (Kwakkel et al., 2010). While the literature provides no consensus on definitions of such levels, in general uncertainty can range from shallow or well-characterized -- in which alternative futures can be specified and probabilities distributions placed over those futures with high confidence -- to deep uncertainty, severe, or extreme uncertainty -- in which not all alternative futures can be specified (that is, surprise is plausible) and probability distributions cannot be specified with confidence. These levels correspond to the confidence scale in the IPCC uncertainty guidance (Mastrandrea et al., 2010). For this assessment, the use of qualitative confidence levels (instead of quantitative) based on expert judgement determined through authors' evaluation of the evidence and levels of agreement, is recommended (Mastrandrea et al., 2010). In model-based analyses, uncertainty can be located in the specification of the system boundary, the conceptual model, the available data, and in different models used to represent the system in question. Both the level and location of uncertainty can affect the appropriate choice of methods and tools in a particular decision context.

_____ START BOX 2-1 HERE _____

Box on scenario building process developed with Chapter 21 regional context – forthcoming.

_____ END BOX 2-1 HERE _____

In recent years the literature has begun to describe two distinct processes for including uncertainty in decision support (Weaver et al., 2012). One process seeks to describe uncertainty as distinct information, independent of other parts of the decision problem. Probabilistic descriptions often take this approach, which follows the assess risks, identify options, evaluate trade-offs loop in Figure 2-2. For instance, probabilistic climate projections are generated to support a wide range of decisions, and thus not tied to any specific choice. In engaging with decision makers, information providers seek to understand what data would prove most useful, for instance temperature and precipitation time series at some level of spatial and temporal resolution, and then seek to provide that data to a wide community of decision makers. The basic structure of IPCC Assessment Reports also follows this pattern, with WGI laying out what is known and uncertain about current and future changes to the climate system. Working Groups II and III then describe impacts resulting from and potential policy responses to those changes. As one advantage, this process promotes a perception of objectivity because those who characterize uncertainty are functionally and often organizationally independent of those who use the uncertainty estimates to make decisions.

In contrast to this 'predict-then-act' process, a second approach seeks to describe uncertainty in the context of the sets of uncertainty factors that would affect judgments about and choices among alternative policies, following the identify options, assess risks, evaluate trade-offs loop in Figure 2-2. The literature offers several names for such approaches, including 'context-first' (Ranger et al., 2010), 'decision scaling' (Brown et al., 2011), 'assess risk of policy' (Lempert et al., 2004; UNDP, 2005; Carter et al., 2007; Dessai and Hulme, 2007) that characterize those uncertain states of the world that would cause a current or proposed policy to fail to meet its goals or the to illuminate the trade-offs among particular policy choices. For instance, Kirshen et al. (2008) provided decision makers in New York City plots that showed how the frequency of large-scale flooding would increase along the city's coastline, without changes to the current infrastructure, as a function of various assumptions about sea level rise. The IPCC's *Reasons for Concern* approach (Smith et al., 2009) aims to summarize the deleterious impacts implied by various greenhouse gas emissions trajectories. In engaging with decision-makers, this assess-risk-of-

policy approach often requires that information providers work closely with decision makers to understand their plans and goals, before customizing the uncertainty description to focus on those key factors. This approach can be very effective at communicating risk and uncertainty, but often needs to be individually customized for each decision context (Lempert and Kalra, 2011; Lempert, 2012) and requires the producers and users to collaborate within a single process.

Within these processes, a number of approaches exist for dealing with uncertainty in CCIAV decisions. Traditional probabilistic approaches treat uncertainty with a single, well-characterized (joint) probability density function over future states of the world. Such approaches have been used in a wide variety of adaptation studies (Hobbs et al., 1997; Chao et al., 1999; Venkatesh and Hobbs, 1999), often within a predict-then-act process, and can prove most useful when the uncertainty is relatively well-characterized or when decision makers seek an authoritative expert judgment to inform their choices.

A variety of axiomatic approaches also exist (Smithson, 1989), such as belief functions (Shafer, 1976), imprecise probabilities (Walley, 1991), certainty factors (Clancey and Shortliffe, 1984), and fuzzy logic (Zadeh, 1983; Prato, 2009, 2011), which aim to provide formalized descriptions of multiple levels of uncertainty, generally combining likelihood with some additional measure of confidence (Climate Change Science Program, 2009). While some examples exist (e.g., Bass et al., 1997; Prato, 2009, 2011), such approaches have not been widely used for CCIAV decisions.

Sets of alternative representations can also be used to characterize uncertainty. Such approaches, often but not always used within a context-first process, aim both to decrease tendencies towards overconfidence as well as facilitate engagement with the analysis among parties with differing expectations and values. These set-based approaches can focus on non-probabilistically weighted collections of future states of the world or can retain a probabilistic formulation by considering a range of probability values or sets of plausible probability density functions, for instance as suggested in the IPCC uncertainty guidance (Mastrandrea et al., 2010). Examples include InfoGap, which has been used to inform CCIAV decisions in water management (Ben-Haim, 2001; Korteling et al., 2013); RDM (robust decision making), which has been used for water management and flood risk management planning (Lempert et al., 2003; Lempert and Groves, 2010; Lempert and Kalra, 2011; Matrosov et al., 2013); and robust control optimization and control theory (Hansen and Sargent, 2008). Note that the climate modelling community has also begun to adopt set-based characterizations of uncertainty (see Parker, 2006).

Scenarios

Scenarios are cognitive tools central to scoping and assessing risk, and in managing risk as adaptation planning *[very high confidence]*. A scenario is not a prediction of what the future will be but rather a description of how the future might unfold. A scenario includes an interpretation of the present, a vision of the future and an internally consistent account of the path from the present to the future (Jäger et al., 2008). Scenario use has expanded significantly as CCIAV research has become more integrated with mainstream activities. Their application has extended beyond climate as noted in the past two assessment reports (Carter et al., 2001; Carter et al., 2007). Climate change has also become a core feature of many scenarios used in regional and global assessments of environmental and socio-economic change (Carpenter et al., 2005; Raskin et al., 2005). Scenarios can be used at a number of stages within the assessment process or to underpin an entire assessment. They serve a variety of purposes, including informing decisions under uncertainty, scoping and exploring poorly understood issues, and integrating knowledge from diverse domains (Parson et al., 2006).

Existing scenario typologies tend to reflect the state of play at the time they are assembled, become outdated as the field evolves and often fail to capture the full range of contemporary scenario development (van Notten, 2006). They seem to be regarded as products of research, rather than as tools designed to function in particular sorts of inquiries (Wilkinson and Eidinow, 2008). Recently published typologies include descriptive (van Notten, 2006), philosophical underpinning (Börjeson et al., 2006) and decision-type (Wilkinson and Eidinow, 2008). These typologies can be grouped according to their function in decision-making. The major groupings are problem-based, solution- or actor-based and reflexive scenarios (Wilkinson and Eidinow, 2008). Exploratory scenarios that explore

value-neutral 'what will happen if' questions and normative scenarios that represent explicit values in a forecasting or back-casting mode are also important pairings (Carter et al., 2007). Problem-based scenarios are developed using deductive and inductive methods whereas actor-based scenarios are normative, so map well onto exploratory and normative scenarios.

Reflexive scenarios are designed to work with wicked problems (Wilkinson and Eidinow, 2008). Problem (exploratory) and solution- or actor-based (normative) scenarios are combined to assess problems, implement decisions and apply ongoing learning in action-based research. Such scenarios require an institutional host, are linked to data measuring progress towards outcomes and periodically updated within an iterative assessment framework to revise decisions (Jones, 2012). Several generations of scenarios produced by IPCC assessments, national climate scenarios in the UK and Australia indicate this capacity may be developing (CSIRO and BoM, 2007; Gawith et al., 2009; Moss et al., 2010) but would require parallel development in a wider set of variables relevant to adaptation and a more institutionalised approach to decision-making support. The new scenario matrix being developed for climate change (Kriegler et al., 2010; Moss et al., 2010) is one vehicle where this may happen.

Linking these typologies with research methods, the major determinants of scenarios can be described as problem–actor, exploratory–normative, top-down–bottom-up (in terms of scale) and forward-looking–back-casting (or prescriptive-diagnostic in terms of time). In methodological terms this sets up a process-goal construct. Forward casting normative scenarios concentrate on the initial state and process, for example a set of specific policies, whereas back-casting will define a normative state in the future; e.g., sustainability, then diagnose how to achieve that state over time given specific starting conditions and a set of key drivers. Reflexive scenarios will combine these approaches.

Scenarios have a somewhat uncomfortable place within the standard research methods applied to assess CCIAV. As outlined in the earlier section on uncertainty, problem uncertainty can range from quantified distributions of variables and outcomes known with high confidence to those that can at best be said to be 'not implausible' (Strzepek et al., 2001; Malone and Yohe, 2002) that are linked to complex situations with deep uncertainty.

There is a tension between the development of climate forecasting as pursued by the modelling community who aim to improve future predictions and scenario development required by the CCIAV community, who require tools for decision support. In terms of calculating event risk, scientific prediction is limited to what is represented in a model, so while its theoretical application may be sound, in a system of multiple drivers and feedbacks, the model itself may be incomplete. Scenarios can fill that gap. For example, Carter et al. (2007) emphasize that climate scenarios are usually purpose-built for specific impact assessments, often modifying climate model output, but rarely use model output directly. Climate may also be only part of the total uncertainty if risk is being assessed from the interaction between climate impacts and social vulnerability.

On the solution side, representing hard-to-define goals is also a difficult issue for prediction. For example, both sustainability and 'dangerous climate change' are both difficult to define due to differing social and cultural constructions of what they may mean. This uncertainty is reflected in the expert literature (Harding, 2006). Uncertain predictions of uncertain goals invite controversy. Given that exploratory scenarios have the capacity to survey a range of plausible pathways and goals in such cases, a participatory process is likely to achieve broader agreement than expert judgment can by itself.

The inability to ascribe likelihood to a single scenario can be overcome by using scenario ensembles, allowing storylines to be compared and contrasted. Quantitative estimates such as warming or population growth can be assessed according to likelihood of exceedance because cumulative statistical functions are more robust to uncertainty than probability distribution functions. Likelihood can be addressed in a Bayesian manner, where participants use a scenario process to update their priors, but in a richer manner than can be achieved with straightforward prediction. For example, a stakeholder's prior model may be completely altered, they may step away from a focusing on the most likely outcome to survey the spectrum of potential likelihood consequence, or they may completely reframe the way they see the issue. The ability to do this collectively also fosters social learning, potentially building a community of practice (Wenger, 2000; Pahl-Wostl, 2002).

By separating risks into tame and wicked problem risks, the need for scenarios with the decision-making process can be better identified *[moderate confidence]*. For tame risks, if probabilities cannot be easily calculated then scenarios can be used to explore the problem and illustrate alternative solutions for evaluation. Wicked problems will probably need to be thoroughly scoped to select the most suitable decision-making process. They may require separate applications of problem and solution-based scenarios or the development of reflexive scenarios. Even if conditional predictions can be used to illustrate climate futures, scenarios may be needed to explore the solutions space involving strategic actions, options planning and governance using both process and goal-oriented methods.

2.2.1.2. Evaluating Trade-Offs and Multi-Metric Valuation

Effective CCIAV decision-making often requires making trade-offs among competing objectives and values. The methods and tools that exist to help evaluate such trade-offs employ a range of alternative decision criteria. The appropriate criteria for any given case depends on decision makers' the goals, the data available, and the types of uncertainties involved. Implicitly and explicitly, these decision criteria are used throughout the discussions of adaptation options, planning, and economics in Chapters 14 through 17 and WG III Chapter 2.

The decision theoretic literature divides criteria relevant to CCIAV decision making into two broad categories: outcomes-based, which compare alternative actions according to the consequences expected to result from them, and process -based, which compare alternative actions according to the process by which any decision is arrived at and, in particular, the extent to which various individuals consent to the risks, costs, and obligations being imposed upon them (Morgan et al., 1990). In general, CCIAV decisions can be judged by both types of criteria.

Process-based criteria focus on the credibility and legitimacy of a decision process. Institutional (Section 2.2.2) and cultural (Section 2.2.3) contexts will strongly influence the appropriateness and importance of such criteria. For some participants and in some situations, process criteria may prove decisive in any judgments about the decision irrespective of the outcome (Dietz and Stern, 2008; Sen, 2009). For instance, many environmental laws require advanced notice and periods of public comment before the government issues any regulations. Legal systems with water rights often give allocation decisions over certain water resources to individuals who can then choose, or not, to sell them to others during periods of drought. Participants may regard any decision that fails to respect these rights as illegitimate. One fundamental purpose of democratic deliberation and decision-making is to confer legitimacy on decisions (Sen, 2009). Process-based criteria can also depend on judgments about uncertainty. For instance, the precautionary principle contains an element of process-based criteria, placing the burden of proof on those introducing new impacts on the environment to prove that they are not harmful. Some utilitarian-based ethical frameworks distrust the ability to compare in any meaningful way social outcomes that make one person better off and another worse off, and thus seek to minimize the scope of decision processes that adjudicate broad social outcomes and seek to expand the scope of decision processes, often market-based, in which individuals only engage in transactions that transfer costs or risks with their explicit consent.

Outcomes-based criteria focus on the extent to which the consequences that flow from a decision met decision makers' goals. Most generally, these criteria fall within the domain of *multi-attribute decision theory* (Keeney and Raiffa, 1993), which provides a framework for balancing among multiple, potentially competing objectives (this branch of decision analysis is also known as multi-criteria decision analysis; for a CCIAV example see Korteling et al. (2013)). In some cases decision support uses decision criteria that recommend a single best decision, often by aggregating all the relevant objectives into a single metric. In other cases, decision support uses criteria that summarize trade-offs for decision makers.

Among criteria that recommend a single best decision, *optimality* provides the best possible outcomes-based choice in those situations where it is possible and appropriate to aggregate the relevant objectives, often expressed as monetary cost. *Cost effectiveness* criteria often prove useful in situations where decision makers can quantify the costs but not the benefits of alternative actions. For instance a water management agency might determine it necessary to be able to maintain a reliable supply of water in the face of the largest drought ever observed in their region, and then choose to invest in the least expensive reservoir able to meet that criteria. *Bounded cost* criteria often prove useful in situations where decision makers have fixed resources to address a problem. For instance, a

city might have a fixed budget to address adaptation to climate change and may wish to allocate those resources in such a way as to reduce risks as much as possible.

Such criteria can also help to summarize trade-offs among multiple objectives. For instance, one could use a cost effectiveness criterion to compare the cost of achieving alternative objectives, such as different levels of reliability for a water agency. More generally, *modern portfolio theory* (Crowe and Parker, 2008) provides what are called Pareto optimal surfaces that balance among multiple objectives. Each point on the surface represents the combination of objectives achieved by some decision, such that it is impossible to perform better for any one objective without performing worse on some other.

The multiple levels of uncertainty addressed in Section 2.2.1.1 can affect the appropriateness of alternative decision criteria. While some criteria can be applied broadly, some are only applicable with some types of uncertainty characterizations (Dessai and Sluijs, 2007). *Optimality* can provide the best possible outcomes-based choice when uncertainties are well-characterized. Criteria also exist to recommend a single best decision in cases where uncertainties are deep. For instance, the *maxi-min* criterion suggests choosing the decision with the best worst-case outcome and the *mini-max regret* criterion (Savage, 1951) suggests choosing the decision with the smallest deviation from optimality in any state of the world. Proposals for 'no regrets' adaptation decisions (Callaway and Hellmuth, 2007; Heltberg et al., 2009) employ such criteria. Hybrid criteria that balance between optimal and worst case performance have also been used to support climate related decisions (Hurwicz, 1951; Aaheim and Bretteville, 2001; Froyn, 2005).

In some cases, however, higher levels of uncertainty can also motivate the use of decision criteria that summarize trade-offs for decision makers. For instance, some CCIAV literature has used robustness, a satisficing criteria (Rosenhead, 1989) that seek decisions that will perform well over a wide range of plausible climate futures, socio-economic trends, and other factors (Dessai and Hulme, 2007; Groves et al., 2008; Wilby and Dessai, 2010; WUCA, 2010; Brown et al., 2011; Lempert and Kalra, 2011). Robustness criteria can often illuminate trade-offs that help decision makers achieve consensus on actions event when they do not agree on expectations about the future. The literature offers differing statements about the relationship between robustness and resilience (Folke, 2006; Gallopín, 2006), but resilience, described in detail in Chapter 20, tends to describe a property of systems, which might be affected by decision makers' choices, while robustness is a property (or not) of the choices made by those decision makers. Methods also exist to summarize trade-offs for decision makers for multiple objectives and higher levels of uncertainty, for instance by suggesting decisions that are robust over many futures and objectives (Kasprzyk et al., 2013).

2.2.1.3. Learning, Review, Evaluation, and Reflexiveness

Learning is a crucial aspect of CCIAV decision-making because climate change is sure to surprise us, both in its impacts and in the technological and behavioural changes that will affect society's ability to respond (National Research Council, 2009a). Much adaptation literature, including the iterative risk management framework (Figure 2-2), thus stresses the importance of decisions, systems, and processes that effectively respond over time to new information. Such new information includes observations of events that have occurred and anticipation of events that may occur in the future. For instance, the resilience literature provides frameworks for identifying systems with the ability to respond successfully to shocks. The climate adaptation literature distinguishes between *coping* and *adapting* (IPCC, 2012), and between *planned* and *unplanned* adaptation, to explore the benefits of appropriate responding to anticipated future events. Chapter 18 discusses the monitoring of impacts, necessary to any successful response. Learning processes are central to the discussions in Chapters 14 through 17 and in Chapter 20.

The concepts of adaptive management and adaptive decision-making, important themes in the CCIAV literature, can help decision makers incorporate learning into their plans. Adaptive management has a specific meaning in the literature, referring to situations in which the choice of policy is strongly influenced by a requirement to generate reliable new information (Holling, 1978, 1996), but the term is often used more generally to refer to policies that are designed to respond to new information. The former, sometimes called active adaptive management, might involve forest managers who purposely pursue alternative management practices on similar plots of land to gather scientific

data on the most effective practices. The latter, sometimes called passive adaptive management, might involve a water management agency that pursues a portfolio of supply investments, largely to manage risk, but also intending to shift investments in the future depending on which prove most successful. In both forms, adaptive management focuses on process and continuous learning (trial and error, small step→evaluate→adjust) (Dessai and Sluijs, 2007).

Methods and tools exist to help decision makers evaluate alternative adaptive strategies. These approaches are often used to represent the benefits and costs of learning in studies and simulation models that support climate-related decisions. The sequential decision approach, commonly used in the climate policy literature, represents policies as a sequence of choices over time, made with different amounts of information (Nordhaus, 1994). The real options approach draws from the finance literature to represent a near-term choice as creating the ability to make specific future choices under certain conditions. Real options approaches have recently been used in some adaptation studies (Hertzler, 2007) as well as those addressing greenhouse gas emissions reductions (Blyth et al., 2007) and investments in emissions reducing energy technologies (Mahnovski, 2007). Control theory provides another such representation (Funke and Paetz, 2011). Each approach can be used with many uncertainty representations and decision criteria.

Successful adaptive management and decision-making requires the inherently complex challenges of monitoring and evaluation (Governance and Social Development Resource Center, 2001). Decision makers concerned with monitoring and evaluation of adaptation policies, programs, and projects may determine what attributes to measure, for instance adaptive capacity, resilience, reduction of exposure, or vulnerability. Other dimensions include temporal scales, structural and non-structural measures (e.g., information sharing-flood forecasting and warning and behavioral changes) (Governance and Social Development Resource Center, 2001; Hedger et al., 2008). In some cases, it may also be useful to define an adaptation baseline(s) in order to evaluate the success of an implemented policy (Ebi et al., 2005; Vidhi and Sharma, 2010).

For example, Bangladesh has proposed a monitoring strategy for their already adopted national adaptation strategy and action plan. The action plan is comprised of six pillars – food security, social protection and health; comprehensive disaster management; infrastructure; research and knowledge management; mitigation and low carbon management; and capacity building and institutional strengthening (Government of Bangladesh, 2009). The plan calls for monitoring and evaluation of interventions for three purposes: their ability to reduce climate change vulnerabilities of human populations and natural and economic systems; their efficiency, flexibility, equity, results, cost-effectiveness and sustainability of the interventions (Hedger et al., 2008; Vidhi and Sharma, 2010); and their ability to avoid maladaptation (Mirza, 2009).

The decision support systems themselves can usefully be designed as learning processes. One useful approach, *deliberation* with analysis, provides an iterative process that begins with the many participants to a decision working together to define its objectives and other parameters, working with experts to generate and interpret decision-relevant information, and then revisiting the objectives and choices based on that information (Figure 2-4). Deliberation with analysis often proves most useful in situations with diverse participants to a decision in a changing environment whose goals emerge from deliberation and may change over time (National Research Council, 2009a; see Box 2-2 on the Louisiana Coastal Master Plan).

[INSERT FIGURE 2-4 HERE
Figure 2-4: Deliberation with analysis decision support learning process.]

Adaptive management and decisions can provide a means to develop strategies robust over a wide range of uncertainties, and has been increasingly pursued in many applications (Williams et al., 2009). However, adaptive management can be difficult to implement (National Research Council, 2009a), in large part because, without appropriate institutions, such strategies can be difficult to maintain. Monitoring and evaluation can prove difficult and costly, decision makers can be reluctant to gather data they may show their policies are not succeeding, and their organizations may not be sufficiently flexible to respond appropriately to new information (Lee 1993). In some cases decision makers may distrust the willingness or ability of their successors to respond to new information and will find it advantageous to enact policies that are difficult to change in the future.

The literature explores the relationships between learning and organizational change that can affect the ability of adaptive strategies to meet their goals in the face of uncertainty. The learning loop framework (Kolb and Fry., 1975; Argyris and Schön, 1978; Keen et al., 2005) divides learning processes into three categories, depending on the degree to which learning promotes transformational change in an organization's strategies. Single-loop learning processes focus on improving an organization's plans (Pelling et al., 2008) by adjusting policies based on the difference between what is expected and what is observed. Double-loop learning, in contrast, uses new information to question basis assumptions and reevaluate current knowledge, objectives, and strategies. Adaptive management, deliberation with analysis, and scenario practice are all processes that aim to routinely facilitate such double-loop learning by using data both to take corrective action and to change the frames through which issues are conceptualized. In triple-loop learning (Argyris and Schön, 1978; Peschl, 2007; Hargrove, 2008), decision makers may begin to question deep underlying principles (Pelling et al., 2008), for instance, considering how institutional and other power relationships determine perceptions of what is to be done and how (Flood and Romm, 1996). In response, they might seek to address how social structures, cultural mores, and other structures might be changed or transformed. The distinction between single-, double-, and triple-loop learning thus helps highlight the types of adjustments decision-makers can consider in the face of potentially significant, abrupt and surprising changes that may result from the interaction of climate change and socio-economic trends.

2.2.2. Institutional Context

Virtually all CCIAV decisions will be made by or influenced by institutions. The institutional context will thus prove an important influence on these decisions and on the way decision support is organized.

2.2.2.1. Institutions for Capacity Building

Institutions are imperative for effective management of climate change risks through proper governance. Institutions are defined as "…systems of rules, decision-making procedures, and programs that give rise to social practices, assign roles to the participants in these practices, and guide interactions among the occupants of the relevant roles" (IDGEC Scientific Planning Committee, 1999). Each institution has a set of objectives and goals that may be explicit or implicit and as such, each displays unique characteristics. The strength and nature of their role in maintaining a cohesive society enables societies to adapt to crises (O'Riordan and Jordan, 1999)**.** Institutions can facilitate environmental protection on one hand but on the other can also accelerate resource depletion by designing and implementing counter-productive policies (Scharpf, 1997). Institutions can constrain and shape human interaction through direct control, through incentives, and through processes of socialization (WGIII; SRREN). The rules and roles of institutions for whatever reason(s) they have been created can be of many forms: formal and informal, visible and latent, and conscious and unconscious (Arts et al., 2006). Governments create formal institutions that play an important role in vulnerability reduction and adaptation (Gupta et al., 2008). Agarwal et al. (2008) analyzed the roles of local institutions in adaptation and categorized them into local public, civil society and private institutions. As adaptation is generally a local issue, local institutions play important roles in the process by interacting with national and regional institutions.

Smit et al. (2001) identified institutions as one of the key determinants of adaptive capacity. Countries with strong institutions are generally assumed to have a greater capacity to adapt to current hazards and disasters as well to the future. However, this is not necessarily true in all cases. Hurricane Katrina of 2005 in the USA and the European heat waves of 2003 demonstrate that strong institutions and other determinants of adaptive capacity do not necessarily reduce vulnerability if not translated to actions (IPCC, 2007)(also see in section 2.3.2.2). Generally for economic and technological reasons, most of developing countries have weaker institutions that are less capable of managing hazards and disasters of catastrophic nature. For example, Lateef (2009) conclude that institutional weaknesses in healthcare and disaster preparedness led to high casualties from the cyclone Nargis in Myanmar in 2008.

Uniform presence of institutions can reduce vulnerability and contribute to increase adaptive capacity. Berman et al. (2012) suggest that institutions play a key role in mediating the transformation of coping capacity into adaptive

capacity and in linking short and long-term responses to climate change. Institutions that can appropriately respond to climate challenges are unevenly distributed especially within marginalized regions or indigenous territories. Examples from Latin American demonstrates that institutional limitations can prevent the effective participation of indigenous people in climate change adaptation initiatives (Kronik and Verner, 2010).

Climate change is a development issue and the risks from climate change could significantly impact sustainable development in developing countries. Mirza (2003) argued that vulnerability to extreme weather events, disaster management and adaptation must be part of the long-term sustainable development planning in developing countries. This will require development assistance to explicitly consider climate change risks, and to include capacity-building to respond to climate change as a part of investments in recovery and infrastructure development. Multilateral institutions are responding to these challenges. For example, the World Bank supports both reactive and pro-active types of projects on adaptation (Agarwal et al., 2008).

Aid is becoming more focused on adaptation to climate change, disaster risk reduction and adaptation are merging at the policy to program levels and traditional activist and advocacy organizations are becoming more professional and being involved in program delivery. Bartley (2007) describes the latter as a form of channeling where foundation patronage and organizational field building is leading to social movement organizations becoming involved in mainstream project delivery. This model fits the growth of adaptation where aid funders such as USAid and foundations such as the Rockefeller and Gates Foundations are providing complementary funding that is fuelling program delivery involving environmental and development NGOs with local stakeholders (Ziervogel and Zermoglio, 2009; Kolk and Pinkse, 2010; Worthington and Pipa, 2010).

Understanding collective institutional or organizational frames offers a way to overcome barriers to adaptation when competing collective frames such as economy versus environment are preventing the integration of both into policy and action (e.g., Hoffman and Ventresca, 1999). Frame structure, content, dynamics and diffusion can be understood in order to encourage social movements to action around an issue, through diagnosis, prognosis and motivation (Benford and Snow, 2000). Discursive frame analysis that understands how various issues are described, the actors involved and their methods of organization. Brulle (2010) discourages targeted public campaigns intending to increase awareness and thus action that are based on cognitively and psychologically-designed appeals to the individual for a more participatory approach based on civic engagement using a process called Analytic Deliberation.

2.2.2.2. Governance, Legal Dimensions, and Decision Implementation

Governance is often visualized as a rigid, centralized, unitary, top-down process of rules and policy development in the public interest that have to be implemented at local level (Commission on Global Governance, 1995). Krahmann (2003) argues that governance is considered as a flexible, diffuse, bottom-up and top-down process that interact between different tiers of government and with a range of social actors. Governance and good governance are often seen as key institutional settings for addressing problems (Botchway, 2001). Climate change governance requires action for both adaptation and mitigation. IPCC (2007) stated that many early impacts of climate change could be effectively addressed through adaptation but the options for successful adaptation diminish and the associated costs increase with increasing climate change. However, adaptation alone is not expected to cope with all the projected effects of climate change, especially not over the long term as most impacts increase in magnitude (IPCC, 2007). Governance of adaptation requires knowledge of anticipated regional and local impacts of climate change (Meadowcroft, 2009).

Climate change and the associated risks have national and international legal dimensions. There are many *national level* legal implications of climate change. Considering Bangladesh as a case study, Freestone et al. (1996) identified that nationally climate change and sea level rise would affect property rights and land tenure, population displacement, rehabilitation and resettlement, and institutional frameworks involving with these issues. The *international legal aspects* of climate change impacts and risks would come from a variety of angles. Sea level rise could alter the *maritime boundaries* of many nations that may lead to new claims by the conflicting nations. The open waterways for shipping is very *likely* to change in specific, measurable ways in the next several decades

Reductions in sea ice in the Arctic may allow new trade passages such as the North West Passage to be established (Chapter 6). Climate change could also lead to access to resources that were previously technically inaccessible and that may result in new territorial claims. Runoff changes in the international rivers due to reduced seasonal precipitation could result in new *water conflicts* and *energy utilization* among the co-basin countries and can also pose challenges to the already signed sharing agreements (Kim, 2010). Additional *food insecurity* due to climate change will pose a moral challenge and human rights question regarding food supply from the developed countries to affected regions. Many national and international legal institutions and instruments need to be updated to face climate related challenges and decision implementation.

2.2.3. Social Context

Decision support for CCIAV must recognize that people and culture with its diverse values, language uses, ethics and human psychological dimensions play a crucial role in the way that people use and process information and take decisions (Kahan and Braman, 2006; Leiserowitz, 2006).

2.2.3.1. Value Setting

The majority of climate change research conceptualizes values as monetary worth, relative worth, or fair return on exchanges, drawing primarily on welfare economics and using cost-benefit analysis or contingent valuation to estimate losses (Watkiss, 2011). These values reflect a neoclassic economic framing of the issue. Increasingly, however, a number of authors have argued that a broader conceptualization of values is needed to understand and respond to climate change (Adger et al., 2009; O'Brien, 2009; O'Brien and Wolf, 2010). Chapter 17 investigates the use of tangible and intangibles in assessing the economics of adaptation, but here we take a broader look at how values influence decision-making.

In this broader conceptualization, values are understood as the subjective, qualitative and intangible dimensions of climate change and its impacts that are of importance to individuals and cultures (O'Brien and Wolf, 2010). Such values may concern how climate change affects, for example, place identity, land-based or traditional practices important for cultures, and the symbolic meanings of places and practices, in particular where irreversible losses may occur. Such values shape how the effects of climate change are perceived and how responses, including adaptation decisions, are addressed.

In the context of dangerous climate change, it has been acknowledged that judgment and "values matter for converting science into policy" (Oppenheimer, 2005, p. 1401). Others argue that the difficulty in compensating for irreversible losses due to incommensurable values points to a need for other principles, such as the precautionary approach, to be utilised in global climate policy (Adger et al., 2011). O'Brien and Wolf (2010) suggest that people's value orientations be allowed to determine what is perceived to be worth preserving and maintaining through adaptation (and indeed mitigation) decision making. Despite a growing recognition that values matter, however, there is limited research that explicitly considers the role that such values play in shaping adaptation decisions.

The importance of values in decision making related to climate change are operating at two levels:

1) Larger socially shared values of a given culture and of groups and individuals within that culture
2) Values related to the work, including decision making, in modern organizations and in management.

The first issue is mainly studied by anthropologists, cross-cultural and environmental psychologists, revealing an important diversity of values across cultures that influence individual, local, national, even international decision-making. Values, as abstract entities, guide decision-making processes and are realized in real acts. The anthropological literature shows the importance of religious, sacred values related to climate (Goloubinoff et al., 1998; Katz et al., 2002; Lammel et al., 2008). Such values can inform the perception of climate change, as well as the actions to protect against its consequences (Crate and Nuttal, 2009).

The values of a given society are fundamental to the development of attitudes, cognition, emotions and behaviors. Kluckhohn and Strodtbeck (1961) identified five basic, relatively stable value orientations (Values Orientation Theory) that allow societies to find value-based solutions to universally important questions. Three of the five value orientations influence climate change related decisions: peoples' relations with time, nature and each other:

- For temporal values, the main cultural differences concern time orientation (past/present/future)
- For the relationship with nature, cultural differences involve mastery, harmony, submission
- For the relationship with each other, the three culturally different value orientations are: hierarchical (lineal); egalitarian (collateral) and individualistic.

Kluckhohn and Strodtbeck (1961) theory influenced a great number of cross-cultural and environmental psychological studies seeking 'universal' dimensions of values and their culturally different manifestations (e.g., Hofstede, 1980; Schwartz, 1992; Hofstede and Hofstede, 2001; Rokeach, 2008).

Environmental decision making is highly influenced by culturally elaborated values. Schultz et al. (2004) link values, attitudes, world views and behaviours to the environment. They differentiated three sets of values, described previously by Stern et al. (1995):

1) *Egoistic values* focused on values and goals oriented toward the interest of the self (me, my future, my wealth, my health)
2) *Altruistic values* focus on others (future generations, humanity, people of the community, children)
3) *Biospheric values* focus on the wellbeing of living things (plants, animals, marine life, birds).

Schultz et al. (2004) tested whether differences in a person's information processing could be correlated with their connection to nature. They concluded that a weak connection with nature is associated with local information processing; conversely, a greater connection is associated with more comprehensive information processing. Many studies have added new perspectives (e.g., Milfont and Gouveia, 2006; Soyez et al., 2009) showing that cultural values can substantially influence the decision-making processes. Values are also related to 'environmental concerns' (Stern and Dietz, 1994; Xiao and Dunlap, 2007) influencing public behaviour toward policies. Schaffrin (2011) insists that geographical aspects, vulnerability and benefits from policies are important in value orientation and can influence the vision global/local and short term/long term dimensions of climate change (e.g., (De Groot and Steg, 2007, 2008; Shwom et al., 2008; Milfont et al., 2010). Pelling et al. (2008) found that accounting for values within officially and unofficially-sanctioned relationships could enhance social learning and therefore adaptive capacity. Nyong et al. (2007) found that the moral economy in indigenous African communities provided direction for implementing both adaptation and mitigation actions.

The cultural theory of risk perception (Douglas and Wildavsky, 1982) has also been used to successfully group beliefs on contentious scientific issues such as climate change using the structural settings *hierarchical* and *egalitarian* with the value settings *individualist* and *communitarian* (Kahan et al., 2007; Kahan, 2008). It has been proposed that such knowledge could contribute to various policies on adaptation by tailoring the framing of those policies according to the belief structures inherent within cultural theory (Adger et al., 2009; O'Brien and Wolf, 2010).

National values also influence local organizational values. Hofstede (1980); Hofstede and Hofstede (2001) using a large database, collected in subsidiaries of the multinational corporation IBM, identified firstly in 40 and later in 76 countries (Hofstede et al., 2010), five value dimensions with significant cross-national differences: power distance, individualism/collectivism, uncertainty avoidance, masculinity/femininity and long/short term orientation.

While a substantive gap exists in research that can apply knowledge of personal and cultural values to decision-making on climate change, this area is receiving a good deal of attention (Nilsson et al., 2004; Leiserowitz, 2006; Lorenzoni et al., 2007; De Groot et al., 2010). The above studies on values can provide important theoretical and methodological tools for further research and its integration into decision making practices. Such research could assist in building legitimate, transparent and inclusive responses including policy on climate change [moderate confidence].

2.2.3.2. Cultural Determinants and Psychology

At the individual level, decision-making is a multi-directional and non-linear cognitive activity. Responses to new information can modify previous decisions, even producing contradictory results. Decision-making in climate change problems cannot be described as rational and can negatively affect environmental behaviour (Grothmann and Patt, 2005; Marx et al., 2007). Many strategies are used by individuals in making adaptation decisions (Fischer and Glenk 2011) suggesting that a uniform approach to problem solving is unlikely to succeed.

Ignatow (2006) distinguishes between two cultural models: the 'spiritual' and the 'ecological' that have different social bases. Western education generally involves the second but not the first. In the spiritual model, nature is sacred, has its own rights and should be kept separate from human society. It is threatened by science and technology and has to be respected. The ecological model represents nature as an ecosystem physically integrated into human society (Bocking, 1994). There is no inherent conflict between the society and nature, thus science and technology can be used to integrate modern society with the natural environment (Oates, 1989).

The perception and representation of nature and the environment are influenced by the dominant modes of thought in a society. Cultural psychology distinguishes between two main systems of thought: holistic and analytical thinking (Lammel and Kozakai, 2005; Lammel et al., 2011). Holistic thinking characteristic of collectivist societies consider that social obligations are reciprocal and individuals take part in a community with strong ties (Peng and Nisbett, 1999; Nisbett et al., 2001), such as in a gift economy. Such holistic thinking is built primarily on the knowledge gained through experience and not through abstract logic. It is dialectical and accepts contradictions and multiple perspectives, trying to find a middle stance between opposing propositions. Holistic thinking is associative and its computations reflect similarity and contiguity.

In more individualistic societies, the analytical model is central. Individual interests take precedence over societal interests; the self is independent and communication comes from separate fields: benchmarks are not common. The object is isolated from its context; the focus is on understanding the characteristics of the object to determine its category membership, and explain and predict events based on its intrinsic rules. Inferences are derived from contextualizing the content structure, using formal logic and avoiding contradiction. Analytical thinking circumscribes symbolic representation systems; instead its formalization is built on structures of rules. Several studies demonstrate the influence of this way of thinking on complex problem-solving (e.g., Badke-Schaub and Strohschneider, 1998; Strohschneider and Güss, 1999; Güss et al., 2010).

An increasingly extensive literature highlights the importance of taking into account cultural/local knowledge, traditional ways of thinking and traditional methods of decision-making when assessing CCIAV (Vedwan, 2006; Nyong et al., 2007; Dube and Sekhwela, 2008).

Psychological factors

The psychological literature on decision in context can help to understand how to make better decisions. Several theories, such as the multi-attribute utility theory (Keeney, 1992), prospect theory (Kahneman and Tversky, 1979; Hardman, 2009), and the cumulative prospect theory relate to decision making under risk or uncertainty (Tversky and Kahneman, 1992). Recent cognitive approaches, such as the one-reason decision process (e.g. (Gigerenzer and Goldstein, 1996) or the decision by sampling theory (Stewart et al., 2006; Stewart and Simpson, 2008) integrate even more psychological factors.

Personal dilemmas are frequently related to utility and probability (short/long term) (e.g., Hoch and Loewenstein, 1991). Social dilemmas are very important because individual utility maximization can cause collective loss ('commons problem') (Hardin, 1968). Decision-making can also be realized without thinking. The dual process theory of thought states that human being possess 'two minds'. System 2 is rational (trade-offs between utility and probability) meanwhile the System 1 is intuitive, an unconscious kind of thought (Myers, 2004; Stanovich, 2005), leading to frequently observed behavioral inconsistency. In terms of cognitive economy, decision making without

thinking or by 'feelings' are automatic, unconscious, fast and effortless and widely used (Slovic et al., 2002; Evans, 2008).

Psychological factors important for decision-making on climate change include: perception, representation, knowledge acquisition, behavior, emotions and understanding of risk (Oskamp and Schultz, 2006; Gifford, 2008; Kazdin, 2009; Reser et al., 2011; Swim et al., 2011). Investigations of public perception and climate change representation (e.g., Böhm and Pfister, 2000; Lorenzoni et al., 2006; Sterman and Sweeney, 2007) suggest that certain perceived characteristics of climate change may lead individuals to underestimate the magnitude of risk (Böhm and Pfister, 2000; Sundblad et al., 2009). Different explanations include (Leiserowitz, 2006): (1) Optimism, downsizing personal risks; (2) The perceived signs of climate change seem to be "natural"; (3) Perceived as normal variations in weather; (4) Natural variation in the world's climate is a low risk; (5) People probably do not have necessary emotional or cognitive capacities to make an adequate risk evaluation. These findings show the importance of experiential factors in understanding phenomena and the strong influence of experiential decision making as contrasted with analytic decision making.

Psychological obstacles in processing climate change information include psychological distances that have four theorized dimensions: temporal, social, and geographical distance, and uncertainty (Spence et al., 2012). Attitudes and behaviors relevant to climate change engagement, include place attachment (Scannell and Gifford, 2013), political affiliation (Davidson and Haan, 2011), and perceived costs and benefit (Tobler et al., 2012).

The relationship between cognition and behavior influences people's adaptive actions, especially to perceived risk and the effectiveness of action. Grothmann and Patt (2005) apply a socio-cognitive model of proactive private adaptation to climate change impacts that predicts, for instance, if a high risk is combined with low capacities response is fatalism, denial and wishful thinking. Emotional factors also play also an important role in climate change perception, attitudes, decision making and actions (Meijnders et al., 2002; Leiserowitz, 2006; Klöckner and Blöbaum, 2010; Roeser, 2012) and even shape organizational decision making (Wright and Nyberg, 2012).

Knowledge about climate change is necessary to increase overall concern and greater perceived efficacy and responsibility (Milfont, 2012). However studies in education (Rajeev Gowda et al., 1997; Boyes et al., 1999; Andersson and Wallin, 2000) show the difficulties in understanding the scientific process of global climate change. Shepardson et al. (2012) insist that a systemic vision of climate is needed for such understanding. Even highly educated adults can have a very elementary cognitive representation of climate change, creating cognitive vulnerability (Lammel et al., 2012). In the USA, limited understanding has led to "wait-and-see policies" and to the absence of effective decision making on adaptation (Sterman and Sweeney, 2007; Dutt and Gonzalez, 2012). Even policy makers have cognitive difficulties in understanding climate change, for instance, in Sweden, their knowledge is less important than journalist's knowledge (Sundblad et al., 2009).

Sterman and Sweeney (2007) propose to communicate climate change issues through clear analogies and metaphors. Other form of intervention to help the development of climate change knowledge and concern, without the experiential factor, can be the simulations by stirring artistic approaches (films, music, paintings) and the activation of emotions (Weber, 2006).

2.2.3.3. Language and Meaning

This section deals with: 1) the various terminologies used by different disciplines that intersect in decision-making on climate change; 2) the relationship between technical and everyday definitions exercised in the decision-making process and 3) the use of narratives to communicate meaning, values and experience.

The previous sections emphasise that decision-making processes need to accommodate both specialist and non-specialist meanings of the concepts they apply. Previous IPCC reports have provided technical definitions for a range of such terms in order to focus climate research and provide rational policy advice. However, the decision-making process surrounding vulnerability and adaptation assessment is broader than the technical aspects addressed in IPCC definitions and language (Adger, 2003; Füssel, 2007; O'Brien et al., 2007). Various disciplines often have

different definitions for the same terms or use different terms for the same action or object, which is a major barrier for decision-making (Adger, 2003). For example, adaptation is defined differently with respect to biological evolution, climate change and social adaptation.

Covering both technical and everyday meanings of key terms can help bridge the analytic and emotive aspects of cognition. For example, words like danger, disaster and catastrophe have technical and emotive aspects (Britton, 1986; Carvalho and Burgess, 2005). Terms where this issue is especially pertinent include adaptation, vulnerability, risk, dangerous, catastrophe and disaster. Other words have definitional issues because they contain different epistemological frames; sustainability and risk being key examples (Harding, 2006; Hamilton et al., 2007). (Budescu et al., 2012) found that people prefer imprecise wording but precise numbers when appropriate and that people's personal lexicons are very different so that uncertainty terms are interpreted very widely, and in the IPCC's case, differently to the uncertainty ranges intended. Many authors advocate that narrow definitions focused solely on climate need to be expanded to suit the context in which they are being used (Huq and Reid, 2004; O'Brien et al., 2007; Schipper, 2007).

The language of risk, because of its central role in decision-making on climate change, is especially important. Risk is a polyseme, a word with multiple, related meanings. A definition of risk therefore needs to encompass its polysemic nature, which technical definitions generally do not (Hansson, 2004). Meanings of risk range from its ordinary use in everyday language to power and political discourse, health, emergency, disaster and seeking benefits. Meanings range from specific local meanings to broad-ranging concepts such as the risk society (Beck and Ritter, 1992; Beck, 2000; Giddens, 2000). Thus, the hierarchy of approach, methodology and methods presented in Section 2.1 can be used to organise such differences in meaning and use.

Linguistic studies conclude that dictionary definitions are inadequate for communicating the complex framings involved in the word risk (Fillmore and Atkins, 1992; Hamilton et al., 2007), finding much richer meanings in text databases. The word risk occurs as both a noun and a verb and reflects harm and chance with negative and positive senses (Fillmore and Atkins, 1992). Hamilton et al. (2007) found an emphasis on health with no overwhelmingly negative or positive tendencies. Informal use tended towards personal risk, whereas formal use was more abstract, being technical and pedagogical. *The only observable pattern is the association with some form of assessment of the risk involved and the uncertainty that defines this assessment* (Hamilton et al., 2007).

These studies suggest that people do assess risk, balancing likelihood and outcome in a similar manner to formal risk assessment, confirming that risk, at least when consciously applied, forms the core of decision-making under uncertainty. The broad, generic description revealed by linguistic analysis is also consistent with the recent move in the risk literature to broad definitions of risk away from narrow technical definitions (Rosa, 2003; ISO, 2009).

In complex situations, the change between the problem-oriented component of risk assessment to the solution-oriented component shows the wording risk changing from a noun to a verb. Problem analysis applies risk as a noun (at-risk), whereas risk management applies risk as a verb (to-risk) (Jones, 2011). This reflects a change from core risk types of Hamilton et al. (2007) such as *asset* and *harm* associated with at-risk to *action* and *agent* associated with to-risk. For simple risks this transition is straightforward, and can be assessed using linear methods because of agreement around values and agency.

In complex situations, problem risk (at-risk) and solution risk (to-risk) compete with each other, often becoming amplified socially and leading to action paralysis (Renn, 2011). For example, unfamiliar adaptations that are themselves risky will force a comparison between the risk of maladaptation and future climate risks, echoing the risk trap identified by Beck where problems and 'solutions' come into conflict (Beck, 2000). Decision support for such complex risks needs to allow for the emotive and cognitive aspects

Much mental representation and subsequent expression is non-verbal. Language is but not the only tool important for communication and learning: visualization, kinetic learning by doing and other sensory applications can be used to communicate science, art and through play (Perlovsky, 2009; Radford, 2009). Much of this is carried out through various narratives. Narratives are accounts of events with temporal or causal coherence that may be goal directed (László and Ehmann, 2012). They range between being individual to organizational and institutional to cultural

narratives and are an innate property of the expression of mind in communication with one's-self or another. As such they are a "tool or process for making sense of events" (Gephart Jr, 1991) and have a strong role in creating social legitimacy. Narratives of issues such as climate change evolve over time and have a great influence on shaping public debate (Hamblyn, 2009).

Two aspects that scientific and adaptation narratives aim to address are (Cohen, 2011; Jones et al., 2013):

1) The transferral of knowledge and ideas to increase agency
2) The responses at an individual/institutional level to an aspect of adaptation, and communicate that experience with others.

The first aspect translates specialist knowledge into a common understanding so that actions can be implemented through a set of discursive frames (Juhola et al., 2011). This narrative bridges the route between scientific paradigm and adaptation methodology. This is often achieved by working with multiple actors in order to creatively explore potential solutions.

The second aspect concerns the stories that relate people's own responses to climatic impacts and other aspects of change (Bravo, 2009; Cohen, 2011). This is a complex area, as the narratives that inform these narratives relate strongly to identity, culture and perceptions of risk and are context specific. They provide the social construction within which decisions may be applied and also inform the nature of responses to future climate events. For example, a community that believes itself to be resilient and self-reliant is more likely to respond proactively, contrasted to a community that believes itself to be vulnerable (Jones et al., 2013). Bravo (2009) maintains that narratives of risk and vulnerability demotivate indigenous peoples whereas scientific and active citizenship narratives provide a framing that promotes resilience.

2.2.3.4. Ethics

The field of climate ethics has been developing over the last 20 years (Jamieson, 1992, 1996; Gardiner, 2004; Gardiner et al., 2010), resulting in a substantial recent literature (e.g., Garvey, 2008; Harris, 2010; O'Brien et al., 2010; Arnold, 2011; Brown, 2012; Thompson and Bendik-Keymer, 2012). Climate ethics can be considered as a social technology used to formalize values (Section 2.2.3.1) and rights into decisions, decision-making processes and actions.

However, the theoretical underpinning of climate change ethics, remains tenuous due to lack of experience, controversies and the complex nature of the problem. In climate change ethics the concept of vulnerability and adaptability do not concern only "nature", the land, in the sense of Leopold (1949), but also the ethical positions toward "some of the poorest and most economically disadvantaged societies of the world" (Pachauri, 2010; vii). It also concerns the co-benefits of the mitigation projects of developed countries (Pachauri, 2010). Climate ethics deals with scientific research results, economic as well as policy. It plays a fundamental role on global climate agreements and decision making.

Climate change can be considered as a primarily ethical question, because of important conflicts of interest (Broom, 2008) requiring complex ethical considerations at all levels. "The dominant discourses about the nature of the climate threat are scientific and economic. But the deepest challenge is ethical" (Gardiner, 2011; xii). The main ethical concerns include: intergenerational equity, distributional issues, scientific uncertainty, economic, policy decisions, international justice, low, voluntary and involuntary risk, cross-cultural relations, human relationship to animals and the rest of nature, technological and the socio-cultural worlds. From a philosophical perspective, climate change is related to environmental and ecological ethics, but previous ethical considerations did not have to consider the globality of the human condition, the distant future, nor the survival of humanity (Gardiner, 2011).

The notion of equity/inequity and responsibility are basic concepts in the United Nations Framework Convention on Climate Change (UNFCCC) Article 3 stating that "The Parties should protect the climate system for the benefit of the present and future generations of humankind, on the basis of equity and in accordance with their common but different responsibilities in respect to capacities" (United Nations, 1992).

Schneider and Lane (2006) distinguish three fields: (1) inter-country equity, (2) intergenerational equity, and (3) interspecies equity. Thomas and Twyman (2005) defined a 4th field, the intra-country or sub-national equity. A 5th topic on ethical factors concerns the necessity of a critical attitude toward future energy alternatives and, recently, geo-engineering. It is necessary to develop equitable solutions in view of protecting the most vulnerable groups and life forms (Wilkinson et al., 2007).

2.2.3.4.1. Inter-country issues

For CCIAV, the major discourse on equity is that the industrialized countries have caused most of the historical emissions, creating a natural debt (Green and Smith, 2002). There is an asymmetry between rich and poor nations concerning the higher impacts and greater vulnerability faced by developing countries and their lack of adaptive capacity with respect to developed countries. The neoclassic economic cost and benefit approach is ethically problematic because it does not cater for these differences (Broom, 2008). Recent policy developments at the international level involve the creation of an Adaptation Fund and fund for least developed countries, and include bilateral and multi-lateral aid agreements (Bouwer and Aerts, 2006; Clemencon, 2008).

2.2.3.4.2. Intergenerational issues

Intergenerational questions are frequently treated as an economic issue. The standard economic vision supposes that world economy grows continually, but important discussions (e.g., Nordhaus, 2007; Stern and Treasury of Great Britain, 2007) also relate to the duty to decide to act now (Stern, 2008). Future harm, and possibly catastrophe, may make the life of future generations difficult or impossible. These dilemmas involve ethical choices (Broom, 2008). Caney (2009) questions if the rights and interests of future people should be subject to a positive discount rate. Some philosophers consider that future generations can't defend themselves within current economic frameworks (e.g., Gardiner, 2011). Classical economics is based on Enlightenment notions and on the principle of abstract logic and disembodied rationality that cannot properly account for the dangers, interdependency and uncertainty under climate change (Nelson, 2011). Asymmetry between the present and future generations has changed: the future was once considered in the light of the past, now is considered in the light of the present (Bensaude-Vincent, 2009). Current economic discussions, in purely monetary terms, represent a unique view in history, as Gardiner (2011) stated, parents and grandparents did care about what they left to children and grandchildren, but this is not being reflected at the broader social scale.

2.2.3.4.3. Biotic ethics

Environmental ethics considers the decisions humans have to make concerning a range of biotic impacts (Schalow, 2000; Minteer and Collins, 2010; Nanda, 2012; Thompson and Bendik-Keymer, 2012). Some authors consider that up to 35% of the world's species could be in danger of extinction due to climate change's consequences (Thomas et al., 2004). These situations may require species relocation but 'assisted colonization' or 'managed relocation' but these proposals raise important ethical and policy questions. Minteer and Collins (2010) propose 5 key themes for decision making: 1. What criteria are used to select candidate populations? 2. How should these methods be combined with traditional ex-situ approaches? 3. Who should such decisions and implements them? 4. What are the key motivations and risks? 5. What constitutes environmental responsibility? Various claims are made for a more pragmatic ethics of ecological decision-making (Minteer and Collins, 2010) consideration of moral duties toward species (Sandler, 2009) and ethically explicit and defendable decision-making (Minteer and Collins, 2005a, b).

2.2.3.4.4. Intra-country inequity

Intra-country inequity relates to human and environmental exposure to risk or health impacts connected to climate change. Climate change ethics need to be further development in this field (Green and Smith, 2002). Of particular

concern are indigenous or marginalized populations who are often exposed to current climate extremes and natural disasters, with climate change exacerbating such ethical dilemmas (Tsosie, 2007).

2.2.3.4.5. Future energy alternatives and geo-engineering

Ethical issues on decision-making related to the fields of adaptation, mitigation or transformation due to climate change are emergent issues and are linked to economic and political decision-making. The limits of adaptation creating a case for geoengineering has come under recent consideration (Travis, 2010) and Chapter 19.

Another feature of climate change ethics concerns individual responsibility. Global climate change may also concern individuals who are 'world citizens'. Some authors advocate a new world ethics (Dower, 1998; Harris, 2010) consisting of moral values, norms and responsibilities applied globally. Cosmopolitan ethics and global justice can lead to successful mitigation and sustainability (Caney, 2006; Harris, 2010) and lead to collective decision-making on public matters through voting procedures (Held, 2004). Climate ethics argue for the necessity of effective responsible and 'moral' decision-making and action, not only by governments but also by individuals (Garvey, 2008). Hansson (2004) maintains moral appraisal is required for evaluating risks and benefits in order to establish equity, especially in the face of uncertainty.

Although the climate change ethics literature is rapidly developing, the related practice of decision-making and implementation needs further development. Moral and ethical issues are discussed at length in WG III, Chapter 3 *Social, Economic, and Ethical Concepts and Methods*.

2.3. Support for Climate-Related Decisions

Growing understanding of the aspects of decision-making (Section 2.2) can improve support for CCIAV decisions. This understanding informs the elements and principles of effective decision support (2.3.1), methods for impacts and vulnerability assessments (Section 2.3.2), the provision of climate information and services (Section 2.3.3), and a wide variety of other applications (Section 2.3.4).

2.3.1. Elements and Principles of Effective Decision Support

Decision support (Section 2.2) consists of three types of elements: 1) **products**: tangible deliverables including data, maps, projections, models and tools; 2) **services**: activities, consultations, and other forms of interactions with decision makers; and 3) **support systems**: individuals, organizations, communications networks, and supporting institutional structures that provide decision support products and services (NRC 2009a). For example, the institution (IPCC) that produced this report represents a decision support system. Much of this report, including Section 2.3.2 below, describes decision support products. These products can be used to inform decision support services, such as those in Section 2.3.3.

_____ START BOX 2-2 HERE _____

Box 2-2. Managing Wicked Problems with Decision Support

A well-designed decision support process, combined with auspicious political conditions, can effectively address 'wicked' (Section 2.1) decision challenges.

The State of Louisiana faces a serious problem of coastal land loss, imperiling the region's economically vital fisheries and heightening the risk of storm surge damage to the City of New Orleans, facilities accounting for about 20% of U.S. oil and gas production, and one of the United States' largest ports (CPRA 2012). Previous efforts at comprehensive coastal protection had been stymied by, among other factors, numerous competing jurisdictions and stakeholders with a wide range of conflicting interests.

In the aftermath of Hurricane Katrina, the state embarked on a new coastal planning effort, this time with extensive decision support. The Louisiana state Coastal Protection and Restoration Authority organized an extension decision support effort with a network of about a dozen research institutions interacting with a 33-member stakeholder group consisting of representatives from business and industry, federal, state, and local governments, nongovernmental organizations and coastal institutions. In dozens of workshops over the course of two years, these stakeholders influenced the development of and interacted with a decision support system consisting of two parts: 1) a regional model that integrated numerous strands of scientific data into projections of future flood risk (Fischbach et al., 2012) and 2) a multi-attribute planning tool that allowed stakeholders to explore the implications of alternative portfolios of hundreds of proposed risk reduction projects over alternative sea level rise scenarios (Groves et al., 2012). This decision support system allowed decision makers and stakeholders to first formulate alternative risk reduction plans and then to visualize outcomes and tradeoffs up to fifty years into the future.

The resulting Master Plan for a Sustainable Coast passed the state legislature on a unanimous vote in May 2012. Deviating strongly from past practice, the plan allocates far more resources to restoring natural barriers than to structural measures such as levees. The plan balances between the interests of multiple stakeholders and contains some projects that offer near-term benefits and some whose benefits will be largely felt decades from now. Many participants and observers of this process credited the extensive analytic decision support for significant contributions to this plan.

_____ END BOX 2-2 HERE _____

The effectiveness of decision support can be judged by the extent to which it increases the likelihood that decision-relevant information is produced and incorporated into decision making. Effective decision support provides users with information they find useful because they consider it credible, legitimate, actionable, and salient (e.g., Jones et al., 1999; Cash et al., 2003; Mitchell, 2006; Reid et al., 2007). Such criteria can be used to evaluate decision support (CITE) and such evaluations lead to common principles of effective decision support, which have been summarized in National Research Council (2009b) as:

1) Begins with user's needs, not scientific research priorities. Users may not always know their needs in advance, so user needs are often developed collaboratively and iteratively among users and researchers.
2) Emphasizes processes over products. While the information products are important, they are likely to be ineffective if they are not developed to support well-considered processes.
3) Incorporates systems that link users and producers of information. These systems generally respect the differing cultures of decision makers and scientists, but provide processes and institutions that effectively link individuals from these differing communities
4) Builds connections across disciplines and organizations, in order to provide for the multidisciplinary character of the needed information and the differing communities and organizations in which this information resides
5) Seeks institutional stability, either through stable institutions and/or networks, which facilitates building the trust and familiarity needed for effective links and connections among information users and producers in many different organizations and communities.
6) Incorporates learning, so that all parties recognize the need for and contribute to the implementation of decision support activities structured for flexibility, adaptability, and learning from experience.

These principles can lead to different decision support processes depending on the stage and context of the decision in question. For instance, decision support for a large water management agency operating an integrated system serving millions of people will have different needs than a small town seeking to manage its ground water supplies. A community in the early stages of developing a response to climate change may be more focused on raising awareness of the issue among its constituencies, while a community with a well-developed understanding of its risks may be more focused on adjudicating trade-offs and the allocation of resources. Each community will have different decision support needs.

Attributes and Resources

Better decisions need to be actionable and effective. Actionable decisions require a clear plan of implementation, have buy-in from stakeholders and if required, an institutional and governance framework. Effective decisions should produce the intended outcomes over a prescribed of time. Outcomes are subject to how a system responds to the decisions that have been made combined with internally and externally-driven change processes. In a simple system, the response will be proportional to the action, but in a complex system, many other factors can intrude. A better decision in the short term may not prove to be better over the long-term if a system changes its behavior or the definition of what is considered positive, changes.

Supporting good decisions requires appropriate resources and attention to the various attributes of decisions. The latter may be grouped into two broad categories: problem-based and solution-based.

Problem-based attributes may include the extent to which a situation is simple or complex. In the former, climate may be the dominant stressor and direct cause and effect can be identified. In the latter, climate may be one of multiple drivers of change, system feedbacks are strong and where adaptive responses are likely to change how the system behaves. Problem-based attributes also include spatial, institutional and time scales. Spatial and institutional scales tend to be associated with top-down and bottom-up directions of assessment. Spatial scales range from local (bottom) to global (top) and institutional scale from local to international. Time scales are associated with short- and long-term as temporal scales and fore- and back-casting in terms of directional scale. These scales can combine in a variety of ways.

Solution-based attributes strongly utilize creativity (Torrance, 1988). Creativity, as part of innovation provides the flexibility to explore the solution space combining problem solving within the broader context of normative goals. Creativity can be linked to the decision-making process and innovation to the development and implementation of tools, both cognitive and technological. Recent research into creativity suggests that rather than being uncontrolled brainstorming where anything goes, creativity is developed through a process of disciplined acts that seeks alternatives within a pre-defined set of boundary conditions (Sternberg, 1988; Sawyer, 2007). For CCIAV these conditions include scientific plausibility and factors such as economic efficiency, distributive fairness, scalability and so on.

In all but the simplest problems, a decision support process will iterate between the deliberation and analysis steps shown in Figure 2-4 (in Sec 2.2.1.3), exercising both problem and solution-based attributes.

Effective decision making also employs resources including leadership, institutions, and knowledge.

Leadership has been described as the ability to motivate others to achieve a set of goals and can be a characteristic of an individual within a group, or an organization (Vroom and Yetton, 1973; Chemers, 1997). Lack of leadership has been identified as a barrier to adaptation (Moser and Ekstrom, 2010). Although there are several theories attached to leadership, the most relevant to CCIAV is situational or contingency theory where leadership style is tailored to fit the situation at hand. This fits the wide range of situations encountered within CCIAV. Situational theory describes how normative or positivist methods are able achieve a particular set of goals. It also undertakes descriptive assessment of how effective different leadership styles are in achieving their normative aims and proposes models based on those findings (Vroom and Yetton, 1973; Margerison and Glube, 1979; Vroom and Jago, 1988; Chemers, 1997). Leadership can be understood through its role in a particular organization or institution via management lens through how innovations implemented by an individual or organization are transferred to other actors. While the expression of leadership may be in the operational arena (e.g., through inspiration by example) its overall aims are generally considered to be strategic to transformational. Three important styles of leadership are transactional, based on a reward/penalty strategy, laissez-faire and transformational, leaders who state goals, develop plans and encourage others to achieve them in a variety of ways (Bass et al., 1996; Eagly et al., 2003).

Institutions have a large number of attributes that encompass the spectrum between defined roles and informal narratives. In some cases institutional change may be required if that institution is contributing to market failures associated with climate change, the perpetuation of unsustainable practises or maladaptation. Institutions in

opposition to responses on climate change also influence decision-making, especially that affecting mitigation policy. Institutions can also respond to particular decisions on a need basis as an actor without altering its identity or path in the process. Institutions also act at different scales – some will be actors, some will provide resources and yet others governance.

Boundary organisations that link different disciplines and or institutions are increasingly being recognised as important to CCIAV decision support (Guston, 2001; Cash et al., 2003; McNie, 2007; Vogel et al., 2007). *A boundary organization is a bridging institution that acts as an intermediary between science and policy, whose goal is to shape perceptions of salience, credibility and legitimacy of available information, and effectively balance any trade-offs among them. This organization carries out information functions, including communication with decision makers, translation of science, and mediation between different views of how to interpret new information*. To serve as this bridge, this organization requires the ability to recognize the importance of location-specific contexts (Ruttan et al., 1994), to create a forum in which information can be co-created by interested parties (Cash et al., 2003), and to facilitate the creation of boundary objects, such as scenarios, and model-based decision support systems (White et al., 2010). Adaptive and inclusive management practices are essential to the functioning of such organizations, particularly in addressing wicked problems such as climate change (Batie, 2008).They also provide a bridge between adaptation to climate and to other processes managing global change processes and sustainable development.

Knowledge is a cultural resource that people can draw from and may also be generated for specific decisions. Malaska and Holstius (1999) describe an Aristotelian approach to good decision-making that requires three kinds of knowledge: purpose and objectives, situational knowledge and knowledge about means and resources. Situational knowledge for CCIAV requires historical and current knowledge of the system and scenarios and/or forecasts of the future. Some of the main challenges for knowledge are to transfer information from specialised sources, such as the scientific knowledge of climate change, through to where it can inform decisions. Often the transfer requires a transformation from specialised statistical knowledge to a generalised form of everyday information, such as may be used by a market or public good climate service. Knowledge generation, demand and transfer are cross-cutting issues that have a huge bearing on decision-making processes.

These resources and attributes can be viewed in how they influence the decision process itself. Figure 2-5 divides the decision-making process into four stages: scoping, analysis, implementation and review, outlining institutional and leadership, and knowledge and information characteristics for each stage. The two loops reflect the loops in Figure 2-2. Most effort in CCIAV research has been put into the first two stages, whereas decision implementation and follow up have been minimal. This does not imply that the analysis stage is discounted – problem analysis and solution evaluation is a significant undertaking in any decision-process, but that is where most current assessments stop.

[INSERT FIGURE 2-5 HERE
Figure 2-5: Selected attributes and characteristics relevant to the decision-making process itself. The two loops in the decision-making process relate to the two loops in Figure 2-2.]

Figure 2-6 combines the time element in planning adaptation to climate change with a systems planning approach at the organisational level. The coping range of climate (covering the spectrum between thriving and tolerance) that a location or actor is adapted to will need to change over time if to avoid increasing vulnerability. The coping range for any activity, location or organisation may be unique. This is combined with scenario use, visioning and strategic planning carried out in an organisational environment. A simplified systems approach builds in levels of leadership with research and development, strategic management and operations. Resources and directions are fed down through the system and feedback detailing progress and exceptional circumstances fed back up. All levels take in the environmental information needed for decision-making and where they cannot make decisions within limits set, send that signal up the line. The risk of crossing a critical threshold may require actions grading from the exercise of different options, revisiting strategic directions or, in extreme cases, revisiting the original vision.

[INSERT FIGURE 2-6 HERE
Figure 2-6: Planning frameworks for climate change showing the coping range, changing climate, thresholds and vulnerability for a single-variable climate scenario with idealised adaptation pathways (top) shows with a systems planning framework for organizations showing how vision, strategy and action can combine in a reflexive manner.]

The cases that follow are intended to elaborate on the role and importance of these attributes and ways in which they may matter. The cases are intended to be examples of situations where decisions could not (or were not) reached and why and where there were effective decisions and why.

2.3.2. Assessing IAV on a Range of Scales

If the goal of decision-making on climate change is to manage climate risks, then decision-making needs to ensure this goal is being achieved. Progress in CCIAV has been gradual, evolving as the scientific understanding of climate change improves. A number of global initiatives are taking place to enable knowledge generation, transfer and use, including the Programme of Research on Climate Change Vulnerability, Impacts and Adaptation – PROVIA (PROVIA web site: http://www.provia-climatechange.org/), the Nairobi Work Programme on impacts, vulnerability and adaptation to climate change – NWP (NWP web site: http://unfccc.int/adaptation/nairobi_work_programme/items/3633.php), and work by the World Bank and regional development banks (World Bank climate change web site: http://climatechange.worldbank.org/).

As noted in Section 2.3.1, boundary organizations contribute to knowledge transfer, and there are examples of such entities contributing to regional CCIAV assessments, including Great Lakes Integrated Sciences and Assessments Center – GLISA (GLISA web site: http://www.glisa.umich.edu/), the UK Climate Impacts Program – UKCIP (UK Climate Impacts Program, 2011), and institutions working on water issues in the U.S., Mexico and Brazil (Kirchhoff et al., 2012; Varady et al., 2012).

2.3.2.1. Assessing Impacts

Climate impact assessment draws on interdisciplinary studies that focus on the interaction between nature and society. An early description of impact models is found in Kates (1985), who summarize various case study experiences based on historic events in determining direct cause and effect, and then proposing a more interactive model, in which initial societal responses would lead to a different impact in the future for a similar climatic event. A short term adjustment could ultimately lead to longer term adaptation by societies, as illustrated for drought adjustment in the Great Plains of the United States, in which a 'lessening' of impacts was observed during subsequent drought events (Warrick, 1980).

Scenario-based climate impact assessments differed from assessments of observed events, however, in that it challenged prevailing models of stability in climate-society relationships. A number of cases of historic events identified how decision makers, when faced with an extreme weather/climate event, held on to old views of such relationships and pursued a 'muddling through' approach (Glantz, 1988). Impact assessment of future climate change would therefore challenge prevailing decision frameworks that implicitly assumed climate stationarity (Milly et al., 2008).

In order for scenario-based impact assessments to contribute to vulnerability and risk assessment, there needs to be a series of translations carried out. Scenarios of projected greenhouse gas concentrations are converted to changes in atmospheric conditions, subsequently to impacts without proactive adaptation, and finally, to an assessment of the effectiveness of various adaptation options. As discussed in Chapter 1, and Section 2.2.1.6, climate change scenarios themselves have changed dramatically since the 1980s with the continued evolution of climate models and emission scenarios. A new scenario process aims to provide Representative Concentration Pathways (RCP) and corresponding climate projections and socio-economic driving scenarios(van Vuuren et al., 2012) that can be used for impact assessments.

This series of translations requires the transformation of data across various scales of time and space, between natural and social sciences, utilizing a wide range of analytical tools created by different fields of study, including agriculture, forestry, water, economics, sociology, and systems modelling. For example, scenarios for climate variables such as temperature and precipitation need to be translated into scenarios or projections for biophysical and socio-economic impact variables such as food supply, coastal erosion, health outcomes, species distribution and so on. Establishing these connections and supporting the translation process is an important function of climate services, described more fully in Section 2.3.3.

The assessment of impacts leads to placing the projected changes within the context of local management and governance, and to anticipate how possible future changes in management and governance over the scenario time frame of 50–100 years might influence the linkages between climate change and the associated socio-economic consequences for the location being assessed. This represents a combination of top-down biophysical assessments of futures and bottom-up socioeconomic assessments of the past and present (Figure 2-7a,b). This inconsistency hampers assessments of future adaptation responses (see Chapter 16). An important challenge, therefore, is to construct impact assessments in which biophysical futures are superimposed on socioeconomic futures (Figure 2-7c). An ongoing effort to address this inconsistency is the construction of a new set of socioeconomic futures, known as Shared Socioeconomic Pathways (SSP), which are storylines corresponding to the new RCPs (Moss et al., 2010; Kriegler et al., 2012).

[INSERT FIGURE 2-7 HERE
Figure 2-7: Approach Used to Inform Adaptation Policy (modified from Dessai and Hulme 2004 (Dessai and Hulme, 2004).a – biophysical and socioeconomic assessments based on historical observations; b –biophysical impact scenario superimposed on historical socioeconomic condition; c – biophysical and socioeconomic assessments based on future scenario.]

More recently, a new generation of scenario-based impact assessments has emerged in which regional case studies are linking biophysical, economic and social analysis tools, in order to describe the interactions between projected biophysical changes and managed systems, assuming various responses by the actors of those managed systems. For example, Ciscar et al. (2011) estimated the costs of potential climate change impacts, without public adaptation policies, in Europe in four market impact categories (agriculture, river floods, coastal areas, and tourism) and one nonmarket impact (human health). They found that if the climate of the 2080s were to occur today, the annual loss in household welfare in the European Union resulting from the four market impacts would range between 0.2–1%. A similar study was conducted in the UK (Hunt, 2008). Net benefits were projected for tourism, health and transportation maintenance in winter, while net losses were projected for buildings and transportation infrastructure due to increased flood risk, and for residential water supplies in Southeast England. In the U.S., Backus et al. (2013) assessed national and state level GDP and employment impacts, assuming the SRES-A1B scenario across the range of climate projections from the CMIP3, incorporating direct impacts on water resources, direct responses to these impacts by agriculture and other water interests, and indirect responses through inter-state migration of affected populations. The combination of direct and indirect responses resulted in an average cumulative GDP loss of 1 trillion U.S. dollars for 2010- 2050.

Another recent innovation is the application of decision support tools within scenario-based impact and adaptation assessments. One example is an assessment of the ability of a community water system in British Columbia, Canada, to meet regulated in-stream flow requirements within scenarios of climate and forest cover changes. In this case, the decision tool used was the Water Evaluation and Planning System model. Of seven scenarios tested, the community water system failed in six scenarios due to projected climate impacts on local stream flow. The exception was the case where forest cover was depleted due to an insect epidemic, similar to what other regions in British Columbia have already experienced, and which is also a projected impact of climate change (Harma et al., 2012).

2.3.2.2. Assessing Vulnerability and Risks

The adaptation to climate change, disaster risk management, and resilience literatures all address the concept of vulnerability, defined as a susceptibility to loss or damage (Adger, 2006; Füssel, 2007), or, the propensity or predisposition to be adversely affected (glossary). Within IPCC AR4 Schneider et al. (2007) identified those vulnerabilities that might be considered 'key', and therefore potentially 'dangerous' (see glossary). What makes an impact 'key' depends on certain criteria related to the climatic event itself, but also to the location or activity of interest. Criteria related to the event itself include the magnitude and timing of the event, its persistence and reversibility, and the likelihood and confidence that the event would occur. In Chapter 19, persistence of conditions of high susceptibility to the climate event is identified as a vulnerability of the activity. Other aspects of the location or activity include its importance in supporting society, its exposure to the event, and its capacity to adapt.

Adaptive capacity has been defined as the ability to adjust, to take advantage of opportunities, or to cope with consequences (Adger et al., 2007; glossary). However, adaptive capacity is context specific, related to both availability of resources and strong governance measures (see Chapter 14). As noted in Section 2.2.2.1, recent experiences in developed countries, such as with the 2003 heat wave in Europe (Haines et al., 2006) and Hurricane Katrina in the USA (Committee on New Orleans Regional Hurricane Protection Projects, 2009) have led to questions about attribution of causes for weather and climate-related impacts. High property damage and loss of life occurred in both cases because of failures in support systems (e.g., flood defence structures, coordinated heat relief programs). In New Orleans, development choices over a lengthy period increased this city's vulnerability to hurricanes by destroying the region's natural flood defences (wetlands, cypress swamps) in favour of navigation channels and flood control levees (Freudenberg et al., 2009).

The concept of 'adaptation deficit' (Burton and May, 2004) may be applicable to cases such as Katrina. Adaptation deficit represents a gap between a deficient state of adaptation and a state of adaptation that avoids adverse impacts (Chapter 17, glossary). Barriers unrelated to scientific knowledge can hamper effective decision making (Adger and Barnett, 2009; Berrang Ford et al., 2011). This may help to explain why an observed hurricane or other weather or climate event can create surprising levels of damage within developed countries. It has also been related to 'residual impacts', which occur due to insufficient adaptation to current or future climate (IPCC, 2007).Within developing countries, Narain et al. (2011) consider the adaptation deficit to be within a larger 'development deficit'. IPCC (2012) cite other 'deficit' indicators, including a Disaster Deficit Index (impact of extreme event combined with financial ability to cope), structural deficit (low income, high inequality, lack of access to resources, etc.), and risk communication deficit.

This difficulty in parsing out the relative influences of climate and development patterns has been identified within assessments of observed trends in property damage from atmospheric extreme events. For example, recent increases in economic losses may be attributed to changes in probabilities of extreme events, changes in human development patterns (more people in harm's way) without changes in climatic extremes, or a complex combination of both (Pielke, 1998; Mills, 2005; Munich Re Group, 2011). IPCC (2012) concluded that increasing exposure has been the major cause, but a role for climate change has not been excluded. Similar challenges will influence assessments of projected damage trends within future scenarios of climate change and development. .

Assessing damage within future scenarios of climate change will require approaches that link both bio-physical futures and socio-economic futures, providing opportunities to expand scenario assessments beyond expressing future human behaviour only through the lens of population growth, GDP growth and discount rates. An example is the assessment of climate change effects on human health, including research-to-decision pathways, monitoring of social vulnerability indicators and health outcomes (English et al., 2009; Portier et al., 2010), and tools for enabling adaptive management (Hess et al., 2012). An example of a regional scale scenario-based vulnerability assessment incorporating sensitivity, exposure, impact and adaptive capacity is a case study for North Rhine-Westphalia in Germany (Holsten and Kropp, 2012). An example of a larger scale study is a vulnerability assessment of ecosystem services for Europe, in which future adaptive capacity was based on indicators from the SRES storylines(Metzger and Schröter, 2006).

It may be difficult to anticipate how a development choice taken in the current or near term could influence future vulnerability to projected climate change, hence the interest in the study of ***emergent risks***, which is the focus of the review in Chapter 19. Interactions between development pathways, climate change impacts, and climate change responses, could create situations for which there is little or no precedent. Assessments based on gradual shifts in mean conditions could underestimate future risk and consequent damage, suggesting the need for process-based methodologies that focus on enhancing resilience (see Section 2.4.2). An example of assessing this type of risk, and the costs and benefits of potential adaptation responses, is a resilience assessment framework for infrastructure networks (Vugrin et al., 2011; Vugrin and Turnquist, 2012).

2.3.3. Climate Information and Services

Climate Services are the link between generation and application of climate knowledge. There is a growing body of literature concerning the development of such services; on their history and concepts (2.3.3.1.); on decision support as its main feature (2.3.3.2.), and the policy implications of climate service as a global practice (2.3.3.3.).

As the concept of Climate Services becomes ever more relevant for the generation and application of climate information on local, regional and national levels; numerous questions arise for decision makers, stakeholders and other private or public users concerning climate variability, monitoring of risks and adaptation planning "as an important component of sustainable development" (Vaughan and Dessai, 2013). The Global Framework for Climate Services (Hewitt et al., 2012) sets as a goal to "enable better management of the risks of climate variability and change and adaptation to climate change, through the development and incorporation of science-based climate information and prediction into planning, policy and practice on the global, regional and national scale" (http://www.wmo.int/pages/gfcs/index_en.php). Miles et al. (2006) define climate services with a strong focus on the connection between climate science and the public demand for information. But many other disciplines are needed to support the development and delivery of climate services. This extended reach, which includes social sciences, is still fragmented and weak. To support the development and delivery of climate services, more than climate projections and scenarios are needed; observations from a variety of sources are needed as well as case-specific communication skills.

While many countries have already established national and regional climate services or are on the way to do so, the literature shows significant differences in the evolution, organization and practice of Regional Climate Services in different countries and parts of the world. The development of Regional Climate Services in the US and parts of Europe is well documented, with an increasing focus on the aspect of communication and decision support. The European Environmental Agency EEA established a clearinghouse, which provides access to the European data centre on greenhouse gas emissions and climate change impacts, vulnerability and adaptation (http://www.eea.europa.eu/themes/climate/intro). It is linked to the European Climate Adaptation Platform, which provides legal and practical information of regional adaptation measures (http://climate-adapt.eea.europa.eu/). Examples for national and regional Climate Services are: Europe and Eastern Asia (Ebinger et al., 2010); Germany's Climate Service Centre CSC (http://www.climate-service-center.de/) and the HGF Regional Climate Offices (Schipper et al., 2009); the Swedish 'SweClim' (Rummukainen et al., 2004), or the UK Climate Impacts Programme (http://www.ukcip.org.uk/).

An awareness of the need for climate services in developing countries is also growing (Semazzi, 2011), which is reflected in an increasing body of literature mostly from science and technology studies on the migration of standardized regional climate models into the 'global South'. While in 2001 only around 21 countries were running regional climate models (RCMs), mostly in OECD states, there are today about 104 countries trained in using the PRECIS RCM (Edwards, 2010). These show considerable differences in size, scope and practise, ranging from large-scale administrative services to ad hoc interventions of research institutes (von Storch and Zwiers, 2012). Regional Climate Services are expanding from the global North to the global South, shifting from simple understandings of climate information covered by linear approaches to ever more complex and wicked problem situations, and finally, increasing in interdisciplinarity by incorporating the social and communication sciences.

2.3.3.1. Climate Services: History and Concepts

In the peer-reviewed literature, the development of North American climate services is well documented (Changnon et al., 1990; Miles et al., 2006; DeGaetano et al., 2010). The idea of establishing climate services on both national and regional levels resulted from the growing concern over the consequences of climate fluctuations and the difficulties to provide and to distribute adequate information. In the beginning, climate services were merely understood as an expansion of the tasks provided by weather services and similar operational organizations, mainly dealing with forecasts, seasonal outlooks, and assessments of risks in a mostly stationary but variable climate. As it turned out, this restricted and mainly technical understanding of those services were barely effective. For example, decision makers had difficulties understanding and using climate data for planning purposes (Changnon et al., 1990; Miles et al., 2006; Visbeck, 2008). Furthermore, data were delivered slowly and were of poor quality; there were problems in obtaining data on appropriate time and space scales, and there was an "inability to access available datasets held by the private sector, states, regional and some federal agencies" (Changnon et al., 1990).

Attempts were made to provide regional climate services with increasingly sophisticated methods, infrastructure, tools, and collaborations. Early definitions of the mission and scope of climate services focused on being user centric, on active research, data stewardship and effective partnership (National Research Council, 2001). More sophisticated and broader agendas understood climate services as a clearinghouse and technical access point to stakeholders, providing education and user access to experts; they should inform the climate forecast community of the information needs, and propose and evaluate adaptation (Miles et al., 2006). But those general definitions and approaches do not reflect the diverse origins of climate services, mainly the difference between private services aimed at specific consumer needs and public ones with a broader agenda.

This static approach does not reflect changing consumer needs or even natural climate change; instead of being supply-focused, public climate services need communicate in the highly challenging environment of technical and institutional networks, monitoring systems, and collaborations with other institutions, stakeholders and decision-makers, as DeGaetano et al. (2010) suggest. Historic approaches and concepts did not meet this challenge in an effective way, being too static, supply oriented and not recognizing the need to include other sciences and methods.

2.3.3.2. Climate Services: Practices and Decision Support

Decision support is an integral part of the climate service concept and is generally acknowledged among government agencies and researchers as necessary for its healthy functioning (Miles et al., 2006; DeGaetano et al., 2010). There is an intense discussion in the climate services literature about the role of decision-support and its products, services and support systems fuelled a growing awareness of the issue of how the supply of scientific information can be reconciled with user demands. These debates focus on the possibilities, ranges and modes of communication. Social-planner models of society and environment relations (Hasselmann, 1990) provide for example insight into the possible economic outcomes of maximal cooperation when properly embedded in an iterative process of contested assumptions. Critics argue that these models present science as a monolithic knowledge provider, free of conflicts about the quality of data and the nature of facts, which is supposed to provide decision-makers with cost-effective solutions for adaptation and mitigation (c.f. Nordhaus, 1991). In its pure form, this 'linear model' approach is said to reveal many deficits in how science, policy-makers and the public interact, so is considered to be inefficient and sometimes misleading (Pielke and Carbone, 2002; McNie, 2007; Pielke, 2007; Sarewitz and Pielke Jr, 2007; Meyer, 2011).

Instead, the dynamic relationship between information and knowledge supply and demand is considered as the focal point for a successful climate service; the supply of scientific information has to be reconciled with user demands in order to produce scientific information which is relevant and suitable for decision making (McNie, 2007; Moser, 2009; Romsdahl and Pyke, 2009; Kandlikar et al., 2011; Pidgeon and Fischhoff, 2011). Furthermore, the communication of uncertainty and risk play a special role in framing science, and scientific data have to be turned into useful information (Shafer, 2004). According to Moser (2009) decision support is a diverse set of meanings and definitions that has come to mean "processes of interaction, different forms of communication, potentially useful data sets or models, reports and training workshops, data ports and websites, engaging any level of governance, at

any stage in the policy- or decision- making process". For Regional Climate Services, this more dialogic approach challenges the communication process as suggested by the National Research Council (National Research Council, 2009a); instead of beginning with users' needs, it seems more useful to link users and producers to ensure that all parties are involved in order to find out what the needs actually are. It also seems counterproductive to seek institutional stability per se, as the NCR suggests; sometimes it is necessary to identify where institutions need to change and to be sufficiently flexible and/or robust to change in line with, and in response to, climate, social and ecosystem changes.

Capacity building remains a crucial problem, especially in the absence of knowledge and awareness. Educational levels, geographic relevance and scale of information or the status of science in society vary highly among stakeholders as does their abilities to use various types of knowledge. It is important to include here both users and providers of knowledge to ensure a successful learning process. This is also true for more informal educational dialog in form of schools, on the web, in zoos or museums. In any case, communications should also include how climate services can be used, as well as their limitations.

For Shafer (2004), the climate service is a "process of two-way communication" and "involves providing context that turns data into information". For von Storch et al. (2011), climate services are "knowledge brokers" that have to establish an effective dialogue between science and the public. This dialogic communication contains two main tasks: "One is to explore the range of perceptions, views, questions, needs, concerns and knowledge in the public and among stakeholders about climate, climate change and climate risks. The other task is to convey the content of scientific knowledge into the public, to media and the stakeholders. This includes communicating the limitations of such knowledge, the known uncertainties and the unknowable, as well as the limited role of science in complex decision processes."

These demands outlined in the discussion and evaluation of decision-support on the regional level rely on and strongly support interdisciplinary approaches, combining information gained from climate science with knowledge gained from the social and communication sciences.

2.3.3.3. The Geo-Political Dimension of Climate Services

An emerging body of literature from the social sciences is observing practices associated with climate knowledge expansion and the implications of this expansion within a policy-relevant context (Yearley, 2009; Grundmann and Stehr, 2010). Science and technology-inspired studies focus on the mobility of climate knowledge into the "global South' or developing countries. Decision support tools developed in universities in the global North such as the climate model PRECIS from the UK Met Office spread all over the world and serve as a link between the developed and developing countries seeking to adapt to future climates. Earth system models such as PRECIS contribute to capacity building in direction to regional or national climate change management. This mobility of knowledge at the interface of science and politics has far reaching implications for the shaping of global geographies of climate knowledge production; these models strengthen the influence of epistemic communities such as the IPCC and other global governance mechanisms (Mahony and Hulme, 2012). Thus, while regional climate models play an increasingly important role in decision making processes (Dessai et al., 2009), critics argue that climate becomes the focal point of planning and development strategies and renders local forms of knowledge subordinate to this 'climate reductionism' (Hulme, 2011).

A growing number of ethnographic studies of local or regional climates and cultures shows the increasing relevance of indigenous forms of knowledge for the practice of Regional Climate Services (Strauss and Orlove, 2003; Crate and Nuttal, 2009; Crate, 2011; Ulloa, 2011). Anthropological studies demonstrate that local forms of knowledge and scientific climate models are not necessarily mutual exclusive; instead, individual case studies show how both forms of knowledge inform each other to the benefit of a place based adaptation to climate variations (Strauss and Orlove, 2003; Orlove and Kabugo, 2005; Orlove, 2009; Strauss, 2009; Orlove et al., 2010). Indigenous knowledge for climate change adaptation was reviewed in IPCC AR4 (IPCC, 2007), in which various examples of local knowledge systems are now being applied to the newer challenge of proactive adaptation to projected climate change. This increased attention to oral histories is leading to new experiments in which these are compared or combined with

remote sensing technologies and model-based scenarios, to co-produce new knowledge, and to create a new discourse on adaptation planning (Nakashima et al., 2012). The challenge will be to carry out these collaborations in a manner that enables their integration into a holistic narrative on future adaptation choices.

A case study from high arctic Canada, demonstrates the initial incommensurability of Inuit and scientific observations of changing weather patterns (Gearheard et al., 2010), followed by a strong correlation when the appropriate phenomena for measurement and appropriate analyses are identified by meteorologists (Weatherhead et al., 2010). Nakashima et al. (2012) analyse how scientists tend to initially discount indigenous observations, when in actual fact, shortcomings in understanding may derive from the practice of science (see also the discussion in chapter 12.3). These cases show that adaptation is and needs to be local; Endfield (2011) argues for a 'reculturing and particularizing of climate discourses' in order to successfully localize global and scientific meta-narratives. The growing number of this kind of study reveals that one strategy will not suite every local situation, and that climate service development is indeed a dialogic process that challenges the knowledge basis of all sides involved.

Social, cultural and communication sciences play a decisive role in this process (Pidgeon and Fischhoff, 2011; von Storch et al., 2011). Cultural values, social actors, national and regional politics enter the stage; science becomes part and parcel of the negotiation process entailing mitigation and adaptation decisions on various scales. To position itself and to react according to the diverse demands, science-based climate services have to become "rooted in society" (Krauss, 2011). The climate science community does not necessarily takes the lead, but becomes part of an inter- and transdisciplinary process, where politics, culture, religion, values etc. become part of climate communication.

2.3.4. Climate-Related Decision Support in Practice

At the societal scale, decision-making generally aims to achieve multiple objectives. A watershed may be managed for domestic water supply, hydroelectricity, agriculture, navigation, recreation, and in-stream requirements for aquatic ecosystems. These may be influenced by requirements for flood control, including maintenance of engineered structures that control flow and levels of lakes, rivers and water storage for later use (dams, reservoirs, canals). A forested region can include timber supply areas, lands set aside for parks and wildlife habitat, and other lands managed to support biofuels. These may be influenced by changes in disturbance regimes (insects, disease, fire, invasive species), and requirements to protect endangered species.

Climate change could influence the achievement of these and similar management objectives. Recent literature on potential climate change effects on natural resources, public health and community planning and management is reviewed in chapters 3–12. As the complexity of management challenges increases due to development and other pressures, including climate change impacts, new decision-making paradigms are emerging. Examples include Integrated Water Resources Management (IWRM), Sustainable Forest Management (SFM), and Sustainable Fisheries Management.

Bates et al. (2008) briefly reviewed the IWRM, describeding it as a participatory process. Sustainability of ecosystems, demand management, and integration of water within social and economic development, would all be explicitly considered as part of a participatory approach to water and land resources planning and implementation (Agarwal et al., 2000; Snellen and Schrevel, 2004). Many countries have recently acknowledged IWRM principles (Garcia, 2008; Jønch-Clausen, 2010), but they contain implementation challenges that may be exacerbated by climate change effects on water cycles and extreme events. Jønch-Clausen (2010) gives examples for the state of Orissa, India and Martz et al. (2007) for the South Saskatchewan River Basin, Canada. Additional discussion on IWRM is found in chapter 3.

SFM aims to maintain and enhance the economic, social and environmental values of forests, but is still an abstract concept (Seppälä et al., 2009). This is in contrast to the more narrowly defined timber-dominant forest management (Wang, 2004). Criteria and indicators for SFM assessment have been identified (McDonald and Lane, 2004; Wijewardana, 2008; Montréal Process, 2009), focusing on biological diversity, productive and protective functions of forests (e.g. maintenance of soil and water resources), maintenance of social and economic benefits (e.g. wood

products, social and spiritual needs), and governance. Climate change is seen as relevant to achieving SFM objectives (Montréal Process, 2009), and consequently, climate change may pose new kinds of vulnerabilities and risks. An example of a vulnerability assessment is illustrated for a case study of SFM in the Austrian Federal Forests of the Eastern Alps (Seidl et al., 2011). At the same time, however, governments and companies are considering assisted migration as an adaptation strategy (Pedlar et al., 2012). Additional discussion of SFM is found in chapter 4.

Sustainable fishing is defined as long term fishing at an acceptable level of biological and economic productivity without leading to ecological changes that foreclose options for future generations (FAO, 2013). Climate change has generally not been included in strategic guidance for fisheries management (Brander, 2010). Industrial fishing has led to depletions of some populations (Pauly et al., 2002), and climate change would create additional stress on marine biodiversity through warming-induced species invasion in high latitudes, and local extinction in tropical regions (Cheung et al., 2009). Ecosystem-based fishery management or EBFM (Zhou et al., 2010), seeks a balance in exploitation of various species. This is complemented by emerging discussion on evaluating harvest management strategies, including a management strategy evaluation or MSE (Sainsbury et al., 2000; Bunnefeld et al., 2011) incorporating monitoring and model simulation of managed systems, enabling simulation of proposed decision rules. Additional discussion of fisheries management is found in chapters 3 and 5-7.

At the national level in the least developed countries (LDCs), National Adaptation Programmes of Action (NAPA) was an important initiative launched by the UNFCCC (2009). NAPAs must be action-oriented and country-driven and be flexible and based on national circumstances. The key preparatory steps include the synthesis of available information on vulnerability to and impacts of climate change and variability, via extensive public participation and consultation. The NAPA process has assisted least-developed countries to assess climate sensitive sectors and prioritize projects to address the most urgent adaptation issues for vulnerable regions, communities, and populations (Lal et al., 2012; UNFCCC, 2012). For example, Sudan prioritized projects through a two-part process of quantitative and consultative criteria and stakeholder involvement (World Resources Institute et al., 2011). The integration of NAPAs with other socio-economic programs can help develop resilience. Rwanda and Bangladesh linked their NAPAs and Poverty Reduction Strategy Papers (PRSPs) in order to facilitate mainstreaming of climate change adaptation. The Bangladesh NAPA also identified adaptation strategies that complimented the PRSP (OECD, 2009). Although many countries have linked their NAPAs with development programs, Hardee and Mutunga (2010) argue that they have not been entirely successful in aligning the NAPA priorities with existing national development planning processes. In this context, they cited ‘population pressure’, which is recognized as an issue for adapting to climate change but not incorporated into national adaptation planning or poverty reduction strategies.

Scaling up and institutionalization of the NAPA process has already begun. Under the Cancun Adaptation Framework developed at COP16, a process was established enabling LDCs to formulate and implement national adaptation plans (NAPs) that would build upon the NAPA experience (UNFCCC, 2013). The main objectives of the NAPs are to identify vulnerabilities, medium- and long-term adaptation needs and to develop and implement strategies and programmes to address those needs and also to mainstream climate change risks.

Many developed countries have made progress towards developing adaptation strategy documents at different levels of governance. Swart et al. (2009) analysed National Adaptation Strategies (NAS) of nine European nations examining their decision making aspects, finding both ‘top-down’ and ‘bottom-up’ (delegation of authorities to local governments) approaches. Dissemination of information on weather, climate, impacts, vulnerability, scenarios, etc. was found to be very critical elements for adaptation decision making. Swart et al. (2009) also identified multiple scales and actors involved in the adaptation decision-making process, these actors having different and contradictory views of adaptation measures.

Climate risk-based decision making is becoming an increasingly widespread practice in both developing and developed countries. For example, the aquaculture industry is rapidly developing in coastal Vietnam but the dikes and structures that protect this industry can be severely damaged by storm surges. In response, Vietnam has initiated large-scale mangrove restoration and rehabilitation programs with the support of international institutions (World Resources Institute et al., 2011). The Tsho Rolpa glacier lake in Nepal was at the risk of outburst due to rapid melting of the glaciers (Adger et al., 2007). Considering the risks, the Government of Nepal started implementing

both short- and long-term measures to prevent the outburst flood event (World Resources Institute et al., 2011). There are many instances of risk-based decision making in developed countries as well. Taking lessons from the 2003 heat waves that killed some 35,000 people across Europe, many European countries have already implemented health-watch warning systems (Alcamo et al., 2007; WHO, 2008).

Awareness of climate change risks has propagated to local levels in many countries. Some municipal governments are already embracing the idea of incorporating climate change adaptation planning within municipal planning instruments, including energy and water system design, disaster risk reduction and sustainability plans (Ford and Berrang-Ford, 2011; Rosenzweig et al., 2011).

Although there is a rapidly growing list of adaptation plans being generated at national and local scales (Berrang Ford et al., 2011), an evaluation of adaptation plans from Australia, United Kingdom and the United States suggests that these plans are largely under-developed. This reflects a preference for capacity building over the delivery of specific vulnerability-reduction measures, indicating that current adaptation planning efforts are still informal and ad hoc, with many institutions 'muddling through' the process (Preston et al., 2011). At the same time, however, anthropologists and other social scientists are documenting the growth in community-based adaptation initiatives, in part through climate change reception studies, which explore how local communities receive and act on climate change information (Baer and Risbey, 2009; Rudiak-Gould, 2011). Details of adaptation planning within urban and rural settlements are addressed in chapters 8 and 9, respectively.

Various enabling factors have been identified in stakeholder engagement processes. Such factors include access to human, social and economic resources, sharing observations and ICT tools (e.g., wireless broadband and wireless sensor networks, geographic information systems and Web based tools), high levels of local awareness, providing information allowing for good public understanding of stresses, risks and trade-offs, mainstreaming strategies, or political leadership and institutions. These factors allow new strategies to be explored and implemented (Shepherd et al., 2006). Enabling factors also include the availability of customized impact and vulnerability assessments for the community of interest and for local practitioners (engineers, planners, resource managers, political leaders) who would serve as champions for adaptation planning, and the existence of local social influences/networks and capacity that enable long term strategic planning and mainstreaming (Gardner et al., 2009; Cohen, 2010). These factors are further discussed in chapter 15 and 16.

Local government officials often lack training on climate change adaptation and require comprehensive guidance. To fill this gap, guidebooks have been produced, in which the process of adaptation planning is framed as both a team-building and project management exercise, activities that are already part of usual practice (Snover et al., 2007; Bizikova et al., 2008; ICLEI Oceania, 2008; CARE International in Vietnam, 2009; Ayers et al., 2012). Practitioner engagement in decision 'games' offers another training resource (Black et al., 2012).

Local scale visualization of impacts and adaptation measures, depicted on realistic landscapes, has become an emerging technology that is being tested to support dialogue on adaptation planning at the local scale (Schroth et al., 2011; Sheppard, 2012). Although visual representations of scenario-based impact assessments may be available for a location, scenario-based adaptation assessments are not, so artistic depictions of potential adaptation measures and outcomes are negotiated with local stakeholders. This kind of exercise is currently being tested in communities within Metro Vancouver, British Columbia, Canada (Shaw et al., 2009; Burch et al., 2010; Sheppard et al., 2011).

2.4. Linking Adaptation with Mitigation and Sustainable Development

2.4.1. Assessing Synergies and Tradeoffs with Mitigation

The IPCC AR4 explored interactions between adaptation and mitigation (Klein et al., 2007). Capacities to adapt and mitigate are driven by similar sets of factors, and opportunities for synergies may be available particularly for agriculture, forestry, urban infrastructure and some other sectors. However, the AR4 concluded that a lack of information made it difficult to assess these synergies.

Similarly, assessments of trade-offs were at an early stage. The AR4 cited some case studies which indicated that if both the effects of mitigation efforts on climate, and the costs of implementing mitigation measures were accounted for, any benefits from reduced climate change impacts (for example, on malaria) would be offset by losses due to reduced rates of economic growth. However, the general state of the literature was that information on trade-offs was scarce, since mitigation studies rarely addressed implications for adaptation, while adaptation studies did not assess implications for emissions ('adaptive emissions').

An illustration of potential trade-offs and synergies, created by individual adaptation and mitigation actions, are shown in Figure 2-8. The upper left and lower right quadrants illustrate trade-offs that can result from actions within particular local-regional circumstances. The potential of these trade-offs to indirectly influence other adaptation and/or mitigation outcomes do not necessarily mean that such actions should be omitted from a climate change response portfolio, but decision making could benefit from the availability of a quantitative analysis of such trade-offs. Recent literature on potential interactions between mitigation and adaptation is reviewed in Chapters 15 and 16.

[INSERT FIGURE 2-8 HERE
Figure 2-8: Adaptation – mitigation trade-offs and synergies (adapted from (Cohen and Waddell, 2009).]

Chapter 20 offers detailed discussion of recent literature on the relationship between adaptation, mitigation, and sustainable development. This includes sustainable risk management (Section 20.3.3). However, the central theme of Chapter 20 is the strategic objective of enhancing climate resiliency.

2.4.2. Linkage with Sustainable Development – Resilience

The idea that climate change response and sustainable development should be integrated within a more holistic decision framework has been broadly discussed, including within IPCC AR4 (Robinson et al., 2006; Klein et al., 2007; Yohe et al., 2007). Practical aspects are being explored as local and sub-national scale actors (such as municipalities, regional districts, states/provinces) seek to incorporate proactive adaptation within long-term official development plans. This has enabled local case studies to be initiated, engaging researchers and practitioners (planners, engineers, water managers, etc.) in scenario-based exercises, building local capacity to plan for a range of climate change scenarios (Bizikova et al., 2010).

Folke et al. (2010) argue that people and nature are interdependent systems, and adaptability is enhanced when actors can enable systems and places to absorb disturbance and reorganize while undergoing change, so as to retain the same function, structure and identity. In other words, this characteristic, known as resilience, is the capacity to change in order to maintain the same identity (see Glossary). The idea of climate-resilient pathways is a central theme of Chapter 20.

Assessment of resilience is described as an approach that focuses on identifying and understanding processes that produce thresholds for fundamental change in a system, and identifying where resilience resides (see Section 2.2.1.2). This can be learned through participatory processes with local experts (Tyler and Moench, 2012), or through system modelling. In an ecosystem study, for example, there would be an evaluation of local sources of exceptional productivity and biodiversity, and how well these sources confer resilience within larger ecoregions. This is being used in the Arctic to map local ecosystem resilience, and to assess future persistence of the capacity of these local sources to support resilience of larger ecoregions, within scenarios of climate change (Christie and Sommerkorn, 2012). Another example is resilience analysis of supply chains, as illustrated by the case of petrochemical supply chains exposed to a hurricane in south-eastern United States (Vugrin et al., 2011).

Enhancing resilience is seen as an important component of increased adaptive capacity. In King County (Seattle) Washington, USA, collaboration between researchers and practitioners enables translation of scientific information from the global scale to local conditions (Snover et al., 2007). This conveys local ownership on impacts and adaptation assessments that feed into long-term decision making, creating a climate plan that is meant to be flexible, adjusting to new information as it becomes available, and supporting permanent research and monitoring of local environmental changes and evaluation of results of actions taken (Saavedra and Budd, 2009).

The King County example describes a shared learning approach to promoting climate change adaptation without being solely focused on 'hard' (technology, infrastructure, etc.) paths. Strengthening adaptive capacity promotes resilience by creating a place-based constituency for long-term monitoring, evaluation and assessment of changing conditions, and of local system performance. However, King County already has strong adaptive capacity, and is well endowed with human and financial resources that could be engaged in proactive adaptation within long term sustainable development planning. Tschakert and Dietrich (2010) indicate that in regions with high and chronic poverty, coupled with low awareness of drivers of global change, there is a gap in understanding about adaptation as a process, and that tools are needed to enable anticipatory learning.

Part of learning about adaptation as a process that can promote resilience, is good communication about management paradigms within various disciplines and fields of practice, and how these paradigms can shift as awareness of climate change and global change increases. Adaptation can have unintended consequences, and so the concept of sustainable adaptation has been proposed (Eriksen et al., 2011). Sustainable adaptation considers effects on social justice and environmental integrity, challenging current (unsustainable) development paths rather than seeking adjustments within them. This concept would recognize the role of multiple stressors in vulnerability, the importance of values in affecting adaptation outcomes, and potential feedbacks between local and global processes.

Within renewable resource management, there has been a paradigm shift from a focus on exploitation to ecosystem stewardship, in which the central goal is to sustain ecosystem capacity to provide services that benefit society as a whole. Chapin et al. (2009) identify differences in characteristics between steady-state resource management and ecosystem stewardship, in that the former would aim to achieve ecological integrity through managing stocks, while the latter's goal would be attaining sustainability benefits through managing feedbacks. For example, with the growing interest in hydraulic fracturing (fracking) to increase production of shale gas, as a cleaner alternative to other fossil fuels, regulation and adaptive environmental management are the subjects of new research on planning and decision making approaches, given the potential for negative feedbacks on water resources. Cases include regulation of coal seam gas exploration in Queensland Australia (Swayne, 2012), and new institutional arrangements to integrate water and energy decision making in Northeastern U.S. (Scott et al., 2011).

For urban areas, Leichenko (2011) categorize 4 types of urban resilience studies: a) urban ecological resilience, b) urban hazards and disaster risk reduction, c) resilience of urban and regional economies, and d) urban governance and institutions. Boyd et al. (2008) promote resilience as a way of guiding future urbanization that would be better 'climatized'. The Asian Cities Climate Change Resilience Network is applying a resilience planning framework, with attention given to the role of agents and institutions (Tyler and Moench, 2012).

Further consideration of disaster risk reduction is provided through the Hyogo Framework for Action (HFA), which considers climate change as an underlying risk factor, and promotes integration of risk reduction and climate change adaptation (UNISDR, 2007). The HFA mid-term review includes discussion on progress and challenges in its implementation, and calls for guidance on good practice for risk assessments, and for effective synergies between national and local levels (UNISDR, 2011).

One recent approach is the concept of Climate Smart Disaster Risk Management (CSDRM). The CSDRM approach seeks to integrate social development with disaster risk management in order to enhance adaptive capacity and address the structural causes of poverty, vulnerability and exposure. Emphasis is placed on strategies to manage uncertainty associated with both the physical and societal nature of disaster risk, with ongoing national and regional consultations throughout Africa and Asia (Mitchell et al., 2010). In small island states, integration of disaster risk management and climate change adaptation is enabled through focused institutional coordination, greater engagement of stakeholders and promotion of community-based adaptation and resilience-building projects (UNISDR, 2012b). Similar initiatives are underway in urban areas (UNISDR, 2012a).

Chapter 15 provides more detailed review of literature on disaster risk reduction.

Beyond paradigm shifts within individual fields of practice, resilience is also being explored as an outcome of social contracts which underpin governance. O'Brien et al. (2009) use examples from Norway, New Zealand and Canada

to illustrate how resilience thinking would frame climate change as a challenge that does not easily fit into existing social contracts of individual communities and nation states, and that new types of arrangements may better serve the goals of resilience and sustainable development within the context of climate change.

Chapter 20 provides more detailed discussion on climate-resilient development pathways, as an explicit objective of long-term planning and decision making.

2.4.3. Transformation – How Do We Make Decisions Involving Transformation?

There is now a growing literature that highlights the importance of transformative adaptation, particularly in the context of a world where the global temperature target of 2°C is exceeded. A recent World Bank report (PIK, 2012), highlights the significant, non-marginal change possible in a '4°C world'. Such climate change outcomes are likely to require new approaches for adaptation decision-making (Stafford Smith et al., 2011). Similar arguments are made by Kates et al. (2012), who suggest that transformational adaptation may be required in situations where incremental adaptation may be insufficient. There is a growing, though still sparse literature that examines such transformational adaptation in different sectors and systems. For example, Rickards and Howden (2012) consider transformational adaptation in Australian agriculture.

Adaptation that is transformative marks a shift towards an approach that includes adaptive management, learning, innovation and leadership, among other elements (O'Brien, 2012). This can be observed in the many adaptation projects that emphasize learning about risks, evaluating response options, experimenting with and rectifying options, exchanging information, and making trade-offs based on public values using reversible and adjustable strategies (McGray et al., 2007; Leary et al., 2008; Hallegatte, 2009; Hallegatte et al., 2011). Learning is an essential element of decision-making that supports transformative change (Tschakert and Dietrich, 2010).

Previously in the chapter we have indicated that complex decision problems often require active stakeholder engagement and participation in the decision-making process. Irvin and Stansbury (2004) identify situations where participatory processes may be most effective for bringing about positive social and environmental change. Recently, Park et al. (2011) have proposed the Adaptation Action Cycles concept as a means to delineate incremental and transformative adaptation and the role of learning in the decision-making process. They suggest that decision-making processes dealing with incremental adaptation are different from those used for transformative adaptation. Supporting transformational adaptation may also require a close examination of the legal and regulatory structures underlying environmental and natural resource management; Ruhl (2010) identifies a number of factors that will determine the connection between environmental law and adaptation, (Craig, 2010) suggests how a flexible approach could support increasing resilience and adaptive capacity of socio-ecological systems.

Much of the existing literature examines gradual adjustment or accommodation to change, and therefore, as (O'Brien, 2012) argues, there is a need to develop a body of research that will provide insights into how systems and structures may be transformed in an ethical and sustainable manner for resilience. This would be accompanied by a revolution in education at all levels of society (O'Brien et al., 2013).

References

Executive Summary

In the last decades, warming has caused a shift towards earlier maximum spring discharge, decreased spring snowpack and sometimes decreased magnitudes of snowmelt floods in regions with seasonal snow storage *(high confidence, high agreement, robust evidence)*. [3.2.3, 26.2.2] Where more winter precipitation falls as rain than snow, winter low flows have increased significantly. Where stream flow is lowest in summer, decreased snow storage has exacerbated summer low flows. River ice in Arctic rivers has been observed to break up earlier. [3.2.3]

Projected climate changes imply large changes in the frequency of floods *(high agreement, robust evidence)*. More frequent intense rainfall events (WG1 SOD 12.4.5.5) would increase the frequency of flooding in small catchments, but the implications for larger catchments are more uncertain because of the limited extent of the intense events. In some areas, reduced snowfall will reduce spring flood peaks. More people will be exposed to floods, notably in Asia, Africa, and Central and South America, and economic losses will increase due to both

increased exposure and anthropogenic climate change *(high confidence, high agreement, limited evidence)*. Vulnerability can be reduced by adaptation.

Projected climate changes would change hydrological regimes substantially *(high agreement, robust evidence)*. Runoff and groundwater recharge are projected to increase at high latitudes and in the wet tropics, and to decrease in most dry tropical regions, controlled mainly by changes in precipitation. Changes in runoff are typically one to three times greater than changes in precipitation. Except in very cold regions, warming brings forward the snowmelt season, altering the seasonal regime. [3.4.5, 3.4.6]

Both increasing greenhouse-gas concentrations and climate change affect vegetation and thus transpiration, runoff and groundwater recharge *(high agreement, medium evidence)*. This impact is very uncertain and locally specific. The active role of vegetation is not considered in most hydrological studies. [Box CC-VW]

Glaciers will continue to lose mass, with meltwater yields from stored glacier ice eventually diminishing as the glaciers shrink *(high agreement, robust evidence)*. The rate of loss per unit of glacierized area will accelerate. The accumulation season will become shorter and the melting season longer, and in almost all regions total accumulation will decrease. In many regions meltwater production will increase during the next several decades but decrease thereafter. Glaciers have long response times and would continue to lose mass even if the climate were to cease to change. [3.4.4]

Drying of soils is projected in most dry regions *(medium confidence, high agreement)*. Projected changes in droughts depend partly on the definition of drought (WG1 SOD 12.4.5.3). [3.4.9]

Climate change is projected to reduce renewable water resources in most semi-arid and arid regions (*high agreement, robust evidence*). This constitutes a key risk, reducing food security. [3.5]

Climate change affects freshwater ecosystems by changing river flow regimes *(high agreement, limited evidence)*. Quantitative responses are known only in a few cases, but this ecological impact may be stronger than that of historic alterations due to human water withdrawals and dams. [3.5.2.4]

Certain approaches to reduce greenhouse-gas emissions imply greater risks for freshwater systems than others *(high agreement, limited evidence)*. Bioenergy crops can require larger amounts of water for irrigation than the amount of water for other mitigation measures. Hydropower has negative effects on freshwater ecosystems which can be reduced by appropriate management. Carbon capture and storage can decrease groundwater quality. In some regions, afforestation can reduce renewable water resources but also flood risk *(high agreement, limited evidence)*. [3.7.2.1]

Water quality changes are linked to warming, changes in rainfall, and climate-related erosion and deforestation (*high agreement, limited evidence*). Projections under climate change scenarios show a risk of deteriorating water quality for municipal supply, even with conventional treatment *(high agreement, limited evidence)*. [3.2.5; 3.5.2.3] Possible positive impacts include reduced risks of eutrophication and algal blooms when nutrients are flushed from lakes and estuaries by more frequent storms and hurricanes, *(high agreement, limited evidence)*. [3.2.5]

Climate change increases investment costs for water and wastewater treatment, while operating costs could rise or fall. Improved or even new water-treatment infrastructure may be needed to address variations in the quantity and quality of water *(high agreement, medium evidence*) but under warmer conditions water and wastewater treatment processes are likely to perform better *(low to medium agreement, limited evidence)*. [3.5.2.3; 3.6]

Hydrological impacts of climate change increase with increasing greenhouse-gas emissions *(high agreement, robust evidence)*. A low-emissions pathway reduces damage costs and costs of adaptation. Impacts of climate change on water resources are likely to reduce economic growth, particularly in developing countries (*high agreement, limited evidence*). [Table 3-2; 3.4; 3.5; 3.6.5]

Adaptive water management techniques offer an opportunity to address uncertainty due to climate change *(high agreement, limited evidence)*. Such techniques include scenario planning, employing experimental approaches that involve learning from experience, and the development of flexible solutions that are resilient to uncertainty. However, there are barriers such as lack of technical capacity, financial resources, awareness, communication, etc. [3.6.2; 3.6.6]

Adaptation to climate change in the water sector provides many opportunities for "no-regrets" improvements (*high agreement, limited evidence*). Of the global cost of adaptation, 85% is required in developing countries (*medium agreement, medium evidence*), in amounts similar to those estimated for the Millennium Development Goals [3.6.1; 3.6.5]. Annual global adaptation costs to maintain baseline levels of water-supply and sanitation services will be 50 to 70% of baseline investment in the sector (*high agreement, limited evidence)*. Some adaptive water-management measures also mitigate climate change (*medium agreement, low evidence*). For example wetland conservation increases carbon storage. [3.7.2]

3.1. Introduction

An adequate, secure water supply is essential for human well-being (Oki and Kanae, 2006), and changes in the hydrological cycle can generate different water-related hazards, and interact with non-climatic drivers and water management (Figure 3-1). Water is the delivering mechanism of climate change impacts to society even sectors on energy, agriculture, and transport. Even though water circulates on the Earth, it is a locally variable resource, and vulnerabilities to water-related hazards differ between regions.

[INSERT FIGURE 3-1 HERE
Figure 3-1: Framework for considering the impacts of climate change on freshwater systems and society. Socio-economic changes, such as GDP, population, and urbanization, will change the way of water managements, exposure and vulnerability of human beings against water related risks, and non-climatic drivers changing water management in terms of quantity and quality, as well as emissions and concentration of Green House Gases (GHGs) and Aerosol, that will lead to changes in precipitation, temperature, and sea level. Water management, non-climatic drivers, and climate change will alter hydrological cycles, and lead to change the impacts and risks for humans and ecosystems in conjunction with the changes in exposure and vulnerability, and hazards such as flood and drought. Water management consists with measures developing infrastructure, such as dykes, dams, and reservoirs, and non-structural measures, such as early warning system. Land cover and land use changes including afforestation, deforestation, and settlement, change of water demand due to economic development and demand changes in food and energy, and anthropogenic changes in pollutant load are examples of non-climatic drivers, and they are inter-acting each other. Mitigation acts on the emission and concentration of GHGs as well as on non-climatic drivers, while adaptation acts on non-climatic drivers and water management which alters exposure and vulnerability. (modified from Figure 3-1, AR4)]

Anthropogenic climate change is one of many stressors of water resources. Non-climatic drivers such as population increase, urbanization, economic development and land-use or natural geomorphic changes also challenge the sustainability of resources by decreasing water supply or increasing demand. In this context, adaptation options for climate change can be seen positively as options for improvement.

The key messages with *high* or *very high confidence* from the Working Group II Fourth Assessment Report (AR4; IPCC, 2007) in respect to freshwater resources were:

- The impacts of climate change on freshwater systems and their management are mainly due to observed and projected increases in temperature and sea level, local changes of precipitation, and changes in the variability of those quantities.
- Semi-arid and arid areas are particularly exposed.
- Higher water temperatures, increased precipitation intensity, and longer periods of low flow exacerbate water pollution, with impacts on ecosystems, human health, water services reliability and operating costs.
- Climate change affects the water-management infrastructure and practice.

- Adaptation procedures and risk-management practices have been developed for the water sector in some countries and regions.
- The negative impacts of climate change on freshwater systems outweigh its benefits.

This chapter assesses observed (Section 3.2) and projected future impacts (Section 3.4) of climate change on freshwater resources and their management, mainly based on research published since AR4. The drivers of hydrological change are summarized in Section 3.3. Impacts, vulnerabilities, and risks for human and environmental systems are assessed in Section 3.5; adaptation issues, including uncertainties and costs, in Section 3.6), and linkages with other sectors in Section 3.7. Current gaps in research and data are summarized in Section 3.8. For further information on observed trends in the water cycle, please see Chapter 2 of the Working Group I ("WGI") contribution to this assessment. See WGI Chapter 4 for freshwater in cold regions and WGI chapters 10 for detection and attribution, 11 for near-term projections, and 12 for long-term projections of climate change. In this Working Group II contribution, impacts on aquatic ecosystems are discussed in Chapter 4 (see also Section 3.5.2.4 below). Chapter 7 describes the impacts of climate change on food production (see also Section 3.5.2.1 for the impact of hydrological changes on the agricultural sector). The health effects of changes in water quality and quantity are covered in Chapter 11, and regional vulnerabilities related to freshwater in Chapters 21-30. Section 3.6.5 discusses impact costs and adaptation costs related to water resources; these costs are assessed more broadly in Chapter 10.

3.2. Observed Hydrological Impacts of Climate Change

3.2.1. Detection and Attribution

A documented hydrological change is not necessarily an impact of anthropogenic climate change. Detection entails showing that part of the documented change is not due to natural random or quasiperiodic variability of the water cycle. For robust attribution to climatic change, all the drivers of the hydrological change must be identified, with confidence levels assigned to their contributions. Human activities like water withdrawals, land-use change, pollution and water management mean that this is usually difficult. Nevertheless, many hydrological impacts can be attributed confidently to their climatic causes (Table 3-1). End-to-end attribution, from human climate-altering activities to impacts on freshwater resources, is not attempted in most studies, because it requires experiments with climate models in which the external natural and anthropogenic forcing is "switched off". However climate models do not currently simulate the water cycle at fine enough resolution for attribution of hydrological impacts to anthropogenic climate change. Until climate models and impact models become better integrated, it is necessary to rely heavily on multi-step attribution, in which hydrological changes are shown to be consistent with climatic changes that may in turn be attributable to human activities.

[INSERT TABLE 3-1 HERE
Table 3-1: Selected examples, mainly from Section 3.2, of the observation, detection and attribution of impacts of climate change on freshwater resources. Observed hydrological changes are attributed here to their climatic drivers, which are not all known to be anthropogenic; in the diagram, symbols with borders represent end-to-end attribution of the impact on resources to anthropogenic climate change.

1: Gedney *et al*. (2006a), Gerten *et al*. (2008); 2: Piao *et al*. (2010); 3: Shiklomanov *et al*. (2007); 4: Hidalgo *et al*. (2009); 5: Collins (2008); 6: Baraer *et al*. (2012); 7: Rosenzweig *et al*. (2007); 8: Min *et al*. (2011); 9: Pall *et al*. (2011); 10: Aguilera and Murillo (2009); 11: Jeelani (2008); 12: Evans *et al*. (2005); 13: Marcé *et al*. (2010); 14: Pednekar *et al*. (2005); 15: Paerl *et al*. (2006); 16: Tibby and Tiller (2007).]

Extreme hydrological events, such as floods, prompt speculation about whether they are "caused" by climate change. Climate change can indeed alter the probability of a particular event. However, to estimate the alteration reliably it is necessary to quantify uncertainties due to natural variability in the changed and the unchanged climates, and also – because of the need for model simulations – uncertainties due to limited ability to simulate the climate.

The probability or risk of the extreme event can be measured by recording the fraction of events beyond some threshold. Call this fraction r_{ctrl} in the actual climate and r_{expt} in the climate in which there is no anthropogenic

climate change, and suppose there are many simulated, paired instances of r_{ctrl} and r_{expt}, with the ratio of risks given by $F = r_{expt}/r_{ctrl}$. The distribution of simulated risk ratios F is an estimate of the likelihood that the climate change has altered the risk.

Figure 3-2 illustrates the probabilistic character of attribution when uncertainty is multi-dimensional. It summarizes a formidable amount of computation, and it is not probable that such graphs will become routine tools for assessing single-event risks in, for example, the insurance industry. Nevertheless Figure 3-2 demonstrates consistency of weather with climate: anthropogenic greenhouse radiation made these floods much more likely. Reducing the computational cost of single-event attribution, possibly by identifying changes in event frequency, requires further study.

[INSERT FIGURE 3-2 HERE
Figure 3-2: Likelihood distributions of the ratio F of risks of flooding in England and Wales in autumn 2000 in several thousand paired simulations without and with anthropogenic greenhouse forcing (based on Pall *et al*., 2011; see also Bindoff *et al*., 2013 (WGI Chapter 10)). Each pair starts from a unique initial state that differs slightly from a common reference state. Vertical line represents no change in risk due to anthropogenic greenhouse forcing. Thin coloured lines: distributions with anthropogenic forcing, obtained with a seasonal-forecast model driven by patterns of attributable warming found beforehand from four climate-model simulations of the 20th century; the forecast model is coupled to a model of basin-scale runoff and hydraulics. Thick black line: aggregate of the four distributions.]

3.2.2. Precipitation, Evapotranspiration, Soil Moisture, Permafrost, and Glaciers

Global trends in precipitation from several different datasets during 1901-2005 are statistically insignificant (Bates *et al*., 2008; Hartmann *et al*., 2013 (WGI Chapter 2)); however, according to regional observations, most droughts and extreme rainfall events of the 1990s and 2000s have been the worst since the 1950s (Baringer *et al*., 2010) and certain trends in total precipitation and numerous indicators of precipitation extremes are observed (Hartmann *et al*., 2013 (WGI Chapter 2)). Recent changes in regional precipitation are attributed mainly to warming, which alters the atmospheric circulation (Lambert *et al*., 2004; Stott *et al*., 2010). Although the models substantially underestimate observed trends, Zhang *et al*. (2007) estimated that in the 20th century anthropogenic forcing contributed significantly to observed increases in precipitation in the Northern Hemisphere mid-latitudes, drying in the Northern Hemisphere subtropics and tropics, and moistening in the Southern Hemisphere subtropics and deep tropics.

Changes in snowfall are indeterminate, as for precipitation, however, consistent with observed warming, a shortening of the snowfall season is observed for most of the Northern Hemisphere, together with shifts towards earlier start and later end dates of the snowmelt season (Takala *et al*., 2009; Tedesco *et al*., 2009).

On a global scale, evaporation increased from the early 1980s up to the late 1990s but not thereafter, although this appears to be due mainly to drying of land surfaces rather than to observed reductions of atmospheric evaporative demand (Jung *et al*., 2010). Observed and estimated global and regional trends in evapotranspiration suggest intensification of the hydrologic cycle (Huntington, 2010). Due to changes in precipitation, in diurnal temperature range, aerosol concentration, (net) solar radiation, vapour pressure deficit, and wind speed, the rate of regional pan evaporation has been steadily decreasing since the 1960s (Fu *et al*., 2009; McVicar *et al*., 2010; Miralles *et al*., 2011; Roderick and Farquhar, 2002; Wang *et al*., 2011). No fundamental physically-based explanation has been provided for the so called “evaporation paradox” that an increase in evaporation is expected, but a decrease has been observed (Fu *et al*., 2009). The evaporation paradox is made more puzzling by robust oceanographic observations of changes in geographical patterns of salinity. Salty parts of the ocean have become saltier and fresher parts fresher, a change attributable only to a more intense water cycle and, with *high confidence*, to human forcing of climate (Pierce *et al*., 2012).

Long-term records of soil moisture content in natural conditions are available in limited regions, such as the former Soviet Union, China, and central USA (Bates *et al*., 2008; Wang *et al*., 2011). Robock *et al*. (2005) reported a long-term increase in summertime soil moisture in Ukraine. Regional downward and upward trends in soil moisture

content have been calculated for China, where a trend to longer, more severe and frequent soil moisture droughts has been experienced over 37% of the land area (Wang *et al*., 2011). For example in South China, increases in dry days and a prolongation of dry periods have been detected (Fischer *et al.*, 2013; Gemmer *et al*., 2011), and can be attributed to increases in warm days and warm periods (Fischer *et al.*, 2011). These findings need to be considered carefully, as the results depend on the type of procedure used to obtain them (e.g. Sheffield and Wood, 2007).

Decreases in the extent of permafrost and increases in its average temperature are widely observed, for example in some regions of the Arctic and Eurasia (Comiso *et al*., 2013 (WGI Chapter 4)) and the Andes (Rabassa, 2009). Soil humidity in permafrost areas and permafrost degradation are strongly connected with the active-layer depth and influence the stability of steep slopes (Harris *et al*., 2009). The release of GHGs due to permafrost degradation can have unprecedented impacts on the climate, but these processes are not well represented in global climate models yet (Grosse *et al*., 2011).

Due to glacier retreat, the formation of new lakes in high-mountain regions is increasing and causes further environmental impacts (Frey *et al*., 2010). As examples of changes on land, fast glacier length and area recession, thinning of the ice cover and an increase of regional snowline elevation are observed in South America (Rabassa, 2009). Almost all small glaciers in the tropical Andes have been shrinking rapidly since the 1980s; current rates are unprecedened since the early 18th century (Rabatel *et al.*, 2013).

3.2.3. Runoff and Stream Flow

There is a general agreement between detected trends in streamflow and the observed regional changes in precipitation and temperature since 1950s. In Europe, streamflow decreased in the south and east and generally increased elsewhere (Stahl *et al*., 2010; 2012), particularly in northern latitudes (Wilson *et al*., 2010); In north America increases were observed in the Mississippi basin and decreases in the US Pacific Northwest and South Atlantic-Gulf regions (Kalra *et al*., 2008). In China, a decrease in streamflow in the Yellow River is consistent with a reduction of 12% in summer and autumn precipitation, whereas the Yangtze shows a small increase in annual runoff driven by an increase in monsoon rains (Piao *et al*., 2010). These and other stream flow trends must be interpreted with caution (Jones, 2011) because of confounding factors such as land-use changes (Zhang and Schilling, 2006), irrigation (Kustu *et al*., 2010) and urbanisation (Wang and Cai, 2010).

In a global analysis of simulated discharges (1948-2004), only about one-third of the top 200 rivers (including the Congo, Mississippi, Yenisei, Paraná, Ganges, Columbia, Uruguay, and Niger) showed significant trends in discharge; 45 recorded decreases and only 19 recorded increases (Dai *et al*., 2009). Decreasing trends in low and mid latitudes are consistent with recent drying and warming in West Africa, southern Europe, South and East Asia, eastern Australia, Western Canada and the USA and northern South America (Dai, 2013). Global increase in runoff has been linked to reduced transpiration due to a decrease of stomatal opening of many plant species at higher CO_2 concentration (Gedney *et al*., 2006b). However, these results are disputed (Peel and McMahon, 2006).

In regions with seasonal snow storage, warming has caused a shift towards earlier maximum spring discharge (*high agreement, robust evidence*) and has increased winter low flows because more winter precipitation falls as rain instead of snow (Clow, 2010; Korhonen and Kuusisto, 2010; Tan *et al*., 2011). There is *robust evidence* of earlier breakup of river ice in Arctic rivers (de Rham *et al*., 2008; Smith, 2000). Where the stream flow is lowest in summer, decreases have exacerbated summer dryness (Cayan *et al*., 2001; Knowles *et al*., 2006).

3.2.4. Groundwater

Attribution of observed changes in groundwater level, storage or discharge to climatic changes is difficult due to additional influences of land use changes and groundwater abstractions (Stoll *et al*., 2011). Observed trends are largely attributable to abstractions and other human actions not related to climate change. To what an extent groundwater abstractions have already been affected by climate change is not known. Detection of changes in groundwater systems and attribution to climatic changes is rare, also due to a lack of appropriate observation wells

and a small number of studies. Observed decreases of the discharge of groundwater-fed springs in Kashmir/India were attributed to observed precipitation decreases (Jeelani, 2008, Table 3-1). A model-based assessment of observed decreases of groundwater levels in four overexploited karst aquifers in Spain led to the conclusion that groundwater recharge as a fraction of observed precipitation decrease declined during the 20th century. This allowed an attribution to observed temperature increase which caused increasing evapotranspiration (Aguilera and Murillo, 2009; Table 3-1).

3.2.5. Water Quality

Most studies published since the AR4 on observed impacts of climate on water quality refer to surface water bodies in high income countries, and cover intervals between 1 and 80 years. Some observed impacts of climate change on water quality are included in Table 3-1. Data for water quality is scarcer than for quantity. Impacts on water quality are linked to either seasonal or interannual variations in any of several variables, including ambient temperature, water temperature, precipitation and precipitation intensity. Droughts and the El Niño Southern Oscillation (ENSO) phenomenon can also affect water quality.

For lakes and reservoirs, the most frequently reported impacts are more intense eutrophication in warmer temperatures, shorter hydraulic retention times and higher nutrient loads resulting from increased storm runoff (*medium to high confidence, high agreement*). Higher runoff additionally results in higher loads of salts, faecal coliforms, pathogens and heavy metals (Paerl *et al.*, 2006; Pednekar *et al.*, 2005; Tibby and Tiller, 2007) (*medium to high confidence, medium to high agreement*; depending on the pollutant). Pathogens have associated impacts on health. For instance, hospital admissions for gastrointestinal illness in elderly people increased by about 10% when turbidity increased in the influent of a drinking water plant during high rainfall events, even though the water was treated in compliance with standards (Emelko *et al*., 2011; Schwartz *et al*., 2000) (*high agreement* based on *limited evidence, medium to high confidence*). In a reservoirin Spain (Marcé *et al.*, 2010), stream flow variations were of greater significance than temperature increasesin depleting the dissolved oxygen content. Possible positive impacts on water quality include reduced risks of eutrophication and algal blooms when nutrients are flushed from lakes and estuaries by more frequent storms and hurricanes (Paerl *et al*., 2008).

For rivers, all of the reported impacts reduced water quality. Greater runoff, instead of diluting pollution, sweeps pollutants , such as sediments, nutrients, organic matter, pathogens, salts and nutrients, from the soil into watercourses (*medium confidence, medium to high agreement*) (Benítez-Gilabert *et al*., 2010; Gascuel-Odoux *et al.*,2010; Howden *et al*., 2010; Loos *et al*., 2009; Macleod *et al*., 2012; Saarinen *et al*., 2010; Tetzlaff *et al.*, 2010). Some pollutants reduced dissolved oxygen concentrations. Increased organic matter content frequently impairs the quality of conventionally treated drinking water (Weatherhead and Howden, 2009) (*medium confidence, high agreement*). In streams in semiarid and arid areas, temperature changes have more impact than precipitation changes on the content of organic matter, nitrates and phosphorus (Benítez-Gilabert *et al.*, 2010; Chang, 2004; Ozaki *et al.*, 2003) (*medium confidence, medium agreement*).

Studies of groundwater quality are still limited. There are reports of elevated concentrations of faecal pollutants during the rainy season or after extreme rain events (*medium to high confidence, high agreement*), with varying response times. Due to impacts on health and the widespread use of groundwater for municipal supply this is an increasing source of concern (Jean *et al.*, 2006; Seidu *et al*., 2013). Faecal pollution during dry periods is extremely variable (Tetzlaff *et al.*, 2010), making any assessment difficult.

Linkages between observed effects on water quality and climate variability should be interpreted cautiously, at a local level, considering the type of water source and pollutant, the hydrological regime and the sources of pollution (*high confidence, high agreement*). Relationships between water quality and climatic variables are non-linear (except for temperature) and time-dependent (*medium confidence, medium agreement*). The pristine states of water systems need to be understood, since water sources are impacted upon for many reasons and effects may be long-lasting (Benítez-Gilabert *et al*., 2010; Howden *et al*., 2010; Kundzewicz and Krysanova, 2010; Senhorst and Zwolsman, 2005; Ventela *et al.*, 2011; Whitehead *et al*., 2009a). If the observed deterioration of water quality

continues, measures already in place to control point and non-point sources of pollution may be inadequate to deal with the negative impacts of climate change (*medium confidence, high agreement*).

[INSERT FIGURE 3-3 HERE
Figure3-3: Observations and projections of the impacts on the quality of water. (Note: This is not the final figure, it is still under production.)]

3.2.6. Soil Erosion and Sediment Load

Precipitation extremes in many regions have increased since 1950 (Seneviratne *et al*., 2012; their Table 3-2), which is expected to increase rainfall erosivity and to enhance soil erosion and sediment load. Warming may affect soil moisture, litter cover and biomass production, bring about a shift in winter precipitation from non-erosive snow to erosive rainfall, and increase melting of permafrost (Kundzewicz *et al*., 2007). The effects of climate change on soil erosion and sediment load are frequently obscure by impacts of human activities on river catchments (agriculture land use, grazing, water management; Walling, 2009).

In the Yellow River basin, where soil erosion results mostly from heavy rainfall events, reduced precipitation has contributed about 30% to a total reduction in sediment yield during 1970-2008, the remainder being attributable to water abstraction, sediment trapping in reservoirs and soil conservation measures (Wang *et al*., 2007; Miao *et al*., 2011). Dai *et al*. (2008), analyzing the decrease in sediment discharge of the Yangtze River over 1956-2002, found that climate change is responsible for an increase of about 3±2%, although on the side sediment decline dam construction (Three Gorges Dam) contributed 88±10% and soil conservation measures 15±5%.

Potential impacts of climate change on soil erosion and sediment production are of concern in regions with accelerated ice retreat either at high altitude or latitude (Walling, 2009). Glacial rivers are expected to discharge more meltwater, which may increase sediment loads. However, the *limited evidence* is inconclusive; there are both decreasing (e.g. Iceland; Lawler *et al*., 2003) and increasing trends (Patagonia; Fernandez *et al*., 2011). In the Himalayas and Tibetan Plateau, glacier areas have shrunk about 2-10% over the past 45 years but sediment yields from the Hindu Kush-Himalayas have decreased by half since the 1980s (from 4.3 Gt/year before the 1980s to <2.1 Gt/year; Li *et al*., 2008) due to intense human activities at altitudes below 500 meters (e.g. sediment retention in dams).

Detection of changes in the occurrence of landslides is complicated by incomplete inventories, both in time and space, and inconsistency in terminology. So far, there is no clear evidence that the frequency or magnitude of shallow landslides has changed over past decades (Huggel *et al*., 2012), even in regions with relatively complete event records (e.g., Switzerland; Hilker *et al*., 2009). Increased landslide impacts (measured by casualties or losses) in south, east, and southeast Asia, where landslides are predominantly triggered by monsoon and tropical cyclone activity, are largely attributed to population growth leading to increased exposure (Petley, 2012).

In summary, there is *low confidence* with *limited evidence* that anthropogenic climate change has made a significant contribution to soil erosion, sediment loads and landslides. The available records are limited in space and time, and evidence suggests that, in most cases, the human impacts are more significant than the impacts due to climate change.

3.2.7. Hydrological Extremes and Their Impacts

There is *low confidence*, due to *limited evidence*, that anthropogenic climate change has affected the frequency and magnitude of floods at global scale. The lack of robust evidence is mainly due to lack of long-term records from unmanaged catchments, most of those available being from headwaters, and the difficulty of attributing detected changes to climate or to human activities (Section 3.2.1). However, recent detection of changes in extreme precipitation and discharge trends (at some catchments) suggests an increased likelihood of flooding at regional scale (*medium confidence*). More locations and studies show increasing trends in heavy precipitation than those

recording a decrease (Seneviratne *et al*., 2012), and flood-damage costs worldwide have been increasing since the 1970s, although partly due to increasing exposure of people and assets (Handmer *et al.*, 2012).

There is no strong evidence for trends in flooding in the USA (Hirsch and Ryberg, 2012), Europe (Benito and Machado, 2012; Kundzewicz, 2013; Mudelsee *et al*., 2003), UK (Hannaford and Hall, 2012), South America, and Africa (Conway *et al*., 2009). However, at smaller spatial scales, increases in flood magnitude and frequency have been detected in parts of northwestern Europe (Giuntoli *et al*., 2012; Hattermann *et al*., 2012; Petrow and Merz, 2009a), while a decrease in frequency was observed in the Pyrenees (Giuntoli *et al*., 2012; Renard *et al*., 2008). Flood discharges in the lower Yangtze region showed an upward trend in the last 40 years (Jiang *et al*., 2008; Zhang *et al*. 2009), and both upward and downward trends were identified in four basins in the northwestern Himalaya (Bhutiyani *et al*., 2008). In Australia, only 30% out of 491 gauge stations showed trends at the 10% significance level, with decreasing magnitudes in southern regions and increasing magnitudes in the northern regions (Ishak *et al*., 2010). In snow-melt dominated regions, there is no compelling evidence of widespread change in flood magnitude in Arctic rivers (Shiklomanov *et al*., 2007) or in Nordic rivers (Wilson *et al*., 2010). Cunderlik and Ouarda (2009) reported significant trends, most of them decreases, in snowmelt-flood magnitudes at almost one fifth of 160 stations. Similar decreases were found for spring and annual maximum flows (Burn *et al*., 2010).

Attribution has been addressed by Hattermann *et al*. (2012), who identified parallel trends in precipitation extremes and flooding in Germany, which for the increasing winter floods are explained in terms of increasing frequency and persistence of circulation patterns favourable to flooding (Petrow *et al*., 2009b). It is *very likely* that the observed intensification of heavy precipitation is largely anthropogenic (Min *et al.*, 2011; see also Section 3.2.1).

There is *high confidence* that socio-economic losses from flooding are increasing, although attribution of the losses to anthropogenic climate change is seldom established (Handmer *et al*., 2012; Kundzewicz *et al*., 2013). Attribution of losses is highly uncertain due to *limited evidence* (Bruce, 1999; Höppe and Grimm, 2009; Mills, 2005; Malmstadt *et al*., 2009; Schmidt *et al*., 2009). There is *high agreement*, but *medium evidence*, that greater exposure of people and assets, and societal factors is related to population and economic growth, contribute to the increased losses (Bouwer *et al*., 2007; Changnon, 2001; Pielke *et al*., 2005). Several studies normalize the loss records for changes in exposure and vulnerability (Bouwer, 2011). Most find no contribution of flooding trends to the trend in losses (Barredo, 2009; Benito and Machado, 2012; Hilker *et al*., 2009), although increased flood-related losses are found for China (Jiang *et al*., 2005) and Korea (Chang *et al*., 2009). However these studies, mostly at country level, do not take into account the regional diversity of trends seen in some long-term peak flow records (Section 3.2.3).

The definition of drought or local dryness (Seneviratne *et al.*, 2012; their Box 3-3) depends upon different perspectives (meteorological, hydrological, and agricultural), the variables considered relevant (precipitation, temperature, evapotranspiration, soil humidity) and the chosen index (e.g., Palmer drought severity index (PDSI), consecutive dry days (CDD), simulated soil moisture anomalies (SMA)).The AR4 (Trenberth *et al*., 2007) reported that the global extent of very dry areas (PDSI $\leq$ -3.0) more than doubled since the 1970s, and that droughts have increased since then particularly in the tropics and sub-tropics (Dai *et al*., 2004). There is substantial uncertainty in drought analyses based on indirect indexes such as the PDSI (Hartmann *et al*., 2013 (WGI Chapter 2); Dai, 2013; Sheffield *et al*., 2012). In a revised assessment using indices such as CDD and SMA rather than the simple PDSI, Seneviratne *et al.* (2012) found that some regions of the world, notably southern Europe and west Africa, have experienced trends toward more intense and longer droughts, while others (e.g. Central North America and Northwestern Australia) exhibited opposite trends (*medium confidence*). They attributed these patterns to anthropogenic influence on precipitation and temperature (*medium confidence*), although with *low confidence* for single regions.

Regarding vulnerability, some studies detect large supply-side reductions due to climate change that may stress existing water systems (Vanham *et al*., 2009), and others show how small reductions can be managed by existing supply systems or by moderate increases in adaptive capacity (Li *et al*., 2010).

3.3. Drivers of Change for Freshwater Resources

3.3.1. Climatic Drivers

Precipitation and potential evaporation are the main climatic drivers controlling freshwater resources. Precipitation is strongly related to the water-vapor content or specific humidity of the atmosphere, because saturation specific humidity depends on temperature: warmer air can hold much more water vapor. Temperature has increased in recent decades while surface and tropospheric relative humidity (the ratio of specific humidity to saturation specific humidity) have changed little (Hartmann *et al*., 2013 (WGI Chapter 2)). This need not imply either more precipitation or more actual evaporation, although commonly both do increase. Among other climatic drivers are atmospheric carbon dioxide (Section 3.2.3) and deposited black carbon and dust (Box 3-1 in Section 3.4.4). Both of the latter, in even very small concentrations, enhance melting of snow and ice markedly by reducing the surface albedo.

The evolution of the climatic drivers is uncertain mainly because of: (1) internal variability of the atmospheric system; (2) inaccurate modelling of the atmospheric response to external forcings (for example anthropogenic greenhouse radiation, solar and volcanic influences, and changes of land use and land cover); and (3) the external forcing itself, as expressed in the range of outcomes from the chosen emissions scenarios. Internal variability and variation between models account for all of the uncertainty in precipitation in the first few decades of CMIP5 projections (Figure 3-4). The contribution of internal variability diminishes progressively. By no later than mid-century, discrepancies between models account for most of the uncertainty in precipitation, but the uncertainty in temperature (Kirtman *et al.*, 2013 (WGI Chapter 11)) is due mostly to divergent scenarios, which never contribute more than one third to the uncertainty in 21st-century precipitation. Uncertainty due to downscaling of the output of climate models, and to the hydrological models themselves, is addressed in Section 3.4.1.

[INSERT FIGURE 3-4 HERE
Figure 3-4: Variance in projections of changes in decadal-mean precipitation for boreal summer (June, July, and August), decomposed into contributions from three sources of uncertainty. Simulations were for 2000-2100 under the SRES A1B, A2 and B1 scenarios, with one ensemble member taken from each of 14 CMIP3 GCM experiments. From Hawkins and Sutton (2011).]

CMIP5 simulations of the water cycle during the 21st century, with constraints from 20th-century observations, can be summarized as follows (Collins *et al*., 2013 (WGI Chapter 12)):

- Surface temperature, which affects the vapor-carrying capacity of the atmosphere and the ratio of snowfall to precipitation, increases by about 1.5 times more over land than over ocean (*very high confidence*).
- Warming is greatest over the Arctic (*very high confidence*), implying zonally variable changes in snowmelt and glacier mass budgets.
- Less precipitation falls as snow and the extent and duration of snow cover decrease (*high confidence*). In the coldest regions, however, increased specific humidity due to warming means that increased winter snowfall outweighs increased summer snowmelt.
- Wet regions become wetter and dry regions become drier (*medium confidence*), although one observational analysis (Sun *et al.*, 2012) is discordant; moreover the models tend to underestimate observed trends in precipitation (Noake *et al.*, 2012) and its observed sensitivity to temperature (Liu *et al.*, 2012).
- Precipitation tends to increase in equatorial, middle and high latitudes and to decrease in subtropical latitudes (*medium to high confidence*), and global average precipitation increases (e.g. Collins *et al*., 2013 (WGI Chapter 12), their Figure 12-41). Precipitation changes become statistically significant only when temperature rises by at least 1.1-1.4°C (Mahlstein *et al.*, 2012). In many regions, projected 21st-century changes lie within the range of late-20th-century natural variability.
- Models consistently project decreases of precipitation in the Mediterranean, Mexico and central America, and parts of Australia, and increases in India and north and central Asia (*high confidence*).
- Evaporation increases almost everywhere, especially at higher northern latitudes and generally in concert with precipitation (Collins *et al*., 2012 (WGI Chapter 12), their Figure 12-25). This leads to decreases of soil moisture in many regions, particularly central and southern Europe, southern North America and southern Africa (*medium confidence*; Collins *et al*., 2013 (WGI Chapter 12), their Figure 12-23).

More intense extreme precipitation events are expected (IPCC, 2012). Among proposed reasons, one is the projected increase in specific humidity: intense convective precipitation in short periods (less than 1 hour) tends to "empty" the atmospheric column (Utsumi *et al.*, 2011; Berg *et al.*, 2013). Annual maxima of daily precipitation that are observed to have 20-year return periods in 1986-2005 are projected to have return periods in 2081-2100 that are shorter in proportion to the intensity of forcing: about 15 (RCP(representative concentration pathway)2.6), 11 (RCP4.5) and 6 (RCP8.5) years (Kharin *et al.*, 2013). Unlike annual mean precipitation, for which the simulated sensitivity to warming is typically 1.5-2.5 % K^{-1}, the 20-year return amount of daily precipitation typically increases at 5-9 % K^{-1}. Agreement between GCM-simulated extremes and reanalysis extremes is good in the extra-tropics but poor in the tropics, where there is *robust evidence* of greater sensitivity (10±4 % K^{-1}; O'Gorman, 2012). In spite of the intrinsic uncertainty of sampling infrequent events, variation between GCMs is the dominant contributor to uncertainty.

GCM-simulated changes in the incidence of meteorological droughts vary widely, so that there is at best *medium confidence* in projections (Seneviratne *et al.*, 2012). Regions where droughts are projected to become longer and more frequent include the Mediterranean, central Europe, central North America and southern Africa.

3.3.2. Non-Climatic Drivers

In addition to climate change, the future of freshwater systems will strongly be impacted by demographic, socio-economic and technological changes, including lifestyle changes. Given the large uncertainty of climate models in translating emissions scenarios into projections of climatic change, a wide range of possible future development of non-climatic drivers is compatible with a wide range of climate change (Moss *et al*., 2010) particularly in terms of the number of population under high water stress (Kiguchi *et al*., 2013). This means that certain projected hydrological changes (Section 3.4) can occur under a wide range of future demographic, social, economic and ecological conditions, and thus may lead to very different impacts and vulnerabilities (Section 3.5). Therefore, the five shared socioeconomic pathways (SSP) socio-economic scenarios, which include narratives and quantifications of population and economic development (IIASA, 2012), can be combined with more than one GHG emissions scenario (representative concentration pathway (RCP)) (Moss *et al*., 2010).

Of particular importance for freshwater systems is the future agricultural land use, and in particular irrigation, as irrigation accounts for about 90% of global water consumption and severely impacts freshwater availability for humans and ecosystems (Döll, 2009). Due to mainly population and economic growth but also due to climate change, irrigation may significantly increase in the future. The share of irrigation from groundwater is expected to increase due to increased variability of surface water supply (Taylor *et al*., 2012a).

3.4. Projected Hydrological Changes

Generally, hydrological changes are evaluated by comparing possible future hydrological conditions to historical conditions. These projected changes are helpful indicators for understanding human impact on nature and for supporting adaptation to climate change. However, for supporting decisions on climate mitigation, it is more helpful to compare hydrological changes that may occur under different future GHG emissions scenarios. Examples of studies that assess hydrological changes and water-related impacts of climate change under different emissions or global warming scenarios are compiled in Table 3-2. They illustrate the benefits of reducing GHG emissions for the Earth's freshwater systems.

[INSERT TABLE 3-2 HERE
Table 3-2: Hydrological changes and freshwater-related impacts of climate change on humans and ecosystems that could be reduced with lower GHG emissions.]

3.4.1. Methodological Developments in Hydrological Impact Assessment

Since the AR4 many assessments of the potential impact of climate change on hydrological characteristics have been published. Most have applied a now-standard methodology to estimate impacts, using information from climate models to perturb a baseline weather record and a hydrological model to simulate river flows, recharge or water quality (see Section 3.6.3 for methods to estimate impacts specifically for water management purposes).

Most climate change impact assessments have been based on the use of a small number (five or fewer) of climate scenarios. An increasing number has used larger ensembles from the AR4 CMIP3 scenario set (Arnell, 2011b; Arnell and Gosling, 2013a; Bae *et al*., 2011; Chiew *et al*., 2009; Gosling *et al*., 2010; Jackson *et al*., 2011) or ensembles of regional and global climate models (Kling *et al*., 2012; Olsson *et al*., 2011). Some studies have developed "probability distributions" of future impacts by combining results from multiple climate projections (see Section 3.6.3) and, sometimes, different emissions scenarios, making different assumptions about the relative weight to give to each scenario (Brekke *et al*., 2009b; Christierson *et al*., 2012; Manning *et al*., 2009). These studies conclude that the relative weightings given are typically less important in determining the distribution of future impacts than the initial selection of climate models considered.

Most assessments have used a hydrological model with the 'delta-method' to create scenarios, applying projected changes in climate derived from a climate model either to an observed baseline or with a stochastic weather generator; several such downscaling methods have been developed (Fowler *et al*., 2007a). Systematic evaluations of different methods have demonstrated that estimated impacts can be very dependent on the approach used to downscale climate model data (Chen *et al*., 2011; Quitana Segui *et al*., 2010), and the range in projected change between downscaling approaches can be as large as the range between different climate models. An increasing number of studies (Fowler and Kilsby, 2007b; Kling *et al*., 2012; Veijalainen *et al*., 2012) have run models with input data produced by bias-correcting regional or global climate model data (Piani *et al*., 2010; van Pelt *et al*., 2009; Yang *et al*., 2010); unlike the delta method, this means that the simulated future weather incorporates changes in variability as projected by the regional model. On the contrary, the delta method only can reflect the projected changes of the mean state and cannot reflect the changes in variability, and various methodologies are proposed and their characterstics are compared. The choice of bias-correction method can cause discrepancy in the results as a choice of emission scenario or GCM (Watanabe *et al*., 2012). A few studies (e.g. Falloon and Betts, 2006; 2010; Hirabayashi *et al*., 2008) have examined river runoff as simulated directly by a high-resolution climate model; because no bias-correction is applied, the pattern of variability in absolute simulated runoff across space is driven by the simulated precipitation, although the simulated change in runoff should be more consistent with the changes as simulated using a hydrological model off-line. However, this has not yet been systematically evaluated.

The effects of hydrological model parameter uncertainty are typically small when compared with the range from a large number of climate scenarios, but can be substantial when only a small number of climate scenarios are used (Arnell, 2011b; Cloke *et al*., 2010; Lawrence and Haddeland, 2011; Steele-Dunne *et al*., 2008; Teng *et al*., 2012; Vaze *et al*., 2010). However, several new studies suggest that the effects of model structural uncertainty can be substantial (Dankers *et al*., 2013; Davie *et al*., 2013; Haddeland *et al*., 2011; Hagemann *et al*., 2012; Schewe *et al*., 2013), due primarily to different representations of evaporation and snowmelt processes. Two global-scale multi-model studies on projected mean annual river runoff or discharge used the output of three (five) GCMs to drive eight (eleven) global hydrological models (Hagemann *et al*., 2012; Schewe *et al*., submitted). It was found that that hydrological and climate models contribute to the overall uncertainty of projected changes of runoff (discharge) water flows to similar extents globally, with distinct spatial patterns of dominance. The uncertainty of projected actual evapotranspiration, however, was determined to be dominated by the hydrological models.

The vast majority of published impact assessments have followed the conventional scenario-driven approach. Other approaches are, however, feasible. Cunderlik and Simonovic (2007) developed an inverse technique, which starts by identifying critical hydrological changes, uses a hydrological model to determine the meteorological conditions which trigger those changes, and then interprets climate model output (via a weather generator) to identify the chance of these meteorological conditions occuring in the future; Fujihara *et al*. (2008a; 2008b) applied the technique in a catchment in Turkey. The advantage of this approach is that it is not necessary to use the hydrological model to simulate future hydrological characteristics. Another scenario-independent approach constructs response

surfaces relating sensitivity of a hydrological indicator to changes in climate. Several studies have used a water-energy balance framework (based on Budyko's hypothesis and formula) to characterise the sensitivity of average annual runoff to changes in precipitation and evaporation (Donohue *et al*., 2011; Renner and Bernhofer, 2012a; Renner *et al.*, 2012b). Prudhomme *et al*. (2010) constructed a response surface showing change in flood magnitudes by running a hydrological model with systematically-varying changes in climate. Not only does this approach show sensitivity of a system to change, it also allows rapid assessment of impacts under specific climate scenarios which can be plotted on the response surface.

3.4.2. Evapotranspiration

Based on global and regional climate models as well as physical principles, it is projected that global evapotranspiration is very likely to increase in a warmer climate resulting in an acceleration of the hydrologic cycle (Collins *et al*., 2013 (WGI Chapter 12)). Many uncertainties in both magnitude and direction of long-term trends are apparent. Evapotranspiration is not only affected by rising temperatures but also by changing radiation, changes in soil water content, decreases in bulk canopy conductance associated with rising CO_2 concentrations and climate change related vegetation changes (Box CC-VW; Katul and Novick, 2009).

An important source of uncertainty in hydrological projections is the response of empirically estimated potential evapotranspiration (PET) to climate change. Kingston *et al*. (2009) using six different methodologies suggest an increase in PET associated with a warming climate. Ekström *et al*. (2007) found that the Blaney-Criddle formulation lead to smaller changes than the Penman-Monteith formula. However, differences in the PET climate change signal of over 100% are found between the methods, with an uncertainty of 20% to 40% to the observed baseline period (1961-1990).

3.4.3. Soil Moisture and Permafrost

Potential evaporation, which would reduce soil moisture, is projected to increase particularly in southern Europe and Central America, Southern Africa and Siberia (Seneviratne *et al.*, 2010). Lower soil moisture increases the risk of extreme hot days (Hirschi *et al.*, 2011; Seneviratne *et al.*, 2006) and heat waves. For a range of scenarios, low soil moisture episodes of 3-6 month duration double in extent and frequency, and droughts longer than 12 months become three times more common, between the mid-20th century and the end of the 21st century. This is particularly the case where reductions in soil moisture are projected (Sheffield and Wood, 2008). Strong natural variability in drought occurrence and intensity makes the generally monotonic increases statistically not different from current climate.

Changes consistent with warming are also evident in the freshwater systems and permafrost ofnorthern regions. The area of permafrost is projected to continue to decline over the first half of the 21st century in all emissions scenarios (see Figure 4-18 in Chapter 4). In the RCP2.6 scenario of an early stabilization of CO_2 concentrations, permafrost area is projected to stabilize at near 20% below the 20th century area, and then begin to increase slightly.

3.4.4. Glaciers

All projections for the 21st century (Church *et al*., 2013) show continued mass loss from glaciers. In glacierized catchments, runoff reaches an annual maximum in summer, not spring as in snow-covered catchments. As the glaciers shrink, their relative contribution decreases and the annual runoff peak shifts towards spring (e.g., Huss, 2011). This shift is expected with *very high confidence* as an impact of warming. The relative importance of high-summer glacier meltwater can be substantial, for example 25% of August discharge in basins draining the European Alps, with area 10^5 km^2 and only 1% glacier cover; high-summer water supply will therefore be reduced noticeably by the projected glacier shrinkage (based on regional scenarios derived from the SRES A2 and B2 scenarios) to only 12% of 2008 extent by 2100 (Huss, 2011). Glacier meltwater also increases in importance during droughts and heat waves (Koboltschnig *et al*., 2007).

If warming proceeds at a constant rate then if, as expected, melting of stored glacier ice per unit area increases and total glacierized area decreases, the total water yield passes through a maximum: "peak meltwater". Peak-meltwater dates have been projected between 2010 and 2050 (different regions of China; Xie *et al.*, 2006); 2010-2040 (European Alps; Huss, 2011); and 2060-2080 (the world; Radić and Hock, 2011). Pending further regional-scale investigations, there is *medium confidence* that the peak response to 21st-century warming will fall within the century in most inhabited glacierized regions, where at present society is benefitting from a transitory "meltwater dividend". Variable climatic forcing leads to complex variations of both the melting rate and the extent of glacier ice, which depend on each other. Peak meltwater can therefore be difficult to identify, but it has been detected with *medium confidence* in some studies (Table 3-1).

If they are in long-term equilibrium, glaciers reduce the interannual variability of water resources by storing water during cold or wet years and releasing it during warm years (Viviroli *et al.*, 2011). As glaciers shrink, however, their diminishing influence may make the water supply less dependable.

Box 3-1. Case Study: Himalayan Glaciers

Like glaciers elsewhere (Comiso *et al*., 2013 (WGI Chapter 4); their FAQ 4.1), Himalayan glaciers are losing mass. They are therefore of growing concern because they are important resources of freshwater for their host countries (Bhutan, China, India, Nepal and Pakistan). The total resource of ice is known only roughly; estimates range from 2100 to 5800 Gt (Bolch *et al*., 2012).

Himalayan glacier mass budgets have been negative on average for the past five decades. The loss rate may have become greater after about 1995, but it has not been greater in the Himalaya than elsewhere (Figure 3-5). A recent large-scale measurement, highlighted in the figure, is the first well-resolved, region-wide measurement of any component of the Himalayan water balance. It suggests strongly that the conventional measurements are not representative of the regional average. Thus Figure 3-5 also illustrates the uncertainty of generalizations from sparse data.

[INSERT FIGURE 3-5 HERE
Figure 3-5: A compilation of all published glacier mass balance measurements from the Himalaya (based on Bolch *et al*., 2012). Each measurement is shown as a box of height ±1 standard deviation centred on the average balance (±1 standard error for multi-annual measurements). Region-wide measurement (Kääb *et al*., 2012) was by satellite laser altimetry. Global average (Comiso *et al*., 2013 (WGI Chapter 4)) is shown as a 1-sigma confidence region.]

Radić *et al*. (2013) projected glacier mass changes for 2006-2100 by simulating the response of a glacier model (Radić and Hock, 2011) to CMIP5 projections from 14 GCMs under scenario RCP4.5. Results for the Himalaya range between 2% gain and 29% loss to 2035; to 2100, the range of losses is 15-78%. The model-mean loss to 2100 is 45% under RCP 4.5 and 68% under RCP8.5 (*medium confidence*). It is *virtually certain* that these projections are more reliable than an earlier suggestion of complete disappearance by 2035 (Cruz *et al*., 2007). At the catchment scale, however, 21st-century projections do not yet present a coherent region-wide picture.

For an imposed warming rate of 0.06 K/year, simulated peak meltwater discharge was reached in hypothetical glacierized basins around 2050 in the drier western Himalaya and around 2070 in the wetter eastern Himalaya (Rees and Collins, 2006). The GCM-forced simulations of Immerzeel *et al*. (2012) in eastern Nepal, in contrast, show runoff increasing throughout the century because increased precipitation over-compensates for the loss of ice; because the monsoon and the melt season coincide here, there is no seasonal shift of peak discharge.

The growing atmospheric burden of anthropogenic black carbon implies reduced glacier albedo, and measurements in eastern Nepal (Yasunari *et al*., 2010) suggest that this could yield 70-200 mm/year of additional meltwater. In global terms, the Himalaya and southern Tibet are a hotspot for deposition of soot, which may outweigh the greenhouse effect as a radiative forcing agent for snowmelt (Qian *et al*., 2011).

Moraine-dammed ice-marginal lakes continue to cause concern (Fujita *et al*., 2009). In the western Himalaya, they are small and stable in size, while in Nepal and Bhutan they are more numerous and larger, and most are growing (Gardelle *et al*., 2011). Thus the hazard has increased, but there has been little progress on the predictability of dam failure.

Himalayan glacier meltwater is an increasing, and during this century is expected to become a decreasing, component of a complex mix of sources of freshwater. Its relative contribution to water resources decreases with distance downstream, being greatest where it enters seasonally arid regions such as the lower Indus, and becoming negligible in the monsoon-dominated Ganges-Brahmaputra (Kaser *et al*., 2010). In the mountains, however, both dependence on and vulnerability to glacier meltwater can be of serious practical concern when measured per head of population.

3.4.5. Runoff and Stream Flow

Since the publication of the AR4 there have been very many catchment-scale studies of the potential impacts of climate change on runoff and streamflow, and many of the spatial gaps identified in AR4 have been plugged to a very large extent. Virtually all of these studies have estimated impacts using scenarios constructed from climate models. The projected impacts in a catchment depend on the sensitivity of the catchment to change in climatic characteristics and on the projected change in the magnitude and seasonal distribution of precipitation, temperature and evaporation. Catchment sensitivity is largely a function of the ratio of runoff to precipitation; sensitivity is greater the smaller the ratio. Figure 3-6 shows projected change in mean monthly runoff for seven catchments across the globe, using the same seven climate model patterns scaled to represent an increase in global mean temperature of 2^{o}C above the 1961-1990 mean (Arnell, 2011b; Hughes *et al*., 2011; Kingston and Taylor, 2010; Kingston *et al*, 2011; Nobrega *et al*, 2011; Thorne, 2011a; Xu *et al*., 2011); changes under the HadCM3 model with 2 and 4^{o}C increases are highlighted. The figure illustrates how the same climate model has a different effect in different catchments, shows considerable variability in estimated impact in each catchment across the seven scenarios and also show non-linear response to increasing forcing (in the Mitano catchment). The uncertainty is largely driven by differences in projected changes in precipitation between different climate models. Incorporating uncertainty in hydrological model structure (Section 3.4.1) would increase further the range in projected impacts at the catchment scale.

[INSERT FIGURE 3-6 HERE
Figure 3-6: Range in change in mean monthly runoff across seven climate models in seven catchments, with a 2^{o}C increase in global mean temperature (above 1961-1990) (Arnell, 2011b; Hughes *et al*., 2011; Kingston and Taylor, 2010; Kingston *et al*., 2011; Nobrega *et al*., 2011; Thorne, 2011a; Xu *et al*., 2011). Changes with the HadCM3 climate model with increases of 2 and 4^{o}C are highlighed.]

A number of studies have used projected changes in runoff and streamflow across the global domain (e.g. Arnell and Gosling, 2013a; Döll and Zhang, 2010; Fung *et al*., 2011; Gosling *et al*., 2010; Schewe *et al*., 2013), and some assessments have used directly the output from global climate models (Hirabayashi *et al*., 2008; Okazaki *et al*., 2012; Tang and Lettenmaier, 2012). (Figure 3-7). Most of these studies have used CMIP3 climate models, although a small number (Okazaki *et al*., 2012; Schewe *et al*., 2013) have used CMIP5 models. The projected changes are dependent on the climate scenarios used, but it is possible to identify a number of consistent patterns. Average annual runoff is projected to increase at high latitudes and in the wet tropics, to decrease in most dry tropical regions. However, there are some regions where there is very considerable uncertainty in the magnitude and direction of change, specifically south Asia and large parts of South America.Both the patterns of change and the uncertainty are largely driven by projected changes in precipitation, with uncertainty in projected changes in rainfall across South Asia being particularly significant. [Cross reference to WG1 to be included here]. Changes in average annual runoff are typically between 1 and 3 times as large as changes in average annual precipitation (Tang and Lettenmaier, 2012).

[INSERT FIGURE 3-7 HERE
Figure 3-7: Relative change in annual discharge at 2°C (2.7°C above pre-industrial) compared to present-day, under RCP8.5. Color hues show the multi-model mean change, and saturation shows the agreement on the sign of change across all 55 GHM-GCM combinations (percentage of model runs agreeing on the sign). (Schewe *et al*., 2013)]

There is a much more consistent pattern of future change in the timing of streamflows in areas with regimes currently influenced by snowfall and snowmelt. A global analysis (Adam *et al*., 2009) with multiple climate scenarios shows a consistent shift to earlier peak flows, except in some regions areas where increases in precipitation are sufficient to result in increased, rather than decreased snow accumulation during winter. The greatest changes are found near the boundaries of regions which currently experience considerable snowfall, where the marginal effect on snowfall and snowmelt of higher temperatures is greatest.

3.4.6. Groundwater

While the relation between groundwater and climate change was rarely investigated before 2007, the number of relevant studies and review papers (Green *et al*., 2011; Taylor *et al*., 2012a) has since then increased significantly. Ensemble studies of the impact of climate change on groundwater recharge and partially also groundwater levels were done for the globe (Portmann *et al*., 2013), all of Australia (Crosbie *et al*., 2012), the German Danube basin (Barthel *et al*., 2010), and aquifers in temperate Belgium and England (Goderniaux *et al*., 2011; Jackson *et al*., 2011), the Pacific coast of the USA and Canada (Allen *et al*., 2010) and for a study site in the semi-arid part of the USA (Ng *et al*., 2010). The number of applied climate models ranged from 4 to 20, and with two exceptions, only one emissions scenario, mostly SRES A2, was taken into account. Due to the uncertainty of climate models, the range of future groundwater changes was large, from significant decreases to significant increases for the individual study areas, and the range of percent changes of projected groundwater recharge mostly exceed the range of projected precipitation changes.

When considering a particular climate scenario, land areas where total runoff are projected to increase (or decrease) roughly coincide with the areas where groundwater recharge and thus renewable groundwater resources are projected to increase (or decrease) (Kundzewicz and Döll, 2009). Changes in precipitation intensity affect groundwater recharge as a fraction of total runoff. Increased precipitation intensity, for example, may decrease groundwater recharge due to exceedance of infiltration capacity (typically in humid areas) or increase it due to a fast percolation through the root zone from where water otherwise would be evapotranspired (typically in semi-arid areas) (Taylor *et al*., 2012b; Liu, 2011). The response of groundwater recharge and levels to climate change is small in case of fine-grained soils and clayey confining layers, and large in case of sandy soils and water table aquifers (van Roosmalen *et al*., 2007). It also depends on the vegetation, in particular as vegetation adapts to climate change and thus modifies the groundwater response to climate change (Box CC-VW).

Decreasing snowfall may lead to lower groundwater recharge even if precipitation remains constant; at sites in the Southwestern USA, snowmelt provides at least 40-70% of groundwater recharge, although only 25-50% of average annual precipitation falls as snow (Earman *et al*., 2006). Due to expected increases in precipitation and streamflow variabililty, climate change is also expected to lead to increased groundwater abstractions (Taylor *et al*., 2012a), lowering groundwater levels and storages.

Coastal groundwater is affected by climate change not only due to changes in groundwater recharge but also due to sea level rise which, together with the rate of groundwater pumping, determines the location of the saltwater/freshwater interface. While most confined aquifers are expected to be unaffected by sea level rise, most unconfined (water table) aquifers are *likely* to suffer from saltwater intrusion and a loss of freshwater volume (Werner *et al*., 2012; Masterson and Garabedian, 2007). Assuming an average salt water density of 1.025 g/cm^3, the thickness of the unconfined freshwater layer decreases by roughly 40 meters if difference between the fresh groundwater table and the sea level is decreased by 1 meter due to either sea level rise or decreased groundwater recharge (Werner *et al*., 2012). Salt water intrusion is mostly a very slow process that may take several centuries to reach equilibrium (Webb and Howard, 2011).

Water table aquifers of flat (coral) islands and delta regions are expected to suffer very strongly from saltwater intrusion due to sea level rise or potentially decreasing groundwater recharge. The latter is also affected by storm surges, with increased upstream transport of saline waters in the rivers which then contaminate the underlying fresh groundwater from above (Masterson and Garabedian, 2007). Even small rates of groundwater pumping near the coast are expected to lead to stronger salinization of the coastal groundwater than sea-level rise during the 21st century (Ferguson and Gleeson, 2012).

Changes in groundwater recharge also affect streamflow in rivers. In a catchment of the Upper Nile basin in Uganda, mean global temperature increases of 4°C or more are projected to decrease groundwater outflow to the river so much that the spring discharge peak disappears and the river flow regime changes from bimodal to unimodal (one seasonal peak only) (Kingston and Taylor, 2010). Changing groundwater tables have an effect on land surface fluxes and thus the climate system which remains to be fully explored (Jiang *et al*., 2009). However, it has been shown that the effect to be strongest in case of semi-arid condition where the groundwater table is less than 7 meter below the ground (Ferguson and Maxwell, 2010).

3.4.7. Water Quality

The impact of climate change on the quality of water occurs through a complex set of natural and anthropogenic mechanisms working in parallel and in series and, occasionally, even at the same time. Projecting future conditions is a difficult task involving the integration of climate models outputs with those used to analyze the transportation and transformation of pollutants in water, soil, and air (Andersen *et al*., 2006; Arheimer *et al*., 2005; Bonte and Zwolsman, 2010; Ducharne, 2008; Marshall andRandhir, 2008; Rehana and Mujumdar, 2012; Towler *et al*., 2010; Trolle *et al*., 2011; Wilby *et al*., 2006). In addition, such models use different scales and have to be adapted and calibrated to local conditions; often a difficult task due to a lack of sufficient and appropriate information. As a result, there is little in the literature with regard to the future impacts of climate change on water quality, and this is available where the uncertainty is high.

From the projections reported (Figure 3-3), it is evident that results are highly dependent on (Bonte and Zwolsman, 2010; Chang, 2004; Kundzewicz and Krysanova, 2010; Sahoo *et al*., 2010; Trolle *et al*., 2011; Whitehead *et al*., 2009a; 2009b) (a) local conditions; (b) climatic and environmental assumptions, such as other types or sources of pollution; and (c) current impacts (i.e., pollution state/reference state). Most projections are useful in affirming that observed impacts will be *likely* to prevail in the future for natural and artificial reservoirs (Bonte and Zwolsman, 2010; Brikowski, 2008; Ducharne, 2008; Loos *et al*., 2009; Marshall andRandhir 2008; Qin *et al*., 2010; Sahoo *et al*., 2010; Trolle *et al*., 2011), rivers (Andersen *et al*., 2006; Bowes *et al*., 2012; Whitehead *et al*., 2009a; 2009b) and groundwater (Butscherand Huggenberger, 2009; Rozemeijer *et al*., 2009), and will be a result of the combination of the change and variations in air/water temperature and precipitation/storm runoff, combined with many other factors that also impact upon the quality of water (Chang, 2004; Whitehead *et al*., 2009a).

3.4.8. Soil Erosion and Sediment Load

Heavy rainfall events are *likely* to increase in the 21st century over many areas on the globe (Seneviratne *et al*., 2012), which may lead to a disproportionate amount of erosion relative to the total rainfall contribution. At global scale, changes in soil erosion in the 2090s compared to the 1980s is expected to increase about 14% (9% attributed to climate and 5% due to land use) with significant increase of 40-50% in Australia and Africa (Yang *et al*., 2003). The largest amounts are expected on erosion-prone semiarid areas where contribution of extreme events may constitute up to 40% of total erosion (Baartman *et al*., 2012). In agricultural lands of temperate regions, soil erosion may respond in complex non-linear ways; for instance in agricultural land on the UK South Downs a rainfall scenario of 10% increase in winter rainfall could give increases of annual erosion by up to 150%, that is be explained by the interaction of the timing of rainfall (winter) during the early growing season (Favis-Mortlock and Boardman, 1995). On the other hand, in central Europe (Austria) regional climate model HadRM3H (SRES A2, 2010-2099) projects a net-decrease of rainfall amount of 10-14% in erosion sensitive months giving rise to decline

in soil erosion in all tillage systems by 11-24% (Scholz *et al*., 2008). Land management practices are critical to reduce soil erosion under projected climate change. In the China's Loess Plateau, GCMs project a soil erosion increase of 5-195% during 2010-2039 under conventional tillage, whereas under conservation tillage shows decreases of 26-77% (Li *et al*., 2011).

Climate change is *likely* to affect sediment load in rivers through soil erosion processes, water discharge, and changes in land use and land cover. For example, an increase in water discharge of 11-14% in two Danish rivers was projected to raise the annual suspended sediment between 9% and 36% during the period 2071-2100 (Thodsen *et al*., 2008). Projected river's sediment flux in response to climate change needs also to consider the sensitivity of land cover to climate change. For instance, Gomez *et al*. (2009) simulated the changes in water flow and suspended sediment flux in the Waipaoa River in New Zealand showing that climate change may reduce the mean flow by 13% in the 2030s and 18% in the 2080s, producing changes of annual suspended sediment flux of ±1 Mt/year by the 2030s, but depending on the climate change scenario by the 2080s it may either decline by 1 Mt/year (under warmer drier conditions) or increase by 1.9±1.1 Mt/year (warmer but not substantially drier). Increases in total precipitation amount, along with melting glaciers, permafrost degradation, and the shift of precipitation patterns from snow to rainfall, will further increase soil erosion and sediment loads of the rivers which are currently fed mainly by glaciers (Lu *et al*., 2010). In a major headwater basin for the Ganges River, an increased precipitation and enhanced melting of glaciers will increase sediment yield by 26% by 2050 (Neupane and White, 2010). In the tropical regions, the intensity of stronger storms from cyclones was projected to increase 2-11% by 2100 (Knutson *et al*., 2010).

In summary, projected increase in heavy rainfall and temperature changes are *very likely* to produce changes in soil erosion and sediment yield; however, overall there is a *low confidence* on the rate of these changes due to the non-linear response of soil erosion and its high dependence on land cover. There impacts of climate change in soil erosion is expected to double the one induced by land use change by 2090s (Yang *et al*., 2003), although management practices may mitigate the sediment yield at catchment scale.

3.4.9. Extreme Hydrological Events (Floods and Droughts)

The SREX report (IPCC, 2012) recognized that projected precipitation and temperature changes imply possible changes in floods, although overall there is *low confidence* in projections of changes in fluvial floods. Projected increases in heavy rainfall would contribute to increases in rain generating local flooding, in some catchments or regions (Kundzewicz, 2013; Seneviratne *et al*., 2012). The studies supporting these assessments relied on a single GCM, which was the major source of *limited evidence* and thus *low confidence* in SREX (IPCC, 2012). Recent literature on global flood projections are based on ensemble from global hydrology models couple with multiple CMIP5 GCM simulations (Dankers *et al*., 2013; Hirabayashi *et al*., 2013). These model experiments show that flood hazards are increasing in more than half of the globe with a great variability even at the scale of individual river basins. In general, these studies show consistent results with increasing flood hazards occurring in parts of South Asia, Southeast Asia, East Africa, Central and West Africa, Northeast Eurasia, and South America. In contrast, a decrease in flood frequency was projected in parts of North and East Europe, Anatolia, Central Asia, central North America, and southern South America (Figure 3-8). This overall pattern is considerably similar to what was described in SREX (IPCC, 2012) as a summary of limited global or continental scale studies where each study relied on a single or a limited number of climate models. Thus, the global/continental-scale flood projection has gained ground and confidence could become higher than SREX (IPCC, 2012). However, uncertainty is still large at the global and continental scales particularly about the magnitude of changes. At local scale, even the sign of the change do not necessarily agree among GCMs (Dankers *et al*., 2013; Hirabayashi *et al*., 2013).

[INSERT FIGURE 3-8 HERE
Figure 3-8: Results of flood hazard change for the 30-year return level of river flow (Q30) from ensemble of 5 CMIP5 GCM simulations under RCP8.5 coupled with nine global hydrology and land surface models (named as impact models (IMs)) that provided simulations of daily river discharge at a global 0.5-degree grid for two 30-year periods (1971-2000 and 2070-2090) (Dankers *et al*., 2013). Top: Number of experiments (out of 45 in total) showing an increase (top left) or decrease (top right) in the magnitude of Q30 of more than 10% in 2070-2099 under RCP8.5, compared to 1971-2000. Bottom left: Average change in the magnitude of Q30 across all experiments.

Bottom right: Ratio of GCM variance to IM variance. GCM variance was computed as the variance of the change in Q30 across all GCMs for each individual IM, and then averaged over the 9 IMs; IM variance was computed as the variance of the change in Q30 across all IMs for each individual GCM, and then averaged over the 9 GCMs. In dark green (purple) areas GCM (IM) variance predominates.]

Projections at the catchment and/or river-basin scale are also being carried out (e.g, Dobler *et al*., 2012; Kay and Jones, 2012; Rojas *et al*., 2012) in addition to examples referred to in SREX (IPCC, 2012) and AR4, although projections for developing countries and regions are still limited (e.g., Ghosh and Dutta, 2012; Hunukumbura and Tachikawa 2012; Khazaei *et al*., 2012) and they tend to rely on a single or a limited number of climate models.

SREX (IPCC, 2012) assessed the projection of drought as: There is *medium confidence* in a projected increase in duration and intensity of droughts in some regions of the world, including southern Europe and the Mediterranean region, central Europe, central North America, Central America and Mexico, northeast Brazil, and southern Africa. Elsewhere there is overall *low confidence* because of insufficient agreement of projections of drought changes (dependent both on model and dryness index). Definitional issues and lack of data preclude *higher confidence* than *medium* in observations of drought changes, while these issues plus the inability of models to include all the factors *likely* to influence droughts preclude stronger *confidence* than *medium* in the projections. Note that the assessment of SREX (IPCC, 2012) is different to a certain degree from the one in AR4, in that confidence has become slightly lower, after carefully re-examining the AR4 assessment and adding post-AR4 studies.

Recently future changes in consecutive dry days (CDD) and simulated soil moisture anomalies (SMA) are calculated based on CMIP5 multi-model outputs, and compared CMIP5-based drought projections with CMIP3-based projections that were shown in SREX (Orlowsky and Seneviratne, 2012). It turns out that CMIP5-based projections are generally consistent with CMIP3-based projections except that drought at northeast Brazil is not clear by the SMA index obtained from CMIP5. Therefore, the above assessment on global-scale drought projection in SREX (IPCC, 2012) could remain almost the same here, even though definitional issues of drought remain yet to be solved.

3.5. Impacts, Vulnerabilities, and Risks

3.5.1. Availability of Water Resources

Approximately 80% of the world's population is currently exposed to high levels of threat to water security, in terms of a range of indicators including water availability , water demand and pollution (Vörösmarty *et al*., 2010). The greatest threats are across much of Europe, in south Asia, eastern and northeastern China, and parts of southern Africa and the eastern United States. Climate change has the potential to alter the availability of water and therefore threats to water security.

Global-scale analyses so far have concentrated on measures of resource availability rather than the multi-dimensional indices used in Vörösmarty *et al*. (2010). All have simulated future river flows or groundwater recharge using global-scale hydrological models. Some have assessed future availability based on runoff per capita (Arnell *et al*., 2011c; Arnell *et al*., 2013b; Fung *et al*., 2011; Gosling and Arnell, 2013; Hayashi *et al*., 2010; Schewe *et al*., 2013), whilst others have projected future human withdrawals and characterized availability by the ratio of withdrawals to runoff or recharge availability (Arnell *et al*., 2011c; Gosling and Arnell, 2013). Döll (2009) constructed a groundwater sensitivity index which combined water availability with dependence on groundwater and the Human Development Index (Figure 3-9). In a study with five climate models driving eleven global hydrological models, climate change was estimated to add, on average, about 40% to the global number of people living under extreme water shortage, for a global mean temperature rise of 2.7°C above pre-industrial (Schewe *et al*., 2013). Up to this temperature rise, each degree of global warming is projected to confront an additional 7% of the global population with a severe decrease in water resources of 20% (Schewe *et al*., 2013; Table 3-2). There are several key conclusions from this set of studies. First, the spatial distribution of the impacts of climate change on resource availability varies considerably with the climate model used to construct the climate change scenario, and particularly with the pattern of projected rainfall change (Arnell *et al*., 2011c; Döll, 2009; Portmann *et al*., 2013; Schewe *et al*., 2013). There is a strong degree of consistency in projections of reduced availability around the

Mediterranean and parts of southern Africa, but much greater variation in projected availability in South and East Asia. Second, some water-stressed areas see increased runoff in the future (Section 3.4.5), and therefore a reduction in exposure to water resources stress -varying with the spatial pattern of projected changes in rainfall. Third, over the next few decades and for increases in global mean temperature of less than around 2°C above pre-industrial, changes in population will generally have a greater effect on changes in resource availability, relative to the present day, than climate change (Fung *et al*., 2011). Climate change would, however, regionally exacerbate or offset population pressures. Fourth, estimates of future water availability are sensitive not only to projections of future climate change and population assumptions, but also to hydrological impact model (Schewe *et al*., 2013) and the specific measure of stress or scarcity used.

[INSERT FIGURE 3-9 HERE
Figure 3-9: Human vulnerability to climate change induced decreases of renewable groundwater resources by the 2050s for four climate change scenarios in which lower (B2) and higher (A2) emissions pathways are interpreted by two global climate models. The higher the vulnerability index (computed by multiplying percent decrease of groundwater recharge by a sensitivity index), the higher is the vulnerability. The index is only defined for areas where groundwater recharge is projected to decrease by at least 10%, as compared to the climate normal 1961-90 (Döll, 2009).]

Under climate change, reliable surface water supply is *likely* to decrease due to increased temporal variations of river flow that are caused by increased precipitation variability and decreased snow/ice storage. Under these circumstances, it might be beneficial to take advantage of the storage capacity of groundwater and increase groundwater withdrawals (Kundzewicz and Döll, 2009). However, this option is only sustainable where groundwater withdrawals remain well below groundwater recharge. Groundwater is *not likely* to ease freshwater stress in those areas where climate change is projected to decrease groundwater recharge and thus renewable groundwater resources (Kundzewicz and Döll, 2009). The percentage of projected global population (SSP2 population scenario) that will suffer from a decrease of renewable groundwater resources GWR of more than 10% by the 2080s as compared to 1971-2000 was computed to range from 24% (mean based on 5 GCMs, range 11-39%) for RCP2.6 to 38% (range 27-50%) for RCP8.5 (Portmann *et al*., 2013; Table 3-2). Considering change of GWR as a function of mean global temperature (GMT) rise, the land areas affected by GWR decreases of more than 30% and 70% increase linearly with GMT between 0°C and 3°C. For each degree of GMT rise, an additional 4% of the global land area is cprojected to suffer from a GWR decrease of more than 30%, and an additional 1% to s a decrease of more than 70% (Portmann *et al*., 2013).

3.5.2. Water Uses

3.5.2.1. Agriculture

Higher temperatures and increased variability of precipitation would, in general, lead to increased irrigation water demand, even if the total precipitation during the growing season remains the same (Bates *et al.*, 2008). Crop transpiration and therefore irrigation water requirements are *likely* affected by physiological and structural crop responses to increased atmospheric CO_2 concentration (Box CC-VW). Using 19 climate models to drive a global vegetation and hydrology, it was projected that global irrigation water requirement on areas presently equipped for irrigation would decrease by on average by 17% by the 2080s (if not limited by poor soils and nutrient availability), while it would remain approximately constant if CO_2 effects were not taken into account (Konzmann *et al.*, 2013). Even with the maximum CO_2-effect, increases of more than 20% are projected for Southern Europe and parts of China, the USA, Russia and Chile (Box CC-VW).

Irrigating crops can influence regional climate considerable. Irrigation is used to produce over 40% of the world's food, this is why irrigation is a one of the key elemements for food security in the future.

Effects of global irrigation on the near surface climate
It has been found (Sacks *et al*., 2009) that irrigation alters climate for instance by indirect effects like an increase in cloud cover. This effect can be significant in some regions, for example: cooling central and southern US, China,

and parts of Asia, in contrast, it warmed Canada by about 1 C°. Nevertheless, the impact is only at a regional level, as agriculture has little impact on the global mean temperatures. Precipitation increase occurs primarily downwind of the major irrigation areas, although precipitation in part of India decreases due to weaker summer (Puma and Cook, 2010).

Irrigation as adaptation strategy

Farmers could optimize production by adapting their use of fertilizers, pesticides and irrigation water to change climatic, political and economic conditions. To manage increasing yield variability and potential decrease in yield levels, irrigation constitutes an additional adaptation option which farmers might use (Finger *et al*., 2011).

About 4% of Sub-Saharan Africa arable land is irrigated. Irrigated land yields are up to five times that of rain fed areas. However, it must be the case that the costs of irrigation (e.g., capital, administrative, political) are high enough to balance or offset the benefits, thus and evaluation should be made considering local conditions (World Bank, 2009).

A study quantifying global changes in irrigation requirements on areas presently equipped for irrigation of major crop types has been realized indicating results from 19 GCMs for the year 2080. It was found a decrease in global irrigation of about 17% in the ensemble median. Additionally, an increase of more than 20% is projected with (*high likelihood*) for some regions such as South Europe and (*lower likelihood*) in Asia and North America.

Shifts in sowing dates constitute an adaptation option, for insance for maize production in Switzerland (World Bank, 2009), but sometimes this have to be combined with irrigation (Meza *et al*., 2009).

Complementary between mitigation and adaptation

A comparison of optimal input levels of nitrogen between rainfed and irrigated farming system shows different adaptation strategies. In rainfed production systems, reduced summer rainfalls lead to a reduction of the optimal production intensity for current and future scenarios. On the contrary, an increased application of nitrogen (i.e., a more intensive production) is an optimal response to climate change if irrigation is available. The difference in yield levels and yield variability between irrigated and rainfed farming systems will be higher with more marked climatic conditions (Finger *et al*., 2011).

3.5.2.2. Energy Production

Large amounts of water are required to produce energy by thermal power plants, hydropower and irrigated bioenergy crops (see Box CC-WE). Therefore, hydrological changes (Section 3.4) are expected to affect energy production, while changes in energy production due to climate change mitigation efforts will alter freshwater systems (Section 3.7.2.1), e.g. water availability for freshwater ecosystems (Section 3.5.2.4).

Hydropower generation is affected by changes in the mean annual river discharge, seasonal flows and daily flow variability as well as increased evaporation from reservoirs and changes in sediment fluxes. Projections of future hydropower generation in the Pacific Northwest of the USA are uncertain mainly due to the uncertainty of projected precipitation (Markoff and Cullen, 2008). Hydropower generation of Lake Nasser (Egypt) was computed to remain constant until the 2050s (based on an ensemble of 11 GCMs) but to decrease, on average (ensemble mean), to 90% of current mean annual production for the A2 (B1) emissions scenario, following the downward trend of mean annual river discharge (Beyene *et al*., 2010; Table 3-2). In snow-dominated basins, increased discharge in winter and lower and earlier spring floods have already been observed (Section 3.2.5) and the trend is *very likely* to continue in the future. This makes the annual hydrograph more similar to seasonal variations in electricity demand, providing opportunities for operating dams and power stations to the benefit of riverine ecosystems (Renofalt *et al*., 2010; for Sweden). In general, climate change requires adaptation of operating rules (Minville *et al*., 2009; Raje and Mujumdar, 2010) which may, however, be restricted by reservoir storage capacity. In California, for example, high-elevation hydropower systems with small storage, which rely on the storage capacity of the snowpack, are projected to suffer from decreased hydropower generation and revenues due to the increased occurrence of spills, unless

precipitation increases significantly (Madani and Lund, 2010). Storage capacity expansion would help increase hydropower generation but might not be costed effective (Madani and Lund, 2010).

Regarding water availability for cooling of thermal power plants, the number of days with a reduced useable capacity is projected to increase in Europe and the USA, caused by increased stream temperatures and occurrence of low flows (van Vliet *et al*., 2012; Flörke *et al*., 2012). Lower emissions also lead to less severe impacts of climate change (Table 3-2). Economic implications of the impact of climate change on thermal power and hydropower production as well as adaptation options are discussed in Chapter 10.

3.5.2.3. Municipal Services

Under anthropogenically altered climate conditions, water utilities are confronted by the following (Bates *et al*., 2008; Black and King, 2009; Bonte and Zwolsman, 2010; Brooks *et al*., 2009; Chakraborti *et al*., 2011; Christierson *et al*., 2012; Hall and Murphy, 2010; Jiménez, 2008a; Major *et al*., 2011; Mukhopadhyay and Dutta, 2010; Qin *et al*., 2010; Thorne and Fenner, 2011b; van Vliet and Zwolsman, 2008; Whitehead *et al*., 2009):

- Higher ambient temperatures is very likely to reduce snowpacks and glaciers, also they are very likely to increase the evaporation rate in lakes, reservoirs and aquifers. Both impacts is very likely to reduce the amount of water naturally stored reducing its availability. At the same time higher ambient temperatures is likely to increase the demand for municipal water as for many other uses. The overall situation resulting in a higher competition for water from different users.
- Shifts in river flows and the occurrence of droughts are likely to increase the need for artificial storage capacity.
- Higher water temperatures which exacerbate algal blooms in surface water potentially demanding for cyanotoxins control. Also a warmer environment potentially leads to changes in the quantity and quality of natural organic matter in water sources that are at the origin of disinfection by-products in chlorinated water. These issues contrast with potential increases in the efficiency of biological water and wastewater treatement processes resulting from increased water temperatures (Tchobanoglous *et al*., 2003).
- Drier conditions, resulting in a higher concentration of pollutants due to a reduction in dilution capacity. For groundwater sources, some pollutants of natural origin, including arsenic, iron, manganese and flurorides are likely to be an additional source of concern in areas already affected from, South East Asia (India), North and Latin America and Africa (Black and King, 2009).
- Elevated storm runoff, leading to higher loads of pathogens, nutrients and turbidity in water bodies from point and non-point sources of pollution. The indicators traditionally used to assess faecal pollution (faecal bacteria), as a result, is likely to be insufficient to track pathogens.
- Sea level rise, leading to increased salinity in aquifers in particular where groundwater recharge is very likely to decrease.

Water supply

With respect to the safe supply of water, many treatment plants are not designed to handle extreme influent variations that occur under climate variable conditions. These demand additional or even different infrastructure for treatment during periods of one to up to several months per year. In order merely to control the increased turbidity that would be *likely* to interfer with the disinfection process, higher coagulant doses would be needed, greater volumes of sludge would then be produced and need to be disposed increasing treatment costs (Zwolsman *et al*., 2010; Arnel *et al*., 2011). Depending on the extent of the impacts and local conditions resulting costs may or not be affordable.

Sanitation service

With regard to sewers, three climatic conditions are of interest from the perspectives of design and operation (NACWA, 2009; Zwolsman *et al*., 2010):

- Wet weather conditions -Heavy rainstorms challenge the existing capacity of sewerage systems due to the need to deal with increased amounts of pluvial water and even wastewater in combined systems, even for short periods of time. The current design, based on critical “design storms” defined through analysis of historical precipitation data, must be modified to include future scenarios. In addition new strategies to

prevent urban floods have to be developed considering not only the future climate but also many other factors such as urban design, land use, the "heat island effect" and topography (Chagnon, 1969).

- Sea level rise -The intrusion of brackish or salty water to sewers necessitates not only additional capacity of wastewater treatment but also processes that are able to operate with more saline wastewater.
- Dry weather conditions -During dry conditions, soil shrink as they lose humidity, eventually causing the cracking of water mains and sewers and with this the infiltration and exfiltration of water/wastewater. The combined effects of higher temperatures, increased concentrations of pollutants, longer retention times, and solids sedimentation may lead to increasing corrosion of sewers, shortening asset life and increasing maintenance costs. This is also likely to cause problems of septicity, higher pollutant contents and increased "first flush" concentrations.

Cities suffering from increased storm runoff are likely to experience the need to treat combined sewer overflows (CSO), due to increased amounts and varieties of pathogens and pollutants. Under drier conditions a high content of pollutants in wastewater, of any type, is to be expected and has to be dealt with (Whitehead *et al*., 2009a; 2009b; Zwolsman *et al*., 2010). This is unlikely to be feasible in low income regions (Chakraborti *et al*., 2011; Jiménez, 2011). At the present time, despite improvements in some regions, water pollution is on the rise globally, and more than 80% of the municipal wastewater in low income countries is discharged untreated into water bodies or to the ground (UNICEF-WHO, 2012; WWAP, 2009). In addition, the disposal of wastewater or faecal sludge is a concern that is just beginning to be studied (*low to medium confidence, limited evidence*) (Seidu *et al*., 2013).

3.5.2.4. Freshwater Ecosystems

Freshwater ecosystems are comprised by biota (animals, plants and other organisms) and their abiotic environment in slow flowing surface waters like lakes, man-made reservoirs or wetlands, in fast flowing surface waters like rivers and creeks, and in the groundwater. They have suffered more strongly from human actions than marine or terrestrial ecosystems. Between 1970 and 2000, populations of freshwater species included in the Living Planet Index declined on average by 50%, compared to 30% for marine and also for terrestrial species (Millenium Ecosystem Assessment, 2005). Climate change is an additional stressor of freshwater ecosystems. It affects freshwater ecosystems not only by increased water temperatures (discussed in Chapter 4) but also by altered flow regimes, water levels and extent and timing of inundation (Box CC-RF).

Wetlands in semi-arid or arid environments are hotspots of biological diversity and productivity, and are endangered by extinction in case of decreased runoff generation, resulting in wetland extinction and loss of biodiversity (Zacharias and Zamparas, 2010).

In addition, climate change leads to water quality changes (Section 3.2.5) which also influences freshwater ecosystems. Furthermore, freshwater ecosystems are likely to be negatively impacted by human adaptation to climate-change induced flood risk as flood control structures affect the habitat of fish and other biota (Ficke *et al*., 2007).

3.5.2.5. Other Uses

In addition to the direct impacts, vulnerabilities, and risks in the water-related sectors, indirect impacts from changes in the hydrological systems are expected in sectors, such as navigation, transportation, tourism, and urban planning (Badjeck *et al*., 2010; Beniston, 2012; Koetse and Rietveld, 2009; Pinter *et al*., 2006; Rabassa, 2009). Further social and political problems can occur, as for example water scarcity and water overexploitation is *likely* to increase the risks of violent conflicts and nation-state instability (Barnett and Adger, 2007; Buhaug *et al*., 2010; Burke *et al*. 2009; Hsiang *et al*., 2011).

As a consequence of snowline rising and glacier vanishing, damage on environmental, hydrological, geomorphological, heritage, and tourism resources is *very likely* to affect glacierized regions and those communities

active in them (Rabassa, 2009). The melting of alpine glaciers and rising snowlines in the European Alps, South American Andes, or Himalayas already affects for example the tourism industry (Beniston, 2012).

3.5.3. Impact Costs of Extreme Events

Reported flood damages (adjusted to inflation) have increased over the period 1980-2011 from an average of 7 billion US$ per year in the 1980s to about 24 billion US$ per year of which an average of 9% was insured (data from Munich Re, 2012). The SREX report (IPCC, 2012) indicated that economic, including insured, flood disaster losses are higher in developed countries, while fatality rates and economic losses expressed as a proportion of gross domestic product (GDP) are higher in developing countries (Handmer *et al*., 2012). Currently about 800 million people worldwide (i.e. over 11% of global population) are living in flood-prone areas, and about 70 million of those people (i.e. 1% of global population) are, on average, exposed to floods each year (UNISDR, 2011). The population living in flood-prone areas has increased faster than overall population or economic growth (Bouwer *et al*., 2007; Bouwer, 2011; Jongman *et al*., 2012), in part explaining the observed increase in flood damage. Average number of deaths since 1980 is on the order of thousands casualties per year, of which over 95% of deaths occurred in developing countries, with the highest number (75%) are concentrated in southern, south-eastern and eastern Asia (Handmer *et al*., 2012). The loss of life has been decreased considerably, particularly in high income areas, due to improved flood protection and management measures (UNISDR, 2011). One of most vulnerable countries in the Asian region is Pakistan that has been affected by three consecutive years of flooding with nearly 2000 deaths in 2010, followed by 2011 and 2012 which flooding caused at least 360 and 480 deaths respectively.

In the case of events related to extreme precipitation (intense rainfall, hail and flash floods), some studies suggest an increase in impacts related to higher frequency of intense rainfall events (Changnon, 2001; 2009; Jiang *et al*., 2005; Miller *et al*., 2008). The lack of evidence that anthropogenic climate change has led to increasing risks applies mainly to developed countries where detail inventory of weather-related loss data are available over time. Moreover, *robust evidence* that anthropogenic climate change has led to increasing losses cannot be attained as far as changes on peak flows are regionally detected, which may required longer observational records or future risk projections that include exposure and vulnerability changes (Fowler and Wilby, 2010; Bouwer, 2011). In developing countries, high uncertainty in the climate change role on increasing flood risk is mainly related to lack of quality and completeness of loss data, and to the high impacts of modest weather and climate events on the livelihoods and people of informal settlements and economic sectors (Handmer *et al*., 2012). The impacts of local weather extremes are largely excluded in the analysis of impacts as there are not systematically reported or documented on national or global databases. These local weather extremes have increased their direct damage costs to society increasing the statistics on the number of flood disaster, in the sense that even small floods has a potential to cause catastrophic impacts.

Water related impacts (floods and droughts) are projected to increase even in case of constant hazard due to the increase in the population exposed and vulnerability (Kundzewicz, 2013). At global scale, there is a marked regional variability (largest losses in Asia), and a wide range of results between climate models. For instance, analysis from 21 climate models under SRES A1b shows that population exposed by 2050 to a doubling flood frequency range from 31 to 449 million people, and the change in risk varies between -9 and +376% (Arnell and Gosling, 2013a). Detail studies estimating future expected economic losses are mainly focussed in Europe, USA and Australia (Handmer *et al*., 2012; Bouwer *et al*., 2012). In the case of Europe (Feyen *et al*., 2012), the current (control period: 1961-1990) €6.4 billion per year annual damage and 200,000 annual population exposed is expected to increase about twice under scenario B2 (€14-15 billion per year and 440.000-470.000 annual people exposed) and about three times under scenario A2 (€18-21 billion per year and with annual population exposed of 510,000-590,000). According to Handmer *et al*. (2012), the main driver for future increasing losses of water relates disasters in developing countries will be socioeconomic in nature as result of changes in population and exposure of people and assets (based on *medium agreement* and *limited evidence*), with effects of climate change amplifying the impacts of expected losses

The costs of inland waterway transport is *likely* to increase due to increased frequency of low water levels, as e.g. was shown in the impositions of ship draft restrictions during the El Niño 1996. Most direct impacts and costs are

still uncertain and ambiguous (Koetse and Rietveld, 2009). On the other hand, extreme high water levels in rivers is *likely* to increasing sedimentation of navigation channels and hence cause higher costs for navigation due to more necessary channel dredging (Pinter *et al*., 2006).

3.6. Adaptation and Managing Risks

In the face of impacts on water resources, floods and droughts and the changes in water use because of climate change, there is need for adaptation and to increase resilience. Moreover, even to take advantages of possible positive impacts there is need for adaptation. Managing the changing risks due to the impacts of climate change is the key in the adaptation in water sectors (IPCC, 2012), and risk management should be part of decision making and used to deal with uncertainty (ISO 31000, Risk Management (ISO, 2009)). In the next sections, in a generic way, adaptation options are discussed, followed by some reflections on the limits for adaptation and its costs. The need to build capacity in this area is also discussed.

3.6.1. Adaptation Options

Since the 3rd IPCC assessment report efforts have been made to identify options for adaptation in the water sector. Many of them are or were applied simply as a response to climate variability and not directly climate change. Climate change provides many opportunities for improvements as “no regret” actions, which are actions able to generate net social and/or economic benefits can be implemented to address both climate variability and climate change. Table 3-3 present different categories of adaptation options reported in the literature.

[INSERT TABLE 3-3 HERE
Table 3-3: Categories of climate change adaptation measures regarding to freshwater.
CC: Particular relevant to climate change, M+A: assist both mitigation and adaptation, M: also assist mitigation]

Adaptation measures, which involve a combination of ‘hard’ infrastructural and ‘soft’ institutional actions, can be helpful in reducing vulnerability. Individual regional measures can be identified by ‘climate proofing’ and implemented as various actions, such as implementing low-regret flood-risk management programs and conduct capacity building (Bates *et al*., 2008; Cooley, 2008; Mertz *et al*., 2009; Olhoff and Schaer, 2010; Sadoff and Muller, 2009; UNECE, 2009).

To avoid adaptation measures with negative results “maladaptation”, scientific research results can be analyzed preceding the planning. Furthermore, low-regret or no-regret adaptation options, where moderate levels of investment increases the capacity to cope with projected risks or where the investment is justified under all plausible future scenarios, might be aspired (World Bank, 2007). One option to obviate maladaptation is to identify and evaluate the use of virtual water in the countries receiving commodities, and to include externalities in the pricing of exports.

A major instrument to explore water-related adaptation measures to climate change is provided with the Integrated Water Resource Management (IWRM), which can be joined with a Strategic Environmental Assessment (SEA) for introducing environmental considerations into IWRM. IWRM is an internationally accepted approach for efficient, equitable and sustainable development and management of water resources and water demands to ensure productive and healthy ecosystems by integrating social, economic, physical, and biological needs and values (GEF-ADB, 2006). In parallel to the implementation of the IWRM approach there is an increase in the attention to adaptive management and robust measures (European Communities, 2009). A robust measure can be defined as a measure that performs well under different future conditions and clearly optimizes prevailing strategies (Sigel *et al.*, 2010).

Past experience suggests that adaptations are best achieved through mainstreaming and integrating climate responses into sustainable development and poverty eradication processes, rather than by identifying and treating them separately (Elasha, 2008). The rationale for integrating adaptation into development strategies and practices is

underlined by the fact that many of the interventions required to increase resilience to climatic changes generally benefit development objectives.

Water development and planning processes in light of climate change and uncertainty in future hydrological conditions are well discussed (Bates *et al*., 2008). Integrating water resources management on actors, reshaping planning processes, coordinating land and water resource management, recognizing water quality and quality linkages, conjunctive use of surface and ground water and protecting and restoring natural systems have been given priority in water management aspects.

3.6.2 Limits to Adaptation

Limits to Adaptation are discussed in detail in Chapter 16 (Section 16.5). Here, barriers to adaptations referring to freshwater resources are highlighted (Burton, 2008). Barriers such as lack of technical capacity, financial resources, awareness, communication etc., are relevant to freshwater resources management. Some of the barriers that are of importance besides technical aspects are the social and economic ones, such as (Butscher and Huggenberger, 2009; Zwolsman *et al*., 2010; Browning-Aiken and Morehouse, 2006): (a) the fact that poor people settle in unsafe areas lacking water services and therefore demand additional public assistance; (b) migration patterns result in demand for services in new areas, sometimes on a temporary basis, resulting in a loss of local knowledge which would aid the selection of low risk areas for settlement; (c) the need to employ better trained staff to deal with problems of water scarcity, which generally only have complex solutions; (d) the need to enforce the law to better use and protect water sources in places where this is not customary; (e) the management of water demand among users in order to satisfy the need for municipal water, including that required for food and energy production.

3.6.3 Dealing with Uncertainty

One of the key challenges to the incorporation of climate change into water resources management lies in the uncertainty in the projected future changes. A large part of the international literature focuses on this uncertainty, mostly concerned with the development of approaches to quantify uncertainty, and a major component of the approaches to water management in the face of climate change (Section 3.6.6) is their treatment of uncertainty.

Some approaches (e.g. in England and Wales; Arnell, 2011a) use a small set of climate scenarios to characterise the potential range in impacts. Much attention, however, has been directed towards methods which use very large numbers of scenarios to produce 'likelihood distributions' of indicators of impact (e.g., Brekke *et al*., 2008; Christierson *et al*., 2012; Hall *et al*., 2012; Lopez *et al*., 2009) for use in risk assessment. The use of multiple scenarios and the temptation to present impacts in terms of probability distributions, however, begs the question of whether such distributions are meaningful (*cross reference to WG2 scenarios chapter*). It has been argued (Dessai *et al*., 2009; Hall, 2007; Stainforth *et al*., 2007) that the attempt to construct probability distributions of impacts is misguided, largely because of the "deep" uncertainty in possible future climates. Deep uncertainty arises because analysts do not know, or cannot agree upon, how systems may change, how models represent possible changes, or how to value the desirability of different outcomes. Stainforth *et al*. (2007) and others therefore argue that it is impossible for practical purposes to construct robust quantitative probability distributions of climate change impacts, and climate change uncertainty needs to be represented differently, for example through the use of a smaller number of plausible scenarios and the less literal interpretation of scenario results.

A section of the literature goes further, arguing that climate models are not sufficiently robust or reliable to provide any basis for adaptation (Anagnostopoulos *et al*., 2010; Blöschl and Montanari, 2010; Koutsoyiannis *et al*., 2008; Lins and Cohn, 2011; Stakhiv, 2011; Wilby, 2010). It is argued that current climate models are frequently biased, and do not reproduce the temporal characteristics -specifically persistence- often found in hydrological records. Existing water resources planning methods, which incorporate uncertainty stochastically and can take persistence into account, are therefore sufficient to address the effects of climate change (Lins and Cohn, 2011; Stakhiv, 2011). This view of climate model performance has been challenged and is the subject of some debate (Huard, 2011;

Koutsoyiannis *et al*., 2011); the critique also assumes that adaptation assessment procedures would only use climate scenarios derived directly from climate model simulations.

Addressing the effects of uncertainty through its quantification in some form of risk assessment, however, is only one way of dealing with uncertainty. An alternative approach starts from the perspective of the characteristics of different adaptation options, and seeks to develop a strategy which is robust and resilient to uncertainty (*cross reference to other WG2 chapters which expand on these terms*) (e.g. Matthews and Wickel, 2009). An example of this approach is provided by Henriques and Spraggs (2011), who considered different responses to future flood risk to critical water supply infrastructure. They used models and scenarios to identify potential risks and their uncertainties, and developed a strategy which enhanced both asset and system resilience. This combined low-regret options to protect individual sites from flooding with longer-term strategies to increase the robustness of the supply network to a wide range of potential disruptions.

Robust decision-making (Lempert *et al*., 1996; 2006; Nassoploulos *et al*., 2012) is a more formalised way of constructing robust and resilient adaptation strategies, and combines features of classic decision analysis and traditional scenario planning. The first stage assesses the performance of a set of defined adaptation actions against a wide range of plausible future conditions. This is similar to traditional scenario planning, but there are two main differences. First, the focus is on adaptation options rather than the future scenarios. Second, the approach involves the assessment of option performance against a very large number of scenarios. The second stage uses the information from the assessment of the initial adaptation options to design revised adaptation options. It does this by identifying, for a given adaptation option, the future scenarios which are particularly challenging, and determining the features of those scenarios that cause problems. The adaptation option is then revised to better cope with these features -and the iteration continues. Even if it is not feasible to identify a single robust strategy (i.e. all the options converge following iteration), the approach does enable the presentation of key tradeoffs and allow decision-makers to determine which risks should be addressed. This approach was applied to the Inland Empire Utilities Agency, supplying water to a region in southern California (Lempert and Groves, 2010). The approach led to the refinement of the company's water resource management plan, making it more robust to the three particularly challenging aspects of climate change identified by the scenario analysis.

3.6.4. Capacity Building

Strengthening the professional capacity and communication on climate change adaptation is essential to cope with the increasing vulnerability to climate change. Capacity building in the water sector means to acquire relevant hydrological and climate information, to make use of this information in water planning processes through e.g. community-based, participatory processes and traditional knowledge, and to acquire financial commitments for adaptation programs. Thus, in implementing successful adaptation measures in the water sector, local people can be properly trained e.g. to manage any instrument or system (e.g., probabilistic decision making tool) that is being set up locally and to transfer technology to low-level water managers. The planning of adaptation projects might be done together with the community so they will understand the use and methodology of appropriate technologies (Bates *et al*., 2008; Halsnæs and Trærup, 2009; Olhoff and Schaer, 2010; Smit and Wandel, 2006; UNECE, 2009; von Storch, 2009).

Finally, the capacity of water management agencies and the water management system as a whole is *likely* to act as a limit on which adaptation measures (if any) can be implemented. The low priority given to water management, lack of coordination between agencies, tensions between national, regional and local scales, ineffective water governance and uncertainty over future climate change impacts constrain the ability of organizations to adapt to changes in water supply and flood risk (Crabbe and Robin, 2006; Ivey *et al*., 2004; Næss *et al*., 2005; Parry *et al*., 2007).

3.6.5. Costs of Adaptation to Climate Change

Considering the importance of adapting to climate change in the water sector, the literature on this topic is relatively limited (EEA, 2007; Kuik *et al*., 2008). Estimates of the costs of adaptation to climate change across sectors at the

global scale were not available until 2006. Since then, five multi-sectoral estimates of these costs have become available (Oxfam, 2007; Stern, 2006; UNDP, 2007; UNFCCC, 2007; World Bank, 2006).

At the local, national, and river basin level, the geographical distribution of these researches is skewed towards developed countries, although examples do exist in developing countries. Adapting urban water infrastructure in sub-Saharan Africa to climate change is estimated to be US$25 billion per year (Muller, 2007). This study assumes that: (a) reliable yields from dams will reduce at the same rate as stream flow (e.g., a 30% reduction in stream flow will mean a 30% reduction in reliable yield, and the unit cost of water will go up by more than 40%); (b) where waste is disposed into streams, a reduction in stream flow by x% will mean that the pollutant load must be reduced by x%; and (c) power generation reduces linearly with stream flow. The costs of adapting existing urban water storage facilities are estimated at $0.05-0.15 billion/year, and the costs of additional new developments are estimated at $0.015-0.05 billion/year. For wastewater treatment, the adaptation costs of existing facilities are estimated at $0.1-0.2 billion/year, and the costs of additional new facilities are estimated at $0.075-0.2 billion/year.

The global costs of adaptation in water resources associated with additional water infrastructure needed.have been assessed (Kirshen, 2007; UNFCCC, 2007; Ward *et al*., 2010). To provide a sufficient water supply, the adaptation costs were estimated to amount to ca. US$531 billion in total for the period up to 2030 given present and future projected water demands and supplies in more than 200 countries (Kirshen, 2007). Of this, US$451 billion (85%) is estimated to be required in developing countries, mainly Asia and Africa. The assessment of Kirshen (2007) was subsequently modified in UNFCCC (2007). In this study, two further costs were included, namely the increased cost of reservoir construction since the best locations have already been taken, and unmet irrigation demands. This report suggests that the total costs of adaptation will be ca. US$898 billion for the period up to 2030. It is assumed that 25% of these costs are specifically related to climate change, and hence the cost of adaptation to climate change in the water supply sector is estimated at ca. US$225 billion up to 2030. This is equivalent to ca. US$11 billion/year (UNFCCC, 2007).

3.6.6. Case Studies

Papers in the refereed literature on adaptation in the water sector fall into four broad groups. One group comprises analyses of the potential effect of different adaptation measures on the impacts of climate change for specific resource systems (for example Connell-Buck *et al*. (2011) and Medellin-Azuara *et al*. (2008) in California, Miles *et al*. (2010) in Washington State USA, Pittock and Finlayson (2011) in the Murray-Darling basin in Australia, and Hoekstra and de Kok (2008) on dike heightening in the Netherlands). The second group presents methodologies for assessing the impacts of climate change specifically for adaptation purposes. For example, Brekke *et al*. (2008; 2009a) and Lopez *et al*. (2009) propose the use of multiple scenarios for risk assessment.

The third group contains approaches for the incorporation of climate change into water resources management practice. A strong theme to this group of studies is the recommendation that water managers should move from the traditional “predict and provide” approach towards adaptive water management (Gersonius *et al*., 2013; Huntjens *et al*., 2012; Mysiak *et al*., 2009; Pahl-Wostl, 2007; Pahl-Wostl *et al*., 2008; Short *et al*., 2012) and the adoption of ‘resilient’ or ‘no-regrets’ approaches (Henriques and Spraggs, 2011; WWAP, 2009). Adaptive water management techniques include scenario planning, employing experimental approaches which involve learning from experience, and the development of flexible solutions that are resilient to uncertainty. These solutions are not entirely technical (or supply-side), and central to the adaptive water management approach is participation and collaboration amongst all stakeholders. However, whilst climate change is frequently cited as a key motivation for the adoption of adaptive water management, there is very little guidance in the literature on precisely how the adaptive water management approach works when addressing climate change over the next few decades. A few examples are given in Ludwig *et al*. (2009). The US Water Utilities Climate Alliance (WUCA, 2010) provide the most comprehensive overview of ways of delivering adaptive water management which explicitly incorporates climate change and its uncertainty. They proposed a framework with three steps -system vulnerability assessment, utility planning using decision -support planning methods, and decision-making and implementation -and summarized planning methods for decision-supports. These include classic decision analysis, traditional scenario planning and robust decision making (Section 3.6.3). Other frameworks that have been proposed based on risk assessment include the threshold-scenario

risk assessment framework (Freas *et al*., 2008), which combines a qualitative threshold risk assessment approach with quantitative scenario-based risk assessment.

The fourth group of studies evaluate the practical and institutional barriers to the incorporation of climate change within water management (Bergsma *et al*., 2012; Engle and Lemos, 2010; Goulden *et al*., 2009; Huntjens *et al*., 2010; Stuart-Hill and Schulze, 2010; Wilby and Vaughan, 2011; Ziervogel *et al*., 2010). The key conclusions from these studies are that institutional structures have the potential to be major barriers to adaptation, that structures which encourage participation and collaboration between stakeholders tend to be most effective, and that the uncertainty in how climate change may affect the water management system is a significant barrier.

There is a considerably smaller literature describing what water management agencies are actually currently doing to adapt to climate change. A number of agencies are beginning to factor climate change into processes and decisions (Kranz *et al*., 2010; Krysanova *et al*., 2010), with the amount of progress strongly influenced by institutional characteristics. This activity largely takes the form of the development of methodologies to be used in practice by water resources and flood managers (e.g. Rudberg *et al*., 2012), and therefore represents attempts to improve adaptive capacity. Much of this activity is reported in the professional 'grey' literature (e.g. Brekke *et al*, 2009a; describing proposed changes to practices in the United States), but some is described in the refereed literature (e.g. Arnell (2011b) describing the evolution of methodologies for water resources assessment under climate change in England and Wales). Several studies report community level activities to reduce exposure to current hydrological variability as a means of adapting to future climate change (e.g. Barrios *et al*., 2009; Gujja *et al*., 2009; Kashaigili *et al*., 2009; Yu *et al*., 2009).

3.7. Linkages with Other Sectors and Services

3.7.1. Impacts of Adaptation in Other Sectors on Freshwater Systems

Adaptation in other sectors such as agriculture and industry might have impacts on the freshwater system and have to be considered while planning adaptation measures in the water sector. For example, improving agricultural land management practices can also lead to reductions in erosion and sedimentation of river channels, while allowing controlled flooding of agricultural land can alleviate flooding in urban areas. Some adaptation measures in other sectors may cause negative impacts in the water sector, e.g. increased irrigation upstream may limit water availability downstream (World Bank, 2007). Furthermore, a project designed for other purposes may also deliver increased climate change resilience as a co-benefit, even without a specifically identified adaptation component (World Bank, 2007; Falloon and Betts, 2010).

3.7.2. Climate Change Mitigation and Freshwater Systems

Many measures for climate change mitigation have an impact on freshwater systems, while freshwater management can affect GHG emissions (Bates *et al*., 2008).

3.7.2.1. Impact of Climate Change Mitigation in Different Sectors on Freshwater Systems

Afforestation of areas suitable according to the Clean Development Mechanism-Afforestation/Reforestation provisions of the Kyoto Protocol (7.5 million km^2) would lead to high and large-scale decreases of long-term average runoff (Trabucco *et al*., 2008). On 80% of the area, runoff is computed to decline by more than 40%, while on 27% runoff decreases by 80-100% were computed, mostly in semi-arid areas (Trabucco *et al*., 2008). For example, economic incentives for carbon sequestration may encourage the expansion of Pinus radiata timber plantations in the Fynbos biome of South Africa, with negative consequences for water supply and biodiversity; afforestation is viable to the forestry industry under current water tariffs and current carbon accounting legislation, but would be unviable if the forestry industry were to pay the true cost of water used by the plantations (Chisholm, 2010). Depending on local conditions, runoff decreases is likely to have beneficial impacts, e.g. on soil erosion,

flood risk, water quality (nitrogen, phosphorus, suspended sediments) and stream habitat quality (Trabucco *et al*., 2008; Wilcock *et al*., 2008).

Renewable energy production in the form of irrigated bioenergy crop production and hydropower generation has negative impacts on freshwater systems (Jacobson, 2009). In the USA, 2% of total consumptive water use in 2005 was due to biofuel production, mainly caused by irrigation of corn for ethanol production, with 2400 m^3 consumptive water use per 1 m^3 of ethanol (King *et al*., 2010). In two scenarios, this fraction increases to 9% in 2030, with future water consumption strongly depending on the degree of irrigation (King *et al*., 2010). Also biofuel crops like switchgrass and jatropha may require irrigation to achieve satisfactory yields. Energy consumption for pumping water for irrigating jatropha in India was estimated to be so high in case of a pumping depth of 60 meter that energy gain by higher crop yields under irrigation is lower than the energy consumption for pumping (Gupta *et al*., 2010). For a biofuel production scenario of the International Energy Agency, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030; in some countries biofuel production is likely to lead to a significant percent increase of water consumption (e.g. Germany, Italy and South Africa), while in others it exacerbates a already high water scarcity (e.g. Spain and China) (Gerbens-Leenes *et al*., 2012). Conversion of native Caatinga forest into rainfed castor beans fields for biofuels in semi-arid Northwestern Brazil may lead to a significant increase of groundwater recharge (Montenegro and Ragab, 2010), but there is the risk of soil salinization due to rising groundwater tables. Hydropower generation leads to fragmentation of river channels and to alteration of river flow regimes that negatively affect freshwater ecosystems, in particular biodiversity and abundance of riverine organisms (Döll, 2009; Poff and Zimmerman, 2010). In particular, hydropower operation often leads to fast sub-daily discharge changes that are detrimental to the downstream river ecosystem (Bruno *et al*., 2009; Zimmerman *et al*., 2010). If, in tropical regions, the ratio of hydropower generation to surface area of the related reservoir is less the 1 MW/km^2, the global warming potential (CO_2-eq. emissions from the reservoir per MWh produced) can be higher than in the case of coal use for energy production (Gunkel, 2009).

CO_2 leakage from saline aquifers used for Carbon Capture and Storage (CCS) to freshwater aquifers is very likely to lead to a pH decline of 1-2 units and increased concentrations of metals, uranium and barium (Little and Jackson, 2010). Pressure buildup caused by gas injection could result in brines or brackish water being pushed into freshwater regions of the aquifer (Nicot, 2008). Displacement of brine into potable water has not been included in a screening methodology for CCS sites in the Netherlands (Ramirez *et al*., 2010). Densification of urban areas to reduce traffic emissions is likely to conflict with provisioning additional open space for inundation in case of floods (Hamin and Gurran, 2009).

3.7.2.2. Impact of Water Management on Climate Change Mitigation

A number of water management decisions affect GHG emissions. Water demand management has a significant impact on energy consumption as energy is required to pump and treat water, to heat it, and to treat wastewater. Water supply and treatment consumes approximately 1.4 % of total electricity consumption in Japan in Japanese Fiscal Year 2008 (MLIT, 2011). Rough estimates for the USA result in a water-related energy consumption that is equivalent to 13% of the total electricity production, with 70% due to water heating and 14% due to wastewater treatment (Griffiths-Sattenspiel and Wilson, 2009). Even though 34% of water withdrawals in the USA are for irrigation, only 5% of the water-related energy consumption occurs in the agricultural sector, mainly for groundwater pumping. For China, where agriculture is responsible for 62% of water withdrawals, groundwater pumping for irrigation accounts for only 0.5% of China's emissions, a small fraction of the 17-20% share of agriculture as a whole (Wang *et al*., 2012).

Emissions from peatland drainage in Southeast Asia contribute 1.3-3.1% of current global CO_2 emissions from the combustion of fossil fuels (Hooijer *et al*., 2010). Peatland rewetting in Southeast Asia is very likely to lead to substantial reductions of net GHG emissions (Couwenberg *et al*., 2010). Climate change mitigation by conservation of wetlands will also benefit water quality (House *et al*., 2010). Irrigation has the potential to lead to increased CO_2 storage in soils due to enhanced biomass production without water stress. Irrigation in semi-arid California did not significantly increase soil organic carbon but strongly increased soil inorganic carbon if irrigation water was rich in

Ca (Wu *et al*., 2008). Water management in rice paddies can reduce emissions. If rice paddies are drained at least once during the growing season, with resulting increased water withdrawals, global CH_4 emissions from rice fields could be decreased by 4.1 Tg/a (15%), and no significant increase in N_2O emissions would occur (Yan *et al*., 2009).

3.8. Research and Data Gaps

Precipitation and river discharge are systematically observed, however, the length and availability of data records are unevenly distributed geographically, and information on other relevant variables, such as soil moisture, snow depth and water equivalent, evapotranspiration, groundwater depth and available groundwater resources, and water quality including sediments, is mostly limited in developing countries. Relevant socio-economic data, such as rates of surface water withdrawal and exploitation of ground water by each sector, arterial drainage, long-range diversion, and information on already-implemented autonomous adaptations for securing stable water supply, are limited even in developed countries. In consequence, assessment capability is limited in general, and especially so in developing countries.

Modeling studies have shown that the adaptation of vegetation to changing climate may have large impacts on the partitioning of precipitation into evapotranspiration and runoff. This feedback should be investigated more thoroughly.

Relatively few results are available on the economic aspects of climate-change impacts and adaptation options related to water resources, which are of great practical importance in regional decision-making that aims for the best mix of mitigation and adaptation. Regional damage curves need to be developed, relating the magnitudes of major causes of water-related disasters (such as intense precipitation, surface soil dryness, and storm surges) to the expected costs.

There is a continuing mismatch between the large (~200-km) scale of climate models and the ~20-km catchment scale at which water is managed and adaptations must be implemented. Increasing the spatial resolution of regional and global climate models, or improving the accuracy of methods for downscaling their outputs, can produce information of more relevance to water management, although robustness of regional climate projections is still constrained by the realism of GCM simulations of large-scale drivers. Climatic extremes of concern in water management generally recur more frequently than the typical engineering criterion of a 1% probability of annual exceedance. Computing capacity will be required to address these problems with more ensemble simulations at high spatial resolution. Robust attribution to anthropogenic climate change of hydrological changes, particularly changes in the frequency of extreme events, is similarly demanding, and further study is required to develop rigorous attribution tools that require less computation.

Interactions among socio-ecological systems are not yet well considered in assessments of the impact of climate change. Particularly, there are few studies on the impacts of mitigation and adaptation measures taken in other sectors on the water sector, and conversely. A valuable advance would be to couple hydrological models, or even the land-surface components of climate models, to data on water-management activities such as reservoir operations, irrigation and urban withdrawals from surface water or groundwater, based on the synthesis of case studies and research achievements from field surveys.

To allow adaptation to climate change by increased reliance of water supply on groundwater and on the coordinated and combined use of ground water and surface water, the following research and data gaps have to be closed:

- Ground-based data on groundwater dynamics and stored groundwater volumes
- A long-term monitoring program for evaluation of the response of groundwater to climate change
- Better understanding of groundwater recharge and groundwater-surface water interactions
- Assessment of experiences of conjunctive use of groundwater and surface water, including managed aquifer recharge

More studies are needed, notably in developing countries, of the impacts of climate change on water quality, and of vulnerability to and ways of adapting to those impacts.

Frequently Asked Questions

FAQ 3.1: How will the availability of water resources be affected by climate change?

Climate models project both increases and decreases of renewable water resources at the regional scale, although sometimes with large uncertainty. Evapotranspiration is very likely to increase over land. Average annual runoff is generally projected to increase at high latitudes and in the wet tropics, and to decrease in most dry tropical regions. Reliable surface water supply is likely to decrease in many regions because of changes in seasonal flow regime due ot decreases in snow and ice storage, groundwater recharge, degradation of water quality, and more variable streamflow due to more variable precipitation.

FAQ 3.2: How will floods and flood damages develop due to climate change?

Projected climate change will change the frequency and magnitude of floods, although the amount and sign of change will vary across the globe. There is considerable uncertainty in the magnitude of regional-scale change due to disagreement between simulations of precipitation. Recent modeling of flood hazards suggests that they will increase over more than half of the globe. More frequent intense rainfall (WG1 SOD 12.4.5.5) would increase the frequency of flooding in small catchments, but the limited extent of intense rainfall events makes the implications more uncertain for larger catchments. The magnitude of spring snowmelt floods is likely to decrease, because less precipitation will fall as snow during winter. The few available studies show strong consistency in projecting increases in flood hazards over central and eastern Siberia, parts of south-east Asia including India, East Africa, Central and West Africa, and northern South America, and decreases in flood hazards in parts of North and East Europe, Anatolia, Central-East Asia, central North America, and southern South America.

Flood hazards will increase flood damages worldwide, enhanced by increasing exposure, particularly on flood-prone valley floors and deltas, of people and assets. Flood disasters may be triggered by weather events that are not statistically extreme but are hazardous because of social conditions that increase exposure and vulnerability. Flood losses in many locations will increase in the absence of additional protection measures, but the increase varies strongly with location, climate model, and the method used to assess exposure and vulnerability.

FAQ 3.3: Are climatic changes more serious than other human impacts on freshwater?

It depends. Impacts of climatic changes on freshwater are different in character from those of other stressors such as land-use change, water withdrawal, artificial drainage of wetlands, dam construction, alteration of river morphology, and water pollution. Climatic changes, such as changes in the amount and intensity of precipitation, are global in scope and affect all compartments of the freshwater system (soil, groundwater, lakes, wetlands and watercourses). The relative seriousness of climate-related stress varies depending on the region, the freshwater compartment and the type of stress. For example no other human stress, apart perhaps from deforestation, could have an impact comparable to that of increased flooding due to more intense rainfall. On the other hand, irrigated agriculture has already led, in some semi-arid regions, to streamflow reductions comparable to or worse than those expected from climatic changes. Finally, the answer depends on the time horizon and on the success of climate-change mitigation. Global population is expected to peak in the mid-21st century, while climatic changes may not peak until much later. The impacts of climate change will therefore become progressively more serious relative to those of other human impacts.

FAQ 3.4: How should water management be adapted in the face of climate change?

Water-resource management under uncertain climate change needs to be approached as a part of natural-resource management, integrated with suitable social measures and development of infrastructure. Restoring and protecting freshwater habitats, and managing natural floodplains, are key elements of such an approach. Adaptive measures that may prove particularly effective include rainwater harvesting, conservation tillage, maintaining vegetation cover, planting trees in steeply-sloping fields, mini-terracing for soil and moisture conservation, improved pasture management, water re-use, desalination, and more efficient soil and irrigation-water management. Possible examples of maladaptive measures include large projects, such as dams and irrigation systems, that fail to offer complete flood protection and that harm the adaptive capacity of other sectors; and unreasonably resource-intensive desalination, pumping of deep groundwater, or water treatment.

FAQ 3.5: Does climate change imply only bad news about water resources?

In a warmer climate the balance between precipitation and evaporation will shift. There will be more of both but not necessarily in the same places. Regions with abundant water at present may have yet more, but regions with deficits may suffer more serious shortages. These changes are already well attested globally, but in most regions it will be some decades before they become statistically detectable. Where water stress is alleviated by glacier meltwater there will be a "meltwater dividend" during the 21st century, although the total yield of meltwater will eventually diminish. Many of the adverse impacts of changes in water resources will be felt in the developing world, where investment in more careful management can be expected to be very cost-effective, for example by improving seasonal availability of water, under climate change.

FAQ 3.6: How are portfolio and no-regrets adaptation measures defined?

A portfolio is a set of measures, defined locally, that are considered promising for adaptation to possible future climates and their variability. The measures can be implemented progressively and flexibly, in a coordinated and complementary way, and can be expected to reduce vulnerability and increase resilience. No-regrets measures are those that will yield benefits regardless of how the climate evolves; they are to be preferred. Providing universal access to safe water is an example of a no-regrets option.

Cross-Chapter Boxes

Box CC-RF. Impact of Climate-Change on Freshwater Ecosystems due to Altered River Flow Regimes

[Petra Döll (Germany), Stuart E. Bunn (Australia)]

It is widely acknowledged that the flow regime is a primary determinant of the structure and function of rivers and their associated floodplain wetlands, and flow alteration is considered to be a serious and continuing threat to freshwater ecosystems (Bunn and Arthington, 2002; Poff and Zimmerman, 2010; Poff *et al.*, 2010). Most species distribution models do not consider the effect of changing flow regimes (i.e. changes to the frequency, magnitude, duration and/or timing of key flow parameters) or they use precipitation as proxy for river flow (Heino *et al.*, 2009).

There is growing evidence that climate change will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (Aldous *et al.*, 2011; Xenopoulos *et al.*, 2005). By the 2050s, climate change is projected to impact river flow characteristics like long-term average discharge, seasonality and statistical high flows (but not statistical low flows) more strongly than dam construction and water withdrawals have done up to the year 2000 (Figure RF-1; Döll and Zhang, 2010). For one climate scenario, 15% of the global land area may suffer, by the 2050s, from a decrease of fish species in the upstream basin of more than 10%, as compared to only 10% of the land area that has already suffered from such decreases due to water withdrawals and dams (Döll and Zhang, 2010). Climate change may exacerbate the negative impacts of dams for freshwater ecosystems but may also provide opportunities for operating dams and power stations to the benefit of riverine ecosystems. This is the case if total runoff increases and, like in Sweden, the annual hydrograph becomes more similar to variation in electricity demand, i.e. with a lower spring flood and increased run-off during winter months (Renofalt *et al.*, 2010).

[INSERT FIGURE RF-1 HERE

Figure RF-1: Impact of climate change on the ecologically relevant river flow characteristics mean annual river flow and monthly low flow Q_{90} as compared to the impact of water withdrawals and dams on natural flows, as computed by a global water model (Döll and Zhang, 2010). Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002.]

Because biota are often adapted to a certain level of river flow variability, the larger variability of river flows that is due to increased climate variability is *likely* to select for generalist or invasive species (Ficke *et al.*, 2007). The relatively stable habitats of groundwater-fed streams in snow-dominated or glacierized basins may be altered by reduced recharge by meltwater and as a result experience more variable (possibly intermittent) flows (Hannah *et al.*,

2007). A high-impact change of flow variability is a flow regime shift from intermittent to perennial or vice versa. It is projected that until the 2050s, river flow regime shifts may occur on 5-7% of the global land area, mainly in semi-arid areas (Döll and Müller Schmied, 2012; see Chapter 3, Table 3-2).

In Africa, one third of fish species and one fifth of the endemic fish species occur in eco-regions that may experience a change in discharge or runoff of more than 40% by the 2050s (Thieme *et al.*, 2010). Eco-regions containing over 80% of Africa's freshwater fish species and several outstanding ecological and evolutionary phenomena are *likely* to experience hydrologic conditions substantially different from the present, with alterations in long-term average annual river discharge or runoff of more than 10% due to climate change and water use (Thieme *et al.*, 2010).

Due to increased winter temperatures, freshwater ecosystems in basins with significant snow storage are affected by higher river flows in winter, earlier spring peak flows and possibly reduced summer low flows (chapter 3.2.3). Strongly increased winter peak flows may lead to a decline in salmonid populations in the Pacific Northwest of the USA of 20-40% by the 2050s (depending on the climate model) due to scouring of the streambed during egg incubation, the relatively pristine high-elevation areas being affected most (Battin *et al.*, 2007). Reductions in summer low flows will increase the competition for water between ecosystems and irrigation water users (Stewart *et al.*, 2005). Ensuring environmental flows through purchasing or leasing water rights and altering reservoir release patterns will be an important adaptation strategy (Palmer *et al.*, 2009).

Observations and models suggest that global warming impacts on glacier and snow-fed streams and rivers will pass through two contrasting phases (Burkett *et al.*, 2005; Vuille *et al.*, 2008; Jacobsen *et al.*, 2012). In the first phase, when river discharge is increased due to intensified melting, the overall diversity and abundance of species may increase. However, changes in water temperature and stream-flow may have negative impacts on narrow range endemics (Jacobsen *et al.*, 2012). In the second phase, when snowfields melt early and glaciers have shrunken to the point that late-summer stream flow is reduced, broad negative impacts are foreseen, with species diversity rapidly declining once a critical threshold of roughly 50% glacial cover is crossed (Figure RF-2).

[INSERT FIGURE RF-2 HERE
Figure RF-2: Accumulated loss of regional species richness (gamma diversity) as a function of glacial cover GCC. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%. Each data point represents a river site and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.]

River discharge also influences the response of river temperatures to increases of air temperature. Globally averaged, air temperature increases of 2°C, 4°C and 6°C are estimated to lead to increases of annual mean river temperatures of 1.3°C, 2.6°C and 3.8°, respectively (van Vliet *et al.*, 2011). Discharge decreases of 20% and 40% are computed to result in additional increases of river water temperature of 0.3° C and 0.8°C on average (van Vliet *et al.*, 2011). Therefore, where rivers will experience drought more frequently in the future, freshwater-dependent biota will suffer not only directly by changed flow conditions but also by drought-induced river temperature increases, as well as by related decreased oxygen and increased pollutant concentrations.

Box CC-VW. Active Role of Vegetation in Altering Water Flows Under Climate Change

[Richard Betts (UK), Dieter Gerten (Germany), Petra Döll (Germany)]

Terrestrial vegetation dynamics, carbon and water cycles are closely coupled, for example by the simultaneous transpiration and CO_2 uptake through plant stomata in the process of photosynthesis, and by feedbacks of land cover and land use change on water cycling.Numerous experimental studies have demonstrated that elevated atmospheric CO_2 concentration leads to reduced opening of stomatal apertures, associated with a decrease in leaf-level transpiration (de Boer *et al.*, 2011; Reddy *et al.*, 2011). This physiological effect of CO_2 is associated with an increased intrinsic water use efficiency (iWUE) of plants, as less water is transpired per unit of carbon assimilated. Records of stable carbon isotopes in woody plants (Peñuelas *et al.*, 2011) corroborate this finding, suggesting an increase in iWUE of mature trees by 20.5% between the 1970s and 2000s. Increases since pre-industrial times have also been found for several forest sites (Andreu-Hayles *et al.*, 2011; Gagen *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and in a temperate semi-natural grassland (Koehler *et al.*, 2010), although in one boreal tree species iWUE ceased to increase after 1970 (Gagen *et al.*, 2011). However, the physiological CO_2 effect is accompanied by structural changes to C3 plants (including all tree species), i.e. increased biomass production, spatial encroachment and, thus, higher transpiration, as confirmed by Free Air CO_2 Enrichment (FACE) techniques (Leakey *et al.*, 2009).

There are conflicting views on whether the direct CO_2 effects on plants already have a significant influence on evapotranspiration and runoff at global scale. AR4 reported work by Gedney *et al.*, (2006) which suggested that physiological CO_2effects (lower transpiration) contributed to a supposed global increase in runoff seen in

reconstructions by (Labat *et al.*, 2004). However, a more recent dataset (Dai *et al.*, 2009) showed different runoff trends in some areas. Detection of ecosystem influences on terrestrial water flows, hence, critically depends on the availability and quality of hydrometeorological observations (Haddeland *et al.*, 2011; Lorenz and Kunstmann, 2012).

A key influence on the significance of increased iWUE for large-scale transpiration is whether overall leaf area of primary vegetation has remained approximately constant (Gedney *et al.*, 2006) or has increased in some regions due to structural CO_2effects (as assumed in models by Piao *et al.*, 2007; Gerten *et al.*, 2008). While field-based results vary considerably between sites, tree ring studies suggest that tree growth did not increase globally since the 1970s in response to climate and CO_2change (Peñuelas *et al.*, 2011; Andreu-Hayles *et al.*, 2011). However, basal area measurements at over 200 plots across the tropics suggest that biomass and growth rates in intact tropical forests have increased in recent decades (Lewis *et al.*, 2009), which is also confirmed for 55 temperate forest plots, with a suspected contribution of CO_2 rise (McMahon *et al.*, 2010). The net impact of CO_2 on global-scale transpiration and runoff therefore remains poorly constrained.

Moreover, model results differ in terms of the importance of CO_2 effects for historical runoff relative to other drivers such as climate, land use change and irrigation water withdrawal. Other than Gedney *et al.*, (2006), Piao *et al.*, (2007) and Gerten *et al.*, (2008) found that CO_2 effects on global runoff were small relative to effects of precipitation, and that land use change (which often acts to decrease evapotranspiration and to increase runoff) was of second-most importance, as also supported by Sterling *et al.*, (2012) data and model analysis. By contrast, using a shorter time period and a smaller selection of river basins, Alkama *et al.*, 2011(2011) suggested that global effects of land use change on runoff have been negligible. Oliveira *et al.*, 2011(2011) furthermore point to the importance of changes in incident solar radiation and the mediating role of vegetation; their global simulations demonstrate, for example, that a higher diffuse radiation fraction during 1960–1990 increased evapotranspiration in the tropics by 3% due to increased photosynthesis from shaded leaves. Since the anthropogenic component of the precipitation and temperature contributions(i.e. of the radiative CO_2 effect) to runoff trends is not yet established, a full attribution of anthropogenic emissions of CO_2 (and other greenhouse gases)is still missing.

Analogously, there is uncertainty about how vegetation responses to future increases in CO_2 will modulate effects of climate change on the terrestrial water balance.21st-century continental- and basin-scale runoff is projected by some models to either increase more or decrease less when CO_2-induced increases in iWUE are included in addition to climate change (Betts *et al.*, 2007; Murray *et al.*, 2012), potentially reducing an increase in water stress due to rising population or climate change (Wiltshire *et al.*, submitted) – although other models project a smaller response (Cao *et al.*, 2009). Direct effects of CO_2 on plants have been modelled to increase future global runoff by 4–5% (Gerten *et al.*, 2008) up to 13% (Nugent and Matthews, 2012), depending on the assumed CO_2 trajectory and whether feedbacks of changes in vegetation structure and distribution to the climate are accounted for. The model analysis by Alkama *et al.*, (2010) suggests that although the physiological CO_2 effect will be the second-most important factor for 21st-centuryglobal runoff and although both physiological and structural effects will amplify compared to historic conditions, runoff changes will still primarily follow the projected climatic changes. Using a large ensemble of climate change projections, Konzmann *et al.*, (2013) put hydrological changes into an agricultural perspective and suggest that direct CO_2 effects on crops reduce their irrigation requirements (Fig. CC-VW-1). Thus, adverse climate change impacts on crop yields might be partly buffered as iWUE improves (Fader *et al.*, 2010), but only if proper management abates limitation of plant growth by nutrient availability or other factors. Lower transpiration under rising CO_2 may also affect future regional climate change itself (Boucher *et al.*, 2009) and may enhance the contrast between land and ocean surface warming (Joshi *et al.*, 2008).

Application of a soil-vegetation-atmosphere-transfer model indicates complex responses of groundwater recharge to changes in different climatic variables mediated by vegetation,with computed groundwater recharge being always larger than would be expected from just accounting for changes in rainfall (McCallum *et al.*, 2010). In a warmer climate with increased atmospheric CO_2 concentration, iWUE of plants increases and leaf area may either increase or decrease, and even though precipitation may slightly decrease, groundwater recharge may increase as a net effect of these interactions (Crosbie *et al.*, 2010). Depending on the type of grass in Australia, the same change in climate is suggested to lead to either increasing or decreasing groundwater recharge in this location (Green *et al.*, 2007). For a location in the Netherlands, a biomass decrease was computed for each of eight climate scenarios indicating drier

summers and wetter winters (A2 emissions scenario), using a fully coupled vegetation and variably saturated hydrological model. The resulting increase in groundwater recharge up-slope was simulated to lead to higher water tables and an extended habitat for down-slope moisture-adapted vegetation (Brolsma *et al.*, 2010).

Future anthropogenic and climate-driven land cover and land use changes will also affect regional evapotranspiration, surface and subsurface water flows, with the direction and magnitude of these changes depending on the direction and intensity of the changes in vegetation coverage,as shown e.g. for a river basin in Iowa (Schilling *et al.*, 2008) or for the Elbe river basin (Conradt *et al.*, 2012).Removal of vegetation acting as source of atmospheric moisture can change regional water cycling and decrease potential crop yields by up to 17%in regions otherwise receiving this moisture in the form of precipitation (Bagley *et al.*, 2012).Changes in vegetation coverage and structure due to long-term climate change or shorter-term extreme events such as droughts (Anderegg *et al.*, 2013) also affect the partitioning of precipitation into evapotranspiration and runoff, sometimes involving complex feedbacks with the climate system such as in the Amazon region (Port *et al.*, 2012; Saatchi *et al.*, 2013). As water, carbon and vegetation dynamics evolve synchronously and interactively under climate change (Heyder *et al.*, 2011) in that e.g. vegetation structure and composition can dynamically adapt to changing climatic and hydrologic conditions (Gerten *et al.*, 2007), it remains a challenge to disentangle the effects of future land cover changes on the water cycle.

Box CC-WE. The Water-Energy-Food Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Ken Strzepek (UNU/USA), FerencToth (IAEA/Hungary), Blanca Elena Jimenez Cisneros (Mexico), Taikan Oki (Japan)]

Water, energy, and food are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure CC-WE-1. The depth and intensity of those linkages vary enormously between regions and production systems. Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Chapter 3.7.2, 7.3.2, 10.2,10.3.4, McMahon and Price, 2011, Macknick et al, 2012a, Cary and Weber 2008). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Kahn and Hajra 2009, Gertenet al. 2011). While food production and transport require large amounts of energy (Pelletier et al 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (7.3.2, Diffenbaugh et al 2012, Skaggs et al, 2012).

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change.]

Most energy production methods require significant amounts of water, either directly (e.g. crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Chapter 10.2.2 and 10.3.4, and Davies et al 2013, van Vliet et al 2012). Water is also required for mining, processing, and residue disposal of fossil fuels. Water for biofuels, for example, has been reported by Gerbens-Leenes et al. 2012 who computed a scenario of water use for biofuels for transport in 2030 based on the Alternative Policy Scenario of the IEA. Under this scenario, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water for energy currently ranges from a few percent to more than 50% of freshwater withdrawals, depending on the region and future water requirements will depend on electric demand growth, the portfolio of generation technologies and water management options employed (WEC 2010, Sattler et al., 2012). Future water availability for energy production will change due to climate change (Chapter 3.5.2.2).

Water may require significant amounts of energy for lifting, transport and distribution, treatment or desalination. Non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced or reclaimed wastewater vs. desalinated seawater (Plappally and Lienhard 2012, Macknick et al, 2012b). Groundwater (35% of total global water

withdrawals, with irrigated food production being the largest user, Döll et al. 2012) is generally more energy intensive than surface water – in some countries, 40% of total energy use is for pumping groundwater. Pumping from greater depth (following falling groundwater tables) increases energy demand significantly– electricity use ($kWhr/m^3$) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard 2012). A lack of water security can lead to increasing energy demand and vice versa, e.g. over-irrigation in response to electricity or water supply gaps.

Other linkages through land use and management, e.g. afforestation, can affect water as well as other ecosystem services, climate and water cycles (4.4.4, Box 25-10). Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security (3.7.2, 4.4.4). Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water (McCornick *et al.*, 2008, Bazilian *et al.*, 2011, Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy demand, bioproductivity and other factors (see Figure WE-1 and Wise et al, 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this Assessment Report.

Table 3-1: Selected examples, mainly from Section 3.2, of the observation, detection and attribution of impacts of climate change on freshwater resources. Observed hydrological changes are attributed here to their climatic drivers, which are not all known to be anthropogenic; in the diagram, symbols with borders represent end-to-end attribution of the impact on resources to anthropogenic climate change.

Observed change	*Attributed to*	*Ref*
Changed runoff (global and continental, 1960-1994)	Reduction of transpiration due to anthropogenic CO_2, but partly offset by more abundant vegetation	1
Reduced runoff (Yellow River, China)	Increased temperature; only 35% of reduction attributable to human withdrawals	2
Earlier annual peak discharge (Russian Arctic, 1960-2001)	Increased temperature and earlier spring thaw	3
Earlier annual peak discharge (Columbia River, western USA, 1950-1999)	Anthropogenic warming	4
Glacier meltwater yield greater in 1910-1940 than in 1980-2000 (European Alps)	Glacier shrinkage forced by comparable warming rates in the two periods	5
Decreased dry-season discharge (Peru, 1950s-2000)	Decreased glacier extent in the absence of a clear trend in precipitation	6
Disappearance of Chacaltaya Glacier, Bolivia (2009)	Ascent of freezing isotherm at 50 meters per decade	7
More intense extremes of precipitation (northern tropics and mid-latitudes, 1951-1999)	Anthropogenic greenhouse-gas emissions	8
Fraction of risk of flooding (England and Wales, autumn 2000)	Extreme precipitation attributable to anthropogenic greenhouse radiation	9
Decreased recharge of karst aquifers (Spain, 20th century)	Decreased precipitation, increased temperature leading to increased evapotranspiration	10
Decreased groundwater recharge (Kashmir, 1985-2005)	Decreased winter precipitation	11
Increased dissolved organic carbon in upland lakes (United Kingdom, 1988-2004)	Increased temperature and precipitation; multiple confounding factors	12
Increased anoxia in a reservoir, moderated during ENSO episodes (Spain, 1954-2007)	Decreased runoff due to decreased precipitation and increased evaporative demand	13
Variable faecal pollution in a saltwater wetland (California, 1969-2000)	Variable storm runoff; 70% of coliform variability attributable to variable precipitation	14
Nutrient flushing from swamps, reservoirs (North Carolina, 1970s-2002)	Hurricanes	15
Increased lake nutrient content (Victoria, Australia, 1984-2000)	Increased air and water temperature	16

Table 3-2: Hydrological changes and freshwater-related impacts of climate change on humans and ecosystems that could be reduced with lower GHG emissions.

Type of hydrological change or impact	Description of indicator	Hyd. change or impact in different emissions scenarios or different degress of global warming	Reference
Decreace of renewable water resources, global scale	Number of people affected by a water resources decrease of more than 20%, in percent of world population (multi-model mean)	Up to 2°C above present (2.7°C above pre-industrial), each degree of warming affects an additional 7%	Schewe *et al*. (submitted)
Decrease of renewable groundwater resources, global scale	Number of people affected by a groundwater resources decrease of more than 10%, in % of world population by the 2080s (mean and range of 5 GCMs)	RCP2.6: 24% (11-39%) RCP4.5: 26% (23-32%) RCP6.0: 32% (18-45%) RCP8.5: 38% (27-50%)	Portmann *et al.* (submitted)
Change of river discharge in six river basins around the world	Mean annual flows, statistical low flows and high flows	With GW increasing from 1°C to 6°C, the percent changes from historic conditions increase in almost all cases	Gosling *et al*. (2011)
River flow regime shift for river in Uganda	Shift from bimodal to unimodal (1 GCM)	Occurs in scenarios with GW of at least 4°C but not for smaller GW	Kingston and Taylor (2010)
River flow regime shifts from perennial to intermittent and vice versa, global scale	Area affected by regime shifts by the 2050s in percent of global land area except Greenland and Antarctica (0.5° grid cell resolution; range of 2 GCMs)	A2: 6.3-7.0 B2: 5.4-6.7	Döll and Müller Schmied (2012)
Change of groundwater recharge in the whole Australian continent	Probability that groundwater recharge decreases to less than 50% of 20th century value by 2050), based on ensemble of 16 GCMs	GW 1.0°C: close to 0 almost everywhere GW 2.4°C: in western Australia 0.2-0.6, in central Australia 0.2-0.3, elsewhere close to 1	Crosbie *et al*. (2012)
Change in groundwater recharge in East Anglia, UK	Percent change between baseline and future groundwater recharge, in %, by the 2050s (1 GCM)	A1f: -26 B1: -22	Holman *et al*. (2009)
Change of river discharge, groundwater recharge and hydraulic head in groundwater in two regions of Denmark		Changes for B2 often larger than for A2	Van Roosmalen *et al*. (2007)
Population living in regions with high water stress	Percentage of global population living in regions of with a per-capita water availability of 1000 m^3/year (2080s, 1 GCM), population according to A2[1]	GW by 2050: 1°C: 62 2°C: 60 4°C: 55	Murray *et al*. (2012)
Salinization of artificial coastal lake IJsselmeer in the Netherlands (a drinking water source)	1 Daily probability of exceedance of maximum allowable concentration (MAC) of chloride (150 mg/l)	GW 1°C, no change in atmosph. circulation: 3.1%, 124 days GW 2°C and change in	Bonte and Zwolsman (2010)

	2 Maximum duration of MAC exceedance (2050, 1 GCM)	atmosph. circulation: 14.3 %, 178 days Reference period: 2.5%, 103 days	
Decrease of hydropower production at Lake Nasser, Egypt	Mean decrease of mean annual hydropower production by the 2050s, in % of current hydropower production (11 GCMs)	A2: 7 B1: 8	Beyene *et al*. (2010)
Reduction in usable capacity of once-through or combination cooling thermal power plants in Europe and USA due to low river flow and excessive water temperature	Number of days per year with with a capacity reduction of more than 50% (for existing power plants) (2031-2060, 3 GCMs)	A2: 24 B1: 22 Without climate change: 16	van Vliet *et al*. (2012)
Flood damages in Europe (EU27)	1 Expected annual damages, in 2006- € 2 Expected annual population exposed (2080s, 2 GCMs)	A2: 18-21 billion €/year , 510.000-590.000 people B2: 14-15 billion €/year , 440.000-470.000 people Reference period: 6.4 billion €/year, 200.000 people	Feyen *et al*. (2012)
Flood damages in Japan	Expected annual damages, in Japanese Yen (¥)	Current 110 billion ¥/year, GCM20 (A1B): 200 billion ¥/year, MIROC-5 (RCP4.5) 150-500 billion ¥/year, MIROC-5 (RCP8.5) 150-330 billion ¥/year.	Fukubayashi *et al*. (2013)

GW: Global warming: mean global temperature increase relative to 1961-90
GCM: General circulation models

Table 3-3: Categories of climate change adaptation measures regarding to freshwater.
CC: Particular relevant to climate change, M+A: assist both mitigation and adaptation, M: also assist mitigation]

ADAPTATION OPTION	CC	M+A	M
Institutional			
Support integrated water resources management (IWRM) , including also the integrated management of land considering specifically negative and positive impacts of climate change		X	X
Promote synergy of water and energy savings and efficient use	X		X
Identify “no-regret policies” and build a portfolio of relevant solutions for adaptation	X		
Increase resilience by forming water utility network working teams	X		
Build adaptive capacity	X		
Improve and share information	X	X	X
Adapt the legal framework to make it instrumental to address climate change impacts	X	X	X
Develop financial tools (credit, subsidies and public investment) for the sustainable management of water, and considering poverty eradication and equity			

Design and operation			
Design and apply decision-making tools that consider uncertainty and fulfill multiple objectives	X		
Revise design criteria of water infrastructure to optimize flexibility, redundancy and robustness	X		
Ensure plans and services are robust, adaptable or modular, good value, maintainable, and with long-term benefits, especially in low income countries	X		
Operate water infrastructure increasing the resilience to climate change by all users and sectors			
Take advantage of using hard and soft adaptation measures			X
Perform programs to protect water resources in quantity and quality			
Increase resilience to climate change by diversifying water sources and improving the reservoir management			
Reduce water abstractions by reducing leaks, implementing water saving programs, cascading and reusing water	X	X (leaks)	
Improve design and operation of sewers and wastewater treatment infrastructure to cope with variations in influent quantity and quality	X		
Provide universal sanitation using technology and methodologies locally adapted and provided the proper disposal/reintegration of used water into the environment or its reuse			
Reduce impact of natural disasters			
Implement monitoring and early warning system			
Develop contingency plans			
Improve defense and site selection for key infrastructure that is at risk of floods	X		
Design cities suppressing and resilient to urban floods			
Actively seek and secure water from a diversity (spatially and source-type) of sources within the region to prevent impacts from droughts			
Promote the efficient use of water from all users and reduction of water demand			
Improve irrigation efficiency and reduce the demand of water for irrigation			X
Promote switching to more appropriate crops (drought resistant, saline resistant; low water demand)			
Apply flood or drought resistant crop varieties	X		
Agricultural irrigation			
Reuse wastewater to irrigate crops and use soil for carbon sequestration	X(partly)		X
Industrial use			
When selecting alternative sources of energy, assess the need for water			
Relocate water-thirsty industries and crops to water rich areas			
Implement industrial water efficiency certifications

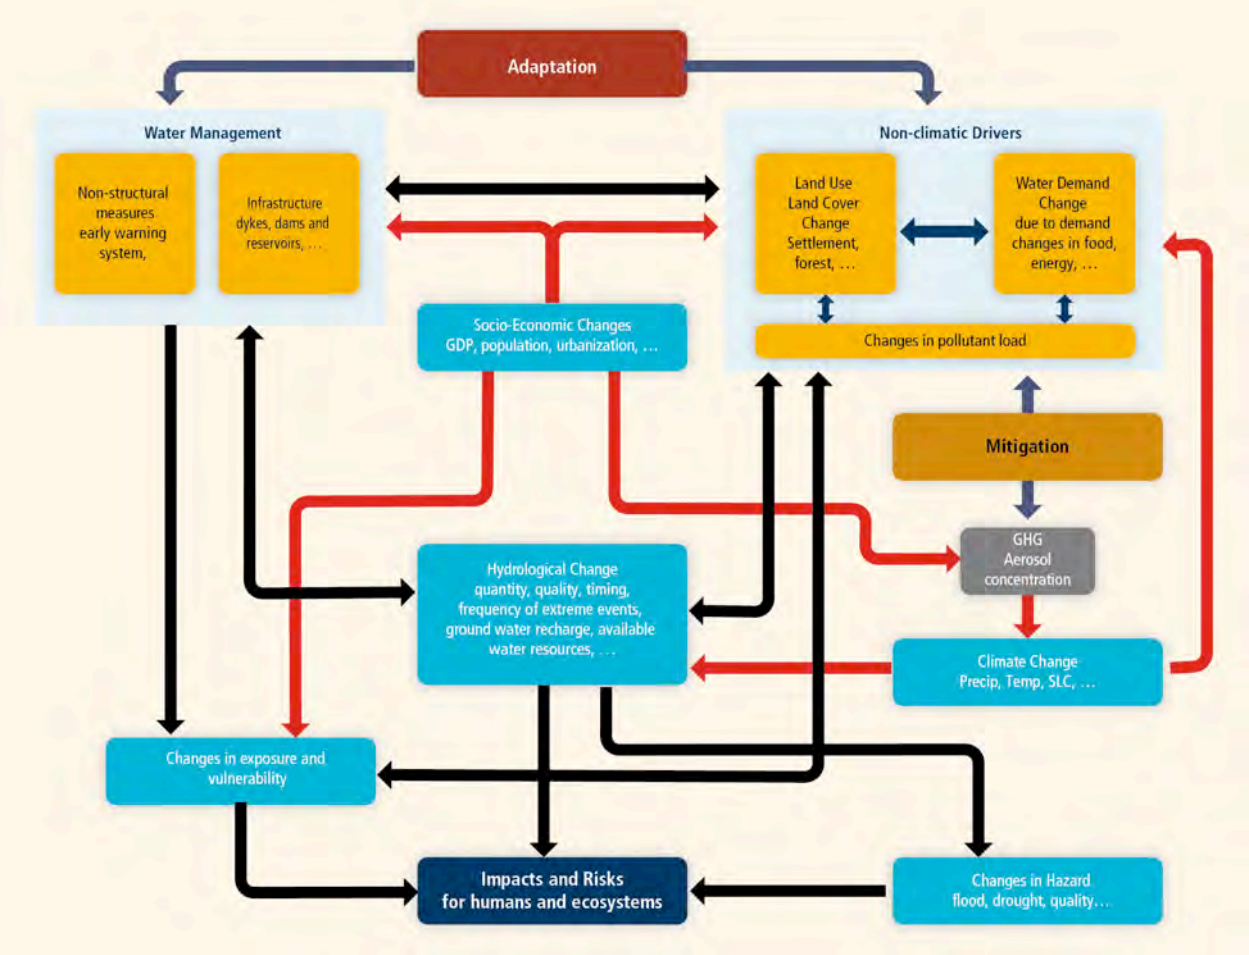

Figure 3-1: Framework for considering the impacts of climate change on freshwater systems and society. Socio-economic changes, such as GDP, population, and urbanization, will change the way of water managements, exposure and vulnerability of human beings against water related risks, and non-climatic drivers changing water management in terms of quantity and quality, as well as emissions and concentration of Green House Gases (GHGs) and Aerosol, that will lead to changes in precipitation, temperature, and sea level. Water management, non-climatic drivers, and climate change will alter hydrological cycles, and lead to change the impacts and risks for humans and ecosystems in conjunction with the changes in exposure and vulnerability, and hazards such as flood and drought. Water management consists with measures developing infrastructure, such as dykes, dams, and reservoirs, and non-structural measures, such as early warning system. Land cover and land use changes including afforestation, deforestation, and settlement, change of water demand due to economic development and demand changes in food and energy, and anthropogenic changes in pollutant load are examples of non-climatic drivers, and they are inter-acting each other. Mitigation acts on the emission and concentration of GHGs as well as on non-climatic drivers, while adaptation acts on non-climatic drivers and water management which alters exposure and vulnerability. (modified from Figure 3-1, AR4)

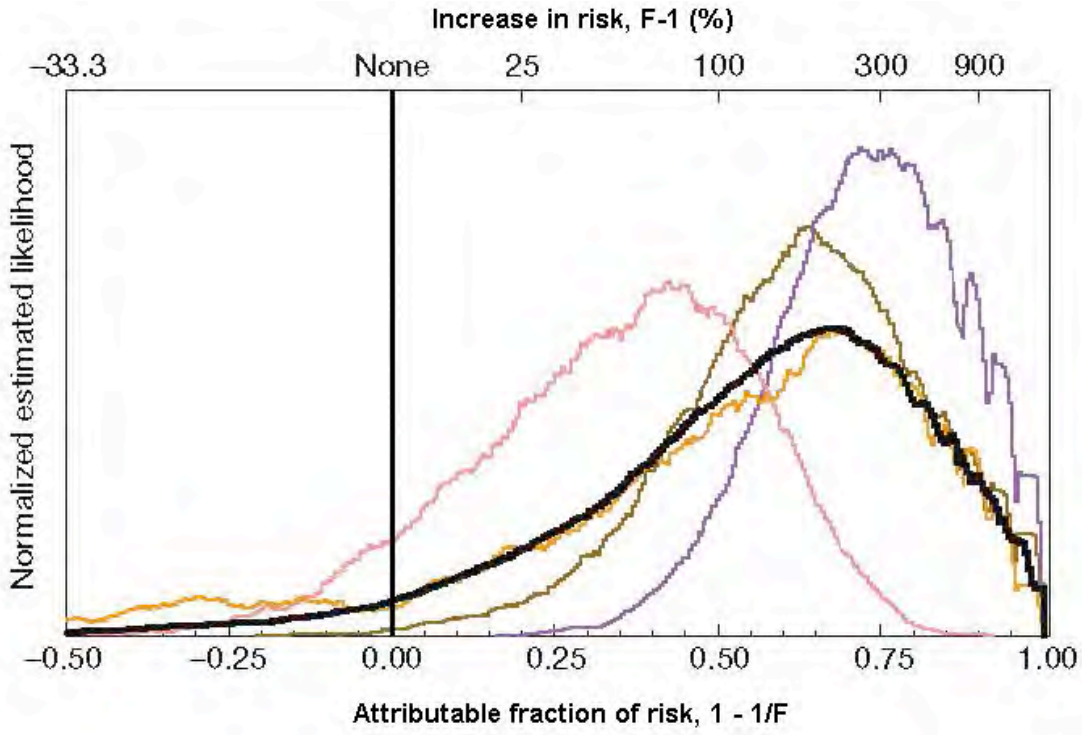

Figure 3-2: Likelihood distributions of the ratio *F* of risks of flooding in England and Wales in autumn 2000 in several thousand paired simulations without and with anthropogenic greenhouse forcing (based on Pall *et al*., 2011; see also Bindoff *et al*., 2013 (WGI Chapter 10)). Each pair starts from a unique initial state that differs slightly from a common reference state. Vertical line represents no change in risk due to anthropogenic greenhouse forcing. Thin coloured lines: distributions with anthropogenic forcing, obtained with a seasonal-forecast model driven by patterns of attributable warming found beforehand from four climate-model simulations of the 20th century; the forecast model is coupled to a model of basin-scale runoff and hydraulics. Thick black line: aggregate of the four distributions.

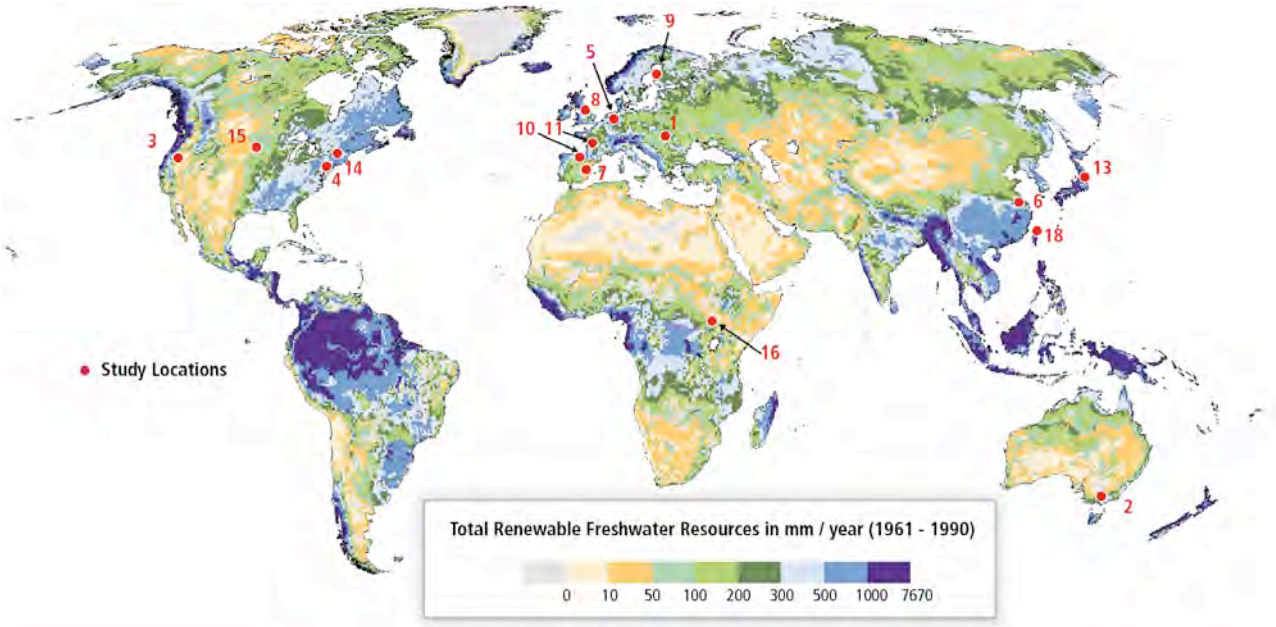

#	Location	Study Period	Observation	Reference
1	Dabube River, Bratsilava, Slovakia	1926-2005	Although the Water temperature is rising the trend of the weighted long term average temperature valus is near zero. Nevertheless the interannual distribution of the average monthly discharged was modified	Halmova et al., 2008
2	Purrumbete, Colac & Bullen Merri Lakes, Victoria, Australia	1984-2000	The increase in air temperature associated with the increase in salinity and nutrient content in water. Increase in salinity as results of variations in effective precipitation	Tibby and Tiller, 2007
3	Lake Tahoe, California and Nevada Sates, US	1970-2007	Increased temperature induced increased thermal stability lowered the dissolved oxygen content	Sahoo et al., 2010
4	Neuse River Estuary, North Carolina, US	1970-1990s	Large storms and hurricanes assited to flush nutrients from the estuatry reducing eutrophication conditions	Paerl et al., 2006; 2008
5	River Meuse, western Europe	1976-2003	Deterioration of the quality of water in terms or temperature, major elements and some heavy metals and metalloids due to droughts. Higher water temperaturescombined with a reduction of the dilution capacity of point source effluents and longer residence time lead to higher nutrient concentrations that induced algae blooms	Van Vliet and Zwolsman, 2008
6	Lake Taihu, Wuxi, Jiangsu, China	2007	The lake that was suffering increased frequencies, intensities and more larger of cyanobacterial blooms. In May, 2007, it suffered an unusual massive bloom that lead to the presence of Microcystis toxins in water. This forced two million people from Taihu city to dring bottled water for a week. This was attributed to an unusually warm spring	Qin et al., 2010
7	Sau Reservoir, Spain	1964-2007	Stream flow variations were of greater significance than temperature increases in the depletion of dissolved oxygen from water	Marce et al., 2010
8	22 upland waters in UK	1988-2002	Dissolved organic increase due to a range of potential drivers, including temperature, rainfall, acid deposition, land-use, nitrogen and CO2 enrichment	Evans et al., 2005
9	Coastal rivers from western Finland	1913-2007	pH (low values) were associated with maximum discharges in rivers because higher rainfalls in bassins with AS (acid sulphate) soils	Sarinen et al., 2010
		1961-2007	CODMs critical values were associated with maximum discharges in rivers because higher rainfalls in bassins with AS (acid sulphate) soils	
10	15 montan pristine rivers from northern Spain	1973-2005	Clear relationship among air temperature increase and the deterioration of water quality (nutrient and COD content in semi arid streams;	Benítez-Gilabert et al., 2010
11	30 coastal rivers and groundwater of Western France	2-6 years	Inter-annual variations on the nutrient content in surface water were realted to changes on air temperature, rainfall and management practices. These variations were not observed on groundwater because of the delay on the response time and the effect of the soil on water.	Gascuel-Odoux et al., 2011
12	Ginock, Scottia	Near 11years	Higher risks of fecal pollution clearly related to rainfall during the wet period	Tetzlaff et al., 2010
13	Japanese streams		Increases on the air temperature were related to increased on the chemical oxygen demand on water, being these higher than those observed from precipitation in arid and semiarid zones	Ozaki et al., 2003
14	SW Penssylvania waters			Chang 2004
15	US	1948-1994	Rainfall and runoff were implicated in site-specific waterborne disease outbreaks	Curriero et al., 2001
16	Northern and Eastern Uganda	1999-2001 2004, 2007	Elevated concentrations of faecal pathogens in groundwater-fed water supplies during the rainy season	Tunwine et al. 2002, 2003; Taylor et al., 2008
17	Walkerton			Auld et al., 2004
18	Taiwan		Epidemic and contamination with enterovirus of a well for supply due to an increased rainfall rate	Jean et al., 2006

Figure3-3: Observations and projections of the impacts on the quality of water. (under production)

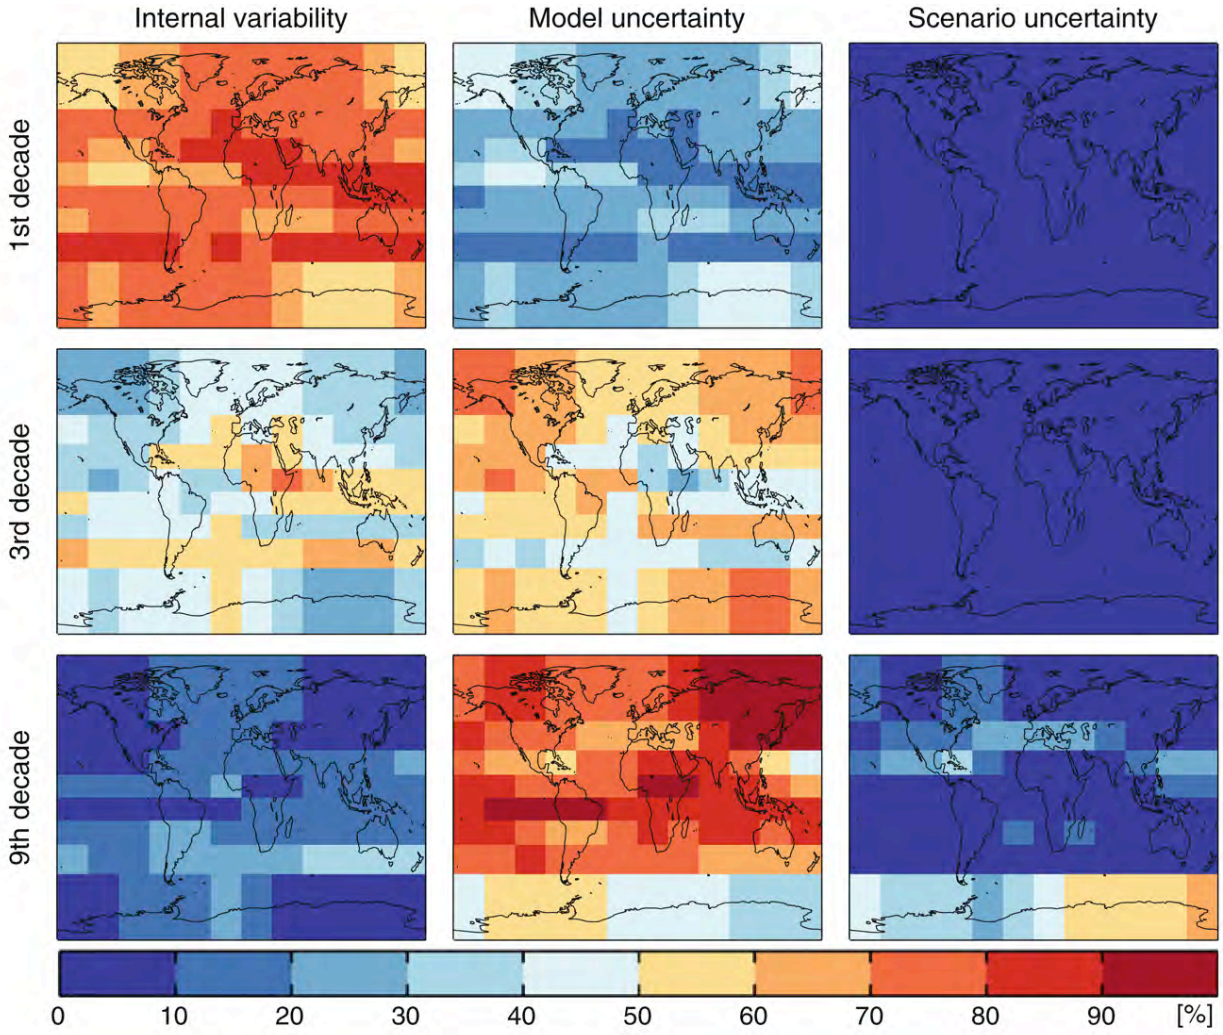

Figure 3-4: Variance in projections of changes in decadal-mean precipitation for boreal summer (June, July, and August), decomposed into contributions from three sources of uncertainty. Simulations were for 2000-2100 under the SRES A1B, A2 and B1 scenarios, with one ensemble member taken from each of 14 CMIP3 GCM experiments. From Hawkins and Sutton (2011).

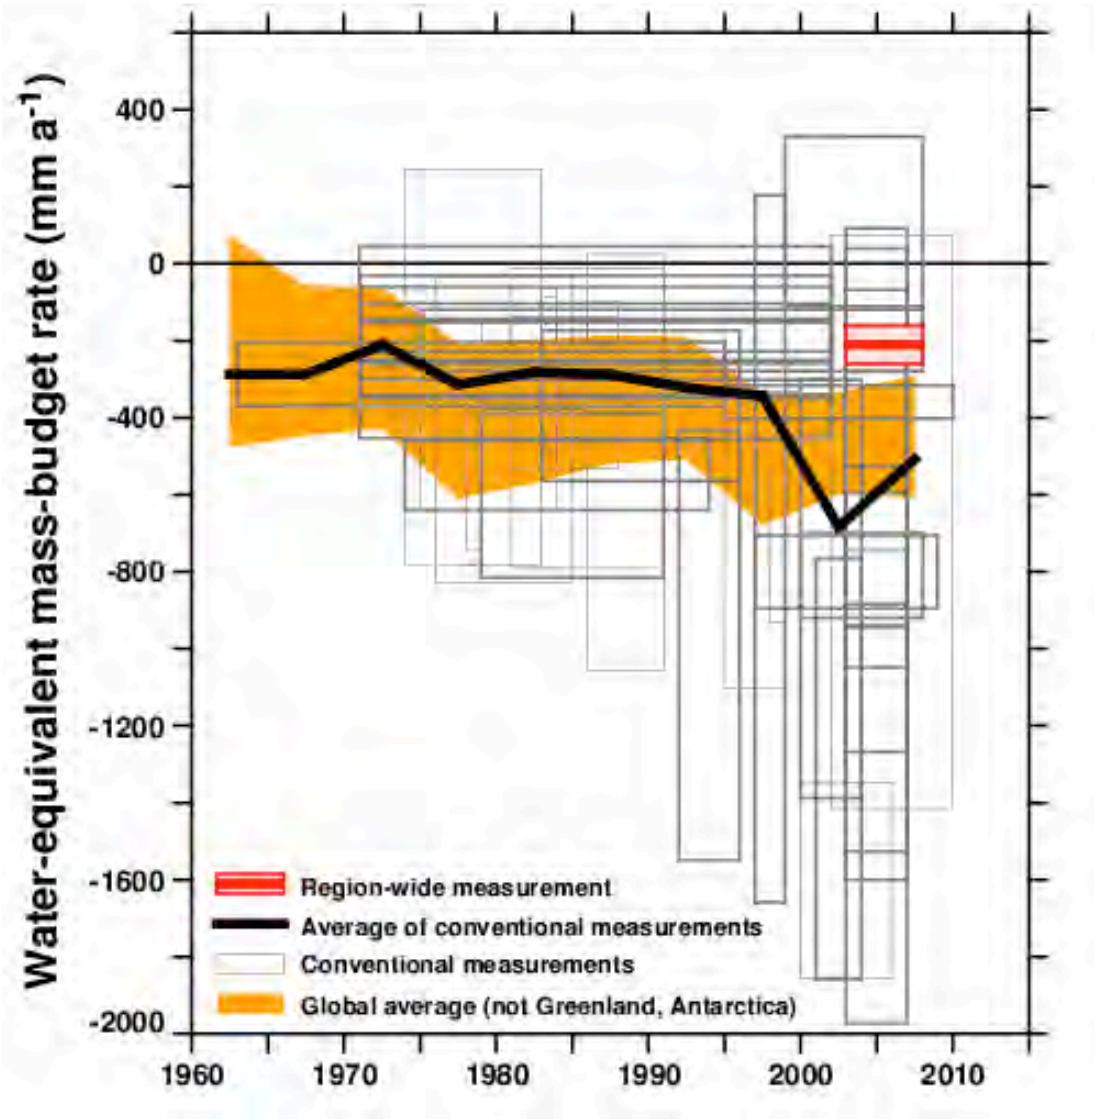

Figure 3-5: A compilation of all published glacier mass balance measurements from the Himalaya (based on Bolch *et al.*, 2012). Each measurement is shown as a box of height ±1 standard deviation centred on the average balance (±1 standard error for multi-annual measurements). Region-wide measurement (Kääb *et al.*, 2012) was by satellite laser altimetry. Global average (Comiso *et al.*, 2013 (WGI Chapter 4)) is shown as a 1-sigma confidence region.

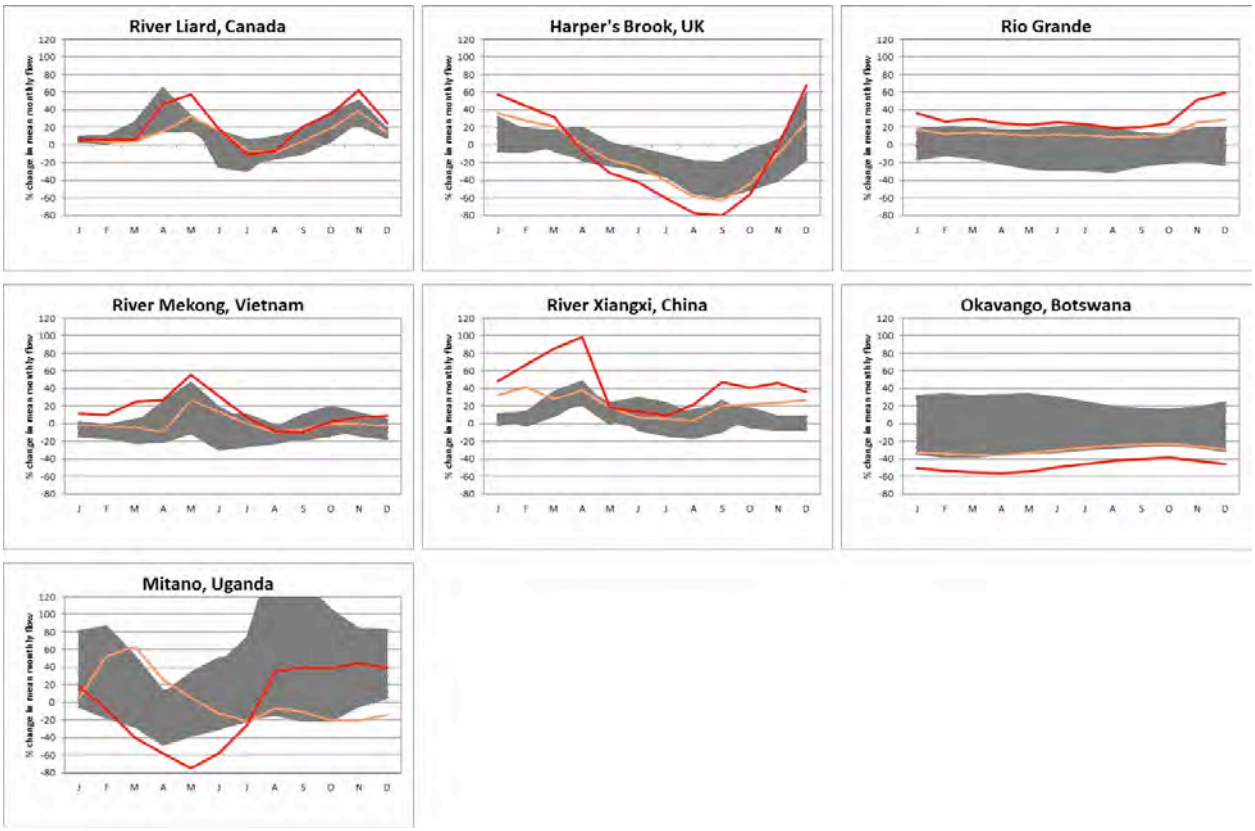

Figure 3-6: Range in change in mean monthly runoff across seven climate models in seven catchments, with a 2°C increase in global mean temperature (above 1961-1990) (Arnell, 2011b; Hughes *et al*., 2011; Kingston and Taylor, 2010; Kingston *et al*., 2011; Nobrega *et al*., 2011; Thorne, 2011a; Xu *et al*., 2011). Changes with the HadCM3 climate model with increases of 2 and 4°C are highlighed.

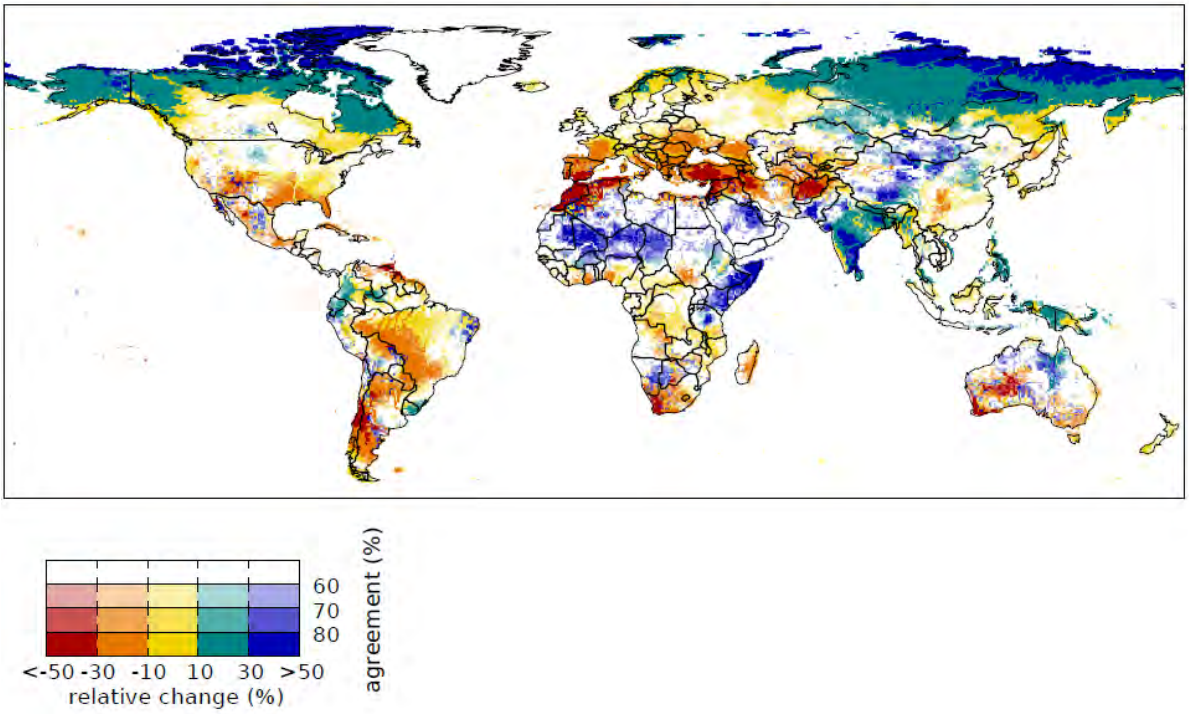

Figure 3-7: Relative change in annual discharge at 2°C (2.7°C above pre-industrial) compared to present-day, under RCP8.5. Color hues show the multi-model mean change, and saturation shows the agreement on the sign of change across all 55 GHM-GCM combinations (percentage of model runs agreeing on the sign). (Schewe *et al.*, 2013)

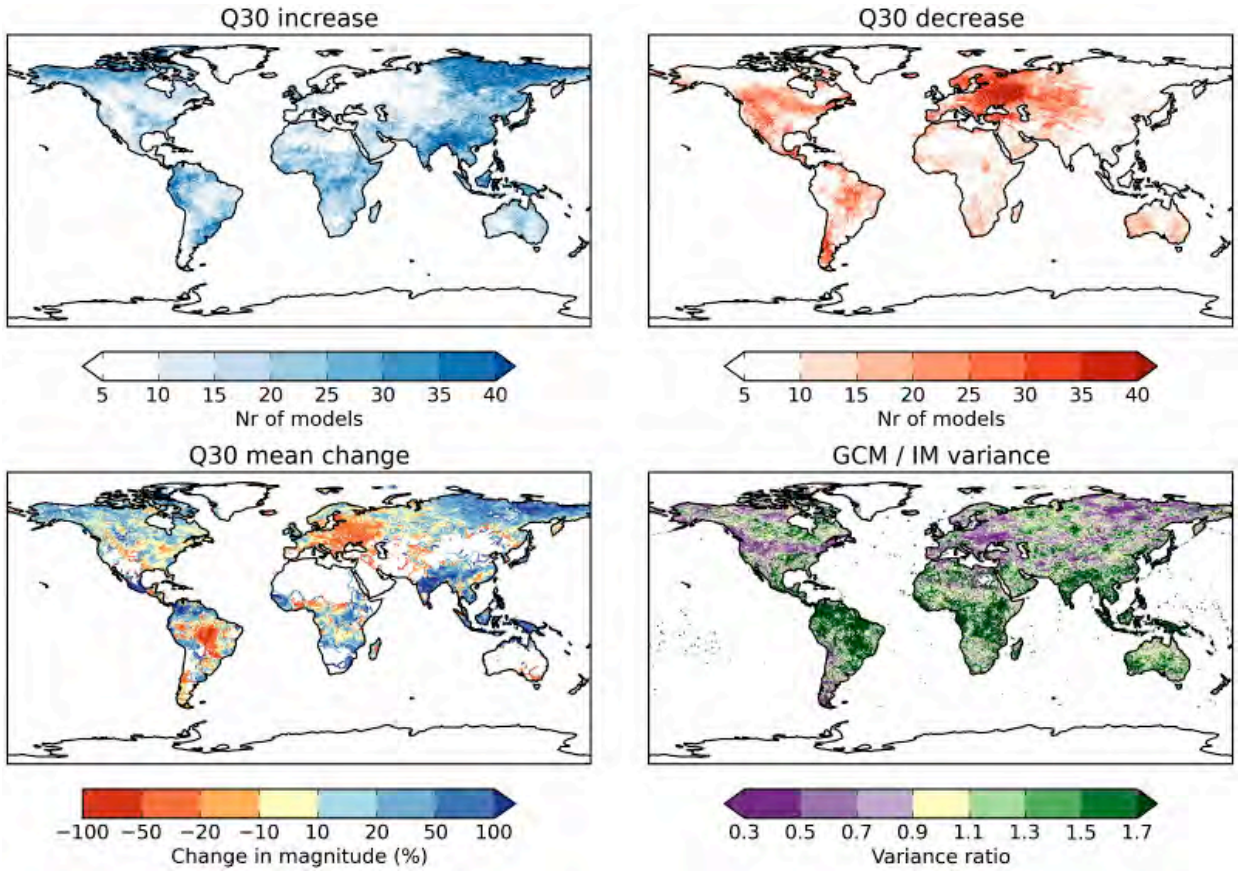

Figure 3-8: Results of flood hazard change for the 30-year return level of river flow (Q30) from ensemble of 5 CMIP5 GCM simulations under RCP8.5 coupled with nine global hydrology and land surface models (named as impact models (IMs)) that provided simulations of daily river discharge at a global 0.5-degree grid for two 30-year periods (1971-2000 and 2070-2090) (Dankers *et al*., 2013). Top: Number of experiments (out of 45 in total) showing an increase (top left) or decrease (top right) in the magnitude of Q30 of more than 10% in 2070-2099 under RCP8.5, compared to 1971-2000. Bottom left: Average change in the magnitude of Q30 across all experiments. Bottom right: Ratio of GCM variance to IM variance. GCM variance was computed as the variance of the change in Q30 across all GCMs for each individual IM, and then averaged over the 9 IMs; IM variance was computed as the variance of the change in Q30 across all IMs for each individual GCM, and then averaged over the 9 GCMs. In dark green (purple) areas GCM (IM) variance predominates.

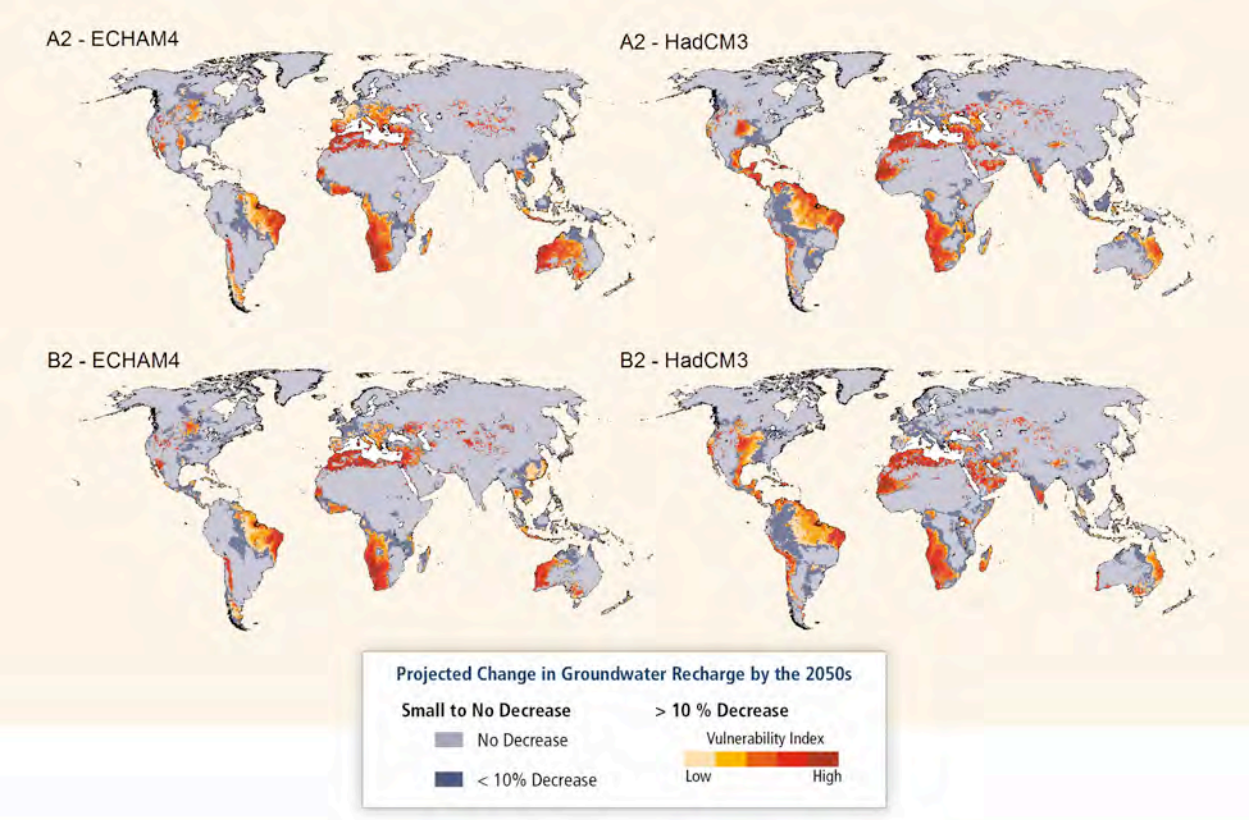

Figure 3-9: Human vulnerability to climate change induced decreases of renewable groundwater resources by the 2050s for four climate change scenarios in which lower (B2) and higher (A2) emissions pathways are interpreted by two global climate models. The higher the vulnerability index (computed by multiplying percent decrease of groundwater recharge by a sensitivity index), the higher is the vulnerability. The index is only defined for areas where groundwater recharge is projected to decrease by at least 10%, as compared to the climate normal 1961-90 (Döll, 2009).

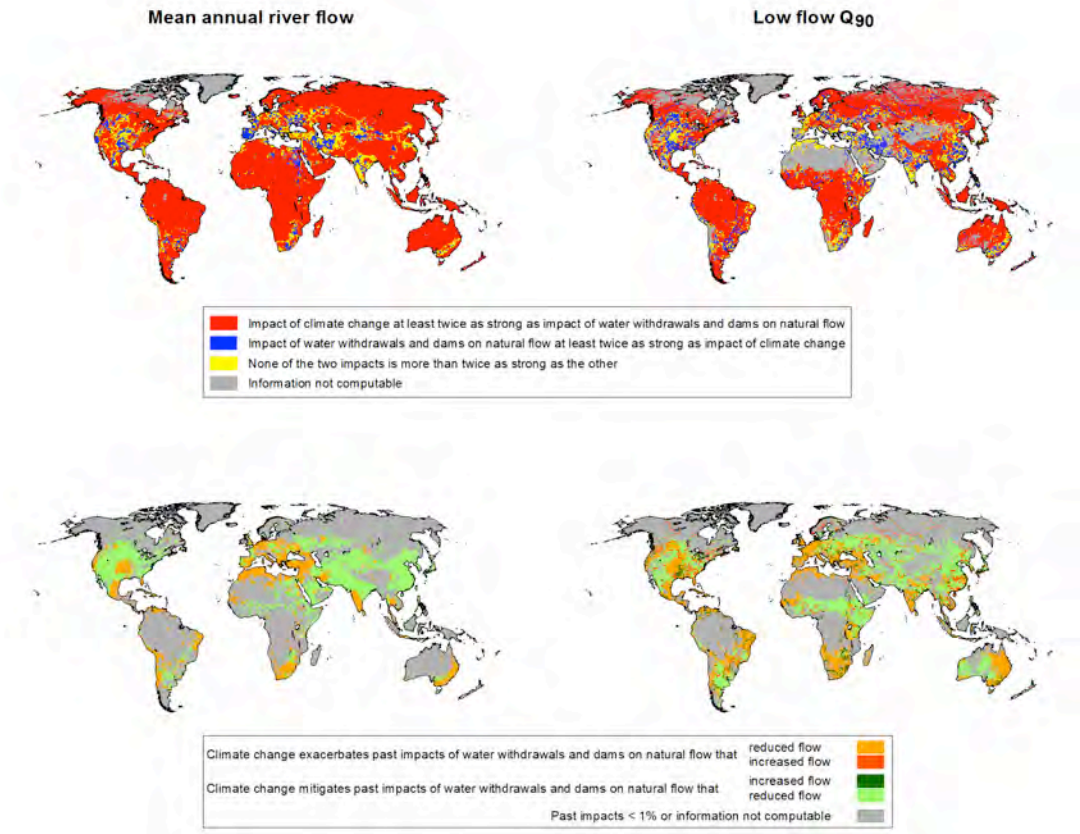

Figure RF-1: Impact of climate change on the ecologically relevant river flow characteristics mean annual river flow and monthly low flow Q_{90} as compared to the impact of water withdrawals and dams on natural flows, as computed by a global water model (Döll and Zhang, 2010). Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002.

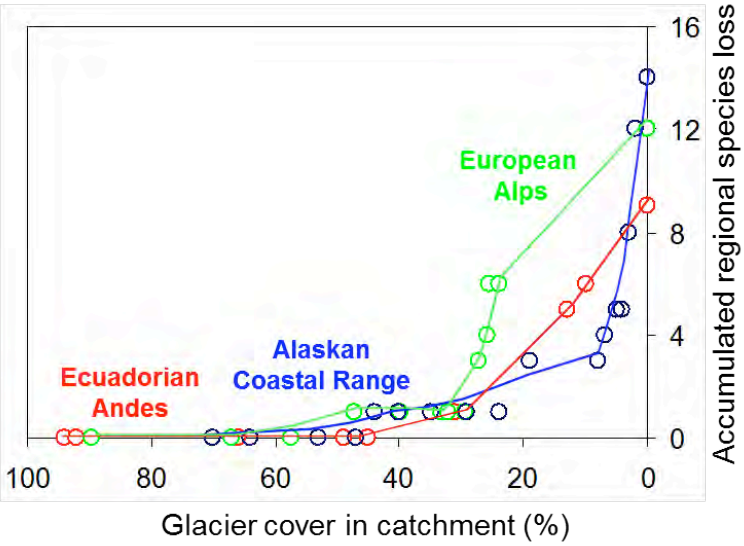

Figure RF-2: Accumulated loss of regional species richness (gamma diversity) as a function of glacial cover GCC. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%. Each data point represents a river site and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.

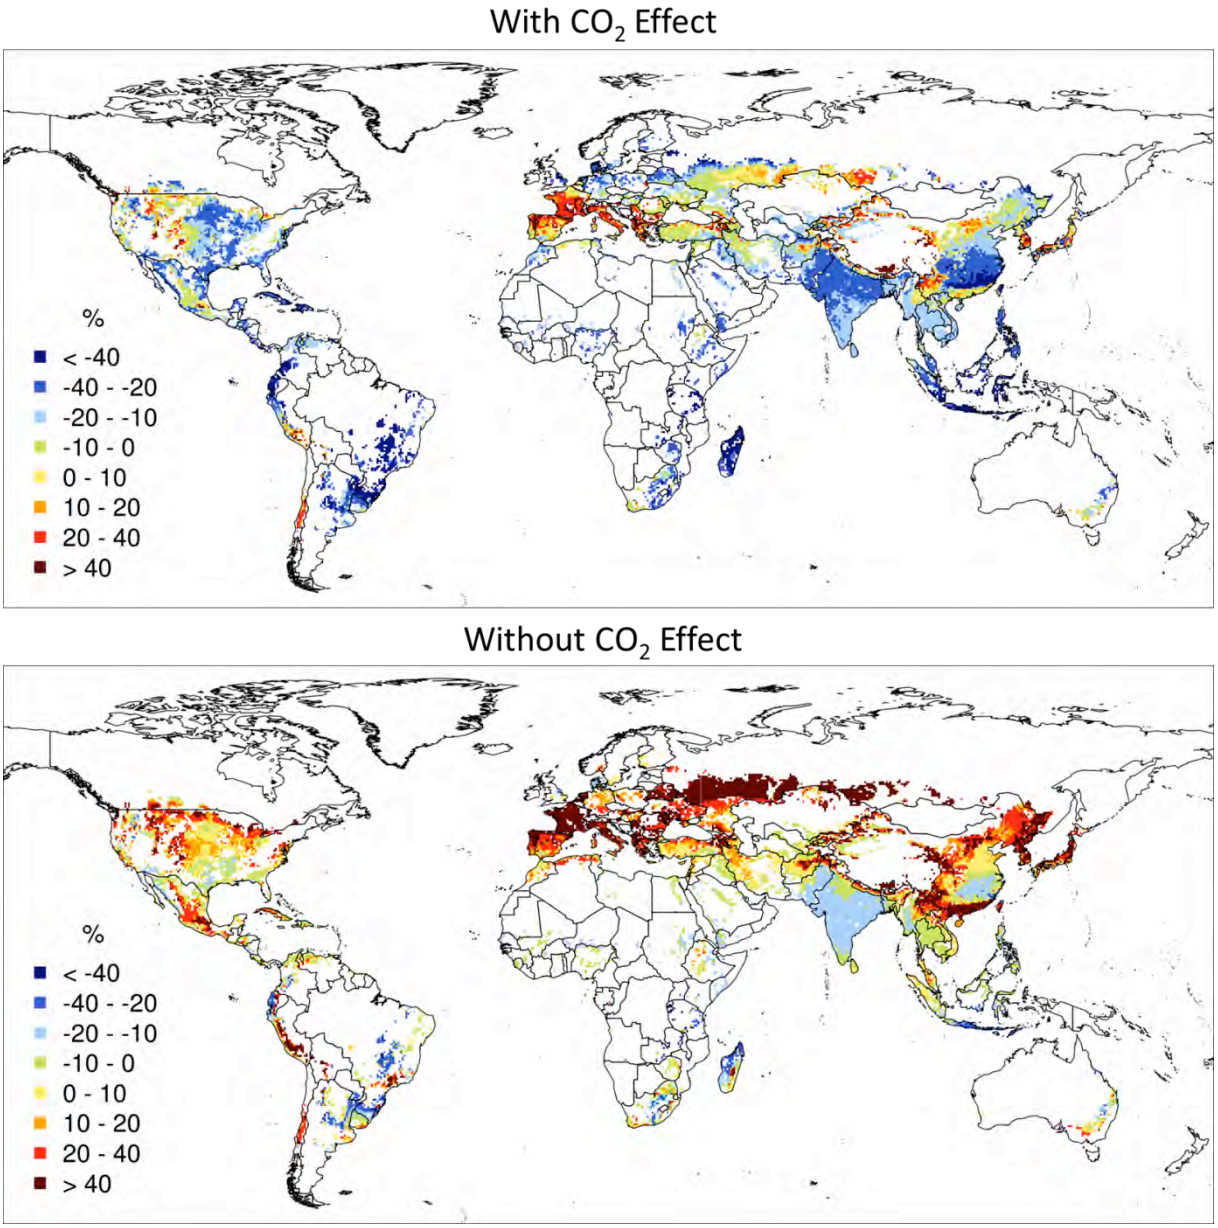

Figure VW-1: Percentage change (ensemble median across 19 GCMs used to force a vegetation and hydrology model) in net irrigation requirements of 12 major crops by the 2080s, assuming current extent of irrigation areas and current management practices. Top: impacts of climate change only; bottom: additionally considering physiological and structural crop responses to increased atmospheric CO_2 concentration. Taken from Konzmann *et al.* (2013).

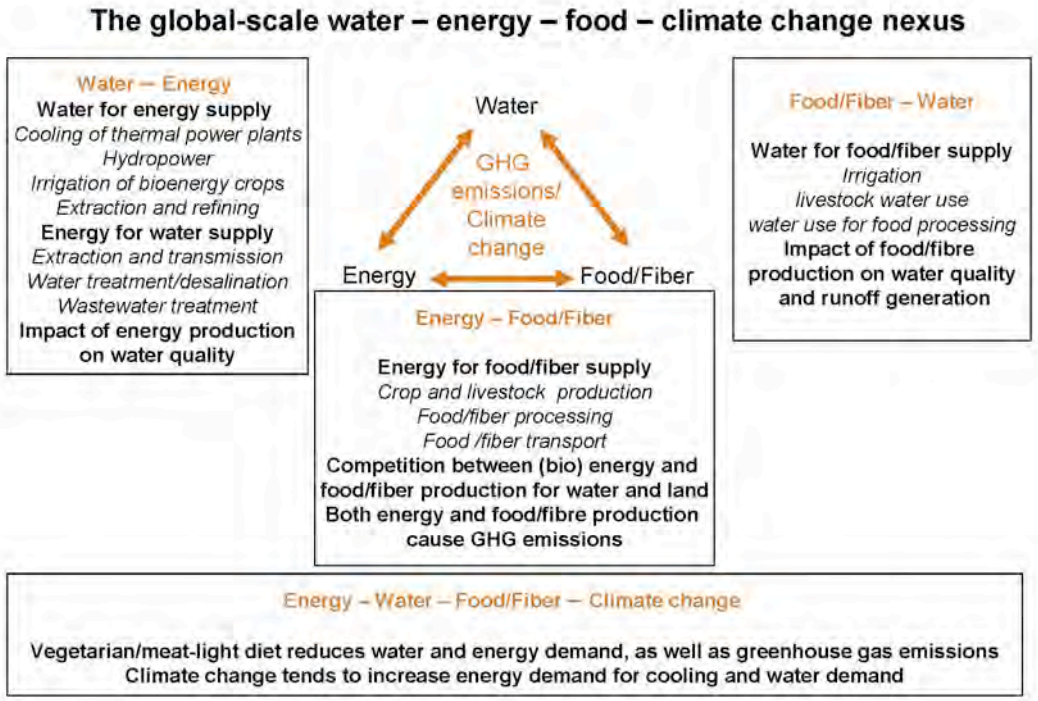

Figure WE-1: The water-energy-food nexus as related to climate change.

Chapter 4. Terrestrial and Inland Water Systems

Executive Summary

There is *high confidence* that the magnitude of future climate change could approach that of many of the largest climatic changes observed in Earth history. There is also *high confidence* that the planet's biota, carbon cycle and associated feedbacks and services responded to this climate change, even when the rates of past global climate change were slower than implied by higher warming scenarios (e.g., RCP 8.5). [4.2.2] However, the impacts of climate change on terrestrial and freshwater ecosystems must also be considered in the context of non-climatic influences, both naturally-occurring and directly driven by humans. There is *high confidence* that most ecosystems change over time, due to biological interactions and natural environmental disturbances, even under climate change slower than projected for low- to medium-range warming scenarios (e.g., RCP2.6 to RCP6.0). [4.2.2]

Few ecosystems can now be considered to be unaffected by human activity. Vegetation cover classed as "primary" and essentially undisturbed by humans is estimated with *high confidence* to have decreased from approximately 95% of the global land area in 1500 AD to less than 40% at the start of the 21st Century, with half of this reduction being at the expense of primary forest. [4.2.1, 4.2.3, 4.2.4] **There is *medium confidence* that significant feedbacks exist between terrestrial ecosystems and the climate. Thus local, regional and global climate may be affected as ecosystems are altered, through climate change itself or other mechanisms, such as conversion to agriculture or human settlement.** These climate feedbacks are driven by changes in surface albedo, evapotranspiration and greenhouse gas emissions. The regions where the climate is affected may be different from the location of the ecosystem change. [e.g. 4.3.3.4]

There is *high confidence* for freshwater ecosystems and *medium confidence* for terrestrial ecosystems that direct human impacts such as land-use change, pollution and water resource development will continue to dominate the threats to ecosystems, with climate change becoming an increasing additional stress through the century, especially for high-warming scenarios such as RCP6.0 and RCP8.5. [4.3.3] Model-based projections imply that direct land cover change will continue to dominate over climate-induced change for low to moderate warming scenarios at global scales (e.g., RCP2.6 to RCP6.0). However, in many areas not subject to intensive human disturbance, there is *high confidence* that even lower levels of projected future climate changes will result in changes in large-scale ecosystem character depending on the nature of regional climate changes. Such changes may not be fully apparent for several decades after reaching the critical regional climate state, due to long response times in ecological systems (*medium confidence*). For higher warming scenarios, some model projections imply climate-driven large-scale ecosystem changes which become comparable with direct human impacts at the global scale (*medium confidence*). There is *high confidence* that rising water temperatures will lead to shifts in freshwater species distributions and compound water quality problems, especially in those systems experiencing high anthropogenic loading of nutrients. There is *medium confidence* that changes in precipitation will significant alter ecologically important attributes of flow regimes in rivers and wetlands and exacerbate impacts from human water use in developed river basins. [Box CC-RF, 4.3.3.3]

There is *high confidence* that the capacity of many species to respond to climate change will continue to be constrained by non-climate factors, including but not limited to the simultaneous presence of land-use changes, habitat fragmentation and loss, competition with alien species, exposure to novel pests and diseases, nitrogen loading, increasing carbon dioxide and tropospheric ozone. [Figure 4-1, 4.2.4-4.2.4.6, 4.3.3-4.3.3.5]

There is *high confidence* that a changing climate exacerbates other threats to biodiversity. In some systems, such as high altitude and latitude freshwater and terrestrial ecosystems, there is *high confidence* that climate changes exceeding those projected under RCP2.6 will lead to major changes in species distributions and ecosystem function. [4.3.2.5, 4.3.3.1, 4.3.3.3, 4.4.1.1] Since the specific changes in individual regions depends on the nature of the projected regional climate change, the confidence in specific future ecosystem changes is limited by the confidence assigned to regional climate change projections by Working Group I.

There is *high confidence* that plants and animal species have moved their ranges, altered their abundance and shifted their seasonal activities in response to climate change in the past. There is also *high confidence* that they are doing so now in many regions and will continue to do so in response to projected future climate change. [4.2.2, 4.3.2, 4.3.2.1, 4.3.2.5, 4.3.3] The broad patterns of species and biome movement towards the poles and higher in altitude in response to a warming climate are well established for the distant (*very high confidence*) and recent past (*medium confidence*). *High confidence* in these past responses, coupled with projections from a diversity of models and studies provide *high confidence* that such responses will be the norm with continued warming. [4.2.1, 4.2.2, 4.3.2, 4.3.2.1, 4.3.2.5] There is *high confidence* that these shifts in species ranges will cause large changes in local abundance under all climate change scenarios: abundance declining in areas where climate becomes unfavorable and potentially increasing in areas where climate becomes more favorable. [4.3.2.5] There is *high confidence* that such changes in species abundance lead to changes in community composition and ecosystem function. There is *high confidence*, based on extensive ground and satellite-based measurements that the seasonal activity of species has responded to warming over the last several decades. [4.3.2, 4.3.2.1, 4.4.1.1] Observations and models of the seasonal activities of species indicate that climate warming disrupts species life cycles and

interactions between species, as well as altering ecosystem function. [4.3.2.1, 4.4.1.1] At local scales, observed and modelled species responses sometimes differ from qualitative predictions based on global scale indices of warming; this can often be explained by large variation in local scale climate response to global warming, changes in climate factors other than average temperature, non-climatic determinants of species distributions, interactions between climate and other simultaneous global change factors such as nitrogen deposition, and species interactions. [4.3.2.1, 4.3.2.5, 4.4.1.1] There is *high confidence* that no past climate changes is a precise analog to the current and projected climatic changes, so species responses inferred from the past only give indications, especially at the local scale. [4.2.2]

There is *high confidence* that climate change is increasing the likelihood of the establishment, growth, spread and survival of some invasive alien species populations in some regions. Alien invasive species are more likely than native species to have traits that favor their survival and reproduction under changing climates. Species movement into areas where they were not present historically will be driven both by climate change and by increased dispersal opportunities associated with human activities. [4.2.4.6]

There is *medium confidence* that even for mid-range rates of climate change (i.e., RCP4.5 and RCP6.0 scenarios) many species will be unable to move fast enough to track suitable climates. Over the last several decades many species have tracked changes in climate. However, there is *medium confidence* that some species have been unable to track recent climatic changes. [4.3.2.5] Populations of species that cannot track future climate change by migrating will find themselves in unfavorable climates and are unable to expand into newly climatically suitable areas. Species in large flat areas are particularly vulnerable because they must migrate over longer distances to keep up with climate change than species in mountainous regions. Species with low migration capacity will also be especially vulnerable: examples include most trees, many plants, and some small mammals. Combinations of low migration capacity and large flat areas are projected to pose the most serious problems for tracking climate; for example, there is *medium confidence* that even the maximum observed and modelled migration rates for mid- and late-successional tree species will be insufficient to track climate change in flat areas even at moderate rates of climate change. There is *high confidence* that barriers to migration such as mountain ranges, dams, habitat fragmentation and occupation of habitat by competing species substantially reduce the ability of species to migrate to more suitable climates. There is *high confidence* that outlier populations (e.g., collections in botanical gardens or parks), as well as intentional and accidental anthropogenic transport will speed migration. [4.3.2.5, 4.3.3.3]

There is *high confidence* that large magnitudes of climate change will negatively impact species with populations that are primarily restricted to protected areas, mountaintops or mountain streams, even those that potentially migrate fast enough to track suitable climates. [4.3.2.5, 4.3.4.1] Climate change is projected with *high confidence* to either create unsuitable climates for species that remain in these areas, or force species out of protected areas and off mountaintops. These effects are foreseen to be modest for low magnitudes of climate change (e.g., RCP 2.6) and very high for the highest magnitudes of projected climate change (e.g., RCP 8.5). There is *high confidence* that species have already started to migrate out of protected areas and towards mountaintops over the last several decades due to a warming climate. [4.3.2.5, 4.3.4.1]

There is *very high confidence* that projected climate changes imply increased extinction risk for a substantial fraction of species during and beyond the 21st century, especially as climate change interacts with other pressures. [4.3.2.5] Uncertainties in regional climate projections, highly variable estimates from comparisons of paleontological extinctions in response to past climate changes, different methods of estimating present and future extinction risk, and the variable adaptive capacity of wild species all contribute to an extremely broad range of estimates of future extinction risk due to climate change. There is *high confidence* that current extinction pressures from habitat modification, over-exploitation and invasive species are continuing, and will interact with growing impacts of climate change. When combined with methodological challenges in modelling future extinction risks, this means there is *low confidence* that global extinction risks due to climate change can be accurately quantified. There is, however, a strong consensus that current climate change pressures and their interactions with other global changes will increase extinction risk for many terrestrial and freshwater species. There is *very low confidence* that observed species extinctions can be attributed to recent climate warming given the very low fraction of species for which global extinction has been ascribed to climate change and tenuous nature of most attributions. However, in

the specific case of Central American amphibians, there is *medium confidence* that recent warming has played a role in their extinctions. [4.3.2, 4.3.2.5]

It is *virtually certain* that the carbon stored in land and freshwater ecosystems in the form of plant biomass and soil organic matter has increased over the past two decades in what is known as the terrestrial carbon sink. There is *low confidence* that the transfer of carbon dioxide from the atmosphere to the land will continue at a similar rate for the remainder of the century. There is *high confidence* that the terrestrial carbon sink is offset to a large degree by carbon released to the atmosphere through forest conversion to farm and grazing land and through forest degradation [4.2.4.1, 4.3.3.1]. There is *medium confidence* that the carbon stored thus far in terrestrial ecosystems is vulnerable to loss back to the atmosphere as a result of climate change (including indirect effects such as increased risk of fires and pest outbreaks) and land-use change. Terrestrial and freshwater ecosystems have been responsible for the uptake of about a quarter of all anthropogenic CO_2 emissions in the past half century. [4.3.2.2 and 4.3.2.3] The net fluxes out of the atmosphere and into plant biomass and soils show large year-to-year variability. As a result there is *low confidence* in the ability to determine whether the net fluxes into or out of terrestrial ecosystems at the global scale have increased or decreased over the past two decades. There is *high confidence* that the factors causing the current increase in land carbon include the positive effects of rising CO_2 on plant productivity, a warming climate, and recovery from past disturbances, but *low confidence* regarding the relative contribution by each of these and other factors. [4.2.4.1, 4.2.4.2, 4.2.4.4, 4.3.2.2] Experiments and modelling studies provide *medium confidence* that increases in CO_2 up to about 600 ppm will continue to enhance photosynthesis and plant water-use efficiency, but at a diminishing rate. [4.2.4.4]. There is also *medium confidence* that other factors associated with global change, including high temperatures, rising ozone concentrations and in some places drought, decrease plant productivity by comparable amounts [4.2.4.3, Box 4-3]. Models provide *high confidence* that nitrogen availability will limit the response of many natural ecosystems to rising CO_2. [4.2.4.2]. There are few field-scale experiments on ecosystems at the highest CO_2 concentrations projected by RCP8.5 for late in the century, and none of these include the effects of other potential confounding factors [4.3.2.2, 4.2.2.3].

There is *medium confidence* that increases in the frequency or intensity of ecosystem disturbances due to fires, pest outbreaks, wind-storms and droughts have been detected in many parts of the world. There is *high confidence* that such changes, which are by definition beyond the range of historical natural variability, will alter the structure, composition and functioning of ecosystems. There is *medium confidence* that such changes will often be manifested as relatively abrupt and spatially-patchy transitions following disturbances, rather than gradual and spatially-uniform shifts in location or abundance. [Box 4-3, Box 4-4, 4.2.4.6, 4.3.3, 4.3.2.5, Figure 4-12]

There is evidence of an increase in tree mortality in many regions over the last decade, but there is *low confidence* in the detection of a global trend in increased mortality or in the attribution of such a global trend to climate change. In some regions, increased tree mortality is sufficiently intense and widespread as to result in forest dieback. Forest dieback constitutes a major risk because of its large impacts on biodiversity, wood production, water quality, amenity, economic activity and the climate itself [4.3.2, 4.3.3.1, 4.3.3.4, 4.3.4, Box 4-2, Box 4-3]. In detailed regional studies, particularly in western and boreal North America, there is *high confidence* that observed tree mortality is detectable and can be attributed to the direct effects of high temperatures and drought, or to changes in the distribution and abundance of insect pests and pathogens related, in part, to warming.

Recent experimental, observational and modelling studies provide *medium confidence* that forests may be more sensitive to future climate change than reported in IPCC AR4 assessment and that tree mortality and forest dieback could become a problem in many regions much sooner than previously anticipated. [4.3.3.1] There is *high confidence* that future climate change impacts on tree mortality and tree ranges could be large, but experimental, observational and modelling studies also indicate that there is *low confidence* associated with model-based projections of the details of these impacts. As such, projections of increased tree growth and enhanced forest C sequestration mediated by increasing growing season length, rising CO_2 concentrations and atmospheric N deposition are being viewed with increasingly greater caution due to the counter-balancing effects of mortality and dieback. [4.3.3.1] The consequences for the provision of timber and other wood products are projected to be highly variable between regions and products depending on the balance of the positive vs. negative effects of global change. [4.3.3.1, 4.3.3.5, 4.3.4]

In the Amazon, there is *medium confidence* that climate change alone will not lead to widespread forest loss during this century. However, there is also *medium confidence* that a combination of severe drought, land use and fire act together to transform mature forests to less dense, fire prone woodland and shrublands. Modelling studies project a range of changes in the regional climate of the Amazon, and very few indicate a state that cannot support rainforest. Nevertheless, many models still project a general drying tendency, and coupled with warming this may increase fire risk. Human land use is associated with fire, so a combination of direct human influence and climate change may still affect the Amazon. [4.3.3.1.3, Box 4-3]

There is *high confidence* that terrestrial and freshwater ecosystems can, when pushed by climate change, cross "tipping points" and abruptly change in composition, structure and function. There is *medium confidence* that the crossing of these tipping points will result in significant increases in carbon emissions to the atmosphere. This has happened many times in Earth history. [4.2.2]. There are plausible mechanisms, supported by experimental evidence and model results, for the existence of ecosystem tipping points in both boreal-arctic systems and the rainforests of the Amazon basin [Boxes 4-3 and 4-4], others may exist. There is a plausible but *low confidence* case that continued climate change could push the boreal-arctic system across such a tipping point in this century and cause an abrupt transformation of the ecology and albedo of this region, as well as the release of greenhouse gases from the thawing permafrost and burning forests. There is *high confidence* that adaption measures will be unable to prevent substantial change in the boreal-arctic system. There is also a plausible but *low confidence* case that continued climate change together with land-use change and fire activity could cause much of the Amazon forest to transform abruptly to more open, dry-adapted ecosystems, and in doing so, put a large stock of biodiversity at elevated risk, and create a large new net greenhouse gas source to the atmosphere. [4.3.3.1]. There is *medium confidence* that the combination of climate change and land-use change in the Amazon will cause accelerated drying and drought frequency in the region and *low confidence* that these Amazon changes will affect rainfall in agricultural regions elsewhere on the planet. [4.3.3.1]. There is *medium confidence* that rigorously applied adaptation measures could lower the risk of abrupt change in the Amazon, as well as the impacts of that change. [Box 4-3, 4.3.3-4.3.3.4, Figure 4-10]. There is *very high confidence* that policy and market-driven interventions have caused a steep decline in deforestation in the Amazon since 2005 that have decreased anthropogenic carbon emissions to the atmosphere by 1.5%. [4.2.4.1, 4.3.3.1]

There is *high confidence* that management actions can reduce, but not eliminate, exposure to climate-driven ecosystem impacts, as well as increase ecosystem adaptability. [4.4] The capacity for natural adaptation by ecosystems and their constituent organisms is substantial, but for many ecosystems and species there is *medium confidence* that this is insufficient to cope without substantial loss of species and ecosystem services, given the rate and magnitude of climate change projected under medium-range warming (e.g., RCP6.0) or high–range warming scenarios (e.g., RCP8.5). The capacity for ecosystems to adapt to climate change can be increased by reducing the other stresses operating on them; reducing the rate and magnitude of change; reducing habitat fragmentation and increasing connectivity; maintaining a large pool of genetic diversity and functional evolutionary processes; assisted translocation of slow moving organisms or those whose migration is impeded, along with the species on which they depend; and manipulation of disturbance regimes to keep them within the ranges necessary for species persistence and sustained ecosystem functioning. [4.4.1-4.4.1.2, 4.4.3]

There is *medium confidence* that management adaptation responses to climate change in some sectors will lead to unintended and unwanted outcomes for terrestrial and freshwater ecosystems. For example, adaptation responses to counter increased variability of water supply for urban and agricultural use, such as building more and larger impoundments and increased water abstraction, will compound the direct effects of climate change in freshwater ecosystems. [4.3.3.3, 4.3.4.5**] There is *very high confidence* that the use of the terrestrial biosphere in climate mitigation actions, such as through introduction of fast-growing tree species for carbon sequestration or the conversion of forest to biofuel plantations, may lead to negative impacts on ecosystems and biodiversity.** The land use scenario accompanying the mitigation scenario RCP2.6, intended to avoid 2°C global warming, features large expansion of biofuel production, displacing natural forest cover. [4.2.4.1]

4.1. Past Assessments

The topics assessed in this chapter were last assessed by the IPCC in 2007, principally in the Working Group II report chapters 3 (Freshwater resources and their management; Kundzewicz *et al.*, 2007) and 4 (Ecosystems, their properties, goods and services; Fischlin *et al.*, 2007). Together they found that 'Observational evidence from all continents and most oceans shows that many natural systems are being affected by regional climate changes, particularly temperature increases'. Although circumstantial evidence was offered that anthropogenic climate change was a cause of the observed changes, it was not possible to attribute a relative proportion of the changes to this cause with any confidence. An important finding was that 20-30% of the plant and animal species that had been assessed to that time were considered *likely* to be at increased risk of extinction if the global average temperature increases exceeded 2-3°C. Fischlin *et al.* (2007) also stated that substantial changes in structure and functioning of ecosystems (terrestrial, marine and other aquatic) are *very likely* under a warming of more than 2-3°C above pre-industrial levels. No timescale was associated with these findings. The report noted that vulnerability to climate change could be exacerbated by the presence of other stresses, such as pollution.

4.2 A Dynamic and Inclusive View of Ecosystems

Ecologists no longer view ecosystems as inherently unchanging unless perturbed by an externally originating disturbance (Hastings, 2004). A growing body of both theory and observation (Scheffer, 2009) supports the emerging view that most ecosystems vary substantively over time in the relative magnitude of their components and fluxes, even under a relatively constant environment. Furthermore, attempts to restrict this intrinsic variation - or that resulting from imposed disturbances - are frequently futile, and may damage the capacity of the ecosystem to adapt to changing environments (Folke *et al.*, 2004). Contemporary treatments of ecosystems treat humans as an integral part of the system, rather than as an external perturbation to the natural state without any feedback to the human system itself (Gunderson and Holling, 2001). The emerging view is of relatively tightly coupled social-ecological systems, which means that their joint dynamics are governed not only by biophysical processes such as energy flows, material cycles, competition and predation, but also by social processes such as economics, politics, culture and individual preferences (Walker and Salt, 2006).

4.2.1. Ecosystems as Adaptive Entities

There is increasing focus on how ecosystems behave in the vicinity of their environmental limits, rather than solely on their behavior near the middle of their domain of their inferred preferred state (Scheffer *et al.*, 2009). The notion of thresholds has become a prominent ecological and political concern (Lenton *et al.*, 2008; Knapp et al 2008, Scheffer *et al.*, 2009; Leadley *et al.*, 2010). Some thresholds reflect a human preference that the ecosystem stays within certain bounds. Others reflect fundamental biophysical properties, for instance the thawing of frozen soils (see Box 4-4); or the physiological tolerance limits of constituent species. A third category of threshold relates to system dynamics under externally-driven change: the point at which the net effect of all the positive and negative feedback loops regulating the ecosystem is positive, causing a small perturbation to become amplified sufficiently to lead to a change in ecosystem state, from which it will not spontaneously return in the short term. The new state will typically exhibit different dynamics, mean composition, sensitivity to environmental drivers and flows of ecosystem services relative to the prior state. This type of threshold is called a tipping point (see glossary).

The early detection and prediction of ecosystem thresholds, particularly tipping points, is an area of active research. There are indications (Scheffer, 2009) that an increase in ecosystem variability signals the impending approach of a threshold.In practice, such signals may not be detectable against background noise and uncertainty until it is too late to avoid the threshold (Biggs *et al.*, 2009). The dynamics of ecosystems are complex and our present level of knowledge is often inadequate to predict an ecosystem outcome with confidence, even if the future climate was precisely known.

The term 'resilience'(see glossary) has attracted a range of meanings in different disciplines. In ecology it is used both in the sense of 'a measure of the ability of these systems to absorb changes of state variables, driving variables

and parameters, and still persist' (Holling, 1973), and also in a broader sense of being able to adapt to change, without necessarily remaining within the same dynamical range (Walker *et al.*, 2004) and has been applied in the context of climate change (e.g. Morecroft *et al.*, 2012). One source of such adaptability is evolution within the populations of organisms making up the ecosystem. Natural selection operates on genetic variability against those individuals less able to survive, compete and successfully reproduce in the altered environment, leading to a shift, over generations, in the tolerance range of the population. Organisms also typically exhibit physiological, developmental or behavioral plasticity, within limits, that does not require genetic change. A particular case occurs when humans in the ecosystem use learning and technology to alter how they interact with the system. A third form of adaptation occurs when the configuration and functional form of interactions within an ecosystem change, in some cases leading to a new stable state (www.regimeshifts.org). It occurs when the abundance of one or more species are greatly altered or are replaced by other species with similar functional attributes. In the extreme, this would constitute a change in ecosystem type.

Field observations over the past century in numerous locations in boreal, temperate and tropical ecosystems have detected shifts of plant species at the biome level upwards in elevation and to higher latitudes (Gonzalez *et al.*, 2010). These shifts have been formally or informally attributed to climate change ([INSERT TABLE 4-1 HERE Table 4-1, Figure 4-1). Projections of potential future vegetation indicate substantial susceptibility of ecosystems to biome shifts (Warszawski *et al*, submitted; Figure 4-2, Box 4-3, Box 4-4).

[INSERT TABLE 4-1 HERE
Table 4-1: Biome shifts from 1700 to the present from published field research that examined trends over periods > 30 y for biomes in areas where climate (rather than land-use change or other factors) predominantly influenced vegetation, derived from a systematic analysis of published studies (Gonzalez *et al.* (2010). Pre-AR4 publications are included to provide a comprehensive review. Shift type: elevational (E), latitudinal (L), examined but not detected (N). Biomes (and abbreviations), from poles to equator: tundra and alpine (UA), boreal conifer forest (BC), temperate conifer forest (TC), temperate broadleaf forest (TB), temperate shrubland (TS), tropical grassland (RG), tropical woodland (RW). Rate of change in temperature (Temp.) and fractional rate of change in precipitation (Precip.) are derived from linear least squares regression of 1901-2002 data (Mitchell and Jones, 2005; Gonzalez *et al.*, 2010). The table provides general regional climate trends at 50 km spatial resolution because the references do not give uniform site-specific climate data to compare across locations. The regional trends are consistent with local trends reported in each reference. * rate significant at $P \leq 0.05$).]

[INSERT FIGURE 4-1 HERE
Figure 4-1: Biome shifts from 1700 to the present at sites in Table 4-1, derived from Gonzalez *et al.* (2010). Temperature change is the rate from linear least squares regression of 1901-2002 temperatures (Mitchell and Jones, 2005; Gonzalez *et al.*, 2010). Numbers refer to the sites in Table 4-1. Arrows indicate general direction of shifts.]

[INSERT FIGURE 4-2 HERE
Figure 4-2: Fraction of land surface at risk of severe ecosystem change as a function of global mean temperature change for all ecosystems models, global climate models and RCPs. The colors represent the different ecosystems models, which are also horizontally separated for clarity. Results are collated in unit-degree bins, where the temperature for a given year is the average over a 30-year window cente4red on that year. The median in each bin is denoted by a black horizontal line. The grey boxes span the 25th and 75th percentiles across the entire ensemble. The short, horizontal stripes represent individual (annual) data points; the curves connect the mean value per ecosystem model in each bin. The solid (dashed) curves are for models with (without) dynamic vegetation composition changes. Right: Fraction of global land surface subject to severe ecosystem change as a function of global mean temperature (left panels) and time (right panels) for the JeDi (upper) and JULES (lower) dynamic global vegetation model driven by the HadGEM2-ES global climate model. The colors represent the different RCPs used to drive the climate model. Good agreement of results at different levels of global warming demonstrates that results are independent of the emissions scenario. (Reproduced from Warszawski *et al.*, submitted)]

4.2.2. What the Paleoecological Record Can and Cannot Tell Us

Paleoclimatic observations and modelling indicate that the Earth's climate has always changed on a wide range of time-scales. In many cases, particularly over the last million years, it has changed in ways that are well-understood in terms of both patterns and causes, (Jansen *et al.*, 2007; IPCC AR5 WGI Chapter 5). Independent paleoecological records demonstrate with *high confidence (robust evidence, high agreement)* that the planet's biota (both terrestrial and aquatic), carbon cycle and associated feedbacks and services have responded to this climatic change, particularly when the climatic change was as large as projected future mid- to high-end change (e.g., MacDonald *et al.*, 2008; Claussen, 2009; Arneth *et al.*, 2010; Willis and MacDonald, 2011; Dawson *et al.*, 2011). Excellent examples of past large climate change events that drove large ecological change include the events that led to the Earth's five mass extinctions in the distant past (i.e., during the Ordovician, ca. 443 Ma, the Devonian, ca. 359 Ma, the Permian, ca. 251 Ma, the Triassic, ca. 200 Ma, and the Cretaceous, ca. 65 Ma; Barnosky *et al.*, 2011). Major ecological change was also driven by climate change during the Paleocene-Eocene Thermal Maximum (PETM, 56 Ma; Wing *et al.*, 2005; Jaramillo *et al.*, 2010), the early Eocene Climatic Optimum (EECO, 53-50 Ma; Woodburne *et al.*, 2009), the Pliocene (5.3 to 2.6 Ma; Haywood and Valdes, 2006; Haywood *et al.*, 2011), and the Last Glacial Maximum (LGM; 21 ka) to Holocene (11 ka) transition (MacDonald *et al.*, 2008; Clark *et al.*, 2009; Gill *et al.*, 2009; Williams *et al.*, 2010b; Prentice *et al.*, 2011; Daniau *et al.*, 2012). The paleoecological record thus provides *high confidence (robust evidence, high agreement)* that large climate change, such as that projected for the 21st century, can result in large ecological changes, including large scale biome shifts, reshuffling of communities and, potentially, species extinctions.

Rapid, regional warming before and after the Younger Dryas cooling event (11.7-12.9 ka) provides a relatively recent analogy for climate change at a rate of a speed that approaches that projected for the 21st century (Alley *et al.*, 2003; Steffensen *et al.*, 2008). Ecosystems and species responded rapidly during this period by shifting distributions and abundances, and there were some notable large animal extinctions, probably exacerbated by humans activities (Gill *et al.*, 2009; Dawson *et al.*, 2011). In some regions, species became locally or regionally extinct, but there is no evidence for climate-driven large-scale extinctions during this period of rapid climate change (Botkin *et al.*, 2007; Willis *et al.*, 2010c), except for a small number of plant species (Jackson and Weng, 1999; Birks and Willis, 2008). However, these climate excursions differ from those projected for the future because they were regional rather than global; may have only regionally exceeded rates of warming projected for the future; and started from a baseline substantially colder than present (Alley *et al.*, 2003). The mid-Holocene around ca. 6 ka provides a very recent example of the effects of modest climate change, because regional warming during this period (ca. 0.5-1.5°C above pre-industrial temperatures in some regions) was the same order of magnitude as the warming the Earth has experienced over the last century. Ecological effects were small compared to periods with larger climate excursions, but even this small degree of warming was characterized by frequent fires in a drier Amazon (Mayle and Power, 2008), development of lush vegetation and lakes in a wetter Sahara (Watrin *et al.*, 2009), temperate deciduous forests in Europe expanding further north and up to higher elevations (Adamik and Kral, 2008), and large-scale migration of Boreal forest into a warmer tundra (Jackson and Overpeck, 2000). Past climate change, even more modest than mid-range projected future change, has also clearly impacted inland water systems (e.g., Smol and Douglas, 2007b; Battarbee *et al.*, 2009; Beilman *et al.*, 2009). However, there are no exact analogues for future climate change: none of the well-studied past periods of large climate change involved simultaneously the rates, magnitude and spatial scale of climate change projected for the next century and beyond (Jansen *et al.*, 2007; Schulte *et al.*, 2010; IPCC AR5 Chapter 5). Direct analogy with the paleoecological record is also unwarranted because future climate change will interact with other global changes such as land-use change, invasive species, pollution and overexploitation of natural resources (Pereira *et al.*, 2010). There is *high confidence (robust evidence, high agreement)* that these interactions will also be important: the paleoecological record provides *medium confidence* (*medium evidence, high agreement*) that exploitation by humans helped drive many large mammal species to extinction during periods of climate change in past (Lorenzen *et al.*, 2011).

It has been demonstrated that state-of-the-art vegetation models are able to simulate much of the biome-level equilibrium response of terrestrial to large paleoclimate change (Prentice *et al.*, 1996; Salzmann *et al.*, 2008; Prentice *et al.*, 2011). These same types of models predict large changes in species ranges, ecosystem function and carbon storage when applied to 21st century climate change (Sitch *et al.*, 2008; Cheaib *et al.*, 2012). Thus, the paleoecological record, and models that have been tested against that record provide a coherent message that biomes

will move, species mixtures will change, novel new plant communities will emerge, and significant carbon changes will take place, all in response to changing and often novel future climates (Williams and Jackson, 2007; Williams *et al.*, 2007b; MacDonald, 2010; Prentice *et al.*, 2011; Willis and MacDonald, 2011); see Section 4.3.2.5 for more specific information on migration rates). As such, the paleoecological record and models provide *high confidence (robust evidence, high agreement)* that it will be difficult or impossible to maintain many ecological systems in their current states if global warming exceeds 2 to 3°C, raising questions about the long-term viability of some current protected areas and conservation schemes, particularly where the objective is to maintain present-day species mixtures (Jackson and Hobbs, 2009; Hickler *et al.*, 2012).

Much of the complex, time-dependent change at regional scales has not yet been simulated by models. The paleoecological record indicates that vegetation in many parts of the world has the potential to respond within years to a few decades to climate change (e.g., Watrin *et al.*, 2009; Williams *et al.*, 2009; Mueller *et al.*, 2009a; Harrison and Goni, 2010), and this same record thus provides a critical model evaluation opportunity that should be more thoroughly exploited to gain confidence in time-dependent simulations of future change, particularly given the complex role that interacting climate change and vegetation disturbance has played in the past (e.g., Marlon *et al.*, 2009; Jackson *et al.*, 2009; Williams *et al.*, 2009; Daniau *et al.*, 2010; Dawson *et al.*, 2011).

The paleoeclimatic record also reveals that past radiative climate forcing change was slower than that anticipated for the 21st century (IPCC AR5 Chapter 12), but even these slower changes often drove surprisingly abrupt, or non-linear, regional change in terrestrial and aquatic systems (e.g., Harrison and Goni, 2010; Williams *et al.*, 2011), as did even slower orbitally-driven change during the most recent Holocene interglacial (e.g., Booth *et al.*, 2005; Kropelin *et al.*, 2008; Williams *et al.*, 2010b; Williams *et al.*, 2011). In all cases, specific periods of abrupt ecological response were regionally distinct in nature and were less synchronous for small, slow changes in forcing (e.g., during the Holocene) than for more global rapid changes listed at the start of this section. State-of-the-art climate and Earth system models are unable to simulate the full range of abrupt change observed in many of these periods (e.g., Valdes, 2011) and thus there is *medium confidence* (*medium evidence, medium agreement*) that these models may not capture some aspects of future climate change and associated ecosystem impacts (Leadley *et al.*, 2010).

4.2.3. Landscapes and Social-Ecological Systems

Ecosystems do not exist in isolation from one another or from human systems. Landscapes, which consist of multiple interacting ecosystems, all experience some degree of interaction with people. The responses of terrestrial and freshwater ecosystems to climate change are therefore mediated by human activities at a range of spatial and temporal scales, and to varying degrees. Together, the social and ecological elements form a linked system (a ‘social-ecological system, SES) in which the degree of coupling can range from very close to slight (Berkes *et al.*, 2003).

4.2.4. Multiple Stressors and the Role of Climate Change

While isolated effects of the main drivers of global change (e.g. climate change, habitat loss, chemical pollution and biological invasions) are increasingly well documented (Millennium Ecosystem Assessment, 2005b; Settele *et al.*, 2010a) there is much less knowledge about their consequences when acting in combination. Multiple stressors can act in a non-additive way (Settele *et al.*, 2010b; Shaw *et al.*, 2002; Larsen *et al.*, 2011), potentially invalidating findings and interventions based on single-factor analysis. In a multifactorial climate change experiment Larsen *et al.*, 2011), demonstrated that non-additive interactions among the climate factors were frequent but most often antagonistic leading to smaller effects than predicted from the single factor effects. Leuzinger *et al.*, (2011) and Dieleman *et al.*, (2012) have synthesized such multifactor interactions and demonstrated that in general, the effect size appears to be reduced when more factors are involved. Leuzinger *et al.* (2011) further showed that models tend to show the opposite trend.

Climatic and non-climatic drivers of ecosystem change must be distinguished if the joint and separate attribution of changes to their causes is to be performed – of paramount importance if the processes of change are to be understood and future changes predicted. Within this section we elaborate on drivers and stressors which often act in concert with climate change, ranging from a high degree of relatedness to climate change (rising CO_2; tropospheric ozone; total, diffuse and UV radiation), over intermediate (land-use change) to low degrees of relatedness (invasive species and N deposition).

4.2.4.1. Land-Use and Cover Change (LUCC)

Land use and land cover continues to change worldwide. In tropical and subtropical areas of Asia, Africa, Oceania and South America, the most widespread land-use changes are conversion of forests and woodlands to annual and perennial agriculture, grazing pastures and commercial plantations, followed by conversion of grasslands and pastures to annual agriculture. Afforestation at the expense of agricultural lands is more frequent in Europe (Rounsevell and Reay, 2009; Schwaiger and Bird, 2010; Miyake *et al.*, 2012) and loss of agricultural land to urban settlements is common in both the developed and developing world. LUCC is both a cause and consequence of climate change. The underlying drivers of LUCC include rising demand for food, fiber and bioenergy, and changes in lifestyle and technologies – some of which are also drivers of climate change. In the future climate change is projected to become a major driver of land cover change and ecosystem functioning, with more than a quarter of the land surface projected to be at risk of severe ecosystem change at global warming of 4°C or above (Figure 4-2). Land cover change can also be caused by change in non-climate environmental drivers such as nutrient loading, pollution and disturbance regimes.

The cause-and-effect entanglement of climate change and LUCC make attribution of consequences to one or the other very difficult. In 13 of the 24 regional land use studies reviewed for this chapter, local-to-regional climate change was at least partly attributed to LUCC, generally with *limited evidence* and *low confidence*. (Direct climate effects attributed to LUCC: Tseng and Chen, 2008; Cui and Graf, 2009; Li *et al.*, 2009; McAlpine *et al.*, 2009; Zhang *et al.*, 2009; Fall *et al.*, 2010; Graiprab *et al.*, 2010; Jin *et al.*, 2010; Mishra *et al.*, 2010; Schwaiger and Bird, 2010; Wu *et al.*, 2010; Gao and Liu, 2011; Carmo *et al.*, 2012. No climate effects attributed: Suarez *et al.*, 1999, Saurral *et al.*, 2008; SuFen *et al.*, 2008; Cochrane and Barber, 2009; Jia *et al.*, 2009a; Rounsevell and Reay, 2009; Martin *et al.*, 2010, Wiley *et al.*, 2010; Clavero *et al.*, 2011; Dai *et al.*, 2011; Viglizzo *et al.*, 2011; Yoshikawa and Sanga-Ngoie, 2011).

LUCC contributes to climate change through changes in the sources or sinks of greenhouse gases and through changes in the absorption of solar energy by the land surface. These factors can have opposite effects and operate at different scales. For instance, conversion of forest to non-forest generally releases carbon dioxide from biomass and soils to the atmosphere, causing warming globally; but also often results in an increase in seasonally-averaged albedo, causing cooling locally and globally (Davin *et al.*, 2007), and a decrease in transpiration, causing warming locally but not globally. Four out of five global climate models suggested local cooling effects following forest conversion to croplands and pastures (Pitman *et al.*, 2009). Equilibrium experiments with the GDFL climate model (Findell *et al.*, 2007) concluded that the land-use change driven climatic impacts *not* mediated by greenhouse gases were generally minor, but significant in a few regions (Eastern Europe, Northern India, and Eastern China). More substantial global effects were projected by van der Molen *et al.* (2011) who found little temperature response to change from forests to pasture or crops in the tropics, increasing towards the Northern Hemisphere mid-latitudes. In high latitudes, changes in snow cover exposure and duration contribute to the albedo increase following forest clearing (Mishra *et al.*, 2010, Levis, 2010).

Afforestation programs are often recommended to promote carbon sequestration (e.g. Fiorese and Guariso, 2013; Singh *et al.*, 2013) but over the long term afforestation may lead to a slight net global warming when the albedo increase effect neutralizes the carbon uptake effect (Schwaiger and Bird, 2010). Wickham *et al.*, (2012) found significant positive slopes in regressions of average annual surface temperatures versus the proportion of forest and argue that the value of temperate afforestation as a potential climate change mitigation strategy is unclear. Changes in albedo, other biophysical effects and some indirect greenhouse effects (such as changes in soil erosion), are not

currently included in the formal rules for accounting for the climate effects of land use activities (Schwaiger and Bird, 2010; Kirschbaum *et al.*, 2012).

The reported effects on precipitation of conversion of forest to pastures and crops vary. Many studies report rainfall decreases, soil moisture decreases and changes in rainfall pattern (e.g. Nepstad *et al.*, 2008; McAlpine *et al.*, 2009; Mendelsohn and Dinar, 2009; Eliseev and Mokhov, 2011). In some cases forest clearing has been reported to enhance local rainfall. Garcia-Carreras and Parker (2011) suggest that enhanced local precipitation can occur over deforested patches due to breezes between forest and cropland. Enhanced rainfall over vegetation boundaries has been shown to occur both in the Amazon (e.g. Knox *et al.*, 2011) and in West Africa (e.g. Garcia-Carreras *et al.*, 2010) as a result of mesoscale processes that are currently not resolved in General Circulation Models.

In China, Han *et al.*, (2012) compared historical data from 244 weather stations predominantly surrounded by cultivated land and 195 stations surrounded by with >70% natural cover. They observed a greater decrease in potential evaporation at stations with significant agricultural influence. In arid and semi-arid regions this was associated with a decrease in wind speed, increase in relative humidity and increase in air temperature compared with natural stations; while in humid and sub-humid regions it was associated with increased wind speed and decreased solar radiation.

Several assessments conclude that LUCC, acting through habitat loss and fragmentation, is the largest cause of contemporary terrestrial and freshwater biodiversity loss, with climate change becoming an increasingly important factor later in the 21st century (Millennium Ecosystem Assessment, 2005a; http://www.cbd.int/gbo3/).

_____ START BOX 4-1 HERE _____

Box 4-1. Future Land Use Pathways and Their Uncertainties

Assessment of climate change effects on terrestrial and inland freshwater ecosystems is incomplete in the absence of information on the direct impacts of people on these systems through land use. The world is undergoing important shifts in land-use patterns. Growth in demand for food, feed, fiber, and fuel has accelerated in recent years, placing new pressures on terrestrial and freshwater ecosystems and outpacing the growth in supply. The principal driver of this acceleration in demand is the rate at which per capita consumption is growing in emerging economies (Tilman *et al.*, 2011). Policy shifts in OECD countries favoring the expansion of biofuel production have contributed to this acceleration (Lapola *et al.*, 2010; Searchinger *et al.*, 2008; Miyake *et al.*, 2012). Growth in demand that outpaces growth in supply, climate-related crop failure (Lobell *et al.*, 2011), declines in the growth of agricultural productivity (Ray *et al.*, 2012) and possibly a shortage of arable land that is not already under cultivation, especially in the temperate zone (Lambin and Meyfroidt, 2011) are all contributing to a rise in commodity prices that may persist through 2020 (OECD/FAO, 2010) and growing pressure on as-yet uncultivated ecosystems on soils that are potentially suitable for cultivation and that are concentrated in tropical latitudes, especially South America and Africa.

Emerging economies start from a relatively low per capita consumption base. The growth of these economies will therefore play an important role in future land use trends. Deforestation in developing countries is now correlated with the export of agricultural commodities (DeFries *et al.*, 2010), providing an early sign of the growing role of agricultural trade with emerging economies as a driver of land-use change. The trajectory of future growth in demand for land- and freshwater-based production remains uncertain, since it depends on economic trends and policies, which are themselves dependent upon complex political and social processes. One of the uncertainties about future land use trends is climate policy. Deforestation rates in the Brazilian Amazon declined 76% (as of 2012) below its ten-year average as a result of policy and market signals (Soares-Filho *et al.*, 2010); this single trend represents a 1.5% reduction in global anthropogenic carbon emissions (Nepstad *et al.*, in press).

These land use trends and the global land cover patterns that they promote have been simulated and mapped within a global grid as input to the Regional Concentration Pathways (RCPs) in preparation for the IPCC AR5. The 4 main RCPs used for future climate projections are accompanied by spatially-explicit future land use scenarios consistent with the emissions scenario and the associated socio-economic scenario (Hurtt *et al.*, 2011) generated by Integrated

Assessment Models using simple methodologies intended to capture the main processes at continental and global scales.

[INSERT TABLE 4-2 HERE
Table 4-2: Summary of drivers and outcomes of land use / cover scenarios associated with Representative Concentration Pathways (Hurtt et al., 2011).]

In the RCPs, land cover change is driven by a number of socioeconomic drivers, including climate policy. The nature of climate policy effects on land use differs between RCPs, with some climate mitigation policy scenarios including conservation of primary vegetation (natural, mature ecosystems) as carbon sinks while others included replacement of primary vegetation with biomass and / or biofuel plantations. The extent to which primary vegetation is replaced by secondary vegetation, crops or pasture also varies between the RCPs (Figure 4-3), but there is no simple linear relationship between the extent of vegetation change and the level of total radiative forcing arising from all sources. Larger reductions in primary vegetation cover are seen in RCP8.5 (the highest emissions scenario) due to a general absence of pro-active measures to control land cover change, but large reductions were also seen in RCP2.6 (an aggressive mitigation scenario with low emissions) due to widespread conversion of land to biomass and biofuel crops coupled with carbon capture and storage. Smaller reductions were seen in RCP6.0 and RCP4.5, with the latter involving conservation of primary forest or regrowth of secondary forest as a mitigation measure. Hence both the highest and lowest emissions scenarios were associated with greater extents of land cover change.

[INSERT FIGURE 4-3 HERE
Figure 4-3: Proportion of global land cover occupied by primary and secondary vegetation (forest and non-forest), cropland, pasture and urban land, from satellite data and historical reconstructions up to 2005 (KleinGoldewijk, 2001), and from scenarios associated with the RCPs from 2005 to 2100 (Hurtt *et al.*, 2011).]

Spatial patterns of the future land cover change in all RCPs were largely similar to patterns of historical change (Figure 4-4) as most future change is projected to be a continuation of past change. By definition, primary vegetation cover cannot increase on the timescales considered here, so in scenarios where cropland and pasture are projected to decrease, these are replaced with secondary vegetation. Both tropical and boreal forest regions are projected to undergo declining primary forest cover in all 4 RCPs, but in RCP6.0 total forest area remains approximately constant.

[INSERT FIGURE 4-4 HERE
Figure 4-4: Fractional cover of primary vegetation at 1850, 2005 based on satellite data and historical reconstructions (KleinGoldewijk, 2001) and at 2100 in scenarios associated with the RCPs (Hurtt *et al.*, 2011).]

_____ END BOX 4-1 HERE _____

4.2.4.2. Nitrogen Deposition

The global nitrogen (N) cycle has been strongly perturbed by human activity over the past century (Gruber and Galloway, 2008; Sutton *et al.*, 2011). Human activities currently transform 160 TgN/year of nitrogen gas in the atmosphere into reactive forms of N that can be readily used by plants and microorganisms in land and in the ocean (Galloway *et al.*, 2008). This is close to the pre-industrial global flux of about 255 TgN/year from all natural sources. The human-caused flow from land to the coastal oceans in rivers is about 50 TgN/y, additional to the estimated natural flux of 30 TgN/year (Galloway *et al.*, 2008). Many of the sources of additional reactive nitrogen share root causes with changes in the carbon cycle - such as increased use of fossil fuels and expansion and intensification of global agriculture - so N deposition, rising CO_2 concentrations and warming are increasing together at global scales (Steffen *et al.*, 2011). This large addition of reactive N into the biosphere can reinforce global warming (e.g., though emission of N_2O associated with fertilizer manufacture and application), or diminish warming (e.g., by increasing C storage in many terrestrial ecosystems). The balance of these effects is difficult to estimate (Erisman *et al.*, 2011; WG1 chapter 6; Hanson *et al.*, 2005). Regional trends in N fluxes differ substantially: N fertilizer use and N deposition are stable or declining in some regions, such as Western Europe; but

N deposition and its impacts on biodiversity and ecosystem functioning are projected to increase substantially over the next several decades in other regions, especially in regions dominated by rapidly-growing emerging economies (Galloway *et al.*, 2008).

Experiments and observations, most of which are in temperate and boreal Europe and North America, show a consistent pattern of increase in the dominance of a few nitrogen-loving plant species and loss of overall plant species richness at N deposition loads exceeding between 5 and 20 kgN/ha/year (Bobbink *et al.*, 2010; but see Stevens *et al.*, 2010a). N deposition is currently above these limits in much of Europe, eastern North America, and Southern Asia (Galloway *et al.*, 2008), including in many protected areas (Bleeker *et al.*, 2011). Experiments examining the interactive impacts of N deposition and elevated CO_2 or climate change on natural systems have increased in number since the AR4, but remain few (Rustad, 2008). Recent studies show that interactions between nitrogen and other global change factors are widespread, strong and complex (Thompson *et al.*, 2008; Langley and Megonigal, 2010; Gaudnik *et al.*, 2011; Hoover *et al.*, 2012; Eisenhauer *et al.*, 2012; but see Zavaleta *et al.*, 2003a for evidence of additive effects). For example, combinations of treatments mimicking future N deposition, elevated CO_2 concentrations and warming had larger negative impacts on pollinator populations than could be predicted from individual treatments (Hoover *et al.*, 2012). Analyses using the multi-factor biodiversity change model GLOBIO3 suggest that N deposition will continue to be a significant contributing factor to terrestrial biodiversity loss in the first third of the century but will be a less important factor than climate change in this period, and a much smaller driver than habitat loss due expansion of agricultural lands (Alkemade *et al.*, 2009). Models that explicitly take into account interactive effects of climate change and N deposition on plant communities project that N deposition impacts will continue to be important, but climate change effects will begin to dominate other factors by the middle of the 21st century (Belyazid *et al.*, 2011).

The impacts of N deposition are often first manifested in freshwater ecosystems, since they collect and concentrate the excess N (and phosphorus) from the land, as well as from sewage and industrial effluents. Primary production in freshwater ecosystems can be either N and P limited or both (Elser *et al.*, 2007), but the biodiversity and capacity of freshwater ecosystems to deliver high quality water, recreational amenity and fisheries services is severely reduced by the addition of nutrients beyond their capacity to process them. Excessive loading of N and P is widespread in the lakes of the northern hemisphere (Bergstrom and Jansson, 2006). The observed symptoms include a shift from nitrogen limitation of phytoplankton in lakes to phosphorus limitation (Elser *et al.*, 2009).

Since the AR4 report there has been an increase in the number of studies using models, observations and experiments to understand and predict the interactive effects of N deposition, climate change and CO_2 on ecosystem function. Broadly, this research shows that ecosystem function is mediated by complex interactions between these factors, such that many ecosystem responses remain difficult to understand and predict (Norby and Zak, 2011; Churkina *et al.*, 2010). For example, experiments, observations and models suggest that the observed increase in productivity and carbon storage in forests in many parts of the world is due to combinations of N deposition, climate change, fertilization effects of rising CO_2, and forest management (Magnani *et al.*, 2007; Huang *et al.*, 2007; Pan *et al.*, 2009; Churkina *et al.*, 2010; Bontemps *et al.*, 2011; Bellassen *et al.*, 2011; de Vries and Posch, 2011; Eastaugh *et al.*, 2011; Norby and Zak, 2011; Shanin *et al.*, 2011; Lu *et al.*, 2012). Despite difficulties in quantifying the relative contributions of these factors and their interactions, it appears that the effects of N deposition and rising CO_2 have generally dominated to date in much of the Northern hemisphere, however, the direct effects of rising temperature and changes in precipitation are may exceed N and CO_2 as key drivers of ecosystem primary productivity in a few decades time. On the other hand, experiments in grasslands show that plant productivity is increased more by N addition (within the projected range for this century) than by elevated CO_2, also within its projected range; and that N effects increase with increasing precipitation (Lee *et al.*, 2010). In contrast to forests and temperate grasslands, N deposition and warming can have negative effects on productivity in other terrestrial ecosystems, such as moss-dominated ecosystems (Limpens *et al.*, 2011). The interactions between N deposition and climate change remain difficult to understand and predict (Ma *et al.*, 2011; Menge and Field, 2007), in part due to shifts in plant species composition (Langley and Megonigal, 2010) and the complex dynamics of coupled C, N and P cycles (Menge and Field, 2007; Niboyet *et al.*, 2011).

4.2.4.3. Tropospheric Ozone

The concentration of ozone in the troposphere (the part of the atmosphere adjacent to terrestrial ecosystems) has been rising over the past 160 years (Horowitz, 2006; Oltmans *et al.*, 2006; Cooper *et al.*, 2010). This is due to increasing anthropogenic emissions of gases which react in the atmosphere to form ozone (Denman *et al.*, 2007), but is also partly due to the increased mixing of stratospheric ozone into the troposphere as a result of climate change (Hegglin and Shepherd, 2009). The key ozone-precursor gases are volatile organic compounds (VOC) and oxides of nitrogen (NO_x). Intercontinenal transport of these precursors is contributing to rising global background ozone concentrations, including in regions where local emissions are decreasing (Dentener *et al.*, 2010).

Negative effects of the current levels of ozone have been widely documented (Mills *et al.*, 2011). A meta-analysis of over 300 articles addressing the effect of ozone on tree growth (Wittig *et al.*, 2009) - largely focussed on northern-hemisphere temperate and boreal species - concluded that current levels of tropospheric ozone are suppressing growth by 7% relative to pre-industrial levels. Modelling studies extrapolating measured dose-response functions suggest a 5 to 30% contemporary reduction in Net Primary Productivity (NPP) worldwide (Sitch *et al.*, 2007) and 1-16% in temperate forests (Ainsworth *et al.*, 2012).

The mechanisms by which ozone affects plant growth are now better known (Hayes *et al.*, 2007; Ainsworth *et al.*, 2012). Chronic exposure to ozone at levels above about 40 ppb generally reduces stomatal conductance and impairs the activity of photosynthetic enzymes (The Royal Society, 2008) although some evidence also suggests ozone exposure may increase stomatal conductance (Wilkinson and Davies, 2010). For the species studied, carbon assimilation rates are generally reduced and respiration increases, leaf area is reduced and leaf senescence accelerated - all leading to a reduction in NPP and biomass accumulation. Gymnosperms are less sensitive than angiosperms. In a modeling study, lower stomatal conductance due to ozone exposure increased river runoff by reducing the loss of soil moisture through transpiration (Huntingford *et al.*, 2011), although studies that measured runoff are contradictory on this issue (Wittig *et al.*, 2007; McLaughlin *et al.*, 2007; Mills *et al.*, 2009; Huntingford *et al.*, 2011).

A modeling study (Sitch *et al.*, 2007) suggests that the negative effects of rising O_3 on plant productivity could offset 17% of the projected increase in global carbon storage due to increasing CO_2 concentrations, but the possible interactive effects between CO_2 and O_3 are poorly understood (The Royal Society, 2008). Reduced stomatal conductance widely observed under elevated CO_2 should help protect plants from ozone damage. Some chamber experiments (Bernacchi *et al.*, 2006) and model studies (Klingberg *et al.*, 2011) suggest this to be the case. The one plot-scale FACE study of CO_2 and O_3 interactions in a temperate forest (Karnosky *et al.*, 2005; Hofmockel *et al.*, 2011) suggests that the effects of O_3 and CO_2 are not independent and may partly compensate for one another.

There is genotypic variation in sensitivity to O_3 (Ainsworth *et al.*, 2012). Other than changing cultivars or species, there is not believed to be much scope for management actions promoting adaptation to higher levels of O_3 (Teixiera *et al.*, 2011; Wilkinson and Davies, 2010). Research into developing ozone resistant varieties and/or chemical protectants against damage may provide management options in the future (Ainsworth *et al.*, 2012, Wilkinson and Davies, 2010).

4.2.4.4. Rising CO_2

The effects of rising CO_2 on the global carbon cycle are discussed in chapter 6 of the WG1 report [Box 6-3, in the SOD]. The discussion here is focused on impacts on terrestrial ecosystems and inland water systems.

Since AR4, investigation of elevated CO_2 effects on plants and ecosystems has focused mainly on Free Air CO_2 Enrichment (FACE) techniques, which have now been in use for approximately 20 years (Leakey *et al.*, 2009) and are considered more realistic than earlier approaches using enclosed chambers because plant community and atmospheric interactions and below-ground conditions are more like those of natural systems. C3 plant species, which includes nearly all tree species, show a general increase in photosynthesis under elevated CO_2, although the response varies between species. Although FACE experiments indicate lower responses of crop yields to elevated

CO_2 than chamber studies, FACE experiments initially suggested greater biomass production of trees (Leakey *et al.*, 2009). But newer results from older stands show that different system respond differently, and only at the Duke forest, a loblolly pine (*Pinus taeda*) stand in North Carolina has biomass accumulation been enhanced several years after canopy closure on rather nutrient poor soils (McCarthy *et al.*, 2010). At most other tree FACE experiments, most of the additional carbon gain has been invested into below-ground pools with short residence time, such as fine roots (Körner *et al.*, 2005; Finzi *et al.*, 2007), and the initial positive response of NPP at the Oak Ridge experiment with sweetgum (*Liquidambar styraciflua*) has disappeared due to progressive nitrogen limitation with stand development (Norby *et al.*, 2010). Acclimation ("down-regulation") occurs under long-term exposure, leading to cessation of effects in some studies (Norby and Zak, 2011) but with on-going stimulation of photosynthetic carbon assimilation due to elevated CO_2 persists at a level of 19 to 46% for approximately 600 ppm CO_2 relative to 370 ppm reported elsewhere (Leakey *et al.*, 2009). Kongstad *et al.* (2012 did not find such increases for a temperate heathland. Paleo records over the Late Quaternary also indicate effects of CO_2 at the ecosystem scale across the globe (Prentice and Harrison, 2009). Generally, nitrogen use efficiency and dark respiration are also both increased under higher CO_2 (Leakey *et al.*, 2009), but in some tree FACE experiments, productivity increases as a result of enhanced CO_2 were sustained by increased nitrogen uptake rather than increased nitrogen use efficiency (Finzi *et al.*, 2007). Transpiration is decreased due to reduced opening of stomatal apertures which does not acclimate to higher CO_2 in the medium term, *i.e.* the scale of several years leading to greater water use efficiency (Leuzinger and Körner, 2010; Leakey *et al.*, 2009; De Kauwe *et al.*, 2013) – this is corroborated by additional evidence from studies of stable carbon isotopes (Barbosa *et al.*, 2010; Koehler *et al.*, 2010; Silva *et al.*, 2010; Maseyk *et al.*, 2011). C4 plant species, which includes most tropical grasses and some crops, undergo photosynthesis via a different biochemical pathway which is not directly affected by elevated CO_2. However, CO_2 rise generally increases water use efficiency of C4 plants which can exert indirect effects on growth (Leakey *et al.*, 2009). Experiments have also shown that elevated CO_2 has potential to stimulate root growth (e.g. Finzi *et al.*, 2007; McMurtrie *et al.*, 2012), mineralisation of soil organic matter (Drake *et al.*, 2011; Carney *et al.*, 2007, but see Finzi *et al.*, 2007) and soil microbial communities (Carney *et al.*, 2007), although Norby and Zak (2011) suggests that elevated CO_2 effects on the microbial community structure are minor. Impacts of CO_2 physiological forcing may extend beyond the organisms themselves – increased water use efficiency may significantly influence hydrological impacts (see Box CC-VW).

Elevated CO_2 can assist in maintaining resilience of individual species against other stresses, such as high temperature, drought and ozone, as ozone exposure decreases with lower stomatal conductance (Sitch *et al.*, 2007). It is also suggested that faster growth rates under higher CO_2 can allow woody plants to become tall enough to withstand ground fires, and hence alter the fire/vegetation regime in rangelands (Bond and Midgley, 2001; Scheiter and Higgins, 2009) It is also suggested that differential species responses to elevated CO_2 are altering competition (Dawes *et al.*, 2011), for example, increasing the likelihood of faster-growing species such as lianas out-competing slower-growing species such as trees (Potvin *et al.*, 2007; Lewis *et al.*, 2009a).

The interactive effects of elevated CO_2 and other global changes (such as climate change, nitrogen deposition and biodiversity loss) on ecosystem function are extremely complex and as yet poorly predictable (Potvin *et al.*, 2007). For example, in one ten-year temperate grassland experiment in Minnesota, elevated CO_2 halved the loss of species richness due to nitrogen addition (Reich, 2009), whereas no such change was reported for a similar experiment in annual grassland on serpentine soils in California (Zavaleta *et al.*, 2003a) or an alpine grassland in France (Bloor *et al.*, 2010) or a Danish heathland ecosystem (Kongstad *et al.*, 2012). Some of the mechanisms of community and production changes under multi-factor forcing may be mediated through changes in plant litter quality, although in the temperate grassland experiment described above the changes in litter decomposition rates were less marked than the changes in the chemical composition of tissues (Knops *et al.*, 2007). Hyvönen *et al.* (2007) review the combined effects of elevated CO_2, temperature, nitrogen deposition and management on carbon sequestration in temperate and boreal forests and conclude that findings extrapolated from experiments that only consider one of these factors in isolation can be misleading. Since FACE experiments either examine CO_2 effects in isolation, or in conjunction with a very limited set of imposed climate changes such as elevated temperature, the extent to which CO_2 responses are affected by a range of temperature changes or other climatic or environmental factors remains poorly studied. A further, broader analysis supports this, and further suggests that the magnitude of CO_2 effects decreases as the scale of study increases (Leuzinger *et al.*, 2011).

Inclusion of CO_2 effects can be a first-order influence on model projections of ecosystem and hydrological responses to anthropogenic climate change. For example, most CMIP3 climate models project a drying, warming trend in Amazonia, and this leads to widespread forest loss being simulated under most climate projections in a model that ignores CO_2 effects (Salazar *et al.*, 2007). However, when CO_2 effects are included, the same model projects forest loss under fewer climate projections (Lapola *et al.*, 2009). The current generation of dynamic global vegetation models (DGVMs; (Sitch *et al.*, 2008), which includes those used within the CMIP5 Earth System Models, uses formulations based on experimental work that pre-dates FACE experiments (e.g., Farquhar *et al.*, 1980; Collatz *et al.*, 1992). However, the DGVMs simulate present-day global carbon budgets that agree with those inferred from observations such as the atmospheric CO_2 record (Sitch *et al.*, 2008).

The effect of CO_2 on plant physiology independent of its role as a greenhouse gas has implications for the definition of "dangerous climate change" in terms of levels of global mean temperature rise, and for the use of "CO_2 equivalent" metrics for comparing different greenhouse gases. Aside from uncertainties in the response to a given change in CO_2 concentration, the relative importance of radiative forcing and "CO_2 physiological forcing" depend on uncertainties in the response of global climate to radiative forcing and also on the relative proportions of CO_2 and other greenhouse gases (Betts *et al.*, 2012). The impacts of, for example, a 2°C rise in global mean temperature may have a very different net impact on ecosystems depending on the change in CO_2 concentration accompanying this rise. A high climate sensitivity and/or a higher proportion of non-CO_2 GHGs would imply a relatively low CO_2 rise at 2°C global warming, so the offsetting effects of CO_2 fertilization and increased water use efficiency would be smaller than for low climate sensitivity and/or a lower proportion of non-CO_2 GHGs. Similarly, inertia in the climate system means that warming would be expected to continue for many decades after stabilisation of GHG concentrations, so the relative contribution of CO_2 physiological effects would diminish over time. Comparison of the effects of CO_2 with other GHGs in terms of the current radiative forcing-based metrics may therefore not be representative of the relative effects of different GHGs on ecosystems and hydrology (Huntingford *et al.*, 2011).

There remain still important limitations on understanding of CO_2 responses. Large-scale FACE experiments have still only been conducted for up to two locations for any particular ecosystem type, and these are in temperate and boreal regions (e.g. Hickler *et al.*, 2008); there is currently no tropical FACE experiment. The scale of controlled experiments is limited to approximately $100m^2$, and extrapolation to larger scales may not be appropriate as other constraints may be important, for example large-scale atmospheric feedbacks (Körner *et al.*, 2007). Similarly, the limited size of FACE experiments means that influences on catchment-scale hydrology have not yet been studied experimentally. The majority of FACE experiments examine CO_2 concentrations of approximately 550 ppmv), which has been projected to be reached by the end of the 21st Century under a number of scenarios including RCP6.0 (van Vuuren *et al.*, 2011), whereas higher concentrations are projected under higher emissions scenarios; RCP8.5 reaches a CO_2 concentration of approximately 900 ppmv by 2100 (van Vuuren *et al.*, 2011). However, the basic physiology of photosynthesis suggest that CO_2 effects saturate at levels of approx. 700 ppmv (Long *et al.*, 2004). Moreover, FACE experiments impose a sudden increase of CO_2 concentration as opposed to the continuous rise measured in the present-day atmosphere. The extent to which photosynthesis and nitrogen and water use efficiency continue to increase with ongoing CO_2 rise therefore remains poorly-constrained. Overall, there is *medium confidence* (*much evidence, medium agreement*) that increases in CO_2 up to about 600 ppm will continue to enhance photosynthesis and plant water-use efficiency, but at a diminishing rate

4.2.4.5. Diffuse Versus Direct Radiation

The quantity and size distribution of aerosols in the atmosphere alters both the amount of solar radiation reaching the Earth's surface and its distribution between direct and diffuse radiation. There are observed trends in diffuse and direct radiation in many parts of the world, usually in the direction of overall 'dimming'. Locally, direct radiation is reduced by up to 30 W m^{-2}, with an accompanying increase in diffuse radiation of up to 20 W m^{-2} (Kvalevåg and Myhre, 2007). The global mean direct and diffuse radiation changes due to aerosols are –3.3 and +0.9 W m^{-2}, respectively (Kvalevåg and Myhre, 2007). For a constant total radiation, an increased fraction received as diffuse radiation theoretically increases net photosynthesis, (Knohl and Baldocchi, 2008; Kanniah *et al.*, 2012) and potentially could alter the hydrological balance and soil temperature. In a global model which included this process, an increase in diffuse fraction of solar radiation due to volcanic and anthropogenic aerosols and cloud cover was

simulated to lead to approximately a 25% increase in the strength of the global land carbon sink between 1960 and 1999; but under a scenario of climate change and decreased anthropogenic aerosol concentration, this enhancement declined to near zero by the end of the 21st Century (Mercado *et al.*, 2009). The influence of form of radiation on plant growth and the land carbon budget is a potentially important unintended consequence of solar radiation management schemes that involve the injection of aerosols into the stratosphere to reduce radiant forcing (Boucher *et al.*, in preparation) but is presently insufficiently researched for adequate assessment.

4.2.4.6. Invasive and Alien Species

Since the IPCC AR4, the number of observations of the spread and establishment of alien species attributed to climate change has increased for several taxa (e.g. Walther *et al.*, 2009) and for particular areas, including mountain tops and polar regions (McDougall *et al.*, 2011; Chown *et al.*, 2012). The aggressive expansion of plant and animal species beyond their historical range is having increasingly negative impacts on ecosystem services and biodiversity (*high confidence*; Brook, 2008; Burton *et al.*, 2010; McGeoch *et al.*, 2010; Simberloff *et al.*, 2013). Climate change will exacerbate some invasion impacts and ameliorate others (Peterson *et al.*, 2008; Bradley *et al.*, 2009; Britton *et al.*, 2010). The spread of alien species has several causes, including habitats made favorable by climate change (Walther *et al.*, 2009), deliberate species transfer and accidental transfer due to increased global movement of goods.

In most cases climate change increases the likelihood of the establishment, growth, spread and survival of invasive species populations (Dukes *et al.*, 2009; Walther *et al.*, 2009; Bradley *et al.*, 2010; Huang *et al.*, 2011; Chown *et al.*, 2012). However, divergent alien species responses and local consequences are expected (e.g. Rahel and Olden, 2008; Frelich *et al.*, 2012; Haider *et al.*, 2012; West *et al.*, 2012). Invasive species compared to native species might have traits that favor their survival, reproduction and adaptation under changing climates; invasive plants in particular tend to have faster growth rates and are particularly favored when resources are not limited (*medium to high confidence*; Buswell *et al.*, 2011; Davidson *et al.*, 2011; Zerebecki and Sorte, 2011; van Kleunen *et al.*, 2010; Willis *et al.*, 2010a; Haider *et al.*, 2012; Matzek, 2012). Invasive plants tend to be more drought tolerant (Crous *et al.*, 2012; Matzek, 2012; Perry *et al.*, 2012), and on average have higher overall metabolic rates, foliar nitrogen concentrations and photosynthetic rates than their native counterparts (Leishman *et al.*, 2007).

Extreme climate events may provide opportunities for invasion by generating disturbances and resource pulses (Diez *et al.*, 2012). Current warming has already enabled many alien species, including plant, vertebrate, invertebrate and single cell taxa, to extend their distributions into new areas (*high confidence* for plants and insects; Walther *et al.*, 2009; Smith *et al.*, 2012). Population declines and range contractions are however predicted for some invasive species in parts of their ranges (Bradley *et al.*, 2009; Bertelsmeier *et al.*, 2012; Sobek-Swant *et al.*, 2012; Taylor *et al.*, 2012;). The expansion of invasive species in some areas and contraction in others will contribute to community re-organisation and the formation of novel ecosystems and interactions in both terrestrial and freshwater habitats (*high confidence*; e.g., Kiesecker, 2011; Britton *et al.*, 2010; Martinez, 2012; see also chapter 4.3.2.5.). For example, invasive grasses will probably be favored over native ones with increasing temperatures (Parker-Allie *et al.*, 2009; Chuine *et al.*, 2012; Sandel and Dangremond, 2012).

Benefits to biodiversity and society as a result of interactive effects of climate change and invasive species will be experienced in individual cases, such as increases in resources available to some threatened species (Caldow *et al.*, 2007), forest structural recovery (Bolte and Degen, 2010) and available biomass for timber and fuel (van Wilgen and Richardson, 2012). The effect of invasions on net changes in carbon stocks are situation specific, and may be either positive or negative (Williams *et al.*, 2007a). Rising CO_2 levels will increase the growth rates of most invasive plant species (Mainka and Howard, 2010), but the effectiveness of invasive species management for sequestering carbon is uncertain and context specific (Peltzer *et al.*, 2010). Longer term, indirect effects of invasive species will be more important than direct, short-term effects, as a result of changes in soil carbon stocks and tree community composition (*low-medium confidence*; Peltzer *et al.*, 2010).

Threat syndromes are formed by synergistic interactions between climate change and invasive species, along with landscape change, habitat disturbance and human-facilitated breakdown of dispersal barriers (Brook, 2008; Angeler and Goedkoop, 2010; Bradley *et al.*, 2010; Winder *et al.*, 2011; Cahill *et al.*, 2013). Climate change and invasive

species change the risk and properties of fire, and the interaction is being reported more frequently as a direct result of higher temperatures and increased invasive plant biomass (*high confidence*; Abatzoglou and Kolden, 2011). In freshwater systems, alien species establishment and survival, species interactions and disease virulence will change as a result of changes in frequency of high-flow events, increasing water temperature, water properties and water demand (*medium confidence*; Schnitzler *et al.*, 2007; Rahel and Olden, 2008; Britton *et al.*, 2010).

A range of climate change-related variables (extreme events, changes in precipitation, temperature and CO_2) will continue to exacerbate the establishment and spread of pests, vectors and pathogens and negatively impact on crop production (*medium confidence*; Robinet and Roques, 2010; Clements and Ditommaso, 2011). Warming has led to the spread of many invasive insect species such as the mountain pine bark beetle and resulted in forest destruction (*high confidence*; Kurz *et al.*, 2008). The interactions between crop growth, climate change and pest dynamics are however complex to predict (West *et al.*, 2012). Management strategies may become less effective as a consequence of decoupling of biocontrol relationships and less effective mechanical control as biomass of invasive species increases (*low to medium confidence*; Hellmann *et al.*, 2008).

4.3. Vulnerability of Terrestrial and Freshwater Ecosystems to Climate Changes

Vulnerability of terrestrial ecosystems to climate change is defined as the combination of three things: the degree to which their climatic environment changes relative to conditions under which the ecosystem evolved; the sensitivity of ecosystem processes to the elements of climate undergoing change; and the degree to which the system (including its coupled social elements) can maintain its structure, composition and function in the presence of such change, either by tolerating the change or adapting to it. See WGII chapter 19 for a fuller discussion on vulnerability concepts.

4.3.1. The Importance of Changes in Disturbance Regime

The species composition at a given location is determined by three factors: the physiological tolerance of the various species that have access to the site in relation to the range of conditions experienced there; interactions with other species, including competitors, symbionts, predators, prey and pathogens; and the ability of species to reach the location in evolutionary or recent times. Occasional disturbances that relieve competition and create opportunities for establishment and success of less-dominant species are important in maintaining diversity. The average environmental conditions are often less of a determinant of species ranges than the extremes, such as the occurrence of exceptionally cold or hot days or droughts exceeding a certain duration, which are often defined as ‘disturbances’. The change in probability of such extremes is typically disproportionately larger than the change in the mean (see IPCC, 2012, but also Diffenbaugh *et al.*, 2005). Fire, floods and strong winds are all examples of biodiversity-sustaining events, provided that their frequency and intensity does not deviate greatly from the regime that prevailed at the location in evolutionary time; outside this range they have adapted to (Connell, 1978).

It is thought that widespread compositional shifts resulting from climate change in interaction with other factors will often be associated with changes in the disturbance regime, rather than physiological tolerance (Thonicke *et al.*, 2008). A ‘disturbance regime’ refers to the totality of different types of disturbance events in a system, each characterized by their probability-intensity function and other relevant attributes, such as their seasonal distribution. A corollary is that disturbance-related change is likely to abrupt rather than gradual.

Change in the fire disturbance regime, in particular, is emerging as a key, mechanism of terrestrial ecosystem change and an early indicator of change that has been detected and in some cases attributed to climate change (Westerling *et al.*, 2006; Littell *et al.*, 2009; Westerling *et al.*, 2011; Moritz *et al.*, 2012).

4.3.2. Evidence of Change in Ecosystems

This section highlights key indices of change in terrestrial and freshwater ecosystems over the recent past. It assesses the degree of confidence that change can be detected and the extent to which changes can be attributed to changes in climate (Figure 4-5). Confidence in detection of change is considered to be very high when there is high agreement between many independent studies, species, ecosystems or regions and where there is robust evidence that the changes over time are statistically significant (see WGII, Chapter 18; Mastrandrea *et al.*, 2010). Note that a slightly different definition than Chapter 18 for detection is used, because detection here is based solely on the presence of a temporal trend and does not attempt to distinguish natural from climate related variation. Confidence in attribution to climate change is very high when three criteria are satisfied: changes correspond to a sound mechanistic understanding of responses to climate change; time series of observations are sufficiently long to detect trends correlated with climate change; and confounding factors can be accounted for or are of limited importance. We have provided estimated levels of confidence even in cases where the capacity for detection or attribution capacity is low or very low, because changes in these ecosystem properties or processes could have large impacts on biodiversity or ecosystem services at regional to global scales. It is also important to account for the spatial distribution of climate change trends: for example, warming trends are very high in the Arctic and small or negative in parts of South America (Burrows *et al.*, 2011). Statements of confidence for detection and attribution are given without references, as detailed traceability is provided in the section 4.3.2, which follows this introduction.

Some of the subsections referred to include assessments of model-based projections of future change, but this analysis of detection and attribution does not cover projected changes in ecosystems. The absence of observed changes does not preclude high levels of confidence in projections of change in the future because 21st century climate change is projected to substantially exceed changes experienced over the last century, and because ecosystem responses to climate change may be non-linear and may appear after considerable time lags.

[INSERT FIGURE 4-5 HERE
Figure 4-5: Confidence in detection of change and attribution of observed responses of terrestrial ecosystems to climate change. Confidence levels have are based on expert judgment of the available literature following the IPCC uncertainty guidance (Mastrandrea *et al.*, 2010), and detection and attribution criteria outlined in Chapter 18. The points in the figure represent global and cross-taxon assessments; the positioning may be different for specific taxa or regions.]

Phenology (see 4.3.2.1) - Since the AR4 report there has been a significant increase in the spatial, temporal and taxonomic coverage through ground-based phenological observation networks, data mining and remote sensing. These observations show that phenology, i.e., the timing of key life history events such as flowering in plants or nesting for birds, has shifted for many but not all species over the last several decades (*high confidence* due to *robust evidence* but only *moderate agreement* when examined across all species). Attribution of temporal shifts in phenology to qualitative expectations of responses due to global warming has given way to more refined analyses and models that account for regional differences in warming trends, urban heat island effects, confounding effects of other global change drivers, and non-linear responses of phenology to warming. These advances notwithstanding, attribution can only be made with *high confidence* because there are a wide range of confounding factors, a substantial fraction of species that have not responded in a predictable manner and discrepancies between phenological shifts in experiments vs. observations.

Primary Productivity (see 4.3.2.2) and Biomass and C Stocks (see 4.3.2.3) - Evidence has accumulated from a wide range of sources including eddy flux towers, inversion of atmospheric CO_2 concentrations, remote sensing and models that, once the effects of deforestation are accounted for, terrestrial ecosystems are currently net sinks for carbon over much of the Northern hemisphere and parts of the Southern hemisphere (*high confidence*). Measurements of increased tree growth over the last several decades, a large sink for carbon, are consistent with this but confounding factors such as N deposition, afforestation and land management make attribution of these trends to climate change difficult (*low confidence*). Most studies speculate that rising CO_2 concentrations are contributing to this trend through stimulation of photosynthesis, but there is no clear, consistent signal of a climate change contribution.

Evapotranspiration (see 4.3.2.4) - Evapotranspiration is now being monitored at a variety of scales ranging from individual plants to large regions. A variety of studies suggest that evapotranspiration increased over the period 1970-1990, but there is substantial uncertainty in this estimate due to low agreement across studies leading to *low confidence* in detection of a trend. The trend of rising evapotranspiration from 1970-1990 has been attributed to global warming, and the absence of a continued trend in from the 1990s onward has been attributed to increased water stress. However, there is *low confidence* in these attributions because of the large number of confounding factors that influence transpiration including N deposition, land management and irrigation.

Species Distributions (see 4.3.2.5) - Depending on the species and species group, there are varying degrees of confidence in the detection of species range shifts and that these range shifts can be attributed to climate change. The number of species studied has considerably increased since the AR4 report as have the number of studies examining the mechanisms underlying range shifts. There is a wide range of evidence from models, field studies, and quantitative comparisons between observed and expected range shifts that some species and species groups, especially arthropods, have shifted their ranges significant distances (10s of km or more) over the last several decades (*high confidence*). Range shifts — that must be distinguished from shifts in community composition — in other key species groups such as plants have been much more difficult to detect, meaning there is only *medium confidence* in detection in range shifts when examined across all species groups. Range shifts in some species groups, e.g., arthropods, correlate well with warming over the last several decades and can be linked to changes in climate through understanding of mechanisms. But for many other species groups range shifts are more difficult to attribute to changes in climate because the climate signal is small, there are many confounding factors, differences between expected and observed range shifts are large, or variability within or between studies is high. Thus there is only *medium confidence* in attribution when examined across all species. An importance advance since the AR4 report is the recognition changes in climate over the last several decades have led to range shifts that are frequently not towards the poles or up in altitude due to many factors including interactions between warming, land use and changes in precipitation (*high confidence*).

Global Species Extinctions (see 4.3.2.5) - There is *high confidence* that global species extinctions are at or above the highest rates of species extinction in the fossil record, and *high confidence* that global extinctions have increased in some species groups, e.g., amphibians, over the last several decades. However, across all taxa there is only *low confidence* that rates of species extinctions have increased over the last several decades. Only a small fraction of observed species extinctions have been attributed to climate change — most have been ascribed to invasive species, overexploitation, habitat loss or habitat modification. As such, there is *very low confidence* that observed species extinctions can be attributed to recent climate warming given the small fraction of species for which global extinction has been ascribed to climate change and tenuous nature of most attributions. However, in the specific case of Central American amphibians, there is *medium evidence* that recent climate warming has contributed to extinctions and *medium confidence* in this attribution. There is *low agreement* among investigators concerning the importance of climate compared to other factors such as invasive disease and habitat loss.

Invasive and Alien Species (see 4.2.4.6) - There is *very high confidence* that species invasions are increasing over the last several decades. There is *high confidence* that recent climate trends have contributed to the establishment, growth, spread and survival of some alien species populations in some regions, but only *low confidence* that the species invasions have generally been assisted by recent climatic trends because of the overwhelming importance of human facilitated dispersal in mediating invasions.

Tree Mortality (see 4.3.3.1, Box 4-2) - Extensive tree mortality appears to be increasing globally, but there is *low confidence* in detection due to a lack of temporal and spatial coverage of tree mortality. In particular, the increase in reporting of mortality may reflect greater observation effort rather than a real increase in mortality. In many cases, tree mortality can clearly be linked directly to climate impacts, especially heat and drought. However, attribution to directional climate change over the last several decades is difficult (*low confidence*) due to lack of time series measurements for a large range of forested systems and the large number of confounding factors mediating tree mortality.

Boreal Forest Regime Shift (see 4.3.3.1.1, Box 4-4) - An increase in tree mortality is observed in many boreal forests, with particularly widespread dieback related to insect infestations in North America. Tree health in boreal

forests varies greatly among regions, which coupled with insufficient temporal coverage means that there is *low confidence* in the detection of a clear temporal trend in morality at the global scale. Models and paleobotanical data indicate that regression of boreal forest at its southern edge is a predictable response to warming. High magnitudes of climate change over most of boreal forest also facilitate attribution to global warming. In some cases, tree mortality can be linked directly or indirectly (e.g., due to changes in insect and pathogen ranges) to fluctuations in climate. However, the lack of long-term data sets and high spatial heterogeneity means that attribution to climate change is of *low confidence*.

Amazon Forest Regime Shift (see 4.3.3.1.3, Box 4-3) - Long-term increases in tree turnover (increased mortality and growth) in the humid tropical forests of the Amazon basin have been documented with *moderate confidence*. In addition, two episodes of extreme drought over the last decade have led to increased mortality of large trees. There is *low confidence* that this represents a trend towards degradation of humid tropical forest, since structural changes in intact forests have been minor. Observed changes in tree turnover have been ascribed to a variety of mechanisms including rising CO_2 effects on vines, recovery from past disturbance and changing climate: the attribution to these various drivers is difficult due to limited temporal and spatial coverage. Models and experiments lend credence to a contribution of climate to increased tree mortality and growth. There is *very low confidence* in attribution of observations to climate change because of the short period of intensive monitoring records and because warming trends over the last several decades are weak in this region.

Tundra Regime Shift (see 4.3.3.4) - Field and satellite measurements indicate an increase in shrub growth and permafrost thawing in many areas of the Arctic tundra. Lack of temporal coverage makes it difficult to know if this is a strong directional signal leading to *medium confidence* in detection of a trend. It is not clear to what extent this presages boreal forest encroachment into tundra, which would have much larger impacts on ecosystem structure and function. Experiments, models and paleontological responses of tundra to past warming all indicate that the increase in shrub coverage and permafrost thawing are predictable responses to climate warming trends. High magnitudes of climate change over the last 50 years for most of the Arctic facilitate attribution. The lack of long-term monitoring data makes it difficult to attribute these changes to climate change with greater than *medium confidence*.

Cultural Landscapes (see 4.3.3.5) - There is *very high confidence* that species composition and landscape structure are changing in cultural landscapes such as Satoyama landscapes in Japan or mixed forest, agricultural landscapes in Europe. Models and experiments suggest that climate change should be contributing to these observed changes. The land use and land management signal is so strong in these landscapes, that there is *very low confidence* that we can attribute these observations to climate change.

Evolutionary and Genetic Adaptation (see 4.4.1.2) - While there are an increasing number of observations of "rapid evolutionary" responses to climate variation, the number of species studied is extremely limited. In addition, it remains difficult to separate phenotypic from genotypic adaptation meaning that there is only *low confidence* that we are detecting a widespread signal of evolutionary or genetic adaptation to climate. An increasing number of models and experiments illustrate that "rapid evolutionary" responses are possible and even probable response to climate change. In a few cases, strong correlations between climate trends and changes in gene frequencies underlying phenological responses to climate trends suggest that climate change is an important driver of rapid evolution. The limited number of well-studied cases means there is only *low confidence* in attribution of adaptation as a generalized response to changes in climate over the last several decades.

4.3.2.1. Phenology

A large number of site-specific studies, and more recently satellite imagery, allow monitoring of phenology. The advance in spring events (e.g. breeding, bud burst, breaking hibernation, flowering, migrating,) has been reported for many regions, especially from the northern hemisphere but fewer in the southern hemisphere and for many plant and animal taxa. Since the AR4 many new studies showing phenological adaptations of species as response to climate change (e.g., amphibians: Kusano and Inoue, 2008; birds: Pulido, 2007; Thorup *et al.*, 2007; mammals: Adamik and Kral, 2008; Lane *et al.*, 2012; plants: Cleland *et al.*, 2007; Gordo and Sanz, 2009; plants and animal taxa: Høye *et al.*, 2007; Primack *et al.*, 2009) and meta analyses were published (observed data: Parmesan, 2006; Parmesan, 2007;

Thackeray *et al.*, 2010; Cook *et al.*, 2012; Ma and Zhou, 2012; Wolkovich *et al.*, 2012; experimental warming experiments: Musolin *et al.*, 2010; Cleland *et al.*, 2012).

Large-scale changes and variations in vegetation have been monitored by satellite since 1982 (White *et al.*, 2009). The Advanced Very High Resolution Radiometer (AVHRR) quantifies the differences in visible and near-infrared wavebands of outgoing radiation (NDVI) which is related to the quantity of photosynthetically-active vegetation. The times of maximum and minimum rate of change of NDVI provide a metric of the growing season. From 1982 to 2008 the NDVI-defined start of the growing season advanced by 5.4 days at the hemispheric scale, and the end was delayed by 6.6 days (Jeong *et al.*, 2011). Rates of change varied over time and at smaller scales. Changes were found to be strongly related to temperature trends, although changes in precipitation may also be key drivers, especially in more arid regions (McPherson, 2007). Studies with the more recent instrument, Moderate Resolution Imaging Spectrometer (MODIS), and other metrics such as Leaf Area Index (the ratio of leaf area to ground area; Ahl *et al.*, 2006) provide a similar picture at large scales, although results can differ at local scales due to the use of different instruments, indices and trend detection methods. The relatively short duration of satellite observations makes trend detection particularly sensitive to the choice of analysis period. Nevertheless, the general emerging picture of an advancement of the start of the growing season length is consistent with ground-based phenology studies. At a regional scale, a combination of species-level observations, meta-analysis, NDVI measurements and phenology modeling to reveal geographically different advancements in spring phenology of Chinese plant communities in different Ecoregions and Biomes between the 1960s and 2000s (Ma and Zhou, 2012).

Changes in breeding phenology are reported from various regions and different taxa (insects, birds, mammals, amphibians; e.g. Parmesan, 2006; Parmesan, 2007; Post *et al.*, 2008; Primack *et al.*, 2009). Various factors can be attributed to changes on breeding phenology, e.g. food availability, increasing spring temperatures. In the northern hemisphere several studies show advancements of egg laying dates in birds (e.g. Parmesan, 2007: -3.70 days/decade ± 0.7, n= 41 species in a meta-analysis). In mammals, Réale *et al.* (2003) found for the female North American squirrel (*Tamiascurus hudsonicus*) an advancement of 18 days of the mean parturition day in 10 years (1992-2002) in the Yukon area, Canada, coinciding with increasing abundance of white spruce cones, the major food source. For the southern hemisphere the opposite pattern, a significant delay of the mean breeding date by 2.8 to 3.7 days between 1950 and 2004 for two of nine seabirds in the Eastern Antarctic (Barbraud and Weimerskirch, 2006).

Patterns of changes in autumn migration in birds are mostly not consistent (delayed, advanced, no change) across analyzed species and regions and appear to be highly related to non-climatic variables (e.g. Sokolov, 2006; Adamik and Pietruszkova, 2008). Phenological response can differ with migration strategy in birds, such as short distant migrants show greater advancements in spring arrivals than long distant migrants (e.g. Saino *et al.*, 2009; but see Parmesan, 2006 for different patterns). Insects show also a variety of phenological responses to changing temperatures (e.g. reviewed in Robinet and Roques, 2010). Development rates speed up and for polyvoltine species an increase in number of generations attributed to increasing temperatures and a lengthening of the growing seasons due to earlier timing of last winter frost and later timing of first fall frosts) are reported (e.g. Menzel *et al.*, 2003; Kunkel *et al.*, 2004; Sunley *et al.*, 2006; Robinet and Roques, 2010)

A variety of environmental drivers could affect behavioral changes in species. Experimental-manipulation shows that higher temperatures lead to significantly earlier egg laying dates of the great tit (*Parus major*) in 5 out of 6 years (Visser *et al.*, 2009), but rates of seasonal warming may also be important (Schaper *et al.*, 2012). In a temperate region (Massachusetts, USA), declining sizes of migration cohorts or of populations appeared to account for a large amount of the variation in previously documented changes in migration times between 1970 and2002 (Miller-Rushing *et al.*, 2008). After accounting for changes in migration cohort size, migration distance, climatic variables, and migration date explained portions of the variation in migratory changes over time. Changes in migration phenology cannot only be attributed to changes in temperature changes but also to differing variability of changed feathers during moulting times, food availability at stop-over places and differing health conditions of individual species (Gordo, 2007).

Snow cover and snow depth can also be important factors. Interactions between temperature precipitation determining snowmelt changes, which is reported to lead to earlier flowering and appearances of plants and arthropods in Greenland between 1996 and 2005 (Høye *et al.*, 2007) and earlier flowering in an alpine plant in the

Rocky Mountains, USA between 1975 and 2008 (Lambert *et al.*, 2010; Hülber *et al.*, 2010). Earlier snow melts are reported to decrease floral resources and can hence affect survival of dependent insects in mountain ranges in the USA across 1980, 1985, 1986 and 1989 (Boggs and Inouye, 2012). Mammals show also changes in phenology as effects of climate change induced changes on snowmelt pattern, especially hibernating species, ranging from advancements of emergence dates from hibernation (Ozgul *et al.*, 2010) due to earlier snowmelts or to delayed emergence dates (Lane *et al.*, 2012) due to delayed snowmelts. Delayed emergence from hibernation was also associated with decreased population growth rate (Lane *et al.*, 2012).

Experiments are an important source of information on physiological and phenological responses to changing climate, but some caution should be exercised when translating their results into future projections using models. Wolkovich *et al.* (2012), in a large meta-analysis, suggested that warming experiments substantially underpredict advances in the timing of flowering and leafing of plants. They also showed that experimentally-derived temperature sensitivities of species did not match the observations in the wild. However, in contrast, Gunderson *et al.* (2012) found good agreement between experimental warming and *in situ* observations. Experiments on wild species may also directly affect results; for example, flipper-tagging of penguins can alter their migratory behavior (Saraux *et al.*, 2011).

Generally, there is a great interspecific variability in phenological responses to changing climatic factors (e.g.: Gunderson *et al.*, 2012). Changes in interspecific interactions, such as predator-prey or interspecific competition for food, stemming from changes in phenological characteristics and breakdown in synchrony between species have been observed. Parmesan (2007) found taxonomic groups to be advancing at significantly different rates, with amphibian breeding date advancing by eight times as much as other groups, birds and butterflies were not significantly different from each other, but both showed spring advancement three times stronger than for herbs and grasses. Since most butterfly species eat herbs and grasses as host plants, this suggests an increasing asynchrony between these two interacting groups. Thackeray *et al.* (2010) draw similar conclusions. Species unable to adjust their behavior, i.e. advancement of spring events to keep track with changing climates could be negatively affected. This may be particularly important in highly seasonal habitats (Both *et al.*, 2010). The degree, direction and strength of the asynchrony due to changing climatic variables depends on differences in the phenology of the interacting species (van Asch and Visser, 2007). Increasing temperatures may either bring species more into synch or more out of synch, depending on their respective starting positions (Singer and Parmesan, 2010), although evidence is more towards a loss of synchrony (Visser and Both, 2005). Changes in (a)synchrony of interacting species is assumed to effect dynamical features of ecological communities such as trophic cascades, competitive hierarchies, and species coexistence (Nakazawa and Doi, 2012). Ahola *et al.* (2007) could show that the competition between the resident *P. major* and the migratory pied flycatcher (*Ficedula hypoleuca*) is increasing when the onset of breeding of both is becoming closer to each other and the abundances of both species are increasing (data: 1953–2005; South-Western Finland). This pattern resulted in a relative host change to more long-distant hosts. van Asch and Visser (2007) report increasing asynchrony of the winter moth (*Operophtera brumata*) and its feeding host oak tree (*Quercus robur*) due to increasing spring temperatures and not changing winter temperatures (based on a descriptive model, oak data: 1975-1999, Netherlands, moth data: 1995-1999; Oosterhout, Warnsborn, Doorwerth, Arnhem; Netherlands). The edible dormouse (*Glis glis*), a nest predator advanced its hibernation termination significantly with -8 days per decade in the Czech Republic between 1975-2005 due to increasing annual spring air temperatures, leading to increased nest predation in three out of four bird surveyed species (Adamik and Kral, 2008)

Cross taxa observations show high variation in species- and location specific responses to increasing temperatures in both direction and magnitude (e.g. Parmesan, 2007; Primack *et al.*, 2009; Thackeray *et al.*, 2010). Uncertainties and biases can be introduced in research that compares different taxonomic groups or geographic regions by often incomplete or non-overlapping time series, averaged geographical scales, lack of consideration of effects of local climatic variability (e.g. wind speed, climatic conditions at stop-over places) and mostly unknown pressures in winter ranges for migratory species (Hudson and Keatley, 2010). With too short time series long term trends in phenological changes cannot be detected, although responses to annual climate variability can often be characterized. However, some studies now extend over several decades (Cook *et al.*, 2008) or even 100 years (Naef-Daenzer *et al.*, 2012)**.** Given the geographical coverage and length over time over which studies are now available, there is high confidence (*robust* evidence, high agreement) that phenological shifts are occurring as a response to a warming climate.

4.3.2.2. Primary Productivity

Primary production is the process of plant growth that underpins energy flow through all ecosystems, enabling provisioning services such as crop, forest, livestock and fisheries harvest. It is also fundamental to the regulation of global carbon cycle (see 4.3.2.3. below). Trends in the amount, seasonal timing, variability, location and type of primary production are therefore important indicators of ecosystem function. Well-established theory, experimentation and observation all agree that primary production is directly and indirectly sensitive to almost all aspects of climate change as well as to many of the other changes simultaneously taking place in the world, such as the factors described in section 4.2.4. The complexity of the interactions between driving factors and the frequently non-linear form of the responses to them means that at a given location the net outcome can be an increase in productivity, no change or a decrease.

At continental-to-global scale two main sources of information on primary productivity are available. The first is precise and frequent measurements of atmospheric carbon dioxide, which once the known signal of fossil fuel emissions is removed, show clear patterns in space and time largely related to the primary productivity of the land and oceans. The relative contribution by the land, which consists of a sink term due to increased net productivity plus a source term due to land-use change, can be estimated using isotope measurements, emission databases and models (Canadell *et al.*, 2007). During the decade 2000 to 2009, land net primary productivity at the global scale continued to be enhanced about 5% relative to the postulated pre-industrial level, leading to a land sink of 2.6 $\pm$ 0.7 PgC/y (see WG1 chapter 6; Raupach *et al.*, 2008; Le Quere *et al.*, 2009). This net uptake of carbon by the land is highly variable year-to-year, in response to global climate models such as ENSO and major volcanic eruptions (Peylin *et al.*, 2005; Sitch *et al.*, 2008; Mercado *et al.*, 2009). It is currently not possible to state with any degree of confidence that the net uptake of carbon on land has either increased or decreased over the past two decades (Raupach *et al.*, 2008).

It is possible to estimate the net uptake on land at subglobal scales, using inversion modelling techniques and the growing network of precision atmospheric observations. There is broad agreement that the net land uptake in largely-untransformed terrestrial ecosystems is globally distributed, almost equally between forested and non-forested ecosystems, but is offset in the tropics by a large carbon emission flux resulting from land-use change, principally deforestation (Pan *et al.*, 2011).

Space-based remote sensing can in principle monitor trends in vegetation cover and leaf area, from which primary productivity can be inferred. A commonly-used metric is the Normalised Difference Vegetation Index (NDVI), for which over 30 years of observations are available, covering most of the global land surface. The observed trends are discussed under the various ecosystem-specific discussions below. In some cases the trends are sufficiently strong and consistent to support a confident statement about the underlying phenomenon, but in many cases they are not. This may mean that no change has occurred, but simply reflect inadequacies in the indicator, method of analysis and length of the record. The AR4 reported a trend of increasing seasonally-accumulated NDVI ("greening") at high northern latitudes (Fischlin *et al.*, 2007; based on Sitch *et al.*, 2007), but later observations show a lower rate and no geographical uniformity (Goetz *et al.*, 2007). More than 25% of North American forest areas, excluding areas recently disturbed by fire, showed a decline in greenness and no systematic change in growing season length, particularly after 2000. NDVI trend analysis studies in rangelands show varying patterns around the world, with substantial areas of disagreement between studies (Millennium Ecosystem Assessment, 2005b; Bai *et al.*, 2008; Beck *et al.*, 2011a; Fensholt *et al.*, 2012). There is agreement that the Sahel showed widespread NDVI increase between the mid 1980s and about 2000, along with an increase in rainfall, but no consensus on whether the detected signal represents increased productivity by grasses, trees or forbs; and to what degree it reveals land management efforts or responses to climate (Anyamba and Tucker, 2005; Hickler *et al.*, 2005; Prince *et al.*, 2007; Hellden and Tottrup, 2008; Seaquist *et al.*, 2009). In the period 2000 to 2009 no NDVI trend was apparent in the Sahel (Samanta *et al.*, 2011).

Tree rings record changes in tree growth over approximately the past millennium. Ring width and the wood density within a ring indicate tree productivity during the period represented by the ring. Isotopes within the ring reveal

changes in the environment to which the tree was exposed. Variations in tree ring parameters arise from many factors, including temperature, moisture stress, CO_2 fertilization and ozone damage. The most recent rings in most published tree ring chronologies date from before the 1990s (Gedalof and Berg, 2010) so tree ring-based conclusions for more recent dates are based on a smaller body of evidence. Sites which are not sensitive to environmental changes may therefore be under-represented. Direct repeated measurements of tree girth increment in forest monitoring plots (discussed in 4.3.2.3) are an alternate data source for recent decades. Tree ring studies may not be representative of forests in general, as most studies were specifically designed to examine growth in response to environmental changes (Gedalof and Berg, 2010).

Many tree ring records show a tendency of accelerated tree growth during much of the 20th century (Briffa *et al.*, 2008), which often correlates with rising temperature. Direct CO_2 effects, inferred from the ring record once the effects of drought and temperature have been accounted for, have been proposed for approximately 20% of the sites in the International Tree Ring Data Base (Gedalof and Berg, 2010) and studied in detail at some sites (Koutavas, 2008). Since the 1980s a number of tree ring records show a decline in tree growth (Wilson *et al.*, 2007). Several possible causes have been suggested for this, including increasing water stress and ozone damage.

4.3.2.3. Biomass and Carbon Stocks

Forests are routinely monitored for management and research purposes, typically by recording species composition and stem size distribution in hundreds of small plots. Forest carbon stock can be estimated from this and forest area data, usually derived from remote sensing. Repeated forest inventories in principle allow the growth rate and change in carbon stock to be estimated. Forest inventories were designed to track timber volumes; inferring total biomass and ecosystem carbon stocks requires further information and assumptions, which make absolute values less certain, but have a lesser effect on trend detection. Forest inventory systems are well-developed for northern hemisphere temperate and boreal forest (Nabuurs *et al.*, 2010; Ryan *et al.*, 2010; Wang *et al.*, 2010a). Data for tropical and southern hemisphere forests and woodlands also exist (Maniatis *et al.*, 2011; Tomppo *et al.*, 2010) but are typically less available and comprehensive (Romijn *et al.*, 2012). More and better data may become available due to advances in remote sensing (e.g. Baccini *et al.*, 2012) and the REDD+ initiative.

Forests have increased in biomass and carbon stocks over the past half century in Europe (Ciais *et al.*, 2008; Luyssaert *et al.*, 2010) and the USA (Birdsey *et al.*, 2006). Canadian managed forests increased in biomass only slightly over 1990-2008, due to fires and beetle outbreaks (Stinson *et al.*, 2011). Several dozen sites across the moist tropics have been monitored to estimate forest biomass changes. In the Amazon (Malhi *et al.*, 2009a; Phillips *et al.*, 2009) forest biomass has generally increased in recent decades, dropping after a drought in 2005. Globally, mature forests are withdrawing from the atmosphere one fourth of human CO_2 emissions while regrowth forests withdraw an additional 17%. This global terrestrial sink is offset by the losses of forest carbon to the atmosphere through tropical deforestation and land-use (Pan *et al.*, 2011).

The carbon stock in global soils, including litter, peatlands and permafrost, is estimated to be in the order of 3300 PgC (Davidson *et al.*, 2011), which is about ten times more than is contained in forest biomass (Kindermann *et al.*, 2008). The size of this stock represents the balance of inputs from primary productivity and soil respiration. Soil respiration increases with increasing temperature, but the sensitivity remains uncertain (Davidson and Janssens, 2006). An analysis of long-term soil respiration measurements from around the world suggests that soil respiration has increased over the past two decades by an amount of 0.1PgC/y, some of which may be due to increased productivity (Bond-Lamberty and Thomson, 2010). Flooded coastal soils also show increases in respiration, larger than increases in production (Kirwan and Blum, 2011).

4.3.2.4. Evapotranspiration and its Role in the Terrestrial Water Cycle

Transpiration is affected by multiple factors (Luo *et al.*, 2008) including temperature, humidity, soil moisture, solar radiation and CO_2 concentration. Total evapotranspiration (ET: transpiration through plant stomata plus evaporation from the ground surface and leaf surfaces) is monitored with flux towers, but since most records are at most 15 years

duration (FLUXNET, 2012) there is insufficient data to calculate large-scale, long-term trends. ET can also be estimated from meteorological observations using the Penman-Monteith equation (Monteith, 1965; Penman, 1948) or simulated with models constrained by observations. Estimates of ET from 1120 globally distributed stations indicate that global land mean ET increased by approximately 2.2% between 1982 and 2002, a rate of increase of 0.5 mm yr^{-2} (Wang *et al.*, 2010b), while other studies using constrained models in combination with other methods indicated trends of between 0.25 mm yr^{-2} to 1.1 mm yr^{-2} during the 1980s and 1990s but with a plateau or even decline since approximately 2000, attributed to reduced net radiation (Vinukollu *et al.*, 2011; Zeng *et al.*, 2012). A multi-model study using a data-driven empirical model and process-based land models (Jung *et al.*, 2010) also suggests that global evapotranspiration rose from the 1980s to the late 1990s but this trend then ceased, with increasing soil moisture limitations being cited as the cause.

Experimental studies demonstrate that increasing CO_2 concentrations leads to a decrease in transpiration and increase in intrinsic water use efficiency (iWUE, the ratio of photosynthesis to stomatal conductance, Leakey *et al.*, 2009), which may act to offset climate-driven ET increases or precipitation decreases to some extent (Luo *et al.*, 2008). A two-year experimental study also showed that warming can also decrease grassland transpiration by leading to earlier spring senescence (Zavaleta *et al.*, 2003b). Historical changes in iWUE can be inferred from records of stable carbon isotopes in woody plants (Peñuelas *et al.*, 2011) and even the bodies of herbivores (Barbosa *et al.*, 2010) since iWUE has been shown to be related to the change in the carbon isotope discrimination $\Delta^{13}C$ (Duquesnay *et al.*, 1998). A meta-analysis of studies at 47 sites across 5 ecosystem types (Peñuelas *et al.*, 2011) suggests that iWUE for mature trees increased by 20.5% between the 1970s and 2000s. Increased iWUE since pre-industrial times (1850 or before) has also been found at several forest sites (Gagen *et al.*, 2011; Andreu-Hayles *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and also in a temperate semi-natural grassland since 1857 (Koehler *et al.*, 2010), although in one boreal tree species iWUE ceased to increase after 1970 (Gagen *et al.*, 2011).

4.3.2.5. Changes in Species Range, Abundance and Extinction

Species respond to climate change through genotypic and phenotypic adaptation, by moving out of unfavorable and into favorable climates, or by going locally or globally extinct (Dawson *et al.*, 2011, Bellard *et al.*, 2012; section 4.2.2). These responses to climate change can potentially have large impacts on biodiversity and ecosystem services. Genotypic adaptation in the face of strong selection pressure from climate change is typically accompanied by large reductions in abundance (see section 4.4.1.2). Species range shifts are accompanied by changes in abundance, local extinctions and colonization that can alter ecosystem services when they affect dominant species such as trees, keystone species such as pollinators, or species that are vectors for disease. Global extinctions result in the permanent loss of unique combinations of genes.

Substantial evidence has accumulated since the AR4 report reinforcing the conclusion that terrestrial plant and animal species' ranges have moved in response to warming over the last several decades and that this movement is projected to accelerate over the coming decades under high rates of climate change. Some changes in species abundances appear to be linked to climate change in a predictable manner with species abundances increasing in areas where climate has become more favorable and vice versa. In contrast, uncertainties concerning attribution of recent and projections of future global species extinctions due to climate change have become more apparent since the AR4 report.

Observed Species Range Shifts - The number of studies looking at observed range shifts and the breadth of species examined has greatly increased since the AR4 report. The most important advances since AR4 concern improvements in understanding the relationship between range shifts and changes in climate over the last several decades. The "uphill and poleward" view of species range shifts in response to recent warming (Parmesan and Yohe, 2003; Parmesan, 2006; Fischlin *et al.*, 2007; Chen *et al.*, 2011) is an useful simplification of species response to changing climate. However, responses to warming are conditioned by changes in precipitation, land use, species interactions and many other factors. Investigations of the mechanisms underlying observed range shifts show that climate signals can often be detected, but the impacts of and interactions between changing temperature, precipitation and land use often result in range shifts that are downhill or away from the poles (Rowe *et al.*, 2010; Crimmins *et al.*, 2011; Hockey *et al.*, 2011; McCain and Colwell, 2011; Rubidge *et al.*, 2011; Pauli *et al.*, 2012;

Tingley *et al.*, 2012; Zhu *et al.*, 2012). There are large differences in the ability of species groups and species within species groups to track changes in climate through range shifts (Angert *et al.*, 2011; Mattila *et al.*, 2011; Chen *et al.*, 2011). For example, butterflies appear to be able track climate better than birds (community shifts - Devictor *et al.*, 2012; but see Chen *et al.* (2011 for range shifts) while some plants appear to be lagging far behind climate except in mountainous areas (Bertrand *et al.*, 2011; Doxford and Freckleton, 2012; Gottfried *et al.*, 2012; Zhu *et al.*, 2012). There is also growing evidence that responses at the "trailing edge" of species distributions (i.e., local extinction in areas where climate has become unfavorable) are often less pronounced than responses at the "leading edge" (i.e., colonization of areas where climate has become favorable), which may be related to differences in the rates of local extinction vs. colonization processes (Doak and Morris, 2010; Chen *et al.*, 2011**;** Brommer *et al.*, 2012; Sunday *et al.*, 2012) and difficulties in detecting local extinction (Thomas *et al.*, 2006).

Rates of recent climate change have varied greatly across the globe ranging from rapid warming to cooling (Burrows *et al.*, 2011; Dobrowski *et al.*, 2013), so taking into account this spatial variation should enhance the ability to detect climate related range shifts. A recent synthesis of range shifts indicates that terrestrial animal species have moved at rates that correspond better with changes in temperature when climate is measured in the regions where the range shifts were observed (Chen *et al.*, 2011), providing greater confidence in attributing range shifts than from range data alone. Average range shifts across taxa and regions in this study were 17 km poleward and 11 m up in altitude per decade, which are 2 to 3 times greater than previous estimates (compare with Parmesan and Yohe, 2003; Fischlin *et al.*, 2007). However, even this approach is an oversimplification since key climate drivers of species range modifications, e.g., temperature and precipitation, frequently have shifted in divergent geographical directions (Dobrowski *et al.*, 2013). Disentangling these conflicting climate signals can help explain complex responses of species ranges to changes in climate (Tingley *et al.*, 2012). Overall, studies since the AR4 report show that species range changes are complex responses to interactions among climate drivers and between climate and non-climate factors. It is the greater understanding of these interactions, combined with increased geographical scope and breadth of species studied that provides *medium confidence* that species ranges have responded to recent changes in climate.

Future Range Shifts - Projections of future species range shifts since AR4 report have been dominated by studies using ecological niche models (ENMs) that estimate future ranges based on current relationships between climate and species distribution (also called “species distribution models”, or "bioclimatic models" when models depend entirely on climate factors; Peterson *et al.*, 2011). A variety of process-based species distribution models are also being developed and more widely used (Kearney *et al.*, 2009; Dawson *et al.*, 2011; Cheaib *et al.*, 2012). Recent model comparisons suggest that in some instances bioclimatic models predict larger range shifts than process-based models (Morin and Thuiller, 2009; Kearney *et al.*, 2010; Cheaib *et al.*, 2012) although in other cases process-based models predict larger shifts (Buckley *et al.*, 2012). Projected future species shifts are broadly coherent with species responses to climate change in the paleontological record and with observed recent species shifts (see section 4.2.2 and above). There has been some progress in model validation, such as the use of hindcasting of observed recent or paleontological range shifts, but validation still needs to be reinforced using a wide array of data types (Green *et al.*, 2008; Pearman *et al.*, 2008; Nogues-Bravo *et al.*, 2010; Dawson *et al.*, 2011). A major limitation of these models is that the vast majority do not account for realistic species displacement rates (i.e., rates at which species are able to shift their ranges); as such, they only indicate changes in areas of favorable and unfavorable climate from which possible shifts in species distribution can be inferred.

A small, but growing number of new analyses and models developed since the A4 report permit the estimation the ability of a large range of species to track climate change. These projections are based on i) past and future climate velocity, which is a measure of the rate of climate displacement across a landscape and provides an indication of the speed at which an organism would need to move in order to keep pace with the changing climatic conditions (Loarie *et al.*, 2009; Burrows *et al.*, 2011; Chen *et al.*, 2011; Sandel *et al.*, 2011; Schippers *et al.*, 2011; Feeley and Rehm, 2012; Schloss *et al.*, 2012; Dobrowski *et al.*, 2013) and ii) species displacement rates across landscapes with and without habitat fragmentation for very broad range of species (e.g., Stevens *et al.*, 2010b; Nathan *et al.*, 2011; Barbet-Massin *et al.*, 2012; Kappes and Haase, 2012; Meier *et al.*, 2012; Schloss *et al.*, 2012; see additional references in Figure 4-6 legend). Figure 4-6 provides a simplified comparison of these rates as means of illustrating the projected abilities of species to track climate. This simplified analysis is coherent with more realistic projections of climate induced species displacement across landscapes, some of which include additional constraints such as

habitat fragmentation or competition (Barbet-Massin *et al.*, 2012; Meier *et al.*, 2012; Schloss *et al.*, 2012). Comparison of these rates indicates whether species are projected to be able to track climate as it changes, i.e., when species displacement capacity exceeds climate velocity. When displacement rates are lower than projected climate velocities this indicates that species may be unable to keep pace with climate change.

Rates of climate change over the 20th and projected for the 21st century are shown in Figure 4-6A. Rates of climate change for global land surfaces are given for IPCC AR5 climate projections for a wide range of greenhouse gas emissions scenarios (i.e., IPCC RCP scenarios, Knutti and Sedlacek, 2012). Rates of global warming for land surfaces have averaged ca. 0.03 °C/yr since 1980. At the low end of projected future rates of warming, rates decrease over time reaching near zero by the end of the century (RCP 2.6). At the high end, projected rates increase over time and culminate above 0.06 °C/yr by the end of the century (RCP 8.5), and can exceed 0.08 °C/yr at the upper bound for this scenario. Background colors in Figure 4-6A indicate the degree to which species may be able or unable to track suitable climates based on corresponding climate velocities (Figure 4-6B) and rates of displacement for a broad range of species groups (Figure 4-6C). Blue background color indicates that nearly all species will be able to track climate change in all areas; orange indicates that some species will be unable to track climate especially in flat areas; and red indicates that many species groups will be unable to track climate except in mountainous regions.

Climate velocity depends on regional rates of climate change and the degree of altitudinal relief (Figure 4-6B, Loarie *et al.*, 2009; Dobrowski *et al.*, 2013). For example, climate velocity is low in mountainous areas, because climatic gradients are strong, and in areas where climate change is low (Figure 4-6B, leftmost axis). Climate velocity is high (Figure 4-6B, rightmost axis) in flat areas (e.g., Amazon basin) or areas where projected climate change is high (e.g., Arctic regions). In flat areas, climate velocity may exceed 8 km/yr for the highest rates of projected climate change (SRES A2 or RCP 8.5).

Rates of displacement vary greatly within and among species groups (Figure 4-6C). Some species groups, notably plants and especially trees, have very low displacement capacity. Other species groups such as butterflies, birds and large vertebrates generally have a very high capacity to disperse across landscapes. Small-ranged species across several groups (amphibians, mammals and birds) are markedly absent from areas with high climate velocities in the past, suggesting a low dispersal capacity (Sandel *et al.*, 2011). Current and future rates of climate change correspond to climate velocities that exceed rates of displacement for several species groups for most climate change scenarios. This is particularly true for mid- and late-successional trees that have maximum displacement rates that are on the order of 10s to a few 100s of m/yr. Overall, many plant species are foreseen to be able to track climates only in areas of mountainous areas, though there is uncertainty concerning the potential role of long-distance dispersal (Pearson, 2006). Primates have substantially higher dispersal capacity than trees; however, a large fraction of primates are found in regions with very high climate velocities (e.g., the Amazon basin), thereby putting them at high risk of being unable to track climates even at relatively low rates of climate change. On a global average, many rodents, as well as some carnivores and freshwater mollusks are projected to be beyond their limits to track climate at high rates of climate change (i.e., >0.06°C/yr). These projected differences in species ability to keep pace with future climate change are broadly coherent with observations of species ability or inability to track recent global warming (see above).

Humans can enhance species displacement by intentionally or unintentionally dispersing individuals or propagules (arrow on right of Figure 4-6C pointing upwards). For example, many economically important tree species may be deliberately moved on large scales as part of climate adaptation strategies in forestry in some regions (Lindner *et al.*, 2010). Human activities can also substantially reduce displacement rates. For example, habitat fragmentation typically reduces displacement rates, sometimes substantially (Eycott *et al.*, 2012; Hodgson *et al.*, 2012; Meier *et al.*, 2012; Schloss *et al.*, 2012; arrow on right pointing downwards). The degree to which habitat fragmentation slows displacement depends on many factors including the spatial pattern of fragmentation and corridors, maximum dispersal distances, population dynamics and the suitability of modified habitats as stepping-stones (Pearson and Dawson, 2003).

Species that cannot move fast enough to keep pace with the rate of climate change will lose favorable climate space and potentially experience large range contractions, whereas displacement that keeps pace with climate change may

allow some species to increase their range size (Menéndez *et al.*, 2008; Pateman *et al.*, 2012). Mountains will provide an extremely important climate refuge for many species because the rate of displacement required to track climate is low (Figure 4-6B, Colwell *et al.*, 2008; Engler *et al.*, 2011; Gottfried *et al.*, 2012; Pauli *et al.*, 2012; but see Dullinger *et al.*, 2012). An important exception is for species that are already at the tops of mountains (or near other boundaries) – they are among the most threatened by climate change because they cannot move upwards (Thuiller *et al.*, 2005; ; Raxworthy *et al.*, 2008; Engler *et al.*, 2011; Sauer *et al.*, 2011). The consequences of losing favorable climate space are not yet well understood. A variety of lines of evidence reviewed below indicate that in the absence of adaptation this leads to declining abundance and eventually local extinction in areas of unfavorable climate, with potentially large effects on biodiversity and ecosystem services (see Box 4-2). Adaptive responses of species are discussed in section 4.4.1.

Significant uncertainties arising from translating rates of warming into climate velocities and from estimating displacement rates mean that the ability to track future climate can only be projected with *low confidence* across all species examined. For trees there is *medium confidence* in these projections due to the large number of studies of past, current and future displacement rates (*robust evidence* and *medium agreement*). Climate velocities are calculated using a variety of methods and spatial resolutions making direct comparisons difficult, so climate velocities in Figure 4-6B are based on semi-quantitative comparisons of several studies (see Figure 4-6 legend) and have only *low confidence* (*limited evidence* and *medium agreement*). For the global average climate velocity (Figure 4-6B, center axis), lowest estimates are about one third of the values on the axis (e.g. Loarie *et al.*, 2009; 0.42 km/yr ≈ 0.03 °C/yr for projected SRES A1B 21st century global land warming). Highest estimates are about four times the values on the axis (Burrows *et al.*, 2011; 2.7 km/yr ≈ 0.02 °C/yr global land warming from 1960-2009), but these high estimates may be artifacts of very large spatial resolutions used in this analysis (Dobrowski *et al.*, 2013). In addition, the rates used in this analysis are based on temperature alone and most analyses suggest that including more climate factors increases climate velocity (Feeley and Rehm, 2012; Dobrowski *et al.*, 2013). Species displacement rates are calculated based on a very wide range of methods including rates of displacement in the paleontological record, rates of current range shifts due to climate warming, models of dispersal and establishment, maximum observed dispersal distances and genetic analyses (e.g., Kinlan and Gaines, 2003; Stevens *et al.*, 2010b). There are often large differences in estimates of dispersal rates across methods (e.g., Kinlan and Gaines, 2003; Stevens *et al.*, 2010b) due to intrinsic uncertainties in the methods and differences in the mechanisms included. For example, estimates of tree displacement rates are frequently based on models or observations that explicitly or implicitly include both dispersal of seeds and biotic and abiotic factors controlling establishment of adult trees. Displacement rates of trees are often more strongly limited by establishment than dispersal (Higgins *et al.*, 2003; Meier *et al.*, 2012). It is reasonable to expect that limits on establishment could also be important for other species groups, but often only dispersal rates have been calculated (e.g., mammals, birds and phytophagous insects). As such, the displacement rates for these species may be optimistic. For some species groups such as trees, there are a wide range of published estimates of displacement rates leading to *high confidence* in the estimates in Figure 4-6C. Considerably less is known about displacement rates for other species groups in response to climate change (e.g., some mammal groups, mollusks), so we have only *low* to *medium confidence* in estimates of their dispersal capacity.

[INSERT FIGURE 4-6 HERE

Figure 4-6: (A) Rate of climate change, (B) corresponding climate velocities and (C) rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention. The thin dotted red arrows give an example of interpretation. Rates of climate change of 0.03 °C/yr correspond to ca. 1.1 km/yr global average climate velocity. When compared to rates of displacement, this would exceed rates for most plants, many primates and some rodents. (A) Observed rates of climate change for global land areas are derived from CRUTEM4 climate data reanalysis, all other rates are calculated based on the average of the CMIP5 climate model ensembles for the historical period and for the future based on the four RCP emissions scenarios. The lower bound (17% of model projections are outside this bound) is given for the lowest emissions scenario and the upper bound for the highest emissions scenario. Data were smoothed using a 20-year sliding window, and rates are based means of between 17 and 30 models using one member per model. Global average temperatures at the end of the 21st century corresponding to each of the RCP scenarios are from Knutti and Sedlacek (2012). Colors in the background synthesize the ability of species to track climate through displacement. (B) Estimates of climate velocity were semi-quantitatively synthesized from seven studies using a diversity of analytical approaches and spatial resolutions (historical - Burrows *et al.*, 2011; Chen *et al.*, 2011; Dobrowski *et al.*, 2013; projected future - Loarie *et al.*, 2009;

Sandel *et al.*, 2011; Schippers *et al.*, 2011; Feeley and Rehm, 2012; Schloss *et al.*, 2012). The three axes represent estimated climate velocities are representative of mountainous areas (left), averaged across all global land area (center, usually geometric means), and regions that are flat or have high rates climate change (right). (C) Rates of displacement for terrestrial plants - predominantly based on dispersal and establishment - were derived from paleobotanical records, modern plant invasion rates and genetic analyses (Kinlan and Gaines, 2003). The box represents ~95% of the observations in Kinlan and Gaines (2003) and the bar represents a qualitative estimate of the median. Displacement estimates for trees are based on reconstructed rates of tree migration during the Holocene (Clark, 1998; Clark *et al.*, 2003; Kinlan and Gaines, 2003; McLachlan *et al.*, 2005; Nathan, 2006; Pearson, 2006) and modeled tree dispersal and establishment in response to future climate change (Higgins *et al.*, 2003; Iverson *et al.*, 2004; Epstein *et al.*, 2007; Goetz *et al.*, 2011; Nathan *et al.*, 2011; Meier *et al.*, 2012; Sato and Ise, 2012). The box represents ~95% of the estimates and the bar is a qualitative estimate of the median. Displacement rates for mammals were based on modeled dispersal rates of wide range of mammal species from Schloss *et al.* (2012). The box represents 1.5 x the inter-quartile range of the estimates in Schloss *et al.* (2012) and the bar is the median. Several groups of mammals have not been plotted because they include a relatively small number of species. Estimates for birds are based on observed rates of displacement (Chen *et al.*, 2011; La Sorte and Jetz, 2010) and on modeled dispersal rates in response to projected climate change (Schippers *et al.*, 2011; Barbet-Massin *et al.*, 2012), but very low confidence in these estimates makes it difficult to set bounds or indicate central tendency. Displacement rates for phytophagous insects are based on observed dispersal rates (Kinlan and Gaines, 2003; Stevens *et al.*, 2010b; Sekar, 2012). The qualitative estimate of median dispersal rate exceeds the highest rates on the axis and is on the order of 100 km/yr. These dispersal rates do not take into account limitations imposed by host plants and habitats. Displacement estimates for freshwater mollusks correspond to the range of dispersal given for passive plus active dispersal mechanisms for upstream movement in Kappes and Haase (2012).]

Observed Changes in Abundance and Local Extinctions - Observations of range shifts imply changes in abundance; i.e., colonization at the "leading edge" and local extinction at the "trailing edge" of ranges. Evidence that the attribution of these responses to recent changes in climate can be made with *high confidence* is reviewed above, in the AR4 report and by Cahill *et al.* (2013). Changes in abundance, as measured by changes in the population size of individual species or shifts in community structure, also have occurred within existing range limits in response to recent global warming (*high confidence*) (Thaxter *et al.*, 2010; Bertrand *et al.*, 2011;Naito and Cairns, 2011; Rubidge *et al.*, 2011; Devictor *et al.*, 2012; Tingley *et al.*, 2012; Cahill *et al.*, 2013; Ruiz-Labourdette *et al.*, 2013). More confident attribution to recent global warming is hindered by confounding factors such as disease, land use change and invasive species (Cahill *et al.*, 2013). A new tentative conclusion since the AR4 is that climate related local extinctions appear to be more strongly related to species interactions than to physiological tolerance limits (*low confidence*) (Cahill *et al.*, 2013). This gives weight to concerns that biological interactions, which are poorly understood and modeled, may play a critical role in mediating the impacts of future climate change on species abundance and local extinctions (Dunn *et al.*, 2009; Bellard *et al.*, 2012; Urban *et al.*, 2012; Hannah, 2012).

A few examples illustrate the types of changes in abundance and local extinctions that are being observed and the challenges in attributing these to recent global warming. Some of the clearest examples of climate-related changes in species populations come from high latitude ecosystems where non-climate drivers are of lesser importance. For example, both satellite data and a large number of long-term observations indicate that shrub abundance is generally increasing over broad areas of Arctic tundra, which is coherent with predicted shifts in community structure due to warming (Epstein *et al.*, 2007; Goetz *et al.*, 2011; Myers-Smith *et al.*, 2011). In the Antarctic, two native vascular plants, Antarctic pearlwort (*Colobanthus quitensis*) and Antarctic hair grass (*Deschampsia antarctica*) have become more prolific over recent decades, perhaps because they benefit more from warming of soils than do mosses (Hill *et al.*, 2011). Penguin populations have declined in several areas of the Antarctic, including a recent local extinction of an Emperor penguin population that has been attributed to regional changes in climate (Trathan *et al.*, 2011). The attribution to regional climate change is well supported, but the link to global warming is tenuous (Barbraud *et al.*, 2011).

Mountains also provide good examples of climate signals in abundance and local extinction because of very strong climate gradients. The AR4 report already highlighted these responses and the case for changes in abundance, in particular plants, has become stronger since then. For example, Pauli *et al.* (2012) reported an increase in species richness from plant communities of mountain tops in the European boreal and temperate zones due to increasing

temperatures and a decrease in species richness on the Mediterranean mountain tops, probably due to a decrease in the water availability in Southern Europe. An increase in the population size of warm adapted species at high altitudes also appears to be attributable to increasing temperatures (Gottfried *et al.*, 2012). However, these attributions are complicated by other anthropogenic influences such as changes in grazing pressure, atmospheric nitrogen deposition, and forest management practices (Gottfried *et al.*, 2012). Altitudinal gradients in local and global extinctions of amphibians also contributed to the attribution of these extinctions to recent global warming, although this attribution remains controversial (see below).

Projected Changes in Abundance and Local Extinction - Ecological niche models do not predict population changes, but the shifts in suitable climates can be used to infer areas where species populations might decline or increase. Projected areas of local extinction from these types of models ranging from near 0% of the current range to more than 95% (Settele *et al.*, 2008; Bellard *et al.*, 2012), and projected local colonization rates are equally variable. There has been progress in coupling species distribution and species abundance models for a wide range of organisms (Keith *et al.*, 2008; Midgley *et al.*, 2010; Matthews *et al.*, 2011; Schippers *et al.*, 2011; Oliver *et al.*, 2012; Renwick *et al.*, 2012). These approaches have the substantial advantage of predicting extinction risk directly, rather than by inference from changes in climate suitability (Fordham *et al.*, 2012). The main conclusion from these studies is species response to climate change is determined by a combination of factors, including its environmental niche, demographics and life history traits, as well as interactions among these factors (Aiello-Lammens *et al.*, 2011; Conlisk *et al.*, 2012; Fordham *et al.*, 2012; Swab *et al.*, 2012).

Changes in abundances will also be accompanied by changes in genetic diversity. At an intraspecific level, future climate change projections are projected to induce severe losses of genetic diversity (Balint *et al.*, 2011). In addition, there is theoretical and observational evidence that range contractions will reduce genetic diversity (Pauls *et al.*, 2013), but that the loss of genetic diversity will depend on rates of migration and range contraction (Arenas *et al.*, 2012). Reductions in genetic diversity may then decrease the ability of species to adapt to further climate change or other global changes. Although future projections of climate change impacts do not appear to result in the loss of more phylogenetic diversity than expected by chance, projected species losses are projected to lead to phylogenetic homogenization across European plant, bird and mammal communities (Thuiller *et al.*, 2011, but see Davies *et al.*, 2011). Climate change may also compound losses of genetic diversity that already occurring due other global changes such as the introduction of alien species or habitat fragmentation (Winter *et al.*, 2009; section 4.2.4.6).

Observed Global Extinctions - Global species extinctions, many of them caused by human activities, are now close to the upper limits of observed natural rates of extinction in the fossil record (Barnosky *et al.*, 2011). Most extinctions over the last several centuries can be attributed to habitat loss, overexploitation or invasive species (Millennium Ecosystem Assessment, 2005a; Hofmann and Todgham, 2010; Cahill *et al.*, 2013). Of the more than 800 global extinctions documented by the IUCN, only 20 have been tenuously linked to recent climate change (Cahill *et al.*, 2013). Mollusks, especially freshwater mollusks, have by far the highest rate of documented extinctions of all species groups (Barnosky *et al.*, 2011). Mollusk extinctions are primarily attributed to invasive species, habitat modification and pollution — changes in climate are rarely evoked as a driver (Lydeard *et al.*, 2004; Regnier *et al.*, 2009; Chiba and Roy, 2011; but see a few cases in Kappes and Haase, 2012; Cahill *et al.*, 2013). Freshwater fish have the highest documented extinction rates of all vertebrates, and again very few have even been tenuously attributed to changing climate (Burkhead, 2012; Cahill *et al.*, 2013). In contrast, changes in climate have been identified as one of the key drivers of extinctions of amphibians (Pounds *et al.*, 2006). There have been more than 160 probable extinctions of amphibians documented over the last two decades, many of them in Central America (Pounds *et al.*, 2006; Kiesecker, 2011). The most notable cases have been the golden toad and Monteverde harlequin frog (*Atelopus varius*) of Central America, which belong to a group of amphibians with high rates of extinction ascribed to global warming with "very high confidence" (Pounds *et al.*, 2006; Fischlin *et al.*, 2007). This case has raised a number of important issues about attribution since i) the proximate causes of extinction of these and other Central American frogs appear to be an extremely virulent invasive fungal infection and land use change, with regional changes in climate as a potential contributing factor and ii) changes in regional climate may have been related to natural climate fluctuations rather than anthropogenic climate change (Sodhi *et al.*, 2008; Lips *et al.*, 2008; Collins, 2010; Anchukaitis and Evans, 2010; Vredenburg *et al.*, 2010; Kiesecker, 2011; McKenzie and Peterson, 2012; McMenamin and Hannah, 2012). While this case highlights difficulties in attribution of extinctions to recent global warming, it also points to a growing consensus that it is the interaction of climate change with other global

change pressures that poses the greatest threat to species (Pereira *et al.*, 2010; Hof *et al.*, 2011; Brook *et al.*, 2008). Overall, there is *very low confidence* that observed species extinctions can be attributed to recent climate warming due to the very low fraction of species for which global extinction has been ascribed to climate change and tenuous nature of most attributions.

Projected Future Species Extinctions - Projections of future extinctions due to climate change have received considerable attention since the AR4 report. The AR4 report stated with *medium confidence* "that approximately 20-30% of the plant and animal species assessed to date are at increasing risk of extinction as global mean temperatures exceed a warming of 2-3°C above pre-industrial levels" (Fischlin *et al.*, 2007). All model-based analyses since the AR4 broadly confirm this concern, leading to *very high confidence* that climate change will contribute to increased extinction risk for terrestrial species over the coming century (Pereira *et al.*, 2010; Sinervo *et al.*, 2010; Pearson, 2011; Warren *et al.*, 2011; Hannah, 2012; Ihlow *et al.*, 2012; Bellard *et al.*, 2012; Sekercioglu *et al.*, 2012; Wearn *et al.*, 2012). More generally, there is broad agreement that climate change will result in shifts in species' ranges and abundances, and that in the context of habitat fragmentation and other global change pressures this will contribute substantially to increased extinction risk of terrestrial species over the coming century (Pereira *et al.*, 2010).

However, work since the AR4 also calls into question the ability of models to accurately quantify future extinction risk. Modeling studies have used a wide range of methods to estimate future extinction risk, generally inferring extinction risk indirectly from changes in availability of habitat and rarely taking into account demographic factors such as dispersal ability and generation time (Akcakaya *et al.*, 2006). All studies project increased extinction risk by the end of the 21st century due to climate change, but these estimates range from below 1% to above 50% of species in the groups that have been studied (Pereira *et al.*, 2010; Bellard *et al.*, 2012; Cameron, 2012). However, most models do not incorporate key processes that link climate change to population change. For example, models rarely account for genetic and phenotypic adaptive capacity, dispersal, the effects of habitat fragmentation and loss, and community interactions as well as, in plants, the effects of rising CO_2 concentrations. A general paucity of approaches to model validation, the large variation in the climate sensitivity of species groups and uncertainties about timescales involved in range reduction to extinction all lead to *very low confidence* that models currently predict extinction risk accurately (Kuussaari *et al.*, 2009; Pereira *et al.*, 2010; Dawson *et al.*, 2011; Pearson, 2011; McMahon *et al.*, 2011; Araujo and Peterson, 2012; Bellard *et al.*, 2012; Fordham *et al.*, 2012; Kramer *et al.*, 2012; Hannah, 2012; Zurell *et al.*, 2012; Halley *et al.*, 2013). In addition, evidence from the paleontological record indicating very low extinction rates over the last several hundred thousand years of substantial natural fluctuations in climate - with a few notable exceptions such as large land animal extinctions during the Holocene - has also led to concern that forecasts of very high extinction rates due entirely to climate change may be overestimated (Botkin *et al.*, 2007; Willis and Bhagwat, 2009; Pereira *et al.*, 2010; Dawson *et al.*, 2011; Hof *et al.*, 2011; Willis and MacDonald, 2011; Wake, 2012). On the other hand, processes not accounted for in most models, such changes in biotic interactions such as pollination or predator-prey networks or non-linear changes in ecosystems with widespread consequences for resident species, mean that future extinction risks may also have been substantially underestimated, at least for certain areas and species groups (Schweiger *et al.*, 2008; Bellard *et al.*, 2012; Urban *et al.*, 2008; Nakazawa and Doi, 2012; Hannah, 2012) or overestimated (Menéndez *et al.*, 2008; Pateman *et al.*, 2012). Finally, there is growing awareness that most modeling analyses have not accounted for climatic variation at fine spatial scales (microclimate) that may increase (Randin *et al.*, 2009; Gillingham *et al.*, 2012; Suggitt *et al.*, 2012; Dobrowski *et al.*, 2013; Franklin *et al.*, 2013) or decrease (Trivedi *et al.*, 2008; Engler *et al.*, 2011) the likelihood of persistence of small populations under future climate change.

4.3.3 Impacts on Major Systems

This section covers impacts of climate change on broad types of terrestrial and freshwater ecosystems of the world. We have placed a particular emphasis on those areas of high vulnerability due to high exposure to climate change or that may be pushed past thresholds or "tipping points" by climate change.

Figure 4-7 provides an overview of two perspectives on estimating ecosystem vulnerability to climate change at the global scale. Figures 4-7A and 4-7B show projected future climate change in relationship to current inter-annual variability (Diffenbaugh and Giorgi, 2012; see similar analyses by Beaumont *et al.*, 2011; Williams *et al.*, 2007b).

This analysis highlights those areas where interannual variability is low compared to projected changes in climate, i.e., where future climate is likely to be outside of temperature fluctuations already experienced by ecosystems (Beaumont *et al.*, 2011; Diffenbaugh and Giorgi, 2012). In this analysis, it is the species and ecosystems around the equator that are projected to be the most exposed to the largest climate changes. High latitude systems do not appear as exposed to climate change in this analysis because they already experience high interannual variability. A number of lines of evidence suggest that this index of climate change is an appropriate way to view species and ecosystem vulnerability. In particular, there is evidence that tropical species have evolved to have narrow thermal limits due to low inter and intra-annual climate variability, and are also already near their upper thermal limits (ectotherms - Deutsch *et al.*, 2008; Huey *et al.*, 2012; birds - Sekercioglu *et al.*, 2012; trees - Corlett, 2011). On this basis, tropical species and ecosystems are predicted to be more sensitive to climate change than species and ecosystems where intra- and inter-annual variability in climate is high (e.g., Arctic and boreal ecosystems). However, there a number of physiological, evolutionary and ecological arguments that species and ecosystem vulnerability to climate change is considerably more complex (Corlett, 2011; Laurance *et al.*, 2011; Gunderson and Leal, 2012; Walters *et al.*, 2012, Gonzalez *et al.*, 2010). Figure 4-7C compares future and contemporary climate focusing on the absolute differences between future and current climates. In this case, high northern latitude systems have the greatest exposure to rising temperature (often exceeding 6°C in the RCP 8.5 scenario, Figure 4-7C), which all else being equal would make them more vulnerable to climate change. Indeed, the greatest degree of recent climate warming has occurred at high Northern latitudes (Burrows *et al.*, 2011) and the strongest and clearest signals of recent climate warming impacts on ecosystems come from these regions. A comparison of modeled biome level vulnerability indicated that temperate and high northern latitude systems are also the most vulnerable in the future (Gonzalez *et al.*, 2010). There has been a tendency to oppose these two points of view; i.e., tropics are most vulnerable due to limited capacity of species to adapt to moderate global warming vs. high northern latitude systems are the most vulnerable because temperature increases are projected to the greatest at these latitudes. There are, however, there are good indications that both types of systems are highly vulnerable, but for different reasons (Corlett, 2011). This analysis highlights some of the reasons why there is a particularly strong focus on climate change impacts on tropical and high latitude systems in the following sub-chapters.

[INSERT FIGURE 4-7 HERE
Figure 4-7: Two climate indexes related to the vulnerability of terrestrial biomes to future climate change based on the RPC 8.5 scenario and the CMIP5 climate model ensemble (from Diffenbaugh and Giorgi, 2012). Panels A and B show the evolution of June-August temperatures in two ca. 20 year time slices around 2055 and 2090 in comparison with the hottest year during the period 1980-2005. Climate change is projected to result in many areas of the tropics and sub-tropics exceeding the temperatures during the 1980-2005 period 100% of the time by 2055. High northern latitude systems exceed this limit less frequently especially in the 2055 time slice. Panel C shows the absolute temperature differences between the 1980-2005 reference period and the 2090 time slice. High northern latitudes are exposed to much greater temperature increases than other regions and this is representative of the regional patterns of climate change for all time slices and emissions scenarios.]

An issue that emerged in the AR4 report and has grown substantially in prominence since then is that of thresholds or 'tipping points' (Lenton *et al.*, 2008; Scheffer *et al.*, 2009; Leadley *et al.*, 2010). Tipping points occur when positive feedback processes dominate over negative feedback loops, and the system begins to change as a result of both its internal dynamics and the external forcings, leading to a change in state that is difficult or slow to reverse (Lenton *et al.*, 2008; Scheffer *et al.*, 2009; Leadley *et al.*, 2010). In the AR5, tipping points are considered "a level of change in system properties beyond which a system reorganizes, often abruptly, and persists in its new state even if the drivers of the change are abated" (Glossary). Many examples of such thresholds have now been identified (Scheffer, 2009). Most are at the local scale, but the potential existence of ecological thresholds at a sufficient scale to have regional or global consequences is high. Posited examples include a drought and temperature threshold in the Amazon beyond which forest dieback and fires could contribute to large C fluxes to the atmosphere, or thawing of Arctic permafrost leading to emissions of CH_4 and CO_2 in sufficient quantities to further warm the Earth and amplify the permafrost warming (Lenton *et al.*, 2008; Leadley *et al.*, 2010). Ecosystem water balance thresholds that are surpassed through changes in temperature and precipitation, both gradual and through extreme events, may be a widespread phenomenon across a range of biomes (Knapp *et al.*, 2008a). Large-scale tipping points have not occurred in the recent past, but there is good evidence for tipping points in the distant past (section 4.2.2) and the sub-sections below highlight reasons for concern that they could occur in the near future. A thorough analysis of all

the highlighted tipping points is not possible in this section, so we have highlighted some of the most important and well-studied tipping points. Others are discussed in Lenton *et al.* (2008) and Leadley *et al.* (2010).

4.3.3.1. Forests and Woodlands

Forests and woodlands, are the principal providers of timber and pulp, biofuel and an important and steady source of good-quality water worldwide. They also supply other services, including food and, cultural services such as recreation. Forests are the habitat of a large fraction of the earth's terrestrial biodiversity, especially in tropical regions (Gibson *et al.*, 2011). Climate change and forests interact strongly. Climate and atmospheric CO_2 concentrations are major drivers of forest productivity and forest dynamics. At the same time forests play an important role in controlling climate through the large amounts of carbon they can store or release, and through direct effects on the climate such as the absorption or reflection of solar radiation (albedo), cooling through evapotranspiration and the production of cloud-forming aerosols (Arneth *et al.*, 2010;Pan *et al.*, 2011; Pielke *et al.*, 2011).

Combinations of ground based observations, atmospheric carbon budgets and satellite measurements indicate that forests are currently a net sink for carbon at the global scale. It is estimated that intact and regrowing forests currently contain 861±66 PgC and stored 4.0 ± 0.7 Pg C $year^{-1}$ globally between 2000 and 2007 (Pan *et al.*, 2011; WG1 Chapter 6; Canadell *et al.*, 2007; Le Quere *et al.*, 2009). The carbon stored in intact and regrowing forests was counterbalanced by a release due to land-use change of 2.8±0.4 Pg C $year^{-1}$ over this same period due to tropical deforestation, resulting in a net C balance for global forests of 1.2±0.8 Pg C $year^{-1}$.

The phrase ’biophysical effects’ is shorthand for the effect forests have on the climate other than through being sources and sinks of greenhouse gases. These effects are now well documented, significant and are increasingly included in models of global and regional climate change. Observations and models indicate that boreal and tropical forests have the largest influence on climate, but for different reasons: boreal forests have low albedo (i.e., reflect less solar radiation); and tropical forests pump more water and aerosols into the atmosphere than non-forest systems in similar climates (Davin and de Noblet-Ducoudre, 2010; Delire *et al.*, 2011; Pielke *et al.*, 2011). Overall, this means that the biophysical effect of boreal forests is to warm the atmosphere and tropical forests to cool the atmosphere, compared to non-forest systems (Davin and de Noblet-Ducoudre, 2010). It has also been shown that forests influence regional precipitation through biophysical effects: deforestation in the tropics can alter regional precipitation (Butt *et al.*, 2011) and there is growing evidence of similar effects in temperate forests (Pielke *et al.*, 2011).

The future of the interaction between climate and forests is unclear. The carbon stored by intact and regrowing forests appears have stabilized compared to the 1990's, after having increased in the 1970's and 1980's (Canadell *et al.*, 2007; Pan *et al.*, 2011). The drivers behind the forest carbon sink vary greatly across regions. They include forest regrowth and simulation of C sequestration by climate change, rising atmospheric CO_2 concentrations and N deposition (Pan *et al.*, 2011). Most models suggest that rising temperatures, drought and fires will lead to forests becoming a weaker sink or a net carbon source before the end of the century (Sitch *et al.*, 2008; Bowman *et al.*, 2009). Fires play a dominant role in driving forest dynamics in many parts of the world and the susceptibility to fire is projected to increase little for the lowest emissions scenario (RCP 2.6), but substantially for the high emissions scenario (RCP 8.5, Figure 4-8). Climate change-mediated disease and insect outbreaks could precipitate this transition (Kurz *et al.*, 2008). The greatest risks for large feedbacks from forests to climate arise from widespread tree mortality and fire in tropical forests and low latitude areas of boreal forests, as well as northward expansion of boreal forests into arctic tundra (Lenton *et al.*, 2008; Kriegler *et al.*, 2009; Good *et al.*, 2011).

[INSERT FIGURE 4-8 HERE
Figure 4-8: Forest Fire Danger Index (FFDI) and its changes simulated with the HadGEM2-ES Earth System Model (Jones *et al.*, 2011). Left column: 30-year mean FFDI (MacArthur, 1973; Noble *et al.*, 1980) for 1980-2010 (top) and 2070-2100 under RCP2.6 (middle) and RCP8.5 (bottom). Right column: differences in 30-year mean FFDI relative to 1980-2010 for 2070-2100 under RCP2.6 (middle) and RCP8.5 (bottom). Maps show 30-year means of

FFDI values calculated using daily model data, following the methodology of (Golding and Betts, 2008). FFDI is not shown where the simulated vegetation cover is less than 10% for the respective time period (colored grey).]

Recent evidence suggests that the stimulatory effects of global warming and rising CO_2 concentrations on tree growth may have already peaked in many regions (Charru *et al.*, 2010; Silva *et al.*, 2010; Silva and Anand, 2013) and that warming and changes in precipitation are increasing tree mortality in a wide range of forest systems, acting via heat stress, drought stress, pest outbreaks and a wide range of other indirect impact mechanisms (Allen *et al.*, 2010a; Box 4-2). Detection of a coherent global signal is hindered by the lack of long-term observations in many regions, and attribution to climate change is difficult due to the multiplicity of mechanisms mediating mortality (Allen *et al.*, 2010a).

Deforestation has slowed over the last decade (Meyfroidt and Lambin, 2011). This includes substantial reductions in tropical deforestation in some regions, such as the Brazilian Amazon, where deforestation rates declined rapidly after peaking in 2005 (Secretariat of the Convention on Biological Diversity, 2010). It is unclear if the global trend to reduced forest loss will continue - there are substantial pressures to deforest for the production of food and biofuels (Wise *et al.*, 2009; Meyfroidt and Lambin, 2011). However, there are a number of signs that tropical deforestation could slow substantially over the next few decades, although this is thought to require continued and substantial technological, institutional and policy innovations (Wise *et al.*, 2009; Meyfroidt and Lambin, 2011; Westley *et al.*, 2011).

_____ START BOX 4-2 HERE _____

Box 4-2. Tree Mortality and Climate Change

Extensive tree mortality and widespread forest die-off linked to drought and temperature stress have been documented recently on all vegetated continents (Allen *et al.*, 2010a; Figure 4-9). Plot level datasets with appropriate spatial and temporal spans to detect long-term tree mortality trends (>20 years) are currently lacking for many regions (Anderegg *et al.*, 2013a), leading to *low confidence* in the ability to detect a global trend. Nevertheless, long-term increasing tree mortality rates associated with temperature increases and drought have been documented in boreal and temperate forests in western North America (van Mantgem *et al.*, 2009; Peng *et al.*, 2011). Increased levels of tree mortality following drought episodes have also been detected across widespread plot networks in multiple tropical forests (Kraft *et al.*, 2010; Phillips *et al.*, 2010) and Europe (Carnicer *et al.*, 2011). Episodes of widespread die-off (high mortality rates of dominant tree species at a landscape scale) have been observed in multiple vegetation types, particularly in western North America, Australia, and southern Europe (Raffa *et al.*, 2008; Carnicer *et al.*, 2011; Anderegg *et al.*, 2013b). Some widespread die-off events have occurred concomitant with infestation outbreaks (Raffa *et al.*, 2008), where pest populations are also directly influenced by climate, such as population release by warmer winter temperatures (Bentz *et al.*, 2010). While strong attribution of extensive tree mortality to recent warming has been made in a few studies, the paucity of long-term studies of the mechanisms driving mortality means that there is *low confidence* that this attribution can be made at the global scale.

Widespread die-off has influenced the species composition, structure and age demographics, and successional trajectories in these forests, and in some cases led to decreased plant species diversity and increased risk of invasion (Kane *et al.*, 2011; Anderegg *et al.*, 2012). Widespread mortality also has multiple effects on biosphere-atmosphere interactions and could play an important role in future carbon-cycle feedbacks through complex effects on forest biophysical properties and biogeochemical cycles (Breshears *et al.*, 2005; Kurz *et al.*, 2008; Anderson *et al.*, 2011).

Projections of tree mortality due to climate stress and potential thresholds of widespread forest loss are currently highly uncertain (McDowell *et al.*, 2011). Most current global scale vegetation models have little-to-no mechanistic representation of tree mortality (Fisher *et al.*, 2010; McDowell *et al.*, 2011). Nonetheless, a global analysis of tree hydraulic safety margins found that more than 70% of surveyed tree species operate close to their limits of water stress tolerance (Choat *et al.*, 2012), indicating that vulnerability to drought and temperature stress will not be limited to arid and semi-arid forests. Furthermore, timescales of tree and plant community recovery following drought are largely unknown, but preliminary evidence from several systems indicates recovery times may be shorter than recent drought return intervals, leading to “compounding” effects of multiple droughts (Mueller *et al.*,

2005; Anderegg *et al.*, 2013b; Saatchi *et al.*, 2013). Projected increases in temperature are also expected to facilitate expansion of insect outbreaks poleward and up in altitude, which may also cause or contribute to widespread tree mortality (Bentz *et al.*, 2010).

[INSERT FIGURE 4-9 HERE
Figure 4-9: Locations of observed drought- and heat-induced tree mortality around the Earth since 1970, documented by peer-reviewed studies. Global forest cover (dark green) and other wooded regions (light green) (FAO, 2005). Studies compiled through 2009 (red dots) are summarized and listed in Allen et al. (2010). Localities and measurement networks not included in Allen *et al.* (2010a), which are largely post-2009 studies, have been added to this map (white dots are specific locations and regional measurement networks are indicated by ovals). New locality references by region: Africa – Mehl *et al.* (2010); Gonzalez *et al.* (2012); van der Linde *et al.* (2011); Asia – Dulamsuren *et al.* (2009); Kharuk *et al.* (2013); Liu *et al.* (in revision); Zhou *et al.* (2013); Australasia – Brouwers *et al.* (2012, 2013); Fensham *et al.* (2012); Matusick *et al.*, 2012, 2013); Europe – Innes (1992); Peterken and Mountford (1996); Linares *et al.* (2009); Galiano *et al.* (2010); Vennetier and Ripert (2010); Aakala *et al.* (2011); Carnicer *et al.* (2011); Sarris *et al.* (2011); Marini *et al.* (2012); Vilà-Cabrera *et al.* (2012);Cailleret *et al.* (2013); North America – Fahey (1998); Barbour *et al.* (2007); Klos *et al.* (2009); Ganey and Vojta (2011); Peng *et al.* (2011); DeRose and Long (2012); Fellows and Goulden (2012); Kaiser *et al.* (2012); Kukowski *et al.* (2012); Millar *et al.*, 2012); Williams *et al.* (2012); Worrall *et al.* (2013); Garrity *et al.* (in review);South America – Enquist and Enquist (2011); Lewis *et al.* (2011); Saatchi *et al.* (2013).]

_____ END BOX 4-2 HERE _____

4.3.3.1.1. Impacts of climate change on boreal forests

Most projections suggest a poleward expansion of forests into tundra regions, accompanied by a general shift in composition towards more temperate plant functional types (e.g., evergreen needleleaf being replaced by deciduous broadleaf; or in colder regions, deciduous needleleaf replaced by evergreen needleleaf; Lloyd *et al.*, 2011; Pearson *et al.*, 2013). At the same time, projections of climate-driven changes in boreal forests over the next few centuries remain divergent on some issues, partly as a result of different processes of change being considered in different models. In particular, the inclusion or exclusion of fire and insects makes a big difference, possibly making the boreal forest more susceptible to a rapid, non-linear or abrupt decline in some regions of the circum-Northern Hemisphere (Bernhardt *et al.*, 2011; Mann *et al.*, 2012; Scheffer *et al.*, 2012). Recent change (Box 4-2) and dynamic vegetation modeling (e.g., Sitch *et al.*, 2008) provide *high confidence* that regions of the boreal forest could witness widespread forest dieback. These shifts put at risk the boreal carbon sink, estimated at 0.5 Pg $year^{-1}$ in 2000-2007 (Pan *et al.*, 2011; Mann *et al.*, 2012).

Whereas boreal forest productivity is widely expected, with *medium confidence*, to increase as a result of warming (Hari and Kulmata, 2008; Bronson *et al.*, 2009; Zhao and Running, 2010; Van Herk *et al.*, 2011), and early analyses of satellite observations confirmed this trend in the 1980s, more recent and longer-term assessments indicate with *high confidence* that many areas of boreal forest have instead experienced productivity declines (Goetz *et al.*, 2007; Parent and Verbyla, 2010; Beck *et al.*, 2011b; de Jong *et al.*, 2011). The reasons for these "browning" trends have been debated but they are not directly related to fire disturbance (because fires produce random rather than systematic trends in time series). The best evidence to date indicates that warming-induced drought, specifically the greater drying power of air (vapor pressure deficit), induces photosynthetic down-regulation of boreal tree species, particularly conifer species, most of which are not adapted to the warmer conditions (Welp *et al.*, 2007; Bonan, 2008; Van Herk *et al.*, 2011). Satellite evidence for warming-induced productivity declines has been corroborated by tree ring studies (Barber *et al.*, 2000; Hogg *et al.*, 2008; Beck *et al.*, 2011b; Porter and Pisaric, 2011; Griesbauer and Green, 2012) and long-term tree demography plots in more continental and densely forested areas (Peng *et al.*, 2011; Ma *et al.*, 2012). Conversely, productivity has increased at the boreal-tundra ecotone where more mesic conditions support an expected warming-induced growth response (Rupp *et al.*, 2001; McGuire *et al.*, 2007; Goldblum and Rigg, 2010; Beck *et al.*, 2011b).

There is *high confidence* that warming and drying, coupled with productivity declines, insect disturbance and associated tree mortality, also favor greater fire disturbance. The boreal biome fire regime has intensified in recent decades, exemplified by increases in the extent of area burned but also a longer fire season and more episodic fires that burn with greater energy output or intensity (Girardin and Mudelsee, 2008; Macias Fauria and Johnson, 2008; Kasischke *et al.*, 2010; Turetsky *et al.*, 2011; Mann *et al.*, 2012). The latter is particularly important because more severe burning consumes soil organic matter to greater depth often to mineral soil, providing conditions that favor recruitment of deciduous species that, in the North American boreal forest, replace what was previously evergreen conifer forest (Johnstone *et al.*, 2010; Bernhardt *et al.*, 2011). Fire mediated composition changes in post-fire succession influence a host of ecosystem feedbacks to climate, including changes net ecosystem carbon balance (Bond-Lamberty *et al.*, 2007; Goetz *et al.*, 2007; Welp *et al.*, 2007; Euskirchen *et al.*, 2009) as well as albedo and energy balance (Randerson *et al.*, 2006; Jin *et al.*, 2012; O'Halloran *et al.*, 2012). The most comprehensive study to date (Randerson *et al.*, 2006) focused on a set of flux tower measurements across a composition gradient, but this study was necessarily limited to a few sites in central Alaska. The extent to which the net effect of these feedbacks will exacerbate or mitigate additional warming is not well known over the larger geographic domain of the boreal biome, except via modeling studies that are relatively poorly constrained due to sparse *in situ* observations.

There is *high confidence* that the vulnerability of the boreal biome to this cascading series of interacting processes (Wolken *et al.*, 2011), and their ultimate influence on climate feedbacks, differs between North America and northern Eurasia. The latter is dominated by deciduous conifer (larch) forest, extending from western Russia across central to eastern Siberia – a region more than twice the size of the North American boreal biome, most of it underlain by permafrost conditions of the Siberian environment. In terms of post-fire succession analogous to the North American boreal biome, larch function more like deciduous species than evergreen conifers, with greater density and biomass gain in more severely burned areas, given adequate seed survival through fire events or post-fire seed dispersal (Zyryanova, 2007; Osawa *et al.*, 2010; Alexander *et al.*, 2012). Although the fire regime has intensified in the last 100 years in Siberia, as well as in North America (Soja *et al.*, 2007; Mann *et al.*, 2012; Ali *et al.*, 2012; Marlon *et al.*, 2013), the likelihood of regime shifts in larch forests is currently unknown, partly because larch are self-replacing (albeit at different densities) and partly because it is largely dependent on the fate of permafrost across the region.

The vulnerability of permafrost to thawing and degradation with climate warming is critical not only for determining the rate of a boreal-tundra biome shift, and its associated net feedback to climate, but also for predicting the degree to which the mobilization of very large carbon stores frozen for centuries will exacerbate additional warming (Schuur *et al.*, 2008; 2009; Tarnocai *et al.*, 2009; Romanovsky *et al.*, 2010; Schaefer *et al.*, 2011; see also Section 4.3.3.4). The extent and rate of permafrost degradation varies with temperature gradients from warmer discontinuous permafrost areas to colder, more continuous areas, but also with the properties of the soil composition and biology (e.g., Mackelprang *et al.*, 2011). The degree of thermokarsting associated with different substrates, and associated topographic relief, is tremendously variable because boreal vegetation in latter successional stages (evergreen conifers in North America) insulate permafrost from air temperature increases; soils with differing silt and gravel content tend to have different ice content that, when melted, produces different degradation and deformation rates; and other factors such as fire disturbance interactions with both vegetation cover and soil organic depth as insulating layers (Jorgenson *et al.*, 2010; Grosse *et al.*, 2011). This variability, and vulnerability, is poorly represented in earth system models (McGuire *et al.*, 2012) and is thus the emphasis of research initiatives currently underway. Carbon management strategies to keep permafrost intact, for example by removing forest cover to expose the land surface to winter temperatures (Zimov *et al.*, 2009) are impractical not only because of the vast spatial domain underlain by permafrost, but also because of the broad societal and ecological impacts that would result.

4.3.3.1.2. Impacts of climate change on temperate forests

The largest areas of temperate forest are found in eastern North America, Europe and eastern Asia. The overall trend for forests in these regions has until recently been an increase in growth rates of trees and in total carbon stocks. This has been attributed to a combination of increasing growing season length, rising atmospheric CO_2 concentrations, nitrogen deposition and forest management – specifically regrowth following formerly more intensive harvesting regimes (Ciais *et al.*, 2008). The relative contribution of these factors has been the subject of

substantial and unresolved debate (Boisvenue and Running, 2006). Most temperate forests are managed such that any change is and will be to a large extent anthropogenic. With the exception of Europe (Ciais *et al.*, 2008), the relative contribution of anthropogenic and environmental factors to forest growth and carbon uptake rates remains to be quantified.

The world's temperate forests act as an important carbon sink (*high confidence* due to *robust evidence; high agreement),* absorbing 0.7±0.08 Pg C $year^{-1}$ from 1990 to 1999 and 0.8±0.09 from 2000 to 2007 (Pan *et al.*, 2011).This represents 34% of global carbon accumulation in intact forests and 65% of the global net forest carbon sink (total sink minus total emissions from land use).

Recent indications are that temperate forests and trees are beginning to show signs of climate stress, including: a reversal of tree growth enhancement in some regions (N America - Silva *et al.*, 2010; Silva and Anand, 2013; Europe - Charru *et al.*, 2010; Bontemps *et al.*, 2011; Kint *et al.*, 2012); increasing tree mortality (Allen *et al.*, 2010a, Box 4-2); and changes in fire regimes, insect outbreaks and pathogen attacks (Adams *et al.*, 2012; Edburg *et al.*, 2012). In north-eastern France, widespread recent declines in growth rates of European beech (*Fagus sylvatica L.*) have been attributed to decreasing water availability (Charru *et al.*, 2010). These trends threaten the substantial role of temperate forests as net carbon sinks, but it is still unclear to what extent the observations are representative for temperate forests as a whole. Several studies find that tree growth rates in temperate forests passed their peak in the late 20th century and that the decline in tree growth rates can be attributed to climatic factors, especially drought or heatwaves (Charru *et al.*, 2010; Silva *et al.*, 2010). Extreme climate events have had a major impact on temperate forests over the last decade (Witte *et al.*, 2011; Kasson and Livingston, 2012; Ciais *et al.*, 2005). Extensive forest fires occurred in Russia during the exceptionally hot and dry summer of 2010 (Witte *et al.*, 2011). The complex interactions between climate and forest management in determining susceptibility to extreme events make it difficult to unequivocally attribute these events to recent climate warming (Allen *et al.*, 2010a). There is *low confidence (limited evidence; medium agreement)* that climate change is threatening the temperate forest carbon sink directly or indirectly.

At the biome level, there remains considerable uncertainty in the sign and the magnitude of the carbon cycle response of temperate forests to climate change. A comparison of DGVM models showed that for identical end of 21st century climate projections, temperate forests are variously projected to substantially increase in total (biomass plus soil) carbon storage, especially as a result of potential gains in tree cover in eastern North America and Europe; or decrease due to reductions in total carbon storage per hectare and loss of tree cover (Sitch *et al.*, 2008). Projections for eastern Asia are less variable: temperate forests remain carbon sinks over the coming century, with carbon storage generally peaking by mid-century and then declining (He *et al.*, 2007; Sitch *et al.*, 2008; Ni, 2011; Peng *et al.*, 2009). However, regional vegetation models for China predict a substantial northward shift of temperate forest (Weng and Zhou, 2006; Ni, 2011). There is little indication from either models or observations that the responses of temperate forests to climate change are characterized by tipping points. The feedback mechanisms operating in boreal and tropical forests which lead to tipping point behavior appear to be less dominant in temperate forests (Bonan, 2008). There is *low confidence (medium evidence; low agreement)* on long-term, climate-driven changes in temperate forest biomass and geographical range shifts.

At the species level, models predict that the potential climatic space for most tree species will shift poleward and up in altitude in response to climate change (Dale *et al.*, 2010; Ogawa-Onishi *et al.*, 2010; Hickler *et al.*, 2012). Associated long-term projected range shifts generally vary from several km to several tens of km per decade, most probably cannot achieve such high rates by natural migration (*e.g.* Chmura *et al.*, 2011, see also 4.3.2.5). Therefore, assisted migration has been suggested as an adaptation measure (see 4.4.2.4). Such shifts would alter biodiversity and ecosystem services from temperate forests (e.g. Dale *et al.*, 2010). Multi-model comparisons for temperate forests, however, illustrate that there are differences in species response and that models differ greatly in the severity of projected climate change impacts on species ranges (Kearney *et al.*, 2010; Kramer *et al.*, 2010; Morin and Thuiller, 2009; Cheaib *et al.*, 2012). Tree growth models project increased tree growth at the poleward and high altitudinal range limits over most of the next century in China (Ni, 2011). New approaches to modelling tree responses, based on the sensitivity of key life-history stages, suggest that climate change impacts on reproduction could be a major limitation on temperate tree distributions (Morin *et al.*, 2007). Comparisons with paleoecological data have helped improve confidence in the ability of models to project future changes in species ranges (Pearman *et*

al., 2008, Allen *et al.*, 2010b, Garreta *et al.*, 2010). Model projections are qualitatively coherent with observations that temperate forest species are already moving up in altitude, probably due to climate warming at the end of the 20th century (Lenoir *et al.*, 2008). There is *medium confidence (medium evidence; medium agreement)* that temperate tree and animal species are migrating poleward and upward altitudinally.

4.3.3.1.3. Impacts of climate change on tropical wet and dry forests

The responses of tropical forests to variability and change in climate and atmospheric CO_2 concentration are superimposed upon the direct influences of human activities. Humans modify the composition and structure of tropical forests through the harvest of individual plants or animals and through management interventions to favor some species or structural features over others. Humans also convert forests to cropland or grazing land and influence forest exposure to ignition sources. Forest conversion is the best understood change that is underway in tropical forests. Climate change effects on tropical forests interact with the direct influences of humans and are understood largely through field studies of the responses of forests to extreme weather events and through models that are able to simulate a growing number of ecological and atmospheric processes.

A key uncertainty in our understanding of future impacts of climate change on tropical forests is the strength of direct CO_2 effects on photosynthesis and transpiration (see section 4.3.2.4). These responses will play an important role in determining tropical forest trends as temperatures and atmospheric CO_2 concentrations rise. There is a physiological basis for arguing that photosynthesis will increase sufficiently to offset the inhibitory effects of higher temperatures on forest productivity (Lloyd and Farquhar, 2008) although heightened photosynthesis does not necessarily translate into an increase in overall forest biomass, (Körner and Basler, 2010). DGVMs and the current generation of Earth System Models, including those used within CMIP5 (e.g., Jones *et al.*, 2011) generally use formulations for CO_2 effects on photosynthesis and transpiration based on laboratory-scale work (Jarvis, 1976; Farquhar *et al.*, 1980; Ball *et al.*, 1987;Stewart, 1988; Collatz *et al.*, 1992; Leuning, 1995; Haxeltine and Prentice, 1996; Cox *et al.*, 1998) that pre-dates larger ecosystem-scale studies, although some models have been optimized on the basis of more recent data (Jones *et al.*, 2011).

A second important source of uncertainty is the rate of future CO_2 and temperature rise (Betts *et al.*, 2012). Modelled simulations of future climate in tropical forest regions indicate with *high confidence (robust evidence, high agreement*) that temperature will increase. Future precipitation change, in contrast, is highly uncertain and varies considerably between climate models (WG1 Annex A), although there is *medium confidence* (*medium evidence, medium agreement*) that some tropical regions, such as the eastern Amazon Basin, will experience lower precipitation (Malhi *et al.*, 2009b). The range of possible shifts in the moist tropical forest envelope is large, sensitive to the responsiveness of water use efficiency (WUE) to rising concentrations of atmospheric CO_2, and varies depending on the climate and vegetation model that is used (Scholze *et al.*, 2006; Zelazowski *et al.*, 2011) (Sitch *et al.*, 2008) Recent model medley studies (Cox *et al.*, 2013; Huntingford *et al.*, 2013) indicate that the future geographical range of moist tropical forests as determined by its shifting climatological envelope is *less likely* to undergo major retractions or expansions by 2100 through climate change alone as previously predicted (Cox *et al.*, 2000).

Changes in the species composition and biomass of moist tropical forests observed in networks of long-term forest plots in moist tropical forests are generally consistent with increasing WUE associated with the rising concentration of CO_2. Lianas and fast-growing tree species are increasing, as is forest biomass (Phillips *et al.*, 2002; Phillips *et al.*, 2005; Lewis *et al.*, 2009a; Lewis *et al.*, 2009b; Lewis *et al.*, 2011). Faster tree growth could also result from changes in solar radiation and the ratio of diffuse to direct radiation (Mercado *et al.*, 2009; Lewis *et al.*, 2009a; Brando *et al.*, 2010). There is *low confidence* (*limited evidence, medium agreement*) that the composition and biomass of Amazon and African forests are changing through the rise in atmospheric CO_2. The potential suppression of photosynthesis and tree growth in tropical forests through rising air temperatures is supported by physiological and eddy covariance studies (Doughty and Goulden, 2008; Lloyd and Farquhar, 2008; Wood *et al.*, 2012), but is not yet observed as changes in forest biomass (except Clark *et al.*, 2003).

Since AR4, there is new experimental and observational evidence of ecological thresholds of drought and fire in moist tropical forests that points to an important indirect role of climate change in driving large-scale changes in moist tropical forests (see Box 4-3). Forest tree mortality increased abruptly above a critical level of soil moisture depletion in two rainfall exclusion experiments (Nepstad *et al.*, 2007; Fisher *et al.*, 2008) and above a critical level of weather-related fire intensity in a prescribed burn experiment (Brando *et al.*, 2012). These experimental results were corroborated by observations of increased tree mortality during the extremely severe 2005 drought in the Amazon (Phillips *et al.*, 2009) and extensive forest fire (Alencar *et al.*, 2006; Aragão *et al.*, 2008; Alencar *et al.*, 2011; Box 4-3). There is *medium confidence* (*medium evidence, high agreement*) that moist tropical forests have many tree species that are vulnerable to drought- and fire-induced mortality during extreme dry periods. There is *low confidence* (*limited evidence, low agreement*) that the severe droughts that have affected the Amazon region are associated with climate change (Shiogama *et al.*, 2011).

There is also a growing body of evidence that severe weather events interact with land use to influence moist tropical forest fire regimes. Many moist tropical forests are not susceptible to fire during typical rainfall years because of high moisture content of fine fuels Cochrane, 2003. Selective logging, drought, and fire itself can reduce this fire resistance by killing trees, thinning the canopy and allowing greater heating of the forest interior; Uhl and Kauffman, 1990; Ray *et al.*, 2005; Curran *et al.*, 2004; Box 4-3). Land use often increases the ignition sources in tropical landscapes (Silvestrini *et al.*, 2011). These relationships are not yet represented fully in coupled climate-vegetation models. There is *high confidence* (*robust evidence, high agreement*) that forest fire frequency and severity is increasing through the interaction between severe droughts and land use.

There are an estimated one million square kilometres of dry tropical forests in the world (Miles *et al.*, 2006), defined as forests occurring in tropical regions characterized by pronounced seasonality in rainfall distribution (Mooney *et al.*, 1995). More than half of the remaining tropical dry forests (54%) are located in South America. Approximately one third of the remaining tropical forests in the Americas are predicted to experience "severe climate change" by 2055, defined as an increase in air temperate of at least 2.5 deg. C and/or a decrease in precipitation of at least 50 mm a^{-1}. Less than one fifth of forests in other tropical dry forest formations are faced with this level of climate risk (Miles *et al.*, 2006). Climate change, deforestation, fragmentation, fire, or human pressure place virtually all (97%) of the remaining tropical dry forests at risk (Miles *et al.*, 2006).

Box 4-3. A Possible Amazon Basin Tipping Point

Since AR4, our understanding of the potential of a large-scale, climate-induced, self-reinforcing transition of Amazon forests to a dry stable state (known as the Amazon "forest dieback") has improved. Modeling studies indicate that the likelihood of a purely climate-driven dieback in 2100 is lower than previously thought (Malhi *et al.*, 2009b; Good *et al.*, 2013; Cox *et al.*, 2013; Huntingford *et al.*, 2013) and there is now *medium confidence* (*robust evidence, medium agreement*) that climate change alone will not lead to widespread forest loss during this century. Meteorological fire danger is projected to increase (Golding and Betts, 2008; Betts *et al.*, submitted; Figure 4-8). Field studies and regional observations, have provided new evidence of critical ecological thresholds and positive feedbacks between climate change and land-use activities that could drive a fire-mediated, self-reinforcing dieback in this century. There is now *medium confidence* (*medium evidence, medium agreement*) that severe drought episodes, land use, and fire interact synergistically to drive the transition of mature Amazon forests to low-biomass, low-statured pyrophilic woody vegetation.

Most primary forests of the Amazon Basin have damp fine fuel layers and low susceptibility to fire, even during annual dry seasons (Uhl and Kauffman, 1990; Ray *et al.*, 2005). Forest susceptibility to fire increases through canopy thinning and greater sunlight penetration caused by tree mortality associated with selective logging (Uhl and Kauffman, 1990; Ray *et al.*, 2005; Barlow and Peres, 2008), previous forest fire (Balch *et al.*, 2008; Brando *et al.*, 2012), severe drought (Alencar *et al.*, 2006), or drought-induced tree mortality (Nepstad *et al.*, 2007; da Costa *et al.*, 2010). The impact of fire on tree mortality is also weather-dependent. Under very dry, hot conditions, fire-related tree mortality can increase sharply (Brando *et al.*, 2012). Under some circumstances, tree damage is sufficient to allow light-demanding, flammable grasses to establish in the forest understory, increasing forest susceptibility to

further burning (Veldman and Putz, 2011). There is *high confidence* (*robust evidence, high agreement*) that logging, severe drought, and previous fire increase Amazon forest susceptibility to burning.

Landscape level processes further increase the likelihood of forest fire. Ignition sources are more common in agricultural and grazing lands than in forested landscapes (Silvestrini *et al.*, 2011) (*high confidence*: *robust evidence, high agreement*), and forest conversion to grazing and crop lands can inhibit regional rainfall through changes in albedo and evapotranspiration (Costa *et al.*, 2007; Butt *et al.*, 2011; Knox *et al.*, 2011) (*low confidence*: *medium evidence, low agreement*) or through smoke, that can inhibit rainfall under some circumstances (Andreae *et al.*, 2004) (*low confidence*: *medium evidence, low agreement*). Apart from these landscape processes, climate change could increase the incidence of severe drought episodes (Shiogama *et al.*, 2011).

In sum, fire-mediated changes in Amazon forests are self-reinforcing through increases in tree mortality, forest susceptibility to fire, ignition sources, and regional rainfall inhibition (Figure 4-10). If current patterns of deforestation, logging, severe drought, and forest fire continue into the future, 55% of the region's forests will be cleared or degraded by 2030, even without invoking positive feedbacks with regional climate, releasing 20±10 Pg of carbon to the atmosphere (Nepstad *et al.*, 2008) (*low confidence*: *low evidence, medium agreement*). The likelihood of a tipping point being reached may decline if extreme droughts (such as 1998, 2005, and 2010) (Marengo *et al.*, 2011) become less frequent, if land management fires are suppressed, if forest fires are extinguished (Soares-Filho *et al.*, 2012), if deforestation declines, or if cleared lands are reforested (Nepstad *et al.*, 2008). The 76% decline in deforestation in the Brazilian Amazon with 80% of the region's forest still standing (INPE, 2012) demonstrates that large-scale mitigation of a fire-mediated tipping point could be feasible.

[INSERT FIGURE 4-10 HERE
Figure 4-10: The forests of the Amazon Basin are being altered through severe droughts, land use (deforestation, logging), and increased frequencies of forest fire. Some of these processes are self-reinforcing through positive feedbacks, and create the potential for a large-scale tipping point. For example, forest fire increases the likelihood of subsequent burning, especially if burning is followed by forest invasion by grasses or flammable herbs. Deforestation inhibits rainfall in the region and provides ignition sources to flammable forests, contributing to this dieback.]

_____ END BOX 4-3 HERE _____

4.3.3.2. Rangelands and Drylands, including Mediterranean-type Systems

The following sections treat a wide range of terrestrial ecosystems covering a large part of the terrestrial surface, whose unifying features are that they are not classified as forests and they typically exhibit strong water stress for several months each year. Grasses, grass-like plants and herbs are usually a major part of their vegetation cover. The principle land use often involves either wild or domestic herbivores.

4.3.3.2.1. Savannas

Savannas are defined as mixtures of coexisting trees and grasses. The geographical distribution of tropical savannas is determined by temperature, the seasonal availability of water, fire and soil conditions (Ellery *et al.*, 1991; Walker and Langridge, 1997; Staver *et al.*, 2011) and is therefore inferred to be susceptible to climate change. The proportion of trees and grasses in savannas is considered inherently unstable under some conditions (DeMichele *et al.*, 2011; Staver *et al.*, 2011; Wake, 2012). Savannas are characterized by annual to decadal fires of relatively low intensity, which are an important factor in maintaining the tree-grass proportions (Beerling and Osborne, 2006), but also constitute a major global source of pyrogenic emissions from land to atmosphere (Schultz *et al.*, 2008; van der Werf *et al.*, 2010). The differential effects of climate change, rising CO_2, fire and herbivory on trees and grasses have the potential to alter the structure, composition and ecosystem service delivery capacity of mixed tree-grass systems (e.g. Hughes *et al.*, 2006). Since tropical savannas occupy about an eighth of the global land surface, and

mixed tree-grass systems outside the tropics cover a similar area, small changes in their structure or fire regime can have globally-significant effects on the emission or uptake of radiatively-active gases and particles.

There is evidence from many parts of the world that the tree cover and biomass in savannas has increased over the past century and in some places, on all continents, continues to do so (*high agreement, robust evidence*: Cabral *et al.*, 2009; Angassa and Oba, 2008; Moleele *et al.*, 2002; Wigley *et al.*, 2009; Witt *et al.*, 2009; Lunt *et al.*, 2010; Rohde and Hoffman, 2012). The general consequences are more carbon stored per unit land area as tree biomass and soil organic matter (Hughes *et al.*, 2006; Liao *et al.*, 2006; Knapp *et al.*, 2007; Throop and Archer, 2008; Boutton *et al.*, 2009), changes in hydrology (Muñoz-Robles et al 2011) and reduced grazing potential (Scholes and Archer, 1997). Increasing tree cover in savannas has been attributed to changes in land management (Joubert *et al.*, 2008; Van Auken, 2009), rising CO_2 (Bond and Midgley, 2012; Buitenwerf *et al.*, 2012), climate variability and change (Eamus and Palmer, 2008; Fensham *et al.*, 2009) or two or more of these factors acting in combination (Ward, 2005; Bond *et al.*, 2008). As yet there are no studies that definitively attribute the relative importance of the various causes of woody plant biomass increase in savannas and grasslands, but there is *medium agreement* and *robust evidence* that climate and atmospheric changes are contributing factors in many cases. The increased growth rate of C3 trees relative to C4 grasses under by rising CO_2 could relieve the demographic bottleneck that keeps trees trapped within the flame zone of the grasses, a hypothesis supported by elevated CO_2 experiments with savanna saplings (Kgope *et al.*, 2010). A vegetation model of grasslands, savannas and forests suggests that rising CO_2 does increase the likelihood of abrupt shifts to woodier states, but the transition will take place at different CO_2 concentrations in different environments (Higgins and Scheiter, 2012). On the other hand, observation of contrasts in the degree of savanna thickening between land parcels with the same CO_2 exposure but different land use histories, topographic position or soil depth (Wu and Archer, 2005; Wiegand *et al.*, 2005) imply that land management, water balance and microclimate are also important. Tree cover in savannas is rainfall-constrained (Sankaran *et al.*, 2005), suggesting that increases in rainfall could lead to increased tree biomass. In some places the savanna boundary is moving into former grasslands on elevation or climate gradients (Breshears, 2006).

It has been projected that drying and greater seasonality, acting in conjunction with increased fire, could lead to more savanna-like conditions in parts of the Amazon basin (Malhi *et al.*, 2009a; Box 4-3). In parts of Central Africa, forests have been observed to be moving into adjacent savannas and grasslands (Mitchard *et al.*, 2009), possibly due to depopulation and fire changes. In northern Australia, forest is expanding into former savanna areas (Brook and Bowman, 2006; Tng *et al.*, 2012; Bowman *et al.*, 2011

4.3.3.2.2. Grasslands and shrublands

Much evidence from around the world shows that dry grasslands and shrublands are highly responsive in terms of primary production, species composition and carbon balance to changes in water balance (precipitation and evaporative demand) within the range of projected climate changes (e.g., Sala *et al.*, 1988; Snyman and Fouché, 1993; Fay *et al.*, 2003; Peñuelas *et al.*, 2004, 2007; Prieto *et al.*, 2009; Wu and Chen, 2013) Other factors being equal, grasslands and shrublands are in cool areas are expected to respond to warming with increased primary production, while those in hot areas are expected to show decreased production. Grasslands are exposed to rising CO_2, which is postulated to stimulate plant production, but more so for temperate grasses, herbs and woody plants with a C3 photosynthetic system than for C4 tropical grasses (see section 4.2.4.4). Some grasslands are simultaneously exposed to elevated levels of nitrogen deposition, which alters species composition, increases primary production up to a point and decreases it thereafter (see section 4.2.4.2, Bobbink *et al.*, 2010; Cleland and Harpole, 2010). Most rangelands are subject to grazing and fire. All these factors may have interactive effects, and species composition changes may overwhelm or alter the physiological climate effects (Suttle *et al.*, 2007).

Drawing on published studies, Ravi *et al.* (2010) found that changing climate and land use have resulted in increased aridity and a higher frequency of droughts in drylands around the world. They predict increasing dominance of abiotic controls of land degradation (in contrast to direct human- or herbivore-driven degradation); in particular highlight changes in hydrology and the erosion of soil by wind.

Rainfall amount and timing have large effects on a wide range of biological processes in grasslands and shrublands, including seed germination, seedling establishment, plant growth, flowering time, root mass, community composition, population and community dynamics production, decomposition and respiration, microbial processes and carbon assimilation (e.g. Peñuelas *et al.*, 2004, 2007; Beier *et al.*, 2008; Sowerby *et al.*, 2008; Albert *et al.*, 2011; Albert *et al.*, 2012; Miranda *et al.*, 2009; Selsted *et al.*, 2012; Walter *et al.*, 2012). In a controlled experiment with communities of tallgrass prairie species in Kansas, Fay *et al.* (2008) showed that changes in the interval between rainfall events and the rainfall delivered by individual storms altered carbon assimilation and respiration rates independently of changes in the total amount of water supplied. A similar experiment on a Mediterranean semiarid grassland community (Miranda *et al.*, 2009) found that delayed watering led to decreases in plant productivity and to delayed flowering. Species diversity was not affected by delayed onset of rain; however, it was reduced by changes in the frequency, amount and seasonality of wetting. In the Mongolian steppe (Shinoda *et al.*, 2010), drought reduced the above ground plant mass but did not substantially affect the root mass. A subset of species did not recover to pre-drought levels once precipitation returned to normal levels. A water and temperature manipulation experiment in China indicated that changes in water balance had a stronger effect on grassland microbial processes leading to carbon storage than changes in temperature (Liu *et al.*, 2009). Engler *et al.* (2011) emphasized that precipitation changes were as important for mountain flora in Europe as temperature changes, and the greatest composition changes will probably occur when decreased precipitation accompanies warming. Vohland and Barry (2009) reviewed the effectiveness of in situ rainwater harvesting (RWH) as an adaptation to climate change in sub-Saharan Africa and concluded that it conferred higher food security and income, but may strengthen conflicts between nomadic and sedentary populations.

Experimental manipulation of six European shrublands on a latitudinal gradient showed the response to warming and drought to depend on site, year and plant species (Peñuelas *et al.*, 2004, 2007). Droughts decreased aboveground net primary production two thirds of the sites. Responses to warming were weaker in the presence of aridity. Gao and Giorgi (2008) identified the southern Mediterranean as particularly vulnerable to water stress and desertification processes under climate change conditions. Analyzing 168 site-years of eddy covariance measurements, Wu and Chen (2013) found summer drought to reduce both summer gross primary production and net ecosystem production in grasslands and crops of North America.

A European gradient study (Emmett *et al.*, 2004), showed that N mineralization in shrublands under either arid or wet conditions is more sensitive to periodic droughts than systems under more mesic conditions. An increase in drought frequency, without an increase in drought severity, leads to loss of soil carbon in moist, carbon-rich moorlands, due to changes in soil structure or soil microbial community leading to increased hydrophobicity and soil respiration (Sowerby *et al.*, 2008, 2010). Responses of shrublands to drought may partly be driven by changes in the soil microbial community (Jensen *et al.*, 2003) or changes in soil fauna (Maraldo *et al.*, 2008).

Beier *et al.* (2008) found that nitrogen limitation reduces acclimation in plant production, as a result of an asymmetrical response to warming between the carbon and nitrogen cycles. Decreased tissue concentrations of phosphorus was also associated with warming and drought (Peñuelas *et al.*, 2004; Beier *et al.*, 2008; Peñuelas *et al.*, 2012). strong interactions of warming with disturbances have been observed leading to increased nitrogen leaching from shrubland ecosystems (Beier *et al.*, 2004).

N fertilization and nighttime warming caused soil and plant community responses within one season in a Chihuahuan semi-arid desert (Collins *et al.*, 2010). In contrast, Grime *et al.* (2008) found little species composition change after 13 years of manipulation of water and temperature in an infertile grassland in England. The community composition of subalpine grasslands in Switzerland have changed relatively little over the past fifty years (Vittoz *et al.*, 2009). The changes that did occur were largely associated with changes in land management rather than climate, although they were consistent with warming trends.

Sommer *et al.* (2010) used global empirical relationships between plant species richness and climate variables such as temperature, moisture and radiation to project richness changes under future climates. This method is independent of the usual species-by-species or biome-based climate niche approach, but its predictions apply to the long-term equilibrium outcome, rather than changes in the next few decades. In most temperate and arctic regions, the capacity

to support richer (i.e. more diverse) communities increases with rising temperature, while the projections indicate a strong decline in capacity to support species-rich communities in most tropical and subtropical regions.

Many grasslands, shrublands and savannas are characterized by relatively frequent but low-intensity fires. The fire frequency, intensity and seasonality in southern Africa are primarily under climate control, and secondarily influenced by management (Archibald *et al.*, 2009). In South America, El Niño-Southern Oscillation climate modes strongly influence on area burned in Colombian grasslands (Armenteras-Pascual *et al.*, 2011). Fire frequency in grasslands and forests in Australia is projected to increase, due to climate change (Pitman *et al.*, 2007). Since it is well-established that plant species composition is sensitive to the fire regime (e.g. Gibson and Hulbert, 1987; Uys *et al.*, 2004; Gill *et al.*, 1999 and many other studies) this provides an indirect mechanism by which climate change can lead to species composition change in grasslands and rangelands.

Relatively little is known regarding the combined effect of climate change, other global change factors and increasing use pressure by large mammal herbivores in rangelands, nor on the consequences for pastoral livelihoods that depend on rangelands (Thornton *et al.*, 2009).

4.3.3.2.3. Deserts

The deserts of the world, defined as land areas with an arid or hyperarid climate regime, occupy 35 % of the global land surface. Deserts are sparsely populated, but the people who do live there are amongst the poorest in the world (Millennium Ecosystem Assessment, 2005b). There is *medium agreement* but *limited evidence* that the present extent of deserts will increase in the coming decades, despite the projected increase in rainfall at a global scale, as a result of the strengthening of the Hadley circulation. The descending air on the poleward side of the Hadley circulation results in decreased rainfall (Mitas and Clement, 2005; Seidel *et al.*, 2008; Johanson and Fu, 2009; Lu *et al.*, 2009; Zhou *et al.*, 2011) and which determines the location of the broad band of warm deserts lands approximately 15-30° N and S of the equator. Recent satellite data show a greening trend in the Sahel, associated with a return to wetter climates following a multidecade dry spell. There may be a feedback to the global climate from an increase in desert extent (Alkama *et al.*, 2012), which differs in sign between deserts closer to the equator than 20° and those closer to the poles. In model simulations, extension of the 'warm deserts' causes warming, while extension of the 'cold deserts' causes cooling, in both cases largely through albedo-mediated effects. Two special circumstances of desert areas are important with respect to climate change. Deserts are expected to become warmer and drier at faster rates than other terrestrial regions (Lapola *et al.*, 2009). Most deserts are already extremely hot, and therefore further warming will probably be physiologically injurious rather than beneficial. Secondly, the ecological dynamics in deserts are rainfall event-driven (Holmgren *et al.*, 2006), often involving the concatenation of a number of quasi-independent events. According to a conceptual model elaborated by Lapola *et al.* (2009) some desert tolerance mechanisms (e.g., biological adaptations by long-lived taxa) may be outpaced by global climate change.

Deserts are expected to become warmer and drier at a faster rate than other terrestrial regions (Stahlschmidt *et al.*, 2011). The warm deserts are already extremely hot, and therefore further warming is generally physiologically injurious rather than beneficial. Ecological dynamics in deserts are rainfall event-driven (Holmgren *et al.*, 2006), often involving the concatenation of a number of quasi-independent events. According to a conceptual model elaborated by Stahlschmidt *et al.* (2011) some desert tolerance mechanisms (e.g., biological adaptations by long-lived taxa) may be outpaced by global climate change.

4.3.3.3. Rivers, Lakes, Wetlands and Peatlands

Freshwater ecosystems are considered to be among the most threatened on the planet (Dudgeon *et al.*, 2006; Vörösmarty *et al.*, 2010). Fragmentation of rivers by dams and the alteration of natural flow regimes have led to major impacts on freshwater biota (Pringle, 2001, Bunn and Arthington, 2002; Nilsson *et al.*, 2005). Floodplains and wetland areas have become occupied for intensive urban and agricultural land use to the extent that many are functionally extinct from their rivers (Tockner *et al.*, 2008). Pollution from cities and agriculture, especially nutrient

loading, has resulted in declines in water quality and the loss of essential ecosystem services (Allan, 2004). As a direct consequence of these and other impacts, freshwater systems have the highest rates of extinction of any ecosystem (as much as 4% pa for some groups - e.g. crayfish, mussels, fishes and amphibians in North America), with estimates that at least 10,000-20,000 freshwater species are extinct or at risk (Strayer and Dudgeon, 2010). This is particularly significant considering that freshwater habitats support 6% of all described species, including approximately 40% of fish diversity and a third of the vertebrate diversity (Dudgeon *et al.*, 2006; Balian *et al.*, 2008).

Peatlands contain large stocks of carbon that are vulnerable to change through land use and climate change. Although peatlands cover only about 3% of the land surface, they hold the equivalent of half of the atmosphere's carbon (as CO_2), or one third of the world's soil carbon stock (Limpens *et al.*, 2008; Page *et al.*, 2011). About 14-20% of the world's peatlands are currently used for agriculture (Oleszczuk *et al.*, 2008) and many, particularly peat swamp forests in Southeast Asia, are still undergoing major transformations through drainage and burning in preparation for oil palm and other crops or through unintentional burning (Limpens *et al.*, 2008; Hooijer *et al.*, 2010). Deforestation, drainage, and burning in Indonesian peat swamp forests can release 1,400 Mg CO_2 ha^{-1} (Murdiyarso *et al.*, 2010), contributing significantly to global GHG emissions, especially during periods of intense drought associated with ENSO when burning is more common (Page *et al.*, 2002). Anthropogenic disturbance has changed peatlands from being a weak global carbon sink to a source (Frolking *et al.*, 2011) with large inter-annual variability.

It is *very likely* that these stressors to freshwater ecosystems and peatlands will continue to dominate as human demand for water resources grows, accompanied by increased urbanization and intensification of agriculture (Vörösmarty *et al.*, 2000; Malmqvist *et al.*, 2007; Dise, 2009). However, climate change will have significant additional impacts on freshwater ecosystems (*high confidence*), from altered thermal regimes, altered precipitation and flow regimes and, in the case of coastal wetlands, sea level rise. Specific aquatic habitats that are most vulnerable to these direct climate effects, especially rising temperatures, are those at high altitude and high latitude, including arctic and subarctic bog communities on permafrost, and alpine and arctic streams and lakes (see 4.3.4.4; Smith *et al.*, 2005; Smol and Douglas, 2007a). It is noteworthy that these high latitude systems currently experience a relatively low level of threat from other human activities (Vörösmarty *et al.*, 2010). Dryland rivers and wetlands, many already experiencing severe water stress from human consumptive use, are also *likely* to be further impacted by decreased and more variable precipitation and higher temperatures. Headwater stream systems in general are also vulnerable to the effects of warming because their temperature regimes closely track air temperatures (Caissie, 2006).

Evidence of rising stream and river temperatures over the past few decades across several continents continues to grow (Chessman, 2009; Kaushal *et al.*, 2010; Langan *et al.*, 2001; Morrison *et al.*, 2002; Ormerod, 2009; van Vliet *et al.*, 2011; Webb and Nobilis, 2007), and has been linked by observational and experimental studies to shifts in invertebrate community composition, including declines in cold sternothermic species (Brown *et al.*, 2007; Chessman, 2009; Durance and Ormerod, 2007; Ormerod, 2009). Rising water temperatures are also implicated in changes in the composition of river fish communities (Buisson *et al.*, 2008; Daufresne and Boet, 2007), especially in headwater streams where species are more sensitive to warming (e.g. Buisson and Grenouillet, 2009), and this will probably restrict the distribution of cool-water species such as salmonids within their current range (Bartholow, 2005; Bryant, 2009; Ficke *et al.*, 2007; Hague *et al.*, 2011). While these changes in river temperature regimes may also open up new habitat at higher latitudes (or altitudes) for migratory (Reist *et al.*, 2006) and cool- and warm water species of fish (Tisseuil *et al.*, 2012), there is *high confidence* that range contraction threatens the long term persistence of some fully aquatic species, including mountain-top endemics; e.g. species of spiny crayfish (Parastacidae: *Eustacus*) in eastern Australia (Ponniah and Hughes, 2004).

The surface and epilimnetic waters in many lakes also show increases in temperature over the past four decades, with warming trends detected in North America, Eurasia and Africa (Adrian *et al.*, 2009). Rising temperatures resulting in early onset and increased duration and stability of the thermocline in temperate lakes during summer (Winder and Schindler, 2004) are projected to favor a shift in dominance to smaller phytoplankton (Parker *et al.*, 2008; Yvon-Durocher *et al.*, 2011) and cyanobacteria (Johnk *et al.*, 2008; Paerl *et al.*, 2011; Wiedner *et al.*, 2007), especially in those ecosystems experiencing high anthropogenic loading of nutrients (Wagner and Adrian, 2009);

with impacts to water quality, food webs and productivity (Gyllström *et al.*, 2005; O'Reilly *et al.*, 2003; Parker *et al.*, 2008; Shimoda *et al.*, 2011; Verburg *et al.*, 2003). Emergent aquatic macrophytes are likely to expand their northward distribution and percentage cover in boreal lakes and wetlands, posing an increasing overgrowth risk for sensitive macrophyte species (Alahuhta *et al.*, 2011). Long-term shifts in macroinvertebrate communities have also been observed in European lakes where temperatures have increased (Burgmer *et al.*, 2007), noting that warming may increase species richness in smaller temperate waterbodies, especially those at high altitude (Rosset *et al.*, 2010). While less studied, it has been proposed that tropical ectotherms will be particularly vulnerable because they will approach critical maximum temperatures proportionately faster than species in high latitude environments, despite lower rates of warming (Deutsch *et al.*, 2008; Hamilton, 2010; Laurance *et al.*, 2011).

There is growing evidence that climate induced changes in precipitation will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (see Box CC-RF; Aldous *et al.*, 2011; Xenopoulos *et al.*, 2005). Freshwater ecosystems in Mediterranean-montane ecoregions (e.g. Australia, California and South Africa), are projected to experience a shortened wet season and prolonged, warmer summer season (Klausmeyer and Shaw, 2009), increasing the vulnerability of fish communities to drought (Magalhães *et al.*, 2007; Hermoso and Clavero, 2011) and floods (Meyers *et al.*, 2010). Shifts in hydrologic regimes in snow-melt systems, including earlier runoff and declining base flows in summer (Stewart *et al.*, 2005; Stewart, 2009), are projected to impact on freshwater ecosystems, through changes in physical habitat and water quality (Bryant, 2009). Declining rainfall and increased inter-annual variability will probably increase low-flow and dry-spell duration in dryland regions, leading to reduced water quality in remnant pools (Dahm *et al.*, 2003), reduction in floodplain egg- and seed-banks (Capon, 2007; Jenkins and Boulton, 2007), the loss of permanent aquatic refugia for fully aquatic species and water birds (Bond *et al.*, 2008; Johnson *et al.*, 2005; Sheldon *et al.*, 2010), and terrestrialization of wetlands (Davis and Thompson, 2010).

Climate induced changes in precipitation will probably be an important factor altering peatland vegetation in temperate and boreal regions, with decreasing wetness during the growing season generally associated with a shift from a *Sphagnum* dominated to vascular plant dominated vegetation type and a general decline of C sequestration in the longer term (Limpens *et al.*, 2008). Mire ecosystems (i.e. bogs, transition bogs and fens) in central Europe face severe climate risk, with increased summer temperatures being particularly important (Essl *et al.*, 2012). Declines in precipitation and longer dry seasons in major tropical peatland areas in southeast Asia, are projected to result in lower water tables more often and for longer periods, with an increased risk of fire (Li *et al.*, 2007; Rieley *et al.*, 2008; Frolking *et al.*, 2011).

Sea level rise will lead to direct losses of coastal wetlands with associated impacts on waterbirds and other wildlife species dependent on fresh water (BMT WBM, 2010; Pearlstine *et al.*, 2010; Traill *et al.*, 2010) but the impact will probably be relatively small compared with the degree of direct and indirect human-induced destruction (Nicholls, 2004). River deltas and associated wetlands are particularly vulnerable to rising sea level, and this threat is further compounded by trapping of sediment in reservoirs upstream and subsidence from removal of oil, gas and water (Syvitski *et al.*, 2009; see Chapter 5.3.1.4). Lower river flows might exacerbate the impact of sea level rise and thus salinization on freshwater ecosystems close to the ocean (Ficke *et al.*, 2007).

4.3.3.4. Tundra, Alpine, Permafrost Systems

The region of the High Arctic, and its tundra-dominated landscapes, has warmed more than the global average over the last century (Kaufman *et al.*, 2009; Hartmann *et al.*, in press. Changes consistent with warming are also evident in the freshwater systems, ecosystems (both plants and animals) and permafrost of the region (Hinzman *et al.*, 2005; Axford *et al.*, 2009; Jia *et al.*, 2009b; Post *et al.*, 2009; Prowse and Brown, 2010; Romanovsky *et al.*, 2010; Walker *et al.*, 2012). Change is widespread , with most of the Arctic experiencing recent change in vegetation photosynthetic capacity and other aspects, particularly in areas adjacent to areas of the Arctic with rapidly retreating sea ice (Bhatt *et al.*, 2010).

There is *high confidence* that continued climate change is projected to cause the terrestrial vegetation and lake systems of the Arctic to change substantially in the future, with an ongoing expansion in woody vegetation cover

projected in tundra regions over the 21st Century in the CMIP5 Earth System Models (Ciais *et al.*, in press) by dynamic global vegetation models driven by other climate model projections, and by observationally-based statistical models (Pearson *et al.*, 2013). Changes may be complex (see Box 4-4) and in some cases involve non-linear and threshold responses to warming and other climatic change (Hinzman *et al.*, 2005; Mueller *et al.*, 2009b; Bonfils *et al.*, 2012). Due to long response times of vegetation to both warming and increased CO_2 (Ciais *et al.*, in press; Falloon *et al.*, 2012) Earth System Models project Arctic vegetation change to continue long after any stabilization of global mean temperature. In some regions, reduced surface albedo due to increased vegetation cover is projected to cause further local warming even in scenarios of stabilized global radiative forcing due to greenhouse gases (Falloon *et al.*, 2012).

In the arctic tundra biome, vegetation productivity has systematically increased over the past few decades, as documented across a range of scales in both North America and northern Eurasia – from the plot level (Myers-Smith *et al.*, 2011; Elmendorf *et al.*, 2012) to the region (Stow *et al.*, 2007) to continental (Jia *et al.*, 2009b) and the circumpolar arctic (Goetz *et al.*, 2007; de Jong *et al.*, 2011). This phenomenon is amplified by retreat of coastal sea ice (Bhatt *et al.*, 2010) and has been widely discussed in the context of increased shrub growth consistent with documented shrub expansion over the last half century through repeat photography and satellite observations (Forbes *et al.*, 2010; Myers-Smith *et al.*, 2011). Deciduous shrubs (i.e., dwarf birch, alder and willow species), in particular, respond to warming with increased growth (Euskirchen *et al.*, 2009; Lantz *et al.*, 2010), but this response is shared with other plant functional types, particularly graminoids (Walker, 2006; Epstein, 2008). Analyses of satellite time series data show the increased productivity trend is not unique to shrub-dominated areas (Jia *et al.*, 2009b; Beck and Goetz, 2011), thus greening is a response shared by multiple vegetation communities and continued changes in the tundra biome can be expected irrespective of shrub presence. Shrub expansion and height changes remain particularly important, however, because they trap snow, mediate winter soil temperature and summer moisture regimes, increase nutrient mineralization, and produce a positive feedback for additional shrub growth (Sturm *et al.*, 2005; Lawrence *et al.*, 2007; Bonfils *et al.*, 2012). Although increased shrub cover and height produce shadowing that reduce ground heat flux and active layer depth, they also reduce surface albedo, increase energy absorption and evapotranspiration (Chapin III *et al.*, 2005; Blok *et al.*, 2010), and produce feedbacks that reinforce shrub densification and regional warming (Lawrence and Swenson, 2011; Bonfils *et al.*, 2012). On balance, these feedbacks can act to partially offset one another, but when coupled with warmer and wetter conditions they act to increase active layer depth and permafrost thaw (Yi *et al.*, 2007; Bonfils *et al.*, 2012).

The arctic tundra biome is also experiencing shifts in two additional phenomena; fire disturbance and permafrost degradation. Both of these processes facilitate conditions for woody species establishment in tundra areas, either through incremental migration or via more rapid "leap-frogging" to areas reinitialized by burning (Epstein *et al.*, 2007; Goetz *et al.*, 2011). When already present at the boreal-tundra ecotone, even sparsely, shrub and tree species show increased productivity with warmer conditions (Devi *et al.*, 2008; Andreu-Hayles *et al.*, 2011; Elmendorf *et al.*, 2012). Tundra fires not only emit large quantities of combusted carbon formerly stored in vegetation and organic soils (Mack *et al.*, 2011; Rocha and Shaver, 2011) but also increase active layer depth during summer months (Racine *et al.*, 2004; Liljedahl *et al.*, 2007) and produce thermokarsting associated with thawing of ice-rich permafrost. There is tremendous variability in the degree of thermokarsting associated with fire disturbance, depending upon the substrate and ice content (Jorgenson *et al.*, 2010) but the combination of thermokarsting and seasonal cryoturbation create conditions that alter vegetation succession (Racine *et al.*, 2004; Lantz *et al.*, 2009; Higuera *et al.*, 2011).

There is *high confidence* that the area of permafrost is projected to continue to decline over the first half of the 21st Century in all emissions scenarios (Figure 4-11). In the RCP2.6 scenario of an early stabilization of CO_2 concentrations, permafrost area is projected to stabilize at a level approximately 20% below the 20th Century area, and then begin a slight recovering trend. In RCP4.5, in which CO_2 concentration is stabilized at approximately 550ppmv by the mid-21st Century, permafrost continues to decline for at least another 250 years. In the RCP8.5 scenario of ongoing CO_2 rise, permafrost area is simulated to approach zero by the middle of the 22nd Century (Figure 4-11).

[INSERT FIGURE 4-11 HERE
Figure 4-11: Simulations of past and future (for three Representative Concentration Pathways - RCPs) northern hemisphere permafrost area with a maximum thaw depth less than 3m deep (Caesar *et al.*, 2012) using the HadGEM2-ES Earth System Model (Jones *et al.*, 2011).]

Frozen soils and permafrost currently hold more than twice the carbon than the atmosphere and thus represent a particularly large vulnerability to climate change (i.e., warming). Although the Arctic is currently a net carbon sink, continued warming will act to soon turn the Arctic to a net carbon source, that will in turn create a potentially strong positive feedback to accelerate Arctic (and global) warming with additional releases of CO_2, CH_4, and perhaps N_2O, from the terrestrial biosphere into the atmosphere (Schuur *et al.*, 2008; Schuur *et al.*, 2009; Maslin *et al.*, 2010; McGuire *et al.*, 2010; O'Connor *et al.*, 2010; Schaefer *et al.*, 2011). Moreover, this feedback is already accelerating due to climate-induced increases in fire (McGuire *et al.*, 2010; O'Donnell *et al.*, 2011). The rapid retreat of snowcover, and resulting spread of shrubs and trees into areas currently dominated by tundra has also already begun, and will continue to serve as a positive feedback accelerating high latitude warming (Chapin III *et al.*, 2005; Bonfils *et al.*, 2012).

There is *medium confidence* that rapid change in the Arctic is also affecting its animals. For example, seven of 19 sub-populations of the polar bear are declining in number, while four are stable, one is increasing and the remaining seven have insufficient data to identify a trend (Vongraven and Richardson, 2011). Declines of two of the sub-populations are linked to reductions in sea ice (Vongraven and Richardson, 2011). Polar bear populations are projected to decline greatly in response to continued Arctic warming (Hunter *et al.*, 2010), and it is expected that the populations of other Arctic animals (e.g., fox and caribou) will be affected dramatically by climate change (Post *et al.*, 2009; Sharma *et al.*, 2009). Simple niche-based, or climatic envelope models have difficulty in capturing the full complexity of these future changes (MacDonald, 2010).

There is *high confidence* that alpine systems are already showing a high sensitivity to on-going climate change and will be highly vulnerable to change in the future. In western North America, warming, glacier retreat, snowpack decline and drying of soils is already causing a large increase in mountain forest mortality, wildfire and other ecosystem impacts (e.g., Westerling *et al.*, 2006; Kelly and Goulden, 2008; Crimmins *et al.*, 2009; van Mantgem *et al.*, 2009; Pederson *et al.*, 2010; Muhlfeld *et al.*, 2011; Schwilk and Keeley, 2012; Park Williams *et al.*, 2012), and disturbance will continue to be an important agent of climate-induced change in this region (Littell *et al.*, 2010). Alpine ecosystems already appear to already be changing in response to climate change in Africa, Tibet, the Alps, the tropics and elsewhere (Cannone *et al.*, 2007, 2008; Lenoir *et al.*, 2008, 2010; Cui and Graf, 2009; Britton *et al.*, 2009; Normand *et al.*, 2009; Chen *et al.*, 2009, 2011; Allen *et al.*, 2010a; Eggermont *et al.*, 2010; Kudo *et al.*, 2011; Laurance *et al.*, 2011; Engler *et al.*, 2011; Dullinger *et al.*, 2012). For example, in a study of permanent plots from 1994 to 2004 in the Austrian high Alps, a range contraction of subnival to nival vascular plant species was indicated at the downslope edge, and an expansion of alpine pioneer species at the upslope edge (Pauli *et al.*, 2007). Thermophilous vascular plant species were observed to colonize in alpine mountain-top vegetation across Europe during the past decade (Gottfried *et al.*, 2012). As with the Arctic, permafrost thawing in alpine systems could provide a strong positive feedback in those systems (e.g., Tibet; Cui and Graf, 2009).

Box 4-4. Boreal – Tundra Biome Shift

Changes in a suite of ecological processes currently underway across the broader arctic region are consistent with earth system model predictions of climate-induced geographic shifts in the range extent and functioning of the tundra and boreal forest biomes (Figure 4-12). Thus far these changes appear to be not so much threshold responses as gradual and systematic shifts across temperature and moisture gradients. Responses are expressed through gross and net primary production, microbial respiration, fire and insect disturbance, vegetation composition, species range expansion and contraction, surface energy balance and hydrology, active layer depth and permafrost thaw, and a range of other inter-related variables. Because the high northern latitudes are warming more rapidly than other parts of the earth, due at least in part to arctic amplification (Serreze and Francis, 2006), the rate of change in these ecological processes are sufficiently rapid that they can be documented *in situ* (Hinzman *et al.*, 2005; Post *et al.*,

2009; Peng *et al.*, 2011; Elmendorf *et al.*, 2012) as well as from satellite observations (Goetz *et al.*, 2007; Beck *et al.*, 2011b; Xu *et al.*, 2013) and captured in earth system models (McGuire *et al.*, 2010).

Gradual changes in composition resulting from decreased evergreen conifer productivity and increased mortality, as well as increased deciduous species productivity, are facilitated by more rapid shifts associated with fire disturbance (Mack *et al.*, 2008; Johnstone *et al.*, 2010). Each of these interacting processes, as well as insect disturbance and associated tree mortality, are tightly coupled with warming-induced drought (Ma *et al.*, 2012; Anderegg *et al.*, 2013a; Choat *et al.*, 2012). Similarly, gradual productivity increases at the boreal-tundra ecotone are facilitated by leap-frog dispersal into areas disturbed by tundra fire and thermokarsting (Tchebakova *et al.*, 2009; Hampe, 2011; Brown, 2010). In North America these coupled interactions set the stage for changes in ecological processes, already documented, consistent with a biome shift characterized by increased deciduous composition in the interior boreal forest and evergreen conifer migration into tundra areas that are, at the same time, experiencing increased shrub densification. The net feedback of these ecological changes to climate is multi-faceted, complex, and not yet well known across large regions except via modeling studies, which are often poorly constrained by observations.

[INSERT FIGURE 4-12 HERE
Figure 4-12: Tundra-Boreal Biome Shift. Earth system models predict a northward shift of Arctic vegetation with climate warming, as the boreal biome migrates poleward into what is currently tundra. Observations of shrub expansion in tundra, increased tree growth at the tundra-forest transition, and tree mortality at the southern extent of the boreal forest in recent decades are consistent with model projections. Vegetation changes associated with a biome shift, which is facilitated by intensification of the fire regime, will modify surface energy budgets and net ecosystem carbon balance. Arrows indicate the magnitude of albedo and net ecosystem carbon balance (NECB) for boreal forest and tundra biomes, and albedo for sea ice and open water.]

4.3.3.5. Highly Human-Modified Systems - Plantations, Bioenergy Systems, Urban Ecosystems, Cultural Landscapes

As the majority of ice-free land surface is dominated by highly human modified systems, we assess their vulnerability to climate change particularly for those systems not dealt with elsewhere, i.e. except agriculture (WGII, chapter 7) and fisheries (WGII, chapter 3).

4.3.3.5.1. Plantation forestry

While a majority of general aspects on forests are already dealt with in section 4.3.3.1, here we focus on issues that are specifically relevant to plantation forests. Forest plantations are established through afforestation of recent non-forest land and reforestation of forest land, often with tree crop replacement (Dohrenbusch and Bolte, 2007; FAO, 2010b). With 7%, they currently cover only a minor fraction of the global forest area, and the largest plantation areas exist in Asia, Europe (excl. Russian Federation) and North and South America (FAO, 2010a). However, the area of forest plantations has grown rapidly by about five million ha from 2000 to 2010 (FAO, 2010b). Most recent plantations have been established in the tropics and subtropics, but also in some temperate regions, in particular in China (Kirilenko and Sedjo, 2007; FAO, 2010a), mostly by afforestation of non-forest area (FAO, 2010b).

In most areas with forest plantations, forest growth rates have generally increased during the last decades - in Europe also because of formally more intensive harvesting (Ciais *et al.*, 2008; Lindner *et al.*, 2010), but the variability is large, and in some areas production has decreased (see 4.3.3.1). In forests that are not highly water-limited, these trends are consistent with higher temperatures and extended growing seasons, but, as in the case of forests in general, clear attribution is difficult because many environmental drivers and changes in forest management interact (*e.g.* Boisvenue and Running, 2006; Ciais *et al.*, 2008; Dale *et al.*, 2010; see also 4.3.3.1).

Regarding future climatically driven changes, results from several studies with forest yield models suggest increases in forest production (Kirilenko and Sedjo, 2007), but these results may be overly optimistic because many models may overestimate potential positive effects of elevated CO_2 (Kirilenko and Sedjo, 2007; see 4.2.4.4) and the effects of disturbances, such as wildfires, forest pests, pathogens and windstorms, which are major drivers of forest dynamics, are often either poorly or not at all represented (Kirilenko and Sedjo, 2007). Using a model that accounts for fire effects and insect damage, Kurz *et al.* (2008), for example, showed that recent insect outbreaks might have caused a transition in the Canadian forest sector from a sink to a source of carbon. Future projections for particular stands or regions are also uncertain because results from different models often differ substantially, both regarding forest productivity (*e.g*. Sitch *et al.*, 2008; Keenan *et al.*, 2011) and potential species ranges (see 4.3.3.1.2). Nevertheless, decreased production is expected in particular in already dry forest regions for which further drying is projected, such as the south-western U.S. (Williams *et al.*, 2010a), and extreme drying might also decrease forest yields in currently not water-limited forests (*e.g.* Sitch *et al.*, 2008; see 4.3.3.1). Plantations in cold-limited areas could benefit from climate change and their productivity could increase if associated changes in disturbances, pests and pathogens do not outweigh the potential positive climatic effects.

Many plantation forests are monospecies stands or sometimes even include only a limited number of clones of one species. In the temperate and boreal zone, native species are commonly used (but in some cases beyond their native range), while in the tropics, conventional tree planting is mainly based on exotic species from a few genera such as *Pinus*, *Eucalyptus* and *Acacia* grown in single-species stands. Low species (and often also genetic) diversity compared with natural stands might render plantation forests particularly vulnerable to climate change (*e.g*. Hemery, 2008). Choosing provenances that are well adapted to current and future climates is extremely difficult because of uncertainties in climate projections (Broadmeadow *et al.*, 2005). Furthermore, it is highly uncertain how forest pests and pathogens will spread as a result of climate change and trade and new pathogen-tree interactions might occur (e.g. Brasier and Webber, 2010). Nevertheless, adaptive forest management can decrease the vulnerability of plantations to climate change (Hemery, 2008; Bolte *et al.*, 2009; Seppälä, 2009; Dale *et al.*, 2010. For example, risk spreading by promoting multi-species mixed stands and natural regeneration, which can increase genetic diversity (Kramer *et al.*, 2010), has been advocated as a plausible adaptation strategy for temperate forests (Hemery, 2008; Bolte *et al.*, 2010). Also in the tropics, recent approaches highlight the use of native species in mixed stands (Erskine *et al.*, 2006; Petit and Montagnini, 2006; Hall *et al.*, 2011), but missing information on the ecology of many of the tropical tree species and little experience in managing mixed tropical tree plantations remains to be a major problem (Hall *et al.*, 2011). At least at the southern border of cold-adapted species, such as Norway spruce (*Picea abies*) in Europe, climate change will *very likely* lead to a shift in the main tree species used for forest plantations (Iverson *et al.*, 2008; Bolte *et al.*, 2010).

4.3.3.5.2. Bioenergy systems

Bioenergy sources include traditional forms such as wood and charcoal and more modern forms such as the industrial burning of biomass wastes, the production of ethanol and biodiesel. While traditional biofuels have been in general decline as users switch to fossil fuels or electricity, they remain dominant energy sources in many less-developed parts of the world, such as Africa, and retain a niche in developed countries. The production of modern bioenergy is growing rapidly throughout the world in response to climate mitigation policies that incentivise their use, or as a strategy to decrease oil dependence and thus increase energy security (Cochrane and Barber, 2009). The WG III chapter on energy addresses their potential as a climate mitigation strategy, while the sensitivity of biofuel crops to climate change should be quite similar to those previously mentioned for plantation forestry (which to a large extent are grown for bioenergy purposes) and/or agricultural systems (WGII, chapter 7). In a review on climate change impacts on biofuel yields in temperate environments (Luckman and Kavanagh, 2000) it was concluded that elevated CO_2 might contribute to increase drought tolerance of bioenergy crops (as it is paralleled by improved plant water use), which may lead to constantly high yields. Generally, potentials of bioenergy production under climate change might be high, but are very uncertain (Ma and Zhou, 2012).

An important part to deal with here is the ecosystem impacts of large-scale land-use changes related to the growing of bioenergy biofuels. Policy shifts in OECD countries favor the expansion of biofuel production, sometimes at the expense of food crop production, and placing new pressures on terrestrial and freshwater ecosystems (Searchinger *et*

al., 2008; Lapola *et al.*, 2010). It is, for example, unclear if the global trend to reduced forest loss will continue - there are substantial pressures to deforest for the production of food and biofuels (Wise *et al.*, 2009; Meyfroidt and Lambin, 2011). Moiseyev *et al.*, (2011) found that in a 20 years perspective it is very little difference between the IPCC scenarios A1 and B2 regarding harvest level in Europe, and that the EU RES policy may only moderately influence the EU forestry and forest industries as long as the wood price paid by the bioenergy producers are below 50-60 US$ per m^3 wood. Under the assumption of doubling the growth rate of demand for bioenergy until 2030, a scenario by Martin *et al.* (2010) would lead to severe consequences for the global forest sector with a global reduction of forest stocks of 2 % or a 4% reduction for Asia.

Bioenergy potentials are strongly influenced by human food requirements (incl. feed required for livestock), thus integrated approaches to optimize food and bioenergy are needed (Ma and Zhou, 2012). Such considerations ignore areas for the conservation of biodiversity and ecosystems. These are more explicitly dealt with by McAlpine *et al.* (2009) and Millar *et al.* (2004), while in both papers the usage of abandoned land, which was previously under agricultural use, is regarded as an option for biomass production which reduces net warming. However, this ignores for example that such habitats may be core elements in cultural landscapes of high conservation value (many species rich grasslands in Europe have been croplands before and later abandoned), and that the productivity of such areas could be too limited for biofuels (Mishra *et al.*, 2010). As an alternative, Fargione (2011) discusses biofuel crop yield increases on existing cropland, with the aim to avoid expansion of agriculture.

4.3.3.5.3. Cultural landscapes

"Cultural landscapes are at the interface between nature and culture, tangible and intangible heritage, biological and cultural diversity—they represent a closely woven net of relationships, the essence of culture and people's identity" (Rössler, 2006, p. 334). They are characterized by a long history of human-nature interactions, where man is the main driver and has often created open landscapes, rich in structures and often also in species. A UNESCO Flagship programme focusses especially on cultural landscapes (Rössler, 2006). These landscapes nowadays are often about to lose their roles as recreational species rich entities due to agricultural intensification and extensification (Huntington *et al.*, 2012). Well researched examples are grassland or mixed agriculture landscapes in Europe or rice landscapes in Asia (Kuldna *et al.*, 2009), while such landscapes may well exist across the globe (e.g., Rössler, 2006; Heckenberger *et al.*, 2007).

In such landscapes, conservation efforts - as all across the globe - often focus on the conservation of ecosystems that contain endangered biotic communities. However, in such cultural landscapes this aim might be hard to achieve due to the very dynamic nature of systems. Keeping species in a favorable conservation status in cultural landscapes (one aim e.g. of European policies; EU Council, 1992), can normally only be achieved through appropriate management, as the vast majority of endangered species in the wider countryside depend on certain types of land use for their survival. This requires profound knowledge of the systems and species involved, and as this is rarely the case, conservation success was limited (see Kirdyanov *et al.*, 2012 for a notable exception).

As in many other cases, population and niche models are available and partly already validated (Kirdyanov *et al.*, 2012). This shows where future challenges are to be found: particularly in the quantification of relative importance of climate change in comparison with the habitat and its management (Settele and Kühn, 2009). So far the majority of changes can be attributed to land use as the most obvious driver (Nowicki *et al.*, 2007), while the impact of climate change can be readily detected in few examples (Devictor *et al.*, 2012), combined effects seem to better explain the overall picture (Schweiger *et al.*, 2008; Schweiger *et al.*, 2012), where attribution to climate change seems low to medium. As a consequence, it has been suggested to adjust the European Natura 2000 protected area network to take into account changing climatic conditions and to enable migration or dispersal of species across the landscape (Heubes *et al.*, 2011; Jin *et al.*, 2010).

4.3.3.5.4. Urban ecosystems

Over half of humanity lives in urban areas (see for definition in chapter 8) with a yearly increase of ca. 74 million people (United Nations *et al.*, 2012). Although urban areas cover only ca. 0.5 % of Earth's terrestrial surface (Schneider *et al.*, 2009) they harbor a large variety of species (McKinney, 2008). Urban areas are themselves drivers of climatic change as they are accounted for a significant proportion of total anthropogenic greenhouse gas emissions (Satterthwaite, 2008) and many urban centers are also heavily impacted by increased minimum and sometimes decreased maximum air temperatures, reduced or increased precipitation and altered biogeochemical cycles (Grimm *et al.*, 2008). An important threat to cities comes from extreme events. Many cities are located at coasts or rivers. However since there is *medium confidence* (based on physical conditions) that projected increases in heavy rainfall events would contribute to increases in local flooding (IPCC, 2012) there is *limited evidence* that urban areas will be over-proportionally affected by floods in the future, however, it is *very likely* that sea level will contribute to rise in future and hence affect coastal urban areas (IPCC, 2012). For the future it is *virtually certain* that the frequency and magnitude of warm days and nights (heat waves) will increase globally (IPCC, 2012). However Leonelli *et al.* (2011) projected with the integration of an urban land-surface model in the HadAM3 Global Climate Model a significant higher increase in the frequency of hot nights in urban areas compared to rural areas. Hence also the social aspects in urban areas (health status, outdoor activities) and urban infrastructures will be increasingly affected (IPCC, 2012). There is *high agreement* among scientists that urban climate effects (e.g., increased temperatures) nowadays are similar to projected changes of climatic variables at a local scale. Similar to all other ecosystems, ecological impacts of changing climatic factors in urban ecosystems will change species compositions as well as compositions of traits. Knapp *et al.* (2008b) found that traits compositions of urban plant communities are changing during urbanization towards adaptive characteristics of dry and warm environments. With increasing temperatures, this effect might to continue also in the future and will hence be exacerbated compared to non-urban surroundings. Urban areas are one of the main starting points for the establishment and dispersal of alien species (e.g. for plants through urban gardening; Li *et al.*, 2009). With increasing air temperatures especially in winter time and the warming effect of urban areas, the number of established alien plants in urban areas might increase (see also 4.2.4.6.). With increasing numbers of alien species, also the BVOC (Biogenic Volatile Organic Compounds) emissions from gardened alien plants will increase (Lloyd and Fastie, 2003; see also 4.2.4.6.).

4.3.4. Impacts on Key Services

Ecosystem services are the benefits which people derive from ecosystems [see glossary]. The classification system proposed by the Millennium Ecosystem Assessment (Millennium Ecosystem Assessment, 2003) is widely used. It recognises *provisioning services* such as food, fiber and water (also known as 'goods' in the economic literature, and which have their own chapters in this assessment); *regulating services* such as climate regulation, pollination, pest and disease control and flood control; *supporting services* (habitat services in TEEB) which are used by people indirectly, through other services, and include items such as primary production and nutrient cycling; and *cultural services* which include recreation, aesthetic and spiritual benefits. The list of ecosystem services is long and growing; and almost all are potentially vulnerable to climate change. The provisioning services are comprehensively dealt with in chapter 3 and chapter 7, and the tourism-based services in chapter 13. This chapter focusses on those regulating services where the link to climate change has been examined.

4.3.4.1. Habitat for Biodiversity

Climate change can alter habitat for species by inducing i) shifts in habitat distribution that are not followed by species, ii) shifts in species distributions that move them outside of their preferred habitats and iii) changes in habitat quality (Urban *et al.*, 2012; Dullinger *et al.*, 2012). There is some evidence that these climate change impacts have already occurred. For example, loss of sea ice is altering habitats for polar bears and may partially explain declines in polar bear populations in some area (see also Chapter 28). However, this is not yet a widespread phenomenon. Models of future shifts in biome, vegetation type and species distributions, on the other hand, suggest that many species could be outside of their preferred habitats with the next few decades due to climate change (Urban *et al.*, 2012).

Hole *et al.* (2009) report that the majority of African birds are projected to move large distances over the next 60 years resulting in substantial turnover of species within protected areas (>50% turnover in more than 40% of Important Bird Areas of Africa) and migration across unfavorable habitats. Many birds may find suitable climate in the large network of protected areas, but will be forced to cope with new habitat constraints. Similarly, Araujo *et al.*, 2011) indicate that approximately 60% of plants and vertebrate species would no longer have favorable climates within European protected areas, often pushing them into unsuitable or less preferred habitats. Wiens *et al.* (2011) project similar effects in the western US, but also find that climate change may open up new opportunities for protecting species in areas where climate is currently unsuitable. Indeed, in some changes climate change may allow some species to move into areas of lower current or future land use pressure including protected areas (Bomhard *et al.*, 2005). These and other studies strongly argue for a rethinking of protected areas networks and of the importance of the habitat matrix outside of protected areas as a key to migration and long-term survival of species.

Over sufficiently long periods, biomes or habitat types may shift their distributions or disappear entirely due to climate change. Non-analog climates are projected to occur in the future (Williams *et al.*, 2007b; Wiens *et al.*, 2011), and in the past climate shifts have resulted in vegetation types that have no current analog (section 4.2.2). The impacts of this on species abundance and extinction risk is difficult to evaluate because species may show substantial capacity to adapt to novel habitats (Prugh *et al.*, 2008; Willis and Bhagwat, 2009; Oliver *et al.*, 2009). This high uncertainty in habitat specificity for many species means it is not possible to predict if species extinctions due to climate induced loss of habitat will be below or far above current extinction rates caused by non-climate factors (Malcolm *et al.*, 2006). This does, however, also reinforce the idea that habitat quality across all components of landscapes will increase in importance for biodiversity conservation in the future.

Effects of climate change on habitat quality are less well studied than shifts in species or habitat distributions. However, several recent studies indicate that climate change may have and probably will alter habitat quality (Iverson *et al.*, 2011; Matthews *et al.*, 2011). For example, climate change induced changes in habitat quality due to decreasing snowfall may partially explain declining songbird populations in southwestern US (Martin and Maron, 2012).

4.3.4.2. Pollination, Pest and Disease Regulation

It can be inferred that global change will result in new communities (Schweiger *et al.*, 2010). As these will have experienced a much shorter (or even no) period of coevolution, drastic changes of ecological interactions like shifts in the use of certain plants by herbivores, in the range of prey of predators or in pollination networks are to be expected (Tylianakis *et al.*, 2008; Schweiger *et al.*, 2012). This might generally result in drastic changes in the provision of services (Montoya and Raffaelli, 2010).

Among the regulating services most strongly related to biodiversity, pollination and biocontrol of pests have to be highlighted. Climate change tends to increase the abundance of pest species particularly in previously cooler climates, but assessments of changes in impacts are hard to make (Payette, 2007). Insect pests are directly influenced, e.g. through the quality of food plants (Payette and Filion, 1985) or via the effects on their natural enemies (predators and parasitoids). Direct impacts are via the relatively high temperature optima of insects, which lead to increased vitality and reproduction (Allen *et al.*, 2010a). Mild winters in temperate areas promote frost susceptible pests. For the vast majority of indirect effects, e.g. spread of insect borne diseases, information is scarce (for further assessments on climate change effects on pest and disease dynamics see WGII, chapters 7 and 11).

Climate change, after land-use changes, can be regarded as the second most relevant factor responsible for the decline of pollinators (Potts *et al.*, 2010; for other factors see Biesmeijer *et al.*, 2006; Brittain *et al.*, 2010a; Brittain *et al.*, 2010b). While the potential influence of climate change on pollination can be manifold (compare Hegland *et al.*, 2009; Roberts *et al.*, 2011; Schweiger *et al.*, 2010), there are only few observations which mostly relate to the de-coupling of plants and their pollinators – especially in relation to phenology (Gordo and Sanz, 2005). While Peñuelas and Boada (2003) states that these phenological effects may be less than feared, an analysis of

phonological observations in plants Wolkovich *et al.* (2012) shows that experimental data on phenology may grossly underestimate phenological shifts. As Willmer's (2003) view is partly based upon experimental observations, it has to be seen whether field evidence might proof something different (compare Phenology Chapter 4.3.2.1.).

In relation to honeybees Le Conte and Navajas (2008) state that the generally observed decline is a clear indication for an increasing susceptibility against global change phenomena, with pesticide application, new diseases and stress (and a combination of these) as the most relevant causes. Climate change might contribute by modifying the balance between honeybees and their environment (incl. diseases). Honeybees also have shown a large capacity to adjust to a large variety of environments and their genetic variability should allow them to also cope with climatic change , that's why the preservation of genetic variability within honeybees is regarded as a central aim to mitigate climate change impacts (Le Conte and Navajas, 2008).

4.3.4.3. Climate Regulation Services

Ecosystems moderate the local climate through a range of mechanisms, including reducing the near-ground wind velocity, cooling the air through shading and the evaporation of water and ameliorating low temperatures through releasing heat absorbed during the day or summer. This service is widely recognized and valued, for instance in the establishment of windbreaks, gardens and urban parks. The focus of this section is on processes operating at much larger scales – the region to the whole globe. Terrestrial ecosystems affect climate at large scales through their influence on the physical properties of the land surface and on the composition of the atmosphere with respect to radiatively-active gases and particles. In the decade 2000-2010, approximately one fourth of the CO_2 emitted to the atmosphere by human activities was taken up by terrestrial ecosystems, reducing the rate of climate change proportionately (4.3.2.3, WG 1 Chapter 6).

One study (Arora and Montenegro, 2011) suggests that the overall effect of tropical afforestation on global temperature is up to 75% greater than would be expected on the basis of increased carbon storage alone, due to physical processes such as changes in evapotranspiration; but in other circumstances the cooling due to land-cover change may be *less* than that estimated from carbon uptake alone, due to decreased albedo (4.2.4.1). Observations and model evidence indicates that, broadly speaking, forests make warm areas cooler and cold areas warmer, through the competing effects of evapotranspiration (cooling) and surface albedo (in dark-canopied forests, generally warming). Model simulations suggest that if more than 40% of the pre-1700 extent of the Amazon forest were to be cleared, rainfall in the region would be reduced (Sampaio *et al.*, 2007). According to satellite observations, the effect of conversion of the Brazilian savannas (*cerrado*) to pasture is to induce a local warming, (Loarie *et al.*, 2011), which is partly offset when the pasture is converted to sugarcane. It has been suggested (Ridgwell *et al.*, 2009) that planting large areas of crop varieties with high-albedo leaves could help regional cooling. Model analysis indicates this strategy could be marginally effective at high latitudes, but have undesirable climate consequences at low latitudes, and measurements show that the current range of leaf albedo in major crops is insufficient to make a meaningful difference (Doughty *et al.*, 2011).

4.3.4.4. Potable Water Supply

Freshwater systems provide a range of ecosystem services that benefit society and are *likely* to be affected by climate change (see Table 4-1; Palmer and Filoso, 2009). Many of the implications of climate change on the provisioning services of water for food production and domestic supply are discussed in detail in WGII Chapter 3. Over 80% of the world's population is currently exposed to high levels of threat to water security because of land use change, pollution and water resource use (Vörösmarty *et al.*, 2010). Under climate change, reliability of surface water supply is *likely* to decrease due to increased temporal variations of river flow that are caused by increased variability in precipitation and decreased snow/ice storage (see WGII Chapter 3). In some Mediterranean regions, e.g. the southwest of Western Australia, significant reductions in surface flows have already forced governments to pursue alternative water sources (desalination, recycled wastewater) (see http://www.watercorporation.com.au/watersupply/index.html). In snow dominated regions, warming will mean that less winter precipitation falls as snow and melting of winter snow occurs earlier in spring (*high confidence*; Barnett

et al., 2005). This means a shift in peak discharge to winter and early spring and away from summer and autumn when human demand is highest. In some locations, water storages may not be sufficient to capture winter runoff, particularly if they are also used to safeguard downstream communities from flooding (Barnett *et al.*, 2005). Climate change not only poses risks to the quantity of water available for human society but also the quality. Warming will exacerbate many of the symptoms of eutrophication, including the increased frequency and intensity of harmful cyanobacterial blooms (Paerl and Paul, 2012). Reduced summer flows in rivers increases residence time for algal growth, increases the risk of low dissolved oxygen events and associated poor water quality, and limits the ability to dilute pollution from point sources (Jeppesen *et al.*, 2010).

4.4. Adaptation and its Limits

Wild organisms and ecosystems can adapt to climate change to some degree using intrinsic mechanisms such as migration, change in behavior and evolution: this is known as autonomous adaptation. These mechanisms rely on the availability of suitable habitat and a clear pathway to it; climate change that is sufficiently gradual to allow response by all organisms; and the retention of genetic variability. There are also biological limits to the magnitude of change which can be adapted to; for instance the tolerable body temperature of all warm-blooded animals falls within a narrow range (Clarke and Rothery, 2008). Where autonomous adaptation mechanisms are inadequate, human-assisted adaption is indicated as a supplementary approach.

4.4.1. Autonomous Adaptation by Ecosystems and Wild Organisms

Autonomous adaptation (see glossary) refers to the adjustments made by ecosystems, including their human components, without external intervention, in response to a changing environment (Smit *et al.*, 2000); also called 'spontaneous adaptation' (Smit *et al.*, 2007). In the context of human systems it is sometimes referred to as 'coping capacity'. The capacity for autonomous adaptation is necessary for resilience but is not synonymous with that term as it is now used (Walker *et al.*, 2004). Here we focus on adaptation to a changing climate in all its manifestations, recognizing that climate change in the narrow sense is necessarily associated with changing CO_2 and ozone, and in practice is usually accompanied by changing land use, abundance of competing or mutualistic organisms and other environmental stressors, such as pollution.

All systems have some capacity for autonomous adaptation, or they would not exist at all. Ecosystems which have persisted for a long time can reasonably be inferred to have a high capacity for autonomous adaptation, at least with respect to the variability which they have experienced in the past. Adaptability to one set of challenges does not automatically confer greater adaptive capacity to a different set of challenges, especially if those challenges are novel (i.e. outside the range of experience of the system). Furthermore, an environmental change that is more rapid than in the past or is accompanied by other stresses may exceed the previously-demonstrated adaptive capacity of the system. Adaptation at one level, for instance by organisms in a community, can confer greater resilience at higher organization levels, such as the ecosystem (Morecroft *et al.*, 2012). The mechanisms of autonomous adaptation of organisms and ecosystems consist of changes in the physiology, behavior, phenology or physical form of organisms, within the range permitted by their genes and the variety of genes in the population; changes in the genetic composition of the populations; and change in the composition of the community, either through in- or out-migration, or local extinction.

4.4.1.1. Phenological and Physiological

The ability to project future impacts of climate change on ecosystems is complicated by the potential for adaptations by species, which may alter apparent relationships between climate variables and species / ecosystem viability. Adaptation by individual species may increase their ability to survive and flourish under different climatic conditions, possibly leading to lower risks of extinction than predicted from statistical correlations between current distribution and climate (Botkin *et al.*, 2007), but may also affect their interdependence with other species leading to disruption of community interactions (Visser and Both, 2005).

Phenology is typically highly adapted to the climate seasonality of the environment in which the organism evolved. The phenology of any species also needs to be keyed to the phenology of other species with which it interacts, such as competitors, food species and pollinators. Thus change in phenology is a sensitive indicator of adaptation (Menzel *et al.*, 2006), but also a potential mechanism of ecosystem disruption if adaptation is insufficiently rapid or coordinated between interdependent species, or is cued to environmental signals that are not affected by climate change, such as day-length (Bradley *et al.*, 1999; Both and Visser, 2001; Parmesan, 2006). The environmental cues for phenological events are complex and multi-layered (Körner and Basler, 2010; Singer and Parmesan, 2010). For instance, late-succession temperate trees require a chilling period in winter, followed by a threshold in daylength, and only then are sensitive to temperature. As a result, projecting current phenological trends forward is risky, since the relative importance of cues can change (Cook *et al.*, 2012). The effects are complex and sometimes apparently counterintuitive, such as the increased sensitivity of flowering in high-altitude perennial herbs in the Rocky mountains to frost as a result of earlier snowmelt (Inouye, 2008).

The importance of adaptation and potential for disruption from different rates of phenological change are illustrated by the consequences of timing of migratory bird activities (see 4.3.2.1.). Breeding is most effective when synchronized with the availability of food, so changes in the phenology of food supplies can exert a selective pressure on birds. In a study of 100 European migratory bird species, those that advanced their arrival showed stable or increasing populations, while that did not adjust their arrival date on average showed declining populations (Møller *et al.*, 2008). In a comparison of nine Dutch populations of the migratory pied flycatcher (*Ficedula hypoleuca*) over two decades, populations declined by 90% in areas where food peaked early in the season and the arrival of the birds was mis-timed, unlike areas with a later food peak which can still be exploited by early-breeding birds (Both *et al.*, 2006). Selection for earlier laying dates has been shown to stronger in warmer years when food supply (caterpillars) peaked early (Coppack and Both, 2002). Systematic cross-taxa studies in the USA and UK indicate different rates of phenological change for different species and trophic levels (Parmesan, 2007; Cook *et al.*, 2008; Thackeray *et al.*, 2010).

It has been suggested that shorter generation times would give greater opportunity for autonomous adaptation through natural selection (Rosenheim and Tabashnik, 1991; Bertaux *et al.*, 2004), but a standardized assessment of 25,532 rates of phenological change for 726 UK taxa indicated that generation time only had limited influence (Thackeray *et al.*, 2010).

The physiological processes in organisms can either adapt through plasticity or genetically (i.e., through evolution). The former is generally regarded as rapid but limited, and the latter as less constrained, but slow (see 4.4.1.2) although long-term studies of a few organisms indicate rapid genetic adaptation to a changing climate (Bradshaw and Holzapfel, 2006). Acclimation to higher temperatures and/or higher CO_2 concentrations is seen in many organisms, but to very widely varying extents and general understanding remains limited (Hofmann and Todgham, 2010). A physiological process with large potential consequences for the global carbon cycle and thus the climate system is the sensitivity of the relationship between organism temperature and respiration rate, particularly in decomposer organisms (Jones *et al.*, 2003). The shape of the relationship varies between locations with different climates and shows apparent acclimation within months or years to a changing climate (Giardina and Ryan, 2000; Luo *et al.*, 2001; Rustad, 2001). The relationship is also dependent on C substrate type and the presence of other respiration-controlling environmental factors, complicating the determination of the inherent rate and its adaptation to a changing climate. Several competing hypotheses can explain the observed reduction in respiration rates in soil warming experiments after an initial peak – physiological adaptation; depletion of readily available substrate (Kirschbaum, 2004); and varying temperature sensitivities in different soil carbon pools (Knorr *et al.*, 2005).

4.4.1.2. Evolutionary and Genetic

Since the AR4 report there has been substantial progress in defining the concepts and tools necessary for documenting and predicting evolutionary and genetic responses to recent and future climate change, often referred to as "rapid evolution". Evolution can occur through many mechanisms including selection of existing resistant genes or genotypes within populations, hybridization, mutation and selection of new adaptive genes and perhaps

even through epigenetics (Chevin *et al.*, 2010; Chown *et al.*, 2010; (Lavergne *et al.*, 2010; Paun *et al.*, 2010; Hoffmann and Sgro, 2011; Anderson *et al.*, 2012b; Donnelly *et al.*, 2012; Franks and Hoffmann, 2012; Hegarty, 2012; Merilä, 2012; Bell, 2013; Zhang *et al.*, 2013). Mechanisms such as selection of existing genes and genotypes, hybridization and epigenetics can lead to adaptation in very few generations, while others, notably mutation and selection of new genes, typically take at least many tens of generations. This means that species with very fast life cycles, e.g., bacteria, should in general have greater capacity to respond to climate change than species with long life cycles such as large mammals and trees. Unfortunately, there remains a paucity of observational or experimental data that can be used for detection and attribution of climate signals and for validation of models and theory.

Observed Evolutionary and Genetic Responses to Rapid Changes in Climate - There is a small, but growing body of observational evidence supporting studies reviewed in the AR4 report that some species have adapted to recent climate warming or to climatic extremes through genetic responses (e.g., plants - Franks and Weis, 2008; Anderson *et al.*, 2012a; Hill *et al.*, 2011; vertebrates - Ozgul *et al.*, 2010; Husby *et al.*, 2011; Phillimore *et al.* (2010; Karell *et al.*, 2011; insects - Buckley *et al.*, 2012; van Asch *et al.*, 2012). For example, Karell *et al.* (2011) found increasing numbers of brown genotypes of the tawny owl in Finland over the course of the last 28 years and attributed it to fewer snow-rich winters, which creates strong selection pressure against the heritable white genotype. Phillimore *et al.* (2010) showed for the common frog in Britain, that population differences in earlier spawning due to increasing spring temperatures could be attributed largely to local genetic adaptation. Using a combination of models and observations Visser and colleagues have built a case for detection and attribution of genetic adaptation in an insectivorous bird (Husby *et al.*, 2011), and in a herbivorous insect that has tracked warming related changes in the budburst timing of its host tree (van Asch *et al.*, 2012). In contrast, many species appear to be maladapted to changing climates or to respond to recent warming through phenotypic plasticity, in part because factors such as limited standing genetic variation, weak heritability of adaptive traits or conflicting constraints on adaptation create low potential for rapid evolution (Knudsen *et al.*, 2011; Ketola *et al.*, 2012; Mihoub *et al.*, 2012; Merilä, 2012). Most studies of rapid evolution suffer from methodological weakness making it difficult to clearly demonstrate a genetic basis underlying observed phenotypic responses to environmental change (Gienapp *et al.*, 2008; Franks and Hoffmann, 2012; Hansen *et al.*, 2012; Merilä, 2012). When combined with recent progress on conceptual frameworks, rapid advances in quantitative genetics, genomics and phylogenetics will substantially improve the detection and attribution of genetic responses to changing climate over the next few years (Davis *et al.*, 2010; Salamin *et al.*, 2010; Hoffmann and Sgro, 2011).

The ability of species to adapt to new environmental conditions through rapid evolutionary processes can also be inferred from the degree to which environmental niches are conserved when environment is changed. There is good evidence that environmental niches are conserved for some species under some conditions (plants - Petitpierre *et al.* (2012; birds - Monahan and Tingley, 2012; review - Peterson *et al.*, 2011), but also evidence suggesting that environmental niches can evolve over time scales of several decades following invasion or changes in climate (Broennimann *et al.*, 2007; Angetter *et al.*, 2011; Konarzewski *et al.*, 2012; Leal and Gunderson, 2012; Lavergne *et al.*, 2013). The paleontological record also provides insight into past evolutionary response in the face of natural climate variation. In general, environmental niches appear to be broadly conserved through time although there is insufficient data to determine the extent to which genetic adaptation has attenuated range shifts and changes in population size (Peterson *et al.*, 2011; Willis and MacDonald, 2011). Phylogeographic reconstructions of past species distributions suggest that hybridization may have helped avoid extinctions during cycles of glaciation and could also play a key role in future adaptation (Soliani *et al.*, 2012; Hegarty, 2012). There is also new evidence that epigenetic mechanisms, such as DNA methylation, can play a role in heritable and potentially very rapid adaptation to climate (Paun *et al.*, 2010; Zhang *et al.*, 2013), but understanding of these mechanisms is too preliminary to know how important they are for adaptation to climate change.

Mechanisms Mediating Rapid Evolutionary Response to Future Climate Change - Studies of extent genetic variability across species ranges and models that couple gene flow with spatially-explicit population dynamics suggest that populations may respond to climate change in ways that are counterintuitive. In some cases, too much or too little gene flow to populations at range margins may have created fragile, maladapted populations, which is in contrast to the current wisdom that populations at the range margins may be best adapted to global warming (Bridle *et al.*, 2010; Hill *et al.*, 2011). Conversely, there is also evidence from experiments, models and observations that populations in the center of species ranges may in some cases be more sensitive to environmental change than those

at range boundaries (Bell and Gonzalez, 2009). Generalization will be complicated by the interactions between local adaptation, gene flow and population dynamics (Bridle *et al.*, 2010).

Substantial progress has been made since the AR4 report in developing models that can be used to explore whether genetic adaptation will be fast enough to track climate change. Models of long-lived tree species suggest that existing genetic variation may be sufficient to significantly attenuate negative impacts of future climate change (Kuparinen *et al.*, 2010; Kremer *et al.*, 2012), which is coherent with observations and experiments (Jump *et al.*, 2006, Jump *et al.*, 2008). However, these studies also indicate that adaptive responses will lag far behind even modest rates of projected rates of climate change, in large part due to the very long generation time of trees. In a species with much shorter generation times, the great tit (*Parus major*), Gienapp *et al.* (2013) found that modeled breeding times tracked climate change, but only at low to moderate rates of change. For a species with an even faster life cycle, van Asch *et al.*, (2007, 2012) predicted that rapid evolution of the phenological response of a herbivorous insect should have allowed it to track recent warming, which it has. This suggests substantial capacity for future adaptation in this insect since current and moderate future rates of future climate change are similar. Kearney *et al.* (2009) on the other hand found that rapid evolutionary responses only modestly affected modeled range shifts in a mosquito species in response to climate change. More broadly, Walters *et al.* (2012) found that modeled extinction risk in ecotherms - species that do not internally regulate their body temperature - is substantially reduced by genetic adaptation at rates of climate change that are roughly less than 0.02°C per generation. Based on these assumptions, species with short generation times such as most insects potentially have the capacity to genetically adapt to even the most rapid rates of projected climate change (Figure 4-6), but species with longer generation times could be at risk of extinction at moderate to high rates of climate change. Recent experimental work on "evolutionary rescue" shows that long-term avoidance of extinction through genetic adaptation to hostile environments can occur under certain conditions (Bell, 2013). Generalizations coming from experiments and theoretical work are that evolutionary rescue requires large initial genetic variation and population sizes and is accompanied by substantial loss of genetic diversity, reductions in population size and range contractions over many generations before population recovery (Bell, 2013; Schiffers *et al.*, 2013). Model-based projections must, however, be viewed with considerable caution because there are many evolutionary and ecological mechanisms that can either speed up or inhibit heritable adaptation to climate change that are not accounted for in most models (Cobben *et al.*, 2012; Norberg *et al.*, 2012; Kovach-Orr and Fussmann, 2013). In some cases, accounting for evolutionary processes in models even leads to predictions of enhanced maladaptation to climate change and more rapid population declines under certain conditions (Ferriere and Legendre, 2013). Phenotypic plasticity is thought to generally improve the odds of adaptation to climate change, but the extent to which it contributes to adaptive capacity depends a great deal on the costs of plasticity in terms of fitness (Chevin *et al.*, 2010). High plasticity in the face of climate change that has low costs can greatly improve the odds of adapting to climate change; however, plasticity that has high fitness costs can have much more modest effects on the odds of adaptation.

The AR4 report concluded that "projected rates of climate change are *very likely* to exceed rates of evolutionary adaptation in many species (*high confidence*)". Work since then provides a similar, but more nuanced view of rapid evolution in the face of climate change. There are few observational studies of rapid evolution and difficulties in detection and attribution, so there is only *medium confidence* that some species have responded to recent changes in climate through genetic adaptations, and insufficient evidence to determine if this is a widespread phenomenon (thus *low confidence* across all species). The lack of adaptation in some species to recent changes in climate, broad support for niche conservatism and models showing limited adaptive capacity especially in species with long generation times, all indicate that high rates of climate change (RCP8.5) will exceed the adaptive capacities of many species (*high confidence*). On the other hand, evidence from observations and models also indicates that there is substantial capacity for genetic adaptation to attenuate phenological shifts, population declines and local extinctions in many species, especially for low rates of climate change (RCP2.6) (*high confidence*). Projected adaptation to climate change is frequently characterized by population declines and loss of genetic diversity for many generations (*medium confidence*), thereby increasing species vulnerability to other pressures and potentially impacting ecosystem functioning and services.

4.4.1.3. Migration of Species

This mode of adaptation has been extensively dealt with in section 4.3.2.5. It is anticipated that the movement of species – individually and collectively – will continue in response to shifting climate patterns. Its effectiveness as an adaptation mechanism is constrained by three factors. First, the rate of migration for many species, in many regions of the world, is slower than the rate of movement of the climate envelope (see Figure 4-6). Second, the ecosystem interactions can only remain intact if all parts of the ecosystem migrate simultaneously and at the same rate. Thirdly, the contemporary landscape and drainage systems contain many barriers to migration, in the form of habitat fragmentation, roads, human settlements and dams.

4.4.2. Human-Assisted Adaptation

Human-assisted adaptation means a deliberate, external intervention with the intent of increasing the capacity of the target organism, ecosystem or social-ecological system to survive and function at an acceptable level in the presence of climate change (see glossary) It is also known as 'planned adaptation' (Smit *et al.*, 2007). This chapter focuses less on the adaptation of people, human communities and infrastructure, since they are the topics of WGII chapters 8 to 17, and more on non-human organisms and ecosystems, while acknowledging the importance of the human elements within the ecosystem. "Assistance" in this context means a range of actions, from ensuring the presence of suitable habitat and dispersal pathways and the reduction or removal of other stressors, to physically moving organisms, storing them and establishing them in new places. In addition to the other approaches assessed in this section, "Ecosystem-based Adaptation" provides an option that integrates the use of biodiversity and ecosystem services into climate change adaptation strategies in ways that can optimize co-benefits for local communities and carbon management, as well as reduce the risks associated with possible maladaption (see Box CC-EA). Note that there are risks associated with all forms human-assisted adaptation (see 4.4.4), particularly in the presence of far-from-perfect predictive capabilities (Willis and Bhagwat, 2009).

4.4.2.1. Reduction of Non-Climate Stresses and Restoration of Degraded Ecosystems

The alleviation of other stresses acting on ecosystems is suggested to increase the capacity of ecosystems to survive, and adapt to, climate change, since the effects are generally either additive or compounding. Ecosystem restoration is one way of alleviating such stresses while increasing the area available for adaptation (Harris *et al.*, 2006). Building the resilience of at-risk ecosystems by identifying the full set of drivers of change and most important areas and resources for protection is the core of the adaptation strategy for the Arctic (Christie and Sommerkorn, 2012). 'Ecosystem-based adaptation' is the phrase increasingly used to cover a package of protective and restorative actions aimed at increasing resilience (e.g. Colls *et al.*, 2009).

4.4.2.2. The Size, Location and Layout of Protected Areas

Additions to, or reconfigurations of, the protected area estate are commonly suggested as pre-adaptations to projected climate changes (Heller and Zavaleta, 2009). This is because for most protected areas, under plausible scenarios of climate change, a significant fraction of the biota will no longer have a viable population within the present protected area footprint. It is noted that the extant geography of protected areas is far from optimal for biodiversity protection even under the current climate; that it is cheaper to acquire land proactively in the areas of projected future bioclimatic suitability than to correct the current non-optimality and then later add on areas to deal with climate change as it unfolds (Hannah *et al.*, 2007)); and that the existing protected area network will still have utility in future climates, even though it may contain different species. Hickler *et al.* (2012) analyzed the layout of protected areas in Europe and concluded that under projected 21st century change and concluded that a third to a half of them would potentially be occupied by different vegetation than they currently represent. The new area that needs to be added to the existing protected area network to ensure future representativeness is situation-specific, but some general design rules apply: orientation along climate gradients (e.g., altitudinal gradients) is more effective than orientation across them (Roux *et al.*, 2008); regional scale planning is more effective than treating each local case

independently (Heller and Zavaleta, 2009); since it is the network of habitats and protected areas that confers resilience rather than any single element; and better integration of protected areas with a biodiversity-hospitable landscape outside is more effective than treating the protected areas as islands (Willis and Bhagwat, 2009).

4.4.2.3. Landscape and Watershed Management

The general principles for management adaptations in United States were summarized from a major literature review by West *et al.*, 2009. They suggest that in the context of climate change a successful management of natural resources will require cycling between 'managing for resilience'' and ''managing for change". This requires the anticipation of changes that can alter the impacts of grazing, fire, logging, harvesting, recreation, and so on. At the national level, the necessary changes in practice to facilitate adaptation include: (1) management at appropriate scales, and not necessarily the scales of convenience or tradition; (2) increased collaboration among agencies; (3) rational approaches for establishing priorities and applying triage; and (4) management with the expectation of ecosystem change, rather than keeping them as they have been. Barriers and opportunities were divided into four categories: (1) legislation and regulations, (2) management policies and procedures, (3) human and financial capital, and (4) information and science.

In 14,000 ha of forested watersheds in central Nova Scotia, Canada, the adaptation to climate change was assessed using the landscape disturbance model LANDIS-II, (Steenberg *et al.*, 2011). The study simulated the impact of three components of timber harvesting: the canopy-opening size of harvests, the age of harvested trees within a stand, and the species composition of harvested trees within a stand. The combination of all three adaptation treatments allowed target species and old forest to remain reasonably well represented without diminishing the timber supply. This minimized the trade-offs between management values and climate adaptation objectives.

4.4.2.4. Assisted Migration

Assisted migration has been proposed when fragmentation of habitats limits migration potential or when natural migration rates are outstripped by the pace of climate change, (Hoegh-Guldberg *et al.*, 2008; Vitt *et al.*, 2010; Chmura *et al.*, 2011; Loss *et al.*, 2011). The options for management can be summarized as: i) try to maintain or improve existing habitat so that species don't have to move, ii) maintain or improve migration corridors, including active management to improve survival along the moving margin of the distribution (Lawson *et al.*, 2012), or iii) intervene heavily by translocating species (Hoegh-Guldberg *et al.*, 2008; Loss *et al.*, 2011). There is *low agreement* in the scientific community whether it is best to increase the resilience of ecosystems to climate change, thus help to preserve existing communities, or to enhance the capacity of ecosystems to transform in the face of the overwhelming forces of species migration and modifications of ecosystem function by climate change.

There is *high agreement* among the scientific and conservation community that maintaining or improving migration corridors or ecological networks is a low-regret strategy, partly because it is also seen as useful in combatting the negative effects of habitat fragmentation on population dynamics (Hole *et al.*, 2011; Jongman *et al.*, 2011). This approach has the benefit of improving the migration potential for large numbers of species and is therefore a more ecosystemic approach than assisted migration for individual species. However, observational and modeling studies show that increases in habitat connectivity do not always improve the population dynamics of target species, may decrease species diversity, and may also facilitate the spread of invasive species (Cadotte, 2006; Brisson *et al.*, 2010; Matthiessen *et al.*, 2010).

There is *medium agreement* that the practice of assisted migration of targeted species is a useful adaptation option (Hoegh-Guldberg *et al.*, 2008; Loss *et al.*, 2011; Vitt *et al.*, 2009; Willis and Bhagwat, 2009; Hewitt *et al.*, 2011). The speed of 21st century climate change and substantial habitat fragmentation in many areas of the world mean that many species will be unable to migrate or adapt fast enough to keep pace with climate change. If this results in significant reductions in range size it will pose problems for long-term survival of the species. Some ecologists believe that careful selection of species to be moved would minimize the risk of undesirable impacts on existing communities or ecosystem function (Minteer and Collins, 2010), but others argue that the history of intentional

species introductions shows that the outcomes are unpredictable and in many cases have had disastrous impacts (Ricciardi and Simberloff, 2009). The number of species that could potentially require assisted migration that could easily overwhelm funding capacity (Minteer and Collins, 2010).The degree and magnitude of phenotypic responses or genetic adaptation to climate change are very variable among species, making decisions regarding which species should be translocated complex and debatable.

4.4.2.5. Ex Situ Conservation

Conservation of plant and animal genetic resources outside of their natural environment, in gardens, zoos, breeding programmes, seed-banks or gene-banks has been widely advocated as an 'insurance' against both climate change and other sources of biodiversity loss and impoverishment (Khoury *et al.*, 2010). There are many examples of existing efforts of this type, some very large and with global scope (e.g. Millennium Seed Bank, Svalbard vault). The Dixon National Tallgrass Prairie Seed Bank is an example of prioritization of species for seed banking, both for restoration purposes and for potential assisted migration in the future (Leishman *et al.*, 2007). A genome scan approach identified four potentially adaptive loci in important grassland species *Arrhenatherum elatium.* Knowledge on adaptive loci might in the long run also help to adapt ecosystems to adverse climate change effects through assisted migration of ecotypes rather than introduction of new species (Colautti *et al.*, 2010).

Several issues remain largely unresolved (Li and Pritchard, 2009). The physiological, institutional and economic sustainability of such efforts into the indefinite future is unclear. The fraction of the intra-specific variation that needs to be preserved for future viability and how much genetic bias is introduced by founder effects and selection pressures applied during ex-situ maintenance is unknown. It remains uncertain whether it is possible to reintroduce species (especially animals) successfully into the wild after generations of ex-situ conservation.

4.4.3. Consequences and Costs of Inaction and Benefits of Action

Failure to act to assist ecosystem adaptation to climate change will plausibly leads to ecological, social and economic *damages*. The necessary actions to cope with unavoidable damages generate *adaptation costs*, while *mitigation costs* are associated with actions to tackle undesired future damages. Examples of these costs, based on recent literature, are shown in Table 2-5 in Rodriguez-Labajos (submitted). The timing of the action also has cost implications: increasing costs that result from must be weighed against the risks associated with premature measures (Szlavik and Csete, 2012). In addition to the direct financial costs of action, further costs may appear through trade-offs between services: e.g. afforestation for climate mitigation is costly in terms water provision (Chisholm, 2010). Traditional agriculture preserves soil carbon sinks, supports on-site biodiversity and uses less fossil fuel than high-input agriculture (Martinez-Alier, 2011), but due to the lower per hectare yields, requires a larger area to be dedicated to cropland.

A comprehensive cost estimate of the effects of climate change on ecosystem service provision is not available. ten Brink *et al.* (2008) report the monetary cost of not meeting the 2010 biodiversity goals in terms of lost value of ecosystem services. Their model incorporates climate change, among other pressures, and concludes that cumulative losses of welfare due to losses in ecosystem service provision could reach an annual amount of 14 trillion Euro (based on values of 2007), in 2050 equivalent to 7% of projected global GDP for that year.

Economic calculations are appropriate when at least one component of the ecosystem services is traded in markets (such as for biofuels; Mishra *et al.*, 2010). If climate regulation services are translated into a tradable item, through carbon markets or payments for avoiding deforestation, then their value can be expressed via market prices (Shaw *et al.*, 2011).

The market price for carbon is volatile, linked to speculation and political agreements on emission reduction. There is a range of estimates from $23/metric ton of carbon to $371, in current 1995 and 2007 dollars respectively (Tol, 2008; Watkiss and Downing, 2008). In the South-African Fynbos region, economic viability of afforestation proved to be highly sensitive to the value of carbon (Chisholm, 2010). The realized prices of the traded carbon have been on

average lower than the figures mentioned above. The proposed global REDD programs, financed by carbon-offset trading, rely on the premises on which market-based payment for ecosystem services (PES) are founded. However, a decade of PES experience demonstrates a clash between market-efficiency criteria and poverty reduction and therefore a risk of regressive wealth redistribution (McAfee, 2012).

Uncertainty about the potential consequences of abrupt changes advises against valuation of ecosystems close to critical thresholds (TEEB, 2009). Similar difficulties can be argued in the presence of irreversible changes, as in the case of irreversible biodiversity losses or damage to cultural services such as World Heritage sites (Viles and Cutler, 2012).

4.4.4. Unintended Consequences of Adaptation and Mitigation Actions in This and Other Sectors

Some issues relevant to this section are also found in 4.2.2 and in Chapter 14.

Several of the alternatives to fossil fuel require extensive use of the land surface. Bio-energy requires land to either be taken from food production or from natural ecosystems. Many renewables require significant land areas. Hydroelectricity usually involves the impoundment of large bodies of water behind dams, leading to flooding of pre-existing ecosystems. Solar energy effectively involves decreasing the albedo of areas of ground surface. Large-scale wind energy involves the location of arrays of turbines across the landscape. As an illustration, the "aggressive mitigation" scenario RPC2.6 relies heavily on both bio-energy and renewables as major components of the energy mix (van Vuuren *et al.*, 2011), so there is clear potential for unintended consequences for terrestrial and inland water systems.

In RCP2.6, although food production remains dominant, the scenario still involves some land use / land-cover change (Box 4-1) in order to facilitate the use of bio-energy. By 2100, bio-energy crops occupy approximately 4 million km^2, approximately 7% of global cultivated land projected at the time. Modification of the landscape and the fragmentation of habitats are major influences on extinction risk (Fischer and Lindenmayer, 2007), especially if native vegetation cover is reduced or degraded, human land use is intensive and "natural" areas become disconnected. Hence, additional extensification of cultivated areas for energy crops may pose extinction risks.

RCP2.6 also includes a substantial increase in renewables above current levels of deployment, either as hydropower, solar or wind. Damming of river systems for hydropower can cause fragmentation of the inland water habitat with implications for fish species, and monitoring studies indicate that flooding of ecosystems behind the dams can lead to declining populations, e.g., of amphibians (Brandão and Araújo, 2007). Large dams may also result in CH_4 emissions due to decay of flooded vegetation in anaerobic conditions and the subsequent release of CH4 from the water surface and especially from water passing through turbines and spillways (Fearnside, 2005; Lima *et al.*, 2008), so dams may act as sources of greenhouse gas emissions.

Concern is often raised over wind turbines posing a danger to birds and bats, but estimating mortality rates is complex and difficult (Smallwood, 2007). It has been estimated that wind farms in Europe and the USA cause between 0.3 and 0.4 wildlife fatalities per gigawatt-hour (GWh) of electricity, and while nuclear and fossil-fuel power stations are estimated to cause approximately 5.2 fatalities per GWh (Sovacool, 2009), although this quantification has been criticized as having key methodological flaws (Willis *et al.*, 2010b). One study found on-site bird populations to be generally affected more by windfarm construction than subsequent operation, with some populations recovering after construction (Pearce-Higgins *et al.*, 2012)

Solar energy systems, by design, aim to maximize the absorption of solar energy and hence widespread deployment of photovoltaics (PV) has the potential to exert a positive radiative forcing on climate through decreased surface albedo. In a scenario of widespread deployment of solar PV, such a forcing is estimated to be 30 times smaller than the avoided radiative forcing arising from the use of PV to substitute fossil fuels, so overall PV still exerts a net reduction of climate warming (Nemet, 2009). Nevertheless, at the local scale there are some plausible circumstances in which the decreased surface albedo substantially reduces the effectiveness of PV as a negative climate forcing (Nemet, 2009).

Adaption measures may also result in unintended consequences. Relocation of agricultural areas as a climate change adaptation measure could pose risks of habitat fragmentation and loss similar to those discussed above in the context of mitigation through bio-energy. Deliberate relocation of vulnerable and important species – assisted migration – may also be a potential conservation measure in the context of facilitating adaptation to climate change (Maclachlan *et al.*, 2007). However this may directly conflict with other conservation priorities, for example by actually facilitating the introduction of invasive species (Maclachlan *et al.*, 2007).

Proactive adaptation measures may also have unforeseen consequences politically. Carey *et al.* (2011) argue that improved water management in a glacial lake in the Peruvian Andes in 1985 led to increased tensions over many years and ultimately local civil action against the authorities in 2008. Introduction of a tunnel to reduce the risk of a glacial lake outburst flood facilitated proactive human management of the lake levels, but in the context of changes in the wider political situation, power struggles arose between different stakeholders due to different and conflicting interests. This may provide an example of how attempts by society to exert more direct control over the environment can lead to unintended impacts.

4.5. Emerging Issues and Key Uncertainties

The presence of thresholds in ecosystem response to climate change, and specifically the type of thresholds characterized as “tipping points’, is a growing concern but remains a major source of uncertainty. In general (Field *et al.*, 2007), negative feedbacks currently dominate the climate-ecosystem interaction, but in several areas, such as the boreal ecosystems, positive feedbacks could dominate, even under moderate warming. For most ecological processes, increasing magnitude of warming shifts the balance towards positive rather than negative feedbacks (Field *et al.*, 2007). For positive feedbacks to propagate into ‘runaway’ processes leading to a new ecosystem state, the strength of the feedback has to exceed that of the initial perturbation. This has not as yet been demonstrated for any large-scale, plausible and immanent ecological process; but the risk is non-negligible and the consequences if it did occur would be severe: thus further research is needed. The issue of biophysical feedbacks between ecosystem state and the climate, over and above the effects mediated through greenhouse gases, is emerging as significant in many areas. Such effects include those caused by changes in surface reflectivity (albedo) or the partitioning of energy between latent energy and sensible heat.

Uncertainty in predicting the response of ecosystems to climate and other perturbations remains a major impediment to determining prudent levels of permissible change. A significant source of this uncertainty stems from the inherent complexity of ecosystems, especially where they are coupled to equally-complex social systems. The high number of interactions can lead to cascading effects (Biggs *et al.*, 2011). Some of this uncertainty can be removed by understanding the systems better, but some will remain irreducible because of the failure of predictive models when faced with mathematical bifurcations – a problem that is well-known in climate science. Probabilistic statements about the range of outcomes are possible in this context, but ecosystem science is mostly as yet unable to conduct such analyses routinely and rigorously. One consequence is the ongoing difficulty in attributing observed changes unequivocally to climate change. More comprehensive monitoring is a key element of the solution.

Studies of the combined effects of multiple simultaneous elements of global change, such as the effects of elevated carbon dioxide and rising tropospheric ozone on plant productivity - which has critical consequences for the suture sink strength of the biosphere, since they of similar magnitude but opposite sign – are needed as a supplement to the single-factor experiments.

Understanding of the tolerable *rate* of climate change is as important as understanding the tolerable *magnitude.* Despite being explicitly required under Article 2 of the UNFCCC, rate studies are currently less developed and more uncertain than magnitude (equilibrium) studies. This includes evidence for the achievable migration rates of a range of species as well as the rate of micro-evolutionary change.

The costs of assisted adaptation ecosystems, biodiversity and ecosystem services to a changing climates is poorly known, as are the costs of failing to do so.

Frequently Asked Questions

FAQ 4.1: How does climate change contribute to species extinction?

Species extinctions are of considerable concern because they represent irreplaceable losses of unique life forms and because species loss has been shown to degrade the functioning of ecosystems in some cases. Most species extinctions in the recent past can be attributed to habitat destruction, invasive species, overexploitation and pollution. Climate change may have already contributed to the extinction of a small number of species, such as frogs and toads in Central America, but the role of climate change in these current extinctions is the subject of considerable debate. Over the coming century, climate change is foreseen to increase extinction risk because some species will not be able to adapt to new environments, nor move areas where climate becomes suitable. There is consensus that minimizing climate change will help protect species from extinctions. Under the highest rates of projected climate change, observations and models indicate that many species will be unable to move fast enough to track suitable climate or their ranges will shrink considerably. There is concern that this will substantially increase extinction risk for a large fraction of species, especially when combined with other global change pressures such as habitat destruction. We are, however, currently unable to accurately quantify this risk. Under the lowest projected rates and amounts of climate change and with the assistance of effective conservation actions, the large majority of species are foreseen to be able to adapt to the new climates, or respond by moving to higher latitudes or altitudes.

FAQ 4.2: Why does it matter that ecosystems are altered by climate change?

Ecosystems are the machinery that delivers things essential for all people, everywhere in the world – including obvious items like food, clean water and timber, but also less-obvious ones such as control of pests and diseases, regulation of the climate and a life-supporting atmosphere and pollination of flowers. When ecosystems change, their capacity to supply these services changes as well, for better or worse. Humans are directly affected, as are the millions of other species dependent on ecosystems. ”Ecosystem change” includes the species it contains and in what amounts and proportions, how the ecosystem looks (e.g. tall or short, open or dense) and how it works (e.g. whether it is productive or unproductive). Climate change, among other factors, has an effect on all these aspects of ecosystems, as well as on the total area occupied by particular ecosystems and its geographical location. Ecosystem change has knock-on effects on many sectors, including human health through altering where diseases are found, agriculture through grazing supply and pollinators, infrastructure through changing risks of flooding. Although in the long-term not all ecosystem changes are detrimental to all people or all species, rapidly-changing ecosystems will require adaptation, perhaps in excess of their adaptive capacity, by both the people and organisms dependent on them.

FAQ 4.3: What are the non-greenhouse gas effects of rising carbon dioxide?

Some greenhouse gases exert influences on the environment other than their impact on radiative forcing. The concentration of carbon dioxide affects photosynthesis and transpiration in plants, with photosynthesis generally being enhanced under higher CO_2 concentrations while transpiration is generally decreased. The growth of plants and/or the efficiency with which they use water can therefore be increased. The response varies considerably between species. Increased atmospheric CO_2 concentration also increases the acidity of water, with negative consequences for organisms with calcium carbonate shells, which cannot be grown under low pH.

FAQ 4.4: What costs are caused by changes in ecosystem services due to climate change?

Climate change will certainly alter the services provided by in ecosystems, and on balance, for high degrees of change, in an overall negative way. For instance, coral reefs protect the coast against extreme storm events, which are predicted to increase under climate change – but the reefs are at risk due to bleaching induced by temperature rise, as well as due to ocean acidification. This service alone has been valued at several 1000 $/ha per hour. Other costly damages could include a decrease in pollination services due to climate change related asynchrony of flowering time of plants and activity periods of pollinators. This service is worth worth EUR 153 billion per year (a value that nearly doubles if you take into account purchasing power parity of the affected countries)

FAQ 4.5: What are the opportunities for better managing ecosystems under climate change?

Management of ecosystems can help to mitigate climate change . Forests, for example deliver a wide set of services, including climate regulation. Ecosystems can also be managed to increase their ability to cope with climate change. Reducing the many other stresses on ecosystems – such as excessive harvest, habitat fragmentation and pollution is an important strategy. Maintaining biological diversity and near-natural disturbance regimes also helps. We may need to take drastic action such as assisting species to migrate, or protecting them out of the wild until such time as they can be reintroduced.

FAQ 4.6: Can land-use and land-cover changes cause changes in climate?

Land-use change can affect the local climate, and even the global climate. It does so by changing the emission or uptake of greenhouse gases, but also by changing how much solar energy is absorbed by the land surface. Depending on the type of change and where it occurs, the effects can be either warming or cooling. The effects on precipitation are equally variable and context-dependent. At a global scale, the conversion of forests to croplands, pastures and urban areas is currently contributing around a fifth of the overall emissions of the greenhouse gases which are causing climate change.

FAQ 4.7: Will the number of alien species increase due to climate change?

An alien species, also called exotic or non-native species is one that has been introduced to a region outside of its native geographic range as a deliberate or accidental consequence of human activity. They are called invasive when they cause ecological and/or economic damages as well as if they spread fast and produced a high amount of fertile offspring. The number of new species and the abundance of some already established alien species will increase in certain areas, such as polar regions, due to climate change improving conditions for these species, e.g. higher winter temperatures or longer growing seasons. Increased globalization of goods and human transportation and increased global land use changes are both likely to increase the frequency, establishment and damages of alien invasive species throughout the world although management actions to prevent the transfer of alien species (e.g. through treatment of ballast water and wood products and strict quarantine protocols applied to crop and horticultural products and embargos on trade and deliberate introductions of known invaders) are more and more applied. Some invasive plants and insects have already been shown to benefit from climate change and will likely establish and spread into new regions, once they are introduced there. However, other invasive species will suffer from climate change and, as for most of the biodiversity, are expected to decrease in range and population size in some regions. Within just the Family of ants, some highly invasive species are expected to benefit from climate change and increase their potential invasive areas, while some others will likely much recede.

Generally, increased establishment success and spread will be most visible for those alien species that have characteristics favored by the changing climate, such as those that are drought tolerant or able to take advantage of higher temperatures.

Box CC-EA. Ecosystem Based Approaches to Adaptation - Emerging Opportunities

[Rebecca Shaw (USA), Jonathan Overpeck (USA), Guy Midgley (South Africa)]

Ecosystem-based approaches to adaptation (also termed Ecosystem-based Adaptation, EBA) integrate the use of biodiversity and ecosystem services into climate change adaptation strategies (e.g., CBD, 2009; Munroe *et al.*, 2011; Munroe *et al.*, 2011). EBA is implemented through the sustainable management of natural resources, as well as conservation and restoration of ecosystems, to provide and sustain services that facilitate adaptation both to climate variability and change (Colls *et al.*, 2009). The CBD COP 10 Decision X/33 on Climate Change and Biodiversity states further that effective EBA also “takes into account the multiple social, economic and cultural co-benefits for local communities”.

The potential for EBA is increasingly being realized (e.g., Munroe *et al.*, 2011), offering opportunities that integrate with or even substitute for the use of engineered infrastructure or other technological approaches. Engineered defenses such as dams, sea walls and levees, may adversely affect biodiversity, resulting in maladaptation due to damage to ecosystem regulating services (Campbell *et al.*, 2009, Munroe *et al.*, 2011). There is some evidence that

the restoration and use of ecosystem services may reduce or delay the need for these engineering solutions (CBD, 2009). Well-integrated EBA is also more cost effective and sustainable than non-integrated physical engineering approaches, and may contribute to achieving sustainable development goals (e.g., poverty reduction, sustainable environmental management, and even mitigation objectives), especially when they are integrated with sound ecosystem management approaches. EBA also offers lower risk of maladaptation than engineering solutions in that their application is more flexible and responsive to unanticipated environmental changes.

EBA provides opportunities particularly in developing countries where economies depend more directly on the provision of ecosystem services (Vignola *et al.*, 2009), to reduce risks to climate change impacts and ensure that development proceeds on a pathways that are resilient to climate change (Munang *et al.*,). In these settings, ecosystem-based adaptation projects may be readily developed by enhancing existing initiatives, such as community-based adaptation and natural resource management approaches (e.g., Khan *et al.*, 2012, Midgley *et al.*, 2012; Roberts *et al.*, 2012)

Examples of ecosystem based approaches to adaptation include:

- Sustainable water management, where river basins, aquifers, flood plains, and their associated vegetation are managed or restored to provide resilient water storage and enhanced baseflows, flood regulation services, reduction of erosion/siltation rates, and more ecosystem goods (e.g., Midgley *et al.*, 2012, Opperman *et al.*, 2009).
- Disaster risk reduction through the restoration of coastal habitats (e.g., mangroves, wetlands and deltas) to provide effective measure against storm-surges, saline intrusion and coastal erosion;
- Sustainable management of grasslands and rangelands to enhance pastoral livelihoods and increase resilience to drought and flooding;
- Establishment of diverse and resilient agricultural systems, and adapting crop and livestock variety mixes to secure food provision. Traditional knowledge may contribute in this area through, for example, identifying indigenous crop and livestock genetic diversity, and water conservation techniques;
- Management of fire-prone ecosystems to achieve safer fire regimes while ensuring the maintenance of natural processes.

It is important to assess the appropriate and effective application of EBA as a developing concept through learning from work underway, and to build understanding of the social and physical conditions that may limit its effectiveness. Application of EBA, like other approaches, is not without risk, and risk/benefit assessments will allow better assessment of opportunities offered by the approach.

Box CC-RF. Impact of Climate-Change on Freshwater Ecosystems due to Altered River Flow Regimes

[Petra Döll (Germany), Stuart E. Bunn (Australia)]

It is widely acknowledged that the flow regime is a primary determinant of the structure and function of rivers and their associated floodplain wetlands, and flow alteration is considered to be a serious and continuing threat to freshwater ecosystems (Bunn and Arthington, 2002; Poff and Zimmerman, 2010; Poff *et al.*, 2010). Most species distribution models do not consider the effect of changing flow regimes (i.e. changes to the frequency, magnitude, duration and/or timing of key flow parameters) or they use precipitation as proxy for river flow (Heino *et al.*, 2009).

There is growing evidence that climate change will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (Aldous *et al.*, 2011; Xenopoulos *et al.*, 2005). By the 2050s, climate change is projected to impact river flow characteristics like long-term average discharge, seasonality and statistical high flows (but not statistical low flows) more strongly than dam construction and water withdrawals have done up to the year 2000 (Figure RF-1; Döll and Zhang, 2010). For one climate scenario, 15% of the global land area may suffer, by the 2050s, from a decrease of fish species in the upstream basin of more than 10%, as compared to only 10% of the land area that has already suffered from such decreases due to water withdrawals and dams (Döll and Zhang, 2010). Climate change may exacerbate the negative impacts of dams for freshwater ecosystems but may also provide opportunities for operating dams and power stations to the benefit of riverine ecosystems. This is the case if total runoff increases and, like in Sweden, the annual hydrograph becomes more similar to variation in electricity demand, i.e. with a lower spring flood and increased run-off during winter months (Renofalt *et al.*, 2010).

[INSERT FIGURE RF-1 HERE
Figure RF-1: Impact of climate change on the ecologically relevant river flow characteristics mean annual river flow and monthly low flow Q_{90} as compared to the impact of water withdrawals and dams on natural flows, as computed by a global water model (Döll and Zhang, 2010). Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002.]

Because biota are often adapted to a certain level of river flow variability, the larger variability of river flows that is due to increased climate variability is *likely* to select for generalist or invasive species (Ficke *et al.*, 2007). The relatively stable habitats of groundwater-fed streams in snow-dominated or glacierized basins may be altered by reduced recharge by meltwater and as a result experience more variable (possibly intermittent) flows (Hannah *et al.*, 2007). A high-impact change of flow variability is a flow regime shift from intermittent to perennial or vice versa. It is projected that until the 2050s, river flow regime shifts may occur on 5-7% of the global land area, mainly in semi-arid areas (Döll and Müller Schmied, 2012; see Chapter 3, Table 3-2).

In Africa, one third of fish species and one fifth of the endemic fish species occur in eco-regions that may experience a change in discharge or runoff of more than 40% by the 2050s (Thieme *et al.*, 2010). Eco-regions containing over 80% of Africa's freshwater fish species and several outstanding ecological and evolutionary

phenomena are *likely* to experience hydrologic conditions substantially different from the present, with alterations in long-term average annual river discharge or runoff of more than 10% due to climate change and water use (Thieme *et al.*, 2010).

Due to increased winter temperatures, freshwater ecosystems in basins with significant snow storage are affected by higher river flows in winter, earlier spring peak flows and possibly reduced summer low flows (chapter 3.2.3). Strongly increased winter peak flows may lead to a decline in salmonid populations in the Pacific Northwest of the USA of 20-40% by the 2050s (depending on the climate model) due to scouring of the streambed during egg incubation, the relatively pristine high-elevation areas being affected most (Battin *et al.*, 2007). Reductions in summer low flows will increase the competition for water between ecosystems and irrigation water users (Stewart *et al.*, 2005). Ensuring environmental flows through purchasing or leasing water rights and altering reservoir release patterns will be an important adaptation strategy (Palmer *et al.*, 2009).

Observations and models suggest that global warming impacts on glacier and snow-fed streams and rivers will pass through two contrasting phases (Burkett *et al.*, 2005; Vuille *et al.*, 2008; Jacobsen *et al.*, 2012). In the first phase, when river discharge is increased due to intensified melting, the overall diversity and abundance of species may increase. However, changes in water temperature and stream-flow may have negative impacts on narrow range endemics (Jacobsen *et al.*, 2012). In the second phase, when snowfields melt early and glaciers have shrunken to the point that late-summer stream flow is reduced, broad negative impacts are foreseen, with species diversity rapidly declining once a critical threshold of roughly 50% glacial cover is crossed (Figure RF-2).

[INSERT FIGURE RF-2 HERE
Figure RF-2: Accumulated loss of regional species richness (gamma diversity) as a function of glacial cover GCC. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%. Each data point represents a river site and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.]

River discharge also influences the response of river temperatures to increases of air temperature. Globally averaged, air temperature increases of 2°C, 4°C and 6°C are estimated to lead to increases of annual mean river temperatures of 1.3°C, 2.6°C and 3.8°, respectively (van Vliet *et al.*, 2011). Discharge decreases of 20% and 40% are computed to result in additional increases of river water temperature of 0.3° C and 0.8°C on average (van Vliet *et al.*, 2011). Therefore, where rivers will experience drought more frequently in the future, freshwater-dependent biota will suffer not only directly by changed flow conditions but also by drought-induced river temperature increases, as well as by related decreased oxygen and increased pollutant concentrations.

Box CC-VW. Active Role of Vegetation in Altering Water Flows Under Climate Change

[Richard Betts (UK), Dieter Gerten (Germany), Petra Döll (Germany)]

Terrestrial vegetation dynamics, carbon and water cycles are closely coupled, for example by the simultaneous transpiration and CO_2 uptake through plant stomata in the process of photosynthesis, and by feedbacks of land cover and land use change on water cycling.Numerous experimental studies have demonstrated that elevated atmospheric CO_2 concentration leads to reduced opening of stomatal apertures, associated with a decrease in leaf-level transpiration (de Boer *et al.*, 2011; Reddy *et al.*, 2011). This physiological effect of CO_2 is associated with an increased intrinsic water use efficiency (iWUE) of plants, as less water is transpired per unit of carbon assimilated. Records of stable carbon isotopes in woody plants (Peñuelas *et al.*, 2011) corroborate this finding, suggesting an increase in iWUE of mature trees by 20.5% between the 1970s and 2000s. Increases since pre-industrial times have also been found for several forest sites (Andreu-Hayles *et al.*, 2011; Gagen *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and in a temperate semi-natural grassland (Koehler *et al.*, 2010), although in one boreal tree species iWUE ceased to increase after 1970 (Gagen *et al.*, 2011). However, the physiological CO_2 effect is accompanied by structural changes to C3 plants (including all tree species), i.e. increased biomass production, spatial encroachment and, thus, higher transpiration, as confirmed by Free Air CO_2 Enrichment (FACE) techniques (Leakey *et al.*, 2009).

There are conflicting views on whether the direct CO_2 effects on plants already have a significant influence on evapotranspiration and runoff at global scale. AR4 reported work by Gedney *et al.*, (2006) which suggested that physiological CO_2effects (lower transpiration) contributed to a supposed global increase in runoff seen in reconstructions by (Labat *et al.*, 2004). However, a more recent dataset (Dai *et al.*, 2009) showed different runoff trends in some areas. Detection of ecosystem influences on terrestrial water flows, hence, critically depends on the availability and quality of hydrometeorological observations (Haddeland *et al.*, 2011; Lorenz and Kunstmann, 2012).

A key influence on the significance of increased iWUE for large-scale transpiration is whether overall leaf area of

primary vegetation has remained approximately constant (Gedney *et al.*, 2006) or has increased in some regions due to structural CO_2effects (as assumed in models by Piao *et al.*, 2007; Gerten *et al.*, 2008). While field-based results vary considerably between sites, tree ring studies suggest that tree growth did not increase globally since the 1970s in response to climate and CO_2change (Peñuelas *et al.*, 2011; Andreu-Hayles *et al.*, 2011). However, basal area measurements at over 200 plots across the tropics suggest that biomass and growth rates in intact tropical forests have increased in recent decades (Lewis *et al.*, 2009), which is also confirmed for 55 temperate forest plots, with a suspected contribution of CO_2 rise (McMahon *et al.*, 2010). The net impact of CO_2 on global-scale transpiration and runoff therefore remains poorly constrained.

Moreover, model results differ in terms of the importance of CO_2 effects for historical runoff relative to other drivers such as climate, land use change and irrigation water withdrawal. Other than Gedney *et al.*, (2006), Piao *et al.*, (2007) and Gerten *et al.*, (2008) found that CO_2 effects on global runoff were small relative to effects of precipitation, and that land use change (which often acts to decrease evapotranspiration and to increase runoff) was of second-most importance, as also supported by Sterling *et al.*, (2012) data and model analysis. By contrast, using a shorter time period and a smaller selection of river basins, Alkama *et al.*, 2011(2011) suggested that global effects of land use change on runoff have been negligible. Oliveira *et al.*, 2011(2011) furthermore point to the importance of changes in incident solar radiation and the mediating role of vegetation; their global simulations demonstrate, for example, that a higher diffuse radiation fraction during 1960–1990 increased evapotranspiration in the tropics by 3% due to increased photosynthesis from shaded leaves. Since the anthropogenic component of the precipitation and temperature contributions(i.e. of the radiative CO_2 effect) to runoff trends is not yet established, a full attribution of anthropogenic emissions of CO_2 (and other greenhouse gases)is still missing.

Analogously, there is uncertainty about how vegetation responses to future increases in CO_2 will modulate effects of climate change on the terrestrial water balance.21st-century continental- and basin-scale runoff is projected by some models to either increase more or decrease less when CO_2-induced increases in iWUE are included in addition to climate change (Betts *et al.*, 2007; Murray *et al.*, 2012), potentially reducing an increase in water stress due to rising population or climate change (Wiltshire *et al.*, submitted) – although other models project a smaller response (Cao *et al.*, 2009). Direct effects of CO_2 on plants have been modelled to increase future global runoff by 4–5% (Gerten *et al.*, 2008) up to 13% (Nugent and Matthews, 2012), depending on the assumed CO_2 trajectory and whether feedbacks of changes in vegetation structure and distribution to the climate are accounted for. The model analysis by Alkama *et al.*, (2010) suggests that although the physiological CO_2 effect will be the second-most important factor for 21st-centuryglobal runoff and although both physiological and structural effects will amplify compared to historic conditions, runoff changes will still primarily follow the projected climatic changes. Using a large ensemble of climate change projections, Konzmann *et al.*, (2013) put hydrological changes into an agricultural perspective and suggest that direct CO_2 effects on crops reduce their irrigation requirements (Fig. CC-VW-1). Thus, adverse climate change impacts on crop yields might be partly buffered as iWUE improves (Fader *et al.*, 2010), but only if proper management abates limitation of plant growth by nutrient availability or other factors. Lower transpiration under rising CO_2 may also affect future regional climate change itself (Boucher *et al.*, 2009) and may enhance the contrast between land and ocean surface warming (Joshi *et al.*, 2008).

Application of a soil-vegetation-atmosphere-transfer model indicates complex responses of groundwater recharge to changes in different climatic variables mediated by vegetation,with computed groundwater recharge being always larger than would be expected from just accounting for changes in rainfall (McCallum *et al.*, 2010). In a warmer climate with increased atmospheric CO_2 concentration, iWUE of plants increases and leaf area may either increase or decrease, and even though precipitation may slightly decrease, groundwater recharge may increase as a net effect of these interactions (Crosbie *et al.*, 2010). Depending on the type of grass in Australia, the same change in climate is suggested to lead to either increasing or decreasing groundwater recharge in this location (Green *et al.*, 2007). For a location in the Netherlands, a biomass decrease was computed for each of eight climate scenarios indicating drier summers and wetter winters (A2 emissions scenario), using a fully coupled vegetation and variably saturated hydrological model. The resulting increase in groundwater recharge up-slope was simulated to lead to higher water tables and an extended habitat for down-slope moisture-adapted vegetation (Brolsma *et al.*, 2010).

Future anthropogenic and climate-driven land cover and land use changes will also affect regional evapotranspiration, surface and subsurface water flows, with the direction and magnitude of these changes

depending on the direction and intensity of the changes in vegetation coverage,as shown e.g. for a river basin in Iowa (Schilling *et al.*, 2008) or for the Elbe river basin (Conradt *et al.*, 2012).Removal of vegetation acting as source of atmospheric moisture can change regional water cycling and decrease potential crop yields by up to 17%in regions otherwise receiving this moisture in the form of precipitation (Bagley *et al.*, 2012).Changes in vegetation coverage and structure due to long-term climate change or shorter-term extreme events such as droughts (Anderegg *et al.*, 2013) also affect the partitioning of precipitation into evapotranspiration and runoff, sometimes involving complex feedbacks with the climate system such as in the Amazon region (Port *et al.*, 2012; Saatchi *et al.*, 2013). As water, carbon and vegetation dynamics evolve synchronously and interactively under climate change (Heyder *et al.*, 2011) in that e.g. vegetation structure and composition can dynamically adapt to changing climatic and hydrologic conditions (Gerten *et al.*, 2007), it remains a challenge to disentangle the effects of future land cover changes on the water cycle.

Box CC-WE. The Water-Energy-Food Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Ken Strzepek (UNU/USA), FerencToth (IAEA/Hungary), Blanca Elena Jimenez Cisneros (Mexico), Taikan Oki (Japan)]

Water, energy, and food are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure CC-WE-1. The depth and intensity of those linkages vary enormously between regions and production systems. Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Chapter 3.7.2, 7.3.2, 10.2,10.3.4, McMahon and Price, 2011, Macknick et al, 2012a, Cary and Weber 2008). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Kahn and Hajra 2009, Gertenet al. 2011). While food production and transport require large amounts of energy (Pelletier et al 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (7.3.2, Diffenbaugh et al 2012, Skaggs et al, 2012).

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change.]

Most energy production methods require significant amounts of water, either directly (e.g. crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Chapter 10.2.2 and 10.3.4, and Davies et al 2013, van Vliet et al 2012). Water is also required for mining, processing, and residue disposal of fossil fuels. Water for biofuels, for example, has been reported by Gerbens-Leenes et al. 2012 who computed a scenario of water use for biofuels for transport in 2030 based on the Alternative Policy Scenario of the IEA. Under this scenario, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water for energy currently ranges from a few percent to more than 50% of freshwater withdrawals, depending on the region and future water requirements will depend on electric demand growth, the portfolio of generation technologies and water management options employed (WEC 2010, Sattler et al., 2012). Future water availability for energy production will change due to climate change (Chapter 3.5.2.2).

Water may require significant amounts of energy for lifting, transport and distribution, treatment or desalination. Non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced or reclaimed wastewater vs. desalinated seawater (Plappally and Lienhard 2012, Macknick et al, 2012b). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user, Döll et al. 2012) is generally more energy intensive than surface water – in some countries, 40% of total energy use is for pumping groundwater. Pumping from greater depth (following falling groundwater tables) increases energy demand significantly– electricity use

(kWhr/m^3) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard 2012). A lack of water security can lead to increasing energy demand and vice versa, e.g. over-irrigation in response to electricity or water supply gaps.

Other linkages through land use and management, e.g. afforestation, can affect water as well as other ecosystem services, climate and water cycles (4.4.4, Box 25-10). Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security (3.7.2, 4.4.4). Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water (McCornick *et al.,* 2008, Bazilian *et al.,* 2011, Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy demand, bioproductivity and other factors (see Figure WE-1 and Wise et al, 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this Assessment Report.
