Table 22-1: Changes and impacts observed in freshwater lakes of Africa.

Lake	Observed Impacts
Kivu	The upper (below 250 m) water layers warmed up by 0.5°C in the 55-year period between 1937 and 2002 in response to increased air temperatures (?)
Tanganyika	Reductions in phytoplankton biomass have been attributed to an average 0.2°C warming at 1 000 m and 1.3°C of the upper waters during the past century and an average 0.9°C warming across the lake. (Sources: (Sarvala *et al*., 2006a; Sarvala *et al*., 2006b; Stenuite *et al*., 2007; Stenuite *et al*., 2009; Verburg and Hecky, 2009))
Kariba	Warmed up by an average of 1.9°C between 1965 and 2009; thermocline has migrated upward by over 80% from the maximum thermocline depth of 30m reported during the late 1960s, and by over 60% from the maximum thermocline depth of 20m reported during the late 1980s.This warming is associated with an average of 0.34°C per decade increase in air temperature in the Zambezi Valley. (Sources: Ndebele-Murisa, 2012, Magadza, 2010) Consequences Observed: reduced fish production, e.g. exotic Tanganyika sardine, Limnothrissa miodon due to decline in the production of palatable Chlorophyceae, leading to decreased zooplankton production and a consequent decline in fish stocks; reduced phytoplankton biomass and has caused seasonal shifts in phytoplankton seasonality. (Sources: (Magadza, 2011; Ndebele-Murisa *et al*., 2011a; Ndebele-Murisa *et al*., 2011b; Ndebele-Murisa *et al*., 2012))
Turkana	Level has dropped 10m between 1975 and 1992 due to reduced river inflows. (Sources(McGinley, 2008; Thomas and Malala, 2009))
Victoria	Water level has dropped over 1.5m in five years. (Sources: Awange et al., 2008; Hecky et al., 2010) The upper (below 250 m) water layers warmed up by 0.5°C in the 55-year period between 1937 and 2002 and since the 1960s respectively in response to increased air temperatures resulting in sharper water-density gradient at depths below 250 m. (Sources: (Odada *et al*., 2006; Kunz *et al*., 2011))
Malawi	A 60-year (1930 to 2000) temperature record shows that the temperature of deep water above 300 m has increased by 0.78°C. Due to reduced cold-water intrusions associated with milder winters, rainfall and cold river inflow are critical factors in controlling thermal structure and the rate of deep-water recharge in this tropical lake. These findings are corroborated by geochemical records obtained from sediment cores of changes in Lake Malawi over the last 730 years, caused by natural climatic forcing and anthropogenic activities. (Sources: (Branchu *et al*., 2010; Lyons *et al*., 2011))
Chilwa	Dried up nine times in the 20th Century at 10-20 year intervals in relation to patterns in rainfall in the lake basin. (Source: (Njaya *et al*., 2011))

Table 22-2: Land inundated and economic impacts in Cape Town based on a risk assessment (Cartwrigth, 2008a).

Sea level rise scenarios	Land inundated	Economic impacts (for 25 years)
Scenario 1 (+ 2.5 to 6.5 m depending on the exposure) 95%	25.1 km^2 (1% of the total CT area)	5.2 billion R (794 million US$)
Scenario 2 (+ 4.5 m) 85%	60.9 km^2 (2% of the total CT area)	23.7 billion R (30.3 billion US$)
Scenario 3 (+6.5 m) 20%	95 km^2 (4% of the total CT area)	54.8 billion R

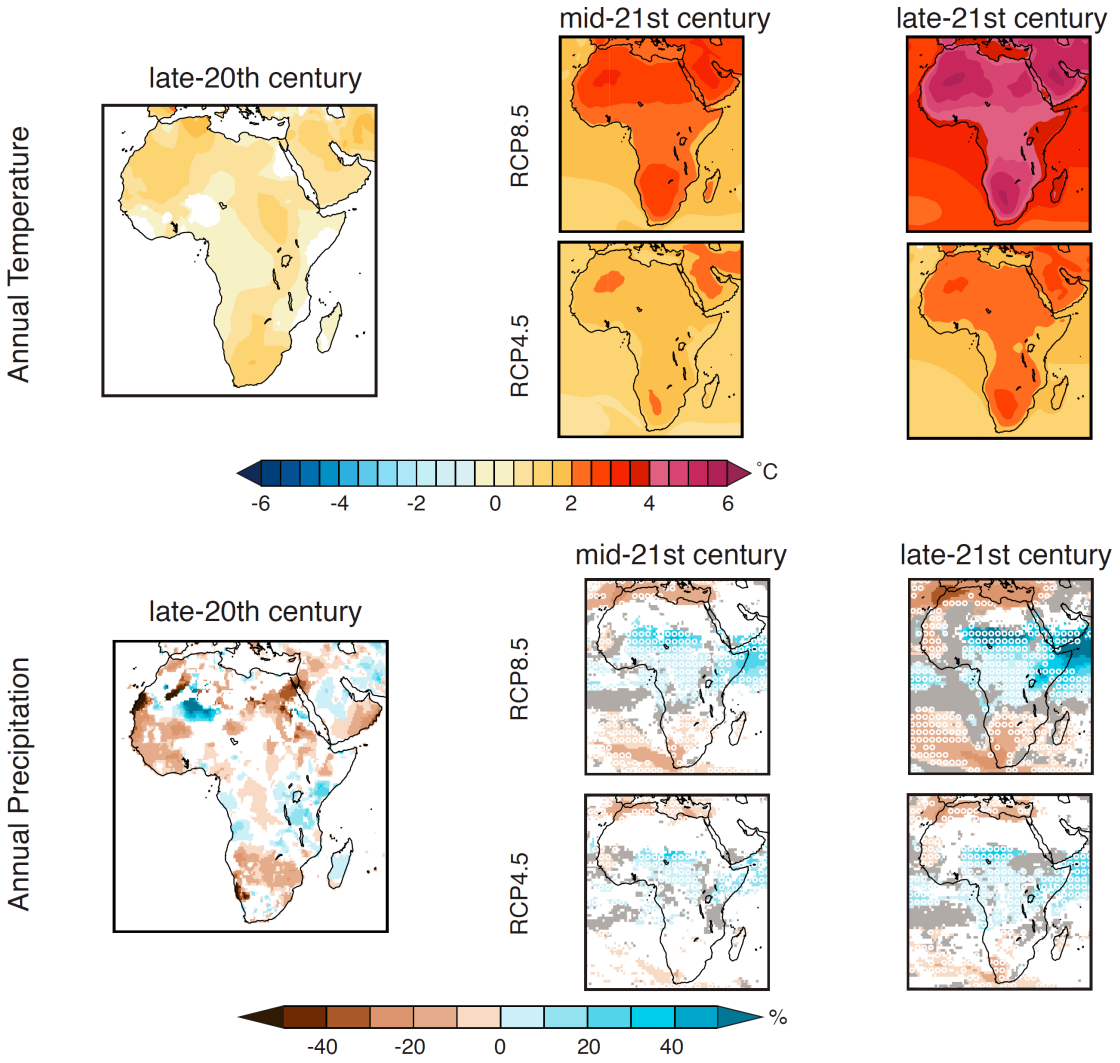
Note: The economic impacts are determined based on the value of properties, losses of touristic revenues and the cost of infrastructure replacement. The total geographical gross product for Cape Town in 2008 was 165 billion of Rands.

Table 22-3. Projected changes in agro-climatic suitability for perennial crops in Africa under an A2 scenario.

Crop	Suitability change	Country	Source
Coffee	Increased suitability at high latitudes; decreased suitability at low latitudes	Kenya	Läderach et al., 2010
Tea	Decreased suitability	Uganda	Eitzinger et al., 2011a,b
	Increased suitability at high latitudes; decreased suitability at low latitudes	Kenya	
Cocoa	Constant or increased suitability at high latitudes; decreased suitability at low latitudes	Ghana, Côte d'Ivoire	Läderach et al., 2011b
Cashew	Increased suitability	Ghana, Côte d'Ivoire	Läderach et al., 2011a
Cotton	Decreased suitability	Ghana, Côte d'Ivoire	Läderach et al., 2011c

Table 22-4: Cross-cutting approaches for equity and social justice in adaptation.

Equitable adaptation approach	Key issues to address for adaptation	Factors that could cause maladaptation	Opportunities	Lessons learned
Gender mainstreamed adaptation in Africa	Lack of empowerment and participation in decision-making (Patt et al, undated) Climate impacts increase women's household roles and may result in girls being kept out of school to assist (Raworth, 2008; UNDP, 2011; Romero Gonzalez et al, 2011) Male adaptation strategies e.g. migration may increase women's vulnerability (Djoudi and Brockhaus, 2011)	Employment opportunities are frequently not sufficiently extended to women in adaptation response frameworks (Madzwamuse, 2010). Failure to incorporate power relations in adaptation responses (Romero Gonzalez et al, 2011; Djoudi and Brockhaus, 2011)	Women's aptitude for long-term thinking, trusting and integrating scientific knowledge, and taking decisions in uncertain conditions (Patt et al, undated) Potential long-term positive changes in women's empowerments, roles and social and economic status (Djoudi and Brockhaus, 2011) Women opportunistically using development projects to adapt to climate change (Nielson, 2010)	Security of tenure over land and resource access is critical for enabling enhanced adaptive capacity of women (African Development Forum, 2010; add refs) Research on understanding different adaptive strategies of benefit for women and men is needed
Child-centered approaches to adaptation	Children and youth represent over 60% of Africa's population, yet their issues are largely absent from adaptation policy (African Development Forum, 2010) Children's differential vulnerability to projected climate impacts is high, particularly to hunger, malnutrition and disasters (Unicef, 2007)	Limits to children's agency related to power imbalances between children and adults, and different cultural contexts (Seballos et al, 2011)	Using approaches that stress agency and empowerment, and 'innovative energies' of youth; build on targeted adaptation initiatives, such as child-centred disaster risk reduction and adaptation (African Development Forum, 2010; Seballos et al., 2011)	Children and youth can play a positive role as change agents for climate adaptation, within an appropriate enabling environment Child-sensitive programmes and policies can reduce risks children face from disasters (Seballos et al, 2011) Funding for climate resilience programmes is necessary to protect children's basic rights (Unicef, 2010; Unicef, 2011)
Human rights-based approaches	Common critical rights issues for local communities are land/resource rights, gender equality, and political voice and fair adjudication of grievances for the poor and excluded (Castro et al, 2012).	Lack of recognition and promotion of their human rights blocks indigenous peoples' coping and adaptation capacities (UNPFII, 2008).	Using the HRBA lens to understand, for example, climate-related disaster risk, necessitates risk analysis to probe the root causes of the vulnerabilities that heighten disaster risk of certain groups, allowing for a structural and sustainable response (Urquhart, 2013)	Applying HRBA presents a framework for addressing conflicting rights and interests, necessary for equitable adaptation responses (Nilsson and Schnell, 2010)



Maps: Change in annual temperature and precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

Figure 22-1: Observed and simulated variations in past and projected future annual average precipitation and temperature.

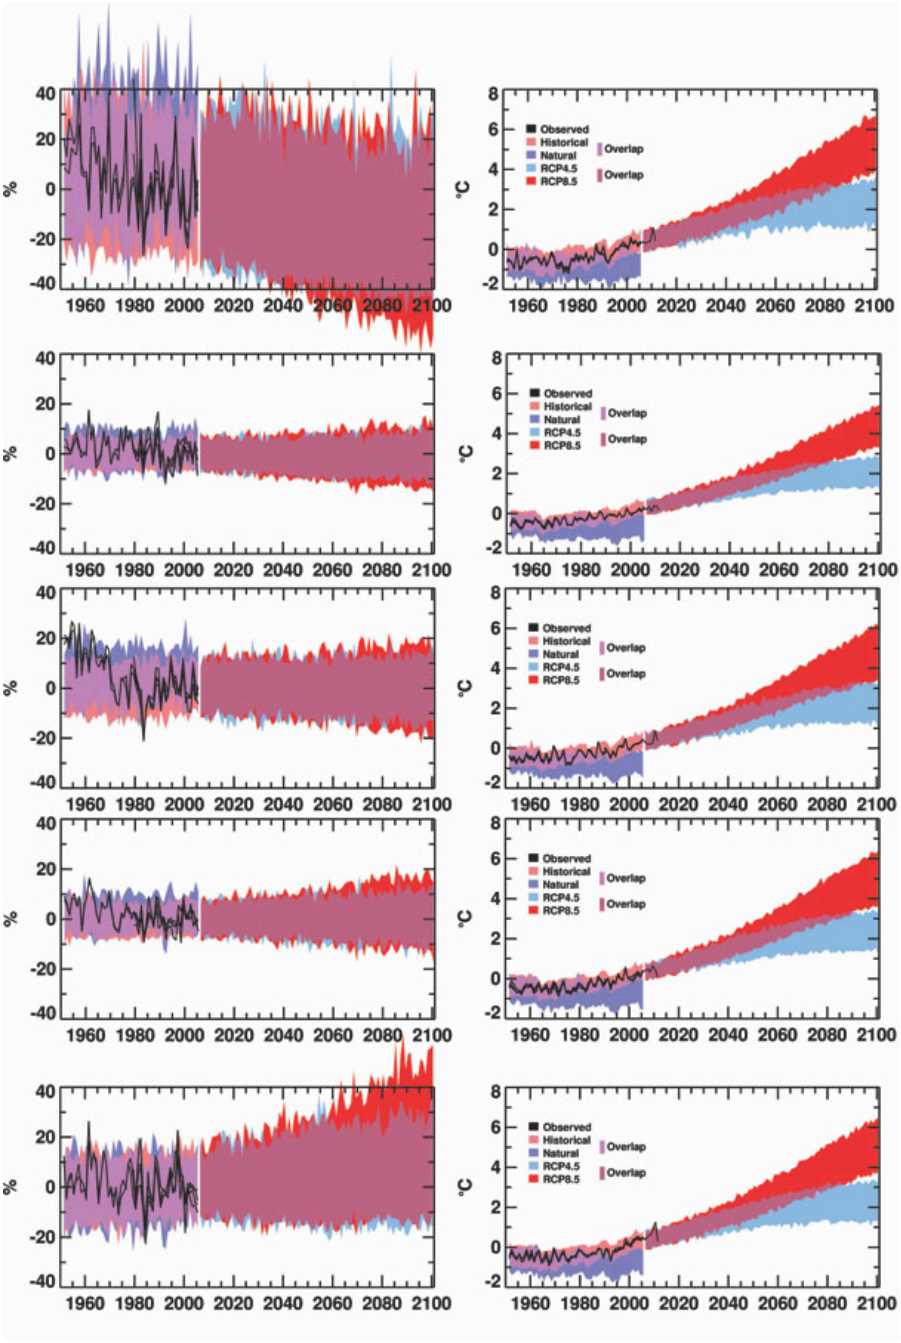


Figure 22-2: Observed and simulated variations in past and projected future annual average precipitation and temperature over five African regions (Arab Maghreb Union- AMU, Common Market for Eastern and Southern Africa – COMSEA, Southern African Development Community – SADC, Economic Community of West African States – ECOWAS, Economic Community of Central African States – ECCAS). Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3. The regions are described in 22.1.2, but COMESA-north covers COMESA north and inclusive of Rwanda, Uganda, and Kenya. Precipitation is included for land territories only, while temperature is included for both land and exclusive economic zone territories.

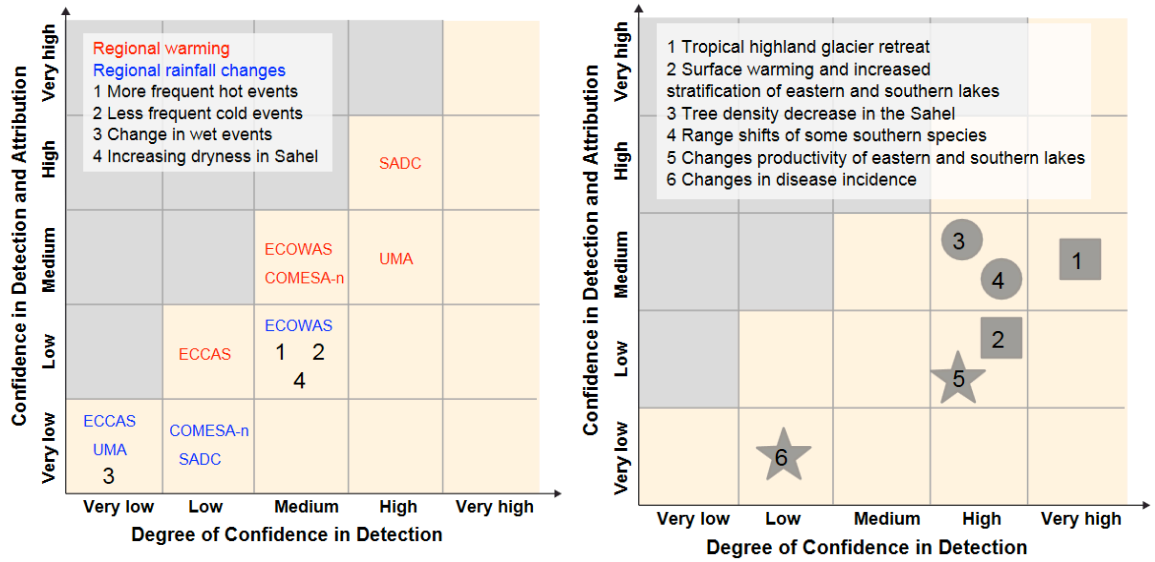

Figure 22-3: Summary of detection and attribution assessments of the relation of observed climate change over Africa with anthropogenic emissions (left) and of the relation of observed changes in natural and human systems with observed regional climate changes (right). All detection assessments are against a no-change reference and all attribution assessments for a major role of anthropogenic emissions (left) or observed regional climate change (right), except for "change in disease incidence" for which the detection assessment is relative to what would have been expected based on changes in livelihoods and health care and for which the attribution assessment is for a minor role of climate change in disease incidence. COMESA-n covers the half of COMESA north of and including Rwanda, Uganda, and Kenya. Discussion of these assessments are in 22.2, 22.3, 22.5.1, WGI AR5 Chapter 10, SREX 3.3, SREX 3.5, and 18.5.1. The detection and attribution assessments follow the specifications described in 18.2.

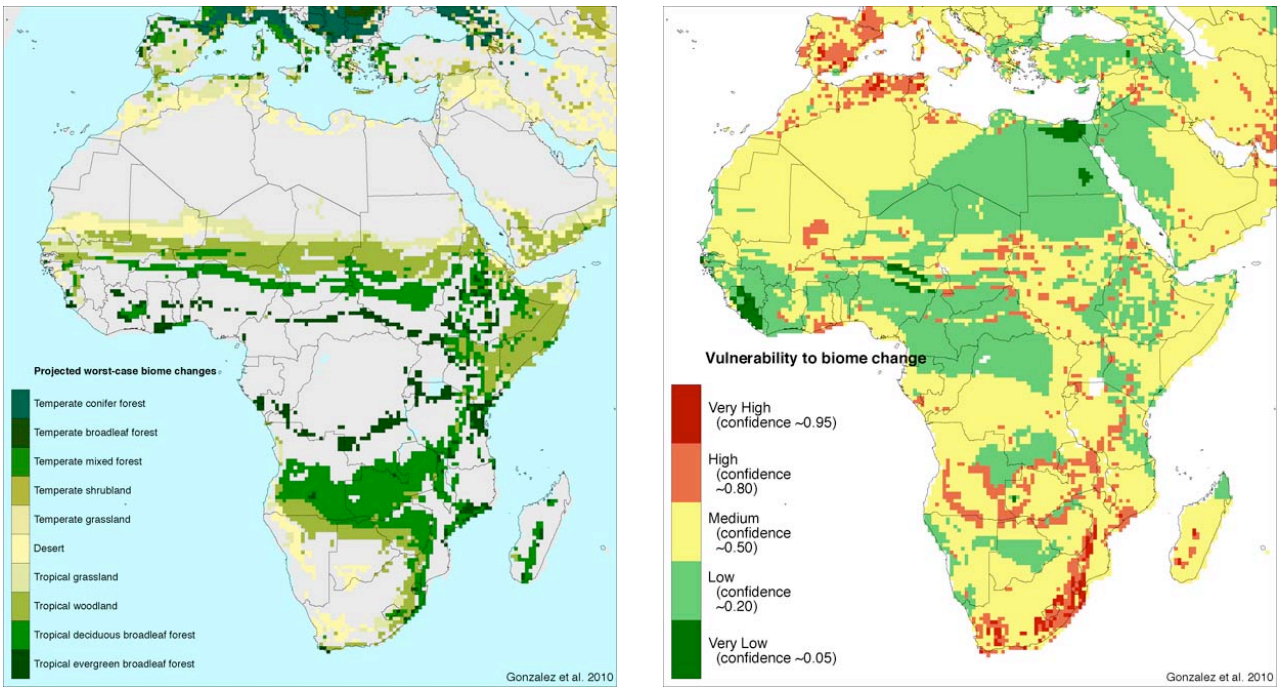

Figure 22-5: (a) Potential changes in vegetation between the periods 1961-1990 and 2071-2100, where any of nine combinations of three GCMs (CSIRO Mk3, HadCM3, MIROC 3.2 medres) and three emissions scenarios (B1, A1B, A2) project change. This is the worst case in comparison to the case of complete agreement of the nine combinations. (b) Vulnerability of ecosystems to biome shifts based on historical climate (1901-2002) and projected vegetation (2071-2100), where all nine GCM-emissions scenario combinations agree on the projected biome change. Source: Gonzalez *et al.* (2010).]

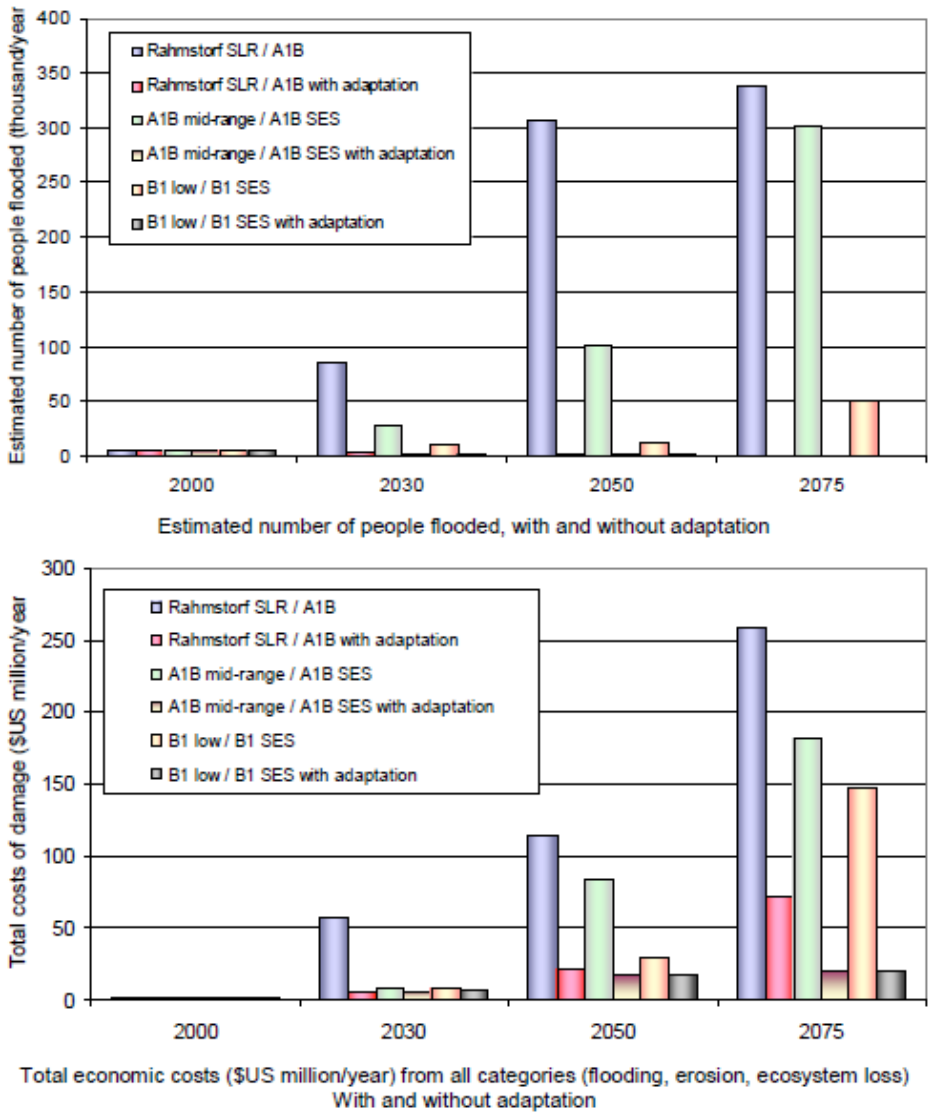

Figure 22-6: Population and economic losses in case of climate change for the whole Kenya coastal zone. Source: (SEI, 2009).

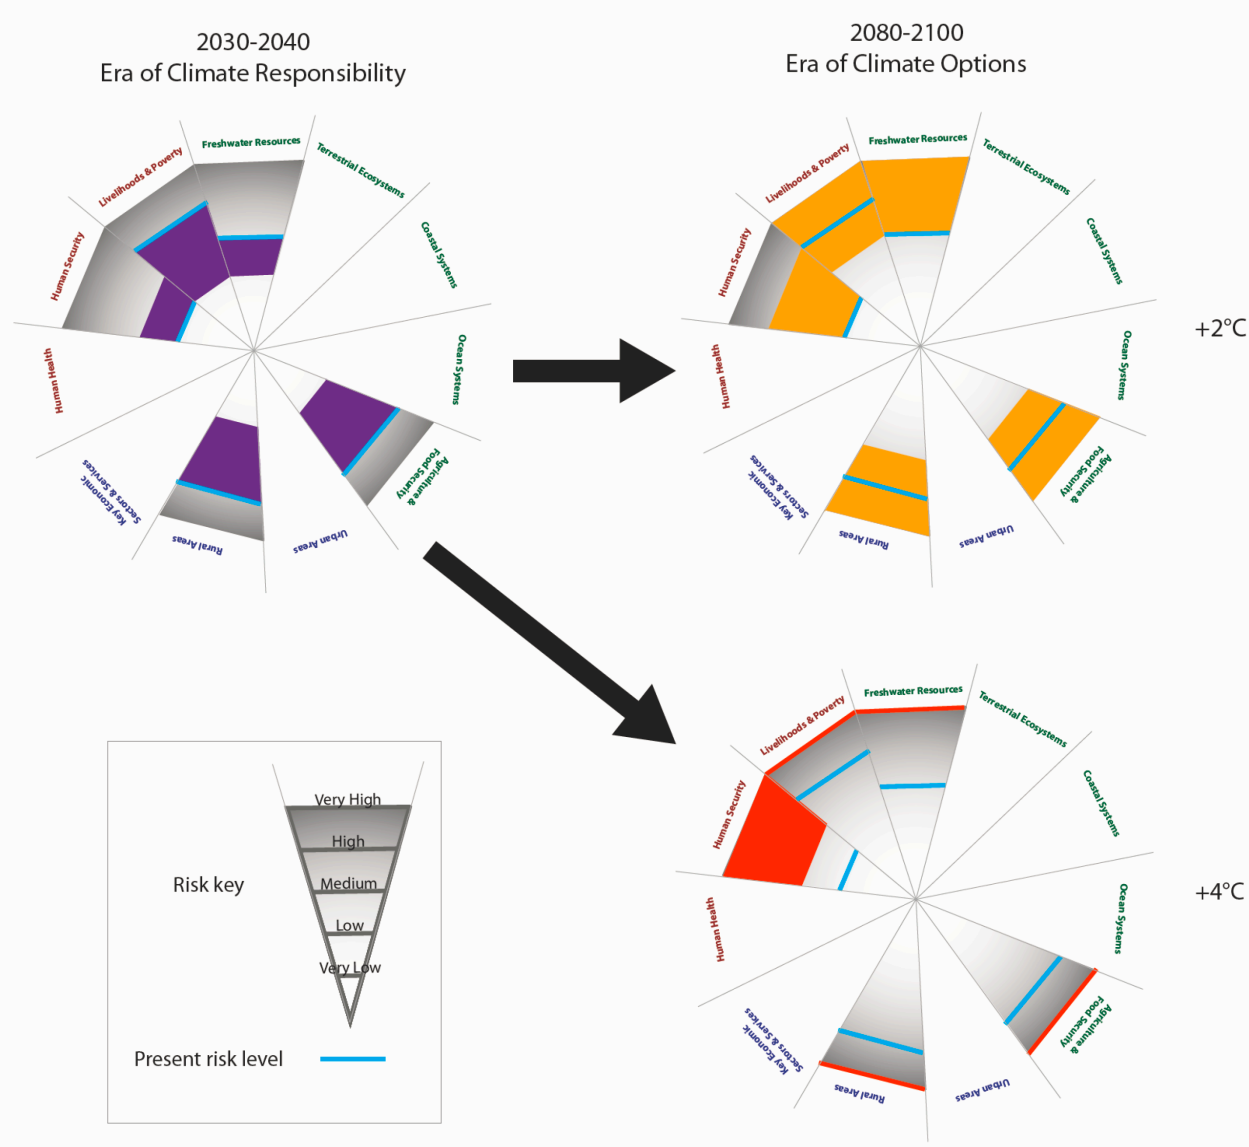

Figure 22-7: Risks for the present (blue line), for the near-term (2°C for 2030-2040) and for the end of the century for 2 temperatures (2°C and 4°C for 2080-2100). Risks are depicted for low adaptation and high adaptation.

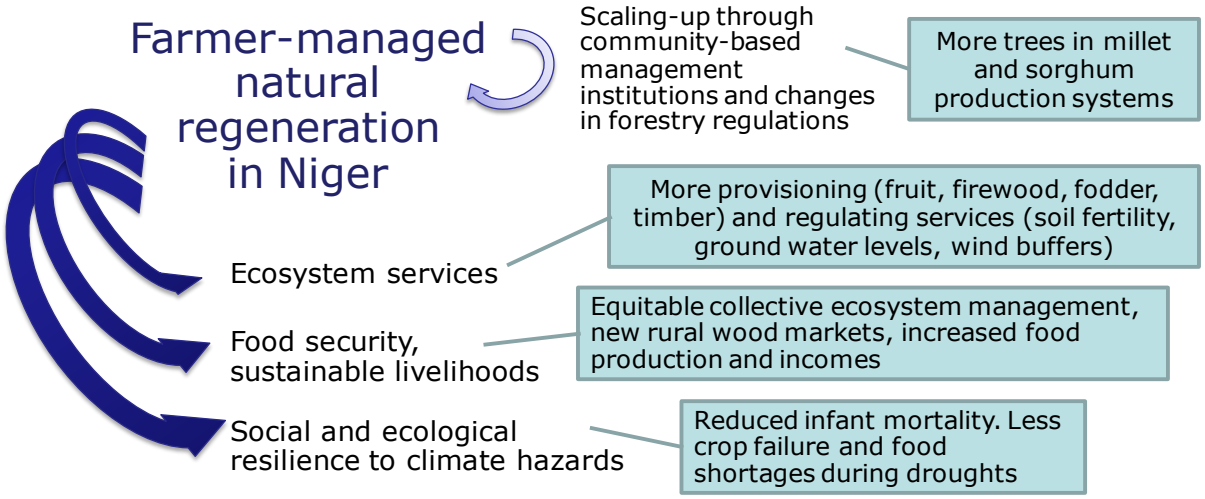

Figure 22-8: Ecosystem-based adaptation - Farmer Managed Natural Regeneration (FMNR): Benefits of ecosystem management for livelihoods and resilience (Garrity et al. 2010; Haglund et al. 2011; Reij et al. 2009; Sendzimir et al. 2011).

Frequently Asked Questions
23.1: Will I still be able to live on the coast in Europe?
23.2: Will climate change introduce new infectious diseases into Europe?
23.3: Will Europe need to import more food because of climate change?

References

Executive Summary

Observed climate trends and future projections confirm the main conclusions of AR4 regarding current and future climate change in Europe [23.2]: climate models project significant changes in temperature [high confidence] and rainfall [high confidence] in Europe [23.2.1] with increases in temperature projected throughout Europe and

increasing precipitation in the North and decreasing precipitation in the South [23.2.2.2]. There will be a marked increase in the frequency and intensity of heat waves [high confidence], meteorological droughts [medium confidence] and heavy precipitation events [high confidence] with variations across Europe [23.2.2.3]; small or no change in wind speed extremes [low confidence] except increases in winter peak wind speed over Northern Europe [medium confidence] [23.2.2.3].

Climate change in Europe has already affected multiple sectors: distribution and composition of animals and plant species [high confidence] [Table 23.6, Table 23.4, 23.6.4]; crop yields in relation to European sub-regions [medium/high confidence] [23.4.1]; health, particularly in Southern Europe [medium confidence] [23.5.1]; forests due to increase of wildfires in Southern Europe [high confidence] and from storms [low confidence] [23.4.4] and European cultural heritage[low confidence] [23.5.4] [Table 23.6]. The observed impacts of extreme weather events indicates the current vulnerability of Europe across multiple sectors [Table 23.3]. Climate change will increase the frequency and intensity of heat waves, particularly in Southern Europe [high confidence] [23.2.2] with adverse implications for health, agriculture, energy production, transport, tourism, labour productivity, and built environment [Table 23.4].

Climate change in Europe will affect multiple sectors [Table 23-4]. All of the ecosystem services (Provisioning, Regulating and Cultural services) will be degraded by climate change at least in one or more European sub-regions. The most affected ecosystem services are: Cultural, Regulating and Provisioning services [Table 23.2].

Climate change will affect economic activity in southern Europe more than other sub-regions [medium confidence] [Table 23.4, 23.9.1], and increase future intra-regional disparity [low confidence] [23.9]. The Mediterranean (part of Southern region) is particularly vulnerable to climate change [high confidence] as multiple sectors will be adversely affected (tourism, agriculture, forestry, infrastructure, energy, population health) [high confidence] [23.9] [Box 23-3]. Compared to AR4, there is more evidence of risks in northern Europe in several sectors. Shifts in agriculture production across sub-regions will occur [medium confidence]. Loss of ecosystem services is projected in Alpine regions [high confidence] [23.10].

Synthesis of evidence across sectors and subregions confirm that there are limits to adaptation from social, economic and technological factors [23.5]. Adaptation is further impeded because climate change affects multiple sectors [23.10]. The majority of assessments are based on climate projections driven by lower emissions than the current trajectory. Limited evidence exists potential impacts in Europe under high rates of warming (>3-4 degrees per century) [23.10], with the exception of some studies of crop yields.

Sectoral impacts

Direct economic river flood damages in Europe have increased over recent decades [high confidence] but this increase is due to development in flood zones and not due to observed climate change [23.3.1.2, SREX 4.5]. Some areas in Europe show changes in river flood occurrence related to observed changes in extreme river discharge [medium confidence] [23.2.3]. Climate change is likely to further increase coastal and river flood risk in Europe and, if unabated, will substantially increase flood damages (monetary losses and people affected) [23.3.1, 23.5.1]. Adaptation can prevent most of the projected damages [high confidence – based on medium evidence, high agreement] [23.3.1; 23.7.1; 23.8.3]. Climate change will increase the problems associated with overheating in domestic housing [medium confidence] [section 23.3.2].

No significant impacts are projected before 2050 in winter or summer tourism except for ski tourism in low altitude and mid altitude sites and under limited adaptation [medium confidence] [23.3.6]. After 2050, tourism activity will decrease in southern Europe [low confidence] and increase in northern/continental Europe [medium confidence]. Artificial snowmaking will prolong the activity of some ski resorts [medium confidence] [23.3.6].

Climate change will affect the impacts of hot and cold weather extremes on transport leading to economic damage and/or adaptation costs, as well as some benefits (e.g. reduction of maintenance costs) during winter [medium confidence] [23.3.3]. Climate change will reduce severe accidents in road transport [medium confidence] and adversely affect inland water transport particularly the Rhine in summer after 2050 [medium confidence]. Damages

to rail infrastructure from high temperatures will increase [medium confidence]. Adaptation through maintenance and operational measures can reduce adverse impacts to some extent.

Climate change will decrease hydropower production from reductions in rainfall in all sub-regions except Scandinavia [high confidence] [23.3.4]. Climate change will have no impact on wind energy production before 2050 [medium confidence] and only a small impact after 2050 [low confidence]. Climate change will inhibit thermal power production during summer [medium confidence] [23.3.4]. Plant modifications and operational changes can reduce adverse impacts. Climate warming will decrease space heating demand [high confidence] and increase cooling demand [high confidence]; the income growth drives largest part of this increase during 2000-2050 period (especially in eastern regions) [medium confidence] [23.3.4]. Energy efficient buildings and cooling systems as well as demand-side management will reduce future energy demands [23.3.4].

Heat-related deaths and injuries will increase, particularly in Southern Europe [medium confidence] [23.5.1]. Climate change will change the distribution and seasonal pattern of some human infections, including those transmitted by arthropods [medium confidence]. The introduction of new infectious diseases due to climate change is unlikely [medium confidence] [23.5.1]. Climate change and sea level rise will damage European cultural heritage, including buildings, local industries, landscapes, and iconic places such as Venice [medium confidence] and some cultural landscapes will be lost forever [low/medium confidence] [23.5.4] [Table 23.5].

Climate change will alter the productivity of bioenergy crops in Europe by shifting their distribution northward [high confidence] [23.4.5]. Elevated atmospheric CO_2 can improve drought tolerance of bioenergy crop species due to improved plant water use, maintaining high yields in future climate scenarios [medium confidence] [23.4.5].

Yields of some arable crop species like wheat have been negatively affected by observed warming in some European countries since 1980s [medium confidence, limited evidence][23.4.1] Compared to AR4, new evidence regarding future yields in Northern Europe, is less consistent regarding the magnitude and sign of change. Climate change will increase yields in Northern Europe [medium confidence] but decrease cereal yields in Southern Europe [high confidence] [23.4.1]. In Northern Europe, climate change will increase the seasonal activity of pests and plant diseases [high confidence] [23.4.1]. Climate change will adversely affect dairy production in Southern Europe because of heat stress in lactating cows [medium confidence] [23.4.2]. Climate warming has caused the spread of blue tongue disease in ruminants in Europe [high confidence] [234.2] and northward expansion of tick vectors [medium confidence] [23.4.2, 23.5.1].

Climate change will change the geographic distribution of wine grape varieties [high confidence] and this will reduce the economic value of wine products and the livelihoods of local wine communities in Southern and Continental Europe [medium/low confidence] [23.4.1, 23.3.5, 23.5.4]. Some adaptation is possible through technologies and good practice [Box 23-1].

Climate change will increase irrigation needs [high confidence] but future irrigation will be constrained by reduced runoff, demand from other sectors, and by economic costs [23.4.1, 23.4.3]. By 2050s, irrigation will not be sufficient to prevent damage from heat waves to crops [medium confidence]. System costs will increase under all climate scenarios [high confidence] [23.4.3]. Integrated management of water is needed to address future competing demands between agriculture, conservation and human settlements [23.7.2].

Observed warming has shifted sea fish species ranges to higher latitudes [high confidence] and reduced body size in species [low confidence] [23.4.6]. Climate change will not decrease net fisheries economic turnover in some parts of Europe (e.g. Bay of Biscay) [low confidence] due to introduction of new (high temperature tolerant) species. Climate change will not entail relocation of fishing fleets [high confidence] [23.4.6]. Observed higher water temperatures have adversely affected both wild and farmed freshwater salmon production [high confidence] [23.4.6]. High temperatures will increase frequency of harmful cyanobacterial blooms [medium confidence] [23.4.6].

Climate warming has adversely affected trends in ground level tropospheric ozone [low confidence] [23.6.1.]. Climate change will increase the frequency of tropospheric ozone events (exceedences) in the future [low

confidence] even assuming future emissions reductions [23.6.1]. Climate change will decrease surface water quality due to higher temperatures [medium confidence] [23.6.3]. There is little evidence regarding the effect of climate change on soil erosion, salinisation or soil fertility [23.6.2].

Observed climate warming has increased forest productivity in northern Europe [medium confidence] [23.4.4] and fire incidence in southern Europe [high confidence] [23.4.4]. Climate change will increase damage from pests and diseases in all sub-regions [high confidence] [23.4.4] and damage from wildfires in Southern Europe [high confidence] and from storms [low confidence] [23.4.4]. Climate change will cause ecological and socio-economic damages from shifts in forest tree species range, with a general trend of a south-west to north-east [medium confidence], and in pest species distributions [low confidence] [23.4.4]. Short-term and long-term strategies in forest management may be an adequate measure to enhance ecosystem resistance and resilience [medium confidence] [23.4.4].

Observed climate change is affecting a wide range of flora and fauna, including plant pests and diseases [medium confidence] [23.4.1, 23.4.4] and the vectors of animal diseases [medium confidence] [23.4.3]. Climate change will cause changes in habitats and species, with local extinction [high confidence] and continental scale shift in Europe [medium/low confidence] [23.6.4]. The habitat of alpine plants will be significantly reduced [high confidence] [23.6.4]. Phenological mismatch will constrain both terrestrial and marine ecosystem functioning under climate change [high confidence] [23.6.4, 23.6.5], with a reduction in some ecosystem services [low confidence] [23.6.4]. The introduction and expansion of invasive species, especially those with high migration rates, from outside Europe will increase with climate change [medium confidence] [23.6.4]. Climate change will entail the loss or movement of coastal wetlands [high confidence] [23.6.5]. Conservation policies and selection of protected areas have not considered so far impact of climate changes. Biodiversity is affected in unprotected areas more than in protected areas but Natura 2000 areas retain climate suitability for species no better and sometimes less effectively than unprotected areas [low confidence] [23.6.4].

Cross-sectoral adaptation

The capacity to adapt in Europe will be higher than for other world regions, but there are important differences in impacts and the capacity to respond within the European sub-regions. In Europe, adaptation policy has been developed at international (EU), national and local government level [23.7] but so far evidence relates to studies of the prioritisation of options, and there is limited systematic information on current implementation (or effectiveness) [Box 23-2]. Some adaptation planning has been integrated into coastal and water management, as well as disaster risk management [23.7.1; 23.7.2; 23.7.3]. There is little evidence of adaptation planning in rural development or land-use planning [23.7.4; 23.7.5]. Economic estimates for adaptation requirements in Europe are available and increasingly from detailed bottom-up sector-specific studies for coastal defences, energy production, energy use, and agriculture [23.7.6]. The costs of adapting dwellings or upgrading coast defence will increase under all scenarios [high confidence] [23.3.2].

There are opportunities for policies that improve adaptive capacity and also help meet mitigation targets [23.8]. Some agricultural practices can potentially mitigate GHG emissions and at the same time adapt crops to increase resilience to temperature and rainfall variability [23.8.2]. Climate policy in transport and energy sectors to reduce emissions can improve population health [23.8.3] [high confidence]. However there are also potential for unintended consequences of mitigation policies in the built environment (especially housing) and energy sectors [23.8.1].

23.1. Introduction

This chapter reviews the scientific evidence published since AR4 on observed and projected impacts of anthropogenic climate change in Europe and adaptation responses. The geographical scope of this chapter is the same as in AR4 with the inclusion of Turkey. Thus, the European region includes all countries from Iceland in the west to Russia (west of the Urals) and the Caspian Sea in the east, and from the northern shores of the Mediterranean and Black Seas and the Caucasus in the south to the Arctic Ocean in the north. Impacts above the Arctic Circle are addressed in the Polar Regions Chapter 28 and impacts in the Baltic and Mediterranean Seas are

addressed in the Open Oceans Chapter 30. Impacts in Malta and other island states in Europe are discussed in the Small Island Chapter 29.

The European region has been divided into 5 sub-regions (see Figure 23-1): Atlantic, Alpine, Southern Northern, and Continental. The sub-regions are derived from climate zones developed by Metzger *et al.* (2005) and therefore represent geographical and ecological zones rather than political boundaries. The scientific evidence has been evaluated according to compare impacts across (rather than within) sub-regions, however, this is not always possible, depending on the scientific information available.

[INSERT FIGURE 23-1 HERE
Figure 23-1: Sub-regional classification of the IPCC Europe region. Based on Metzger et al., 2005.]

23.1.1. Scope and Route Map of Chapter

The chapter is structured around key policy areas. Sections 23.3 to 23.6 summarise the latest scientific evidence on climate sensitivity, observed impacts and attribution, projected impacts and adaptation options, with respect to four main categories of impacts:

- production systems and physical infrastructure;
- agriculture, fisheries, forestry and bioenergy production;
- health and social welfare and;
- protection of environmental quality and biological conservation.

The benefit of assessing evidence in a regional chapter is that integrated impacts across sectors can be described, as well as cross-sectoral decision making required to address many climate change issues.

The chapter also evaluates the scientific evidence in relation to the five sub-regions discussed above. The majority of the research in the Europe region is for impacts in countries in the European Union due to targeted research funding through the European Commission which means that countries in eastern Europe and Russia are less well represented in this chapter. Further, regional assessments may be reported for the EU15, EU27 or EEA (32) group of countries [see supplemental information for list of countries in each group].

This chapter includes several sections that were not in AR4. Because many adaptation and mitigation policies are now in place in Europe, the evidence for potential co-benefits and unintended consequences of such strategies is reviewed (Section 23.8). The implications of climate change for the distribution of economic activity within European region is discussed in Section 23.9. The final section synthesise the key findings with respect to: observed impacts of climate change, key vulnerabilities and identifies research gaps.

23.1.2. Policy Frameworks

Since AR4, there have been significant changes in Europe in responses to climate change. More countries now have adaptation and mitigation policies in place. An important force for climate policy development in the region is the European Union (EU). EU Member States have mitigation targets, as well as the overall EU target, with both sectoral and regional aspects to the commitments.

Adaptation policies and practices have been developed at the international, national and local levels although research on implementation of such policies is limited. Due to the vast range of policies, strategies and measures it is not possible to describe them extensively here. However, adaptation in related to cross-sectoral decision-making is discussed in section 23.7 (see also Box 23-2 on national adaptation policies). The EU Adaptation Platform catalogues adaptation actions reported by Member States. The EU adaptation strategy is due in March 2013. See Chapter 15 for a more extensive discussion of institutions and governance in relation to adaptation planning and implementation in Europe.

23.1.3. Conclusions from Previous Assessments

AR4 documented a wide range of impacts of observed climate change in Europe (AR4 WG2 Chapter 12). The SREX confirmed increases in warm days, warm nights and decreases in cold days and cold nights since 1950 (*high confidence*, SREX-3.3.1). Extreme precipitation increased in part of the continent, mainly in winter over western-central Europe and European Russia (*medium confidence*, SREX-3.3.2). Dryness has increased mainly in Southern Europe (*medium confidence*, SREX-3.3.2). Climate change was expected to magnify regional differences within Europe for natural resources (in particular for agriculture and forestry) because water stress was projected to increase over central and southern Europe (AR4-12.4.1, SREX-3.3.2, SREX-3.5.1). Many climate related hazard were projected to increase in frequency and intensity, but with significant variations within the region (AR4-12.4).

The AR4 identified that climate changes would pose challenges to many economic sectors and was expected to alter the distribution of economic activity within Europe (*high confidence*). Adaptation measures were evolving from reactive disaster response to more proactive risk management. A prominent example was the implementation of heat health warning systems following the 2003 heat wave event (AR4 WG2 12.6.1, SREX 9.2.1). National adaptation plans were developed and specific plans were incorporated in European and national policies (AR4 WG2 12.2.3, 12.5) but these were not integrated comprehensive, or evaluated (AR4 WG2 12.8).

23.2. Current and Future Trends

23.2.1 Non- Climate Trends

Countries in the European region are diverse with respect to both demographic and economic trends. Population health and welfare in all European countries has been improving, with reductions in adult and child mortality rates. However, inequalities both within and between countries in Europe persist (Marmot *et al.*, 2012). Population is generally increasing in the EU27 countries, primarily due to net immigration although population growth is slow (total and working age population) (Rees *et al.*, 2012). Some countries, including the Russian Federation, have had decreases in population since the 1990s. Migration pressure into Europe is increasing (Eurostat, 2011a) but within the EU27 movement between countries is encouraged as part of economic policy. The ageing of the population is a significant trend in Europe, as in all high income populations. This will have both economic and social implications, and many regions are likely to experience a decline in labour force (Rees *et al.*, 2012).

Since AR4, economic growth has slowed (or stalled) in several European countries. In some countries, this has been associated with a reduction in social protection measures and increased unemployment (Eurostat, 2011b). The longer term implications of the financial crisis in Europe are unclear, although it will probably lead to some modification of the economic outlook and may affect future social protection policies (with implications for adaptation).

Agriculture is the most dominant European land use and. Europe is one of the world's largest and most productive suppliers of food and fibre. Rapid changes to farming systems in the post-war decades allowed an unprecedented increase in agricultural productivity, but also had a number of negative impacts on the ecological properties of agricultural systems, such as carbon sequestration, nutrient cycling, soil structure and functioning, water purification, and pollination. Most scenario studies suggest that agricultural land areas will continue to decrease in the future as they have done over the past 50 years (see Busch (2006) for a discussion). Agriculture accounts for 22 % of total national freshwater abstraction in Europe and more than 80 % in some southern European countries (EEA, 2009). Limited water availability is already a significant problem in many parts of Europe and the situation is likely to deteriorate further in future decades. Economic restructuring in some eastern European countries has led to a decrease in water abstraction for irrigation, suggesting the potential for future increases in irrigated agriculture and water use efficiency (EEA, 2009). Water allocation between upstream and downstream countries is challenging in regions exposed to prolonged droughts such as the Euphrates-Tigris river basin, where Turkey plans to more than double water abstraction by 2023 (EEA, 2010a).

The forested areas of Europe account for approximately 35% of the land area (Eurostat, 2009). The majority of forests now grow faster than in the early 20th century due to advances in forest management practices, genetic improvement and in central Europe, the cessation of site-degrading practices such as litter collection for fuel. It is also very likely that increasing temperatures and CO_2 concentrations, nitrogen deposition, and the reduction of air pollution (SO_2) have had a positive effect on forest growth. Land use scenarios suggest that forested areas will expand in Europe in the future on land formerly used for agriculture (Rounsevell *et al.*, 2006).

Soil degradation is already intense in parts of the Mediterranean and central-eastern Europe and, together with prolonged drought periods and increased numbers of fires, is already contributing to an increased risk of desertification. Projected risks for future desertification are the highest in the same areas (EEA-JRC-WHO, 2008).

Europe has relatively moderate urban sprawl levels. Urbanisation is projected to increase all over Europe (Reginster and Rounsevell, 2006), but especially rapidly in Eastern Europe, with the magnitude of these increases depending on population growth, GDP growth and land use planning policy. Although changes in urban land use will be relatively small in area terms, urban development has major impacts locally on environmental quality. A recent past and likely future trend in Europe is peri-urbanisation in which residents move out of cities to locations with a rural character, but retain a functional link to cities by commuting for employment purposes (Reginster and Rounsevell, 2006) (Rounsevell and Reay, 2009). Other important environmental trends include improvements in outdoor air quality and declines in water quality (eutrophication) in some areas (ELME, 2007).

Several scenario studies have been completed for Europe covering socio-economic indicators (Mooij de and Tang, 2003), land use (Verburg *et al.*, 2010; Letourneau *et al.*, 2012)(Haines-Young *et al.*, 2012), land use and biodiversity (Spangenberg *et al.*, 2011), crop production (Hermans *et al.*, 2010), demographic change (Davoudi *et al.*, 2010), economics (Dammers, 2010) and European policy trends (Helming *et al.*, 2011)(Lennert and Robert, 2010). Many of these scenario studies also account for future climate change (see Rounsevell and Metzger (2010) for a review). Long term projections (to the end of the century) will be described under the new Shared Socio-economic Pathway scenarios (SSPs) (Kriegler *et al.*, 2010). Detailed country and regional scale socio-economic scenarios have also been produced for the Netherlands (WLO, 2006), the UK (UK National Ecosystem Assessment, 2011) and Scotland (Harrison *et al.*, 2012). Probabilistic representation of socio-economic futures have been developed for agriculture and land use change at the global scale level including Europe (Baumanns *et al.*, 2012; Hardacre *et al.*, 2012), although a lack of evidence remains about the use of probabilistic information (Bryson et al., 2010) or scenarios in general for policy making.

23.2.2. Observed and Projected Climate Change

23.2.2.1. Observed Climate Change

The average temperature in Europe has continued to increase, but with regionally and seasonally differences in the rate of warming. Since the 1980s, warming has been strongest over Scandinavia, especially in winter, whereas the Iberian Peninsula warmed mostly in summer (Haylock *et al.*, 2008). The decadal average temperature over land area for the period 2002-2011 is 1.3°C+/- 0.11°C above the 1850-1899 average (EEA, 2012), based on HadCRUT3 {{1535 Brohan, P. 2006}}, MLOST {{1537 Smith, T.M. 2008}} and GISSTemp {{1536 Hansen, J. 2010}}. Consistent with previous trends, the rate of warming has been greatest in high latitudes in Northern Europe (see also Polar Regions chapter 28). Observed regional climate change is also described in Chapter 21.

High-temperature extremes (hot days, tropical nights, and heat waves (Vautard R et al, 2013) have become more frequent, while low-temperature extremes (cold spells, frost days) have become less frequent in Europe (EEA, 2011). The recent cold winters in northern and western Europe reflect the high natural variability in the region (Peterson *et al.*, 2012), and do not contradict the general warming trend. In Eastern Europe, including the European part of Russia, summer 2010 was exceptionally hot, with an amplitude and spatial extent that exceeded the previous 2003 heat wave (Barriopedro *et al.*, 2011). These two heat waves revised the seasonal temperature records over approximately half of Europe.

Annual precipitation trends in the 20th century showed an increase in Northern Europe (10–40%) and a decrease in some parts of Southern Europe (up to 20 %) (EEA, 2008)(Del Rio *et al.*, 2011). At the continental scale, winter snow cover extent has a high variability and a non significant negative trend over the period 1967-2007 (Henderson and Leathers, 2010). For a more detailed assessment on regional observed changes in temperature and precipitation extremes (see Table 3-2 of SREX, (Berg *et al.*, 2013). Windspeeds have declined over Europe over the last decades (Vautard *et al.*, 2010) but there is a *low confidence* in this trend due to problematic anemometer data and climate variability (SREX, section 3.3).

Europe is marked by increasing mean sea level with regional variations, except in the Baltic sea where the relative sea level decreases due to vertical crustal motion (Haigh *et al.*, 2010; Menendez and WoodWorth, 2010; Albrecht *et al.*, 2011; EEA, 2012). Extreme sea levels increased due to mean sea level rise (*medium confidence*, SREX, section 3.5, (Haigh *et al.*, 2010; Menendez and WoodWorth, 2010). Few studies exist on waves (SREX, section 3.5, (Charles *et al.*, 2012) leading to a *low confidence* (based on poor evidence) of anthropogenic influence on the observed trends.

23.2.2.2. Projected Climate Changes

There is now more knowledge about the range of possible future climates in Europe, particularly sub-regional information from high resolution climate model output and downscaling (WGII Chapter 21). Within the recognized limitations of climate projections (see WGI Annex 1 (Atlas) and WGII Chapter 21), new research on inter-model comparisons have provided a more robust range of future climates with which to assess future impacts (WGI Chapter 9). Since AR4, climate impact assessments are able to use a range of temperature and rainfall changes rather a single average measure (ensemble mean). Europe is fortunate to have access to comprehensive and detailed sets of climate projections for decision making (SREX, section 3.2.1, (Mitchell *et al.*, 2004)(Fronzek *et al.*, 2012; Jacob *et al.*, 2013).

Even under a climate warming limited to 2°C compared to pre-industrial times, the climate of Europe is simulated to depart significantly in the next decades from today's climate (Jacob and Podzun, 2010)(Van der Linden and Mitchell). Climate models show significant agreement in warming (magnitude and rate) all over Europe, with strongest warming in Southern Europe in summer, and in Northern Europe in winter (Kjellström *et al.*, 2011)(Goodess *et al.*, 2009)(Schmidli *et al.*, 2007).

Precipitation signal is regionally and seasonally very different. Trends are less clear, but agreement in precipitation increase in Northern Europe and decrease in Southern Europe, the zone in between has less clear sign of change (*medium confidence*) (Kjellström *et al.*, 2011). Changes in the annual cycle indicate a decrease in precipitation in the summer months up to Southern Sweden, an increase in winter precipitation with more rain than snow and a decrease of long term mean snow pack (although snow-rich winters will remain) (Räisänen and Eklund, 2011). There is lack of information about past and future changes in hail occurrence. Changes in future circulation patterns are inconsistent, except in Northern Europe (Beck *et al.*, 2007)(Kjellström *et al.*, 2011)(Pryor and Barthelmie, 2010)(Pryor and Schoof, 2010)(Rockel and Woth, 2007)(Ulbrich *et al.*, 2009). Mean wind speed trends are rather uncertain due to shortcomings in wind simulations in GCMs (SREX and (McInnes *et al.*, 2011)).

Recent results highlight that regional coupled simulations over the Mediterranean region provide a better characterization of impact parameters, such as snow cover and aridity index. These simulations have detected changes in key impact indicators, such as snow or river discharge, which were not revealed by CMIP3 global simulations (Dell'Aquila *et al.*, 2012).

For the period 2081-2100 (compred to 1986-2005) the projected global sea level rise is in the range 0.29-0.55 for RCP2.6, 0.36-0.63 for RCP4.5, 0.37-0.64 for RCP6.0 and 0.48-0.82 for RCP8.5 (*medium confidence*, WG1, section 13.7.2). However, at the regional scale, changes can differ from the mean changes (Slangen *et al.*, 2012). There is a *low confidenc*e on projected regional changes (WG1, 13.7). Some high-end (low probability/high impact) estimates of extreme mean sea-level rise projections have been made for The Netherlands (Katsman *et al.*, 2011), indicating

that the mean sea-level could rise globally between 0.55 and 1.15 m, and locally (the Netherlands) by 0.40 to 1.05 m.

23.2.2.3. Projected Changes in Climate Extremes

There will be a marked increase in many types of extremes in Europe, in particular, in heat waves, droughts and heavy precipitation events (WGII Chapter 21, Lenderink and Van Meijgaard, 2008). Table 23-1 describes projected changes of selected climate parameters and climate indices for the period 2071-2100 with respect to 1971-2000, spatially averaged for the five Europe sub-regions.

[INSERT TABLE 23-1 HERE
Table 23-1: Projected Changes of Selected Climate Parameters and Indices[1] for the Period 2071-2100 with Respect to 1971-2000 Spatially Averaged for Europe Subregions. A) A1B scenario. Numbers are based on 9 (indicated with*) and 20 (indicated with **) regional model simulations taken from EU-ENSEMBLES project for the SRES A1B emission scenario. The likely range defines the range of 66% of all projected changes around the ensemble median. B) RCP4.5 scenario. Numbers are based on 7 (indicated with *) and 8 (indicated with **) regional model simulations taken from EURO-CORDEX project for the RCP 4.5 emission scenario. The likely range defines the range of 66% of all projected changes around the ensemble median.]

A detailed assessment on extremes in the future climate is reported in WGII Chapter 21 and SREX. There is a general *high confidence* concerning changes in temperature extremes (toward increased number of warm days, warm nights and heat waves, SREX, Table 3-3). Figure 23-2 shows projected changes in the mean number of heat waves in an extended summer season for the period 2071-2100 compared to 1971-2000 for SRES A1B and RCP4.5 with large differences depending on the emission scenario. The increase in likelihood of some individual events due to anthropogenic change has been quantified for the 2003 heat wave (Schär and Jendritzky, 2004), the warm winter of 2006/2007 and warm spring of 2007 (Beniston, 2009).

Changes in extreme precipitation depend on the region, with a *high confidence* of increased extreme precipitation in Northern Europe (all seasons) and Central Europe (except summer). Future projections are inconsistent in Southern Europe (all seasons) (SREX Table 3-3). Figure 23-3 shows projected seasonal changes of heavy precipitation events for the period 2071-2100 compared to 1971-2000 for SRES A1B and RCP4.5.

[INSERT FIGURE 23-2 HERE
Figure 23-2: Projected changes in the mean number of heat waves occurring in the months May to September for the period 2071-2100 compared to 1971-2000 (number per season) (Jacob et al, 2013). Heat waves are defined as periods of more than 5 consecutive days with daily maximum temperature exceeding the daily maximum temperature of the May to September season of the control period (1971-2000) by at least 5°C. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test). For the eastern part of Turkey, unfortunately no regional climate model projections are available. A) Changes represent average over 9 regional model simulations (A1B) taken from the EU-ENSEMBLES project. B) Changes represent average over 8 regional model simulations (RCP4.5) taken from the EURO-CORDEX project.]

[INSERT FIGURE 23-3 HERE
Figure 23-3: Projected seasonal changes of heavy precipitation defined as the 95th percentile of daily precipitation (only days with precipitation > 1mm/day are considered) for the period 2071-2100 compared to 1971-2000 (%) (Jacob *et al.*, 2013). For the eastern parortunately no regional climate model projections are available. The figures are sorted as follows: left side (DJF, JJA) and right side (MAM, SON). Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test). A) Changes represent average over 20 regional model simulations (A1B) taken from the EU-ENSEMBLES project. B) Changes represent average over 7 regional model simulations (RCP4.5) taken from the EURO-CORDEX project.]

A number of studies based of GCMs and RCMs exhibit a small tendency toward increased extreme wind speed (A1B scenario, 2081-2100 relative to 1981-2000) in Northern Europe in winter in relation to changes in storm tracks (*medium confidence*, SREX, Figure 3-8 (Pinto *et al.*, 2007a; Pinto *et al.*, 2007b)(Rockel and Woth, 2007)(Donat *et al.*, 2010)(Pinto *et al.*, 2010)(Rauthe *et al.*, 2010)(Schwierz *et al.*, 2010)(Donat *et al.*, 2011)(McInnes *et al.*, 2011)(Haugen and Iversen, 2008). Over northern Europe small increase in winter peak wind speed is projected (WGII chapter 21, 21.4.1.1.3). In other parts of Europe, changes are inconsistent.

Extreme sea level events will increase (*high confidence*, WG1, 13.8, SREX 3.5.3), mainly dominated by the global mean sea level increase. Storm surge are expected to vary along the European coasts. Significant increases are projected in the eastern North Sea (increase of 6-8% of the 99th percentile of the storm surge residual, 2071-2100 compared to 1961-1990, based on the B2, A1B and A2 SRES scenarios (Debernard and Rÿed, 2008) and West of British Isles and Ireland (Debernard and Rÿed, 2008)(Wang *et al.*, 2008), except South of Ireland (Wang *et al.*, 2008). There is *medium agreement* for the South of North Sea and Dutch coast were trends vary from increasing (Debernard and Rÿed, 2008) to stable (Sterl *et al.*, 2009). There is a *low agreement* on the trends in storm surge in the Adriatic sea (Jordà *et al.*, 2012; Lionello *et al.*, 2012; Troccoli *et al.*, 2012)(Planton *et al.*, 2011).

23.2.3. Observed and Projected Trends in the Riverflow and Drought

Observed changes have occurred in river discharges in response to changing precipitation patterns and glacier mass balances (AR5 WG2 Chapter 3). Streamflows have decreased in the south and east of Europe and increased in northern Europe in small natural catchments (Stahl *et al.*, 2010)(Wilson *et al.*, 2010)(AR5 WG2 3.2.3). In general, there are large uncertainties in establishing flood trends in Europe (Kundzewicz *et al.*, 2013). In France, upward trends in low flow indices were observed over 1948-1988 and downward trends over 1968-2008 (Giuntoli *et al.*, 2013). Some studies show increases in extreme river discharge (peak flows) in parts of Germany (Petrow *et al.*, 2009)(Petrow *et al.*, 2007), the Meuse river basin (Tu *et al.*, 2005), parts of Central Europe (Villarini *et al.*, 2011), Russia (Semenov, 2011), and Northwestern France (Renard *et al.*, 2008); other studies show decreases in extreme discharges, for example, in the Czech Republic (Yiou *et al.*, 2006), or no change (Switzerland; (Schmocker-Fackel and Naef, 2010); Germany; (Bormann *et al.*, 2011). This pattern fits with analyses at the European level, because the high variability of extreme discharges is driven by atmospheric circulation variations (Bouwer *et al.*, 2008) (Kundzewicz *et al.*, 2010) [see also SREX report, AR5 WG2 Chapter 3]. One study suggests that river training partly masks increasing flood flows in the Rhine basin (Vorogushyn *et al.*, 2012). The attribution of the UK 2000 summer flood to anthropogenic forcing was proposed by (Pall *et al.*, 2011) although later study has shown a weaker effect (Kay *et al.*, 2011).

Future climate change is projected to affect future hydrology of river basins [SREX report, AR5 WG2 Chapter 4]. Europe wide analyses indicate increases in the occurrence of high river discharges (100-year return period) in Continental Europe, but decreases in some parts of Northern and Southern Europe (Dankers and Feyen, 2008)(Rojas *et al.*, 2012). In contrast, studies of future changes in individual catchments indicate increases in the occurrence of extreme discharges, to varying degrees, in Finland (Veijalainen *et al.*, 2010), Denmark (Thodsen, 2007), Ireland (Wang *et al.*, 2006)(Steele-Dunne *et al.*, 2008)(Bastola *et al.*, 2011), the Rhine basin (Lenderink *et al.*, 2007)(Te Linde *et al.*, 2010a)(Krahe *et al.*, 2009; Hurkmans *et al.*, 2010), the Meuse basin (Leander *et al.*, 2008)(Ward *et al.*, 2011), the Danube basin (Dankers *et al.*, 2007), and French Mediterranean basins (Quintana-Segui *et al.*, 2011). Substantial declines in low flows could occur in the UK (Christierson *et al.*, 2012), as well as in Turkey (Fujihara *et al.*, 2008).

Lack of observational data,and the complex definitions related to different perspectives (meteorological, agricultural, hydrological, socioeconomic) of droughts make the analyses of observed changes in drought characteristics difficult (SREX, Chapter 3, Box 3-3). Southern Europe has experienced trends towards more intense and longer droughts, but they are still inconsistent (Sousa *et al.*, 2011). Drought trends in all other subregions were not statistically significant (SREX chapter 3, section 3.5.1). Regional and global climate simulations project (with medium confidence) an increase in duration and intensity of droughts in central and southern Europe and the Mediterranean region (Gao and Giorgi, 2008; Feyen and Dankers, 2009; Vidal and Wade, 2009)(Tsanis *et al.*, 2011) WG2 Chapter 21) using different definitions of droughts (see also SREX chapter 3, section 3.5.1). In a study by

Wong et al. (Wong *et al.*, 2011) it is shown that even in regions where summer precipitation is expected to increase, soil moisture and hydrological droughts may become more severe due to increasing evapotranspitation.

Figure 23-4 illustrates projected changes the length of dry spells for the period 2071-2100 compared to 1971-2000 (in days) for SRES A1B and RCP4.5. For A1B emission scenariothe projected increase in dry spells is much larger in Southern Europe.

[INSERT FIGURE 23-4 HERE
Figure 23-4: Projected changes in the 95th percentile of the length of dry spells for the period 2071-2100 compared to 1971-2000 (in days) (Jacob et al., 2013). Dry spells are defined as periods of at least 5 consecutive days with daily precipitation below 1mm. For the eastern part of Turkey, unfortunately no regional climate model projections are available. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test). A) Changes represent average over 20 regional model simulations (A1B) taken from EU-ENSEMBLES project. B) Changes represent average over 7 regional model simulations (RCP4.5) taken from EURO-CORDEX project.]

23.3. Implications of Climate Change for Production Systems and Physical Infrastructure

23.3.1. Settlements

New studies since AR4 confirm that European urban areas and related production systems, physical infrastructure and human settlements, are at risk (combination of hazard probability, exposure and vulnerability) from changes in weather extremes, such as flooding, mass movements, and wildfires (see section 23.4.4). Europe currently has a high flood risk, due to the presence of highly urbanised areas in river basins and on coastlines. New studies since AR4 confirm that climate change is likely to increase flooding (coastal, river and pluvial) in Europe in some areas, even with an upgrade of flood defences. Risk assessments have attempted to quantify more policy-relevant outcomes, such as population at risk of flooding and economic damage costs and health and environmental outcomes. New risk assessments have also included economic growth and population growth.

23.3.1.1. Coastal Flooding

Extreme sea level events and coastal flood risk are projected to increase in Europe [Section 23.2.2, SREX report, AR5 WG2 Chapter 5] and remain a key challenge for several major European cities (Nicholls *et al.*, 2008)(Hallegatte *et al.*, 2008)(Hallegatte *et al.*, 2011). Important energy infrastructure, including 158 major oil and gas infrastructure and terminals, and 71 operating nuclear reactors are located at exposed coastal locations (Brown *et al.*, 2013). Climate change may increase the frequency of severe storm surges, particularly in north-western Europe (see Section 23.2.2.3). Upgrading coastal defences would substantially reduce the impacts and damage costs (Hinkel *et al.*, 2010). Without adaptation, the number of people affected by coastal flooding in the 2080s is projected to increase in the range of 775,000 to 5.5 million people per year in the EU27 under the SRES B2 and A2 scenarios (Ciscar *et al.*, 2011). The Atlantic, Northern and Southern European regions are projected to be most affected by coastal floods. Direct costs from sea level rise in the EU27 without adaptation could reach 17 billion Euros per year by 2100 (Hinkel *et al.*, 2010), with wider costs being higher (Bosello *et al.*, 2012). The highest damage costs are estimated for the Netherlands, Germany, France, Belgium, Denmark, Spain and Italy (Hinkel *et al.*, 2010).

Changes in future flood losses due to climate change have also been estimated for Copenhagen (Hallegatte *et al.*, 2011), the UK coast (Mokrech *et al.*, 2008)(Purvis *et al.*, 2008)(Dawson *et al.*, 2011), the North Sea coast (Gaslikova *et al.*, 2011), port cities including Amsterdam and Rotterdam (Hanson *et al.*, 2011), and the Netherlands (Aerts *et al.*, 2008). The increasing cost of insurance and unwillingness of investors to place assets in affected areas is a potential growth impediment to the economy in coastal regions and islands (Day *et al.*, 2008). One study estimated that a 1m sea-level rise in Turkey would potentially affect 3 million additional people and put 12 billion USD capital value at risk, with adaptation costs at around 20 billion (10% of GNP) (Karaca and Nicholls). In Poland, up to 240,000 people would be affected by increasing flood risk on the Baltic coast (Pruszak and Zawadzka, 2008).

23.3.1.2. River and Pluvial Flooding

The observed increased trend in flood disasters and flood damages in Europe is well documented (see 18.4.2.1 for detailed discussion), however, the main cause of the increase is increased exposure of persons and property in flood risk areas (Barredo, 2009). Several new studies provide estimates of the impact of changing precipitation patterns on future economic losses from river flooding, with uncertainties depending on modelling approaches and scenarios (Bubeck *et al.*, 2011). In particular, studies now also quantify the contribution of changes in population and economic growth, generally indicating this contribution to be about equal or larger than climate change per se (Feyen *et al.*, 2009)(Maaskant *et al.*, 2009)(Bouwer *et al.*, 2010)(Te Linde *et al.*, 2011)(Rojas *et al.*, 2012). These studies indicate that some regions may see increasing risks, but others may see decreases or little to no change (Bubeck *et al.*, 2011)(ABI, 2009)(Feyen *et al.*, 2009)(Lugeri *et al.*, 2010)(Mechler *et al.*, 2010)(Feyen *et al.*, 2012)(Lung *et al.*, 2012). A European (EU15) analysis estimated that river flooding could affect 250,000-400,000 additional people by the 2080s, and lead to more than a doubling of annual average damages, with the main increases projected in Central Northern Europe and the UK (Ciscar, 2009)(Ciscar *et al.*, 2011). When economic growth is included with projected flood frequency changes, river flood losses in Europe were projected to increase 17-fold under the A1B scenario (Rojas *et al.*, 2012).

Few studies have estimated future damages from inundation in response to an increase in intense rainfall (Hoes, 2006). Processes that influence flash flood risks include increasing exposure from urban expansion, and forest fires that lead to erosion and increased surface runoff (Lasda *et al.*, 2010). Some studies have costed adaptation measures but these only partly offset anticipated impacts from intense rainfall (Zhou *et al.*, 2012).

23.3.1.3. Mass Movements

Very few studies are available on observed trends or future projections in the frequency of landslides (Crozier, 2010). Landslides are strongly connected to intense precipitations and the local conditions of slope stability. In the European Alps, an apparent increase in the frequency of rock avalanches and large rock slides was documented over the period 1900-2007 (Fischer *et al.*, 2011) and also projected an increase in the frequency for landslides for the future (Huggel *et al.*, 2010), while (Jomelli *et al.*, 2007) and Huggel et al. (Huggel *et al.*, 2012) describe a complex response to climate change. Some land use practices changes have led to increased landslide hazards, counterbalancing favourable climate trends, as reported in Calabria (Polemio and Petrucci, 2010) and in the Apenines (Wasowski *et al.*, 2010). There is a medium confidence that landslides that are related to glacier retreat and temperature will be affected by climate change. The evolution of precipitation driven phenomena such as shallow landslides is rather uncertain because of the difficulty to estimate local precipitation trends with accuracy and other factors such as land use. A study of the Mam Tor landslide in the UK indicated a possible increase in stability towards 2100 in response to rainfall changes (Dixon and Brook, 2007). Climate warming may have contributed to the observed decrease in the frequency of snow avalanches in the Alps (Eckert *et al.*, 2010)(Teich *et al.*, 2012), although one study suggest that conditions for avalanches may become more favourable with warming in the future (Castebrunet *et al.*, 2012).

23.3.2. Housing

Housing infrastructure in Europe is vulnerable to extreme weather events. Despite a wide body of literature on the thermal modelling of the existing housing stock, exactly why and how dwellings currently overheat is uncertain (Crump *et al.*, 2009) and there is very little observational data as to the actual extent of current overheating in countries in Europe. Buildings that were originally designed for certain thermal conditions will need to function in a drier and hotter climate in the future (WHO, 2008). The impact of rising temperatures on comfort (and hence energy demand for cooling and heating) is well understood. Climate change in Europe seems set to result in increased use of cooling energy and reduced use of heating energy. For example, a study of energy demand in Slovenia (Dolinar *et al.*, 2010) projected reductions of energy use for heating of up to 25% depending on the region but up to six times more energy for cooling. More estimates of changes in summer and winter energy demand are described below in

Energy Section, although the assumptions regarding future air conditioning uptake are often not clear. Further, the potential trade-offs and synergies in future energy use for residential heating and space cooling conditioning in the context of future emissions (mitigation) and adaptation is discussed in section 23.8.1 below. A range of adaptive strategies are available to address impacts of climate change on buildings including effective thermal mass and solar shading (Wilby, 2007). There is little evidence regarding the estimated costs of retrofitting European housing stock (Parry *et al.*, 2009).

Climate change may increase the frequency and intensity of drought-induced soil subsidence (Corti *et al.*, 2009). One study indicates that it is likely that the level of damage in France, for example, has more than doubled in the period 1989-2002 compared to the period 1961–1990 (Corti *et al.*, 2009). This is mostly a consequence of increased temperature since the 1990s, suggesting a link to climate change. Some European regions were affected for the first time by soil subsidence following the hot summer of 2003, possibly as a consequence of lack of adaptation.

With respect to the outdoor built environment, there is limited evidence regarding the potential for differential rates of radiatively-forced climate change in urban compared to rural areas (McCarthy *et al.*, 2010). An urban land surface scheme coupled to a global model was used to quantify the impact of large-scale and local drivers of climate change on the urban environment and indicated that these effects should not be treated independently when making projections of urban climate change. Climate change was found to increase the number of 'hot' days by a similar amount for both urban and rural situations but rural and urban increases differed significantly for the frequency of 'hot' nights. Modelling of London's nocturnal heat island indicated an increase in magnitude of urban heat island under project climate scenarios (Wilby, 2008). Modification of the external environment, via enhanced urban greening for example, provides other opportunities for modification of risks and co-benefits for health and welfare.

23.3.3. Transport

Systematic and detailed knowledge on the effects of climate change on transport in Europe remains limited (Koetse and Rietveld, 2009).

On *road transport*, in line with AR4, in case of increased precipitation, an increase in collisions but a decrease of their severity is expected due to reduced speed (Brijs *et al.*, 2008)(Kilpeläinen and Summala, 2007). However, lower traffic speed will cause welfare losses due to additional time spent driving (Sabir *et al.*, 2010). Future severe snow and ice-related accidents will also decrease, but the effect of fewer frost days on total accidents is unclear (Andersson and Chapman, 2011a)(Andersson and Chapman, 2011b). Severe accidents caused by extreme weather are projected to decrease by 54-72% in 2020-2070 compared to 2007 (Nokkala *et al.*, 2012).

For *rail*, consistent with AR4, increased buckling due to higher temperatures, as observed in 2003 in the UK, is expected to increase the average annual cost for heat-related delays in some regions, while opposite effects are expected for ice and snow-related delays (Dobney *et al.*, 2010)(Lindgren *et al.*, 2009). The impacts of extreme precipitation, as well as the net overall regional effect of climate change remain unclear. Efficient adaptation comprises proper maintenance of track and track bed.

Regarding *inland waterways*, the navigability of rivers will be affected. In Rhine, for temperature increases by 1-2 ^{o}C by 2050, high water levels in winter will occur more frequently and, from 2050, days with low water levels during summer will also increase (Jonkeren *et al.*, 2011)(Te Linde *et al.*, 2011)(Te Linde, 2007)(Hurkmans *et al.*, 2010). Future low water levels will imply restrictions on the load factor of inland ships, increasing transport prices, as was the case in the Rhine and Moselle market in 2003 (Jonkeren, 2009)(Jonkeren *et al.*, 2007). Potential adaptation includes modal shift, increased number of navigational hours per day in periods with low water levels and infrastructure modifications (e.g. canalization of river parts) (Jonkeren *et al.*, 2011; Krekt *et al.*, 2011). Using smaller ships could be an attractive option if most barges were not considerably below the optimal size (Demirel, 2011). Regarding *long range ocean transport*, the economic attractiveness of the Northwest Passage and the Northern Sea Route depends also on factors such as passage fees, bunker prices and cost of alternative sea routes (Verny and Grigentin, 2009)(Liu and Kronbak, 2010)(Lasserre and Pelletier, 2011).

On *air transport*, estimates on climate change impacts are very few. Pejovic et al. (Pejovic *et al.*, 2009) found that for London's Heathrow Airport, future temperature and wind changes would have a minor net annual change effect (but much larger seasonal variations), while thunderstorms, snow and fog will increase weather-related delays.

23.3.4. Energy Production, Distribution, and Use

On *wind energy*, no significant changes are expected before 2050 in Northern, part of the Alpine and upper Continental Europe (Pryor and Schoof, 2010)(Pryor and Barthelmie, 2010)(Seljom *et al.*, 2011)(Barstad *et al.*, 2012). After 2050, in line with AR4, sites in these regions may experience a small (<10-15%) increase in energy density (W/m^2) during winter and a decrease in summer (Harrison *et al.*, 2008). For Southern and Atlantic Europe, estimations are more uncertain and present spatial and seasonal variations (Rockel and Woth, 2007)(Bloom *et al.*, 2008)(Najac *et al.*, 2011)(Nolan *et al.*, 2012; Pašičko *et al.*, 2012). The impact of future increases in extreme wind speeds in Northern and Continental Europe (see section 23.2.1) on the operation and maintenance of wind farms remains unclear.

For *hydropower*, Scandinavia will face an increase of power generation up to 14% during 2071-2100 compared to historic or present levels (Golombek *et al.*, 2012)(Johannesson *et al.*, 2012)(Haddeland *et al.*, 2011); for 2021-2050, increases up to 8.5% were estimated, while others predicted increases even by 15-20% (Seljom *et al.*, 2011; Hamududu and Killingtveit, 2012). In Continental and part of Alpine Europe, reductions by 6-46% were estimated, depending on the emission scenario, location and time horizon (Schaefli *et al.*, 2007)(Mauser and Bach, 2009)(Paiva *et al.*, 2011; Pašičko *et al.*, 2012)(Stanzel and Nachtnebel, 2010). For Southern Europe, a decreased production by 5-15% in 2050 compared to 2005 has been estimated (Hamududu and Killingtveit, 2012). Improved water management, including pump storage if appropriate, stands as the main adaptation option (Schaefli *et al.*, 2007)(García-Ruiz *et al.*, 2011).

Biofuel production is covered in section 23.4.6. No literature on climate change impacts on solar energy production was found (since AR4). On *thermal power*, in line with AR4, van Vliet et al. (Van Vliet *et al.*, 2012) estimated a 6-19% decrease of the summer average usable capacity of power plants by 2031–2060 compared to 1971-2000, while lower figures have been also estimated (Linnerud *et al.*, 2011)(Förster and Lilliestam, 2010). Closed-cooling circuits are efficient for adaptation (Koch and Vögele, 2009) but are usually feasible only for new plants. In *power transmission*, increasing lighting faults and decreasing snow-sleet-and blizzard faults for 2050-2080 were estimated for UK (McColl *et al.*, 2012).

By considering both heating and cooling, the *total annual energy demand* in Europe as a whole during 2000-2100 is estimated to decrease following climate change (Isaac and van Vuuren, 2009). Seasonal changes will be prominent, especially for electricity (see Figure 23-5), with summer peaks arising also in countries with moderate summer temperatures (Hekkenberg *et al.*, 2009). Heating degree days under a +3.7 ^{o}C scenario are expected to decrease by 11-20% between 2000 and 2050 due solely to climate change (Isaac and van Vuuren, 2009). For cooling, very large percentage increases up to 2050 are estimated by the same authors for most of Europe as the current penetration of cooling devices is low; then, increases by 74-118% in 2100 (depending on the region) from 2050 are expected under the combined effect of climatic and non-climatic drivers. In the Mediterranean, cooling degree days by 2060 will increase, while heating degree days will decrease but with substantial spatial variations (Giannakopoulos *et al.*, 2009). Following climate change, a net annual increase of future electricity generation cost in most of the Mediterranean and a decrease in the rest of Europe was estimated (Eskeland and Mideksa, 2010)(Mirasgedis *et al.*, 2007)(Pilli-Sihlova *et al.*, 2010; Zachariadis, 2010). Future building stock changes and retrofit rates are critical for impact assessment and adaptation (Olonscheck *et al.*, 2011). Passive-cooling alone may not to be enough, while energy efficient buildings and cooling systems, and demand-side management are effective adaptation options (Artmann *et al.*, 2008; Jenkins *et al.*, 2008; Day *et al.*, 2009; Breesch and Janssens, 2010; Chow and Levermore, 2010).

23.3.5. Industry and Manufacturing

Research on the potential effects of climate change on future consumption patterns (e.g. soft drinks, ice creams) is very limited, and based on current sensitivity to seasonal temperature (Mirasgedis *et al.*, 2013). Climate change may also affect supply chains, utilities and transport infrastructure with implications for some industries (see also chapter 10). Higher temperatures may alter the products' quality and safety by favouring the growth of food borne pathogens or contaminants (Jacxsens *et al.*, 2010; Popov Janevska *et al.*, 2010) (see also section 24.5.1). The production of some high value crops is likely to be affected by climate warming (see 23.4.1 and Box 23-1 on Wine).

23.3.6. Tourism

In line with AR4, in northern areas of Continental Europe, as well as Finland, southern Scandinavia and southern England, climate for general tourist activities especially after 2070 is expected to improve significantly during summer and less during autumn and spring under different emission scenarios (Amelung and Moreno, 2011); (Amelung *et al.*, 2007)(Nicholls and Amelung, 2008), although local weather may not be a major barrier for these activities (Denstadli *et al.*, 2011). For the Mediterranean, climate for light outdoor tourist activities is expected to deteriorate in summer mainly after 2050 but improve during spring and autumn (Amelung and Moreno, 2009) (Hein *et al.*, 2009) (Perch-Nielsen *et al.*, 2010)(Amelung *et al.*, 2007)(Giannakopoulos *et al.*, 2011). Though, other studies concluded that before 2030 (or even 2060) this region as a whole will not become too hot for beach or urban tourism (Moreno and Amelung, 2009)(Rutty and Scott, 2010). Observed visitation data and questionnaires indicate that beach tourists are not deterred by moderately high temperatures but by rain (De Freitas *et al.*, 2008)(Moreno, 2010)(Moreno and Amelung, 2009). Tourist arrivals depend also on the age of tourists and the climate at their country of origin, economic and environmental conditions at destinations (e.g. water stress, increased further by climate change and tourist development) (Hamilton and Tol, 2007)(Moreno and Amelung, 2009; Perch-Nielsen *et al.*, 2010)(Lyons *et al.*, 2009; Eugenio-Martin and Campos-Soria, 2010)(Rico-Amoros *et al.*, 2009). The future capacity of accommodation and transport networks in destinations is also important.

Regarding ski tourism, in agreement with AR4, climate change will affect natural snow reliability and consequently the ski season's length, especially in cases without or limited artificial snowmaking (OECD, 2007)(Steiger, 2011)(Steiger, 2010b)(Moen and Fredman, 2007). Low-lying areas will be the most vulnerable (Uhlmann *et al.*, 2009; Endler *et al.*, 2010; Serquet and Rebetez, 2011; Steiger, 2011; Endler and Matzarakis, 2011a). The response of tourists to marginal snow conditions remains largely unknown (Scott et al., 2012), while changes in weather extremes may also be critical (Tervo, 2008). Up to mid-century, demographic changes may have a higher impact on skiing tourism than climate change (Steiger, 2012). Artificial snowmaking has physical and economic limitations, especially in small/ medium sized and low-altitude ski stations (Sauter *et al.*, 2010)(Steiger, 2010a; Steiger, 2010b)(Steiger and Mayer, 2008), and increases water and energy consumption. Other options may include shift to higher altitudes, operational changes, technical measures and year-round tourist activities, although it is still uncertain whether they can fully compensate climate change adverse impacts. Mountainous areas may face improved climatic conditions for summer tourism due to climate change (Endler *et al.*, 2010; Perch-Nielsen *et al.*, 2010; Serquet and Rebetez, 2011; Endler and Matzarakis, 2011b).

23.3.7. Insurance and Banking

The financial sector has a large base in Europe, and its global and regional activities are potentially affected by climate change (see AR5 WG2 Section 10.7 for a more detailed discussion). The insurance and banking sector is affected by problems with accurate pricing of insurance, shortage of capital after large loss events (weather disasters), and by an increasing burden of losses that can affect markets and insurability, within but also outside the European region (CEA, 2007; Botzen *et al.*, 2010a; Botzen *et al.*, 2010b). On the other hand, risk transfer mechanisms including insurance are also an important means to cover and reduce losses from extreme weather (Botzen and van den Bergh, 2008; CEA, 2009)(Herweijer *et al.*, 2009).

Banking is potentially affected through physical impacts from climate change on their assets and investments, as well as regulation and/or through mitigation actions by changing demands regarding carbon emissions from activities related to their investments and lending portfolios. Few banks have adopted climate strategies that also address adaptation (Furrer *et al.*, 2009)(Cogan, 2008).

Windstorm losses that are generally well covered in Europe by building and motor policies and create a large exposure to the insurance sector. Studies indicate an overall increase storm hazard (see Section 23.2.2.3) and possibly insured losses (see Chapter 17.7.3 for a full discussion), but the natural variations in storm frequency are large. There is no evidence that the increase in historic European storm damages is due to anthropogenic climate change. The increasing number and value of buildings and infrastructure is a major driver at present (Barredo, 2010). Flood losses in the UK in 2000, 2007 and 2009 have put the insurance market under further pressure, with increasing need for the government to reduce risk (Ward *et al.*, 2008)(Lamond *et al.*, 2009). Other losses of concern to the European insurance industry are building subsidence losses related to drought (Corti *et al.*, 2009), insured hail damage to buildings (Kunz *et al.*, 2009) (Botzen *et al.*, 2010b)(GIA, 2011).

The financial sector can adapt through adjustment of premiums, restricting or reduction of coverage, further risk spreading, and importantly incentivising risk reduction (Clemo, 2008; Botzen *et al.*, 2010a)(Crichton, 2007)(Crichton, 2006)(Wamsler and Lawson, 2011)(Surminski and Philp, 2010). Willingness-to-pay studies in Scotland and the Netherlands show that public attitudes would support insurance of private property and public infrastructure damages in the case of increasing flood risk (Botzen *et al.*, 2009)(Glenk and Fisher, 2010). Government intervention is needed in many European countries to provide compensation and back-stopping of private insurance schemes in the event of major losses (Aakre and Rübbelke, 2010; Aakre *et al.*, 2010). Hochrainer *et al.* (Hochrainer *et al.*, 2010; Hochrainer *et al.*, 2010) analysed the performance of the EU Solidarity Fund system that supports European governments in the event of large losses, and argue there is a need to shift its focus from compensation to incentivising risk reduction. Alternative forms of private insurance mechanisms, such as long-term (multi-year) contracts for European flood risks suffer from uncertainty related to future risks under climate change, leading to additional risk to private insurance firms (Aerts and Botzen, 2011).

23.4. Implications of Climate Change for Agriculture, Fisheries, Forestry and Bioenergy Production

23.4.1. Plant (Food) Production

In AR4, Alcamo et al. (2007) reported that crop suitability is *likely* to change throughout Europe, and crop productivity (all other factors remaining unchanged) is *likely* to increase in Northern Europe, and decrease in Southern Europe, and the eastern part of Continental Europe.

The frequency and severity of climatic extremes affect agricultural systems (Tubiello *et al.*, 2007)(Coumou and Rahmstorf, 2012) Table 23-5). Climate-induced variability in wheat production has increased in recent decades in France, Italy and Spain (Brisson *et al.*, 2010)(Hawkins *et al.*, 2013) and in some Hungarian regions (Ladanyi, 2008), while in the northernmost agricultural areas of Europe, no consistent reduction in yield variability was recorded despite warming (Peltonen-sainio *et al.*, 2010). In 2003 and 2010, Western Europe and Western Russia, respectively, experienced their hottest summers since 1500 (Luterbacher *et al.*, 2004)(Barriopedro *et al.*, 2011); grain-harvest losses in affected regions reached 20 and 30%, respectively (Ciais *et al.*, 2005; Aerts and Botzen, 2011; Aerts and Botzen, 2011). The 2004/2005 hydrological year was characterised by an intense drought throughout the Iberian Peninsula and cereals production fell on average by 40% (EEA, 2010b). In 2011, the hottest and driest spring on record in France since 1880 reduced annual grassland production and annual grain harvest by 20 and 12%, respectively (AGRESTE, 2011)(Coumou and Rahmstorf, 2012). In the Czech Republic, the grain yield sensitivity to a 1◦C temperature increase during the growing season was -11% and -10% for winter wheat and spring barley, respectively, over 1961-2007 (Trnka *et al.*, 2012).

In many European countries cereal yields have declined in recent decades (Olesen *et al.*, 2011) although the national statistical yields are below the agro-climatic potential yield (Supit *et al.*, 2010). Cereal yields have been negatively affected by warming in some European countries since 1980, for example, in France by -5% for wheat and -4% for

maize (Lobell *et al.*, 2011). Restricted crop inputs and changes in crop rotations, as well as the increased frequency of high temperatures and droughts during grain filling, have reduced wheat yield growth in France (Brisson *et al.*, 2010; Kristensen *et al.*, 2011). In contrast, in eastern Scotland, warming is estimated to have contributed to 23–26% of observed increase potato yields since 1960 (Gregory and Marshall, 2012). In North-East Spain, an increased water deficit in the reproductive stage since the 1960s has reduced grape yield by up to 30 kg/ha per millimetre (Camps and Ramos, 2012). This is consistent with agro-climatic modelling showing a widespread decline over the period 1976-2005 in the climatic potential of crop yields, especially in Italy, central and eastern Europe (Supit *et al.*, 2010).

Insight into the potential effect of climate change on any particular species or crop system requires the combination of a wide range of emission scenarios, global circulation models (GCM) and impact studies (Trnka *et al.*, 2007)(Soussana *et al.*, 2010). For a global temperature increase of 5° C, agroclimatic indices adjusted to reflect the effects of atmospheric CO_2 concentration on evapotranspiration and based on outputs from three GCMs, show increased drought stress and shortening of the active growing season with an increasing number of extremely unfavourable years in a number of European regions (Trnka *et al.*, 2011). In the EU27, a 2.5 °C temperature increase in the 2080s could lead to small changes in crop yields, whereas a 5.4 °C scenario could reduce yields by 10% (Ciscar *et al.*, 2011). A study combining three GCMs and two emission scenarios (B1 and A2) with a weather generator and the crop modelling system GCMS applied to wheat, maize and sugar beet, and assuming neither impacts by weeds, pests and diseases nor limitations by nutrients, indicates an initial benefit from the increasing CO_2 concentration for rainfed crop yields in most European regions, contrasting by the end of the century with yields declines in most regions (Supit *et al.*, 2012). Under the A2 scenario, wheat yield is projected to increase at the end of the century compared to the baseline period 1990–2008 (Supit *et al.*, 2012). Another study, using the CropSyst model and bias-corrected downscaled simulations for the A1B emission scenario, shows based on outputs from the HadCM3 GCM, that disease (wheat leaf rust and corn grey leaf spot) limited yields of rainfed wheat and maize would be reduced despite the increase in atmospheric CO_2 by 5-20% in ca. half of the European cropping area in the 2030's compared to a reference period centred on the year 2000, while the corresponding yield changes would be non-significant or slightly positive based on the ECHAM GCM (Donatelli *et al.*, 2012).

The regional distribution of climate change impacts on agricultural production is *likely* to vary widely (Iglesias *et al.*, 2012)(Donatelli *et al.*, 2012), Figure 23-6). Southern Europe would experience the largest yield losses that would reach about 25 % by 2080 under a 5.4 °C temperature increase (Ciscar *et al.*, 2011). Conditional on increased water shortage and extreme weather events (heat, drought) rainfed summer crop failure is *very likely* to rise sharply (Bindi and Olesen, 2011)(Ferrara *et al.*, 2010)(Ruiz-Ramos *et al.*, 2011) in Southern Europe. The Central Europe regions would experience moderate declines in crop yields (Ciscar *et al.*, 2011), as a result of warmer and drier conditions by 2050 (Trnka *et al.*, 2010; Trnka *et al.*, 2011). In Western Europe, for the 2050s, increased heat stress around flowering is *likely* to increase significantly in wheat which may result in considerable yield losses (Semenov, 2009).

For Northern Europe, there is diverging evidence concerning future impacts. Positive yield changes combined with the expansion of climatically suitable areas could lead to crop production increases for a large range of scenarios (between 2.5 and 5.4°C warming) (Bindi and Olesen, 2011). However, at high latitudes, even accounting for the positive effects of CO_2 fertilization, impacts on cereal production could become negative with a high risk of marked yield loss beyond 4°C global temperature increase (Rötter *et al.*, 2011). Increased climatic variability would limit winter crops expansion in the northernmost agricultural areas of Europe (Peltonen-sainio *et al.*, 2010), but spring crops from tropical origin like maize for silage could become cultivated in Finland by the end of this century (Peltonen-Sainio *et al.*, 2009).

[INSERT FIGURE 23-6 HERE
Figure 23-6: Percentage change in simulated water-limited yield for winter wheat in 2030 with respect to the 2000 baseline under the A1B scenario as modelled using ECHAM5 (left column) and HadCM3 (right). Upper maps to do not take adaptation into account whereas the bottom maps show the result for the best adaptation strategy for cell (Source: Donatelli et al. 2012).]

Ozone is the most important air pollutant that affects agricultural production. For the European Union, compared to a baseline without crop injuries from ozone, wheat and maize yield reduction from ozone were estimated at 7% in 2000 and would reach 6 and 10 % in 2030 for the B1 and A2 scenarios, respectively (Avnery *et al.*, 2011a; Avnery *et al.*, 2011b). Crop sensitivity to ozone tends to decline with increasing atmospheric CO_2 and in areas where warming is accompanied by drying, such as southern and continental Europe. In contrast, the ozone sensitivity of crops would remain high at higher latitudes the absence of declining air and soil moisture (Fuhrer, 2009).

Some economically damaging weeds, such as the shallow rooted *Alopecurus myosuroides* in UK, could become less competitive with wheat owing to more frequent and severe drought stress events under climate change that favour deeper rooted crop plants such as wheat (Stratonovitch, 2012). However, deep rooted weeds (Gilgen *et al.*, 2010) and weeds with contrasting physiology, such as C_4 species, may become better adapted to future conditions and pose a more serious threat (Bradley *et al.*, 2010).

For crops remaining in their original geographical range, generally warmer conditions would exacerbate arthropod-borne diseases (many viruses and phytoplasmas) and those root and stem diseases that first infect hosts during the autumn and winter, such as stem canker of oilseed rape and eyespot of wheat (West *et al.*, 2012). Rising temperatures during the vegetation period, enhances the appearance of a black rot fungus in fruit trees of Northwestern Europe, but this does not hold for other fruit rot species (Weber, 2009) and some pathogens like cereal stem rots (e.g. *Puccinia striiformis*) (Luck *et al.*, 2011) and grapevine powdery mildew (Caffarra *et al.*, 2012) could be limited by increasing temperatures. By the 2050s, more severe *Fusarium* blight epidemics are projected in southern England (Madgwick *et al.*, 2011), while the European corn borer (*Ostrinia nubilalis*) would extend its climate niche in Central Europe (Trnka *et al.*, 2007). Increased damages from plant pathogens and insect pests are projected by 2050 in Nordic countries which have hitherto been protected by cold winters and geographic isolation (Hakala *et al.*, 2011; Roos *et al.*, 2011). Yield losses from phoma stem canker epidemics could increase to up to 50 per cent in South England and greatly decrease yield of untreated winter oilseed rape (Butterworth *et al.*, 2010). Increasing temperatures might have a detrimental impact on grapevine yield due to increased asynchrony between larval development of the European grapevine moth and the larvae-resistant growth stages of grapevine (Caffarra *et al.*, 2012). Disease management will also be affected with regard to timing, preference and efficacy of chemical, physical and biological measures of control and their utilization within integrated pest management strategies (Kersebaum *et al.*, 2008).

Farmers across Europe are currently adapting to climate change (Olesen *et al.*, 2011). Simple, no-cost adaptation options such as advancement of sowing and harvesting dates or the use of longer cycle varieties may be implemented although such options may become less successful in a more variable climate (Moriondo *et al.*, 2010; Moriondo *et al.*, 2011)(Howden *et al.*, 2007). Such "autonomous" adaptation by farmers could result in a general improvement of European wheat yields in the 2030s compared to the 2000s (Donatelli *et al.*, 2012) (Figure 23-6). However, earlier sowing is often prevented by lack of soil workability and frost-induced soil crumbling (Oort, 2012). Observations suggest that farmer sowing dates are advancing slower (e.g. by only 0.2 days per decade over the last 50 years, (Siebert and Ewert, 2012) than crop phenology (Menzel *et al.*, 2006)(Siebert and Ewert, 2012)(Oort, 2012) in Europe. Simulation studies which anticipate on earlier sowing may thus be overly optimistic.

Further adaptation options include: changes in crop species, fertilization, irrigation, drainage, land allocation and farming system (Bindi and Olesen, 2011). In South Italy, for a global mean temperature change of 2°C (above pre-industrial levels), adaptation measures (irrigation and fertilization) would alleviate the negative effects of climate change on crop (tomato and durum wheat) productivity (Ventrella *et al.*, 2012). At the high range of the projected temperature changes, only plant breeding aimed at increasing yield potential jointly with drought resistance and adjusted agronomic practices, such as sowing and adequate nitrogen fertilizer management, may reduce risks of yield shortfall (Olesen *et al.*, 2011)(Rötter *et al.*, 2011)(Ventrella *et al.*, 2012). Climate change alters breeding targets. The identification of the most CO_2-responsive genotypes (Ainsworth *et al.*, 2008) and of heat, drought- and salinity-tolerant genotypes (Tester and Langridge, 2010)(Semenov and Shewry, 2011) as well as the preservation of the option value provided by plant genetic diversity, is a pre-requisite to provide starting lines for breeding programmes (Jump *et al.*, 2009). However, crop breeding is challenged by temperature and rainfall variability, since: i) breeding has not yet succeeded in altering crop plant development responses to short-term changes in

temperature (Parent and Tardieu, 2012) and ii) distinct crop drought tolerance traits are required for mild and severe water deficit scenarios (Tardieu, 2012).

Achieving increased adaptation action will necessitate integration of climate change-related issues with other risk factors, such as market risk (Howden *et al.*, 2007)(Knox *et al.*, 2010). Adaptation to increased climatic variability may imply an increased use of between and within species genetic diversity in farming systems (Smith and Olesen, 2010). The development of insurance products against weather-related yield variations by using precipitation options (Musshoff *et al.*, 2011) may be a tool to reduce risk aversion by farmers. Adaptive capacity to variable and changing conditions is largely attributable to the characteristics of farm types (Reidsma *et al.*, 2009) which may vary given long-term farm structural change induced by climate change (Mandryk *et al.*, 2012). The long term economic viability of farming systems under future scenarios is better characterised by combining ecological and economic optimisation models at the farm scale (Moriondo *et al.*, 2010b).

23.4.2. Livestock Production

Livestock production is impacted by heat. High temperatures lead to a reduction in animal voluntary intake and put a ceiling on dairy milk yield from feed intake (Tubiello *et al.*, 2007). For intensive dairy systems in the Netherlands, heat stress affected dairy production above a daily mean temperature of 18 degrees C (André *et al.*, 2011). For finishing pigs, a meta-analysis shows that growth performance decreases at an accelerating rate when daily temperature increases above a threshold comprised between 21 and 30° (Renaudeau *et al.*, 2011). With dairy cattle in Italy, the mortality risk increased by 60% as a result of exposure during breeding to a combination of high air temperature and air humidity (Crescio *et al.*, 2010). For domesticated animals, climate change adaptation involves changes in diets and farm buildings (Renaudeau *et al.*, 2012) as well as genetic improvement programmes targeting adaptive and performance traits in locally adapted genotypes (Hoffmann, 2010).

Atmospheric CO_2 rise, warming and altered precipitation patterns may change the amount timing and quality of forage production in Europe (Soussana and Luscher, 2007). Experimental manipulation shows the resilience of semi-natural grassland vegetation to prolonged experimental heating and water manipulation (Grime *et al.*, 2008). Nevertheless, even under elevated CO_2, annual grassland production in a French upland site was significantly reduced by four years exposure to climatic conditions corresponding to the A2 emission scenario for the 2070s (Cantarel *et al.*, 2013). Repeated exposure of grasslands to summer droughts increased weed pressure by tap rooted forbs such as *Rumex* (Gilgen *et al.*, 2010). With grass based dairy systems, simulations under the A1B scenario with an ensemble of downscaled GCMs show by the end of the century increases in potential dairy production in Ireland and France, however with increasing risks of summer-autumn forage production failures at French sites (Fitzgerald *et al.*, 2010; Graux *et al.*, 2012) . In continental Europe, grass based dairy systems could suffer from rising water deficits and forage yield variability (Trnka *et al.*, 2009). With sown forage grasses, Mediterranean populations were more resilient than temperate populations to soil water deficit and to heat (Poirier *et al.*, 2012) and could therefore be used to breed better adapted plant material.

The spread of bluetongue virus (BTV) in sheep across Europe has been partly attributed to climate warming (Arzt *et al.*, 2010)(Guis *et al.*, 2012) and was caused by increased seasonal activity of the *Culicoides* vector (Wilson and Mellor, 2009). Climate change is unlikely to extend the distribution of vector *Culicoides imicola* but may increase its abundance in Southern Europe (Acevedo *et al.*, 2010). Ticks, the primary arthropod vectors of zoonotic diseases in Europe, have *likely* changed distributions with climate warming (van Dijk *et al.*, 2010)(Randolph and Rogers, 2010; Petney *et al.*, 2012)(23.5), Climate warming may also increase the risk of fly strike incidence but this can be managed through changes in husbandry practices (Wall and Ellse, 2011). For Europe, climate change is not project to increase by the 2080s the overall risk of incursion of Crimean-Congo haemorrhagic fever virus in livestock through infected ticks introduced by migratory bird species (Gale *et al.*, 2012). The probability of introduction and large-scale spread of Rift Valley Fever in Europe is also very low (Chevalier *et al.*, 2010). Epidemiological surveillance and increased coordinated regional monitoring and control programmes have the potential to reduce the incidence of vector-borne animal diseases (Chevalier *et al.*, 2010)(Wilson and Mellor, 2009).

23.4.3. Water Resources and Agriculture

Future projected trends confirm (Falloon and Betts, 2010) the widening of water resource differences between Northern and Southern European regions reported in AR4 (Alcamo *et al.*, 2007). Under the A1B scenario multi-model simulations show for the 21st century that Nordic river basins have the highest probability of exceeding past high flows during winter, while in Central and Southern European basins the probability of reduced low flows in summer is highest (Weiss, 2011). Simulations using ensemble of GCMs and regional climate models under the A2 emission scenario, show significant reductions by the end of the century in groundwater recharge and/or water table level for river basins located in Northern France (Ducharne *et al.*, 2010), Belgium (Goderniaux *et al.*, 2011), Southern Italy (Senatore *et al.*, 2011) and Spain (Guardiola-Albert and Jackson, 2011), while non-significant impacts were found for aquifers in Switzerland and in England (Stoll *et al.*, 2011)(Jackson *et al.*, 2011). In Northern Europe, negative impacts on water quality are expected due to the intensification of agriculture (Bindi and Olesen, 2010). In the Seine river basin, even with reduced N fertilizer application, groundwater nitrate concentrations would increase during the 21st century (Ducharne *et al.*, 2007). Changes in seasonal precipitation distribution, such as less precipitation in summer and higher rainfall during winter, can enhance nitrate leaching due to lower nitrogen use efficiency in dry periods with higher residual mineral nitrogen after harvest and increased percolation during winter (Kersebaum *et al.*, 2008).

Projections in most European regions, show deteriorating agroclimatic conditions and reduced suitability for rainfed agricultural production (Daccache *et al.*, 2012)(Trnka *et al.*, 2011)(Daccache and Lamaddalena, 2010)(Henriques *et al.*, 2008). Water demand for crop irrigation is projected increase by 40 to 250% by 2100, depending on the crop, in the Fluvià watershed (Catalonia, NE Spain) under the B1 and A2 scenarios (Savé *et al.*, 2012).

Increased irrigation may, however, not be a viable option in a number of European regions because of the reduction in total runoff and of declining groundwater resources, especially in the Mediterranean area (Olesen *et al.*, 2011). Supplementary irrigation in central and eastern England would be constrained by water availability, since in the corresponding catchments water resources are already over-licensed and/or over-abstracted (Daccache *et al.*, 2012). In the French Beauce region, one of the hotspots for irrigation in Europe, water resources reliability is threatened by climate change induced decline in groundwater recharge and to a lesser extent by the increase in potential demand for irrigation (Ducharne *et al.*, 2010). For a tributary of the Ebro river in Spain, drying is projected to occur mainly during the summer with a reduction in the amount of water available for irrigation, due to projected seasonal reductions in reservoir levels (Majone *et al.*, 2012). The need for irrigation may also appear in regions without irrigation infrastructure, as observed during the 2003 summer heat wave and drought in France (van *et al.*, 2010). In Southern Italy, climate change could increase the number of failures for current irrigation systems up to 54-60%. System costs would increase by 20-27% when designed according to the future irrigation demand (Daccache and Lamaddalena, 2010). Even though the adoption of irrigation leads to higher and less variable crop yields in the future, economic benefits of this adoption decision are expected to be rather small. Thus, without changes in institutional and market conditions, no adoption is expected in countries like Switzerland (Finger *et al.*, 2011).

For Northern Europe, agricultural adaptation may be shaped by increased water supply and flood hazards. The need for effective adaptation will be greatest in Southern and south-eastern regions of Europe which already suffer most from water stress, as a result of increased production vulnerability, reduced water supply and increased demands for irrigation (Trnka *et al.*, 2009)(Falloon and Betts, 2010). High frequency of rainy conditions complicates soil workability (Olesen *et al.*, 2011). Earlier sowing dates may allow earlier irrigation and a reduction of the water application (Gonzalez-Camacho *et al.*, 2008). An increased soil organic matter content may facilitate better soil water retention during drought and enhance infiltration capacities (Lee *et al.*, 2008). Areas with poor water-holding soils could be managed extensively for groundwater recharge harvesting, while better water-holding soils could be used for high input crop production (Wessolek and Asseng, 2006). Improved water management in upstream food production areas could mitigate adverse impacts downstream (Kløve *et al.*, 2011). Alternative options such as the use of low-energy systems, improving irrigation efficiency, switching to deficit irrigation and changing cropping patterns to increase water use efficiency can be used as adaptation pathways (Daccache and Lamaddalena, 2010)(Schutze and Schmitz, 2010).

Water use by agriculture affects aquatic ecosystems through stream flow reduction, alteration in stream flow patterns, wetland degradation and declining water quality. Terrestrial ecosystems are affected through changes in groundwater levels and alterations to runoff due to land use changes (Kløve *et al.*, 2011). Under economically focussed regional futures, water supply availability increases at the expense of the environment. Under environmentally focussed futures, irrigation demand restrictions are imposed. In a global market-drive future irrigation demand is price sensitive and has an impact on the type of crops under all climate scenarios (Henriques *et al.*, 2008). More bioenergy production may result in more water stress in some river basins and regions, in particular in southern Europe and during dry summers (Dworak *et al.*, 2009).

23.4.4. Forestry

Observed and future responses of forests to climate change include changes in growth rates, phenology, species composition, increased fire and storm damage, and increased insect and pathogen damage.

Forest growth and phenology

Tree mortality and forest decline due to severe drought events were observed in forests populations in many Mediterranean countries (Affolter *et al.*, 2010)(Bigler *et al.*, 2006; Raftoyannis *et al.*, 2008) as Italy (Bertini *et al.*, 2011)(Giuggiola *et al.*, 2010), Cyprus (ECHOES Country report, 2009), Greece (Raftoyannis *et al.*, 2008) and in the pre-Alps in France (Rouault *et al.*, 2006; Allen *et al.*, 2010)(Nageleisen, 2008; Giuggiola *et al.*, 2010) not only in arid regions but also in wet forests not normally considered at risk of drought (Choat *et al.*, 2012). Phenological advancement in the leaf bud burst and flowering timing was recorded in deciduous species of Southern and Central Finland (Linkosaloa *et al.*, 2009) and crown defoliation was observed in southern European forests due to climate change during 1987-2007 (Carnicer *et al.*, 2011). Despite such negative trends, an increase in forest productivity was observed since 1986 in Italian mountain beech due to the increase of average temperatures (Rodolfi *et al.*, 2007).

Climate change will affect growth and regeneration of forest tree populations in Europe (Lavalle et al., 2009). Future projections show that in Northern and Atlantic Europe the increasing atmospheric CO_2 and warmer temperatures are expected to result in positive effects on forest growth and wood production, at least in the short–medium term (Lindner *et al.*, 2010). On the other hand, in Southern and conitnental Europe increasing drought and disturbance risks will cause adverse effects and productivity is expected to decline (Lindner *et al.*, 2010). The CO_2 fertilization in both Central Europe and Mediterranean will have positive effects on growth although these results contrast with habitat reductions and decline of stand regeneration (Hlásny *et al.*, 2011; Keenan *et al.*, 2011; E Silva *et al.*, 2012).

Species composition

Shifts in forest tree species range due to climate change has been predicted by model-based projections for the period 2070-2100, with a general trend of a south-west to north-east, under A1B scenario, and uphill shifts in suitable habitats for forest categories (Feehan *et al.*, 2009)(Casalegno *et al.*, 2007) causing large ecological and socio-economic impacts and becoming an important issue to be addressed for forest management (Giuggiola *et al.*, 2010; Hemery *et al.*, 2010; García-López J.M. and Alluéa, 2011). By 2100 climate change is expected to reduce the economic value of European forest land by 14 to 50 % under A1B climate scenario, which equates to a potential damage of several hundred billion Euros unless effective countermeasures are taken, owing to the decline of economically valuable species (Hanewinkel *et al.*, 2012).

Fire and storm damage

In Southern Europe, fire frequency and fire extent significantly increased due to climate change in recent decades especially in the Mediterranean basin (Marques *et al.*, 2011; Pausas and Fernández-Muñoz, 2012) including an expansion of fire-prone areas (Fernandes *et al.*, 2010; Koutsias *et al.*, 2012) and a lengthening of the fire season (Lavalle *et al.*, 2009; Albert and Schmidt, 2010). Extreme weather events (drought, heat waves and strong winds) increased the incidence of forest fires in Southern Europe (Camia and Amatulli, 2009; Hoinka *et al.*, 2009; Carvalho *et al.*, 2011; Koutsias *et al.*, 2012; Salis *et al.*, 2013). The most severe events in France, Greece, Italy, Portugal, Spain, and Turkey in 2009 were associated with strong winds that spread fires during a hot, dry period (see also

(EEA, 2008). However, the observed fire trend is also attributable to changes in land use (Marlon *et al.*, 2008; Carmo *et al.*, 2011), socio-economic development and fire-policy factors (Martinez-Casasnovas and Ramos, 2009; Romero-Calcerrada *et al.*, 2010; Koutsias *et al.*, 2012; Pausas and Fernández-Muñoz, 2012; {{1545 Pezzatti 2011;}}.

Fire is expected to become more prevalent also in the future due to climate change causing negative effects on forest ecosystems and significant emissions of greenhouse gases due to biomass burning (Pausas *et al.*, 2008; Vilén and Fernandes, 2011; Chiriacò *et al.*, 2013), even if often difficult to precisely quantify (Chiriacò *et al.*, 2013). The future climate change impacts on forest fires in Mediterranean basin might depend on the balance between higher flammability due to warmer and drier conditions, socio-economic drivers and landscape planning to reduce fuel loads and fire hazard (Moreira *et al.*, 2011). The fire risk is projected to increase in the Mediterranean region (Lindner *et al.*, 2010; Carvalho *et al.*, 2011; Dury *et al.*, 2011; Vilén and Fernandes, 2011) with increase in the occurrence of high fire danger days (Moreno and Amelung, 2009; Arca *et al.*, 2012) and in fire season length (Pellizzaro *et al.*, 2010). The annual burned area is projected to increase by a factor of 3 to 5 in the Mediterranean area compared to the present under the A2 scenario by 2100 (Dury *et al.*, 2011). In Northern Europe, fires are projected to be less frequent due to increased humidity (Rosan and Hammarlund, 2007).

The most severe damage to forests in Central Europe occurs during winter storms caused by Northern Hemispheric mid-latitude cyclones. Increasing growing stock, warm winter temperature and high precipitation, increasing maximum gust wind speed have contributed to the recent increase in windstorm damage to forests (Usbeck *et al.*, 2010). The future storm tracks may shift further north with the consequent possibility of increased risk of damage. Boreal forests will get more vulnerable to autumn/early spring storm damage due to expected decrease in period of frozen soil (Gardiner *et al.*, 2010). Increased storm losses by 8-19% under A1B and B2 scenarios respectively is projected in Western Germany for 2060-2100 compared to 1960-2000, with the highest impacts in the mountainous regions (Pinto *et al.*, 2010; Klaus *et al.*, 2011).

[INSERT FIGURE 23-7 HERE
Figure 23-7: Projected fire risk in Europe for two time periods (2011–2040 and 2041–2070) based on high-resolution regional climate models from the ENSEMBLES project under the SRES A1B emission scenario.]

Insect and pathogen damage

Many opportunist fungi and insects benefit from climate change both directly, because of the survival of a greater number of individuals, and indirectly, because of the changes induced in host phenology (Slippers and Wingfield, 2007). A development of diseases caused by thermophilous pathogens was observed in many European forests (Marcais and Desprez-Loustau, 2007). In temperate zones of Continental Europe, fungi are even more problematic damage agents than insects, with some species that benefit from milder winters and others that spread during drought periods from south to north (Drenkhan *et al.*, 2006; Hanso and Drenkhan, 2007). Projected increased late summer warming events will favour a second generation of bark beetle in southern Scandinavia and a third generation in lowland parts of central Europe (Jönsson *et al.*, 2011). Spruce bark beetle will be able to initiate a second generation in South Sweden during 50% of the years around the mid century and in 63-81% of the years at the end of the century under A2, A1B and B2 scenarios (Jönsson *et al.*, 2009). Bark beetle damages in Austrian spruce forests are projected to double until 2100 assuming no adaptation measures (Seidl *et al.*, 2009).

Forest management and land use

Projected shortening frost periods and thawing permafrost may strongly reduce the accessibility of forests in the Boreal zone with implications for the timber supply (Keskitalo, 2008). Climate change together with socio-economic and technological drivers will influence future European land use leading to declines in the agricultural area and increase in forested and urban areas that would potentially reduce GHG emissions and enhance carbon sinks (Rounsevell and Reay, 2009). Possible response approaches to the impacts of climate change on forestry include short-term and long-term strategies that focus on enhancing ecosystem resistance and resilience (Millar *et al.*, 2007). Fragmented small-scale forest ownership can constrain adaptive capacity (Lindner *et al.*, 2010). Forest management with thinning and shrub removal could decrease competition for water and increase carbon uptake. (Giuggiola *et al.*, 2010). Ongoing changes in species composition from conifers to broadleaves and increasing harvest level might lower the vulnerability through reduction of share of old and vulnerable stands (Schelhaas *et al.*,

2010). Strategies to anticipate severe forest mortality in the future include preference of species better adapted to relatively warm environmental conditions (Resco *et al.*, 2007). The selection of tolerant or resistant families and clones may also reduce the risk of damage by pests and diseases in pure stands (Jactel *et al.*, 2009).

23.4.5. Bioenergy Production

Climate change is *likely* to change the distribution of key bioenergy crops. Dedicated crops for bioenergy in temperate regions, including tree species grown as short rotation coppice (SRC) and intensive forestry, and C4 grasses such as Miscanthus and switchgrass, will respond to climate change by shifting their potential distribution and altering their potential productivity and yields. The potential distribution of temperate oilseeds (e.g. oilseed rape, sunflower), starch crops (e.g. potatoes), cereals (e.g. barley) and solid biofuel crops (e.g. sorghum, Miscanthus) is predicted to increase in northern Europe by the 2080s, due to increasing temperatures, and decrease in southern Europe due to increased drought. Mediterranean oil and solid biofuel crops, currently restricted to southern Europe, are predicted to extend further north due to higher summer temperatures. Four global climate models, (HadCM3, CSIRO2, PCM and CGCM2) predict that bioenergy crop production in Spain is especially vulnerable to climate change, with many temperate crops predicted to decline dramatically by the 2080s. The choice of bioenergy crops in southern Europe will be severely reduced in future unless measures are taken to adapt to climate change (Tuck *et al.*, 2006).

The physiological responses of bioenergy crops C3Salicaceae trees and C4 grasses to rising atmospheric CO_2 concentration would improve drought tolerance due to improved plant water use, consequently yields in temperate environments may remain high in future climate scenarios (Oliver *et al.*, 2009). A future increase in potential biomass production due to elevated CO_2 outweighs the increased production costs resulting in a northward extension of the area where SRC is greenhouse gas neutral (i.e. it produces exactly the amount of biomass that is required to have the avoided emissions compensate for the total emissions from crop management and bio-energy production). However, the northward expansion of SRC would erode the European terrestrial carbon sink due to intensive management and high turnover of SRC respect to conventional forest where usually harvesting is less than annual growth (Liberloo *et al.*, 2010).

23.4.6. Fisheries and Aquaculture

In AR4, Easterling *et al.* (2007) reported that the recruitment and production of marine fisheries in the North Atlantic are *likely* to increase. Warming induces a shift of species ranges toward higher latitudes and seasonal shifts in life cycle events (Daufresne *et al.*, 2009) (see also 23.6.4). In European seas, warming causes a displacement to the north and/or in depth of fish populations. These displacements of species distribution areas have a direct impact on fisheries (Rosenzweig *et al.*, 2008)(Tasker, 2008)(Cheung *et al.*, 2009; Cheung *et al.*, 2010). A widespread reduction in body size in response to climate change in aquatic systems has been observed through long-term surveys and experimental data showing a significant increase in the proportion of small-sized species and young age classes and a decrease in size-at-age (Daufresne *et al.*, 2009). In the northern North Sea, due to species reorganisation (Beaugrand and Reid, 2012), a general decrease in the mean size of zooplankton over time has been observed. Smaller zooplankton species may have general implications for energy transfer efficiency to higher trophic levels, and for the sustainability of fisheries resources (Pitois and Fox, 2006)(Beaugrand and Kirby, 2010). In British waters, the lesser sandeel (*Ammodytes marinus*), which is a key link in the food web, shows declining recruitments since 2002 that are inversely correlated with temperature and is projected to further decline in the future with a warming climate (Heath *et al.*, 2012). In the Baltic Sea, marine-tolerant species will be disadvantaged and their distributions will partially contract; conversely, habitats of freshwater species will likely expand, Although some new species would be expected to immigrate because of an expected increase in sea temperature, only a few of these species would be able to successfully colonize the Baltic because of its low salinity (Mackenzie *et al.*, 2007).

Numerous studies confirm the amplification through fishing of the effects of climate change on population dynamics and consequently on fisheries (Planque *et al.*, 2010). Over the past decade, the cod stock has not been restored from its previous collapse (Mieszkowska *et al.*, 2009)(ICES, 2010). In the North Sea, the decline of cod during the 1980-2000 period results from the combined effects of overfishing and of an ecosystem regime shift due to climate change

(Beaugrand and Kirby, 2010). Analyses of fish species richness over 1997-2008 of North Sea and Celtic Seas did not detect the impact of fisheries (ter Hofstede *et al.*, 2010), as the steep decline in boreal species (Henderson, 2007) was compensated for by the arrival of southern (Lusitanian) species (Lenoir *et al.*, 2011). An observed weakening of the Iberian upwelling in the inner shelf has slowed down the introduction of nutrients, leading to changes in phytoplankton communities that favour the proliferation of harmful algal blooms, thereby reducing the permitted harvesting period for the mussel aquaculture industry.

The areal extent of some habitats that are suitable for aquaculture can be reduced by sea-level rise. In addition, ocean acidification may disrupt the early developmental stages of shellfish (Callaway *et al.*, 2012). Climate change may also reinforce parasitic diseases and impose severe risks for aquatic animal health. As water temperatures increase, a number of endemic diseases of both wild and farmed salmonid populations are *likely* to become more prevalent and difficult to control and threat levels associated with exotic pathogens may rise (Marcos-Lopez *et al.*, 2010). For oysters in France, toxic algae may be linked to both climate warming and direct anthropogenic stressors (Buestel *et al.*, 2009). With freshwater systems, summer heat waves boost the development of harmful cyanobacterial blooms (Johnk *et al.*, 2008). Therefore, current mitigation and water management strategies, which are largely based on nutrient input and hydrologic controls, must also accommodate the environmental effects of climate change (Paerl and Huisman, 2009)(Halpern *et al.*, 2012).

In the Iberian-Atlantic fishing grounds, the biomass and profits from sardine fishery will further decrease with greater intensity if the effects of global warming on the water temperature become more significant (Perez *et al.*, 2010)(Garza-Gil *et al.*, 2010). In the Bay of Biscay, a major part of the gross economic turnover associated with catches of fish species would potentially not be affected by long-term changes in climate (Floc'h *et al.*, 2008). In the Portuguese coast, a commercial opportunity for fisheries could arise since most the new potential species were marketable species and not many current species were lost under different climate scenarios (Vinagre *et al.*, 2011). Fishing fleets which presently target marine species (e.g. cod, herring, sprat, plaice, sole) in the Baltic may have to relocate to more marine areas or switch to other species which tolerate decreasing salinities. A temporary marine reserve policy in the Eastern Baltic could postpone the negative effects of climate change on fish stocks (Rockmann *et al.*, 2009).

Fishery management thresholds that trigger reductions in fishing quotas or fishery closures to conserve local populations (e.g. cod, salmon) will have to be reassessed as the ecological basis on which existing thresholds have been established changes, and new thresholds will have to be developed for immigrant species (Mackenzie *et al.*, 2007)(Beaugrand and Reid, 2012).

Integrative assessment help examine policy options (Miller *et al.*, 2010). Experimentation and innovation at local to regional levels is critical for a transition to ecosystem-based management (Osterblom *et al.*, 2010). Human social fishing systems dealing with high variability upwelling systems with rapidly reproducing fish species may have greater capacities to adjust to the additional stress of climate change than human social fishing systems focused on longer-lived and generally less variable species (Perry *et al.*, 2010; Perry *et al.*, 2011). However, the political and social implications of impacts on fisheries are hard to project. The climate-related northward movement of mackerel to Icelandic waters may create economic problems for fisheries in EU and policy debates (Arnason, 2012).

23.5. Implications of Climate Change for Health and Social Welfare

23.5.1. Human Population Health

Climate change is likely to have a range of health effects in Europe. Further studies since AR4 have confirmed the effects of heat on mortality and morbidity in European populations and particularly in older people and those with chronic disease (Åström *et al.*, 2011)(Kovats and Hajat, 2008). With respect to sub-regional vulnerability, populations in southern Europe appear to be most sensitive to hot weather (Åström *et al.*, 2013)(Baccini *et al.*, 2011)(Corobov *et al.*, 2011 (in press))(Iñiguez *et al.*, 2010; Tobías *et al.*, 2010), and also will experience the highest heat exposures (Iñiguez *et al.*, 2010; Tobías *et al.*, 2010) (Figure 23-2). However, elderly populations in central (Hertel *et al.*, 2009) and northern Europe (Rocklöv and Forsberg, 2010)(Armstrong *et al.*, 2011)(Varakina *et al.*,

2011) are also vulnerable to heat wave events. Adaptation measures to reduce heat health effects include heat wave plans (EEA-JRC-WHO, 2008) which have been shown to reduce heat-related mortality in Italy (Schifano *et al.*, 2012) and France. There is little information about how future changes in housing and infrastructure (e.g. retrofitting houses, installing cool rooms in residential homes) would reduce the regional or local burden of heat-related mortality. Most published risk assessments do not include consideration of adaptation (Huang *et al.*, 2011). Further work has been done to characterize heat stress as an occupational hazard (see chapter 11).

Climate change will increase the frequency and the intensity of major heat wave events (Figure 23-2), which are associated with significant acute impacts on mortality and morbiditiy (Robine *et al.*, 2008)(Solymosi *et al.*, 2010). Several studies have estimated the impact of climate scenarios on future heat-related mortality at the city level. A comparison of additional mortality in 15 cities (Baccini *et al.*, 2011) estimated highest attributable burdens in Budapest and Athens (A2 emissions scenario), with least impacts in Dublin, Zurich and Ljubljana by 2030. For most countries in Europe, the current burden of cold-related mortality is greater than the burden of heat mortality, although few studies have quantified benefits of climate warming in terms of the reduction of cold related mortality (Doyon *et al.*, 2008). A Europe-wide assessment, estimated that increase in heat-related mortality would only exceed the decrease in cold-related mortality at some point during the last third of the century assuming no adaptation, and an increased variance in daily temperature distributions (Ballester *et al.*, 2011).

Mortality and morbidity associated with flooding is becoming better understood although the surveillance of health effects of disasters remains inadequate. Additional mortality due to flooding has been estimated in the Netherlands due to sea level rise (Maaskant *et al.*, 2009); and in the UK for river flooding (Hames and Vardoulakis, 2012) but estimates of future mortality due to flooding are highly uncertain. There remains limited evidence regarding the long term mental health impacts of flood events (Paranjothy *et al.*, 2011)(Murray *et al.*, 2011).

Evidence about future risks from climate change with respect to infectious diseases is still limited (Semenza *et al.*, 2012)(Randolph and Rogers, 2010). There have been developments in mapping the current and potential future distribution of important vectors in Europe. The Asian tiger mosquito *Aedes albopictus*, is an important vector of dengue and other arboviruses, such as Chikungunya (Queyriaux *et al.*, 2008). The vector is currently present in many countries in southern and eastern Europe (ECDC, 2009). An assessment of the potential impact of climate change indicated limited potential for eastward expansion (ECDC, 2009)(Fisher *et al.*, 2011; Caminade *et al.*, 2012). A study in Italy projected the potential for northward shift of the vector's distribution in that country (Roiz *et al.*, 2011). For *Ae. Aegypti* (dengue vector that is not present in Europe), there are some areas that could potentially become suitable under climate change by 2050, including the Mediterranean areas of Spain, France and Italy as well as south-eastern Europe (ECDC, 2012). However, the risk of introduction of dengue remains very low because it would depend upon the upon the introduction and expansion of the *Ae. Aegypti* together with the absence of effective vector control measures (ECDC, 2012).

Visceral and cutaneous leishmaniasis are sandfly-borne diseases currently present in the Mediterranean region. A comprehensive review described that climate change is unlikely to affect the distribution of these infections in the near term (Ready, 2010). However, in the long term (15-20 years), there was potential for climate change to facilitate the expansion of either vectors or current parasites northwards . The risk of introduction of exotic Leishmania species was considered very low due to the low competence of current vectors (Fischer *et al.*, 2010a). The effect of climate warming on the risk of imported or locally-transmitted (autochthonous) malaria in Europe has been assessed in Spain (Sainz-Elipe *et al.*, 2010), France (Linard *et al.*, 2009) and the UK (Lindsay *et al.*, 2010). Disease re-emergence would depend upon many factors including: the introduction of a large population of infectious people or mosquitoes, high levels of people-vector contact, resulting from significant changes in land use, as well as climate change.

Since AR4 there have been several studies and reviews that have investigated the impact of climate change on food safety, at all stages from production to consumption (FAO, 2008; Jacxsens *et al.*, 2010; Popov Janevska *et al.*, 2010)(Miraglia *et al.*, 2009). The transmission of salmonellosis (a food pathogen) is sensitive to temperature but this sensivity has declined in recent years (Lake *et al.*, 2009) and the overall incidence of salmonellosis is declining in most European countries (ECDC, 2011). Climate change may also have affects on food consumption patterns (the reduction in consumption of animal products would benefit methane emissions reduction). Weather affects pre and

post harvest mycotoxin production but the implications of climate change are unclear. Cold regions may become liable to temperate-zone problems concerning contamination ochratoxin *A, patulin* and *Fusarium* toxins (Paterson and Lima, 2010). A control of the environment of storage facilities may avoid post-harvest problems but at additional cost (Paterson and Lima, 2010).

Other potential consequences concern marine biotoxins in seafood following production of phycotoxins by harmful algal blooms and the presence of pathogenic bacteria in foods following more frequent extreme weather conditions (Miraglia *et al.*, 2009). There is little evidence that climate change will affect human exposures to contaminants in the soil or water (e.g. persistent organic pollutants). Risk modelling is often developed for single exposure agents (e.g. a pesticide) with known routes of exposure. These are difficult to scale up to the population level. The multiple mechanisms by climate may affect transmission or contamination routes also makes this very complex (Boxall *et al.*, 2009).

Adaptation in the health sector has so far been largely limited to the development of heat health warning systems. A survey of national infectious disease experts in Europe identified several institutional changes that needed to be addressed to improve future responses to climate change risks: ongoing surveillance programs, collaboration with veterinary sector and management of animal disease outbreaks, national monitoring and control of climate-sensitive infectious diseases, health services during an infectious disease outbreak and diagnostic support during an epidemic (Semenza *et al.*, 2012).

23.5.2. Health Systems and Critical Infrastructure

Critical national infrastructure is defined as the assets (physical or electronic) that are vital to the continued delivery and integrity of the essential services upon which a country relies, the loss or compromise of which would lead to severe economic or social consequences or to loss of life. Extreme weather events, such as floods, heat waves and wild fires are known to damage critical infrastructure. The UK floods in 2007 leds to significant damage to power and water utilities, and damage to communications (including roads) responsible for 10% and 7% of the total costs, respectively (Chatterton *et al.*, 2010). Several countries have undertaken reviews of flood risks to hospitals, schools, water treatment/pumping stations. In 2007, a forest fire in Greece caused the closure of a major road and access to the international airport. Major storms in Sweden and Finland have led to loss of trees, with damage to the power distribution network, leading to electricity blackouts lasting weeks, as well as the paralysis of services such as rail transport and other public services that depend on grid electricity.

Health systems (hospitals, clinics) are also vulnerable to extreme events. The heat waves of 2003 and 2006 had adverse effects on patients and staff in hospitals from overheating of buildings. Evidence from France and Italy indicate that death rates in in-patients increased significantly during heat wave events (Ferron *et al.*, 2006; Stafoggia *et al.*, 2008). Further, higher temperatures have had serious implications for the delivery of health cares, as well drug storage and transport.

23.5.3. Social Impacts

There is little evidence regarding the implications of climate change for employment and/or livelihoods in Europe. However, the evidence so far (as reviewed in this chapter) indicates that there are likely to be changes to some industries (e.g. tourism, agriculture) that may lead to changes in employment opportunities by region and by sector in the longer term, particularly after mid-century.

The current burden for weather disasters is high (see above). Flooding can have long lasting effects of the affected populations (Schnitzler *et al.*, 2007). Households are often displaced while their homes are repaired. A flood event in the UK found that a significant proportion of persons were still displaced 12 months after the event (Whittle *et al.*, 2010). Little research has been carried out on the impact of extreme weather events such as heat waves and flooding on temporary or permanent displacement in Europe (EC, 2009a). Coastal erosion associated with sea level rise, storm surges and coastal flooding will require coastal retreat in some of Europe's low lying areas (Nicholls and

Cazenave, 2010)(Philippart *et al.*, 2011). Managed retreat is also an adaptation option in some coastal areas. Concerns have been raised about equality of access to adaptation within coastal populations at risk from climate change. For example, a study in the UK found that vulnerability to climate change in coastal communities is likely to be increased by social deprivation (Zsamboky *et al.*, 2011).

In the European region, the indigenous populations are present in Arctic regions are considered vulnerable to climate change impacts on livelihoods and food sources (Arctic Climate Impact Assessment, 2005) [12.3.4, 28.2.4]. Research has focussed on indigenous knowledge, impacts on traditional food sources and community responses/adaptation (Mustonen and Mustonen, 2011a; Mustonen and Mustonen, 2011b). However, these communities are also experiencing rapid social, economic and other non-climate-related environmental changes (such as oil and gas exploration) [see 28.2.4]. A study of European reindeer husbandary found that socio-economic factors were likely to be much more important than climate change for future sustainability (Rees *et al.*, 2008) [28.2.3.5].

23.5.4. Cultural Heritage and Landscapes

Climate change will affect the built environment that is culturally valued (Storm *et al.*, 2008) through extreme events and chronic damage to materials (Brimblecombe *et al.*, 2006; Brimblecombe and Grossi, 2010; Brimblecombe, 2010a; Brimblecombe, 2010b; Grossi *et al.*, 2011)(Sabbioni *et al.*, 2010). Cultural heritage is a non renewable resource and impacts from environmental changes are assessed over long timescales (Brimblecombe and Grossi, 2008)(Grossi *et al.*, 2008; Bonazza *et al.*, 2009a; Bonazza *et al.*, 2009b; Brimblecombe and Grossi, 2009; Brimblecombe and Grossi, 2010). Climate change may also affect indoor environments where cultural heritage is preserved (Lankester and Brimblecombe, 2010) as well as visitor behaviour at heritage sites (Grossi *et al.*, 2010).

Surface recession on marble and compact limestone will change in response to climate change. In the 2080s, Central Europe, Norway, the northern UK and Spain will experience surface recession ranging between 20 and 30 μm/y. Conversely, a decrease in surface recession of about 1-4 μm/y is projected for Southern Europe, reducing risk (Bonazza *et al.*, 2009a). Marble monuments located in the Mediterranean will continue to experience high levels of thermal stress (Bonazza *et al.*, 2009b). However, frost damage will reduce across Europe because of warming, except in Northern, and Alpine and permafrost areas (Iceland) (Grossi *et al.*, 2007; Sabbioni *et al.*, 2008). Damage to porous materials due to salt crystallisation may increase all over Europe (Benavente *et al.*, 2008; Grossi *et al.*, 2011). In Northern and Eastern Europe, wood structures will need additional protection against rainwater and some structures may need additional protection from high winds (Sabbioni *et al.*, 2010). AR4 concluded that then current flood defence schemes would not protect Venice from climate change. Venice now has a flood forecasting system, as well as the MOSE system of flood barriers (Keskitalo, 2010) but recent evidence suggests that climate change may lead to a decrease in the frequency of extreme storm surges (Troccoli *et al.*, 2011 (in press)).

Europe has many unique rural landscapes, which reflect the cultural heritage that has evolved from centuries of human intervention. Examples include, amongst others, the cork oak based Montado in Portugal, the Garrigue of southern France, Alpine meadows, grouse moors in the UK; machair in Scotland, peatlands in Ireland, and vineyards. Many, if not all, of these cultural landscapes are sensitive to climate change and even small changes in the climate could have significant impacts on their capacity to function as they have done in the past (Gifford *et al.*, 2011). Because of their cultural importance, many such landscapes are protected through rural development and environmental policies. Alpine meadows, for example, are culturally important within Europe, but although there is analysis of the economic (tourism, farming) and functional (water run-off, flooding, carbon sequestration) aspects of these landscapes there is very little understanding of the consequences for the cultural aspects of these areas and the societies who depend on them. Other European uplands, such as peat rich uplands in northern Europe have begun to consider landscape management as a means of adapting to the effects of climate change (e.g. the moors for the future partnership in the Peak District National Park, UK). For a discussion of the cultural implications of climate change for vineyards see Box 23-1.

Box 23-1. Implications of Climate Change Impacts for European Wine and Vineyards

There is a significant body of research on the impacts of climate change on wine production and the cultural landscapes embodied in vineyards (Metzger and Rounsevell, 2011) (White *et al.*, 2009). Wine production in Europe accounts for more than 60% of the global total (Goode, 2012) and makes an important contribution to cultural identity. It is also an exemplar of how climate change can affect not only the biophysical response of plants and the geographic distribution of wine grape varieties, but also consumer perceptions of wine that are associated with the cultural diversity of regional production. Taken together these effects make the European wine sector highly sensitive to climate change and one that is already taking climate adaptation seriously (Goode, 2012).

Apart from impacts on grapevine yield, higher temperatures are also expected to affect wine quality in some regions and grape varieties by changing the ratio between sugar and acids (Bock *et al.*, 2011)(Santos *et al.*, 2011)(Duchêne *et al.*, 2010). In western and central Europe, projected future changes could benefit wine quality, but might also demarcate new potential areas for viticulture (Malheiro *et al.*, 2010). Adaptation measures are already occurring in some vineyards (e.g. vine management, technological measures, production control and to a smaller extent relocation) (Battaglini *et al.*, 2009; Holland and Smit, 2010; Malheiro *et al.*, 2010; Duarte Alonso and O'Neill, 2011; Moriondo *et al.*, 2011; Santos *et al.*, 2011).

Whilst the distribution of grape suitability will change in response to climate change, relocation as an adaptation option is constrained by the concept of 'terroir', which combines the influence of a location's soils, climate and topography with the knowledge and traditions of wine producers, into a unique expression of landscape culture (Metzger and Rounsevell, 2011). Vineyards may be displaced geographically beyond their traditional boundaries, and in principle, wine producers could adapt to this problem by growing grape varieties that are more suited to warmer climates. Such technical solutions, however, do not account for the unique characteristics of wine production cultures and consumer perceptions of wine quality that strongly affect the prices paid for the best wines (Metzger and Rounsevell, 2011)(White *et al.*, 2009). It would become very difficult, for example, to produce fine wines from the cool-climate Pinot Noir grape within its traditional 'terroir' of Burgundy under many future climate scenarios, but consumers may not be willing to pay current day prices for red wines produced from other grape varieties (Metzger and Rounsevell, 2011). An additional barrier to adaptation is that wine is usually produced within rigid, regionally-specific, regulatory frameworks that often prescribe, amongst other things, what grapes can be grown where, e.g. the French AC or the Italian DOC and DOCG designations. Suggestions have been made to replace these rigid concepts of regional identity with a geographically flexible 'terroir' that ties a historical or constructed sense of culture to the wine maker and not to the region (White *et al.*, 2009).

23.6. Implications of Climate Change for the Protection of Environmental Quality and Biological Conservation

Terrestrial and freshwater ecosystems provide a number of vital services for people and society, such as biodiversity, food, fibre, water resources, carbon sequestration and recreation (Stoate *et al.*, 2009). Intensively managed ecosystems contribute mostly to vital provisioning services (e.g. agro-ecosystems provide food via crops and livestock, and forests provide wood). The condition of the majority of services shows either a degraded or mixed status across Europe with some exceptions, however, such as the recent enhancements in timber production and climate regulation in forests (Harrison *et al.*, 2010). Appropriate agricultural management practices are critical to realizing the benefits of ecosystem services (Power, 2010). Table 23-2 summarises the potential implications of climate change for ecosystem services in Europe.

[INSERT TABLE 23-2 HERE
Table 23-2: Impacts of climate change on ecosystem services.]

23.6.1. Air Quality

Climate change will have complex and local effects on pollution chemistry, transport, emissions and deposition. Outdoor air pollutants have adverse effects on human health, biodiversity, crop yields and cultural heritage. The main outcomes of concern are both the average (background) levels and peak events for tropospheric ozone, particulates, sulphur oxides (SO_x) and nitrogen oxides (NO_x). Future pollutant concentrations in Europe have been assessed using atmospheric chemistry models, principally for ozone (Forkel and Knoche, 2006; Forkel and Knoche, 2007). Reviews have concluded that GCM/CTM studies find that climate change per se (assuming no change in future emissions or other factors) is likely to increase summer tropospheric ozone levels (range 1–10 ppb) by 2050s in polluted areas (that is, where concentrations of precursor nitrogen oxides are higher) (AQEP, 2007; Jacob and Winner, 2009)[see also 21.4.1.3.2.]. The effect of future climate change alone on future concentrations of particulates, nitrogen oxides and volatile organic compounds is much more uncertain. Climate warming also affects natural emissions volatile organic compounds (VOCs) which are ozone precursors (Hartikainen *et al.*, 2012). One study has projected an increase in fire-related air pollution (O3 and PM10) in Southern Europe (Carvalho *et al.*, 2011).

Overall, the model studies are inconsistent regarding future projections of background level and exceedences. Recent evidence has shown adverse impacts on agriculture from even low concentrations of ozone, however, there is more consistent evidence now regarding the threshold for health (mortality) impacts of ozone. Therefore, it is unclear whether increases in background levels below health-related thresholds would be associated with an increased burden of ill health.

Some studies have attributed an observed increase in European ozone levels to observed warming (Meleux *et al.*, 2007), which appears to be driven by the increase in extreme heat events in 2003, 2006 and 2010 (Solberg *et al.*, 2008). Peak ozone events were observed during the major heat waves in Europe in multiple countries. Fire events have had an impact on local on air quality (Hodzic *et al.*, 2007; Liu *et al.*, 2009; Miranda *et al.*, 2009).

23.6.2. Soil Quality

The current cost of erosion, organic matter decline, salinisation, landslides and contamination is estimated to be EUR 38 billion annually for the EU25 (JRC-EEA, 2010), currently borne by society in the form of damage to infrastructures due to sediment runoff and landslides, treatment of water contaminated through the soil, disposal of sediments, depreciation of land around contaminated sites, increased food safety controls, and costs related to the ecosystem functions of soil (JRC-EEA, 2010).

Projections show significant reductions in summer soil moisture in the Mediterranean region, and increases in the north-eastern part of Europe (Calanca *et al.*, 2006). Soil water content will decline, saturation conditions will be increasingly rare and restricted to periods in winter and spring, and snow accumulation and melting will change, especially in the mid-mountain areas (García-Ruiz *et al.*, 2011). For the A2 emission scenario and a set of land use scenarios in Tuscany, even with a decline in precipitation volume until 2070, in some month higher erosion rates would occur due to higher rainfall erosivity (Marker *et al.*, 2008). However, a case study on cropped systems in Upper-Austria based on the A2 emission scenario (regional climate model HadRM3H) projects a small reduction in average soil losses under climate change in all tillage systems, however with high uncertainty (Scholz *et al.*, 2008). For a case study hillslope in Northern Ireland, with the A2 scenario downscaled GCMs generally result in erosion decreases, whereas large increases are projected when land use is changed from the current cover of grass to an arable crop which requires annual tillage (Mullan *et al.*, 2012). For scenario period 2071-2100, climate-change-induced changes in suspended sediment transport would increase for two Danish river catchments by 17 and 27% in alluvial and non-alluvial rivers, respectively, for steady-state land use scenarios (Thodsen, 2007; Thodsen *et al.*, 2008).

Under a business as usual land management scenario, taking into account the impacts of climate change on net primary productivity, a comparison of three soil models forced by climate scenarios derived from the HadCM3

climate model indicate a 10 % decline by 2070 in the organic carbon stocks of mineral soils for the croplands of European Russia and the Ukraine. Part of this decline could be mitigated by an environmentally sustainable management scenario (Smith, 2007). For EU25 plus Switzerland and Norway, projections under the A2 scenario for 1990 to 2080 of mineral soil organic carbon stocks in cropland and grassland soils show a small increase in soil carbon on a per area basis under future climate (+1 to +8%) for cropland and (+3 to +6%) for grassland (Smith J. *et al.*, 2005.). Similar values of soil organic C stock increase were simulated by a pasture model under the A1B climate scenario for two French grassland sites (Graux *et al.*, 2012). In these studies, soil carbon decline was faster in regions experiencing rapid warming combined with high soil moisture (e.g. Northern Europe), than in regions exposed to increased drought incidence (e.g. Southern Europe).Climate change may affect the distribution and degradation of organic pollutants, including persistent organic pollutants (Valle *et al.*, 2007).

Adaptive land-use management has a large potential for climate change response strategies concerning soil protection. In central Europe, compared to unsustainably high soil losses for conventional tillage, conservation tillage systems reduced modelled soil erosion rates under future climate scenarios by between 49 and 87% (Scholz *et al.*, 2008). Preserving upland vegetation cover is a win-win management strategy that will reduce erosion and loss of soil carbon, and protect a variety of services such as the continued delivery of a high quality water resource (House *et al.*, 2011)(McHugh, 2007). By absorbing up to twenty times its weight in water, increased soil organic matter can contribute to reduce risks of flooding. Maintaining water retention capacity is thus important, e.g. through adaptation measures (Post *et al.*, 2008). Soil conservation methods like zero tillage and conversion of arable to grasslands would maintain their protective effect on soil resources, independent of the climate scenario according to an up-scaling and modelling approach in SW-Germany that considered, however, in limited way climate-induced changes in the frequency and intensity of heavy rainstorms (Klik and Eitzinger, 2010).

23.6.3. Water Quality

Climate change may affect water quality in several ways, with implications for food production and forestry (see above 23.4.3), ecosystem functioning (Table 23-2), human and animal health, and compliance with European and national quality targets including those of the Water Framework Directive. Overall, because of the high heat capacity of water, shallow waters will witness a more rapid temperature increase and a parallel decrease in saturating oxygen concentrations. Since AR4, there is further evidence of adverse effects caused by short-term weather events: reductions in dissolved oxygen, algal blooms (Ulén and Weyhenmeyer, 2007)(Mooij *et al.*, 2008) during hot weather, and contamination of surface and coastal waters with sewage and/or chemicals (pesticides) after rainfall (Boxall *et al.*, 2009). A reduction in rainfall may lead to low flows which increase concentrations of biological and chemical contaminants. Reduced drainage can also enhance sedimentation in drainage systems and hence enhance particle-bound P-retention and reduce P-load to downstream higher order streams (Hellmann and Vermaat, 2012).

Future impacts of climate change on water quality include increased nutrient fluxes (Delpla *et al.*, 2011); impacts from increased water temperature and discharge reduction in the Seine river (Ducharne, 2008) and increased nutrient loads in Danish watersheds (Andersen *et al.*, 2006); increased summer temperature and drought leading to more favourable conditions for algal blooms and reduced dilution capacity of effluent in the Meuse river (van Vliet and Zwolsman, 2008). Several studies have investigated potential adverse impacts on nutrient flushing episodes and surface water quality in the UK (Whitehead *et al.*, 2006; Whitehead *et al.*, 2009)(Wilby *et al.*, 2006; Howden *et al.*, 2010; Macleod *et al.*, 2012)(See also AR5 WG2 Chapter 4.3.2.5). A modelling study on projected future water quality impacts for all EU27 countries indicated increased nutrient loadings in Northern Europe due to increased surface runoff in Southern Europe due to increased evapotranspiration (Jeppesen *et al.*, 2011).

23.6.4. Terrestrial and Freshwater Ecosystems

Habitats

Current and future climate changes have negative effects of habitat loss on species density and diversity (Mantyka-pringle *et al.*, 2012). Potential habitat shrinkage is occurring even when CO_2 physiological effects and water availability are taken into account (Rickebusch *et al.*, 2008).

Projected habitat loss is greater for species at higher elevations where, up to 36–55% of alpine plant species, 31–51% of subalpine plant species and 19–46% of montane plant species will lose more than 80% of their suitable habitat by 2070–2100 under B1and A1FI scenarios respectively (Engler *et al.*, 2011). Habitats of 150 alpine plant species on European Alps will suffer an average range size reduction of 44-50% and on average 40% of the range still occupied at the end of the century will be climatically unsuitable creating an extinction debt (Dullinger *et al.*, 2012). Suitable climatic conditions for Europe's breeding birds are projected to shift nearly 550 km northeast by the end of the century (Huntley *et al.*, 2007). In Great Britain mean altitude of the uplands is projected to increase for both B1 and A1FI scenarios by 2071–2100 with important implications on habitats, with in the eastern and southern regions low altitude areas (< 300 meters) being the most vulnerable (Clark *et al.*, 2010a).

In respect to the baseline distribution (1961-1990), British blanket peat and sub-arctic palsa mires, will reduce substantially suitable area by the period 2030-2049 under A1B and A2 emission scenarios (Fronzek *et al.*, 2006; Fronzek *et al.*, 2010; Gallego-Sala *et al.*, 2010; Clark *et al.*, 2010b; Fronzek *et al.*, 2011). Also changes in low flows result in reduction of fen and bog areas becoming marginal or unsuitable due to dryness (Harrison *et al.*, 2008). Across most of central, eastern and southern Europe, reduced hydro periods (the length of time and portion of year the wetland holds ponded water) and increased temperatures with parallel reduced oxygen in shallow waters and wetlands will have profound impacts on aquatic habitats and habitat connectivity in river networks may become increasingly fragmented (Elzinga *et al.*, 2007; Della Bella *et al.*, 2008; Blaustein *et al.*, 2010; Gómez-Rodríguez *et al.*, 2010; Hartel *et al.*, 2011; Morán-López *et al.*, 2012; Morán-López *et al.*, 2012).

Despite some local successes and increasing responses (including extent and biodiversity coverage of protected areas, sustainable forest management, policy responses to invasive alien species, and biodiversity-related aid), the rate of biodiversity loss does not appear to be slowing (Butchart *et al.*, 2010). Protected areas play a key role for conservation of biodiversity under climate change compared to unprotected areas, although by 2080, 58 ± 2.6% of the species would lose suitable climate in protected areas. Natura 2000 areas will be not effective or more impacted than unprotected areas, under A1FI, A2, B1, B2 scenarios (Araújo *et al.*, 2011). Similar concerns about effectiveness of protected areas are found for butterflies in Germany (Filz *et al.*, 2012). It has been highlighted the importance of taking into account the climate change projections on the selection of conservation areas (Araújo *et al.*, 2011; Filz *et al.*, 2012; Virkkala *et al.*, 2013).

Plant species

Observed changes in plant communities in European mountainous regions show a shift of species' ranges to higher altitudes due to climate warming (Pauli *et al.*, 2012) resulting in species richness increase in boreal-temperate mountain regions (+3.9 species on average) and decrease in Mediterranean mountain regions (–1.4 species) in 2001-2008 (Pauli *et al.*, 2012). Decline of the more cold adapted species and increase of the more warm-adapted has been observed, suggesting a progressive decline of cold mountain habitats and their biota (Gottfried *et al.*, 2012). The pollen season starts on average 10 days earlier than 50 years ago, an advance of 2.5 days per decade of spring and summer (Feehan *et al.*, 2009).

The most dramatic changes for plant species could occur in Northern Europe, where more than 35% of the species composition in 2100 could be new, and in Southern Europe, where up to 25% of the species now present would disappear (Alkemade *et al.*, 2011). Large range contractions up to 72% in 2080 due to climate change is projected for temperate tree species in European lowlands under A2 scenario (Casalegno et al., 2007). The increase in climatic aridity may compromise the survival of several populations of *Pinus sylvestris* in the Mediterranean basin

(Giuggiola *et al.*, 2010) while for the dominant Mediterranean tree species, Holm oak, a substantial range expansion is projected under A1B emissions scenario (Cheaib *et al.*, 2012). The scattered distributions of tree species, exacerbated in many cases by human activity, may make them more vulnerable to climate change because they probably have less ability to reproduce or adapt to shifting climate space than more widespread species (del Barrio *et al.*, 2006; Hemery *et al.*, 2010). By 2100, in southern Europe a great reduction in phylogenetic diversity of plant, bird and mammal assemblages will occur, and gains are expected in regions of high latitude or altitude for 2020, 2050 and 2080. However, losses will not be offset by gains and a trend towards homogenization across the continent will be observed (Thuiller *et al.*, 2011).

Animal species

Breeding seasons are lengthening, allowing extra generations of temperature-sensitive insects such as butterflies, dragonflies and pest species to be produced during the year (Feehan *et al.*, 2009). Climate change is altering the timing of spring migration of several bird species with species-specific response (Jonzén *et al.*, 2006; Rubolini *et al.*, 2007a; Rubolini *et al.*, 2007b). Climate change, together with land-use change, is likely to cause impacts on the abundance of birds of different breeding habitat, latitudinal distribution, and migratory behaviour, particularly on distance migrants (Jonzén *et al.*, 2006). Farmland birds and long-distance migrant species in Germany, Switzerland, and Austria declined whereas wetland bird species with southerly ranges increased in abundance (Lemoine *et al.*, 2007a; Lemoine *et al.*, 2007b). A northward shift in bird community composition has been observed (Devictor *et al.*, 2008) even if common species of European birds with the lowest thermal maxima showed the sharpest declines between 1980 and 2005(Jiguet *et al.*, 2010). Northern European species of butterflies appeared to be the most vulnerable in Europe (Heikkinen *et al.*, 2010). However, there is much species-to-species variation with individualistic response to climate change leading to the formation of new future non-analogous communities with species composition unlike any found today (Keith *et al.*, 2009).

Projections for 120 native terrestrial non-volant European mammals suggest that up to 5-9% are at risk extinction during the 21st century, while 32-46% or 70-78% may be severely threatened under A1 and B2 climatic scenarios (Levinsky *et al.*, 2007). Climate cooling would be more deleterious for the persistence of amphibian and reptile species than warming, even if decreases in the availability of water will be also problematic (Araújo *et al.*, 2006). Changes in temperature and precipitation will result in both changes in migratory species and adaptation of migratory activity (Schaefer *et al.*, 2008). Furthermore phenotype adaptation may allow species to persist *in situ*, conserving community composition (Schaefer *et al.*, 2008). However, populations not showing a phenological response to climate change fail to adjust to climate change and may decline (Molnar *et al.*, 2008) or causing ecological mismatches (Saino *et al.*, 2011). Climate change can affect trophic interactions, as co-occurring species do not necessarily react in a similar manner to global change (Schweiger *et al.*, 2012). Novel emergent ecosystems composed of new species assemblages arising from differential rates of range shifts of species can occur (Montoya and Raffaelli, 2010).

Invasive species

Climate change can exacerbate the threat posed by invasive species to biodiversity, both by direct and indirect effects such as changes to farm practices and introductions of exotic material and effects of other environment changes such as elevated CO_2 concentration and change in temperature and precipitation (West *et al.*, 2012). The western corn rootworm (maize pest in North America) has invaded Europe in recent years (Aragòn and Lobo, 2012). The 22.2% of the total number of mammal species in Europe are alien species (Genovesi *et al.*, 2012). Planktonic species typically encountered in tropical areas were observed in natural shallow lakes in the southwest of France during 2006 and 2007 possibly as a result of minimum temperatures increases registered over the last 30 years and could have played a key role in algal survival through winter (Cellamare *et al.*, 2010). The woody shrub Lantana (*Lantana camara* L.) that is highly invasive in many countries of the world may become climatically suitable under future climates in Europe (Taylor *et al.*, 2012). Climate scenarios of milder conditions for Atlantic Europe could lead to Giant rhubarb (*Gunnera tinctoria* (Molina) Mirbel.) and Brazilian giant rhubarb (*Gunnera manicata* L.) becoming more widely invasive (Skeffington and Hall, 2011). However the threat posed by invasive species to

biodiversity should be carefully considered as some studies demonstrate that fewer than 15% of species have more than 10% of their invaded distribution outside their native climatic niche (Petitpierre *et al.*, 2012).

23.6.5. Coastal and Marine Ecosystems

Climate change will affect Europe's coastal and marine ecosystems, altering the biodiversity, functional dynamics and ecosystem services of coastal wetlands, dunes, inter-tidal and subtidal habitats, offshore shelves, seamounts and currents (Halpern *et al.*, 2008) with changes in eutrophication, invasive species, species range shifts, changes in fish stocks and habitat loss (Doney *et al.*, 2011)(EEA, 2010e). The degree to which these changes will impact Europe's coasts and seas will vary temporally and spatially, requiring a range of adaptation strategies, targeting different policy scales, audiences and instruments (Philippart *et al.*, 2011)(Airoldi and Bec, 2007).

Europe's northern seas are experiencing greater increases in sea surface temperatures (SSTs) than the southern seas, with the Baltic, North and Black seas warming at 2-4 times the mean global rate (Philippart *et al.*, 2011)(Belkin, 2009). In the Baltic, decreased sea ice will lead to more exposed coastal areas and storms, changing the coastal geomorphology (BACC, 2008)(HELCOM, 2007). Warming SSTs will continue to influence biodiversity and drive changes in depth and latitudinal range for intertidal and sub-tidal marine communities, particularly in the North and Celtic seas (Hawkins *et al.*, 2011)(Sorte *et al.*, 2010)(Wethey *et al.*, 2011).

Warming is affecting food chains and varying rates of phenologies (Durant *et al.*, 2007), for example the reorganization in the timing and location of phytoplankton and zooplankton affects prey availability for North Sea cod (Beaugrand *et al.*, 2010)(Beaugrand and Kirby, 2010). Temperature-driven changes have affected the distribution of fisheries in all seas within the past 30 years, e.g., a decrease in the range of Atlantic cod in northern seas, while an increase in the abundance of coastal species such as the anchovy in subtropical regions. The range of the red mullet is increasing in extent from Norway to the northwest of Africa including the Mediterranean and Black Sea. In the Bay of Biscay, responses to climate change in 20 species of flatfish from 1987 to 2006 show that expanding species have a lower latitude range, than the declining species (Hermant *et al.*, 2010).

Warmer waters are also linked to invasive species which displace native species, further altering trophic dynamics, and productivity of coastal marine ecosystems, requiring a redefinition of invasive and native species (Molnar *et al.*, 2008)(Rahel and Olden, 2008). Changes in the semi-enclosed seas will be indicative of future conditions in other coastal-marine ecosystems (Lejeusne *et al.*, 2009). In the Mediterranean, a relatively high proportion of endemic species has been associated with the arrival of alien species at the rate of one introduction every 4 or 5 weeks in recent years (Streftaris *et al.*, 2005). While in the Mediterranean the endemic species distribution remained stable, most non-native species have spread northward by an average of 300 km since the 1980s, resulting in an area of spatial overlap with invasive species replacing natives by nearly 25% in 20 years (Beaugrand and Kirby, 2010).

Other future impacts of climate change in Europe's coastal-marine ecosystems include changes in circulation and nutrients in both open and semi-enclosed seas and coastal areas. Stratification of open seas will be primarily affected by the timing and strength of wind, whereas coastal areas will be vulnerable to storm surges (Philippart *et al.*, 2011). Freshwater input from melting of land-based ice has increased since the 1960s with a 10-30% increase from riverine input anticipated by 2100. Freshening of marine salinity is expected in upcoming decades throughout the North East Atlantic, with the Arctic freshening during the 21st century due to river run off, ice melt, and increases in the rate of the global water cycle. Drier summers along Biscay and Iberian coasts may lead to a decrease in nutrient input and enrichment with less runoff. Eutrophication will continue as a major issue in the Baltic (HELCOM, 2009). Yet, wetter winters and summers in the Arctic and North Sea may lead to higher nutrient input (OSPAR, 2010). Eutrophication and deteriorating marine water quality will lead to fewer fish, more jelly fish and more frequent algal blooms particularly in the semi-enclosed seas such as the Baltic (HELCOM, 2009). Before the end of 2100, surface waters of the Baltic Sea could inhibit calcium forming species, more so than the Black and Mediterranean Seas (CIESM, 2008).

Dune systems will be lost due to coastal erosion from combined storm surge and sea level rise in some places, requiring restoration and economic measures (Day *et al.*, 2008)(Ciscar *et al.*, 2011)(Magnan *et al.*, 2009). In the

North Sea, the Iberian coast, and Bay of Biscay, a combination of coastal erosion, infrastructure and sea defences may lead to narrower coastal zones ("coastal squeeze") (EEA, 2010e)(Jackson and McIlvenny, 2011)(OSPAR, 2010).

23.7. Cross-Sectoral Adaptation Decision-making and Risk Management

Most scientific studies on impacts and adaptation in Europe consider single sectors or outcomes, and have been discussed in previous sections of this chapter. For decision-making, more comprehensive and multi-sectoral approaches are required.

Since AR4, considerable progress has been made to advance planning and implementation of adaptation measures as well as the costing of adaptation (Section 23.7.6). Many European countries have now developed a series of national studies and strategies to address adaptation (see Box 23-2). The European Union has started a process of adaptation planning, focussing on information sharing (e.g. through the Climate Adaptation platform) as well as proposals for legislation following up on the White Paper on Adaptation (Dreyfus and Patt, 2012) and the EU Adaptation Strategy (to be published in March 2013).

_____ START BOX 23-2 HERE _____

Box 23-2. National and Local Adaptation Strategies

Several studies have evaluated national or local adaptation strategies with respect to implementation (Biesbroek *et al.*, 2010). Many adaptation strategies were found to be agendas for further research, awareness raising and/or coordination and communication for implementation (e.g. (Pfenniger *et al.*, 2010)(Dumollard and Leseur, 2011). Actual implementation often relates to natural hazard prevention, environmental protection, coastal zone and water resources management. The implementation of planned adaptation at the national level was attributed to political will and good financial and information capacity (Westerhoff *et al.*, 2011)(Biesbroek *et al.*, 2010)(Swart *et al.*, 2009) found for seven national adaptation strategies that while there is a high political commitment to adaptation planning and implementation, evaluation of the strategies and actual implementation is yet to be defined. One of the earliest national adaptation strategies (Finland) has been evaluated, in order to compare identified adaptation measures with those launched in different sectors. It has found that while good progress has been made on research and identification of options, few measures have been implemented except in the water resources sector (Ministry of Agriculture and Forestry, 2009).

At the local government level, adaptation plans are being developed in several cities, including London (GLA, 2010), Madrid, Manchester, Copenhagen, Helsinki, and Rotterdam. Adaptation in general is a low priority for many European cities, and many plans do not have adaptation priority as the main focus (Carter, 2011). Many studies are covering sectors sensitive to climate variability, as well as sectors that are currently under pressure from socioeconomic development. A recent assessment found a lack cross-sector impact and adaptation linkages as an important weakness in the city plans (Hunt and Watkiss, 2011). Flexibility in adaptation decision making needs to be maintained (Hallegatte *et al.*, 2008)(Biesbroek *et al.*, 2010).

_____ END BOX 23-2 HERE _____

23.7.1. Coastal Zone Management

Coastal zone management and coastal protection plans that integrate adaptation concerns are now implemented. Underlying scientific studies increasingly assess effectiveness and costs of options (Hilpert *et al.*, 2007)(Kabat *et al.*, 2009)(Dawson *et al.*, 2011) (see also section 23.7.6). Measures to mainstream adaptation into sectoral policies need to provide early response measures for floods and coastal erosion, and ensure that climate change considerations are incorporated into marine strategies with mechanisms for regular updating (OSPAR, 2010; UNEP, 2010).

In the Dutch plan for coastal protection (Delta Committee, 2008), adaptation to climate change, increasing river runoff and sea level rise plays a prominent role. It also includes synergies with nature conservation, increasing storage for water supply (Kabat *et al.*, 2009), and links to urban renovation. Its cost estimates are included in Section 23.7.6. While that plan mostly relies on large scale measures, new approaches such as small-scale containment of flood risks through increasing compartimentalisation are also studied (Klijn *et al.*, 2009). The UK government has developed extensive adaptation plans (TE2100) to adjust and improve flood defences for the protection the Thames Estuary and London from future storm surges and flooding (Environmental Agency, 2009). An elaborate analysis has provided insight in the pathways for different adaptation options and decisions that depend on the eventual sea-level rise.

23.7.2. Integrated Water Resource Management

Water resources management has experienced a general shift from "hard" to "soft" measures which allow more flexible responses to environmental change (Pahl-Wostl, 2007). Integrated water resource management explicitly includes the consideration of environmental and social impacts (Wiering and Arts, 2006). Climate change has been incorporated into water resources planning in England and Wales (Arnell, 2011)(Charlton and Arnell, 2011)(Wade *et al.*, 2012) and in the Netherlands (de Graaff *et al.*, 2009). The robustness of adaptation strategies for water management in Europe has been tested in England (Dessai and Hulme, 2007) and Denmark (Haasnoot *et al.*, 2012; Refsgaard *et al.*, 2013). Other studies have emphasised the search for robust pathways, for instance in the Netherlands (Kwadijk *et al.*, 2010; Haasnoot *et al.*, 2012). Public participation has also increased in decision making, e.g. river basin management planning (Huntjens *et al.*, 2010), flood defence plans (e.g. TE2100), and drought contingency plans (Iglesias *et al.*, 2007). Guidance has been developed on the inclusion of adaptation in water management (UNECE, 2009) and river basin management plans (EC, 2009b). A study of policymakers, including local basin managers, identified several important barriers to the implementation of adaptation strategies in the water sector (Brouwer *et al.*, 2013).

23.7.3. Disaster Risk Reduction and Risk Management

A series of approaches to disaster risk management are employed in Europe, in response to national and European policy developments to assess and reduce natural hazard risks. New developments since the AR4 include assessment and protection efforts in accordance with the EU Floods Directive (European Parliament and Council, 2007), the mapping of flood risks, as well as other proposals to reduce impacts from natural hazards and improve civil protection response. But most countries have so far focussed on hazard assessment and less on analysis of possible impacts (de Moel *et al.*, 2009). The effectiveness has been assessed of flood protection (Bouwer *et al.*, 2010) and also non-structural or household level measures to reduce losses from river flooding (Botzen *et al.*, 2010a) (Dawson *et al.*, 2011). Some studies show that current plans may be insufficient to cope with increasing risks from climate change, as shown for instance for the Rhine river basin (Te Linde *et al.*, 2010a; Te Linde *et al.*, 2010b).

Other options that are being explored are the reduction of consequences, responsive measures, as well as other options for insuring and transferring losses (see SREX report; and Section 23.3.7). The Netherlands carried out a large-scale analysis and simulation exercise to study the possible emergency and evacuation response for a worst-case flood event (ten Brinke *et al.*, 2010). Increasing attention is also being paid in Europe to non-government actions that can reduce possible impacts from extreme events. Terpstra and Gutteling (2008) found through a survey that individual citizens are willing to assume some responsibility for managing flood risk, and they are willing to contribute to preparations in order to reduce impacts. Survey evidence is available for Germany and the Netherlands that, under certain conditions, individuals can be encouraged to adopt loss prevention measures (Thieken *et al.*, 2006)(Botzen *et al.*, 2009). Small businesses can reduce risks when informed about possibilities immediately after an event (Wedawatta and Ingirige, 2012).

23.7.4. Land Use Planning

Through effects on land use and the spatial configurations of cities, spatial planning policies can build resilience to the impacts of climate change (Bulkeley, 2010). However, the integration of adaptation considerations into spatial planning is limited to a general level of policy formulation that lacks concrete instruments and measures for implementation in practice (Mickwitz *et al.*, 2009)(Swart *et al.*, 2009). There is evidence to suggest a systematic failure of planning policy to account for climate and other environmental changes (Branquart *et al.*, 2008) and a lack of institutional frameworks in support of adaptation is a major barrier to the governance of adaptation through spatial planning (ESPACE, 2007). In many countries, climate change adaptation is treated primarily as a water management or flooding issue, which omits other important aspects of adaptation leading to partial solutions (Mickwitz *et al.*, 2009)(Wilson, 2006)(Van Nieuwaal *et al.*, 2009). For example, in the UK, surveys of local authorities found an overall increase in the area covered by buildings in areas at risk from flooding compared with change across the locality as a whole (2001-2011) (ARUP, 2011).

City governance is also dominated by the issues of climate mitigation and energy consumption rather than assisting cities in adapting to climate change through spatial planning (Bulkeley, 2010). Some cities, e.g. Rotterdam, have started to create climate adaptation plans and this process tends to be driven by the strong political leadership of mayors (Sanchez-Rodriguez, 2009). The Helsinki Metropolitan Area's Climate Change Adaptation Strategy (HSY, 2010) is a regional approach focusing on the built urban environment in the cities of Helsinki, Espoo, Vantaa and Kauniainen, and their surroundings with approximately 1.2 million inhabitants (ca. 20% of the Finnish population). It includes approaches for dealing with increasing heat waves, more drought periods, milder winters, increasing (winter) precipitation, heavy rainfall events, river floods, storm surges, drainage water floods and sea level rise.

Green infrastructure provides climate adaptation and mitigation benefits as well as offering a range of other benefits to urban areas, including health improvements, better amenity value, inward investment, increasing property values and the reduction of noise and air pollution. Thus green infrastructure is an attractive climate adaptation strategy since it simultaneously contributes to the sustainable development of urban areas (Gill *et al.*, 2007; James *et al.*, 2009). Urban green space and green roofs can moderate temperature and decrease surface rainwater run-off (Gill *et al.*, 2007). Despite the benefits however of urban green space, conflict can occur between the use of land for green space and building developments (Wilson, 2008).

European policies for biodiversity (e.g. the European Biodiversity Strategy (EC, 2011)) look to spatial planning to help protect and safeguard internationally and nationally designated sites, networks and species, as well as locally valued sites in urban and non-urban areas, and to create new opportunities for biodiversity through the development process (Wilson, 2008). Conservation planning in response to climate change impacts on species will involve several strategies that better manage isolated habitats, increase colonisation capacity of new climate zones and optimise conservation networks to establish climate refugia (Vos *et al.*, 2008).

23.7.5. Rural Development

Rural development is one of the key policy areas for Europe, yet there is little or no discussion about the role of climate change in affecting future rural development. The EU White Paper on adapting to climate change (EC, 2009a) encourages Member States to embed climate change adaptation into the three strands of rural development aimed at improving competitiveness, the environment, and the quality of life in rural areas. It appears however that little progress has been made in achieving these objectives.

The EUs Leader programme was designed to help rural actors improve the long-term potential of their local areas by encouraging the implementation of sustainable development strategies. A significant number of Leader projects address climate change adaptation, but only as a secondary or in many cases a non-intentional by-product of the primary rural development goals. The World Bank's community adaptation project has seen a preponderance of proposals from rural areas in Eastern Europe and Central Asia (Heltberg *et al.*, 2012) suggesting that adaptation based development needs in Eastern Europe are currently not being met by policy.

23.7.6. Economic Assessments of Adaptation

Compared to studies assessed in AR4 (AR4 WG2, Chapter 17.2.3), costs estimates for Europe are increasingly derived from bottom-up and sector-specific studies, aimed at costing response measures (Watkiss and Hunt, 2010), in addition to the economy-wide assessments (Aaheim *et al.*, 2012). The evidence base, however, is still fragmented and incomplete. The coverage of adaptation costs and benefit estimates is dominated by structural (physical) protection measures, where effectiveness and cost components can be more easily identified. For energy, agriculture, infrastructure there is medium coverage of cost and benefit categories. For other sectors, such as health and welfare, estimates are generally lacking. Table 23-3 summarises some of the more comprehensive cost estimates for Europe for sectors at regional and national level. It is stressed that the costing studies use a range of methods and metrics and relate to different time periods and sectors, which renders robust comparison difficult. As an example, the large differences in the cost estimates between coastal and river protection in Europe and the Netherlands (Table 23-3) are due to the objectives for adaptation and the large differences in the level of acceptable risk: e.g. Rojas *et al.* (2012) assess a 1 in 100 year level of protection for Europe, while the Netherlands has set standards up to 1 in 4,000 and 10,000 year level return periods. More detailed treatment of the economics of adaptation is provided in AR5 WG2 Chapter 17.

[INSERT TABLE 23-3 HERE
Table 23-3: Adaptation cost estimates for European countries.]

23.8. Co-Benefits and Unintended Consequences of Adaptation and Mitigation

The impacts of and responses to climate change cannot be considered in isolation. Scientific evidence for decision making is more useful if impacts are considered in the context of impacts on other sectors and in relation to adaptation, mitigation and other important policies (Mokrech *et al.*, 2012). The benefits of adaptation and mitigation policies can be felt in the near term and in the local population, although benefits relating to greenhouse gas emissions reduction may not be apparent until the longer term (Zylicz, 2010). The benefits of adaptation measures are often assessed using conventional economic analyses, some of which include non-markets costs and benefits (externalities)(Watkiss and Hunt, 2010). This section will describe policies, strategies and measures where there is good evidence regarding mitigation/adaptation costs and benefits. Few studies have quantified directly the trade-offs/synergies for a given policy.

23.8.1. Production and Infrastructure

Mitigation policy (decarbonisation strategies) is likely to have important implications for dwellings across Europe. The unintended consequences of mitigation in the housing sector include: changes to household energy prices and adverse effects from decreased ventilation in dwellings (Davies and Oreszczyn, 2012). Energy efficiency interventions may effect indoor summer temperatures, some acting to reduce temperatures and others acting to increase temperatures (Mavrogianni *et al.*, 2012) and on the concentration of indoor pollutants (Shrubsole *et al.*, 2012). The effect of mitigation measures such as electrical equipment improvements is more complicated; a simulation of a typical UK office indicated that the reduction of internal heat gains as a result of more energy efficient PCs, low energy LCD display technology, improved power management and energy efficient lighting can reduce the peak cooling requirement by up to 27% even under a 2030 warming climate, i.e. +1 ^{o}C compared to 2005 (Jenkins *et al.*, 2008; Jenkins, 2009). However, as space heating requirements would also increase following these interventions, the location, type and dominant energy use of the building will determine its overall energy gain or loss to maintain comfort levels.

Adaptation measures such as the use of cooling devices will probably increase a building's energy consumption if no other mitigation measures are applied. There have been few studies on the future demand for energy-intensive space cooling in Europe, although the majority of energy modelling studies assume increased uptake driven by

climate and non-climate factors (see chapter 10). The potential for cooling dwellings without increased energy consumption, and with health benefits is large (Wilkinson *et al.*, 2009).

When looking at the broader context of urban infrastructures, despite existing efforts to include both adaptation, and mitigation into sustainable development strategies at city level (e.g. Hague, Rotterdam, Hamburg, Madrid, London, Manchester), priority on adaptation still remains low (Carter, 2011). There is potential to develop strategies that can address both mitigation and adaptation solutions, as well as have health and environmental benefits (Milner *et al.*, 2012). In energy supply, the adverse effect of climate change on water resources in some coastal regions in southern Europe may further enhance the development of desalination plants as an adaptation measure, consequently increasing energy consumption and thus greenhouse gases emissions.

In tourism, adaptation and mitigation may be antagonistic, as in the case of artificial snowmaking in European skiing resorts which requires significant amounts of energy and water (OECD, 2007; Rixen *et al.*, 2011) and the case of desalination for potable water production which also requires energy. However, depending on the location and size of the resort, implications are expected to differ and thus need to be investigated on a case-by-case basis. A similar relationship between adaptation and mitigation may hold for tourist settlements in southern Europe, where expected temperature increases during the summer may require increased cooling in order to maintain tourist comfort and thus increase greenhouse gas emissions and operating costs. Furthermore, a change of tourist flows as a result of tourists adapting to climate change may affect transport emissions, while mitigation in transport could also lead to a change in transport prices and thus possibly affect tourist flows.

23.8.2. Agriculture, Forestry, and Bioenergy

Agriculture and forestry face two challenges under climate change, both to reduce emissions and to adapt to a changing and more variable climate (Smith and Olesen, 2010)(Lavalle *et al.*, 2009). The agriculture sector contributes to about 10% of the total anthropogenic greenhouse gas (GHG) emissions in the European Union (EEA, 2010b). Estimates of European carbon dioxide, methane and nitrous oxide fluxes between 2000 and 2005 suggest that methane emissions from livestock and nitrous oxide emissions from agriculture are fully compensated for by the carbon dioxide sink provided by forests and by grassland soils (Schulze *et al.*, 2010). However, projections suggest a significant decline of the forest carbon sink until 2030 in the baseline scenario of about 25–40 compared to 2010 estimate. Including additional bioenergy targets of EU member states has an effect on the development of this sink, which is not accounted in the EU emission reduction target (Bottcher *et al.*, 2012).

Many agricultural practices can potentially mitigate GHG emissions, the most prominent of which are improved cropland and grazing land management and restoration of degraded lands and cultivated organic soils (Smith and Olesen, 2010). Reducing excesses of nitrogen fertilization and substitution of mineral N fertilizers by biological N fixation, as well as improved nutrition of domestic ruminants to reduce methane from enteric fermentation and improved manure management can play a significant role. Lower, but still significant mitigation potential is provided by water and rice management and agro-forestry (Smith and Olesen, 2010). Preserving European soil and forest carbon stocks through careful land use planning and agricultural and forestry management will be required to avoid positive feedbacks on global warming (Schulze *et al.*, 2010) especially during heat and drought extreme events (Ciais *et al.*, 2005). Synergies and trade-offs between mitigation and adaptation need to be incorporated into economic analyses of the mitigation costs (Smith and Olesen, 2010).

In arable production systems, adapting by increasing the resilience to temperature and rainfall variability would have positive impacts on mitigation by reducing soil erosion, as well as soil organic carbon and nitrogen losses. Improving soil water holding capacity through adding crop residues and manure to arable soils or by adding diversity to the crop rotations may contribute both to adaptation and to mitigation (Smith and Olesen, 2010). In contrast, increased irrigation under climate change will increase energy use and may reduce water availability for hydro-power (reduced mitigation potential) (Wreford *et al.*, 2010). Nevertheless, irrigation may enhance soil carbon sequestration in arable systems (Rosenzweig *et al.*, 2008)(Rosenzweig and Tubiello, 2007). In livestock intensive systems, warmer conditions in the coming decades might trigger the implementation of enhanced cooling and ventilation systems (Rosenzweig and Tubiello, 2007), thereby increasing energy use and associated GHG emissions.

In grass-based livestock systems, adaptation by adjusting the mean annual animal stocking density to the herbage growth potential (Fitzgerald *et al.*, 2010)(Graux *et al.*, 2012) is *likely* to create a positive feedback on GHG emissions per unit area (Soussana and Luscher, 2007; Soussana *et al.*, 2010).

Mitigation measures may encourage the production of energy crops, or forestry, in areas that are vulnerable to extreme events (e.g. fires, storms, droughts) or with high water demand, therefore increasing demands on adaptation (Wreford *et al.*, 2010). Conversely, the potential expansion of agriculture at high latitudes may release large amounts of carbon and nitrogen from organic soils, thereby leading to increased demands on mitigation (Rosenzweig and Tubiello, 2007). Available land for bioenergy crops is foremost to be found in Eastern Europe (De Wit *et al.*, 2011). The total available land in Europe (EU27 and Ukraine) for bioenergy crop production could amount to 900 000 km^2 by 2030. Agricultural residues of food and feed crops may provide an additional source for biofuel production. Up to 246 Mt agricultural residues could be available for biofuel production (assuming up to 50% of crop residues can be used without risks for agricultural sustainability) which is comparable to feedstock plantations of 15-20 million hectares (Fischer *et al.*, 2010b). Bioenergy crops could occupy significant areas of rural land within 20 years in the UK (Haughton *et al.*, 2009).

23.8.3. Social and Health Impacts

Significant research has been undertaken since AR4 on the health co-benefits of mitigation policies (see WGIII chapters on Housing, Transport and Energy, and WGII chapter 11). Several assessment have quantified benefits in terms of lives saved by reducing particulate air pollution, and trying to coherent policy objectives for emissions reductions in local and global pollution. Policies that improve health from changes in transport and energy can be said to have a general benefit to population health and resilience (Haines *et al.*, 2009a; Haines *et al.*, 2009b).

Changes to housing and energy policies also have indirect implications for human health. Researches on the benefits of various housing options (including retrofitting) have been intensively addressed in the context of low energy, healthy and sustainable housing (see WGIII).

23.8.4. Environmental Quality and Biological Conservation

Marine protected areas (MPAs) provide place-based management of marine ecosystems through various degrees and types of protective actions. MPA networks are generally accepted as an improvement over individual MPAs to address multiple threats to the marine environment. While MPA networks are considered a potentially effective management approach for conserving marine biodiversity, they should be established in conjunction with other management strategies, such as fisheries regulations and reductions of nutrients and other forms of land-based pollution. Information about interactions between climate change and more "traditional" stressors is limited. MPA managers are faced with high levels of uncertainty about likely outcomes of management actions because climate change impacts have strong interactions with existing stressors, such as land-based sources of pollution, overfishing and destructive fishing practices, invasive species, and diseases. Management options include ameliorating existing stressors, protecting potentially resilient areas, developing networks of MPAs, and integrating climate change into MPA planning, management, and evaluation (Keller *et al.*, 2009). Results in a Mediterranean coastal zone demonstrate that the declaration of a marine reserve alone does not guarantee the sustainability of marine resources and habitats but should be accompanied with an integrated coastal management plan (Lloret and Riera, 2008).

Figure 23-8 illustrates the consequences of the relationships between mitigation and adaptation options and biodiversity (Paterson and Lima, 2010)(Paterson *et al.*, 2009). There are very few management approaches that are win-win-win in terms of mitigation, adaptation and biodiversity and some of these (e.g. forest pest control) have limited implications in terms of adapting to climate change. Other adaptation options, such as desalinisation, sea defences and flood control infrastructure have decidedly negative effects on both mitigation and biodiversity. However, some approaches, such as forest conservation and urban green space (see earlier) have multiple benefits and potentially significant effects.

[INSERT FIGURE 23-8 HERE
Figure 23-8: Adaptation and mitigation options and their effects on biodiversity. Based on Paterson et al., 2009.]

There has been relatively little research about the impacts of future land use demand for bioenergy production, food production and urbanisation on nature conservation.

23.9. Intra-Regional and Inter-Regional Issues

Climate change will have a range of impacts in different European sub-regions. The adaptive capacity of populations is likely to vary significantly within Europe. Adaptive capacity indicators have been developed based on future changes in socio-economic indicators and projections (Metzger *et al.*, 2008; Lung *et al.*, 2012)(Acosta-Michlik *et al.*, 2013; Greiving et al., ESPON). These studies concluded that the Nordic countries have higher adaptive capacity than most of the Southern European countries, with countries around the Mediterranean having a lower capacity than the countries around the Baltic Sea region. Eastern European countries have, in general, lower adaptive capacity than Western or Northern European countries.

23.9.1. Implications of Climate Change for Distribution of Economic Activity within Europe

Table 23-4 summarises the future impacts by each sub-regions. A key finding is that all regions are vulnerable to some impacts from climate change but that these impacts differ significantly in type between the sub-regions. Impacts in neighbouring regions (inter-regional) may redistribute economic activities across the European landscape. The sectors most likely to be affected by climate change, and therefore with implications for economic activity and population movement (changes in employment opportunities) include: tourism, agriculture, and forestry.

[INSERT TABLE 23-4 HERE
Table 23-4: Assessment of future climate change impacts by sub-region and sector (by 2050, medium emissions).]

Economic assessments of impacts across sectors and across Europe indicate large variations across subregions (Ciscar *et al.*, 2011). Annual loss in household welfare in the EU27 resulting from the four market impacts (agriculture, river floods, coastal areas, and tourism) would range between 0.2-1% by 2080s (Ciscar *et al.*, 2011). Northern Europe is the only region project to have net economic benefits in these sectors, driven mainly by the positive effects on agriculture. Coastal systems, agriculture, and river flooding are the most important of the four market impacts assessed.

Impacts of climate change losses on local economies are more serious in a large-scale scenario when neighbouring provinces are also affected by drought and heat wave events. This is due to the supply-side induced price increase leading to some passing on of disaster costs to consumers (Mechler *et al.*, 2010). Growing temperatures across Europe could affect the relative quality of life in different regions which in turn could change the intensity and direction of internal migration flows (as one factor in individuals migration decision making strategy could be temperature) (Kerr and Kerr, 2011).

Climate change may also affect policies regulating agriculture and fisheries across European sub-regions. The Less Favoured Areas (LFA) scheme is a broad European policy mechanism for improving the viability of agriculture in areas with natural handicaps. Land suitability for agricultural production is classified based on climate, soil, and terrain criteria. By 2030, part of Northern Europe would leave areas with climate constraint zone basically because of mean annual temperature increase, while part of central and South Europe would enter these areas as a result of increased aridity (Donatelli *et al.*, 2012). The European Union Common Fisheries Policy is also questioned by changes in the distribution of fish stocks which could affect total allowable catches and their allocations to member states (Arnason, 2012).

23.9.2. Climate Change Impacts Outside Europe and Inter-Regional Implications

In an increasingly globalised world, impacts of climate change in other countries are likely to affect countries within the Europe region. Further, the region is very closely linked to its near neighbours. Countries around the Mediterranean share similar ecologies and therefore some vulnerability (see Box 23-3; see also Chapter 22).

_____ START BOX 23-3 HERE _____

Box 23-3. Climate Change Impacts in the Mediterranean

The Mediterranean area (which encompasses two IPCC regions: Europe and Africa) is particularly vulnerable to climate change. Mediterranean ecosystems have been strongly modified from millennia of human occupation and use. At present, habitat loss and degradation, as well as extraction, pollution, eutrophication and the introduction of alien species, and recently climate change, are the most important threats that affect the greatest number of taxonomic groups occurring in the Mediterranean Sea (Costello *et al.*, 2010; Coll *et al.*, 2012). Areas with high marine biodiversity in the Mediterranean Sea are mainly located along the central and north shores, with lower values in the south-eastern regions (Coll *et al.*, 2012). Areas of potential high cumulative threats are widespread in both the western and eastern basins, with fewer areas located in the south-eastern region. The interaction between areas of high biodiversity and threats for invertebrates, fishes and large animals in general (including large fishes, marine mammals, marine turtles and seabirds) is concentrated in the coastal areas of Spain, Gulf of Lions, north-eastern Ligurian Sea, Adriatic Sea, Aegean Sea, south-eastern Turkey and regions surrounding the Nile Delta and north-west African coasts. Socio-economic factors are likely to increase competition for water and land degradation in the region (Hoff, 2012). Agricultural production will be exposed to increased heat waves and droughts with a potential for negative impacts that will be exacerbated by the competition for water with other sectors (see 23.4.3). It is uncertain if tourism flows will decline in the Mediterranean countries (see 23.3.6). Climate change is expected to trigger a more severe fire regime and more difficult conditions for ecosystem restoration after fire (Anav *et al.*, 2010)(Moriondo *et al.*, 2006)(Duguy *et al.*, 2012).

_____ END BOX 23-3 HERE _____

The high volume of international travel increases Europe's vulnerability to invasive species, including the vectors of human and animal infectious diseases. The transport of animals and animal products has faciliated the spread of animal diseases (Conraths and Mettenleiter, 2011). Important "exotic" vectors that have become established in Europe include the vector *Aedes albopictus* (Becker, 2009) (see Section 23.5.1 above) and a novel vector of blue tongue virus (see 23.4.3).

Another inter-regional implication concerns the changes in the location of commercial fish stocks shared with non-member states. Such changes may render existing international agreements regarding the sharing of yield from these stocks obsolete giving rise to international disputes (Arnason, 2012). For instance, in the North Atlantic, the mackerel stock has recently been extending beyond the EU jurisdiction into the Exclusive Economic Zones of Iceland and the Faroe Islands (Astthorsson *et al.*, 2012).

There are few robust studies of future climate-change related population movement either within or into the European region. Although several studies have proposed a role of climate change to increase migration pressures in low and middle income countries in the future, there is little robust information regarding the role of climate, environmental resource depletion and weather disasters in future inter-continental population movements (Kolmannskog and Myrstad, 2009; Kolmannskog, 2010). The effect of climate change on external migration flows into Europe is highly uncertain (see chapter 12.4.1 for a more complete discussion). Modelling future migration patterns is complex and so far no robust approaches have been developed.

23.10. Synthesis of Key Findings

23.10.1. Key Vulnerabilities

Context to key vulnerabilities:

- Many key vulnerabilities are already well known since the AR4, but some new vulnerabilities are emerging in AR5
- The policy/governance context in Europe is extremely important in determining key vulnerabilities (either mitigating or exacerbating vulnerability) since Europe is a highly regulated region.
- Vulnerability will be strongly affected by changes in the non-climate drivers of change (e.g. economic, social, governance, technological drivers), and for many sectors this will be more important than climate change.
- Future vulnerability will also be strongly affected by cross-sectoral (indirect) interactions, e.g. flooding-ecosystems, agriculture-species, agriculture-cultural landscapes, and so on.
- Extreme events (heat waves and droughts) have had significant impacts on populations as well impacts on multiple economic sectors, and resilience to future heat waves has only been addressed within some sectors.

Already known vulnerabilities (AR4) confirmed in AR5:

- More heat-related deaths and health issues due to an increase in heat waves, particularly in Southern Europe.
- Increases in pests and diseases, with implications for plant, animal and human health.
- Increase in energy demand in summer and reduction in winter.
- The key vulnerability for forests arises from species decline and increase in wild fires and pests and diseases
- Alpine species in particular are vulnerable to climate change (due to a lack of migration potential)
- The ski tourism sector is highly vulnerable to reductions in snow cover arising from warming
- Decrease of the hydropower potential in southern regions and increase in northern regions
- Reduced production in some thermal power plants due to cooling water shortages
- Coastal zones (including both natural environments and settlements) are highly vulnerable to sea level rise
- Settlements across Europe are vulnerable to flooding.

Emerging vulnerabilities:

- Arable crop yields. There is new evidence to suggest that crop yields and production may be more vulnerable as a result of increasing climate variability. This will limit the potential poleward expansion of agricultural production. Limits to genetic progress to adapt are increasingly reported.
- Water will be less available and will be in increased demand and degraded state of water tables. There is the potential for increased competition between the agricultural, domestic, power sector, industrial and natural (animal and plant species) users of water. Future problems are likely to occur unless integrated water management is widely adopted.
- Increased summer energy demand, especially in southern Europe, requires additional power generation capacity, which will be under-utilised during the rest of the year, entailing higher supply costs.
- New evidence regarding implications during summer on inland waterways (decreased access) and long range ocean transport (increased access).
- Housing will be affected, with increased overheating under no adaptation and damage from subsidence and flooding. Passive cooling measures alone are unlikely to be sufficient to address adaptation in all regions and types of buildings. Retrofitting current housing stock will be expensive.
- An emerging concern is the vulnerability of cultural heritage, including monuments/buildings and cultural landscapes. Some cultural landscapes will disappear. Grape production is highly sensitive to climate, but production (of grape varieties) is strongly culturally-dependent and adaptation is potentially limited by the regulatory context.
- Terrestrial and freshwater species are vulnerable from climate-change shifts in habitats. There is new evidence that species cannot populate new habitat due to habitat fragmentation (urbanization). Observed migration rates are less than that assumed in modelling studies. There are legal barriers to introducing new

species (e.g. forest species in France). New evidence that phenological mismatch will cause additional adverse effects on some species.

- Good evidence that climate change will increase distribution and seasonal activity of pests and diseases. Limited evidence that such effects already occurring. Increased threats to plant and animal health. Public policies are in place to reduce pesticide use in agriculture use and antibiotics in livestock, and this will increase vulnerability to the impact of climate change on agriculture and livestock production.
- Extreme events affect multiple sectors and have the potential to cause a systemic impact. Past events indicate the vulnerability of transport, energy agriculture, water resources and health systems. Resilience to very extreme events varies by sector, and by country.
- A positive (and emerging) effect that may reduce vulnerability is that many European governments (and individual cities) have become aware of the need to adapt to climate change and so are developing and/or implementing adaptation strategies and measures.
- Lack of institutional frameworks is a major barrier to adaptation governance. In particularly, the systematic failure in land use planning policy to account for climate change.

[INSERT TABLE 23-5 HERE
Table 23-5: Multi-sectoral impacts of climate extremes during the last decade in Europe.]

23.10.2. Effects of Observed Climate Change in Europe

Table 23-6 summarises the evidence with respect to key indicators in Europe for the detection of a trend and the attribution of that trend to observed changes in climate factors. The attribution of local warming to anthropogenic climate change is less certain (see Chapter 18 for a full discussion). Further and better quality evidence since 2007 supports the conclusion of AR4 (Europe chapter, Alcamo et al., 2007) that climate change is affecting land, freshwater and marine ecosystems in Europe. Climate warming has caused advancement in the life cycles of many animal groups, including frogs spawning, birds nesting and the arrival of migrant birds and butterflies (see WGII chapter 4 and review by Feehan *et al.* (2009). There is limited evidence that observed climate change is already affecting agricultural, forest and fisheries productivity (see 23.4).

The frequency of river flood events, and annual flood and windstorm damages in Europe have increased over recent decades, but this increase is mainly due to increased exposure and the contribution of observed climate change is unclear (high confidence – based on robust evidence and high agreement)(SREX 4.5.3, (Barredo, 2010). The observed increase in the frequency of hot days and hot nights (high confidence, WGI) is likely to have increased heat-related health effects in Europe (medium confidence), and well as a decrease in cold related health effects (medium confidence) (Christidis *et al.*, 2010). Multiple impacts on health, welfare and economic sectors were observed due to the major heat wave events of 2003 and 2010 in Europe (Table 23-5) (see Chapter 18 for discussion on attribution of events).

[INSERT TABLE 23-6 HERE
Table 23-6: Observed changes in ecological and human systems.]

23.10.3. Key Knowledge Gaps and Research Needs

There is a clear mismatch between the volume of scientific work on climate change since the AR4 and the insights and understanding required for policy needs.

Some specific research needs have been identified:

- More research on co-benefits and unintended consequences of adaptation options, and the effects of adaptation in one sector on other sectors in Europe. For example, air conditioning.
- Improved economic tools and methods for costing and valuation of specific adaptation options including the use of this information in decision making.

- Synergies and trade-offs between mitigation and adaptation need to be further researched and incorporated into economic analyses of the mitigation costs.
- Effects of climate change on infrastructure and the built environment, in the context of adaptation and mitigation policies.
- Impacts from high end climate change (above 4°C), with a lack of impact studies in Europe.
- Resilience of cultural landscapes and communities, and how to manage adaptation, particularly low technology (productively marginal) landscapes
- Climate change impact on ecosystem services (including valuation of ecosystem services) and how this would contribute to the improvement of management of natural resources.
- Development /improvement of regional climate services (seasonal, decadal forecasts)
- Impact of climate change on rural development in order to inform policy in this area.
- Capacity of local and national government to respond to climate change.
- Information on governance (including local and national institutions) for adaptation in the built environment, and infrastructure, including flood defences, over-heating, urban planning.
- More research on the assessment and quantification of climate for tourism, as well as on the response of tourists to past and future marginal climatic conditions for tourism.
- More research on the impacts of climate change on transport, especially on the vulnerability of road and rail infrastructure in different regions, and on the contribution of climatic and non-climatic parameters in the vulnerability of air transport (e.g. changes in air traffic volumes, airport capacities, air traffic demand, weather at the airports of origin, intermediate and final destination).
- [needs to be more specific] Better characterization of the determinants of changes in yield and food quality and improvement of technologies for precision farming.
- Research on the resilience/vulnerability of populations to extreme events, including responses to flood and heat wave risks.
- Development of better risk models for vector borne disease, including public health implications and for animal diseases.

A major barrier to research is lack of access to data, which is also variable across regions and countries, specifically socio-economic data, climate data, forestry, routine health data. Reasons include: government agencies require commercialisation, inappropriate confidentiality. There is a need for long term monitoring of environmental and social indicators and to ensure open and access to data (environment, crop, etc) for long term and sustainable research programmes. Cross-regional cooperation could also ensure compatability and consistency of parameters across the region.

Frequently Asked Questions

FAQ 23.1: Will I still be able to live on the coast in Europe?

It depends where you want to live (and when). Coastal areas are affected by storm surges that will increase in frequency and extent due to sea level rise. Most of this increase in risk will occur after the middle of this century. Models of the coast line suggest that populations in the north western region of Europe are most affected and many countries will need to strengthen their coastal defences (including the Netherlands, Germany, France, Belgium, Denmark, Spain and Italy). The decision to protect an area of coastline will depend on the value (market and non-market values) of the land, its infrastructure or economic productivity, and its conservation potential (valuing species or ecosystems). Some countries have already raised their coastal defence standards. More innovative options (than defence or abandonment) are also being explored such as to adapt dwellings and commercial buildings to occasional flooding. Upgrading coastal defenses can significantly reduce (but not fully eliminate) adverse impacts of sea level rise but coasts are also faced with erosion, excessive development, and other types of environmental degradation not related to climate change. The combination of raised sea defences and coastal erosion may lead to narrower coastal zones in the North Sea, the Iberian coast, and Bay of Biscay.

FAQ 23.2: Will climate change introduce new infectious diseases into Europe?

New (emerging) diseases appear all the time and current diseases change distribution or prevalence (increases and decreases). The factors that determine whether a disease changes distribution include: importation from increased

international travel of persons, vectors or hosts, changes in vector or host susceptibility, drug resistance, climate change, and land use or other habitat changes that affect vectors or hosts. Tropical diseases is a term used to describe diseases that are now only present in the tropics, but malaria was once endemic in Europe and its mosquito vectors are still present. Malaria is not established in Europe despite imported cases because infected persons are quickly detected and treated. Maintaining health surveillance is therefore extremely important. Finally, when an outbreak has occurred (i.e. the introduction of a new disease) determining the causes is very difficult. It is likely that a combination of factors will be important. A suitable climate is a necessary but not a sufficient factor for the introduction of new infectious diseases.

FAQ 23.3: Will Europe need to import more food because of climate change?

Agriculture is the most dominant European land use, accounting for almost half of the total EU27 land area. Europe is one of the world's largest and most productive suppliers of food and fibre, but also imports large amounts of agricultural commodities. A reduction in crop yields, particularly wheat in southern Europe, is expected under future climate scenarios. A shift in cultivation areas of added-value crops, such as wine, may also occur. Loss of food production may be compensated by increases in other European sub-regions, under normal climate variability and long term changes. However, if ability of the European market to sustain climate shock events is impaired, the region would require exceptional food importation.

Table 23-2: Assessment of climate change impacts on ecosystem services by sub-region and sector. Assessment assuming medium economic development, with land use change and no planned adaptation.

	Southern	Atlantic	Continental	Northern	Alpine
Provisioning services:					
Food production	Decreasing	Increasing to decreasing	No change to decreasing	Increasing to decreasing	Increasing to decreasing
Livestock production	Decreasing	Increasing to decreasing	Decreasing	Increasing	Increasing to decreasing
Fibre production					Decreasing
Bioenergy production	Decreasing			Increasing	Increasing
Fisheries production	No change to decreasing	No change to decreasing	Decreasing	No change to decreasing	
Timber production	Decreasing	No change to increasing	Increasing to decreasing	Increasing	Increasing to decreasing
Non-wood forest products	Decreasing			No change to increasing	
Regulating services:					
Climate regulation (carbon sequestration)					
- General/forests	Increasing to decreasing	No change to increasing	No change to increasing	Increasing to decreasing	Increasing
- Wetland	No change to decreasing	No change to decreasing	Decreasing	No change to decreasing	
- Soil carbon stocks	Decreasing	Increasing to decreasing	Decreasing	Decreasing	Decreasing
Pest control	Decreasing		Increasing	Increasing	Increasing
Natural hazard regulation					
- Forest fires regulation	Decreasing	Decreasing*	Decreasing*		
- Erosion, avalanche, landslide regulation					Increasing to decreasing
- Flooding regulation					Decreasing
- Drought regulation	Decreasing		No change to decreasing		
Water quality regulation		Decreasing		Decreasing	
Cultural services:					
Recreation (fishing, nature enjoyment)	Decreasing	Decreasing		Increasing to decreasing	Decreasing
Tourism (skiing)				Decreasing	Increasing
Aesthetic/heritage (landscape character, cultural landscapes)	Decreasing	Decreasing	No change to decreasing		Decreasing
Biodiversity	Decreasing	Increasing to decreasing	Decreasing	Increasing to decreasing	

* Forest fires or moorland wildfires increase

Table 23-3: Selected published adaptation cost estimates for European countries.

Population	Cost estimate	Time period	Sectors/Outcomes	Reference
Europe	€2.5–5 billion/a	By 2080s	Coastal protection	Brown et al., submitted b
Europe	€1.7 billion/a €3.4 billion/a €7.9 billion/a	By 2020s By 2050s By 2080s	Protection from river flood risk	Rojas et al., submitted
Netherlands	€1.2–1.6 billion/a €0.9–1.5 billion/a	up to 2050 2050–2100	Protection from coastal and river flooding	Delta Committee, 2008
Sweden	total of up to €10 billion	over period 2010-2100	Multi sector	Swedish Commission on Climate and Vulnerability, 2007
Greece	170-770 million €	2071-2100	Higher electricity generation cost resulting from higher summer energy demand for cooling	Mirasgedis et al., 2007
Cyprus	239 million €	2010-2030	Higher electricity generation cost resulting from higher summer energy demand for cooling	Zachariadis, 2010
Spain	8.8-30.6 million €/a	2008-2050	Higher costs to electricity users and costs paid in the carbon market (emissions trading)	Pilli-Sihvola et al., 2010
Europe (Rhine river)	194-263 million €	Future climatic conditions similar to those of 2003	Higher transport prices for goods as a result of load restrictions on inland ships (due to low river water levels in summer)	Jonkeren, 2009

Table 23-4: Assessment of climate change impacts by sub-region and sector (by 2050, medium emissions)
With economic development, with land use change. No further planned adaptation.

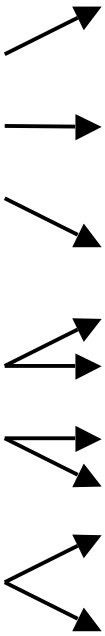
Code. Green means a “beneficial change” and Red means a “harmful”, ? No relevant literature found



FOOTNOTES

[1] Simulations have been performed, but mostly for the period after 2070.

[2] The increasing trend is for Norway.

[3] The decreasing trend refers mainly to the number of severe accidents.

[4] Impacts have been studied and quantified for UK only. The increasing trend stands for summer delays and the decreasing trend for winter delays.

[5] In both seasons, no significant impacts are expected by 2020, while more substantial changes are expected by 2080. For 2050 impacts are assumed to vary linearly (although this may not be the case).

[6] The constant trend stands for the Mediterranean, where some studies estimate no changes due to climate change at least until 2030 or even 2060.

Table 23-5: Multi-sectoral impacts of climate extremes during the last decade in Europe.

Year	Region	Meteorological Event/ Breaking Record*	Production Systems and Physical Infrastructure, settlements	Agriculture, Fisheries, Forestry, Bioenergy	Health and Social Welfare	Environmental Quality and Biological Conservation
2003	Europe	Hottest summer in at least 500 years (Luterbacher *et al.*, 2004)	Damage to road and rail transport systems. Reduced/ interrupted operation of nuclear power plants (mostly in France). High transport prices in Rhine due to low water levels.	Grain harvest losses of 20% (Aerts and Botzen, 2011)	Approx 35,000 deaths in August in Central and Western Europe (Robine *et al.* 2008)	Water quality. High outdoor pollution levels. (EEA 2012)
2004/ 2005	Iberian Peninsula	Hydrological drought		Grain harvest losses of 40% (EEA, 2010b)		
2007/ 2008	England and Wales, Southern Europe	May–July wettest since records began in 1766. Hottest summer on record in Greece since 1891 (Founda & Giannakopoulos 2009)	Disruption, economic loss and social distress turned the summer 2007 floods into a national catastrophe. Broad-scale estimated total losses were £4 billion (Chatterton et al. 2010),	Social distress.		
2010	Western Russia	Hottest summer since 150 (Barriopedro *et al.*, 2011)		Fire damage to forests. Crop yields	Heat mortality in Moscow region (Revich and Shaposhnikov, 2010)	High outdoor pollution levels. (Revich and Shaposhnikov, 2010.
2011	France	Hottest and driest spring on record in France since 1880	Reduction on snow cover for skiing	Decline in crop yields. (AGRESTE, 2011)		

* based on Coumou and Rahmstorf, 2012.

Table 23-6: Limits to Adaptation Measures in Europe.

Area/Location	System	Adaptation measures	Limits to adaptation measure(s)	References
Low altitude/ small-size ski resorts	Ski tourism	Artificial snowmaking	Climatic, technological and environmental constraints Economic viability Social acceptability of charging for previously free skiing. Social acceptability of alternatives for winter sport/leisure.	(Landauer et al., 2012) (Steiger, 2010a; Steiger, 2010b) (Steiger and Mayer, 2008)(Unbehaun et al., 2008)
Thermal power plants/ cooling through river intake and discharge	Once-through cooling systems	Closed- circuit cooling	High investment cost for retrofitting existing plants	(van Vliet et al., 2012)(Koch and Vögele, 2009)(Hoffman et al., 2013)
Rivers used for freight transport	Inland transport	Reduced load factor of inland ships	Increased transport prices (Rhine and Moselle market)	(Jonkeren, 2009) (Jonkeren et al., 2007)
		Use of smaller ships	Existing barges below optimal size (Rhine)	(Demirel, 2011)
Agriculture, Northern and Continental Europe.	Arable crops	Sowing date as agricultural adaptation	Other constraints (e.g. frost) limit farmer behaviour	(Oort, 2012).

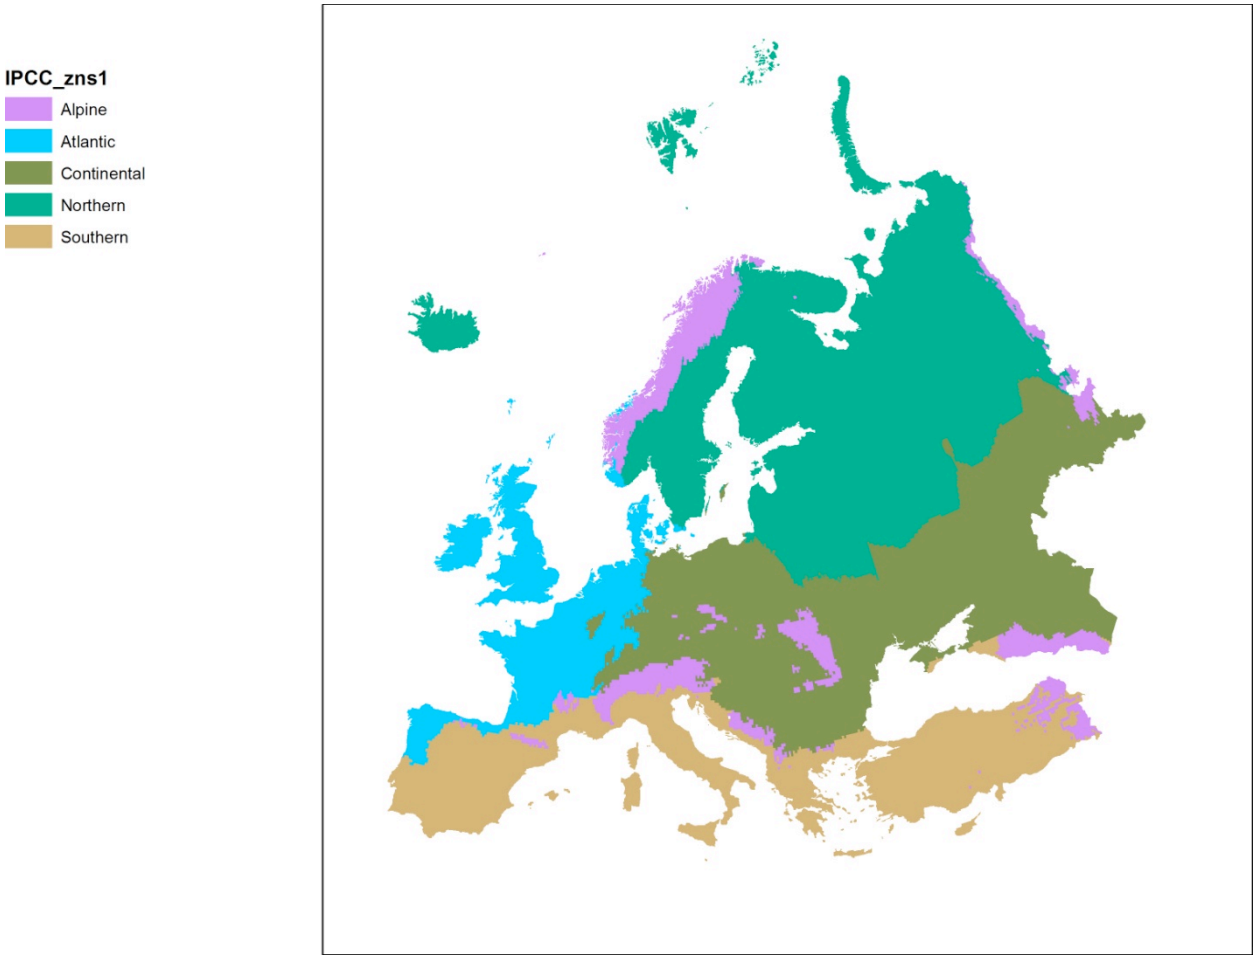

Figure 23-1: Sub-regional classification of the IPCC Europe region. Based on Metzger et al., 2005.

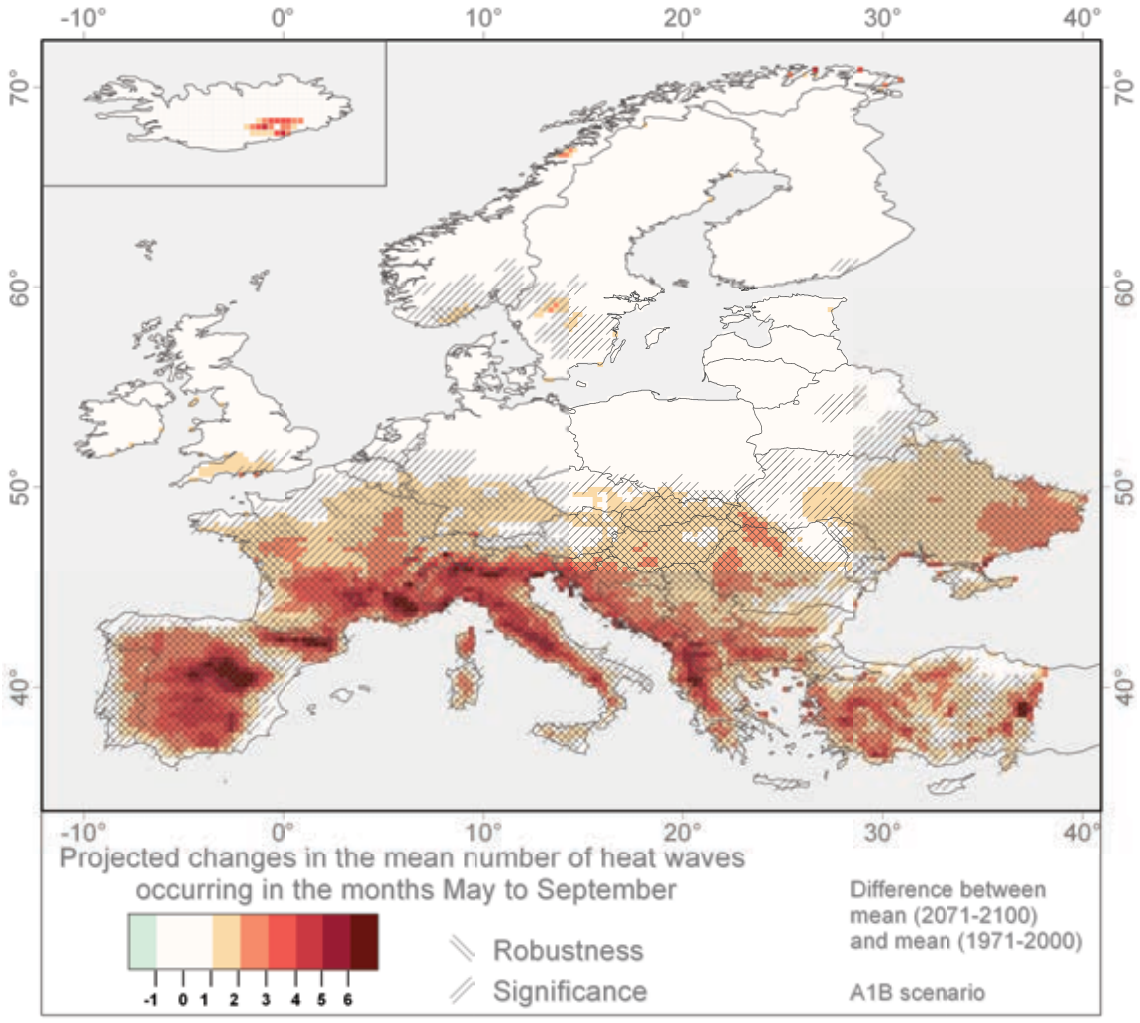
Figure 23-2: Projected changes in the mean number of heat waves occurring in the months May to September for the period 2071-2100 compared to 1971-2000 (number per season) (Jacob et al, 2013). Heat waves are defined as periods of more than 5 consecutive days with daily maximum temperature exceeding the daily maximum temperature of the May to September season of the control period (1971-2000) by at least 5°C. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test). For the eastern part of Turkey, unfortunately no regional climate model projections are available.

A) Changes represent average over 9 regional model simulations (A1B) taken from the EU-ENSEMBLES project.



B) Changes represent average over 8 regional model simulations (RCP4.5) taken from the EURO-CORDEX project.

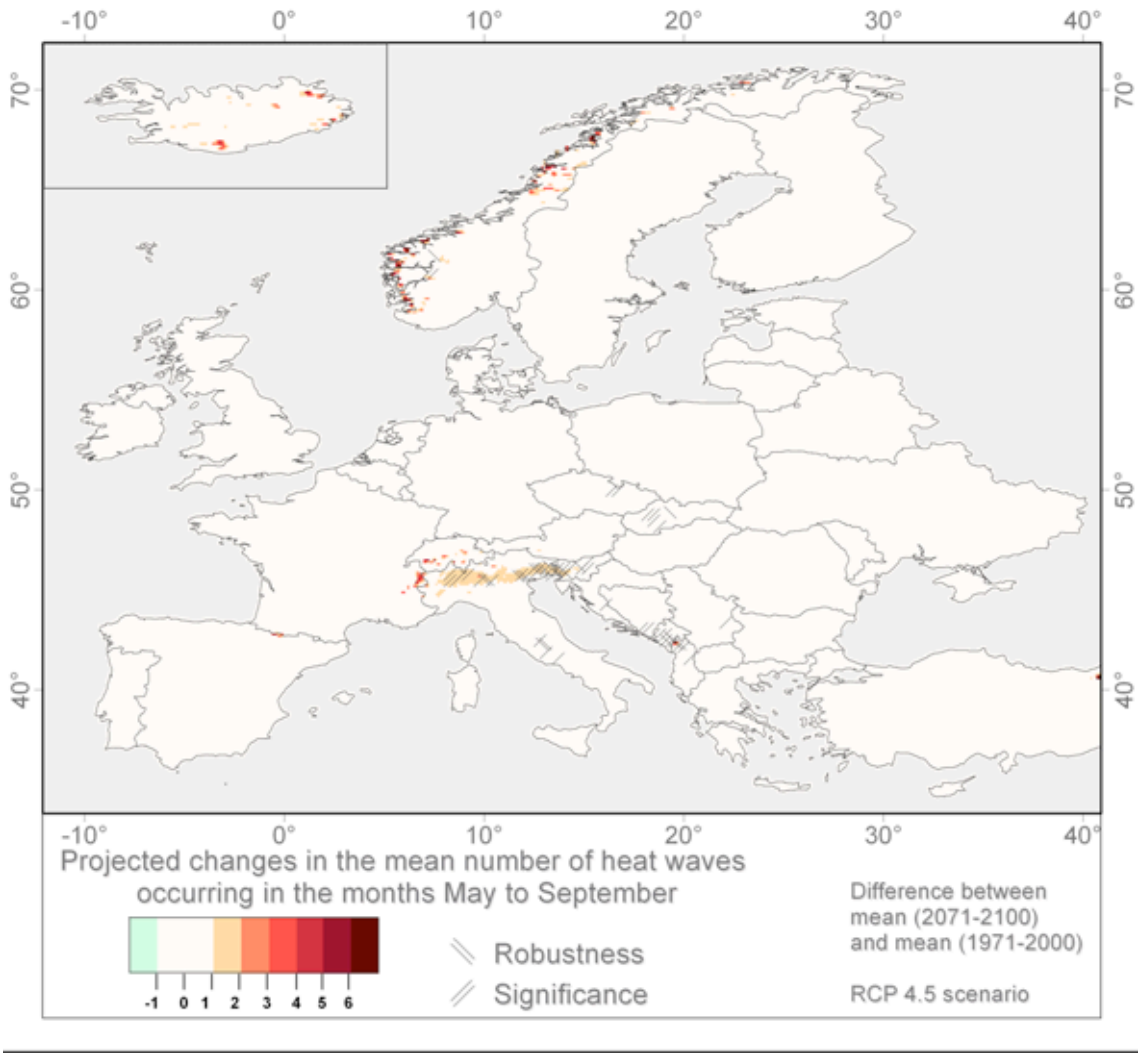


Figure 23-3: Projected seasonal changes of heavy precipitation defined as the 95th percentile of daily precipitation (only days with precipitation > 1mm/day are considered) for the period 2071-2100 compared to 1971-2000 (%) (Jacob et al., 2013). For the eastern part of Turkey, unfortunately no regional climate model projections are available. The figures are sorted as follows: left side: DJF, JJA; right side: MAM, SON. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test).

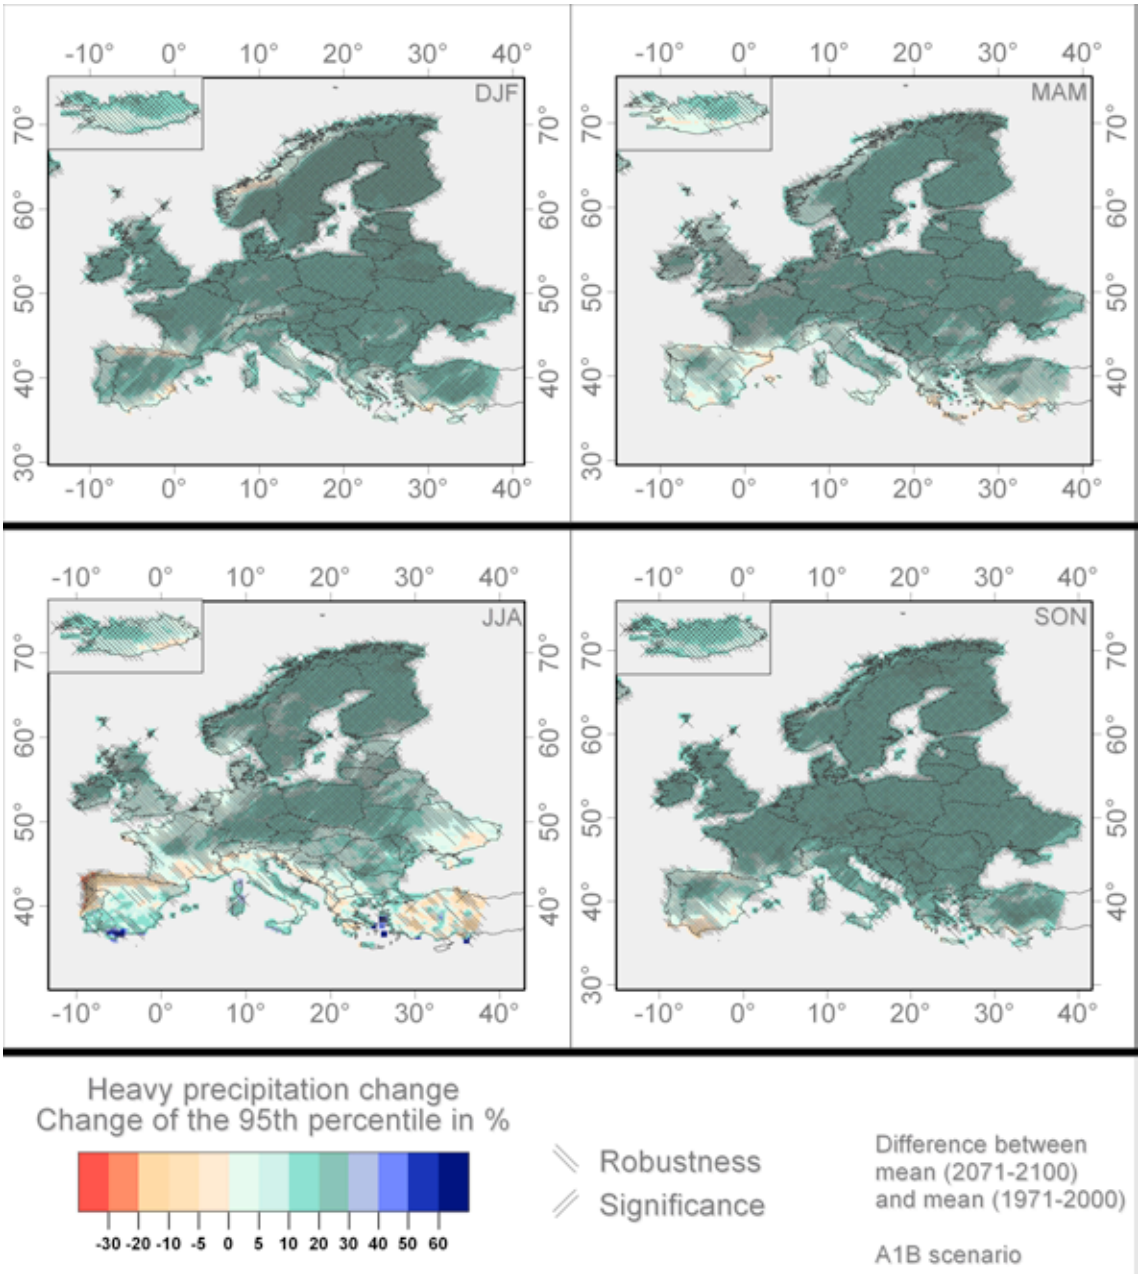
A) Changes represent average over 20 regional model simulations (A1B) taken from the EU-ENSEMBLES project.



B) Changes represent average over 7 regional model simulations (RCP4.5) taken from the EURO-CORDEX project.

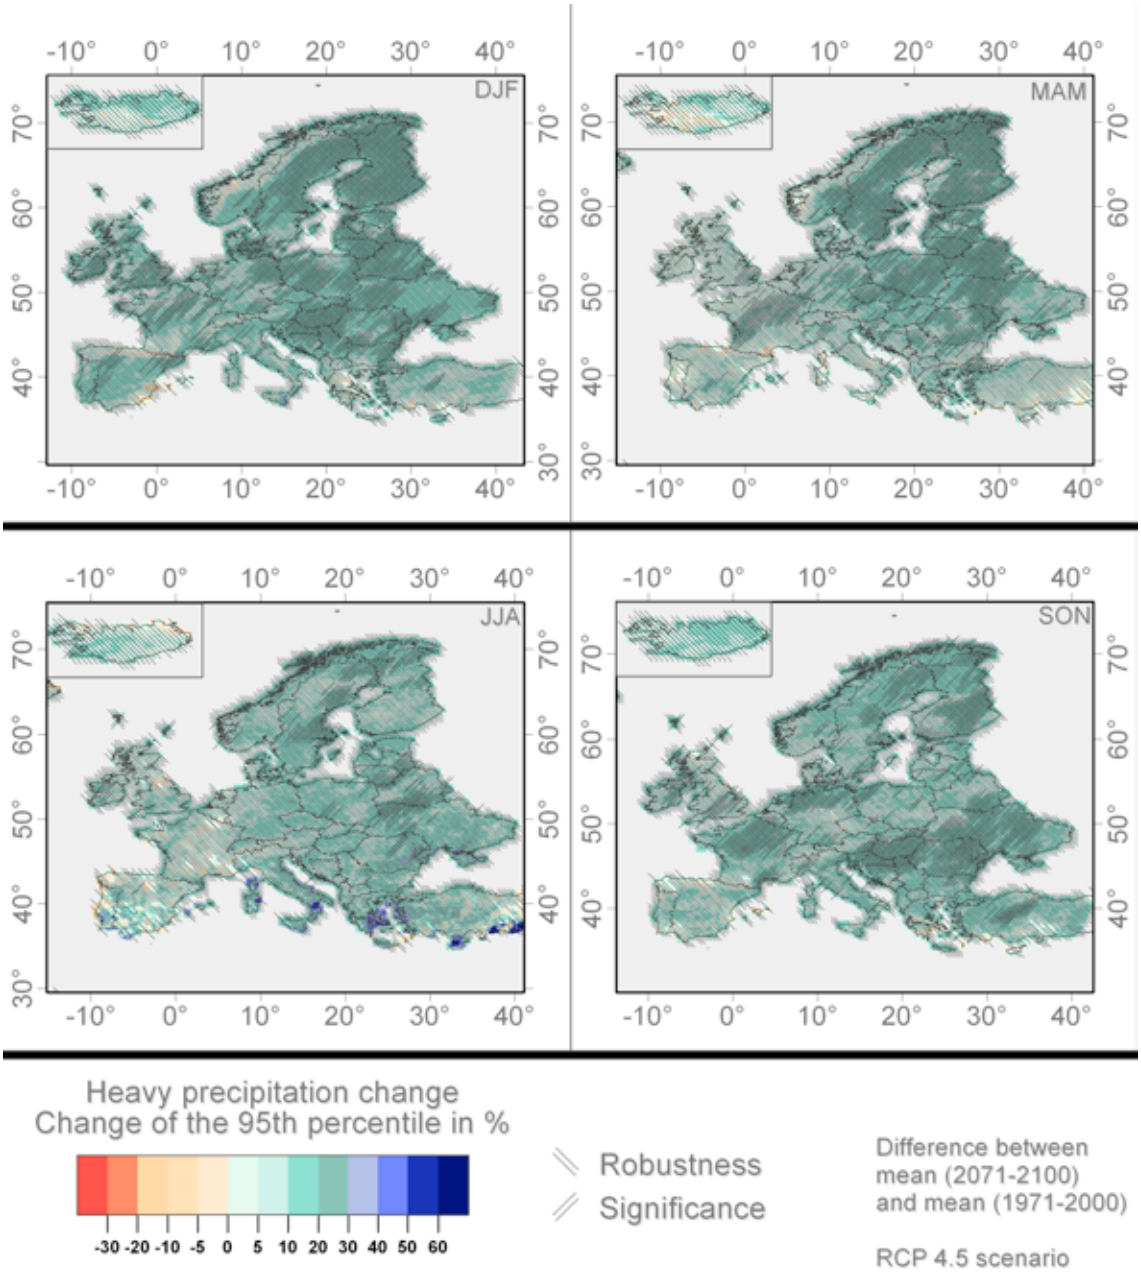


Figure 23-4. Projected changes in the 95th percentile of the length of dry spells for the period 2071-2100 compared to 1971-2000 (in days) (Jacob et al., 2013). Dry spells are defined as periods of at least 5 consecutive days with daily precipitation below 1mm. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test)..For the eastern part of Turkey, unfortunately no regional climate model projections are available .

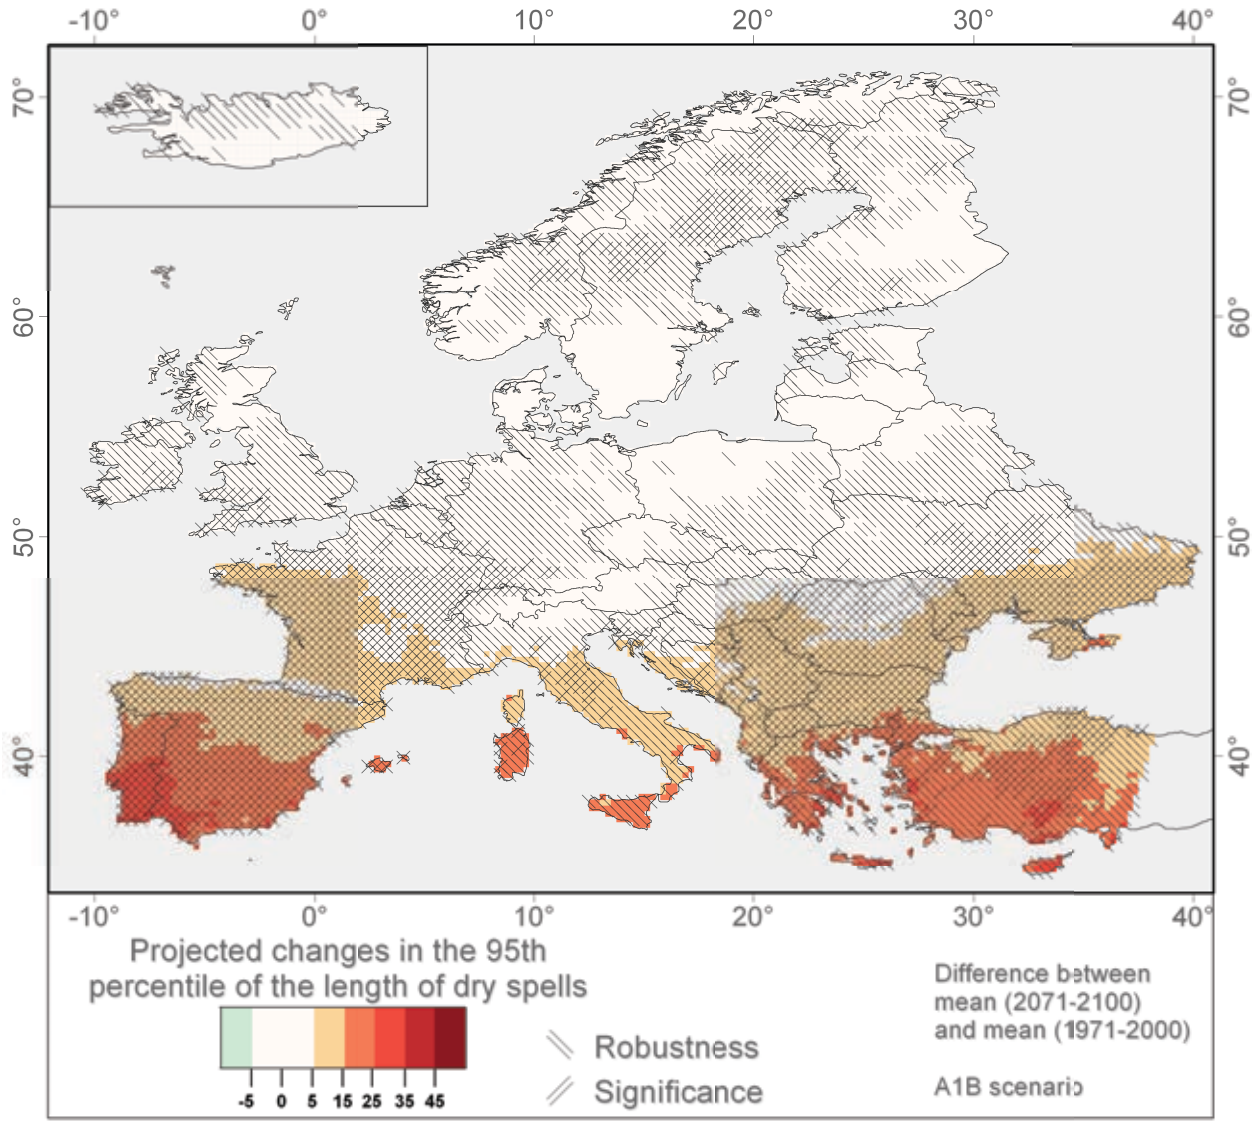
A) Changes represent average over 20 regional model simulations (A1B) taken from EU-ENSEMBLES project.



B) Changes represent average over 7 regional model simulations (RCP4.5) taken from EURO-CORDEX project.

Executive Summary

Warming trends and increasing temperature extremes have been observed across most of the Asian region (high confidence) [24.3]. Increasing trends in annual mean temperatures and numbers of warm days, and a decreasing trend in cold days, have been observed across most of the Asian region, including the Tibetan Plateau, during the 20th century, with the warming trend continuing into the new millennium. Annual mean precipitation trends are characterized by strong variability, with both increasing and decreasing trends observed in different parts of Asia.

Water scarcity is expected to be a major challenge for most of the region due to increased water demand and lack of good management (medium confidence) [24.4.3]. Water resources are important in Asia given the massive population. However, there is low confidence in future precipitation projections at a regional scale and thus in freshwater availability in most parts of Asia. Shrinking of glaciers in Central Asia and the Himalayas is projected to affect water resources in downstream river catchments. Population growth and increasing demand arising from higher standards of living could worsen water security in many parts in Asia and affect many people in future. Better water management strategies are needed to ease water scarcity. Water saving technologies and changing to drought tolerant crops have been found to be successful adaptation options in the region.

The impacts of climate change on food production and food security in Asia will vary by region with many regions experiencing a decline in productivity (medium confidence) [24.4.4]. This is evident in the case of rice production. Most models, using a range of GCMs and SRES scenarios, show that higher temperatures will lead to lower rice yields as a result of shorter growing periods and heat-induced sterility. There are a number of regions that are already near the critical temperature threshold. However, CO_2 fertilization may at least in part offset yield losses in rice and other crops. In Central Asia, some areas could be winners (cereal production in northern and eastern Kazakhstan could benefit from the longer growing season, warmer winters and slight increase in winter precipitation), while others could be losers (western Turkmenistan and Uzbekistan, where frequent droughts could negatively affect cotton production, increase water demand for irrigation, and exacerbate desertification). In the Indo-Gangetic Plains of South Asia there could be an up to 50% decrease in the most favorable and high yielding wheat area due to heat stress at 2x CO_2. There are many potential adaptation strategies, such as crop breeding, but research on their effectiveness is limited.

Terrestrial systems are under increasing pressure from both climatic and non-climatic drivers (high confidence) [24.2.2, 24.4.2, 24.4.3]. The projected changes in climate will impact vegetation and increase permafrost degradation in Asia during the 21st Century. The largest changes are expected in cold northern and high-altitude areas, where boreal and subalpine trees will *likely* invade treeless arctic and alpine vegetation, and evergreen conifers will *likely* invade deciduous larch forest. Large changes may also occur in arid and semi-arid areas, but uncertainties in precipitation projections make these difficult to predict. Vegetation change in the more densely populated parts of Asia will be constrained by the impact of vegetation fragmentation on seed dispersal. The impacts of projected climate changes on the vegetation of the lowland tropics are currently poorly understood. Trends in phenological timing consistent with the impacts of regional warming are widespread in eastern Asia, particularly for plants. Permafrost degradation will spread during the 21st century from the southern and low-altitude margins, advancing northwards and upwards [24.4.2.3]. Many models agree on the direction of change, but rates of change vary greatly between different projections. The Altai-Sayan, Pamir and Tien Shan glaciers have lost on average 10% of their area and 15% of their ice volume since 1960. Rates of further glacier degradation depend mainly on increases in summer air temperature and changes in precipitation [24.9.3].

Coastal and marine systems in Asia are also under increasing pressure from both climatic and non-climatic drivers (high confidence) [24.4.3]. It is very *likely* that mean sea level rise will contribute to upward trends in extreme coastal high water levels and in the Asian Arctic there is *high agreement* and *medium evidence* that rising sea-levels will interact with projected changes in permafrost and the length of the ice-free season to cause increased rates of coastal erosion. Coastal freshwater swamps and marshes will be vulnerable to saltwater intrusion with rising sea-levels**.** Widespread damage to coral reefs correlated with episodes of high sea-surface temperature has been reported in recent decades and there is *high confidence* that such damage will increase during the 21st century as a result of both warming and ocean acidification.

Multiple stresses caused by rapid urbanization, industrialization and economic development will be compounded by climate change (high confidence) [24.4, 24.5, 24.6, 24.7]. Climate change is expected to adversely affect the sustainable development capabilities of most Asian developing countries by aggravating pressures on natural resources and the environment. Development of sustainable cities in Asia with fewer fossil fuel driven vehicles and with more trees and greenery would have a number of co-benefits including public health.

Extreme events will have greater impact on human health, security, livelihood, and poverty sectors with different magnitude and types in Asia (high confidence) [24.4.6]. More frequent and intense heat-waves in Asia will increase mortality and morbidity in vulnerable groups. Increases in heavy rain and temperature will increase the risk of diarrheal diseases and malaria. Increases in flood and drought will exacerbate rural poverty in parts of Asia due to negative impacts on rice crop and increases in food prices and the cost of living.

There are regions within Asia that are not sufficiently represented in studies of observed climate change, in particular Central and West Asia [24.8]. Numerical data on trends in precipitation is hard to find compared to trends in temperature. Furthermore, research data on changes in extreme climate events does not cover most Asian regions. Studies of both observed and projected impacts on biodiversity, boreal forest dynamics, CO_2 fertilization of crops and plants, and urban settlements are limited. More trans-disciplinary research is needed on direct and indirect health effects from climate change impacts on air and water quality and water quantity in different parts of Asia. The vulnerability, impacts and adaptation of aggregated household welfare, livelihoods and poverty need to be adequately studied.

24.1. Introduction

Asia is defined here as the land and territories of 51 countries/regions (see Figure 24-1). It can be broadly divided into six sub-regions based on geographical position and coastal peripheries (see Table 24-1). These are (in alphabetical order) Central Asia (5 countries), East Asia (7 countries/regions), North Asia (2 countries), South Asia (8 countries), Southeast Asia (12 countries) and West Asia (17 countries). Asia has a diversity of social, cultural and economic characteristics. The population of Asia in 2011 was reported to be about 4,207 million, which is about 60% of the world population (UN, 2011). The population density is about 134 per square kilometer (PRB, 2012). The highest life expectancy at birth is 83 (Japan) and the lowest is 49 (Afghanistan). In 2009, the GDP per capita ranged from US$ 543 (Afghanistan) to US$ 45,903 (Japan) (World Bank, 2013). Almost half of the population in Asia lives below the poverty line, where their income is below US$ 1.25 per day by 2005 prices (World Bank, 2013).

[INSERT FIGURE 24-1 HERE

[INSERT TABLE 24-1 HERE
Table 24-1: The 51 countries/regions in the six sub-regions of Asia.]

24.2. Major Conclusions from Previous Assessments

24.2.1. Climate Change Impacts

Climate change, variability and extreme events

Observed. Warming is strongest over the continental interiors of Asia, and warming in the period 1979 onwards was strongest over China in winter and eastern Asia in spring and autumn. [WG1 AR4 3.2.2.7]. From 1900 to 2005, precipitation increased significantly in northern and central Asia but declined in parts of southern Asia [WGI AR4 SPM]. A warming trend in daily temperature extremes was observed for much of Asia (medium confidence) [SREX 3.3.1]. No systematic spatially coherent trends in heavy precipitation have been found in most of Asia, except for a weak increase in the frequency of extreme precipitation that was observed in northern Mongolia (low to medium confidence) [SREX 3.3.2]. However, both positive and negative statistically significant trends have been found at sub-regional scales throughout Asia (low to medium confidence) [SREX 3.3.2]. A decreasing trend was observed in rainfall in the South Asian and East Asian monsoons, due to a rise in sea-surface temperature [SREX 3.4.1]. Coastal areas of Asia have reported that sea level rise has accelerated relative to the long-term average and is greater than the global average [WG2 AR4 10.3.1].

Future projections. Future projections show that warming will be least rapid in Southeast Asia, stronger over South Asia and East Asia, and greatest in the continental interior, with the most pronounced warming at high latitudes in North Asia [WG2 AR4 10.3.1]. Annual precipitation projections indicate an increase in most of Asia during this century [WG2 AR4 10.3.1]. An increase in heat waves is also projected for South Asia, East Asia, and Southeast Asia [WG2 AR4 10.3.1]. Future projections suggest that heavy precipitation will increase in West and South Asia, as well as the Asian monsoon region, notably in Bangladesh and in the Yangtze river basin [SREX 3.3.2], while projection results for the South Asian monsoon precipitation point to both increases and decreases in precipitation (low confidence) [SREX 3.4.1].

Climate change impacts

Observation. Changes in drought patterns have been reported for the monsoon regions of Asia with variations at the decadal time scale (low confidence) [SREX 3.5.1]. Studies in East Asia show increasing dryness in the second half of the 20th century (medium confidence) [SREX 3.5.1]. Flood observation results show that there is an upward trend in the annual flood maxima of the lower Yangtze, increasing likelihood for extreme floods in the Mekong river, and both upward and downward trends in four selected river basins of the northwestern Himalaya (low confidence) [SREX 3.5.2].

Projections. Global and regional studies project a higher likelihood of hydrological drought by the end of the century, with a substantial increase in the number of drought days in southern Asia from Indochina to southern China, while increases in drought are projected for inland China and central Eurasia [SREX 3.5.1]. Projections point to an increase in the risk of floods in most humid Asian monsoon regions (low confidence) [SREX 3.5.2].

24.2.2. Vulnerabilities and Adaptive Strategies

Vulnerable sectors. Crop yields in the past few decades have declined in many parts of Asia due to increasing water stress arising partly from increasing temperature, increasing frequency of El Niño events and reductions in the number of rainy days (medium confidence) [WG2 AR4 10.2.4.1]. Studies suggest that in the future as well substantial decreases are probable, not only in cereal production potential (medium confidence) [WG2 AR4 10.ES], but also in the production of livestock, fisheries, and aquaculture [WG2 AR4 10.4.1.1; WG2 AR4 10.4.1.3]. Most projections suggest that increasing urbanization and population in Asia could result in increased food demand and reduced food supply due to limited availability of cropland area and yield declines [WG2 AR4 10.4.1.4]. Food insecurity and loss of livelihood would be further exacerbated by the loss of cultivated land and nursery areas for fisheries by inundation and coastal erosion in tropical Asia [WG2 AR4 10.4.1.4]. Changes in the hydrological cycle

with corresponding changes in the water resources have been observed, with a noticeable regional variability, in all of Asia [WG2 AR4 10.2.4.2]. One of the most pressing environmental problems in South and Southeast Asia will be the expansion of areas under severe water stress as the number of people living under severe water stress is projected to increase substantially in absolute terms [WG2 AR4 10.4.2.3]. Oceanic, coastal, and other natural ecosystems have suffered degradation as a result of global warming, sea-level rise and changes in intensity and amount of precipitation [WG2 AR4 10.2.4.3; WG2 AR4 10.2.4.4]. Projections show that all coastal areas in Asia are facing an increasing range of stresses and shocks, the scale of which now pose a threat to the resilience of both human and environmental coastal systems, and could be additionally exacerbated by climate change [WG2 AR4 10.4.3.1]. Many plant and animal species are at risk of becoming extinct as a consequence of the combined effects of climate change and habitat fragmentation (medium confidence) [WG2 AR4 10.ES; WG2 AR4 10.2.4.5]. Central, East, South and Southeast Asia reported deaths and disorders from heat waves and outbreaks of infectious diseases linked to rising temperatures and rainfall variability, particularly in low-income areas with poor water and sanitation safety (medium confidence) [WG2 AR4 10.ES; WG2 AR4 10.2.4.6]. Substantial direct impacts on public health and livelihood can be expected also in the future due to possible increases in climate change related diseases, as well as heat stress [WG2 AR4 10.4.5]. Climate change is also expected to adversely affect the sustainable development capabilities of most Asian developing countries by aggravating pressure on natural resources and the environment, in addition to factors such as rapid urbanization, industrialization and economic development (high confidence) [WG2 AR4 10.ES ; WG2 AR4 10.7].

Vulnerable areas. Regions of South and Southeast Asia were reported as vulnerable to climate change, due to the exposure of their population to severe water stress [WG2 AR4 10.4.2.3]. Furthermore, the same regions are expected to experience higher endemic morbidity and mortality due to diarrheal disease related to climate change (high confidence) [WG2 AR4 10.ES; WG2 AR4, 10.4.5]. Increases in coastal water temperature would exacerbate the risk of cholera in South Asia (high confidence) [WG2 AR4 10.ES; WG2 AR4 10.4.5]. Crop yields in South and West Asia could decrease by a third by the middle of this century (medium confidence) [WG2 AR4 10.ES; WG2 AR4 10.4.1.1]. Glaciers on the Tibetan Plateau are projected to shrink at an accelerated pace, thus possibly increasing the number and intensity of glacial melt-related floods and leading to slope destabilization and a decrease in river flows as glaciers recede (medium confidence) [WG2 AR4 10.ES; WG2 AR4 10.4.2.1; WG2 AR4 10.2.4.2]. Projected sea-level rise would result in significant losses of coastal ecosystems, along with increased risk of flooding on the coasts of South and Southeast Asia (high confidence) [WG2 AR4 10.ES; WG2 AR4 10.4.3.1]. Sea-level rise and declining river runoff, coupled with extreme events such as flooding and intensifying storm surges, would have adverse impacts on human settlements, aquaculture industry and infrastructure of Asia's densely populated megadeltas (high confidence) [WG2 AR4 10.4.3.2; SREX 4.4.3]. Stability of wetlands, mangroves and coral reefs around Asia is likely to be increasingly threatened (high confidence) [WG2 AR4 10.ES; WG2 AR4 10.4.3.2; WG2 AR4, 10.6.1].

Adaptive strategies. Adaptive strategies for the agricultural sector that have been identified in AR4 are intended to increase adaptive capacity by modifying farming practices, improving crops and livestock through breeding, investing in new technologies and infrastructure, and making changes in management philosophy through education and the provision of climate change-related information [WG2 AR4 10.5.1]. In the water sector, dealing with water use inefficiency and the promotion of recycled water were found useful in many agricultural areas in Asia [WG2 AR4 10.5.2]. Along the coast, protection, such as dike heightening and strengthening, is considered to be important in responding to sea-level rise [WG2 AR4 10.5.3]. Most forests in Asia would benefit from comprehensive inter-sectoral programs that combine measures to control deforestation and forest degradation [WG2 AR4 10.5.4].

Implementation of monitoring and warning systems would be helpful in reducing the impacts of climate change on human health [WG2 AR4 10.5.5]. Effective adaptation and adaptive capacity in Asia, particularly in developing countries, will continue to be limited by several ecological, social and economic, technical and political constraints [WG2 AR4 10.5.7]. These constraints also include alterations of the physical environment, as well as the adaptive capacities of some ecosystems, spatial and temporal uncertainties associated with forecasts of regional climate, limited national capacities in climate monitoring and forecasting, and lack of coordination in the formulation of responses [WG2 AR4 10.5.7]. Countries of Asia facing serious domestic conflicts, pervasive poverty, hunger, epidemics, terrorism and other urgent and pressing concerns may not view climate change and the need to implement adaptation as immediate priorities [WG2 AR4 10.5.7]. Slow changes in the political and institutional landscape, and in the existing legal and institutional framework, remain inadequate to facilitate implementation of

comprehensive and integrated responses to climate change [WG2 AR4 10.5.7]. In order to address such constraints the following measures would be of use: improving access to high-quality information about the impacts of climate change; adaptation and vulnerability assessment by setting in place early warning systems and information distribution systems to enhance disaster preparedness; reducing the vulnerability of livelihoods and infrastructure to climate change; promoting good governance, including responsible policy and decision making; empowering communities and other local stakeholders so that they participate actively in vulnerability assessment and implementation of adaptation; and mainstreaming climate change into development planning at all scales, levels and sectors [WG2 AR4 10.5.7].

_____ START BOX 24-1 HERE _____

Box 24-1. What's New on Asia in AR5?

- Improved country coverage on observed and future impacts of climate change
- Increase in number of studies reflecting advances in assessment tools (e.g. more use of remote sensing and modelling of impacts); with an evaluation of detection and attribution where feasible.
- More conclusions now have confidence statements, while confidence levels have changed in both directions since AR4.
- Expanded coverage of issues; for example discussion on the Himalayas has been expanded to cover observed and projected changes as well as impacts [Box 3-2] including on tourism [10.6.2]; livelihood assets such as water and food [9.3.3.1; 13.3.1.1; 18.5.3; 19.6.3]; poverty [13.3.2.3.]; cultural erosion [12.3.2]; flood risks [18.3.1.1; 24.2.1]; health risks [24.4.1.2; 24.4.6.2] and forest distribution [24.4.2.2].

_____ END BOX 24-1 HERE _____

24.3. Observed and Projected Change

24.3.1. Observed Climate Trends and Variability

Temperature. In accordance with the findings of AR4, increasing trends in annual mean temperature at the country scale have been observed across most of the Asian region, including the Tibetan Plateau, during the 20th century, with the warming trend continuing into the new millennium (see Table 24-2). The contribution of the urban heat island effect to the temperature increase have also been pointed out (Fujibe, 2011; Ren, 2008). Despite a limited amount of information, a stronger upward trend is observed for winter mean temperatures, as compared to the summer means in East Asia, as well as in Bangladesh, Nepal, and over eastern Khengay and across the Khentey Mountains, Mongolia (Kim and Roh, 2010; Khattak *et al*., 2011, Schaefer and Domroes, 2009; Shahid, 2010). On the other hand, decreasing trends were observed for the summer diurnal temperature range in the northwestern part of Kashmir, India (Roy and Balling, 2005), and for the mean minimum temperature in Karachi, Pakistan (Sajjad *et al*., 2009).

[INSERT TABLE 24-2 HERE
Table 24-2: Summary of key observed past and present annual mean temperature trends in Asian countries/regions.]

Precipitation. Annual mean precipitation trends are characterized by strong variability, with both increasing and decreasing trends observed throughout Asia (see Table 24-3). In India, Japan, and Kazakhstan no clear national trend was observed, although on a subnational level both positive and negative trends were observed. Total summer precipitation shows an increasing trend in Southeast and Northwest China and a decreasing trend in Central China (Yao *et al*., 2008).

[INSERT TABLE 24-3 HERE
Table 24-3: Summary of key observed past and present annual mean precipitation trends in Asian countries/regions.]

24.3.2. Observed Changes in Extreme Climate Events

As summarized in 24.2.1, based on SREX, trends of extreme events have been observed throughout Asia and additional events have been recorded.

Temperature extremes. Warm days and nights are significantly increasing in such regions as West Asia, South Asia, Southeast Asian coasts and Northeastern Siberia. They are, in contrast, significantly decreasing in regions including Mongolia, North China, Afghanistan and Pakistan, and Malaysia (Fang *et al*., 2008). Extreme warm-month events have strong spatial dependence, with smaller variability over the Tibetan Plateau, the North China plain and coastal areas of South China, and larger variability over North China (Wan, 2009).

Heat waves. Trends in heat waves displayed noticeable regional variability. Regional wet heat waves are more frequent and intense in China (Ding and Qian, 2011).

Heavy precipitation. Regionally and sub-regionally varying trends have been observed in heavy precipitation over the Asian continent. The western part of Russia shows increases in heavy precipitation considerably with exceeding areas of decrease, in eastern part, speeds of the increase in heavy precipitation are lower and those of decrease, higher, than in Western part (Bogdanova *et al*., 2010). Heavy precipitation has mainly increased in West Japan and in autumn, although weak positive trends have been found in most other regions and seasons (Fujibe *et al*., 2006; Fujibe, 2008). The frequency of extreme rainfall has increased in Southeast China (Yao *et al*., 2008) and the frequency and intensity have increased in Korea (Im *et al*., 2008; Ho *et al*., 2003; Im *et al*., 2011). The intensity of extreme wet days has increased and the frequency of extreme wet days significant decreased in some parts of Peninsular Malaysia (Zin *et al*., 2010). Variability in the frequency and intensity of extreme rainfall during the monsoon season has been observed in India (Goswami *et al*., 2006; Rajeevan *et al*., 2008)

Dryness. Spatially varying trends in dryness, indicated by different measures (Consecutive Dry Days, Soil Moisture Anomalies, Palmer-Drought Severity Index) were observed within most Asian regions. Soil moisture droughts have become more severe, prolonged, and frequent during the past 57 years in China, especially northeastern and central China (Wang *et al*., 2011a)

Cyclones. Typhoon influence has increased in subtropical East Asia and considerably decreased over the South China Sea due to changes in the large-scale steering flow (tropospheric cooling in the last 20 years was suggested as cause) (Wu *et al*., 2005). Tropical cyclone frequency shows a decreasing trend over most parts of China, except at some locations in the low reaches of the Yangtze River (Ying *et al*., 2011). Duration of the most extreme winds, including tropical storms and typhoons, has been growing over Southeast Asian seas, mainly the South China Sea and the Philippine Sea (Rozynski *et al*., 2009). Frequency of typhoon passage has decreased significantly in the East China Sea and Philippine Sea in the 1980-2001 periods, relative to 1951-1979, and a continuous downward trend over the Philippine Sea has been observed. (Ho *et al*., 2004). Tropical cyclone frequency has decreased in the northwestern Pacific, while in the southeastern Pacific it increased until the early 1990s and then decreased moderately (Chen, 2009).

24.3.3. Socio-Economic Scenarios for Climate Modeling and Assessment of Impacts, Adaptation and Vulnerabilities

In the process of assessing climate change for the purposes of AR5, scenarios called Representative Concentration Pathways (RCPs) were developed, in which a wider range of potential future radiative forcing pathways were presented. Subsequently, socio-economic and climate scenarios have been developed in parallel by utilizing the RCPs [WG2 AR5 FOD 1.1.3; WG3 AR5 FOD 6.1.3]. The purpose of developing the four RCP scenarios was to compare climate change, climate change impacts, and emission pathways under different stabilization targets (Moss *et al*., 2010). Shared Socio-economic Pathways (SSPs) and Shared Climate Policy Assumptions (SPAs) have also been developed to provide scenario elements such as Economic Growth, Globalization, Distribution/ Equity, Environmental Ethics and Values, Institutions and Governance, Technological Change and Access, and Population and Demographics (Kriegler *et al*., 2012; van Vuuren *et al*., 2012). SSPs and SPAs are essential for assessment of

impacts, adaptation and vulnerabilities (IAVs) because Asian countries have a huge variety of current socio-economic conditions [24.1] and their future socio-economic situation could be varied under scenario assumptions. Many Asia-specific research projects have been conducted for assessing future socio-economic conditions in connection with the achievement of a low-carbon society under the constraints of climate change stabilization (e.g. Winyuchakrit *et al*., 2011; Akashi *et al*., 2012; Shukla *et al*., 2010). On the other hands, few IAV research studies including or focusing on Asia have been reported in which IAVs are discussed in relation to differences in climate change and future socio-economic conditions (Hasegawa *et al*., submitted)

24.3.4. Projected Climate Change

The projected changes for temperature and precipitation in Asia are summarized based on AR5 WG1 SOD (see Table 24-4 and Figure 24-2).

[INSERT TABLE 24-4 HERE
Table 24-4: Summary of projected changes for a variety of climate parameters [WG1 AR5 SOD Ch. 14.]

[INSERT FIGURE 24-2 HERE
Figure 24-2: Change in annual temperature and precipitation in Asia.]

24.4. Observed and Projected Impacts, Vulnerabilities, and Adaptation

The key obserced and future climate change impacts in Asia are summarized based on sub-section from 24.4.1 to 24.4.6 (see Tables 24-5 and 24-6).

[INSERT TABLE 24-5 HERE
Table 24-5: Summary of key observed past and present climate change impacts in Asia.]

[INSERT TABLE 24-6 HERE
Table 24-6: Summary of key future climate change impacts in Asia.]

24.4.1 Freshwater Resources

24.4.1.1. Sub-Regional Diversity

The water sector in Asia is significantly vulnerable to shifts in climate due to the dependence of its huge agricultural sector on precipitation, river runoff, and groundwater (see Table 24-5). Hence, adequate water supply is one of the major challenges in Asia, particularly Central Asia (Vorosmarty *et al*., 2010). Regional assessments of the environmental impact of the freshwater situation are greatly needed (Pfister *et al*., 2009). Growing demand for water is driven by soaring population, increasing urbanization, and thriving economic growth. Arid countries of the Middle East and Central Asia face major challenges in ensuring a freshwater supply, which will continue to decline with the decrease in precipitation, groundwater recharge and surface runoff (Kitoh *et al*., 2008). Mismanagement of water resources is increasing tension among five Central Asian states of the former Soviet Union – Kazakhstan, Kyrgyzstan, Turkmenistan, Uzbekistan, and Tajikistan (Lioubimtseva and Henebry, 2009; Siegfried *et al*., 2010).

24.4.1.2. Observed Impacts

Water availability has varied in most river catchments in China during the past several decades, detected with high confidence, but this can be attributed with low confidence to climate change rather than other human activities (see Table 24-5). No evidence shows significant changes in the Kherlen River Basin in Mongolia (Brutsaert and Sugita, 2008). The surface water resources of Central Asia are primarily generated in mountain glaciers. Increased runoff

from shrinkage of glaciers has been observed in the Himalayas (Zhang *et al*., 2011; case study box in Ch.3; case study 24.9.3) and Central Asian mountains due to increased temperature (high confidence in detection and attribution, Casassa, G., P. Lopez, *et al*., 2009; Shrestha and Aryal, 2011). Apart from water availability, climate change is correlated with surface water quality (medium confidence in detection and attribution, Prathumratana *et al*., 2008; Delpla *et al*., 2009; Huang *et al*., 2009 ; Park *et al*., 2010; Zhang *et al*., 2007), which may increase health risk (Tornqvist *et al*., 2011). It is also noticeable that groundwater quality is also related to climate change (Thakur and Ojha, 2010; Winkel *et al*., 2011; Fendorf *et al*., 2010; Gunawardhana and Kazama 2012). It has been suggested that the water crisis in Asian countries is partly caused by poor management (Biswas and Seetharam, 2008).

24.4.1.3. Projected Impacts

Projected impacts of future climate change (A1B scenario with 5 GCMs) on water availability in Asia, considering the future demand, differ substantially among river basins (Immerzeel *et al*., 2010). The water demand in most Asian countries is gradually increasing because of increases in population, irrigated agriculture (Lal, 2011) and growth in the industrial sectors. Tropical Asia will experience severe dry and wet spells that will reduce water supply reliability and increase chances of flooding. Even though precipitation in northern and temperate Asia is expected to increase overall (Park *et al*., 2010), socio-economic development will pose a challenge to freshwater resources. Projections (A2 scenario with multiple GCMs) suggest that throughout much of Russia a warmer climate would decrease water availability due to the increase in evaporation, but on the other hand precipitation would increase which tends to increase water availability (Alcamo *et al.,* 2007). In China, a projection (A2, PRECIS) suggests that there will be insufficient water for agriculture in the 2020s and 2040s due to the increases in water demand for non-agricultural uses, although positive trends in precipitation may occur in some areas (Xiong *et al*., 2010). In a study of the Mahanadi River Basin in India, the future water availability projection (A2, CGCM2) indicated an escalating trend in excess river runoff (runoff after meeting water demand), thereby increasing the future possibility of floods for the month of September, yet the outcomes for April indicate an accelerating water scarcity (Asokan and Dutta, 2008). In the Ganges, effects of climate change could become large enough to offset the large increases in demand in a +4ºC world, due to a projected large increase in rainfall (2ºC and 4ºC temperature increase from ensemble GCMs; Fung *et al*., 2011). Given the already very high level of water stress in many parts of Central Asia, projected temperature increases and precipitation decreases (SRES scenarios from IPCC AR4 23 models) in the western part of Kazakhstan, Uzbekistan, and Turkmenistan could exacerbate the problems of water shortage and distribution (Lioubimtseva and Henebry, 2009). Considering the dependence of Uzbekistan's economy on its irrigated agriculture, which is consuming more than 90% of the available water resources of the Amu Darya basin, climate change related impacts on river flows would also strongly affect the economy (Schlüter *et al*., 2010). Fresh water resources in coastal areas might be reduced over the next century in Asia, except for Southeast Asia, with the vulnerable areas including South India, the Bangladesh region and China (A2 scenario, HadCM3; Ranjan *et al*., 2009).

24.4.1.4. Vulnerabilities to Key Drivers

It is suggested that river discharge will be influenced by rainfall change and rapid melting of snow and frozen soil in the river catchment (Tachibana *et al*., 2008) associated with climate change (Jian *et al*., 2009). Snowfall and snow melting is estimated to be very sensitive to climate warming because the surface air temperatures in heavy snow regions in Monsoon Asia are near 0°C even during winter. The seasonal cycle of river runoff would be modified and affect water management in heavy snow regions in Asia (Ma *et al*., 2010; Im *et al*., 2010; Sato *et al*., 2012; Yamanaka *et al*., 2012). Water management in river basins needs to be coordinated among countries, for example water management in the Syr Darya river basin relates to Kyrgyzstan, Tajikistan, Uzbekistan, Turkmenistan, Kazakhstan (Siegfried *et al*., 2010).

24.4.1.5. Adaptation Options

Asia is by far the largest user of irrigation water in terms of volume. During the second half of the 20th century, Asia has built many reservoirs and almost tripled its surface water withdrawals for irrigation. Reservoirs partly mitigate the seasonal differences and increase water availability for irrigation (Tyler and Fajber, 2009; Biemans *et al.*, 2011). However, they might not be able to continue the same supply because of a change in reservoir inflow due to the effects of climate and socioeconomic change. To adapt to the climate change impacts on water resources, many Asian countries apply water saving technologies in irrigation (Ngoundo *et al.*, 2007; Tischbein etal., 2011) and other consumptive purposes (Fleskens *et al.*, 2007), change to more drought-tolerant crops (Thomas, 2008; Zhao *et al.*, 2010), increase water supply (Sadoff and Muller, 2009), and improve management (Kranz *et al.*, 2010). In monsoonal Asia, development of water control systems has contributed to improved rice harvests (Hatcho *et al.*, 2010).

Four strategies (a new flood map, an early warning system, a relief program, and more community education) have been developed in the Sarawak River system in Malaysia to reduce the excessive flood loss (Mah *et al.*, 2011). Hazard mapping could help both decision-makers and local communities to understand the current situation and, through this, it would be possible to anticipate or assess the flexibility to adapt to future changes through proper planning and technical design. Examples include mapping in the Himalayan region (Eriksson *et al.*, 2009), risk mapping of slope failure in Japan (Ono *et al.*, 2011) and proposed investments in river regulation and storage in Nepal to control floods and to augment low-season flows in India and Bangladesh in the Ganges River Basin (Sadoff and Muller, 2009).

The equitable sharing of water and the drought-proofing of rural livelihoods will require an increasing physical capacity to store water (van der Zaag and Gupta, 2008). Moreover, policy processes in the current water management regime are strongly shaped by informal institutions and the lack of enforcement of formal regulations. The high degree of centralization of the management regime (Webster and McElwee, 2009) and the lack of vertical integration are possible explanations for the rather low adaptive capacity (Schlüter *et al.*, 2010). Legal aspects of water management also need to be considered in South Aisa (Uprety and Salman, 2011; D'Agostino and Sovacool, 2011).

24.4.2. Terrestrial and Inland Water Systems

24.4.2.1. Sub-Regional Diversity

Asia supports examples of all the major natural terrestrial ecosystem types, with the predominant types differing between sub-regions. North Asia is a region of tundra, boreal forests and grasslands, Central and West Asia are dominated by desert and semi-desert ecosystems, and the Tibetan Plateau is covered in a variety of largely treeless alpine ecosystems. These four sub-regions have relatively low human population densities in most areas, except for parts of Central and West Asia, and are still largely covered in natural ecosystems, although some of these have been extensively modified. In the three remaining sub-regions, in contrast, natural ecosystems have been completely replaced over large areas by human-dominated landscapes. The major natural ecosystems of East Asia included temperate deciduous and subtropical evergreen forests, giving way to boreal forest in the northeast and to grasslands and deserts in the west. South Asia and Southeast Asia were largely covered in tropical forests, with deciduous and semi-evergreen forests most extensive in South Asia and evergreen rain forests more important in Southeast Asia. South Asia also has extensive semi-desert areas in the west and northwest, and a variety of alpine ecosystems in the north, while Southeast Asia supports a small area of alpine vegetation and ice above the treeline in New Guinea. Asia includes several of the world's largest river systems (Indus, Ganga-Brahmaputra-Meghna, Irrawaddy, Mekong, Pearl [Zhu Jiang], Yangtze [Chang Jiang], Yellow [Huang He], Amur, Lena, Yenisei, Ob, Mamberamo, Fly, Sepik) with their associated deltas, as well as the world's deepest freshwater lake, Lake Baikal, the semi-saline Caspian Sea, and the saline and now greatly shrunken Aral Sea.

24.4.2.2. Observed Impacts

Temperatures have shown a largely consistent rise across Asia since 1970, but changes in precipitation have been complex and varied [WG1 AR5 SOD Ch. 14]. In general, observations of biological changes in terrestrial ecosystems consistent with the impacts of climate change are more common in the cold and/or arid north and west of the region, and at high altitudes, where rising temperature and, in some areas, increasing precipitation have relaxed constraints on the growth of plants and the distributions of both plants and animals. In contrast, there have been very few reports from the tropical lowlands of impacts and none that can be linked to recent climate change with high confidence. Many changes in inland water systems have also been reported, but the impacts of climate change have been difficult to disentangle from natural variability and a wide variety of other, concurrent, human impacts (Bates *et al*., 2008; Wang *et al*., 2011b; Zheng, 2011).

Phenology and growth rates. The most widely reported impacts attributed to the observed climate trends have been changes in the timing of life-history events in plants and animals. Combining information from species-level observations of plants, satellite measurements of 'greenness' (Normalized Difference Vegetation Index, NDVI) and modeling, Ma and Zhou (2012) conclude that plant growth in China has started on average 2.9 days per decade earlier since the early 1980s and that this is *likely* a response to spring warming. The shift was largest in forests and smallest in grasslands and shrublands, where changes in precipitation may be more important. Regional studies in northern and eastern China, and in Japan, using observational or satellite data, have shown similar general trends, with earlier greening in spring, delayed senescence in autumn, and thus a longer growing season, associated with rising temperatures, although the details vary between sites and species (Doi and Katano, 2008; Bai *et al*., 2010; Guo *et al*., 2010; Li and Zhou, 2010; Yu *et al*., 2010; Cai *et al*., 2012; Chen and Xu, 2012; Dai *et al*., 2013; Ogawa-Onishi and Berry, 2013). Earlier spring flowering associated with rising temperatures has also been recorded for a variety of tree species across temperate China and Japan (Doi, 2007; Doi and Katano, 2008; Wu *et al*., 2009; Bai *et al*., 2010; Fan *et al*., 2010; Fujisawa and Kobayashi, 2010; Ge *et al*., 2011; Dai *et al*.., 2013), with cherry trees in Kyoto now flowering earlier than they have at any time in the previous 1200 years (Primack *et al*., 2009). In temperate East Asia, these changes in plant phenology have been detected with high confidence and can be attributed to climate change with medium confidence. Changes in animal phenology have also been reported from China, Japan and South Korea, but their direction varies between species and locations, and the relationship with climate change is often unclear (Kusano and Inoue, 2008; Lee *et al*., 2011; Kobori *et al*., 2012; Ogawa-Onishi and Berry, 2013).

In the boreal forests of northern Asia, satellite data, validated with ground observations, shows a trend to earlier greening from 1982 to the 1990s, which is strongest in Central Siberia, followed by a slight delay in many areas (Delbart *et al*., 2008). On a continental scale, boreal forest leafing advanced by 3.9 days per decade for 1982-1999 and was earlier in the mid-1990s in Central Siberia than at any time since 1920. A general trend to earlier spring green-up from 1982 to 2006 is also evident from satellite NDVI data for the Hindu-Kush-Himalayan region, from Afghanistan to Myanmar, with the strongest temporal trends in the west (Panday and Ghimire, 2012). A more detailed study of the Himalayas over the same period found that the growing season had advanced by an average of 1.9 days per decade, with no change at the end of the season, in apparent response to a mean warming of 1.5 ºC (Shrestha *et al*., 2012). There was a great deal of spatial heterogeneity, with areas in the drier western Himalayas more likely to have negative correlations with spring temperatures and a positive response to rainfall. In the Trans-Himalayan region of Nepal, wetter areas followed regional trends, but semi-arid areas had a delayed and shortened growing season from 2000 to 2009, as a result of a decline and delay in snow cover (Paudel and Andersen, 2012). Patterns were heterogeneous for 1981-2008 in Central Asia, where temperatures are generally increasing and precipitation decreasing (Kariyeva *et al*., 2012). NDVI data showed an earlier start to the growing season in much of the region, but a substantially later start in desert and semi-desert areas in Turkmenistan and southern Uzbekistan. On the Tibetan Plateau, the start of spring growth in meadows and steppe advanced until the mid-1990s, after which it retreated, so there was no overall significant trend over the period 1982-2006, despite continued warming and increases in spring NDVI (Yu *et al*., 2012). These trends may be related to unfulfilled winter chilling requirements of the grasses. Herbarium records from Tibet show earlier flowering by 5 days per decade for a set of 41 species over the period 1961-2000 (Li *et al*., 2013).

Recent changes in the growth rates of plants have also been widely reported and, where long records are available from tree rings, these changes can be linked to recent climate change (high confidence in detection, medium confidence in attribution to climate change). A reconstruction of summer temperatures for East Asia north of 23ºN for the period 800-1989, based on a network of tree-ring data, suggests that recent instrumental temperatures have exceeded those during past warm periods of similar length, but this difference was not statistically significant (Cook *et al*., 2013). In areas where temperature limits tree growth, recent decades have generally seen an increase in growth rates correlated with rising temperatures (e.g., Duan *et al*., 2010; Sano *et al*., 2010; Shishov and Vaganov, 2010; Borgaonkar *et al*., 2011; Xu *et al*., 2011; Li *et al*., 2012; Cao *et al*., 2012; Chen *et al*., 2012 a, b, c, d; Chen *et al*., 2013), while in areas where drought limits growth, there have been increases (Yang *et al*., 2010) or decreases (Dulamsuren *et al*., 2010a, 2011; Kang *et al*., 2012; Wu *et al*., 2012; Lu *et al*., 2013) in growth reflecting decreasing or increasing aridity. In the boreal forest zone, changes in tree growth varied between species and locations, despite consistent warming, with suggested reasons for decreased growth including drought stress, pollution, declining solar radiation, and direct temperature stress (Lloyd and Bunn, 2007; Goetz *et al*., 2011).

Where ground-based data is absent, satellite NDVI data can be used as a proxy for changes in vegetation density and photosynthetic capacity, which in turn reflect plant growth, although there are problems with both the NDVI data and its interpretation (Zhao *et al*., 2012; Xu *et al*., 2012). For Asia as a whole, the spatial pattern of trends in NDVI for 1988-2010 largely matches data on microwave-based surface soil moisture, with a greening trend dominant except where water is limiting (Dorigo *et al*., 2012). Changes in NDVI at high latitudes (>60ºN) in 1982-2008 show considerable spatial and temporal variability, despite a consistent warming trend, reflecting variations in water availability as well as non-climatic factors (Jeong *et al*., 2013). Arctic tundra generally showed increased greening between 1982 and 2005, while boreal forests were more variable, in agreement with tree-ring data (Goetz *et al*., 2011; de Jong *et al*., 2012). An overall greening trend for 2000-2011 north of the boreal forest correlated with increasing summer warmth and, to a lesser extent, summer ice retreat (Dutrieux *et al*., 2012). In China, NDVI trends have varied in space and between time periods, reflecting the varying balance between the positive impacts of rising temperature and negative impacts of increasing drought stress (Peng *et al*., 2011; Sun *et al*., 2012). In Central Asia, where NDVI is most sensitive to changes in precipitation (Gessner *et al*., 2013), there was a complex and heterogeneous pattern for 1982-2009, with an initial regional greening trend stalled or reversed in some areas and time periods (Mohammat *et al*., 2013). In the desert boundary regions (precipitation 200 mm yr^{-1}) of South, Central and Northern Asia, NDVI data showed that the bare soil area declined in 1982-1998, but expanded in 1998-2008 (Jeong *et al*., 2011). In the northern deserts (Karakum, Taklimakan and Gobi), these changes were related to an initial increase then decline in precipitation, while temperature continued to rise, while in the southern deserts (Lut and Thar) non-climatic factors appear to be more important. The steppe region of northern Kazakhstan has also shown an overall browning (lower NDVI) trend in 1982-2008, linked to declining precipitation (De Jong *et al*., 2012).

The carbon budget of all terrestrial ecosystems in East Asia (China, Mongolia, North and South Korea, Japan) from 1990 to 2009 was estimated using a combination of inventory and satellite-based data, ecosystem modeling (using 10 models), and atmospheric inversion models (Piao *et al*., 2012). Although there are large uncertainties in each approach, the results together suggest that the region as a whole was a significant carbon sink over this period (average -0.294 Pg C yr^{-1}), with the negative impacts of drought in some areas largely overcome by the positive impact of CO_2 fertilization.

The distributions of species and biomes. Also widely reported are changes in the distributions of plant and animal species: generally upwards in elevation (e.g. Soja *et al*., 2007; Round and Gale, 2008; Bickford *et al*., 2010; Kharuk *et al*., 2010 a, b, e; Moiseev *et al*., 2010; Chen *et al*., 2011; Jump *et al*., 2012) or polewards (e.g. Tougou *et al*., 2009; Ogawa-Onishi and Berry, 2013) in response to recent warming (high confidence in detection, medium confidence in attribution to climate change). Movements of dominant plant species can eventually lead to changes in the distributions of major vegetation types (biomes). Evidence for biome shifts has so far been reported only from the north of the region and at high altitudes, where it involves trees invading treeless tundra, steppe or alpine meadows, or the invasion of the forest understory by species from adjacent biomes (Soja *et al*., 2007; Kharuk *et al*., 2006; Bai *et al*., 2011; Singh *et al*., 2012; Wang and Liu, 2012; Ogawa-Onishi and Berry, 2013). In Uttarakhand, in the Indian Himalayas, the treeline has moved upwards into the alpine zone by an average of 388 m between the 1970s and 2006 (Singh *et al*., 2012).

Larch-dominated forest occupies about half the area of Siberia. Invasion of dark needle conifers (DNC, e.g. Siberian pine, spruce and fir) and birch into the larch habitat over the last three decades has been observed, correlating with winter temperature increases (Kharuk *et al.*, 2010c). Siberian pine and spruce have high invasion potential both along the margin and in the centre of the larch-dominated zone. The process is wildfire dependant. On the western and southern margins of this zone, DNC regeneration has formed a second layer in the forest canopy, which could eventually replace the larch in the overstorey. In mixed stands, both larch and fir growth have increased over time, but the fir growth increase has been larger which may presage a shift in competitive balance between these species. Overall, it is *likely* that prevalence of evergreen conifers in areas currently dominated by deciduous larch species is increasing (Kharuk *et al.*, 2010c, d; Osawa *et al.*, 2010; Lloyd *et al.*, 2011). At the same time, climate change has driven larch stand crown closure, and larch invasion into tundra at a rate of 3–10 m/year was observed in the northern forest-tundra ecotone in Siberia in the last three decades of the 20th century (Kharuk *et al.*, 2006). Shrub expansion in arctic tundra as result of an increase in shrub growth, infilling of existing patches and the shrub line advancing into tundra has also been observed in the forest-tundra ecotone of Northern Asia (Myers-Smith *et al.*, 2011; Blok *et al.*, 2011; WG2 AR5 28.2.3.1.). Shrub growth is often strongly correlated with growing season temperatures, but is also influenced by fire, permafrost thaw and herbivory. Shrub and tree invasion of alpine meadows has also been reported in NW Yunnan, on the southeast edge of the Qinghai-Tibetan Plateau, between 1990 and 2009, and partly attributed to increasing temperatures and decreasing snow cover (Baker and Mosely, 2007; Brandt *et al.*, 2013).

In northern Asia, the position of the ecotone between boreal forest and tundra is controlled largely by air temperature during the growing season and annual precipitation, but forest fires can also catalyze change (Soja *et al.*, 2007). In contrast, soil moisture and light are the main factors governing the forest-steppe ecotone, although competition between trees and grasses, as well as fires, are also important (Soja *et al.*, 2007; Zeng *et al.*, 2008; Dulamsuren *et al.*, 2010 a, b; Eichler *et al.*, 2011). This ecotone in the western Khentey Mountains, northern Mongolia, has experienced a significant increase in summer temperature and decrease in summer precipitation since 1961. Siberian larch tree-ring analysis shows a strongly decreasing annual increment since the 1940s (Dulamsuren *et al.*, 2010a). Regeneration of larch decreased as well and is now virtually lacking in this forest. Studies on a wider scale show a great deal of heterogeneity in the responses of Mongolian taiga forests to recent climate changes, but declines in larch growth and regeneration are more widespread than the opposite trend (Dulamsuren *et al.*, 2010b).

Permafrost and glaciers. Degradation of permafrost, including reductions in area and increased thickness of the active layer, has been reported from parts of Siberia, Central Asia, and the Tibetan Plateau (Romanovsky *et al.*, 2010; Wu and Zhang, 2010; Zhao *et al.*, 2010; Yang *et al.*, 2013) (*high confidence*). Russia contains more permafrost than any other country: more than half of the Russian part of Northern Asia lies in permafrost zones, which constitutes a significant portion of the Northern Hemisphere permafrost area (FNCRF, 2010). Monitoring in most of the permafrost observatories in Asian Russia shows substantial warming of permafrost during the last 20 to 30 years (Romanovsky *et al.*, 2008, with supplement; 2010). Typical magnitude of warming varied from 0.5 to 2°C for different locations at the depth of zero annual amplitude. The main warming occurred between the 1970s and 1990s, with no significant warming after 2000. However, since 2007-2008 warming has resumed at many locations predominantly near the Arctic coasts. In Northwest Siberia, new closed taliks (areas of unfrozen ground) and an increase in the depth of preexisting taliks have been observed during last 20 to 30 years. Permafrost formed during the Little Ice Age is thawing at many locations and Late Holocene permafrost has begun to thaw at some undisturbed locations in northwest Siberia. Permafrost thawing is most noticeable within the discontinuous permafrost domain in Northern Asia, while in the continuous permafrost zone it is starting to thaw at some limited locations. As a consequence, the boundary between continuous and discontinuous permafrost zones is moving northward (Romanovsky *et al.*, 2008, with supplement; 2010). Over many thousands of years, the soil layer and bogs in the permafrost zone of Northern Asia have been accumulating huge amounts of organic matter. As permafrost thaws, reinforcement of the greenhouse effect is possible due to growing emissions of greenhouse gases [WG2 AR5 FOD 4.3.4.4.; WG2 AR5 FOD 19.3.5.].

The Qinghai-Tibet Plateau (QTP) and Central Asian region, including parts of Southern Siberia, Mongolia, Western China, Kazakhstan, and adjacent countries/regions, represent the largest area underlain by mountain permafrost in the world. Ongoing monitoring at numerous sites across the QTP regions over the past several decades has revealed

significant permafrost degradation caused by climate warming and human activities such as deforestation, forest fire, road construction and grazing: areas of permafrost are shrinking, the depth of the active layer is increasing, the lower limit of permafrost is rising, and the seasonal frost depth is thinning (Zhao *et al*., 2010; Li *et al*., 2008). The lower altitudinal limit of permafrost has moved up by 25 m in the north during the last 30 years and between 50 and 80 m in the south over the last 20 years in accord with long-term temperature measurements. Ground temperature at a depth of 6 m in 2001 has been higher by about 0.1-0.3°C than in 1996 according to data taken from seven natural sites on the Plateau (Cheng and Wu, 2007; Li *et al*., 2008). Over the period from 1995 to 2007, the mean rate of increase of the active layer thickness (ALT) was 7.5 cm/year (Wu and Zhang, 2010). Ground temperatures at the bottom of the active layer warmed on average by 0.06°C/year over the past decade (Zhao *et al*., 2010). In the alpine headwater regions of the Yangtze and Yellow Rivers, rising temperatures and permafrost degradation have resulted in lower lake levels, drying swamps and shrinking grasslands (Cheng and Wu, 2007; Wang *et al*., 2011c).

In the Kazakh part of Tien Shan Mountains, the increase in permafrost temperature during 1974-2009 at depths of 14-25 m varied from 0.3°C to 0.6°C. The average active layer thickness (ALT) increased by 23% in comparison to the early 1970s. In the eastern Tien Shan Mountains, in the headwaters of the Urumqi River, China, significant permafrost warming took place as the air temperature increased (Marchenko *et al*., 2007; Zhao *et al*., 2010). In Mongolia, mean annual ground temperature at 10-15 m depth over the past 10-40 years increased on average by 0.02-0.03°C/year in the Hovsgol Mountain region, and by 0.01-0.02°C/year in the Hangai and Hentei Mountain regions. During the past 15–20 years permafrost warming was greater than during the previous 15-20 years (1970s-1980s). The average rate of increase in mean annual ground temperature in Mongolia was about 0.15°C/decade (Sharkhuu *et al*., 2008; Zhao *et al*., 2010).

Mountain glaciers occur across Asia from the Arctic to the tropics [WG1 AR5 SOD Ch. 4]. Those in the polar section of the Ural Mountains are small (< 1km^2) and in total lost 20-30% of their mass in 1953-1981, with the main change in 1953-1963 and intensive degradation resuming since 1990 (Anisimov *et al*., 2008). Those in the Kodar Mountains of Southeast Siberia are also small (< 2 km^2) and the exposed ice area declined by c. 44% between ca. 1963 and 2010, with 40% loss since 1995, coinciding with a strong warming trend in June-August temperatures initiated in the 1980s (Stokes *et al*., 2013). In Northeast Siberia, the Suntar Khayata Range glaciers lost 19.3% of their area between the middle of the 20th century and 2003 and the Chersky Range glaciers lost 28 % in 1970-2003 (Ananicheva *et al*., 2005, 2006). Changes in the Kamchatka glaciers are driven by both temperature increase and volcano activity, with the area of some glaciers decreasing, while others increased because they are covered by ash and clinker (Anisimov *et al*., 2008). Glaciers of Georgia and Azerbaijan on the southern macroslope of the Greater Caucasus Range decreased in area by 31.2% in 1895-2000 (Anisimov *et al*., 2008). Yao *et al*. (2012) estimated that reduction in total area for glaciers on Tibetan Plateau and the surrounding areas during the past three decades, from the 1970s to 2000s, was c. 9%. In Papua, western Indonesia, the tropical mountain glaciers on Puncak Jaya have retreated rapidly since 1972, with rising temperatures thought to be the major factor (Prentice and Glidden, 2010; WG1, Ch. 4, AR5 SOD). Central Asian and Altai-Sayan glaciers are considered in more detail in the case study [24.9.3] and the Himalayan glaciers are considered in section 24.4.1 and in WG1 AR5 SOD Ch. 4.

24.4.2.3. Projected Impacts

The projected impacts in the literature assessed here include extrapolations from the observed trends, inferences from experiments, and projections from a variety of modeling approaches, based on projected climate change and projections for other factors, including carbon dioxide levels and land-use changes.

Phenology and growth rates. If air temperatures continue to rise, current trends towards an earlier spring and longer growing season in temperate and boreal forest areas are expected to continue, although photoperiod or chilling requirements may reduce the response in some plant species (Richardson *et al*., 2013). Changes in the timing and amount of precipitation will be at least as important as warming for semi-arid and arid ecosystems, making growth and phenological responses harder to predict, as shown by the varied responses of different plant species to experimental warming in the northern Mongolian steppe (Liancourt *et al*., 2012). The phenological drivers for tropical forests are not yet understood.

Distributions of species and biomes. The current distribution of vegetation across the region is controlled primarily by climate (particularly temperature, rainfall and snowfall, and their seasonality), modified over large areas by soils, permafrost, topography, and a variety of human impacts. In the longer term, therefore, climate change is expected to change this distribution (e.g. Wang, 2013). However, the rate at which this change in vegetation is realized will be constrained by many factors, including seed dispersal, competition from established plants, rates of soil development, and habitat fragmentation. Atmospheric CO_2 concentrations are an additional factor, with rising concentrations increasingly favoring C3 over C4 plants, and thus an increase in woody vegetation at the expense of grassland (Higgins and Scheiter, 2012; Wang, 2013).

Climate projections for Asia strongly suggest that the warming trend will continue, but projections for precipitation are still uncertain [WG1 AR5 SOD Ch. 14]. In Northern Asia, these changes in climate will lead to large and relatively predictable changes in the distribution of potential natural ecosystems (Ni, 2011; Tchebakova *et al*., 2011; Insarov *et al*., 2012), although the transitional stages will be less predictable. If current climate projections are correct, it is *likely* that the boreal forest will expand northward and eastward, and the tundra area will decrease, during the 21st century (Golubyatnikov and Denisenko, 2007; Korzukhin and Tcelniker, 2010; Lucht *et al*., 2006; Sitch *et al*., 2008; Tchebakova *et al*., 2010; Woodward and Lomas, 2004). However, for a shorter time horizon, some forest retreat and tundra advance by 2020 in Central Siberia have been projected (Tchebakova *et al*., 2011). Because models vary in accordance with their structure as well as biome classifications, climatic projections, CO_2 level and other characteristics used as inputs, the magnitude of the forest expansion varies greatly across models: Tchebakova *et al*. (2010) and Lucht *et al*. (2006) project that 93-100% of tundra area will be covered by boreal forest at the end of 21st century, Kaplan and New (2006) predict a 42% reduction in tundra area between 2026 and 2060, whereas Golubyatnikov and Denisenko (2007) estimate that 97% of tundra will remain unaltered by the mid-21st century.

The combination of boreal forest expansion and the continued invasion of the existing larch-dominated forest by dark-needle conifers could lead to a situation where larch reaches the Arctic shore, as has happened previously in the Holocene, whereas the traditional area of larch dominance will turn into mixed taiga forest (Kharuk, 2006, 2010c). Both replacement of summer-green conifers (larch) with evergreen conifers (DNC) and expansion of boreal forest and shrubs into regions now occupied by tundra decrease albedo. This change would cause heating of the atmosphere, a response that, in its turn could possibly accelerate the replacement of larch by DNC and of tundra by boreal forest (McGuire *et al*., 2007; Kharuk *et al*., 2006, 2010d). Energy budget feedback to the regional summer climate from the tundra to forest transition is estimated at 5.0 Wm^{-2} (McGuire *et al*., 2007). Overall there is a risk that future climate and environmental change, along with fire and permafrost degradation, could change some Siberian ecosystems, particularly disturbed forests and ecosystems on permafrost, from carbon sinks to sources of both CO_2 and CH_4 (Shvidenko *et al*., 2013).

The direction and rate of change in the extent of steppe vegetation is less clear, in part because of uncertainty in precipitation trends. One projection is that steppe area will increase by 27% for the decade beginning in 2090 (Tchebakova *et al*., 2010) while another is that it will decrease by up to 65% for late 2030s–early 2050s (Golubyatnikov and Denisenko, 2007). Reasons for the differences between these estimates include different projection horizons and vegetation classifications used. Increasing aridity may expand the deserts of northern China, and push the steppe to the northeast (Zhang *et al*., 2011), while a retreat of the southern limit of the taiga would expand the steppe area in the north (Dulamsuren *et al*., 2010b).

The forest regions of East Asia are expected to remain forested, but climates suitable for evergreen forests will expand north into the deciduous forest zone and the potential distribution of tropical forests will expand along China's southern coast (Choi *et al*., 2011; Wang, 2013). As observed elsewhere in the world, however, vegetation changes within lowland forest regions are expected to lag behind climate change by decades or even centuries, as fragmentation limits seed dispersal and long-lived forest dominants persist (e.g., Bertrand *et al*., 2011; Zhu *et al*., 2012). For example, climate models predict a large increase in the potential habitat for the evergreen broad-leaved tree species *Quercus acuta* in Japan, but short-distance seed dispersal by rodents will limit the ability of this species to occupy new areas (Nakao *et al*., 2011). On the Tibetan Plateau, multiple vegetation and climate models suggest that alpine vegetation will be largely replaced by forest and shrubland, with tundra and steppe retreating to the north of the plateau (Liang *et al*., 2012; Wang, 2013). In drier parts of the plateau, permafrost degradation will favor

plants that are tolerant of water stress (Cheng and Wu, 2007; Yang *et al*., 2013). The same models suggest that a large area of desert will persist in northwest China (Wang, 2013). Impacts in Central and West Asia will depend critically on the changes in precipitation, which are still highly uncertain. Projections for China from an atmospheric-vegetation interaction model under the SRES B2 scenario suggest that the arid northwest of the country is the most vulnerable ecoregion, with severe damage to desert ecosystems possible (Wu *et al*., 2010).

In the tropics and subtropics (<30ºN), many areas, including much of the Arabian Peninsula, India, southeastern China, and Southeast Asia, are expected to have climates by 2080 that do not occur anywhere on Earth at present (García- López and Allué, 2012), making predictions particularly difficult. In India, a dynamic vegetation model (IBIS) was combined with climate projections for 2100 (HadRM3 model, A2 and B2 scenarios) to produce projections for forest areas (Chaturvedi *et al*., 2011). More than a third of forest grids were projected to change forest type, with most changes from deciduous to evergreen forest in response to increasing rainfall, although fragmentation, loss of seed dispersal agents, and other human pressures are expected to slow these changes. The forests of the upper Himalayas, parts of Central India, northern Western Ghats and Eastern Ghats, appear to be most vulnerable to climate change. In the equatorial tropics, the relatively small annual temperature range means that by 2100 many lowland habitats are likely to experience temperatures every day that are outside the current range of extremes (Beaumont *et al*., 2010). The potential impacts of these novel climatic conditions are largely unknown (Corlett, 2011). If the frequency and severity of droughts increases, this is *likely* to interact with forest fragmentation and logging to increase fire risk (Daniau *et al*., 2012) and could also increase the risk of drought-induced tree mortality (Kumagai and Porporato, 2012).

An increasing number of studies have projected impacts on animals using a variety of modeling techniques. Hughes *et al*. (2012) projected the effects of both climatic (A2 and B1 scenarios) and vegetation changes on the distribution and diversity of bats in SE Asia. All projections predicted widespread declines in local bat species richness, northward range shifts for many species, and large reductions in the distribution of most species. Projections for the potential ranges of 63 species of galliform birds (pheasants, partridges and their relatives) in China (A2 scenario, 2071-2100) showed large (>50%), mostly northward, range shifts for 29 species (Li *et al*., 2010), while projections for the 13 species of nuthatches (Sittidae) in Asia (A2 and B2 scenarios, 2040-2069) found that most ranges would retract along their southern fringes and at lower elevations, with the largest range contractions in SE Asia and peninsular India (Menon *et al*., 2009). Projections for 17 endemic bird species in Taiwan (A2 and B2 scenarios, 5 GCMs) suggested 15 species would decrease their area of distribution by 2100 because of a shift to higher elevations, while two species from relatively low altitudes would increase (Ko *et al*., 2012). Projections for the distributions of 161 butterfly species in Thailand (A2 and B2 scenarios, 2070-2099) suggested that species richness within currently protected areas will decline c. 30%, but that these areas will continue to include a similar proportion of the highest priority sites for conservation (Klorvuttimontara *et al*., 2011). Projections for three dominant bamboo species in the Qinling Mountains, China (A2 and B2 scenarios, four GCMs) suggest substantial reductions in their ranges by 2100, with potentially adverse consequences for the giant pandas for which they comprise almost the entire current diet (Tuanmu *et al*., 2012). Projections for vegetation cover in the range of the threatened Yunnan snub-nosed monkey in southwest China in 2050 and 2100 (A1B scenario) suggest an increased area of the most suitable habitat, but greater fragmentation (Wong *et al*., 2013). Projections for snow leopard habitat in the Himalayas (15 GCMs, downscaled, B1, A1B and A2 scenarios) suggest this may contract by around 30% as forests move upslope and replace the open habitats this species needs (Forrest *et al*., 2012).

Permafrost. In the Northern Hemisphere as a whole, a 20-90% decrease in permafrost area and a 50-300 cm increase in active layer thickness (ALT) driven by surface warming is projected for 2100 by different models under SRES A1B, A2, B1 scenarios (Schaefer *et al*., 2011). The wide range of permafrost degradation projections may be result of different scenarios used, intensity of land atmosphere feedbacks and of difference in model internal structures. In Asia, it is *likely* that permafrost degradation during the 21st century will spread from the southern and low-altitude margins, advancing northwards and upwards as numerous models predict, but rates of change vary greatly between different model projections (Cheng and Wu, 2007; Riseborough *et al*., 2008; Romanovsky *et al*., 2008, with supplement; Anisimov, 2009; Eliseev *et al*., 2009; Nadyozhina *et al*., 2010; Schaefer *et al*., 2011; Wei *et al*., 2011). The spatially distributed permafrost model (Sazonova and Romanovsky, 2003) has been applied to the entire permafrost domain of Northern Eurasia, Central Asia and the QTP (Romanovsky *et al*., 2008, with supplement). If air temperatures continues to increase in accordance with the MIT 2D climate model output for the

21st century (Sokolov and Stone 1998), that is 2.2°C warming by 2031-50 and 4.7°C by 2080-2099 compared with 1981-2000 (Romanovsky *et al.*, 2008, with supplement), models show that permafrost that is presently discontinuous with temperatures between 0 and -2.5° C will cross the threshold by the end of 21st century and will be thawing actively. The most intense permafrost degradation in Russia is projected for Northwest Siberia. According to this model, the Late Holocene permafrost will be actively thawing everywhere except for the south of East Siberia and the Far East of Russia by the middle of 21st century. Almost all Late Holocene permafrost will be thawing, and some Late Pleistocene permafrost will begin to thaw in Siberia by the end of 21st century (Romanovsky *et al.*, 2008, with supplement). Near-surface permafrost is expected to remain only in Central and Eastern Siberia and in part of Tibet in the late 21st century. Depths of seasonal thaw are projected to exceed 1 m (2 m) in the late 21th century under the SRES B1 (A1B or A2) scenario in these regions (Eliseev *et al.*, 2009).

On the Qinghai-Tibet Plateau (QTP) and in northeastern China, substantial retreat of permafrost is expected during the 21st century due to the combined influence of climatic warming and increasing anthropogenic activities. No significant change will take place in permafrost conditions on the QTP over the next 20 to 50 years, but more than half of the permafrost in the southern and eastern parts of the plateau may become relict and/or even disappear by 2100 according to modeling results (Cheng and Wu, 2007). The result of permafrost degradation can dry the ground surface, and desertification may become an important environmental issue for the QTP (Cheng and Wu, 2007). In northeastern China, the southern limit of permafrost is expected to shift northwards, the total permafrost area to shrink, and the area of unstable permafrost to expand, with adverse consequences for associated wetlands and forests (Sun *et al.*, 2011; Wei *et al.*, 2011).

Inland Waters. Climate change impacts on inland waters will continue to interact over most of Asia with a wide range of other human impacts, including dam construction, pollution, and catchment land-use changes (see also Chapter 3, this volume). Increases in water temperature will be the most pervasive impact of climate change on both living organisms and a wide range of temperature-dependent ecological, chemical, and physical processes (Hamilton, 2010; Dudgeon, 2011, 2012). Coldwater fish will be threatened as rising water temperatures make much of their current habitat unsuitable (Yu *et al.*, 2013). The other major impact of climate change is expected to be on flow regimes in running waters and consequently on riverine habitats and species that are sensitive to flow extremes (droughts and floods) [see Box CC-RF: Freshwater ecosystems and altered river flows]. However, in the Mekong River, planned hydropower reservoirs are expected to have a larger impact on flow regimes than climate change (Lauri *et al.*, 2012). Regionally threatened natural habitats that depend on seasonal inundation, including floodplain grasslands and freshwater swamp forests, will be particularly vulnerable (Maxwell, 2009; Bezuijen, 2011). In Cambodia, the unique and hugely productive Tonle Sap Lake floodplain depends on an annual flood pulse from the Mekong River (Lamberts and Koponen, 2008; Arias *et al.*, 2012). Changes in river flow, in turn, have a direct impact on the freshwater to saltwater gradient where the river meets the sea, with reduced dry season flows combining with sea-level rise to increase saltwater intrusion in deltas (Hamilton, 2010; Dudgeon, 2012), although non-climatic human impacts will probably continue to dominate in most Asian estuaries (Syvitski *et al.*, 2009). Lakes will also be affected by climate change, but in most of Asia it is very difficult to disentangle the impacts of water pollution, hydro-engineering and climate change (Battarbee *et al.*, 2012). The ecology of China's largest freshwater body, Lake Poyang, is sensitive to the hydrological regime, which is potentially influenced by both engineering projects and climate change (Ye *et al.*, 2011; Zhang *et al.*, 2012). The unique ecosystem of Lake Baikal is expected to be impacted most by changes in ice duration and transparency, followed by water temperature and wind mixing (Moore *et al.*, 2009). Recent long-term trends towards earlier ice break-up, later freeze-up, and decreasing duration and thickness of ice cover, in close correspondence with rising air temperatures, are expected to continue in Arctic lakes and rivers, with unknown implications for freshwater and riparian ecosystems (Prowse *et al.*, 2011).

Thresholds and irreversible changes. Specific thresholds for terrestrial and inland water systems have not yet been identified. Studies of future climate change impacts on terrestrial ecosystems in China under the SRES B2 scenario suggest that moderate to severe impacts will increase significantly when temperatures increase by more than 2°C, but do not suggest a sharp threshold (Wu *et al.*, 2010). Species extinctions are the most likely irreversible change, with species that are unable to track climate change as a resulted of limited dispersal ability, habitat fragmentation, or non-climatic constraints, such as specialized soil requirements, most vulnerable (Heller and Zavaleta, 2009).

24.4.2.4. Vulnerabilities to Key Drivers

Changes in temperature are the most robust predictions and the most pervasive climate impact. Adverse impacts from rising temperature are *likely* in the wetter areas of north Asia and at high altitudes, with permafrost melting impacting ecosystems across large areas (Cheng and Wu, 2007; Tchebakova *et al*., 2011), but the impacts of higher temperatures in the tropical and subtropical lowlands are still unclear (Corlett, 2011). The biodiversity of isolated tropical, subtropical, and warm-temperate mountains may be most vulnerable to warming, because many species already have small geographical ranges that will shrink further in a warming climate (Liu *et al*., 2010; Chou *et al*., 2011; La Sorte and Jetz, 2011; Noroozi *et al*., 2011; Peh *et al*., 2011; Jump *et al*., 2012; Tanaka *et al*., 2012a). Many freshwater habitats are similarly isolated and their restricted-range species may be equally vulnerable (Dudgeon, 2012). Freshwater systems are also potentially vulnerable to increases in the frequency and intensity of extreme rainfall events (droughts or floods), even if average conditions are unchanged (Hamilton, 2010).

For much of Asia, increases in aridity, as a result of declining rainfall and/or rising temperatures, are the key concern. Because aridity is projected to increase in the northern Mongolian forest belt during the 21st century (Sato *et al*., 2007), the larch covered area will *likely* be reduced (Dulamsuren *et al*., 2010a). This will have far-reaching consequences for Mongolia's biodiversity and capacity to store water and carbon. It is likely it will also have significant socioeconomic consequences because the economy depends on the sustainable exploitation of natural resources. Even where mean rainfall remains adequate, any increase in drought frequency and/or severity will increase vulnerability to human-caused fires. The frequency and scale of both natural and manmade fires have recently increased in the tundra and taiga-tundra zones, as a result of warming, especially summer droughts (Kumpula *et al*., 2011; Nuttall 2005; Walker *et al*., 2011). If droughts intensify in the tropical lowlands of SE Asia, then the synergies between warmth, drought, logging, forest fragmentation and fire (Daniau *et al*., 2012), which may be further acerbated by feedbacks between deforestation, smoke aerosols and reduced regional rainfall (Aragão, 2012; Tosca *et al*., 2012), could greatly increase the vulnerability of fragmented forest landscapes to both fire and climate change.

24.4.2.5. Adaptation Options

The capacity of natural ecosystems to adapt of their own accord is currently poorly understood (WGII AR5 FOD Ch. 4), but some of the 'impacts' reported in this chapter, such as phenological changes, could be considered adaptive if they help the species to survive and flourish. Suggested general strategies for maximizing the adaptive capacity of ecosystems include: reducing non-climate impacts, monitoring climate impacts, maximizing landscape connectivity, and making protected area networks robust to future climate scenarios (Hannah, 2010; Shoo *et al*., 2011; Klorvuttimontara *et al*., 2011; Murthy *et al*., 2011; Mandych *et al*., 2012). In northeastern China, where climate change is expected to increase the risk of damaging forest fires, strengthening early warning and monitoring systems, paying attention to post-fire recovery, and the use of prescribed burning to reduce fuel loads are among the suggested strategies for adaptation (Tian *et al*., 2011). For Papua New Guinea, three general strategies have been suggested for adapting biodiversity conservation to climate change: conserving habitats across the full range of physical settings, including combinations of elevation and geology; protecting 'climatic refugia', where climate change is expected to be less than the regional mean; and increasing landscape connectivity (Game *et al*., 2011). A trial application of a formal process for adaptation to protect biodiversity in Vietnam used the 13 terrestrial ecoregions as basic planning units, for each of which social, economic and ecological trends were assessed, climate change scenarios identified, and key policy responses and actions developed (Booth *et al*., 2013). More generally, there is increasing recognition of the need to incorporate climate change adaptation into all forest conservation and development programs (e.g. in India; Chaturvedi *et al*., 2011; Murthy *et al*., 2011). There is a lack of scientifically well-founded recommendations and programs aimed at development of adaptation plans for the forest-tundra ecotone in North Asia at the state level (Anisimov *et al*., 2010). Comprehensive monitoring, assessments and projections that can anticipate numerous development scenarios are needed to elaborate a plan for adaptation to the cumulative effects of resource development, climate change, and demographic changes that are occurring (Walker *et al*., 2011). Similar problems are widespread in other parts of Asia, although awareness of the need for adaptation plans is increasing.

At the species level, distribution models are increasingly used to forecast the potential future distributions of species in the face of climate change, identifying areas where the species is most likely to persist and where it is most threatened, as well as potential new habitats (e.g., Higa *et al.*, 2013; Yu *et al.*, 2013). Restoration of ecological habitats within and between protected areas may help facilitate the movement of species across climatic gradients in response to climate change (Klorvuttimontara *et al.*, 2011; Hughes *et al.*, 2012). Key seed dispersal agents may need to be protected because of their potential role in long-distance plant movements in fragmented landscapes (Corlett, 2009). Assisted migration (or 'managed translocation') of genotypes and species is an increasingly common suggestion for plants and animals where adjustments to climate change are constrained by natural rates of movement, although the risks and benefits in each case need to be considered carefully (e.g. Liu *et al.*, 2010; Olden *et al.*, 2010; Tchebakova *et al.*, 2011; Ogawa-Onishi *et al.*, 2011; Dudgeon, 2012; Ishizuka and Goto, 2012). *Ex situ* conservation can provide back-up for some of the populations and species that are most at risk from climate change (Chen *et al.*, 2009).

24.4.3. Coastal Systems and Low-Lying Areas

24.4.3.1. Sub-Regional Diversity

Asia's long coastline includes the full global range of muddy, sandy, and rocky shore types, as well as extensive estuarine systems. Asia's tropical and subtropical coasts support an estimated 45% of the world's total mangrove forest and include the most mangrove-rich country (Indonesia) and the largest single tract of mangrove forest (the Sundarbans of Bangladesh and India) (Giri *et al.*, 2011). Low-lying areas near the coast of equatorial SE Asia support most of world's peat swamp forests (see also 24.8.2), which are a massive store of carbon, as well as extensive areas of other forested swamp types. Intertidal salt marshes are widespread along temperate and arctic coasts, while a variety of non-forested wetlands occur inland, including freshwater marshes and peat bogs. Asia also supports around 40% of the world's coral reef area (Spalding *et al.*, 2001; Burke *et al.*, 2011), mostly in SE Asia, with the most extensive reefs and the world's most diverse reef communities in the 'coral triangle' (in Indonesia, Malaysia, the Philippines, and Papua New Guinea; see also Chapter 30, this volume, Box 30-3). Seagrass beds are also widespread, although less well studied, and Asia supports the majority of the world's seagrass species (Green and Short, 2003). Six of the seven living species of sea turtle are found in the region and five species nest on Asian beaches (Spotila, 2004). Kelp forests and other seaweed beds are important on temperate coasts (Bolton, 2010; Nagai *et al.*, 2011). Permafrost and sea-ice influence coastal processes in the far north (Are *et al.*, 2008). The sea-ice itself supports a specialized community of mammals, including the polar bear, walrus, several species of seals, and the beluga and bowhead whales, as well as birds, fish and other species (Kovacs *et al.*, 2011; Chapter 28, Sections 28.2.3.3. and 28.2.3.4.).

24.4.3.2. Observed Impacts

Most of Asia's non-Arctic coastal ecosystems are under such severe pressure from non-climate human impacts that climate impacts are hard to detect. For example, observations of impacts from rising sea levels in Asia have reflected coastal subsidence rather than the impact of climate change, since most major deltas in Asia are now sinking (as a result of groundwater withdrawal, floodplain engineering, and trapping of sediments by upstream dams) at rates many times faster than the global sea-level is rising (Syvitski *et al.*, 2009). Widespread impacts can be attributed with *high confidence* to climate change, however, for coral reefs, where the temporal and spatial patterns of large-scale bleaching events generally correlate well with higher than normal sea surface temperatures (Hoegh-Guldberg, 2011; Krishnan *et al.*, 2011; Coles and Riegl, 2013; Lough, 2012). Increases in coastal water temperatures are also one of the most plausible explanations for widespread declines in beds of large seaweeds in temperate Japan: the Isoyake phenomenon (Nagai *et al.*, 2011). Warming coastal waters have also been implicated in the northwards expansion in Japanese waters of tropical and subtropical macroalgae and toxic phytoplankton (Nagai *et al.*, 2011), fish (Tian *et al.*, 2012), and tropical corals, including key reef-forming species (Yamano *et al.*, 2011), over recent decades. The decline of large temperate seaweeds and expansion of tropical species in southwest Japan

has been linked to rising sea surface temperatures (Tanaka *et al.*, 2012b), and the changes in the seaweed community have, in turn, impacted fish communities (Terazono *et al.*, 2012).

The impact of warming is also evident on sparsely populated Arctic coastlines, where erosion appears to be accelerating. In Arctic Asia, changes in permafrost and in storm wave energy caused by sea-level rise and sea-ice retreat have resulted in increased coastal retreat, in spite of the fact that most of the year coasts are protected by continuous ice cover (Are *et al.*, 2008; Razumov, 2010; Handmer *et al.*, 2012). In the central part of the Laptev Sea, coastal retreat has accelerated by 1.5-2 times in recent decades (Anisimov *et al.*, 2010). Average erosion rates of Asian Arctic coastlines range from 0.27 m/year (Chukchi Sea) to 0.87 m/year (East Siberian Sea). A number of segments in the Laptev Sea and in the East Siberian Sea are characterized by rates greater than 3 m/year (Lantuit *et al.*, 2012). The decline in the extent of arctic sea-ice documented in AR4 has continued, but the impacts on ice-dependent species and ecosystems in Arctic Asia are so far unclear [WG1 AR5 SOD Ch. 4; WG2 AR5 FOD Ch. 28].

24.4.3.3. Projected Impacts

It is *likely* that there will be an overall increase in marine biodiversity at temperate latitudes as temperature constraints on the distributions of warm-water taxa are relaxed, but biodiversity in tropical regions may fall if, as some evidence suggests, tropical marine species are already near their thermal maxima (Cheung *et al.*, 2009, 2010). An experimental study in Singapore found that the activity and survival of marine invertebrates in seven phyla was reduced by water temperatures only 2-3ºC above present (Nguyen *et al.*, 2011). In contrast, two shallow-water marine fish species from Indonesia showed exceptional tolerance of high temperatures (Eme *et al.*, 2011). Individual fish species are projected to shift their ranges northwards in response to rising sea surface temperatures (Tseng *et al.*, 2011; Okunishi *et al.*, 2012; Tian *et al.*, 2012). A combination of projected shifts in species distributions and expected changes in total primary production may lead to a regional redistribution of fisheries potential, with large declines in the tropics and large increases in high-latitude regions (Cheung *et al.*, 2010; WG2 AR5 FOD Ch. 6). A more recent study using a very different modeling approach produced broadly similar projections (Blanchard *et al.*, 2012). Another modeling study suggested that the combined effects of changes in distribution, abundance and physiology will reduce the body size of marine fishes, particularly in the tropics and intermediate latitudes (Cheung *et al.,* 2012). Projected impacts are greatest for coral reefs, where a continuation of current trends in sea-surface temperatures and ocean acidification suggests that existing coral-dominated reefs will largely disappear by mid-century (Vivekanandan *et al.*, 2009; Hoegh-Guldberg, 2011; Burke *et al.*, 2011). In the seas around Japan, warming would permit the expansion of coral habitats to the north, but ocean acidification is expected to limit this, with coral habitats sandwiched between excessive warming to the south and acidification in the north (Yara *et al.*, 2012). However, the capacity of coral communities to adjust by changes in species composition, or by the acclimation and/or adaptation of coral species, is not well understood (Ateweberhan and McClanahan, 2010; Fabricius *et al.*, 2011; Guest *et al.*, 2012; Howells *et al.*, 2012). The impacts of ocean acidification on other organisms are also currently poorly understood (Hendriks *et al.*, 2010; WGII AR5 FOD Ch. 6).

The uncertainties in future sea-level rises are still large (WG1 AR5 SOD Ch. 13). The major projected impacts include coastal flooding, increased erosion, and saltwater intrusion into surface and groundwater. In the absence of other impacts, coral reefs may grow fast enough to keep up with rising sea-levels (Brown *et al.*, 2011), but mangroves, salt marshes, and seagrass beds will decline unless they can move landwards or they receive sufficient sediment to keep pace, and beaches may erode (Gilman *et al.*, 2008; Bezuijen, 2011; Forbes, 2011). Loucks *et al.* (2010) predict a 96% decline in tiger habitat in Bangladesh's Sunderbans mangroves with a 28 cm sea-level rise if sedimentation does not increase surface elevations. Coastal freshwater swamps and marshes will be vulnerable to saltwater intrusion with rising sea-levels. However, in most river deltas, the global sea-level rise will continue to be outpaced by local subsidence for non-climatic reasons (Syvitski *et al.*, 2009).

Cyclones affect most of the Asian coastline, except in the far north, west, and 10º either side of the equator. Natural coastlines are resilient, but large cyclones can have a devastating impact on isolated ecosystem fragments. However, current trends in cyclone frequency and intensity are unclear (Seneviratne *et al.*, 2012; WG1 AR5 SOD Ch. 14; see Box CC-TC). A combination of cyclone intensification and sea-level rise could potentially result in a large increase in coastal flooding (Knutson *et al.*, 2010). Cyclones can also have a large impact on the productivity of coastal

waters through increased nutrient run-off and water circulation (Qiu *et al*., 2010). In addition to any changes in cyclone activity, sea turtles nesting beaches may be impacted by rising temperatures and sea-levels, but the capacity of turtle populations to adapt is not well understood (WGII AR5 FOD Ch. 6).

In the Asian Arctic it is *likely* that rates of coastal erosion will increase as a result of interactions between rising sea-levels and projected changes in permafrost and the length of the ice-free season (Pavlidis *et al*., 2007; Lantuit *et al*., 2012). The most sensitive region to potential increases in permafrost and sea surface temperatures on the Asian Arctic coast is the Kara Sea region (Lantuit *et al*., 2012). Sea level rise may have different influences on coastal processes depending on the sediment budget equilibrium, playing a minor role if there is a strong imbalance in the sediment budget, but appearing to be the main factor if the sediment budget is balanced (Leont'yev, 2008). The most prominent changes in the dynamics and morphology of the coastal zone are expected where the coasts are composed of loose permafrost rocks and are therefore subject to intensive thermal abrasion. Assuming that sea level will rise by 0.5 m over the next century, modeling studies predict that the rate of recession due to thermal erosion will increase 1.5- to 2.6-fold for the coasts of Laptev Sea, East Siberian sea and of West Yamal in the Kara Sea compared to the rate observed in first years of the XXI century. This rate will vary across the Asian Arctic coast from 3 to 9 m/year (Pavlidis *et al*., 2007).

24.4.3.4. Vulnerabilities to Key Drivers

As discussed in the previous section, offshore marine systems appear to be most vulnerable to rising water temperatures, plus the impacts of ocean acidification, particularly for calcifying organisms such as corals. Sea-level rise will be the key issue for many coastal areas, particularly if it is combined with changes in cyclone frequency or intensity, or in Arctic Asia, with a lengthening open-water season. The expected continuing decline in the extent of sea-ice in the arctic may threaten the survival of some ice-associated mammals and other organisms (WG1 AR5 SOD Ch. 4; WGII AR5 FOD Ch. 6), with the expansion of human activities in previously inaccessible areas an additional problem (Kovacs *et al*., 2011).

24.4.3.5. Adaptation Options

The connectivity of marine habitats and the relatively high dispersal abilities of many marine organisms should maximize the capacity for autonomous (spontaneous) adaptation in natural and semi-natural coastal systems and is expected to keep the extinction rate below that projected for terrestrial habitats (Cheung *et al*., 2009). Where natural connectivity is insufficient, as between the heat-tolerant coral populations of the Arabian/Persian Gulf and the Southeast Asian reefs threatened by rising temperatures, than 'assisted colonization' (by moving adult fragments or larval stages) is a possible option, although only as a last resort (Coles and Riegl, 2013). Creating marine protected areas in locations where sea surface temperatures are projected to change least may increase their future resilience (Levy and Ban, 2013). 'Hard' coastal defenses, such as dykes, levees and sea walls, may protect settlements, but at the cost of preventing adjustments by mangroves, salt marshes and seagrass beds to rising sea-levels. The acquisition of landward buffer zones that provide an opportunity for future inland migration could mitigate this problem (Erwin, 2009), but is rarely practical. Large sections of Asia's coastline are already highly degraded and there are many opportunities for restoration of coastal systems (Crooks *et al*., 2011).

24.4.4. Food Production Systems and Food Security

It is projected that climate change will affect food security in the middle of the 21st century, with the largest numbers of food-insecure people located in South Asia (Porter *et al*., 2014 Chapter 7).

24.4.4.1. Sub-Regional Diversity

AR4 Section 10.4.1.1 pointed out that there will be regional differences in the impacts of climate change on food production. Research since then has validated this divergence and new data are available especially for West and Central Asia (see Tables 24-5 and 24-6). These differences will be apparent in the discussion below. In addition, new studies have supplied more detailed data about the impacts on crop production. In AR4 Section 10.4.1, climate change was projected to lead mainly to reductions in yield. New research shows there will also be gains for specific regions and crops in given areas. Thus, the current assessment encompasses an enormous variability depending on the regions and the crops grown.

24.4.4.2. Observed Impacts

While there is consensus that climate change will affect food production systems and food security, the precise nature and timing of these impacts, as well as their implications for human livelihoods, are still uncertain (Hertel *et al*., 2010). There are limited data in Asia for observed impacts of climate change on food production systems. In Jordan, it was reported that in 1999, the total production and average yield for wheat and barley were the lowest among the years 1996 to 2006. This could be explained by the low rainfall during that year, which was 30% of the average (high confidence in detection, low confidence in attribution). These results suggest that both crops are vulnerable to climatic variations (Al-Bakri *et al*., 2010). In China, rice yield responses to recent climate change at experimental stations were assessed for the period 1981–2005 (Zhang *et al*. 2010). The study concluded that there are variable climate to yield relationships, considering inter-annual variations at a regional scale. In some places, yield fluctuations were positively correlated with temperature when they were also positively related with solar radiation. However, in other places, lower yield with higher temperature was accompanied by a positive correlation between yield and rainfall (high confidence in detection, high confidence in attribution). Crop responses to high temperatures can be accurately estimated from experiments in controlled environments; however, such experiments are generally not feasible given the large number of crops. Instead, the general effects of climate change on a wide variety of crops can be estimated by collecting and analyzing data from various agricultural systems on yield changes due to recent regional temperature increases. In Japan, where mean air temperature has risen at 1ºC per the past 100 years, information on changes in agricultural production (cereal, soybean, fruit tree, vegetable and livestock), were collected by surveys of the public institutes of agricultural research in 47 prefectures. Recent effects of warming were analyzed by comparing those data to literature on relations between crop growth and temperature (Sugiura, et al, 2012). Effects of recent warming, include phenological changes in many crops, increases in fruit coloring disorders and incidences of chalky rice kernels, reductions in yields of wheat, barley, vegetables, flowers, milk and eggs, and alterations in the type of disease and pest.

Another possible approach to assessing observed impacts of climate change is to combine local knowledge with scientific assessments. For example, the nomadic herders of Mongolia demonstrated a detailed understanding of weather and climate, including an account of climatic change that integrates multiple indicators (Marin, 2010). However, their evidence of change is only partly supported (or even contradicted) by meteorological records, larger scale predictions and general circulation models.

24.4.4.3. Projected Impacts

Production. AR4 Section 10.4.1.1 mainly dealt with cereal crops (rice, wheat corn). Since then, impacts of climate change have been modeled for additional cereal crops and sub-regions. In semi-arid and arid regions of Western Asia, a review paper (Ratnakumar *et al*., 2011) has shown that rainfed agriculture is sensitive to climate change both positively and negatively. A rise in CO_2 concentration may benefit the semi-arid crops by increasing crop water-use efficiency and net photosynthesis leading to greater biomass, yield and harvest index. C_3 plants responded with a higher average increment in biomass production than C_4 plants. For example, wheat yield increased by 10-20% with elevated CO_2 (350 ppm to 700 ppm). In Yarmouk basin, Jordan, simulation with DSSAT showed that wheat and barley yields will decline by 10-20% and 4-8% respectively with a 10-20% reduction in rainfall (Al-Bakri *et al*., 2010). Conversely, with an increase in rainfall of 10–20% the expected yield increased by 3–5% for barley and 9–

18% for wheat. However increased air temperatures had mixed results. Increasing temperature by 1, 2, 3 and 4°C resulted in deviations from expected yield of -14%, -28%, -38% and -46% for barley and -17%, +4%, +43% and +113% for wheat.

In the Swat and Chitral districts of Pakistan (mountainous areas with average altitudes of 960 and 1500 m above sea level, respectively), there were mixed results as well (Hussain and Mudasser, 2007). Projected temperature increases of 1.5 and 3 °C would lead to wheat yield declines (by 7% and 24% respectively) in Swat district but increases (by 14% and 23%) in Chitral district. If precipitation increases by 5–15% during the growing season, the study showed a negligible impact on wheat yield. Also in Pakistan, modeling studies show that wheat yields are expected to decline by 6-8 % under B2 and A2 scenarios by the 2080s, whereas rice yields decline by 16-19% under the same conditions (Iqbal et.al. 2009). In India, climate change impacts on sorghum were analyzed using the Info Crop-SORGHUM simulation model (Srivastava *et al*., 2010). A changing climate was projected to reduce monsoon sorghum grain yield by 2-14% by 2020, with worsening yields by 2050 and 2080. In addition, climate change was projected to reduce winter crop yields up to 7% by 2020, up to 11% by 2050 and up to 32% by 2080. In the Indo-Gangetic Plains, a higher reduction in wheat yields is projected (see below), unless appropriate cultivars and crop management practices are adopted (Ortiz *et al*., 2008).

In China, modeling studies of the impacts of climate change on crop productivity have had mixed results. Rice is the most important staple food in Asia. Studies show that climate change will alter productivity in China but not always negatively. With rising temperatures, the process of rice development accelerates and reduces the duration for growth. In one study, using the SRES B2 scenario without a CO_2 fertilization effect, the average simulated yield of irrigated rice along the Yangtze River decreased by 14.8%, and the yield of rain-fed rice decreased by 15.2% by 2021–2050 (Shen *et al*., 2011). With CO_2 fertilization factored in, the simulated yield of irrigated rice decreased by 3.3% and the yield of rain-fed rice decreased by 4.1% on average. Tao *et al*. (2008) reported similar findings using all 20 combinations of four scenarios (A1F1, A2, B2, B1) and five GCMs (HadCM3, PCM, CGCM2, CSIRO2, ECHAM4). Without CO_2 fertilization effects, the growing period would be shorter and yield would decrease. The median values of yield decrease ranged from 6.1% to 18.6%, 13.5% to 31.9%, and 23.6% to 40.2% for air temperature increases of 1, 2, and 3 °C, respectively. However, if CO_2 fertilization effects were included, the median values of yield changes ranged from -10.1% to 3.3%, -16.1% to 2.5%, and -19.3% to 0.18% for the same temperature increases. Other studies have also shown that higher temperature would seriously lower rice yields due to shorter crop duration (Xiong *et al*., 2010; Yao *et al*., 2007).

In contrast, Zhang *et al*. (2010) reported that rice yield responses to temperature were broadly positive, which means that yields were not limited by an increase in minimum, maximum or mean temperatures. The authors hypothesize that solar radiation level is the major climatic driver for yield fluctuations at these Chinese experimental stations, and the positive yield correlation to temperature can be explained by the correlations between radiation and temperature, which were positive at most studied stations. Thus, the positive effect of radiation on rice yield overwhelmed temperature's negative effect.

Wassman *et al*. (2009a, 2009b) provide the most comprehensive review of climate change impacts and adaptation for rice in the region. A key conclusion of the report is that, in terms of risks of increasing heat stress, there are parts of Asia where current temperatures are already approaching critical levels during the susceptible stages of the rice plant. These include: Pakistan/North India (October), South India (April, August), East India/Bangladesh (March-June), Myanmar/Thailand/Laos/Cambodia (March-June), Vietnam (April/August), Philippines (April/June), Indonesia (August) and China (July/August).

There have also been simulation studies for other crops in China. In the Huang-Huai-Hai Plain, China's most productive wheat growing region, modeling indicated that winter wheat yields would increase on average by 0.2 Mg ha-1 in 2015-2045 and by 0.8 Mg ha-1 in 2070-2099, due to warmer nighttime temperatures and higher precipitation, under A2 and B2 scenarios using the HadCM3 model (Thomson *et al*., 2006). Yields were positively influenced by increasing precipitation projected under the climate change scenarios, with the highest average yields in the 2085 time period when the precipitation increase was greatest. Liu *et al*. (2010c) worked on a wheat-maize cropping system in the same plain. Generally, climate change (2 and 5ºC increase in temperature; precipitation increasing and decreasing by 15 and 30%; atmospheric CO_2 enrichment to 500 and 700 ppmv) would result in a mean relative yield

change (RYC in %) of −10.33% with a standard deviation of 20.27%, and the lowest and highest RYC values of −46% and +49%. However when CO_2 fertilization effects were included, a positive change in RYC was obtained. In addition, increasing precipitation mitigates the negative impact of increasing temperatures on yield. On average, without CO_2 enrichment, the mean RYC for irrigated land is less negative (−18.5±12.6%) than for rainfed land (−21.5±14.2%), but with CO_2 enrichment there was no significant difference between irrigated and rainfed yields. These results show that CO_2 enrichment reduces the impact of irrigation.

The potential climate change impacts on the productivity of five major crops (canola, corn, potato, rice, and winter wheat) in eastern China have also been investigated using the RegCM3 regional climate model under the A2 scenario (Chavas *et al*., 2009). Aggregate potential productivity (i.e. if the crop is grown everywhere) with CO_2 fertilization increased 6.5% for rice, 8.3% for canola, 18.6% for corn, 22.9% for potato, and 24.9% for winter wheat, although with significant spatial variability for each crop. However, without the enhanced CO_2-fertilization effect, potential productivity declined in all cases, by 2.5-12%.

Extreme weather events are expected to negatively affect agricultural crop production (IPCC, 2012; Handner *et al*., 2012). For example, extreme temperatures could lower yields of rice (Tian *et al*., 2010; Mohammed and Tarpley, 2009). With higher precipitation, flooding could also lead to lower crop production [SREX Ch. 4]. For example, cyclone Sidr which hit Bangladesh in 2007 caused more than 3,000 deaths and the damage to agriculture was estimated to be in excess of US$3 billion (Paul, 2009; Islam *et al*., 2011; Hasegawa, 2008). Another example is from the Philippines which lies in the typhoon belt with an average of 20 tropical cyclones per year in addition to other extreme weather events (Yumul *et al*., 2011; Yumul *et al*., 2010). One study showed that relative losses per crop as part of the annual farm household income due to one tropical cyclone for yellow corn, banana, and rice were 64%, 24%, and 27%, respectively (Huigen and Jens, 2006).

Farming systems and crop areas. Since AR4 [WG2 AR4 10.4.1.2], more information is available on the impacts of climate change on farming systems and cropping areas in more countries in Asia and especially in Central Asia. In general, recent studies validate the northward shifts of crop production with current croplands under threat from the impacts of climate change as mentioned in AR4.

Climate change threatens the food security of West Asia where most of drylands are comprised of rangelands (Thomas, 2008). The region has the world's lowest rate of renewable water resources per capita and is already the major grain importing region of the world. Climate change will exacerbate existing threats to food production and security such as high population growth rates, water scarcity, and land degradation.

In Central Asia, changes in temperature and precipitation regimes could to lead to changes in the area suitable for rain-fed production of cereals and other food crops, changing sustainable stocking rates, and modifications of crop irrigation requirements (Lioubimtseva and Henebry, 2009). The region is expected to become warmer during the coming decades and increasingly arid, especially in the western parts of Turkmenistan, Uzbekistan, and Kazakhstan. The impacts on food production will vary by country. Some parts of the region could be winners (cereal production in northern and eastern Kazakhstan could benefit from the longer growing season, warmer winters and slight increase in winter precipitation), while others could be losers (particularly western Turkmenistan and Uzbekistan, where frequent droughts could negatively affect cotton production, increase already extremely high water demands for irrigation, and exacerbate the already existing water crisis and human-induced desertification). In addition Central Asia and the Caucasus is the second most vulnerable region of the world to crop loss by pollinator loss (Christmann and Aw-Hassanb, 2011). Honey bees (*Apis mellifera*) are important in crop pollination, but bees are highly sensitive to change of temperatures and can provide service only on sunny, warm, dry and not too windy days. The tolerance of local honey bees to climate change needs further elucidation.

In India, the Indo-Gangetic Plains are under threat of a significant reduction in wheat yields (Ortiz *et al*., 2008). This area produces 90 million tons of wheat grain annually (about 14-15% of global production). Climate projections based on a doubling of CO_2 using a CCM3 model downscaled to a 30 arc-second resolution as part of the Worldclim data set showed that there will be a 51% decrease in the most favorable and high yielding area due to heat stress. About 200 million people (using the current population) whose food intake relies on crop harvests would experience adverse impacts.

In Sri Lanka, a number of studies reviewed by Eriyagama *et al*. (2010) showed varying results. Tea cultivation at low and mid-elevations is more vulnerable to the adverse impacts of climate change than at high elevations. Projected coconut production after 2040 in all climate scenarios will not be sufficient to meet local consumption. The total impact on agriculture (rice, tea, rubber and coconut) production ranges from a decrease of US$96.4 million (-20%) to an increase of US$342 million (+72%) depending on the climate scenarios.

In eastern China, a study showed corn and winter wheat production would benefit significantly from climate change in the North China Plain (Chavas *et al*., 2009). Rice would remain dominant in the southeast but emerges in the northeast, potato and corn yields would become viable in the northwest, and potato yields suffer in the southwest. The study defined vulnerable and emergent regions under future climate conditions as those having a greater than 10% decrease or increase in productivity, respectively.

Rice growing areas are also expected to shift with climate change throughout the region. In Japan, increasing water temperature (1.6–2.0 °C) could lead to a northward shift of the isochrones of safe transplanting dates for rice seedlings (Ohta and Kimura, 2007). As a result, rice cultivation period will be prolonged by approximately 25–30 days. This will allow greater flexibility in the cropping season than at present, resulting in a reduction in the frequency of cool-summer damage in the northern districts. Iizumi *et al*., (2007) assesses the potential reduction of cool-summer damage in northern Japan and supports this conclusion. In addition, ensemble-based probabilistic assessments for rice-yield in Japan are available from Iizumi *et al*., (2011) and Okada *et al*., (2011).The latter paper assesses the impacts on both rice yield and eating quality.

In Indonesia, a marked increase in the probability of a 30-day delay in monsoon onset in 2050 is projected, as a result of changes in the mean climate, from 9-18% today (depending on the region) to 30-40% at the upper tail of the distribution (Naylor *et al*. 2007). In addition, there would be an increase in precipitation later in the crop year (April-June) of around 10% but a substantial decrease (up to 75% at the tail) in precipitation later in the dry season (July-September). However, the increase in April-June rainfall would not compensate for reduced rainfall later in the crop year, particularly if water storage for agriculture was inadequate. Secondly, the extraordinarily dry conditions in July-September could preclude the planting of rice and all other crops without irrigation during these months by 2050. In Sri Lanka, studies on future rice production have had mixed results. A study reviewed by Eriyagama *et al*., 2010 showed that a 0.1-0.5°C increase in temperature could depress rice yield by approximately 1-5%. However, another study suggested that rice yields will respond positively (increases of 24 and 39% in the two seasons) to elevated CO_2 even at higher growing temperatures (>30°C) in subhumid tropical environments. The real threat to rice cultivation might be changes in the amount of precipitation and its temporal distribution. Climate change is expected to affect water supply for rice cultivation in Sri Lanka (De Silva *et al*., 2007). During the wet season, impacts on irrigated rice production are projected to be positive in the extreme south of the country, confirming results of a previous study. However, the impacts will be negative across most of Sri Lanka. During the wet season, average rainfall would decline by 17% (A2) and 9% (B2), with rains ending earlier. Consequently, the average paddy irrigation water requirement would increase by 23% (A2) and 13% (B2).

Similarly in the whole of China, Xiong *et al*. (2010) reported there would be insufficient water for agriculture in the 2020s and 2040s, due to increases in water demand for non-agricultural uses, using the HadAM3H GCM and the PRECIS regional model, especially under the A2 scenario (see also 24.4.1.3). The proportion of water demanded by rice (which consumes 79% of the total baseline potential water demand of three grain crops) is projected to increase, because of significant increases in the projected water demand by rice under A2 (+62% for the 2020s above the baseline, and +58% for the 2040s), and moderate increases under B2 (5% and 2% for the 2020s, and the 2040s, respectively). However, due to increases in demand in other sectors (domestic, environmental and industrial) captured in the socio-economic scenarios (SES), the water available for agriculture decreases dramatically under A2 by 5% (2020s) and 21% (2040s) and under B2 by 3% (2020s) and 16% (2040s).

High quality fruits are cultivated in a narrow temperature zone. In Japan, the current main apple producing districts have annual mean temperature of 6-14°C with mean temperature of 13-21°C from April to October. Many parts of these districts may become unfavorable for apple cultivation by the 2060s (Sugiura *et al*., 2005).

Fisheries and aquaculture. Asia dominates the global production of food from both capture fisheries and aquaculture, with China, Indonesia, India, the Philippines and Myanmar in the top ten for capture fisheries and China, India, Vietnam, Indonesia, Thailand, Bangladesh, the Philippines and Japan in the top ten for aquaculture (FAO 2010). More than half of the global marine fish catch in 2008 was in the West Pacific and Indian Ocean, and the lower Mekong River basin supports the largest freshwater capture fishery in the world. Fish production is also a vital component of regional livelihoods, with 85.5% of the world's fishers (28 m) and fish farmers (10 m) in Asia in 2008. Many more people engage in capture fisheries part-time. Fish catches in the Asian Arctic are relatively small, but are important for local cultures and regional food security (Zeller *et al*. 2011).

Inland fisheries will continue to be vulnerable to a wide range of on-going threats, including overfishing, habitat loss, water abstraction, drainage of wetlands, pollution, and dam construction, making the impacts of climate change hard to detect. Most concerns have centered on rising water temperatures and the potential impacts of climate change on flow regimes, which in turn are expected affect the reproduction of many fish species (Allison *et al*., 2009; Barange and Perry, 2009; Bezuijen, 2011; Dudgeon, 2011; see also section 24.4.2.3). Sea-level rise is expected to impact both capture fisheries and aquaculture production in river deltas (De Silva and Soto, 2009). For marine capture fisheries, Cheung et al. (2009, 2010) used a dynamic bioclimate envelope model to project the distributions of 1066 species of exploited marine fish and invertebrates for 2055, based on the SRES A1B scenario. This analysis suggests that climate change may lead to a massive redistribution of fisheries catch potential, with large increases in high-latitude regions, including Asian Russia, and large declines in the tropics, particularly Indonesia. Other studies have made generally similar predictions, with climate change impacts on marine productivity expected to be large and negative in the tropics, in part because of the vulnerability of coral reefs to both warming and ocean acidification (see also section 24.4.3.3), and large and positive in arctic and subarctic regions, because of sea-ice retreat and poleward species shifts (Doney *et al*., 2012; Sumaila *et al*., 2011; Blanchard *et al*., 2012). Predictions of a reduction in the average maximum body weight of marine fishes by 14-24% are an additional threat to fisheries (Cheung et al., 2012). Studies on the economically important yellowtail in Japanese waters have shown a northward extension in the winter distribution during the warm 1990s and project a 3º northward shift in latitude by 2050 under the A1B scenario (Tian *et al*., 2012). Similarly, the important Pacific saury is expected to shift its range polewards by < 6º (Tseng *et al*., 2011)

Future food supply and demand. AR4 Section 10.4.1.4 was largely based on global models that included Asia. There are now several quantitative studies of both the whole continent and individual countries. In general, these show that the risk of hunger, food insecurity and loss of livelihood due to climate change will be high, as discussed below.

Rice is a key staple crop in Asia and 90% or more of the world's production is from Asia. An Asia-wide study revealed that climate change scenarios (using 18 GCMs for A1B; 14 GCMs for A2 and 17 GCMs for B1) would reduce rice yield over a large portion of the continent (Masutomi *et al*., 2009). The most vulnerable regions were western Japan, eastern China, the southern part of the Indochina peninsula, and the northern part of South Asia. In these areas, a rise in temperature during the growing periods would be the main cause of the decreases in yield. The negative impacts of climate change were diminished, but not totally eliminated, by the positive effect of CO_2 fertilization. In a global study, Hertel *et al*. (2010) showed that under the low-productivity scenario (due to climate change), prices for major staples would rise 10–60% by 2030 in Asia. Poverty rates in some non-agricultural household could rise by 20–50% in parts of Asia and fall by significant proportions for agriculture households.

In Russia, climate change may also lead to "food production shortfall", which was defined as an event in which the annual potential (i.e. climate-related) production of the most important crops in an administrative region in a specific year falls below 50% of its climate-normal (1961–1990) average (Alcamo *et al*., 2007). The frequency of shortfalls in the main crop growing regions is around 2 years/decade under climate baseline conditions, but could climb to 5–6 years/decade in the 2070s (using the ECHAM and HadCM3 models and the A2 and B2 scenarios). The increasing shortfalls were attributed to severe droughts. The study estimated that the number of people living in these regions may grow to 82–139 million in the 2070s. Increasing frequency of extreme climate events will pose an increasing threat to the security of Russia's food system.

Tchebakova *et al*., (2010) analyzed the agroclimatical potential of Central Siberia in the 21st century. They concluded that climate changes to come for the years 2020 and 2080 (HadCM3 with B1 and A2 scenarios) will in general be beneficial for this territory. "From 50 to 85% of Central Siberia is predicted to be climatically suitable for agriculture by the end of the century, and only soil potential would limit crop advance and expansion to the North. Crop production could increase twofold. Future Siberian climatic resources could provide the potential for a great variety of crops to grow that previously did not exist in these lands." (Tchebakova *et al*., 2010).

Most of the studies reviewed in the previous sections predict negative impacts of climate change on crop yield and therefore presumably on food supply. Climate change may also lead to an increase in food supply in some countries. For example, climate change may provide a windfall for wheat farmers in parts of Pakistan. Warming temperatures would make it possible to grow at least two crops (wheat and maize) a year in the mountain areas (Hussain and Mudasser, 2007). It will also allow more time for land preparation for the subsequent maize crop, with beneficial effects on yield. The increased productivity of the wheat–maize cropping system is expected to improve food security, increase farm income and reduce overall poverty of the farm households in the area.

Pests and diseases. AR4 contained a generalization about the possibility of increasing pests and diseases due to climate change. Since then there have been very few studies of climate change impacts on pests and diseases which support this conclusion. For example in South Asia, warming temperatures could lead to higher incidence of spot blotch (caused by *Cochliobolus sativus*), already a serious constraint on wheat production at present. An increasing mean minimum temperature in March showed a positive relationship with spot blotch severity (Sharma *et al*., 2007). Sharma *et al*. (2010) recommended the regular monitoring of pest populations in future to determine if a threshold has been exceeded and if control measures are required. This information will also be valuable for forecasting pest populations, severity of damage, and pest outbreaks. Climate change may also modify the effectiveness of biological control (e.g. natural enemies), biopesticides, and synthetic insecticides.

24.4.4.5. Adaptation Options

Since AR4, there have been additional studies of recommended and potential adaptation strategies and practices in Asia (see Table 24-7) and there is new information for West and Central Asia. There are also many more crop-specific and country-specific adaptation options available.

[INSERT TABLE 24-7 HERE
Table 24-7: Summary of adaptation options for agriculture in Asia.]

Farmers have been adapting to climate risks for generations. Indigenous and local adaptation strategies have been documented for Southeast Asia (Peras *et al*., 2008; Lasco *et al*., 2011; Lasco *et al*., 2010) and could be used as a basis for future climate change adaptation. Social and institutional aspects of climate change adaptation have also been investigated in the Philippines. Agent-based modeling showed that smallholder farmers face a number of constraints in adapting new technologies to cope with climate risks (Acosta-Michlik and Espaldon, 2008). In general, lack of knowledge and money were the most important reasons for not adopting drought-related technical measures. In the above studies there are many non-farm related adaptation strategies, such as selling valuables, sending family workers to work overseas, and migrating to another location. Local government units can also play a catalytic role in climate change adaptation as shown by the experience of Albay province in the Philippines, which has been in the forefront of climate change adaptation activities in the country (Lasco *et al*., 2013; Lasco *et al*. 2008). The main initiatives include legislating local policies on climate change adaptation, integrating climate change adaptation and disaster risk management, and the implementation of on-the ground activities. In addition, they have become a national player in climate change adaptation in the Philippines.

24.4.5. Human Settlements, Industry, and Infrastructure

24.4.5.1. Sub-Regional Diversity

Asia, being the largest continent in the world in terms of area and population, is both diverse and complex. Sustainable development will be challenged as climate change compounds the pressures that rapid urbanization, industrialization and economic development have placed on natural, social and economic resources (IPCC, 2007b). Settlement patterns, urbanization and changes in socioeconomic conditions greatly influence trends in exposure and vulnerability to climate extremes (IPCC, 2012). Population distribution is uneven within Asia, with two subregions, East Asia and South-Central Asia, accounting for 80% of the total (UNFPA, 2010). Moreover, a few Asian countries account for 69% of the world's rural population, with India and China alone accounting for 45%, followed by Bangladesh, Indonesia and Pakistan, each with over 100 million rural inhabitants. Much of the increase projected for the world population is expected to come from 39 high-fertility countries, of which nine are located in Asia. Although population growth rates have been decreasing in almost all subregions of Asia since 2000 (UN ESCAP, 2011), growth continues to be high, particularly in countries with low human development performance, leading to large populations with limited adaptive capacity (World Bank 2012).

Notwithstanding considerable challenges in measurement (Satterthwaite 2006), around one in every five urban dwellers in Asia lives in large urban agglomerations and almost 50% of urban dwellers live in small cities (UN, 2012). However, there is wide subregional variation. For example, North and Central Asia are the most urbanized areas, with over 63% of the population living in urban areas, with the exception of Kyrgyzstan and Tajikistan, followed by East and Northeast Asia, where rapid urbanization in the last two decades has led to half the population living in cities (UN ESCAP, 2011; UN Habitat, 2010). South and Southwest Asia are the least urbanized subregions, with only a third of their populations living in urban areas. However, these regions have the highest urban population growth rates within Asia at an average of 2.4% per year during 2005-2010 (UN-ESCAP, 2011). By the middle of this century, Asia's urban population will increase by 1.4 billion and will account for over 50% of the global population, with China and India projected to account for about a third of the increase in the coming decades (UN, 2012).

Most Asian countries are witnessing significant development opportunities as well as a myriad of challenges. In 2010, seven Asian economies (China, India, Indonesia, Japan, Korea, Malaysia and Thailand) shared 78% of Asia's population and 87% of Asia's GDP (ADB, 2011). However, across all the subregions of Asia, poor people and urban slum dwellers tend to live in high-risk areas, such as unstable slopes and flood plains, and often cannot afford well-built houses. The poorest people are expected to suffer the most from climate change (UN-Habitat, 2011).

24.4.5.2. Observed Impacts

Asia has in the past suffered from many disasters related to natural hazards (IPCC, 2012). The data also reveals a strong increase in loss and damage caused by such disasters over recent years (Munich Re 2011; CRED 2012). However, the literature suggests that this increase can be attributed to climate change only with low confidence [18.4.1]. Asia experienced the highest number of weather- and climate-related disasters in the world during the period 2000-2008 and suffered huge economic losses, accounting for the second highest proportion (27.5%) of the total global economic loss. Losses of human lives, cultural heritage, and ecosystem services are difficult to value and monetize, and thus are poorly reflected in estimates of monetary losses. Impacts on the informal or undocumented economy, as well as indirect effects, can also be very important in some areas and sectors, but are generally not counted in reported estimates of losses (IPCC, 2012).

Flood mortality risk is heavily concentrated in Asia. The top ten countries, based on numbers of lives lost, are India, Bangladesh, China, Vietnam, Cambodia, Myanmar, Sudan, Korea, Afghanistan and Pakistan (UNISDR, 2009). Severe floods in Mumbai in 2005 following 944 mm rainfall within 24 hours have been attributed to both climatic factors and non-climatic factors, such as lack of early warning, preparedness and response capacities at the local level, lack of modern rain gauges, poor urban drainage systems, blockages in the natural drainage channels, poor waste management, poor urban planning, lack of civic sense among citizens, among others (IPCC, 2012; Surjan *et*

al., 2009). Yet, despite the increasing number of people living in floodplains, strengthening of capacities to address the mortality risk associated with major weather-related hazards, such as floods, has resulted in a downward trend in mortality risk relative to population size, as in East Asia, where mortality risk is now at a third of its 1980 level (UNISDR, 2011). Note also that many areas of Asia have seasonal shortfalls in the availability of water, which is also a growing crisis (ADB *et al*., 2012).

24.4.5.3. Projected Impacts

A large proportion of Asia's population lives in low elevation coastal zones that are particularly at risk from climate change hazards, including sea-level rise, storm surges and typhoons [5.3.2.1; 8.2.2.5; Box CC-TC]. Human settlements include rural villages, small and mid-sized cities, megacities and periurban fringes, but most attention in terms of projected climate change impacts has been given to Asia's urban areas, particularly to megacities. Depending on the region, half to two-thirds of Asia's cities with 1 million or more inhabitants are exposed to one or even multiple hazards, with floods and cyclones being the most important ones (UN, 2012). The risk of underestimating the impact of rare or more severe natural disasters on urban areas is high. Asian mega-deltas are particularly susceptible to extreme impacts due to a combination of high-hazard river, coastal flooding and increased population exposure from expanding urban areas with large proportions of high vulnerability groups (IPCC, 2012).

Floodplains. Three of the world's five most populated cities (Tokyo, Delhi and Shanghai) are located in areas with high risk of floods (UN, 2012). Flood risk and associated human and material losses are heavily concentrated in India, Bangladesh, and China. At the same time, the East Asia region in particular is experiencing increasing water shortages, affecting its socioeconomic, agricultural, and environmental conditions negatively, which is attributed to lack of rains and high evapotranspiration, as well as over-exploitation of water resources. Any increase in climatic and weather extremes is expected to aggravate the problem of pollution and flooding. Aging infrastructure may hinder the operation of sewer systems, particularly in Central Asia (IPCC, 2012).

Coastal Areas. By the year 2025, 70% of Asia's urban population will live in the coastal areas, with the majority located in low-elevation coastal zones (Balk *et al*., 2009). Climate change is expected to increase the risk of cyclones, flooding, landslides and drought, the adverse events which have a direct influence on urban and rural settlements, infrastructure and industries alike. Large parts of South, East and Southeast Asia are exposed to a high degree of cumulative climate-related risk (UN-Habitat, 2011). Asia has more than 90% of the global population exposed to tropical cyclones (IPCC, 2012; see Box CC-TC). Damage due to storm surge is sensitive to any change in the magnitude of tropical cyclones. For example, projections for the inner parts of three major bays (Tokyo, Ise, and Osaka) in Japan indicated that a typhoon that is 1.3 times as strong as the design standard, combined with a sea-level rise of 60 cm, would cause damage costs of about US$3, 40, and 27 billion, respectively, in the investigated bays (IPCC, 2012; Suzuki, 2009).

Exposure of the world's large port cities (population exceeding 1 million inhabitants in 2005) to coastal flooding due to sea-level rise and storm surge now and in the 2070s have been estimated, taking into account scenarios of socio-economic and climate changes. About 40 million people (0.6% of the global population or roughly 1 in 10 of the total port city population in the cities considered) are currently exposed to a 1 in 100 year coastal flood event (Hanson *et al*. 2011). The bulk of exposed assets in Asia are currently concentrated in Japan, where 46% of the population, 47% of industrial production and 77% of commercial sales are concentrated in ocean-front cities, towns and villages (Yasuhara, *et al*., 2011). Mumbai, Kolkata, Dhaka, Guangzhou, Ho Chi Minh City, Shanghai, Bangkok, Rangoon, and Hai Phòng will be the cities with the greatest population exposure to coastal flooding in 2070 (IPCC, 2012). Port authorities from around the world perceive sea-level rise as an issue of great concern (Becker *et al*., 2012). There is consensus that planned rapid expansion of ports should take into account adaptation measures as the new infrastructure may still be in use at the end of the century.

Population and Assets. Asia has a large – and rapidly expanding – proportion of the global urban exposure and vulnerability related to climate change hazards [SREX 4.4.3]. By the 2070s, the top Asian cities in terms of population exposure (including all environmental and socioeconomic factors) are expected to be Kolkata, Mumbai, Dhaka, Guangzhou, Ho Chi Minh City, Shanghai, Bangkok, Rangoon, and Hai Phòng (Nicholls *et al*., 2008). The

top Asian cities in terms of assets exposed included Guangdong, Kolkata, Shanghai, Mumbai, Tianjin, Tokyo, Hong Kong, and Bangkok. Hence, cities in Asia, particularly those in China, India and Thailand, become even more dominant in terms of population and asset exposure, as a result of the rapid urbanization and economic growth expected in these countries. This study also estimates that by 2070, population and asset exposure within Asia's large port cities will be disproportionately concentrated in China, India, Japan, Thailand, Vietnam, Bangladesh, Myanmar and Indonesia (Nicholls *et al*., 2008). Vulnerability and potential impacts in Asia's small and medium sized cities is less understood despite their demographic importance (see above). This is partially due to questions around measurement and administrative definitions (Satterthwaite, 2006).

In line with the rapid urban growth and sprawl in many parts of Asia, the periurban interface between urban and rural areas deserves particular attention when considering climate change vulnerability (see also chapter 18.4.1). Garschagen et al. (2011) find, for example, that periurban agriculturalists in the Vietnamese Mekong Delta are facing a multiple burden since they are often exposed to overlapping risks resulting from (a) socio-economic transformations, such as land title insecurity and price pressures; (b) local biophysical degradation, as periurban areas serve as sinks for urban wastes; and (c) climate change impacts, as they do not benefit from the inner-urban disaster risk management measures. Nevertheless, the periurban interface is still underemphasized in studies on impacts, vulnerability and adaptation in Asia. Settlements on unstable slopes or landslide-prone areas face increased prospects of rainfall-induced landslides (IPCC, 2012).

Water-scarcity, especially in summer, is now beyond the control of local governments in urban areas in a number of cities and towns in Asia. Groundwater sources, which are affordable means of high-quality water supply in cities of developing countries, are threatened due to over-withdrawals. Aquifer levels have fallen by 20-50 meters in cities such as Bangkok, Manila and Tianjin and between 10 and 20 meters in many other cities (UNESCO, 2012). The drop in groundwater levels often results in land subsidence, which can enhance hazard exposure due to coastal inundation and sea-level rise especially in settlements near the coast, and deterioration of groundwater quality. Cities susceptible to human-induced subsidence (mainly, developing country cities in deltaic regions with rapidly growing populations) could see significant increases in exposure (Nicholls *et al*., 2008).

Industry and Infrastructure. The impacts of climate change on industry include both direct impacts on industrial production and indirect impacts on industrial enterprises due to the implementation of mitigation activities (Li, 2008). The impact of climate change on infrastructure deterioration cannot be ignored, but can be addressed by changes to design procedures, including increases in cover thickness, improved quality of concrete, and coatings and barriers (Stewart *et al*., 2012). Climate change and extreme events may have a greater impact on large and medium-sized construction projects (Kim, 2007).

In July 2005, across Northwest India, the flooding affected an area of over 35,500 km^2, affecting 20 million people and causing economic damages of around US$3–5 billion (Swiss Re, 2006; Munich Re, 2006). Estimates suggest that by upgrading the drainage system in Mumbai, losses associated with a 1-in-100 year flood event today could be reduced by as much as 70%, and through extending insurance to 100% penetration, the indirect effects of flooding could be almost halved, speeding recovery significantly (Ranger, 2011). On the east coast of India, clusters of districts with poor infrastructure and demographic development are also the regions of maximum vulnerability, so extreme events are likely to be more catastrophic in nature for the people living in these districts. Moreover, the lower the district is in terms of the infrastructure index and its growth, the more exposed it is to the potential damage from extreme events and hence people living in these regions are likely to be highly vulnerable (Patnaik, 2009). In 2008, the embankments on the Kosi River (a tributary of the Ganges) failed and the channel shifted by as much as 120 km (Sinha, 2008), displacing over sixty thousand people in Nepal and three and a half million in India. Transport and power systems were disrupted across large areas. However, the embankment failure was not caused by an extreme event but represented a failure of interlinked physical and institutional infrastructure systems in an area characterized by complex social, political, and environmental relationships (Moench, 2010).

Climate change apparently has little influence on general travel decisions for tourism, even though weather extremes such as tropical storms are relevant, as revealed by a case study from Israel (Gossling and Hall, 2006). Tourist perceptions of weather and climate vary widely. Many Asian countries are major tourist destinations and more studies are needed to understand the impact of climate change on tourism. With respect to beach tourism, large

developing countries and small islands states may be among the most vulnerable due to high exposure and low adaptive capacity (Perch-Nielsen, 2010). A number of Asian countries were found vulnerable in this regard.

24.4.5.4. Vulnerabilities to Key Drivers

The impacts of climate change on human settlements, industry and infrastructure will not only be due to sea-level rise and extreme weather events. Disruption of basic services such as water supply, sanitation, energy provision, and transportation system have implications for local economies and "strip populations of their assets and livelihoods", in some cases leading to mass migration (UN-Habitat, 2010). Such impacts are not expected to be evenly spread among regions and cities, across sectors of the economy or among socioeconomic groups. They tend to reinforce existing inequalities and disrupt the social fabric of cities and exacerbate poverty.

A study of Chittagong, Bangladesh, concludes that urban adaptation and strengthening of local government capacity to reduce vulnerability of the urban poor is not considered a priority in national climate change adaptation policy (Ahammad, 2011). As a result, those most at risk from climate extremes are not given adequate attention. In addition, unequal access to education, health and other public services not only contribute to an increase in income disparities, but can also increase vulnerabilities to climate extremes. In the last two decades, 11 economies of Asia, accounting for more than four-fifths of the region's population, have experienced a widening gap between rich and poor (ADB, 2012). These development challenges can increase the impacts of climate extremes and undermine opportunities arising from adaptation.

Rapid economic growth in Asia is translating into land-use related changes, faster construction of buildings and infrastructure, and corresponding industrial development. While such development is improving the quality of life, it is also creating more impervious surfaces and thus increasing both the localized heat-island effect as well as flooding in dense urban environments. UN-Habitat (2010) states that "Climate change has direct effects on the physical infrastructure of a city – its network of buildings, roads, drainage, and energy systems – which in turn impact the welfare and livelihoods of its residents". The increasing frequency and intensity of extreme climatic events and slow-onset changes will increase the vulnerability of urban economic assets and subsequently the cost of doing business.

In northern Asia, thawing of permafrost can affect residential buildings, pavements, pipelines used to transport petroleum and gas, pump stations and extraction facilities. Ice roads, an important form of transportation for many northern activities may not be passable when permafrost thaws (Kelmelis, 2011; Smith, 2011; Forbes, 2011; FNCRF, 2010).

24.4.5.5. Adaptation Options

An ADB and UN report estimates that "about two-thirds of the $8 trillion needed for infrastructure investment in Asia and the Pacific between 2010 and 2020 will be in the form of new infrastructure, which creates tremendous opportunities to design, finance and manage more sustainable infrastructure" (ADB, 2012). A recent study estimated that direct and indirect losses for a 1-in-100 year flooding in Mumbai could triple by the 2080s compared with the present (increasing from US$700 to US$2,305 million), and suggests adaptation measures to reduce future damages (Ranger *et al.*, 2011). The massive investment required may not be affordable for most of the developing countries of Asia (Zevenbergen and Herath, 2008). Hallegatte *et al.* (2011) suggests that adaptation measures, especially in developing countries, offer a 'no regrets' solution "where basic urban infrastructure is often absent (e.g. appropriate drainage infrastructure), leaving room for actions that both increase immediate well-being and reduce vulnerability to future climate change". Adaptation measures, such as improvements to a city's drainage systems and extending insurance to 100% penetration, can reduce losses associated with a 1-in-100 year flood event by 50-70% (Ranger *et al.*, 2011).

The role of urban planning and urban planners in adaptation to climate change impacts has recently been emphasized (IPCC, 2012; Fuchs *et.al.*, 2011). City planners with greater understanding of climate change related

hazards and capable of communicating associated risks can effectively utilize spatial planning and social infrastructure as tools for adaptation in cities (Fuchs *et.al.*, 2011). Climate-sensitive urban planning is effective as a long-term adaptation measure if it takes into account climate variability, including uncertainty, and systems vulnerability and capacity (IPCC, 2012). Based on a review of governmental adaptation strategies in selected cities (including Ho Chi Minh City and Singapore in Asia), Birkmann *et al.* (2010) argue that a paradigm shift is needed in urban climate change adaptation, away from a focus on solely adapting physical infrastructure, towards also adapting planning, management and governance modes to be able to deal with the uncertainty and the unprecedented challenges implied by climate change. Garschagen and Kraas (2011) call for a stronger consideration of the multiple other challenges for urban governments in line with the comprehensive social, economic and political transformation underway in many of Asia's transition countries and emerging economies. Urban climate change adaptation in Asia cannot be debated without putting these debates into the context of these current and future transformations in the human domain. Institutional and cultural challenges can also emerge when transferring global concepts (e.g. on resilience) to Asia in order to guide the political processes around urban climate change adaptation. This is because the institutional set-up might limit the opportunity for implementing the respective management principles, for example on co-learning, self-organization or bottom-up decision making (Garschagen *et al.*, 2011). Paying particular attention to the national specifics, Revi (2008) suggests a framework for adapting Indian cities to climate change.

Climate change is expected to influence the demand for space cooling and heating (van Vuuren *et al.*, 2011). Air conditioning can reduce vulnerability to heat waves, but the extra energy demand will be in the range 750,000-1,350,000 GWh with a 3.7 °C increase in surface temperatures under different population scenarios and increasing incomes by the year 2100 (Akpinar-Ferranda and Singh, 2010). Green infrastructure has an important role in mitigating the impacts of climate change on urban areas, including reducing energy demand and improving stormwater management (Barber *et al.*, 2009; Gaffin *et al.*, 2012). Urban park systems, street trees, green roofs (Oberndorfer *et al.*, 2007), green walls, permeable pavements and other green infrastructure can improve urban climate and hydrology, while providing ecological and health co-benefits.

A tried method for adapting pavements, railroads, and oil and gas pipelines for the thawing of permafrost is thermal stabilization. Monitoring the buildings' basements and their timely stabilization is the main adaptation measure for residential and industrial buildings. Projected changes in permafrost should be considered by planners of new infrastructure, residential and industrial buildings. A key component of informing policy and decision-making is quantitative scientific research concerning past, present, and future permafrost changes and impacts (FNCRF, 2010; Anisimov *et al.*, 2010; Forbes *et al.*, 2011).

24.4.6. Human Health, Security, Livelihoods, and Poverty

24.4.6.1. Sub-Regional Diversity

Asia is predominantly an agrarian society as is evident from 58% of its total population living in rural areas, out of which 81.8% are dependent on agriculture for their livelihoods (FAOSTAT, 2011). In addition, agriculture employs 24.7% of the total population in these countries and contributes 15.3% of the total value-added GDP (FAOSTAT, 2011; World Bank, 2011). Asia also has high levels of rural poverty compared to urban poverty, with relatively higher poverty incidence in the eight least developing countries in the region (FAOSTAT, 2011). The high incidence of rural poverty and hunger is closely related to heavy dependence on natural resources that are directly influenced by changes in weather and climate, indicating a close connection between rural livelihoods and poverty (IFAD, 2010; Haggblade *et al.*, 2010).

Although Asia has emerged as an economic power during recent decades, there is still a considerable gap in progress in developmental indicators when compared to rest of the world (World Bank, 2011). In terms of these indicators, Southeast Asia is the third poorest region in the world after Sub-Saharan Africa and Southern Asia, and ranks poorly in terms of labor productivity, access to food, maternal health, and forestation (UN, 2009). Consequently, as a large proportion of rural populations depend on agriculture, agriculture has been identified as a key driver of economic growth in the region (World Bank, 2007).

Impacts on human security in Asia will primarily manifest through direct and indirect impacts on water resources, agriculture, coastal areas, resource-dependent livelihoods and on urban settlements and infrastructure, with implications for human health and well-being. To a large extent, regional disparities on account of socio-economic context and geographical characteristics among others, define the differential vulnerabilities and impacts within countries in Asia (Sivakumar and Stefanski 2011; Thomas, 2008).

24.4.6.2. Observed Impacts

Floods and health. Epidemics have been reported in the aftermath of floods and storms (Bagchi, 2007) due to decreased drinking water quality (Harris *et al*., 2008; Hashizume *et al*., 2008; Kazama *et al*., 2012; Solberg, 2010), proliferation of mosquitos (Pawar *et al*., 2008), exposure to rodent-borne pathogens like hantavirus and leptospira (Kawaguchi *et al*., 2008; Zhou *et al*., 2011) and to intermediate host snails of shistosoma (Wu *et al*., 2008). Contaminated flood waters in urban environments have caused exposure to pathogens and toxic compounds, as noted in for example India and Pakistan (Sohan *et al*., 2008; Warraich *et al*., 2011). Mental disorders and posttraumatic stress syndrome are also observed in disaster prone areas (Li *et al*., 2010; Udomratn, 2008), and have in India been linked to age and educational level (Telles *et al*., 2009).

Heat and health. The effects of heat on mortality and morbidity, mainly in terms of hospital admission, have been studied in many countries throughout Asia, with a specific focus on effects among the elderly and persons with cardiovascular and respiratory disorders (Guo *et al*., 2009; Huang *et al*., 2010; Kan *et al*., 2007). Associations between temperature rise and mortality have been shown for India, Thailand (McMichael *et al*., 2008) and several cities in East Asia, including Japan, South Korea, China and Taiwan (Chung *et al*., 2009; Kim *et al*., 2006). Several studies have analyzed the health effects of air pollution in combination with increased temperatures (Lee *et al*., 2007; Qian *et al*., 2010; Wong *et al*., 2010; Yi *et al*., 2010). Intense heat waves have also been shown to affect outdoor workers in South and East Asia (Hyatt *et al*., 2010; Nag *et al*., 2007).

Drought and health. Prolonged drought in combination with windy conditions increases the exposure to sand and dust, often mixed with toxic compounds (Wang *et al*., 2011d). There are indications that dust storms in South West, Central and East Asia increase hospital admissions and worsen asthmatic conditions, as well as causing skin and eye irritations (Griffin *et al*., 2007; Hashizume *et al*., 2010; Kan *et al*., 2012; Tam *et al*., 2012). Prolonged drought may also lead to wildfires and haze exposure, with increased morbidity and mortality, as observed in Southeast Asia (Johnston *et al*., 2012). Drought can also cause disruption of food security that leads to increases of malnutrition (Kumar *et al*., 2005), and consequently increase susceptibility to infectious diseases.

Water-borne diseases. Many pathogens and parasites multiply faster at higher temperatures. Increases in temperatures have been correlated with outbreaks of water-borne diseases in for example East Asia (Huang *et al*., 2008; Onozuka *et al*., 2010¸ Zhang *et al*., 2007). Other studies from South and East Asia have shown a correlation between diarrheal outbreaks and a combination of higher temperatures and heavy rainfall (Chou *et al*., 2010; Hashizume *et al*., 2007; Majra and Gur, 2009). Increasing coastal water temperatures have been correlated with outbreaks of systemic *Vibrio vulnificus* infection in Israel (Paz *et al*., 2007) and Taiwan (Kim and Jang, 2010). Cholera outbreaks in coastal populations in South Asia have been associated with increasing water temperatures and algal blooms (Huq *et al*., 2005). More distal climate modes, such as El Niño and the Indian Ocean Dipole, that arise from ocean-atmosphere interactions in the tropical Pacific and Indian Ocean, respectively, have been associated with cholera epidemics in Bangladesh (Pascual *et al*., 2000; Rodó *et al*., 2002; Hashizume *et al*., 2011)

Vector-borne diseases. Increasing temperatures affect vector-borne pathogens during the extrinsic incubation period and shorten the life-cycles of vectors, thereby facilitating larger vector populations and enhanced disease transmission, whilst vector's ability to acquire and maintain a parasite/pathogen tails off at higher temperatures (Paaijmans *et al*., 2012). Several Asian studies have focused on the emergence of dengue fever. Outbreaks have been correlated with temperature and rainfall with varying time lags (Sriprom *et al*., 2010; Hsieh and Chen 2009, Nitatpattana *et al*., 2008; Shang *et al*., 2010; Su, 2008; Hii *et al*., 2009; Hashizume *et al*., 2012). Outbreaks of the vaccine-preventable Japanese encephalitis have been linked to rainfall in studies from the Himalayan region (Bhattachan *et al*., 2009; Patridge *et al*., 2007), and to a combination of rainfall and temperatures in South and East

Asia (Bi *et al*., 2007; Murty *et al*., 2010). Malaria prevalence is often influenced by other factors than climate variability, but studies from India and Nepal have found correlations with rainfall (Dahal, 2008; Dev and Dash, 2007; Devi and Jauhari, 2006; Laneri *et al*., 2010), whereas temperature was linked to malaria distribution and seasonality in Saudi Arabia (Kheir *et al*., 2010). The re-emergence of malaria in central China has been attributed to rainfall and increases in temperature close to water bodies (Zhou *et al*., 2010). Temperature, precipitation, and the virus-carrying index among rodents have been found to be correlated with the prevalence of hemorrhagic fever with renal syndrome in China (Guan *et al*., 2009; Yan *et al*., 2008).

Livelihoods and Poverty. There have been significant changes in terms of livelihood diversification in Asia over recent decades due to rapid economic development (see Table 24-5). Estimates suggest that currently about 51% of total income in rural Asia comes from non-farm sources (Haggblade *et al*., 2010; Haggblade *et al*., 2009), out of which a major proportion comes from local non-farm business and employment. There has also been steady growth in the proportion of remittances contributing to rural income (Estudillo and Otsuka, 2010). Asia has made significant improvements in poverty eradication over the past decade (World Bank, 2008). At the subregional level, East Asia has recorded a rapid reduction in poverty, followed by South Asia (IFAD, 2010). A significant part of the reduction has come from population shifts, rapid growth in agriculture, and urban contributions (Janvry and Sadoulet, 2010). Literature suggests that climate change negatively impacts livelihoods (see Table 24-5) and that these impacts are directly related to natural resources affected by changes in weather and climate. One of the important factors to be considered while evaluating the past impacts of climate change on agriculture is the play of several factors that have made the region's agriculture less sustainable, which include input non-responsive yields, soil erosion, natural calamities, and water and land quality related problems (Dev, 2011). These factors have predisposed the region's livelihoods to climate change vulnerability. Rural livelihoods are more severely impacted than the urban ones due to the predominantly agricultural population and the poor are more vulnerable to livelihood loss.

24.4.6.3. Projected Impacts

Health effects. An emerging interregional public health concern in Asia is increasing mortality and morbidity due to heat waves. An ageing population in Asia will increase the number of people at risk, especially those with cardio-vascular and respiratory disorders. The rapid urbanization and growth of megacities in Asia add to the magnitude of the problem with the urban heat island effect that may increase downtown temperatures considerably compared to surrounding rural areas (Tan *et al*., 2010), even though local adaptation of the built environment and urban planning will define the magnitude of the impacts on public health. The relationship between temperature and mortality often shows a U-shaped curve (Guo *et al*., 2009). Studies from both tropical and temperate environments in Asia show increased mortality in particular in rural environments during cold events, even if temperatures do not fall below 0°C (Hashizume *et al*., 2009; Wu *et al*., 2011). However, some studies on cold-related deaths in developing areas suggest that other factors than climate are important contributors here, and that climate change will not decrease cold-related deaths to any larger extent in such environments (Honda and Ono 2009). Heat stress disorders and consequent productivity loss among workers have also been reported in Asia (Lin *et al*., 2009; Langkulsen *et al*., 2010).

Climate change will affect the local transmission of many climate-sensitive diseases. Increases in heavy rain and temperature are projected to increase the risk of diarrhoeal diseases in for example China (Zhang *et al*., 2008). The impact of climate change on malaria risk will differ between areas, as projected for West and South Asia (Husain and Chaudhary, 2008; Garg *et al*., 2009; Majra and Gur, 2009), whilst a study reported that the impact of socio-economic development is larger than that of climate change (Béguin *et al*., 2011). Some studies have developed climate change-disease prevalence models, for example one for schistosomiasis in China shows an increased northern distribution range of the disease with climate change (Kan *et al*., 2012, Zhou *et al*., 2008). Impacts of climate change on fish production (Qiu *et al*., 2010) is being studied, along with impacts on chemical pathways in the marine environment and consequent impacts on food safety (Tirado *et al*., 2010b), including seafood safety (Marques *et al*., 2010).

Livelihood and Poverty. Floods, droughts and changes in seasonal rainfall patterns are expected to negatively impact crop yields, food security and livelihood in vulnerable areas (Dawe *et al*., 2008; Douglas, 2009; Kelkar *et al*.,

2008). Rural poverty in parts of Asia could be exacerbated (Skoufias et al., 2011) due to negative climate change impacts on the rice crop and increases in food prices and the cost of living (Hertel et al., 2010; Rosegrant, 2011). The poverty impacts of climate change would be heterogeneous among countries and social groups (see Table 24-6). In a low crop productivity scenario, food exporting countries, such as Indonesia, the Philippines and Thailand, would benefit from climate change related global food price rises and be able to reduce poverty, while countries such as Bangladesh would experience a net increase in poverty of 15% by 2030 (Hertel et al., 2010). Regression analyses conducted by Skoufias *et al.* (2011) indicate significant negative impacts of a shortfall in rainfall on the welfare of rice farmers in Indonesia, compared to a delay in the onset of rainfall. These impacts may lead to global mass migration and related conflicts (Laczko and Aghazarm, 2009; Barnett and Webber, 2010; Warner, 2010; World Bank, 2010). Climate-driven changes in tundra and forest-tundra biomes can influence indigenous peoples of the North Asia due to their traditional livelihood: nomadic tundra pastoralism, fishing and hunting (Kumpula *et al.*, 2011).

24.4.6.4. Vulnerabilities to Key Drivers

Key vulnerabilities vary widely within the region. Climate change can exacerbate current socio-economic and political disparities and add to the vulnerability of Southeast Asia and Central Asia to security threats that may be transnational in nature (Jasparro and Taylor, 2008; Lioubimtseva and Henebry, 2009). Apart from detrimental impacts of extreme events, vulnerability of livelihoods in agrarian communities also arises from geographic settings, demographic trends, socio-economic factors, access to resources and markets, unsustainable water consumption, farming practices and lack of capacity to adapt (Mulligan *et al.*, 2011; Acosta-Michlik and Espaldon, 2008; Allison *et al.*, 2009; Knox *et al.*, 2011; Lioubimtseva and Henebry, 2009; Byg and Salick, 2009; Salick and Ross, 2009; Salick *et al.*, 2009; Xu *et al.*, 2009; Winters *et al.*, 2009; UN, 2009). Urban wage labourers were found to be more vulnerable to cost of living related poverty impacts of climate change than those who directly depend on agriculture for their livelihoods (Hertel *et al.*, 2010). In Southeast Asia, an important topic of focus is forests and fires; for example the vulnerability of agriculture, forestry and human settlements on peatland areas in Indonesia (Murdiyarso and Lebel, 2007). Human health is also a major area of focus for Asia (Munslow and O'Dempseya, 2010), where the magnitude and type of health effects from climate change will differ within Asia depending on differences in socio-economic and demographic factors, health systems, the natural and built environment, land use changes, and migration in relation to local resilience and adaptive capacity. The role of institutions is also critical, particularly in influencing vulnerabilities arising from social heterogeneity based on gender (Ahmed and Fajber, 2009), caste and ethnic differences (Jones and Boyd, 2011), and securing climate-sensitive livelihoods in rural areas (Agrawal and Perin, 2008).

24.4.6.5. Adaptation Options

Cross-sectorial collaborations will be needed for the development of sustainable adaptive measures with interactions between the health sector and disaster preparedness programs, water management, sanitation, urban planning, the food industry and the animal health sector. Disaster preparedness on a local community level could include a combination of indigenous coping strategies, early-warning systems, and adaptive measures (Paul and Routray, 2010). Heat warning systems have been shown to be successful in preventing deaths among risk groups, as in Shanghai (Tan *et al.*, 2007). Also proven successful is the implementation of new work practices to avoid heat stress among outdoor workers, as shown in studies from Japan and the UAE (Joubert *et al.*, 2011; Morioka *et al.*, 2006). As described in section 24.7, there are many win-win solutions for public health from the interaction of adaptation and mitigation measures that involve urban environments and air pollution. Early warning models have been developed for haze exposure from wildfires, in for example Thailand (Kim Oanh and Leelasakultum, 2011). Early warning models are also being tested in infectious disease prevention and vector control programs, as for malaria in Bhutan (Wangdi *et al.*, 2010) and Iran (Haghdoost *et al.*, 2008), or are being developed, as for dengue fever region-wide (Wilder-Smith *et al.,* 2012).

The available literature suggests a need for identifying and promoting technologies and policy options that will provide both mitigation potential and sustained income generation potential in a changed climate (Bhandari *et al.*,

2007; Rosenzweig and Tubiello, 2007; Paul *et al*., 2009a). Interesting examples seem to emerge on how some practices provide completely unexpected livelihood benefits which otherwise may not be captured in standard evaluation frameworks, as in the case of the introduction of traditional flood mitigation measures in China which could positively impact the local livelihoods, leading to reductions in both the physical and economic vulnerabilities of communities (Xu *et al*., 2009). A significant amount of literature has stressed the greater role of local communities in decision making (Alauddin and Quiggin, 2008) and in prioritization and adoption of adaptation options (Prabhakar *et al*., 2010; Prabhakar and Srinivasan, 2011). Defining adequate community property rights, including solving issues such as land tenure, reducing income disparity, exploring market-based and diversified off-farm livelihood options, moving from production-based approaches to productivity and efficiency decision-making based approaches, and promoting integrated decision-making approaches, have been suggested (Merrey *et al*., 2005; Brouwer *et al*., 2007; Paul *et al*., 2009; Niino, 2011; Stucki and Smith, 2011).

Climate resilient livelihoods can be fostered through the creation of a bundle of capitals (natural, physical, human, financial and social capital) and poverty eradication (see Table 24-8). In general, greater emphasis on agricultural growth has been suggested as an effective means of reducing rural poverty (Janvry and Sadoulet, 2010; Rosegrant, 2011). Bundled approaches are known to facilitate better adaptation than individual adaptation options (Acosta-Michlik and Espaldon, 2008; Fleischer *et al*., 2011). Community-based approaches, as against top-down interventions, have been suggested to identify adaptation options that address poverty and livelihoods, as these techniques help capture information at the grassroots (Aalst *et al*., 2008), and help integration of disaster risk reduction, development, and climate change adaptation (Heltberg *et al*., 2010), connect local communities and outsiders (Aalst *et al*., 2008), and address the location-specific nature of adaptation (Iwasaki *et al*., 2009; Rosegrant, 2011). Some groups can become more vulnerable to changes after being 'locked into' specialized livelihood patterns as shown in the case of fish farmers in India (Coulthard, 2008).

[INSERT TABLE 24-8 HERE
Table 24-8: Summary of adaptation options for securing livelihoods in Asia.]

24.4.7 Valuation of Impacts and Adaptation

Research on the valuation of climate change impacts and adaptation in Asia has been highly limited. However, recently there is growing research attention to the assessment of the aggregate costs of climate change impacts and adaptation. For instance, in Bangladesh, by 2050, the total adaptation cost is estimated at US$5.7 billion to offset the added inundation from climate change, including US$3.3 billion to protect infrastructure, such as roads, railways, river embankments, and drainage from inland monsoon floods, and US$2.4 billion for storm-surge protection (World Bank, 2011). There are a few studies focusing on dispersed sectors though without comprehensive economic valuation of the costs and benefits of adaptation. Examples of such studies include exploring low-cost adaptation strategies for reducing the net vulnerability of sorghum production systems in India (Srivastava *et al*., 2010); assessing vulnerability and adaptation of agriculture and food security, water resources and human health in Central Asia (Lioubimtseva and Henebry, 2009); socio-economic impacts of drought and flood in South Asia (Muhammed *et al*., 2007); investigation of vulnerability and adaptive capacity to climate variability and water stress in the Lakhwar watershed in Uttarakhand State, India (Kelkar *et al*., 2008); assessing socio-economic vulnerability and adaptation measures in West Coast of Peninsular Malaysia (Drainage and Irrigation Department, 2007); and simulating impacts on rice yields in a number of Asian countries (Matthews *et al*. 1997). In addition to changes in temperature and rainfall, changes in the frequency of extreme climatic events could be damaging and costly to agriculture (Aydinalp and Cresser, 2008; Muhammed *et al*., 2007; Su *et al*., 2009).

A study of the economics of climate change in Southeast Asia with a focus on Indonesia, the Philippines, Thailand, and Vietnam (ADB, 2009) reported that many of the impacts from climate change are not in traditional economic sectors such as agriculture, including fisheries and aquaculture, forestry and mining, with the result that their valuations are difficult with uncertainly and incomplete information. Furthermore, some of the economic and social valuations, such as loss of life or damage to ecosystems, can be contentious. Without further mitigation or adaptation (under the A2 scenario), the PAGE2002 integrated assessment model projects for the four countries to suffer a mean loss of 2.2% of gross domestic product (GDP) by 2100 on an annual basis, if only the market impact

(mainly related to agriculture and coastal zones) is considered. This is well above the world's mean GDP loss of 0.6% each year by 2100 due to market impact alone. In addition, the mean cost for the four ASEAN countries by 2100 could reach 5.7% of the GDP if non-market impacts related to health and ecosystems are included and 6.7% of the GDP if catastrophic risks are also taken into account.

The PAGE2002 model also found that the cost of adaptation for agriculture and coastal zones (mainly the development of drought- and heat-resistant crops and the construction of sea walls) would be about $5 billion/year by 2020 on average, and that this investment would be paid back in the future. For instance, the annual benefit of avoided damage from climate change is expected to exceed the annual cost by 2060 and, by 2100, benefits could reach 1.9% of GDP, compared to the cost at 0.2% of GDP, with the results at mean and 5% probability level under the A2 scenario. This shows that the benefits from adaptation are projected to outweigh the costs of implementing adaptation measures in the long term. It was also stressed that there are currently great uncertainties associated with the economic aspects of climate change (ADB, 2009). Adaptation cannot entirely remove the projected damage of climate change, and thus must be complemented with global mitigation of CO_2 in order to avoid the greater impact of future climate change (Begum *et al*., 2011; ADB, 2009; MNRE, 2010).

24.5. Adaptation and Managing Risks

24.5.1. Conservation of Natural Resources

Even without climate change, natural resources are already under severe pressure in most of East, Southeast, and South Asia, as well as in much of Central and West Asia, and parts of North Asia and the Tibetan Plateau. The extraordinarily high rates of deforestation and forest degradation in Southeast Asia have received most attention (Sodhi *et al*., 2010; Miettinen *et al*., 2011), but ecosystem degradation, with the resulting loss of natural goods and services, is also a major problem in other forest types and in non-forest ecosystems. These pressures result from rising populations and rapid economic development, exacerbated by poor governance and the low priority of natural resource conservation. The impacts of projected climate change are expected to intensify these pressures in most areas, but the relative importance of climate and non-climate stressors is difficult to predict in most cases. Coral reefs are an exception, with climate change and ocean acidification a clear threat to all reefs in the region and thus the millions of people who depend on them (Hoegh-Guldberg, 2011; Burke *et al*., 2011; see also Chapter 30, this volume).

With natural resource conservation already under stress, the focus has been on actions that would be beneficial even without climate change, including minimizing non-climate pressures on natural resources and restoring connectivity to allow movements of genes and species between fragmented populations (Lindenmayer *et al*., 2010). Authors have also suggested a need to identify and prioritize for protection areas that will be subject to the least damaging climate change ('climate refugia') and to identify additions to the protected area network that will allow for expected range shifts, for example by extending existing protected areas to higher altitudes or latitudes (Hannah, 2010; Hole *et al*., 2011; Shoo *et al*., 2011). Moving beyond this focus on wild species and ecosystems, ecosystem-based approaches to adaptation aim to use the resilience of natural systems to buffer human systems against climate change, with potential social, economic and cultural co-benefits for local communities (see Box CC-EA: Ecosystem-based approaches to adaptation – emerging opportunities).

24.5.2. Flood Risks and Coastal Inundation

Many coasts in Asia are exposed to extreme weather, as well as more gradual changes in climate and sea level, and are accordingly anticipated to face threats from floods and coastal inundation. Responding to a large number of climate change impact studies for each country over the past decade (e.g. Karim and Mimura, 2008; Pal and Al-Tabbaa, 2009; World Bank, 2010), various downscaled tools to support, formulate and implement climate change adaptation policy for local governments are under development. One of the major tools is vulnerability assessment and policy option identification with Geographical Information Systems (GIS). These tools have been developed for flood risk management so far, and most give consideration in varying degrees to climate change impacts, such as

long-term rises in sea-level. These tools are expected to be of assistance in examining city-specific solutions in response to city-specific impacts characterized by distinct climatic, hydrological and socioeconomic features, and in building the adaptation capacity of stakeholders in the community as a result.

These tools and systems sometimes take community-based approaches. The background to these is as follows: vulnerability and exposure to climate change at the coast is exacerbated by population growth, socio-economic growth and urbanization, however assessments of vulnerabilities have uncertainties and limitations and do not necessarily provide suitable information for local stakeholders to take appropriate action at the local level. Therefore bottom-up approaches are potentially more effective in building adaptive capacity by involving local stakeholders (Van Aalst *et al*., 2008). As local stakeholders have different sets of understanding, conflict assessment is needed to plan and implement adaptation policy (e.g. Baba *et al*., 2012). Also, community-based approaches may have a limitation in that they place greater responsibility on the shoulders of local people without necessarily increasing their capacity proportionately (Allen, 2006). As the nature of adaptive capacity varies, depending on the formulation of social capital and institutional context in the local community, it is essential for the approaches to have an understanding of local community structures (Adger, 2003). If the approaches satisfy these conditions, flood risks and coastal inundation exacerbated by climate change would be perceived as issues for the current generation and adaptation policy would be better understood by local stakeholders.

24.5.3. Economic Growth and Equitable Development

Economic, social, and environmental equity is an enduring challenge in many parts of Asia. Generally, the level of wealth (typically GDP) has been used as a measure of human vulnerability of a country or region, but this approach has serious limitations (Mattoo and Subramanian, 2012; Dellink *et al*., 2009; Bosetti and Frankel, 2009). In many cases, social capital, an indicator of equity in income distribution within countries, is a more important factor in vulnerability and resilience than GDP per capita (Lioubimtseva and Henebry, 2009; Islam *et al*., 2006). Furthermore, political and institutional instabilities can undermine the influence of economic development (Lioubimtseva and Henebry, 2009). Poor and vulnerable countries are at greater risk from the impacts of climate extremes as their options for coping which such events are limited. This is particularly true for developing countries in Asia with a high level of natural resource dependency. Provision of adequate resources based on the burden sharing and the equity principle will serve to strengthen appropriate adaptation policies and measures in such countries (Su *et al*., 2009). Mainstreaming adaptation into government's sustainable development policy portrays a potential opportunity for good practice to build resilience and reduce vulnerability, depending on effective, equitable and legitimate actions to overcome barriers and limits to adaptation (Lioubimtseva and Henebry, 2009; Agrawala and van Aalst, 2005; Lim *et al*., 2005; ADB, 2005). It requires growth with economic stability, development with social equity and poverty eradication, and the continued functioning of ecosystems as life support systems to sustain development.

24.5.4. Mainstreaming and Institutional Barriers

The level of climate change adaptation mainstreaming is most advanced in the context of official development assistance, where donor agencies and international financial institutions have made significant steps towards taking climate change adaptation into account in their loan and grant making processes (Gigli and Agrawala, 2007; Klein *et al*., 2007b). In contrast, within developing countries, actual projects on the ground to mainstream adaptation to climate change remain limited and significant institutional and cognitive barriers remain (Yohe *et al*., 2007; Gigli and Agrawala, 2007). For example, in the Philippines, the factors that hinder climate change mainstreaming include: national priorities that are geared towards what are perceived to be more pressing concerns, such as employment generation and education, and a pervasive lack of awareness of the impacts of climate change on sustainable development (Lasco *et al*., 2009). However, there are massive investments in infrastructure projects designed to adapt to weather-related hazards. Local government units could play a crucial role, as shown by the experience of Albay province in the Philippines which pioneered climate action at the grassroots level (Lasco *et al*., 2012)

While some practical experiences of adaptation in Asia at the regional, national and local level are emerging, there can be barriers that impede or limit adaptation. These can include lack of financial resources for adaptation implementation, institutional barriers, biophysical limits to ecosystem adaptation and others (Moser and Ekstrom, 2010). Regional adaptation strategies are necessary to tackle issues such as food security. There are already some groups, such as the Association of South East Asian Nations (ASEAN), but there is a need for global and regional strategic partnerships in this regard (Singleton *et al*., 2010). The success of deployment, implementation and sustainability of adaptation options can be influenced by the political economy of the region. Issues with resource availability might not only result from climate change, but also from weak governance mechanisms and the breakdown of policy and regulatory structures, especially with common-pool resources (Moser and Ekstrom, 2010). Furthermore, the impact of climate change depends on the inherent vulnerability of the socio-ecological systems in a region as much as on the magnitude of the change (Evans, 2010). Recent studies linking climate-related resource scarcities and conflict call for enhanced regional cooperation (Gautam, 2012).

24.5.5. Role of Higher Education in Adaptation and Risk Management

To enhance the development of young professionals in the field of climate change adaptation, it is of utmost importance to include the topic in higher education, especially in formal education programs. Shaw *et al*. (2011) emphasized the need for higher education in adaptation and disaster risk reduction in the Asia-Pacific region through: environment disaster linkage, focus on hydro-meteorological disasters, and emphasizing synergy issues between adaptation and risk reduction. Similar needs have also been highlighted by Ryan *et al*. (2010), Nomura and Abe (2010), Chhokar (2010) and Niu *et al*. (2010). Higher education should be done through lectures and course work, field studies, internships, and establishing education-research linkages by exposing the students to field realities. In this regard, guiding principles could include: an inclusive curriculum, a theoretical focus, field orientation, multi-disciplinary courses and practical skill enhancement. Bi-lateral or multi-lateral practical research programs on adaptation and risk management by the graduate students and young faculty members would expose them to the real field problems.

24.6. Adaptation and Mitigation Interactions

Climate change mitigation benefits climate change adaptation in Asia by increasing the prospects that adaptation can address many unavoidable impacts, and adaptation benefits mitigation by somewhat moderating the impacts of particular GHG concentration levels due to reduced sensitivities or increased coping capacities. One of the most prominent examples is increasing the efficiency and affordability of air conditioning, which would extend space conditioning benefits to a larger share of populations with rising standards of living, while at the same time reducing carbon emissions associated with electricity generation. Other examples include the development of sustainable cities in Asia with less fossil fuel driven vehicles (mitigation) and with more trees and greenery (carbon storage as well as adaptation to the urban heat island effect), which would have a number of co-benefits including public health – a promising strategy for “triple win” interventions (Romero-Lankao *et al*., 2011). A further example is China’s leadership in promoting solar energy technologies, where reduced requirements for carbon-based electricity generation are combined with technological change, job creation, and skill development that enhance adaptive capacities.

Other possible synergies (and/or conflicts) tend to be more subtle. In general, integrated mitigation and adaptation responses tend to focus on either land-use changes, often involving ecosystem functions, or on technology development and use. For instance, changes in land use, such as agroforestry, may provide both mitigation and adaptation benefits (Verchot *et al*., 2007), or otherwise depending on how they are implemented. Agroforestry practices will provide carbon storage and may at the same time decrease soil erosion, increase the resilience against floods, landslides and drought, increase soil organic matter, reduce the financial impact of crop failure, as well as have biodiversity benefits over other forms of agriculture as shown, for example, in Indonesia (Clough *et al*., 2011). Integrated approaches are often needed when developing mitigation-adaptation synergies, as seen in waste-to-compost projects in Bangladesh (Ayers and Huq, 2009). Linking adaptation to mitigation makes mitigation action more relevant for many low-income regions.

In addition to agroforestry, any ecological adaptation measures that increase plant biomass and/or soil carbon content, such as ecosystem protection and reforestation, will contribute to climate mitigation by carbon sequestration. However, exotic monocultures may fix more carbon than native species mixtures while supporting less biodiversity and contributing less to ecological services. Compromises that favor biodiversity-rich carbon storage that is resilient to future climate change may be necessary (Díaz *et al*., 2009). The potential for both adaptation and mitigation through forest restoration is greatest in the tropics (Sasaki *et al*., 2011). At higher latitudes (>45ºN), reforestation can have a net warming influence by reducing surface albedo (Anderson-Teixeira *et al*., 2012). The expansion of biofuel crops on abandoned and marginal agricultural lands could potentially make a large contribution to the mitigation of global carbon emissions, but could also have large negative consequences for both carbon emissions and biodiversity if it results directly or indirectly in the conversion of carbon-rich natural ecosystems to cropland (Fargione *et al*., 2010; Qin *et al*., 2011). Mechanisms, such as REDD+, that put an economic price on land-use emissions could reduce the risks of these negative consequences from biofuel expansion (Thomson *et al*., 2010), but the incentive structures need to be worked out very carefully (Busch *et al*., 2012).

There has also been an emphasis on forests and their management for providing resilient livelihoods and reducing poverty (Persha *et al*., 2010; Larson, 2011; Noordwijk, 2010; Chhatre and Agrawal, 2009). Securing rights to resources was found to be essential for greater livelihood benefits to the poor indigenous and traditional people (Macchi et al., 2008). Because of this, the need for REDD+ schemes to respect and promote community forest tenure rights has been emphasized (Angelsen, 2009). It has also been suggested that indigenous people can provide a bridge between biodiversity protection and climate change adaptation (Salick, 2009), which appears to be missing in the current discourse on ecosystems based adaptation. However, there are arguments against REDD+ supporting poverty reduction due to its inability to promote productive use of forests, which may keep communities in perpetual poverty (Campbell, 2009).

On rivers and coasts, the use of hard defenses (e.g. sea-walls, channelization, bunds, dams) to protect agriculture and human settlements from flooding may have negative consequences for both natural ecosystems and carbon sequestration by preventing natural adjustments to changing conditions. Conversely, setting aside landward buffer zones along coasts and rivers would be positive for both (Erwin, 2009), although this will often be difficult in practice. The very high carbon sequestration potential of the organic-rich soils in mangroves (Donato *et al*., 2011) and peatswamp forests (Page *et al*., 2011) provides opportunities for combining adaptation with mitigation through restoration of degraded areas.

Several mitigation technologies and measures will have public health benefits, such as controlled composting, state-of-the-art incineration, expanded sanitation coverage, and waste water management (Bogner *et al*., 2008). There are potentially large benefits for both public health and other sectors from climate change mitigation policies that reduce exposure to outdoor and indoor air-pollution (Haines *et al*., 2009). Decarbonizing electricity production efforts in India and China are projected to decrease mortality due to reduced PM5 and PM2.5 particulate matters (Markandya *et al*., 2009). Mitigation policies to reduce fossil fuel vehicles will increase air quality and decrease the health burden, particularly in urban environments as projected in India (Woodcock *et al*., 2009). The use of more public transportation, as well as increased walking and cycling, and fewer private cars could also improve public health (Woodcock *et al*., 2007). Abandoning the use of biomass fuel or coal for in-door cooking and domestic heating would substantially increase indoor air quality and respiratory and cardiac health among, in particular, women and children in India and China (Wilkinson *et al*., 2009). In reverse, actions to reduce current environmental-public health issues may often as an additional bonus have beneficial mitigation effects, like traffic emissions reduction programs in China (Wu *et al*., 2011) and India (Reynolds and Kandlikar, 2008). At the same time, climate change adaptation technologies, such as improved stormwater and wastewater management, can reduce electricity requirements for water pumping and water treatment; and advances in information, communication, and control technologies can contribute to both adaptation and mitigation efforts. Among financial means, low-risk liquidity options such as microfinance programs and risk transfer products can help lift the rural poor from poverty and accumulate assets (Barret *et al*., 2007; Jarvis *et al*., 2011).

24.7. Intra-regional and Inter-regional Issues

24.7.1. Trans-boundary pollution

Many Asian countries and regions face long-distance and trans-boundary air pollution problems. In eastern China, Japan and the Republic of Korea, these include dust storms that originate in the arid and semi-arid regions upwind, with impacts on climate, human health and ecosystems (Huang *et al.*, 2013). The susceptibility of the land surface to wind erosion is strongly influenced by vegetation cover, which is in turn sensitive to climate change and other human impacts. In the humid tropics of Southeast Asia, in contrast, the major trans-boundary pollution issue involves smoke aerosols from burning of biomass and peatlands [24.9.2], mostly during clearance for agriculture. Apart from the large impact on human health, these aerosols may be having a significant effect on rainfall in equatorial regions, leading to the possibility of climate-feedbacks, with fires reducing rainfall and promoting further fires (Tosca et al., 2012; WG1 AR5 SOD Ch. 7). Pollutants of industrial origin are also a huge problem in many parts of the region, with well-documented impacts on human health [24.4.6] and the climate [WG1 AR5 SOD Ch. 7 and 8].

24.7.2. Trade and Economy

A well-functioning international trading system can help support adaptation to the challenges of climate change. Hence welfare gains from reforms to trade policies may be greater than normally measured if they also reduce GHG emissions globally (Huang *et al.*, 2011). In recent years, there has been a growing interest in the environmental impacts of regional trade liberalization. A study by Gumilang *et al.* (2011) suggests that overall AFTA (ASEAN Free Trade Agreement) has had a greater impact on the Indonesian economy than IJEPA (Indonesia–Japan Economic Partnership Agreement), while the adoption of both agreements contributes to increasing CO_2 emissions by 0.47% compared to the business-as-usual case. This is mainly due to the high emission coefficient of the transportation sector. On the other hand, the agreements did have a positive impact on water pollution indicators.

China's high economic growth and flourishing domestic and international trade has resulted in increased consumption and pollution of water resources. For instance, Guan and Hubacek (2007) found that North China, as a water scarce region, effectively exports about 5% of its total available freshwater resources, while accepting large amounts of wastewater from other regions' consumption. By contrast, South China, a region with abundant water resources, is effectively importing water from other regions, while their imports are creating wastewater polluting other regions' ecosystems.

24.7.3. Migration and Population Displacement

There is an emerging body of literature suggesting growing nexus between migration and climate change (International Organization for Migration, 2008; Piguet *et al.*, 2011). The global report of Internal Displacement Monitoring Center (2011) enlists climate related natural hazards such as floods and droughts as some of predominant causes for internal displacement. In 2010 alone, 38.8 million people were internally displaced 85% of them were due to hydrological hazards and 77% of displacements took place in Asia alone. Rapid-onset environmental changes such as floods are increasingly playing a role in migration in the case of Mekong Delta (Warner, 2010). Migration has also received attention in the literature as an adaptation option (Reuveny, 2007; Warner, 2010; ADB, 2012; The Government Office for Science, 2011). While some form of environmentally induced migration may be adaptive, other forms of environmental migration may indicate a failure of social-ecological systems to adapt (Warner, 2010), suggesting need for differentiating the root cause of migration and treating them through new forms of governance that connects the migrants with those who returned and remained.

Migration has become one of the strategies to sustain livelihoods in the wake of climate and environmental change (Barnett and Webber, 2010). The shift towards non-farm income activities, including migration, appears to be more prominent in countries and communities with least access to land (Winters *et al.*, 2009) and in those communities with better access to education (Estudillo and Otsuka, 2010). Increasing migration has led to increasing migration-

induced remittances contributing to Asian economies and decreased the poverty gap, but had negligible effect on the poverty rate (Vargas-Silva *et al*., 2009).

Migration could have negative impacts on the migrants as observed in the case of Bangladesh where migrant workers had to live and work under poor conditions such as crowded shelters, poor sanitation, conflict and competition with local population, and exploitation (Penning-Rowsell *et al*., 2011). Though forced migration can result from implementing some adaptation options such as construction of dams, the negative outcome from these migrations could be overcome by putting in place proper safeguards (The Government Office for Science, 2011). The most favorable approach is to deal with migration within a development framework and by incorporating into adaptation strategies (ADB, 2012; The Government Office for Science, 2011). Only such inclusive approach would make difference in whether climate induced migration would emerge as forced displacement or planned and facilitated adaptation strategy.

24.8. Research and Data Gaps

There are still regions within Asia that are not sufficiently represented in studies of observed climate change and its impacts, in particular Central and West Asia. Also, numerical data on trends in precipitation is hard to find compared to trends in temperature. Furthermore, research data on changes in extreme climate events does not cover most Asian regions. For freshwater resources studies, research priorities are as follows: (1) to increase the knowledge of future rainfall changes in regions by model ensembles to provide a better idea of future water supply, (2) to develop water management strategies across scales to adapt future changes in water demand and supply associated with climate change, (3) to elaborate more studies on successful water saving technologies and other adaptation options.

Scientific understanding of the impacts of climate change on ecosystems and biodiversity in Asia is currently limited by the poor quality and low accessibility of biodiversity information (GEO-5 Assessment Report, 2012). National biodiversity inventories are incomplete and very few sites have the accurate baseline information needed to identify changes brought about by climatic trends and other stressors. Quantitative information for sites in protected areas where non-climate impacts are minimized will be particularly valuable in the future. New and old data need to be digitized and made available on-line. Current warming projections suggest that large areas in the Asian tropical lowlands will experience climates in 2100 that have not existed anywhere on Earth for several million years (García-López and Allué, 2012). This novelty makes reliance on extrapolation from our current, limited, understanding of climatic controls on biological processes dangerous, and underlines the need for new research. Key priorities include the temperature dependence of carbon fixation by tropical trees and the thermal tolerance and acclimation capacity of both plants and animals (Corlett, 2011).

Boreal forest dynamics will be influenced by complex interactions between rising temperatures and CO_2 concentrations, permafrost thawing, forest fires, and insect outbreaks (Osawa *et al*., 2010; Zhang *et al*., 2011b). Understanding this complexity will require enhanced monitoring of biodiversity and especially of species ranges, improved modeling, and a greater knowledge of species biology (Anisimov *et al*., 2008). Long-term monitoring of biome boundary shifts and vegetation change is also needed because of slow rate of these changes. In remote and inaccessible areas such monitoring has been provided since 1978 by broad-swath satellite remote sensing data, however lack of coincidence in estimates of vegetation vigor provided by remote sensing techniques and by vegetation models requires further research and inter-calibration of methods (Xu *et al*., 2012).

There are still many gaps in our understanding of climate change impacts and vulnerabilities in the agricultural sector as well as appropriate adaptation options. The most studied crop is rice but there are still significant uncertainties in terms of accuracy of models, effect of CO_2 fertilization, and regional effects (Shuang-He *et al*., 2011; Zhang *et al*., 2010; Masutomi *et al*., 2009). For other crops, there is even greater uncertainty in terms of magnitude and direction of impacts of rising temperatures, precipitation changes, and CO_2 fertilization.

There is a need to increase knowledge of heat and air pollution interactions and health effects in different risk groups, in both urban and rural environments. There are research gaps in climate change impacts on children's

health in different socioeconomic and regional context to fill in. More trans-disciplinary research is needed on direct and indirect health effects from climate change impacts on water quality and quantity in different parts of Asia. Studies on social-economic and institutional dimension should also be given priority. For example, the impacts of climate change on women and their role in climate change adaptation needs to be investigated (Mula *et al*., 2010). There is also a need to identify low cost adaptation options and a need for scaling up of the same, considering the majority of population lives below the poverty line in some of the least developed countries. Greater understanding of various existing policy processes in place-specific geographic context, their compatibilities and non-compatibilities, is also needed. For example, interventions to increase livelihood options through conservation initiatives that may restrict access to natural resources for the very people that rely upon them for their living might make them more vulnerable (Roman and McEvoy, 2010). Research on adaptation and mitigation interactions that promotes sustainable development should be increased, as well as research on possible economic gains from different adaptation-mitigation strategies and measures.

More focused research will support the tackling of climate change impacts, vulnerability and adaptation in urban settlements, especially cities with populations under 500,000, which share about half the region's urban population. Since urban areas account for over 80% of Asia's GDP, research priorities could include detailed estimates of the impact of climate change on various sectors of the urban economy, including the tourism industry (UN-Habitat, 2011). Research on promoting adaptation polices at the municipal level should also be given consideration. It is assumed that the existing policies should be expanded into adaptation; however the implementation of adaptation measures is still in its infancy.

Climate change will not have uniform impact on the population within a country, but rather depends on location, socio-economic conditions and level of preparedness (Begum *et al*., 2011). Negative impacts on agricultural productivity would have significant impacts on the aggregated household welfare, livelihoods and poverty in the region (Zhai and Zhuang, 2009) and this needs to be adequately studied. Low cost options are limited, despite the number of people living below the poverty line in some of the least developed countries such as Bangladesh (Iwasaki *et al*., 2009; Rawlani and Sovacool, 2011). Greater understanding is required on linkages between local livelihoods, ecosystem functions, and land resources for creating a positive impact on local livelihoods and poverty reduction in areas with greater dependency on natural resources (Paul *et al*., 2009). Keeping in view the interconnected nature of the problems across geographical, social and political scales, an emphasis on increased regional collaboration in scientific research and policy making was suggested for reducing climate change impacts on water, biodiversity and livelihoods in the Himalayan region (Xu *et al*., 2009).

While mitigation efforts are essential, the literature suggests that work must begin on building understanding of the impacts of climate change and moving forward with the most cost-effective adaptation measures (Stage, 2010; Mathy and Guivarch, 2010; Cai *et al*., 2008; ADB, 2007). Consequently, for devising mitigation policies, the key information needed are the most cost-effective mitigation measures within sector and across sectors (Mathy and Guivarch, 2010; Cai *et al*., 2008; Nguyen, *et al*., 2007). The costs and benefits of climate change adaptation cannot be analyzed using economic aspects only; other aspects such as climate science, behavioral science, legal and moral aspects also have crucial implications for the outcome of the analysis (Stage, 2010; Agrawala and Fankhauser, 2008; Lecocq and Shalizi, 2007; Begum *et al*., 2006; Metroeconomica, 2004).

24.9. Case Studies

24.9.1. Transboundary Adaptation Planning and Management – Lower Mekong River Basin

The *Lower Mekong River Basin (LMB)* covers an area of approximately 606,000 sq km across the countries of Thailand, Laos, Cambodia and Vietnam (Hinkel and Menniken, 2007). More than 60 million people in the densely populated LMB are heavily reliant on natural resources, in particular agriculture and fisheries for their well-being (MRC, 2009; UNEP, 2010). As two of the five top rice exporting countries globally, Thailand and Vietnam produced 51% of the world's rice exports in 2008. The majority of rice production in these countries is located in the LMB (Mainuddin *et al*., 2011a). About two-thirds of the Mekong Basin's population is involved in fishing to sustain their livelihoods; fishing is particularly important for rural households (Hortle, 2009; Mainuddin et al., 2011b).

Although there is no precise data on the economic value of the LMB fisheries, the total value of inland fisheries in the entire Mekong River Basin (lower and upper) is US$3.9 – 7.0 bn per year, with the export of fish from the four LMB countries reaching about US$5.6 billion in 2008 (FAO, 2008; Mainuddin *et al*., 2011b; MRC, 2010a).

[INSERT FIGURE 24-3 HERE
Figure 24-3: Map of Lower Mekong Basin from Mekong River Commission Technical Paper No. 24, 2009 (MRC, 2009).]

Across the LMB countries observations of climate change over the past 30-50 years include (MRC, 2010b): an increase in temperature (for all riparian countries), rainfall increases in the wet season and decreases in the dry season (e.g. Thailand and Vietnam), intensified flood and drought events (e.g. Laos), and sea level rise (Vietnam's Mekong Delta). Agricultural output has been noticeably impacted by climate-related events. For example in Cambodia from 1996 to 2001, 70% of rice production loss occurred due to flooding and 20% due to droughts (MRC, 2009). In Laos, the areas of rain-fed rice fields destroyed by flooding were 55,172 ha per year on average between 1995 and 2005, accounting for 7% of the country's total cropland (MRC, 2009).Vietnam and Cambodia have been ranked as the countries most vulnerable to the impacts of climate change on their fisheries (Halls, 2009; Allison et al, 2009).

National level climate change adaptation plans have been formulated in all four riparian countries, but a commonly shared scientific forecast on possible future climate impacts as well as an integrated and coordinated adaptation program across the LMB does not exist to date. A range of individual studies that assess future LMB climate differ in the use of underlying climate models and emission scenarios. The existing studies however broadly share a set of expected *future climate changes* in the Mekong Basin (MRC, 2009): increases in temperature, wet season rainfall, and flooding frequency and duration along the Mekong River; decreases in dry season rainfall; sea level rise and salinity intrusion in the Mekong delta.

While significant uncertainties about both the magnitude and location-specific impacts of climate change in the LMB remain, it is expected that *vulnerabilities* will be exacerbated in three areas:

1) Changes in the spatial distribution of agricultural output rates and an overall reduction in food security (MRC, 2009; MRC, 2010b)
2) Loss of fertile land and population displacement in the Mekong river delta (MRC, 2009; MRC, 2010b)
3) Reduced fish survival, growth and reproductive success (UNEP, 2010)

A series of hydropower dams along the Mekong River and tributaries will change the hydrology in the LMB. Climate change, together with impacts from infrastructure development and land-use changes, will exacerbate these changes, likely resulting in disruption to fisheries, with a potential loss in both species diversity and production (Grumbine *et al*., 2012; Ziv *et al*., 2012; Wyatt and Baird, 2007).

To address the climate change related vulnerabilities, adaptation needs primarily arise in areas of improving water management, farming and fishing practices, as well as coastal protection (Johnson et al., 2010; Hoanh et al., 2003; Neo, 2012a). Transboundary initiatives to address climate change are driven by multiple actors, including the Mekong River Commission (MRC), the United Nations Development Program (UNDP) and the Asia Development Bank's Greater Mekong Sub-region programme (ADB GMS) among others (MRC, 2009; Lian and Bhullar, 2011). Despite these initiatives, strong inter-governmental policy development and planning coordination between ministries and different levels of government are largely absent, which has adversely affected the development and implementation of appropriate large scale adaptation strategies (Lian and Bhullar, 2011).

Key challenges and barriers for effective future transboundary adaptation planning and management include*:*

- Lack of a commonly shared scientific forecast on possible future climate impacts across LMB countries as the basis for transboundary adaptation planning (MRC, 2009)
- Sub-optimal coordination among adaptation stakeholders and sharing of best practices across countries (MRC, 2009)
- Insufficient mainstreaming of climate change adaptation into the broader policy frameworks of the national governments in all the four LMB countries (MRC, 2009; Lian and Bhullar, 2011)

- Insufficient integration of transboundary policy recommendations into national climate change plans and policies (Kranz *et al*., 2010)

A stock-take study on the state-of-adaptation practice in the LMB was concluded recently (Ding, 2012; Neo, 2012b; Schaffer and Ding, 2012), showing that only 11% (= 45) projects out of a total of 417 climate change related projects were truly adaptation efforts. Of these 45 projects around 60% are targeting agriculture sectors and rural communities. The stock-take exercise found that no programmatic adaptation approaches were in place, but adaptation practice rather occurred on a project-by-project basis, with single country projects accounting for 89% of all adaptation projects in the LMB. The portfolios of these 45 adaptation projects are characterized by a broad range of actors that do not operate under a coordinated framework. Projects are rather reactive in nature, being developed in response to extreme local weather events or observed water shortages and lack elements of forward-looking strategic and anticipatory planning of expected future climate changes. The private sector is not involved in any adaptation project. Overall adaptation funding and capacity levels to scale up adaptation are limited.

The above study also developed a framework to identify 'successful' climate change adaptation projects in the LMB. Applying this framework to the identified 45 projects, 5 were characterized as successful and documented via case studies (Panyakul, 2012; Khim, 2012; Roth and Grunbuhel, 2012; Mondal, 2012; Brown, 2012). These case studies address issues of building coping capacity for farmers (Panyakul, 2012) or building multi-scale adaptation capacity (Roth and Grunbuhel, 2012) among others.

Common features of these 'successful' projects are:

- Local stakeholder knowledge together with analytical baseline assessments form the basis of robust initial gap assessments and input to the adaptation project planning.
- Multiple local stakeholders, especially local communities, are actively engaged throughout the course of the project.
- The participatory process in each stage of the project develops ownership at the local level and facilitates adoption of good adaptation practices.

Recognizing the state of adaptation practice, funding and capacity development challenges, similarities of climate risk across the LMB countries, diversity of funding and implementing actors and national sovereignty needs, Schaffer and Ding (2012) propose a multi-stakeholder Regional Climate Change Adaptation Action Network approach to enhance the effectiveness and efficiency of future climate change action. This proposed approach follows the theory and successful examples of the Global Action Networks (GANs) (Waddell, 2005; Waddell and Khagram, 2007; WCD, 2000; GAVI, 2011) with the intent of scaling up and improving mainstreaming of adaptation in the LMB.

24.9.2. Tropical Peatlands in Southeast Asia

Tropical peatlands develop only in flat lowland regions with year-round rainfall and are most extensive in Southeast Asia, particularly on the islands of Sumatra, Borneo, and New Guinea (Posa *et al*., 2011). The largest areas are on coastal plains and river deltas, but peatlands can also develop inland on flat or gently convex areas between rivers. They eventually form dome-shaped structures less than 20 m deep that are above the local water table and fed only by rainwater. The modern peatlands of Southeast Asia are relatively young ecosystems, having started growth between the Late Glacial and Mid-Holocene, and peat accumulation appears to have ceased during the late Holocene in Central Kalimantan, possibly as a result of enhanced El Niño activity (Dommain *et al*., 2011). In recent times these peatlands covered around 250,000 km^2 and contained more than 65 Gt of carbon, with two-thirds of this in Indonesia (Page *et al*., 2011). Although traditionally viewed as species-poor, peat swamp forests provide an important habitat for much of the region's fauna, including orangutans and a high diversity of specialized freshwater fish (Posa *et al*., 2011).

Southeast Asian peatland ecosystems were largely intact in 1970 but have been massively impacted over the last 20 years, as a result of logging and conversion to oil palm and pulpwood (Acacia spp.) plantations (Murdiyarso *et al*., 2010). Between 1990 and 2010, forest cover on the peatlands of Peninsular Malaysia, Sumatra and Borneo fell from

77% to 36%, to be replaced by industrial plantations of unknown sustainability and degraded areas covered in ferns, grasses and shrubs (Miettinen *et al*., 2011a). Draining the peat leads to shrinkage and microbial decomposition, and makes the peat itself highly flammable, so the degraded peatlands have become globally significant carbon sources, particular during ENSO-associated droughts (Miettinen *et al*., 2011b; Page *et al*., 2011). Pressures for peatland conversion continue despite these concerns. Tropical peatlands will be very vulnerable to any reduction in rainfall and/or increase in rainfall seasonality over the coming decades, since dry periods lead to lower water tables, enhanced peat decomposition, and greater susceptibility to fire (Page *et al*., 2011). On the other hand, the exceptionally high carbon content makes tropical peatlands a very attractive target for greenhouse gas mitigation projects involving the restoration of groundwater levels (Jaenicke, 2011).

24.9.3. Glaciers of Central Asia and Siberia

The Altai, Pamir, and Tien Shan glaciers represent significant part of the Asian alpine cryosphere supplying up to 40% of water to the Aral, Balkhash and IssikKul Lakes, and Ob and Tarim rivers (Aizen *et al*., 1995; 1998; Surazakov *et al*., 2007). All rivers, except the Ob R. discharge water to central Asian arid endorheic basins populated with over 150 million people from Turkmenistan, Afghanistan, Uzbekistan, Tajikistan, Kyrgyzstan, Kazakhstan, Mongolia and Xinjiang and other north-western provinces of China, and Russia. The rate of glacier area change varies (see Table 24-9). In the last 50 years (1960-2009), central Asian glaciers lost on average 10% of their area and 15% of their ice volume [WG1 AR5 Ch. 4 Section 4.3]. The estimation was based on two sources of remote sensing data over Altai-Sayan, Tien Shan and Pamir: Corona KH Mapping Program (1968-1975), Landsat ETM+ and ASTER images (1999-2003) plus ALOS PRISM 2009. The Altai-Sayan glaciers were evaluated since 1960 using aerial photos, the Tien Shan and Pamir glaciers were computed from 1973-1975 (Aizen, 2011). The accuracy of the changes in glacier area was derived from an independent study of the Akshiirak massif in Tien Shan (Aizen *et al*., 2007). The comparison revealed a 0.7% error in total area, this error was due to differences in manual glacier digitizing and the spatial resolution of the images used in the two studies. Error in total volume of glacier loss is 0.21% (Aizen *et al*., 2006). For the period from 1973 to 2003 glacier ice melt increases total river runoff in heavy glacierized basins by 8% compared to the period from 1942 to 1972 (Aizen *et al*., 2007; Aizen, 2011). The studies on regional (Aizen *et al*., 1997; 2010) and local (Finaev, 2004) climate change in Central Asia revealed a positive trend in annual/warm season air temperatures with more significant rate of air temperature growth at low elevations. According to Giese et al., (2007) warming was not steady, there were three main thrusts: 30^{th}, 50^{th} and 70^{th}. Investigations on precipitation changes revealed negative trend over the SE Mongolia (Yatagai and Yasunari 1994), Northern China (Xu 2001) and inner /central Tien Shan (Aizen *et al*., 1997). Aizen *et al*. (2010), Finaev (2004) analyses declared that the average annual precipitation did not change significantly throughout central Asia, increasing only 0.9%. Areas with surplus precipitation were larger than areas with precipitation deficit, while the absolute values of positive differences were lower than the negative absolute values. Surplus precipitation occurred in winter and at low altitudes, in regions surrounding the Tien Shan mountains.

The glaciers of the Altai-Sayan mountains are located in the most northern periphery of the Central Asia mountain system at a south edge of the Arctic basin in Siberia (see Figure 24-4). Altai-Sayan glaciers lost on average 14% area from 1960s to 2009 (Surazakov *et al*., 2007; Shahgedanova *et al*., 2010; Aizen, 2011). The accelerated glacier melt and glacier area reduction in the Altai-Sayan was caused mainly by an increase of summer air temperatures by 1.03ºC for the last 50 years (Savelieva et al, 2000; Aizen et al., 2010). The elevation of glaciers in the Pamir mountains reaches 7,700 m a.s.l. (Muztagata-Kongur glacierized massifs). Pamir glaciers nourish the Amu Dariya River, the major Aral Sea water stream. During the last 50 years (1960-2009), the largest glacier area losses (up to 12-15%) have been observed in the western and south-western Pamir and the smallest in central and eastern Pamir (3- 5%) (Khromova *et al*., 2006; Aizen *et al*., 2010: 2011). The Fedchenko Glacier in central Pamir, which is the world's largest alpine glacier outside of the Polar regions (Kotlyakov, 1997; Aizen, 2011; Lambrecht *et al*., 2013) (72 km long, 714 km^2 area, and 900 m max ice thickness) retreated 755 m between 1958 and 2009, losing only 2 km^2. The Tien Shan glaciers are located in the largest mountain system in central Asia, stretching 2000 km from west to east. The Tien Shan glaciers are the major sources of water for Balkhash and IssikKul lakes, and the Sir Darya and Tarim rivers. Summer precipitation decreased by 10% and the Tien Shan glaciers lost 8.5% of their total area on average during the last 50 years. The largest glacier area lost is observed in the northern and western Tien Shan (14.3%) due to a decrease in annual precipitation (-20mm) at elevations above 3,000 m a.s.l. and increased air

temperatures by 0.44°C. Smaller glacier recessions have been observed in the inner and central Tien Shan (10% and 5% respectively). In central Tien Shan glacier recession is minimal due to high-elevated accumulation areas (up to 7,000 m a.s.l.). Thus, the central Tien Shan and central Pamir glaciers have been revealed as more stable glaciers to climate changes in central Asia (Aizen, 2011; Bamber, 2012; Jacob *et al*., 2012; Lambrecht *et al*., 2013). The eastern Tien Shan lost 12% of the total glacier area. On average, air temperatures increased by 0.8°C and precipitation decrease by 7% at the equilibrium line altitude (ELA) between the 1960s and 2009 in Tien Shan (Aizen, 2011).

[INSERT TABLE 24-9 HERE
Table 24-9: Recent publications on central Asia glaciers changes.]

[INSERT FIGURE 24-4 HERE
Figure 24-4: The difference in losses of glacier area in Altai-Sayan, Pamir and Tien Shan. Remote sensing data analysis from 1960s (Corona) through 2009 (Landsat, ASTER and Alos Prism).]

Simulation models forecast that significant glacier degradation will begin when (ELA) has increased by 600 m compared to the end of the 20th century (Aizen *et al.,* 2007). Then, the area covered by central Asian glaciers may shrink by 40% and the glacier volume by 60% of the current state. The IPCC WGI TAR in five AOGCMs under a range of forcing scenarios for 2100 compared to 1961 to 1990 predict, on average, an increase in regional air temperature of 2ºC to 8ºC (about 4ºC) and an increase in magnitude of precipitation of 0.8-1.2 (about 1.1 times) (Giorgi *et al*., 2001). If the air temperature increases to the greatest predicted value, i.e. by 8ºC, and precipitation increases to its maximum predicted value, i.e. by 1.24 times the current rate, then the model predicts a 970 m increase in ELA and the number of Tien Shan glaciers, glacier covered areas, and glacier volume are predicted to shrink correspondingly by 94%, 69%, and 75% of the current state. However, under the threshold predicted conditions, if air temperature increases by 8ºC and precipitation decreases to the minimum predicted value, i.e. by 0.84 times the current rate, then current glaciations will disappear. If air temperature increases to the minimum predicted value, i.e. by 2ºC, and if precipitation increases to the maximum predicted value 1.24 times the current value, then the simulation model predicts almost no changes in the number of glaciers, glacier covered area (GCA), and glacier volume, while glacier runoff will increase by 1.25 times of the current value (Aizen *et al.,* 2007).

Further changes in glacier water resources availability will bring the CA closer to a tipping point of an irreversible ecological and socio-economical collapse, significantly contribute to progressive droughts and land degradation. Inflowing water discharges only through seepage or evaporation without glacier/snow transition, eventually develop saline water, many lakes will contract and the ecosystems will disrupt. In basins with small glacierized areas, the disappearance of small glaciers has already led to a decline in river discharge, strongly affecting downstream agriculture and settlements of the densely populated arid region [24.4.1].

The Altai and inner Tien Shan glaciers did not exist in the Bølling-Allerød (BP) and regenerated during the Young Dryas episode. Central Asian glaciers survived the warmest periods during the last 12,500 years, i.e., Holocene Thermal Maximum (circa 7,600BP), Medieval Climate Optimum, when mean air temperature was about 4.2ºC higher than modern, i.e. the annual average temperature in the last three decades. Since that, the mean air temperature should be at least 5ºC higher than modern (Aizen *et al*., 2013) to complete modern glacier disappearance (Aizen *et al.,* 2010).

24.9.4. Is the Aral Sea Dying?

The Aral Sea (see Figure 24-5) was a very large lake in Central Asia that was the fourth largest in area in the world before the 1960s (Letolle, 2008; Kostianoy and Kosarev, 2010). It is located in the Karakum and Kyzylkum deserts. Navigation and the fisheries (yearly catches of 44,000 tons) were developed there. The deltas of two major rivers of Central Asia, the Amudarya and the Syrdarya, that bring waters to the Aral Sea, were known for their fisheries, biodiversity, reed production, and muskrat rearing. The local population used to work in water infrastructure related spheres (Nihoul *et al.,* 2002; Zonn *et al.,* 2009).

[INSERT FIGURE 24-5 HERE
Figure 24-5: The satellite view of the Aral Sea acquired on 7 September 2012 from MODIS-Aqua. Image courtesy by A.G. Kostianoy (P.P. Shirshov Institute of Oceanology, Moscow, Russia) and D.M. Solovyov (Marine Hydrophysical Institute, Sevastopol, the Ukraine), based on the LAADS Web, NASA-Goddard Space Flight Center data (http://ladsweb.nascom.nasa.gov/). The red line indicates the Aral Sea coastline back in 1960. The yellow line indicates the border between Kazakhstan and Uzbekistan.]

Since 1960, the water resources of the Amudarya and Syrdarya rivers have been excessively used in order to increase irrigation of agricultural lands as well as to create artificial water reservoirs, which later proved to be irrational (Glantz, 1999; Kostianoy and Kosarev, 2010). Hence the water balance of the Aral Sea was disrupted, and irreversible changes in the regime of the sea occurred which later led to one of the "largest ecological disasters of the twentieth century" (Letolle and Mainguet, 1993; Micklin and Williams, 1996; Glantz, 1999). For the last fifty years a progressive desiccation of the Aral Sea and deterioration of its environment has been observed. During those years the sea surface shrunk from 66,100 km^2 (1961) to 10,400 km^2 (2008); the sea volume decreased to 110 km^3 from 1,066 km^3 (1961); the sea level fell by 24 m (in 1961 the maximum depth was 69 m); and its salinity (mineralization) increased from 10 to 116 p.p.t. in the western part and to 210 p.p.t. in the eastern part of the Large Aral Sea (Kostianoy and Wiseman, 2004; Zavialov, 2005; Kostianoy and Kosarev, 2010).

The ongoing Aral Sea desiccation and salinization have resulted in critical changes in its shape, physical and chemical state, and biodiversity. Related economic activities lost their importance. The consequences of the sea degradation represent a big threat to the quickly growing population in the Priaralie (from 14 m people in 1960 to 45 m in 2006) due to such factors as water quality loss, lack of fresh water, dust and salt storms, salinization of soils, various diseases, and regional climate change (Kostianoy and Kosarev, 2010).

Irrational use of waters of Amudarya and Syrdarya is not the only reason for the Aral Sea desiccation. Regional climate change (decrease in precipitation and increase in air temperature) also seems to play a significant role in this process. Assessments of the water amount precipitated over the Amudarya catchment area for the period between 1979 and 2001 showed a critical decrease from about 7.5 to 4.5 km^3 per month on average (Nezlin *et al.,* 2004). According to estimates of the IPCC AR4, the rise in the mean annual air temperature in the Aral region in 1960–2000 was 1^0C (IPCC, 2007; Lioubimtseva and Henebry, 2009). Thus, regional climate change significantly influenced the water balance of the Aral Sea in the past 30 years, leading to its "supplementary" desiccation in addition to irrational water use.

By 2012, the main progress in saving the Aral Sea was achieved only in the Kazakh part, with the Kokaral dam construction between the eastern part of the Large Aral Sea and the Small Aral Sea in August 2005 (Kostianoy and Kosarev, 2010). Today, the Small Aral Sea is slowly reviving and small fishery production is growing, while the Large Aral Sea keeps on disappearing. Since 2010, the former eastern part of the Large Aral Sea has been a wetland which is periodically filled with snowmelt and rain water and partly desiccated in the dry seasons. The western part of the Large Aral Sea, being a relatively narrow and deep lake, may slowly die in the absence of an external water supply (Kostianoy and Kosarev, 2010; Micklin, 2010; Breckle *et al.,* 2012; Kostianoy, 2012).

Frequently Asked Questions

FAQ 24.1: What will be the projected impact of climate change on freshwater resources in Asia by the 2050s?
Asia is a huge and diverse region, so both climate change and the impact on freshwater resources will vary greatly across it. Adequate water resources are particularly important for Asia because of the heavy dependence of the agricultural sector on precipitation, river runoff and groundwater. There is low confidence in the future climate projections of precipitation on a regional scale and thus in predictions of climate change impacts on water resources availability. However, water scarcity is expected to be a big challenge in many Asian regions because of increasing water demand from population growth and higher standards of living. Shrinkage of glaciers in central Asia is expected to increase due to climate warming, which will influence downstream river runoff in these regions. Better water management strategies are needed to ease water scarcity. Water saving technologies and changing to more drought tolerant crops have been found to be successful adaptation options in the region.

FAQ 24.2: How will climate change affect biodiversity and ecosystems in Asia?

Rising temperatures are already leading to changes in the timing of life-history events, including leafing, flowering and leaf fall in plants, and migration and breeding in animals, and these changes are expected to continue. Changes in temperature and, less predictably, rainfall will also lead to changes in the distributions of plants and animals, most dramatically in Northern Asia, where boreal forest and shrubs will expand into tundra, and evergreen conifers will invade deciduous larch forest. On mountains, species will move upslope. In much of Asia, however, fragmentation of natural ecosystems will limit the ability of species to track changes in climate, increasing the risk of extinctions. Impacts on inland waters will interact with a wide range of other human impacts, including dam construction and pollution, but are expected to have an overall negative impact on the biota. Negative impacts on coastal and marine biodiversity are likely in the tropics, with coral reefs particularly vulnerable to both warming and ocean acidification, and also for ice-dependent species in the Arctic.

FAQ 24.3: How is climate change affecting permafrost in Asia?

Permafrost (permanently frozen ground) has degraded in recent decades in Siberia, Mongolia, China and Central Asia, and it is projected that permafrost degradation during the 21st century will spread from the southern and low-altitude margins, advancing northwards and upwards. In the Asian Arctic, changes in permafrost and in storm wave energy, as a result of sea-level rise and retreating sea ice, make coasts more vulnerable to erosion. It is projected that rates of coastal erosion in Asian Arctic will increase during the 21st century.

FAQ 24.4: How will climate change affect food production and food security in Asia?

Climate change impacts on crop production will be generally negative for most crops in Asia. For rice, most simulation models show that higher temperatures will lead to lower rice yields as a result of a shorter growing period. However, some studies indicate that the CO_2 fertilization effect could lead to rice yield increases despite climate change. This uncertainty on the overall effects of climate change and CO_2 fertilization is also generally true for other crops such as wheat, sorghum, barley, and maize among others. The impacts of climate change specifically changes in temperature and precipitation regimes on food production and food security will vary within regions and countries, increasing yields for some areas (e.g. cereal production in north and east Kazakhstan) and decreasing yields for others (e.g. wheat in the Indo-Gangetic Plain of South Asia). There are many potential adaptation strategies, such as crop breeding, changing crop varieties, adjusting planting time, water management, diversification of crops and a host of indigenous practices.

FAQ 24.5: How will climate change affect human health in different parts of Asia?

More frequent and intense heatwaves will increase mortality and morbidity in vulnerable groups in urban areas. The transmission of infectious disease will be affected due to changes in air and water temperatures (such as cholera epidemics in coastal Bangladesh, and schistosomiasis in inland lakes in China) and altered rain patterns and water flows (e.g., affecting diarrheal outbreaks in rural children). Changes in the geographical distribution of vector-borne diseases will be most noted close to their distribution limits. Outbreaks of the vaccine-preventable Japanese encephalitis in the Himalayan region and malaria in India and Nepal have been linked to rainfall.

FAQ 24.6: Who are the people most at risk in Asia from climate change?

People living in low lying coastal zones and flood plains are probably most at risk from climate extremes in Asia, with vulnerability increased by rising sea-levels. Such areas are home to 50% of Asia's urban population. Asia has more than 90% of the global population exposed to tropical cyclones. Settlements on unstable slopes or landslide prone areas face increased likelihood of rainfall induced landslides. Rural poverty in parts of Asia could be exacerbated due to negative climate change impacts on the rice crop and increase in food price and cost of living. Urban population growth will lead to urban land-use and land-cover changes and in turn will have impacts on climate.

FAQ 24.7: What are the challenges in research on climate impacts, vulnerabilities and adaptation in Asia?

Because of its size and diversity, gaps in data are a bigger challenge for Asia than in other parts of the world. For example, trends in precipitation are less available than data on trends in temperature, data on observed climate change and changes in extreme climate events does not cover most Asian regions. For freshwater resources, new models of future rainfall changes, developing of water managing strategies and study on water saving technologies

are needed. Biodiversity data and data on biome boundaries shift are incomplete, and long-term monitoring, especially in protected areas is needed to fill these gaps. Studies on agricultural sector and appropriate adaptation options, on social-economic and institutional dimension, on urban settlements and industry should also be given priority. A particular challenge is to assess how the comprehensive economic, social and cultural transformation processes happening in most parts of Asia will influence future dynamics in vulnerability patterns and adaptive capacity of different countries, economic sectors and social groups.

Cross-Chapter Box

Box CC-TC. Case Study Building Long Term Resilience from Tropical Cyclone Disasters

[Yoshiki Saito (Japan), Kathleen McInnes (Australia)]

Tropical cyclones (also referred to as hurricanes and typhoons in some regions) cause powerful winds, torrential rains, high waves and storm surge, all of which can have major impacts on society and ecosystems. For example, Bangladesh and India account for 86% of mortality from tropical cyclones (Murray *et al*., 2012), which is mainly due to the rarest and most severe storm categories (i.e. Categories 3, 4, and 5).

About 90 tropical cyclones occur globally each year (Seneviratne et al, 2012) although interannual variability is large. Changes in observing techniques particularly after the introduction of satellites in the late 1970s, confounds the assessment of trends in tropical cyclone frequencies and intensities. Therefore, SREX concluded that there is *low confidence* that any observed long-term (i.e. 40 years or more) increases in tropical cyclone activity are robust, after accounting for past changes in observing capability (Seneviratne, *et al.,* 2012; Chapter 2). There is also *low confidence* in the detection and attribution of century scale trends in tropical cyclones. Future changes to tropical cyclones arising from climate change are *likely* to vary by region. This is because there is *medium confidence* that for certain regions, shorter-term forcing by natural and anthropogenic aerosols has had a measurable effect on tropical cyclones. Tropical cyclone frequency is *likely* to decrease or remain unchanged over the 21st century, while intensity (i.e. maximum wind speed and rainfall rates) is *likely* to increase. Regionally specific projections have *lower confidencelower confidence* (see WG1 Box 14.2).

Longer term impacts from tropical cyclones includes salinisation of coastal soils and water supplies and subsequent food and water security issues from the associated storm surge and waves (Terry and Chui, 2012). However, preparation for extreme tropical cyclone events through improved governance and development to reduce their impacts provides an avenue for building resilience to longer term changes associated with climate change.

Densely populated Asian deltas are particularly vulnerable to tropical cyclones due to their large population density in expanding urban areas (Nicholls *et al*., 2007). Extreme cyclones in Asia since 1970 caused over 0.5 million fatalities (Murray *et al*., 2012) e.g., cyclones Bhola in 1970, Gorky in 1991, Thelma in 1998, Gujarat in 1998, Orissa in 1999, Sidr in 2007, and Nargis in 2008. Tropical cyclone Nargis hit Myanmar on 2 May 2008 and caused over 138,000 fatalities. Several-meter high storm surges widely flooded densely populated coastal areas of the Irrawaddy Delta and surrounding areas (Revenga *et al*., 2003; Brakenridge *et al*., 2012). The flooded areas were captured by a NASA MODIS image on 5 May 2008 (Figure TC-1).

[INSERT FIGURE TC-1 HERE
Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. (From Brakenridge *et al*., 2012).]

Murray *et al*. (2012) compared the response to cyclone Sidr in Bangladesh in 2007 and Nargs in Myanmar in 2008 and demonstrated how disaster risk reduction methods could be successfully applied to climate change adaptation (Murray et al, 2012). Sidr, despite being of similar strength to Nargis, caused far fewer fatalities (3,400 compared to over 138000) and this was attributed to advancement in preparedness and response in Bangladesh through experience in previous cyclones such as Bhola and Gorky. The responses included the construction of multi-storied cyclone shelters, improvement of forecasting and warning capacity, establishing a coastal volunteer network, and

coastal reforestation of mangroves. Birkmann and Teichman, (2010) caution that while the combination of risk reduction and climate change adaptation strategies may be desirable, different spatial and temporal scales, norm systems, and knowledge types and sources between the two goals can confound their effective combination.

Table 24-1: The 51 countries/regions in the six sub-regions of Asia.

Sub-region	Countries/Regions	
Central Asia (5)	• Kazakhstan • Kyrgyzstan • Tajikistan	• Turkmenistan • Uzbekistan
East Asia (7)	• China, Hong Kong Special Administrative Region (Hong Kong) • China, Macao Special Administrative Region • Japan	• North Korea • People's Republic of China (China) • South Korea • Taiwan Province of China (Taiwan)
North Asia (2)	• Mongolia	• Russia (East of Urals)
South Asia (8)	• Afghanistan • Bangladesh • Bhutan • India	• Maldives • Nepal • Pakistan • Sri Lanka
Southeast Asia (12)	• Brunei • Indonesia • Lao People's Democratic • Malaysia • Myanmar • Papua New Guinea	• The Philippines • Republic Cambodia • Singapore • Thailand • Timor-Leste • Vietnam
West Asia (17)	• Armenia • Azerbaijan • Bahrain • Georgia • Iran • Iraq • Israel • Jordan	• Kuwait • Lebanon • Occupied Palestinian Territory • Oman • Qatar • Saudi Arabia • Syria • United Arab Emirates • Yemen

Table 24-2: Summary of key observed past and present annual mean temperature trends in Asian countries/regions.

Sub-region	Countries/Regions	Unit	Change (Period)	Reference
Central Asia	Kazakhstan	°C/10y	+0.31 (1936-2005)	Kryukova *et al*., 2009
	Kyrgyzstan	°C	+1.6 (1901-2000)	Iliasov *et al*., 2003
	Tajikistan	°C/10y	+0.1 to +0.2 (1940-2005)	Karimov *et al*., 2008
East Asia	Hong Kong	°C/10y	+0.12 (1885-2008), +0.16 (1947-2008), +0.27 (1979-2008)	Ginn *et al*., 2009
	Japan	°C/100y	+1.15 (1898-2010)	JMA, 2011
	China	°C/10y	0.09±0.017 (1900-2006), 0.26±0.032 (1954-2006), 0.45±0.13 (1979-2006)	Li *et al*., 2010
		°C/10y	+0.03 to +0.120 (1906-2005), +0.03 to +0.120 (1908-2007)	Ren *et al*., 2012
	South Korea	°C	+1.87 (1908-2008), +1.37 (1954-2008), +1.44 (1969-2008)	Kim *et al*., 2010
	Taiwan	°C/10y	+0.14 (1911-2009), +0.19 (1959-2009), +0.29 (1979-2009)	Hsu *et al*., 2011
North Asia	Mongolia	°C	+2.14 (1940-2005)	Dagvadorj *et al*., 2009
	Russia	°C	+1.29 (1907-2006), +1.33 (1976-2006)	Anisimov *et al*., 2008
South Asia	Afghanistan	°C	+0.6 (1960-2008)	Savage *et al.*, 2009
		°C/10y	+0.13 (1960-2008)	
	Bangladesh	°C/10y	+0.097 (1958-2007)	Shahid, 2010
	India	°C	+0.56 (1901-2009)	Attri and Tyagi, 2010
		°C/100y	+0.68 (1880-2000)	Lal, 2003
		°C/y	+0.0056 (1948-2008)	Ganguly, 2011
	Nepal	°C/y	+0.06 (1977-1994)	Shrestha *et al.*, 1999
	Pakistan	°C	+0.57 (1901-2000), +0.47±0.21 (1960-2007)	Chaudhry *et al.*, 2009
		°C/10y	+0.099 (1960-2007)	
	Sri Lanka	°C/y	+0.005 to +0.035 (1961-2000)	Iqbal, 2010
		°C/10y	+0.3 to +0.93 (1869-2007), +0.75 to +0.94 (1910-2007)	de Costa, 2008
Southeast Asia	The Philippines	°C	+0.648 (1951-2010)	PAGASA, 2011
		°C/y	+0.0108 (1951-2010)	
West Asia	Armenia	°C	+0.85 (1935-2007)	Gabrielyan *et al*., 2010
Tibetan Plateau		°C(°C/10y)	+1.8 (0.36/10y) (1961-2007)	Wang *et al*., 2008
		°C/10y	+0.447 (1962-2001)	Xu *et al*., 2008

Table 24-3: Summary of key observed past and present annual mean precipitation trends in Asian countries/regions.

Sub-region	Countries/Regions	Unit	Change (Period)	Reference
Central Asia	Kazakhstan	No definite national trend. (1936-2005)		Kryukova *et al.*, 2009
	Kyrgyzstan	mm	+23 (+6%) (1901-2000)	Iliasov *et al.*, 2003
	Tajikistan *plain region	%	+8 (insignificant) (1940-2005)	Karimov *et al.*, 2008
	*mountainos region	%	-3 (insignificant) (1940-2005)	Karimov *et al.*, 2008
	Turkmenistan	mm/10y	+12 (1931-95)	MNPT, 2000
East Asia	Hong Kong	mm/10y	+25 (1885-2008)	Ginn *et al*., 2009
	Japan	No clear trend		MEXT *et al*., 2009
	South Korea	%	+5.6 (2001-2008)	Kim *et al*., 2010
North Asia	Mongolia	mm/y	-0.1 to -2.0 (1940-2005)	Dagvadorj *et al*., 2009
	Russia	mm/10y	+7.2 (1976-2006)	Anisimov *et al*., 2008
South Asia	Afghanistan	mm/m	-0.5 (1960-2008)	Savage *et al*., 2009
		%/10y	-2 (1960-2008)	
	Bangladesh	mm/y	+5.53 (1958-2007)	Shahid, 2010
	India	No significant national trend (1901-2009)		Attri and Tyagi, 2010
	Pakistan	mm	+61 (1901-2007), -156 (1901-54), +35 (1955-2007)	Chaudhry *et al*., 2009
	Sri Lanka	mm/y	-1.55 to -19.06 (1961-2000)	Iqbal, 2010
Southeast Asia	Indonesia *Brontas Catchment	mm/y	-1.23 to -24.25 (1955-2005)	Aldrian and Djamil, 2008
West Asia	Armenia	%	-6 (1935-2007)	Gabrielyan *et al*., 2010
Tibetan Plateau		mm/y	+0.614	Xu *et al.*, 2008

Table 24-4: Summary of projected changes for a variety of climate parameters [WG1 AR5 SOD Ch. 14].

Sub-region	T/P	Projected changes
Central and North [AR5 WGI SOD 14.7.8]	T	Central: Similar warming magnitude in winter and summer. Northern: A stronger warming trend during winter.
	P	Central: Less certain Northern: *Very likely* increase. Central and Northern: *Likely* increase of extremes
East [AR5 WGI SOD 14.7.9]	T	*Very likely* increase by end of 21st C., more in summer than in winter. *Virtually certain* increase significantly over East Asia by end of 21st C., with larger magnitude over northern China and in winter (high confidence).
	P	Decrease mainly in winter, since there is very little precipitation in summer under present-day conditions. *Likely* increase of East Asian summer monsoon intensity throughout 21st C. and of summer precipitation over whole of East Asia (medium confidence) *Likely* increase over Yangtze River Valley, Korean peninsula and Japan during Meiyu-Changma-Baiu season in May-July. *Very likely* increase of extremes over most of southeastern China in all seasons, and over Japan in summer.
West and South [AR5 WGI SOD 14.7.10]	T	West and South: *Virtually certain* increase (high confidence)
	P	West and South: 'Wet gets wetter and dry becomes drier' but with large uncertainties West: *Likely* less precipitation in April to September half year (low to medium confidence) South: *Likely* more precipitation than at present (low to medium confidence)
Southeast [AR5 WGI SOD 14.7.11]	T	*Very likely* continuous warming through 21st C. (high confidence). *Likely* substantial sub-regional differences *Very likely* greater increase at night than during the day for all seasons *Very likely* continuous increase in hot days and warm nights, and decline in cooler weather.
	P	*Likely* averaged increase across the region with strong geographical variations (medium confidence)
T: Temperature, P: Precipitation		

Table 24-5: Summary of key observed past and present climate change impacts in Asia.

Sub-Region	Countries/Regions (Area)	***Parameters:*** Observed changes	Period	References
Central Asia	Kazakhstan (Steppe region in north)	***Normalized Difference Vegetation Index (NDVI):*** Decline (browning)	1982-2008	De Jong *et al.*, 2012
	Kazakhstan (Northern Tien Shan Mountains)	***Permafrost temperature at depths of 14-25 m:*** +0.3 to +0.6°C	1974-2004	Marchenko *et al.*, 2007; Zhao *et al.*, 2010
		Active layer thickness: +23%		
	Uzbekistan (Zerafshan River Basin)	***Water monthly discharge:*** Significant increases in spring and decreases in summer	1923-2006	Olsson *et al.*, 2010
	Kazakhstan, Uzbekistan, Kyrgyzstan (Main lakes)	***Surface area change:*** -49.62% (Aral Sea), -75.7% (Balk hash) , -2.61% (Ebinur), -8.37% (Issyk-Kul) +5.85% (Zaysan), -9.18% (Bosten)	1975-2007	Bai *et al.*, 2012
East Asia	Japan (Upper part of Kurobe Dam, Toyama)	***Runoff:*** Decreased by 40mm, slightly decreased and more in winter and spring, less in summer	1974-2004	Shinohara *et al.*, 2009
	Japan (Multiple sites)	***Spring leafing and flowering:*** Earlier by < 3 days per decade	Last 60 years	Ogawa-Onishi & Berry, 2013
		Changes in species distributions: Northwards by < 126 km per decade	Last 50-70 years	
	Japan (Seas around Japan)	***Changes in species distributions:*** Northwards expansion of fish, corals and algae.	Recent decades	Nagai *et al.*, 2011; Yamano *et al.*, 2011; Tian *et al.*, 2012.
	China (Shiyang River basin)	***Streamflow:*** Five of eight catchments showing significant decreasing trends	1950-2005	Ma *et al.*, 2008
	China (Dongjiang River)	***Runoff:*** Not significant change. Clear increased trend at two of three stations in low-flow period	1956-2000	Liu *et al.*, 2010a
	China (Tarim River Basin)	***Streamflow:*** Three of four river with increasing streamflow except Akesu River	1960-2005	Zhang *et al.*, 2010
		Mainstreams runoff: Decreased by 41.59% (1970s), 63.77% (1980s), 75.15% (1990s)	1957-2003	Hao *et al.*, 2008
		Runoff: In 1990s runoff from headwaters of Aksu and Yarkand River increased by 10.9%	1955-2000	Chen *et al.*, 2007b
	China (Baimashi Basin)	***Runoff:*** Decreased by 1.88% per year, decreasing from 1960s	1950-2000	Wang *et al.*, 2010
	China (Upper reaches of Tarim River Basin)	***Runoff:*** Aksu River showed a significant increasing trend with 10.9%. Three of four rivers showed an increase trend with one showed subtle reduction	1958-2004	Yaning *et al.*, 2009
	China (Laohahe Basin)	***Runoff:*** Runoff in 1980-2008 decreased by 36% compared with 1964-1979	1964-2008	Jiang *et al.*, 2011
	China (Hun-Tai River Basin)	***Streamflow:*** Downward trends	1961-2006	Zhang *et al.*, 2011
	China (Kaidu River Basin)	***Runoff:*** Increasing with rate of 8.4mm/decade; 1994-2009 increased 26.4% compared to 1960-1993	1960-2009	Chen *et al.*, 2012
	China (Haihe River Basin)	***Runoff:*** Significant downward trends	1957-2000	Wang *et al.*, 2012
	China (Pearl River, Yangtze River, Yellow River, Liao River, Songhua River)	***Runoff:*** Increased by 10% (Pearl River), had little change (Yangtze River), decreased by 80% (Yellow River), decreased by 54% (Liao River), decreased by 14% (Songhua River)	1951-2000	Xu, K. H. *et al.*, 2010
	China (Qinghai-Tibetan Plateau)	***Active layer thickness along Qinghai-Tibetan Highway:*** Mean rate of +7.5 cm/year	1995- 2007	Wu & Zhang, 2010
		Position of lower altitudinal limit of permafrost in north: Moved up by 25 m	Last 30 years	Cheng & Wu, 2007; Li *et al.*, 2008
		Position of lower altitudinal limit of permafrost in south: Moved up by 50-80 m	Last 20 years	
		Total area of glaciers of QTP and surrounding areas: Decreased by c. 9%, from 13363 ± 668 km^2 to 1213 ± 607 km^2	1970s-2000s	Yao *et al*., 2012
	China (Whole country)	***Start of plant growth in spring:*** Earlier start by 2.9 days per decade	Last 30 years	Ma and Zhou, 2012
	China	***Rice yield*****:** Positive correlation to temperature.	1981-2005	Zhang *et al*., 2010
	Taiwan (Mountains)	***Plant distributions:*** Upper limits shifted upwards by 3.6 m per year	1906-2006	Jump *et al.*, 2012
North Asia	Mongolia (Kherlen River Basin)	***Underground water storage:*** No evidence for long-term storage change	1947-2006	Brutsaert, W. *et al.*, 2008
	Mongolia (Khentey Mountains)	***Growth of Siberian larch forest in forest-steppe ecotone:*** a. Tree-ring analysis shows a decreasing annual increment. b. Regeneration of larch decreased	1940s -2010	Dulamsuren *et al.*, 2010a; 2010b
	Mongolia (Hovsgol Mountain region)	***Mean annual ground temperature at 10 m depth:*** Increased on average by 0.02-0.03°C/year	Last 10-40 years	Sharkhuu *et al.*, 2008; Zhao *et al.*, 2010
	Mongolia (Hangai and Khentei Mountain regions)	***Mean annual ground temperature at 10 m depth:*** Increased on average by 0.01-0.02°C/year	Last 10-40 years	Sharkhuu *et al.*, 2008; Zhao *et al.*, 2010

	Russia, East of Urals (Siberia)	***Forest-tundra ecotone:*** a. Larch stands crown closure, and larch invasion into tundra at a rate of 3-10 m/year. b. Shrub expansion in arctic tundra as result of an increase in shrub growth.	1970-2000	Kharuk *et al.*, 2006; Myers-Smith *et al*., 2011; Blok *et al*., 2011
		Distribution of dark needle conifers (DNC), Siberian pine, spruce and fir: Invasion of DNC and birch into larch habitat	1980-2010	Kharuk *et al.*, 2010c, d; Osawa *et al.*, 2010; Lloyd *et al.*, 2011
		Permafrost temperature at zero annual amplitude: Warming of permafrost in most permafrost observatories in Asian Russia by 0.5-2°C.	1970s-1990s	Romanovsky *et al.*, 2008, with supplement; Romanovsky *et al.*, 2010
		Permafrost temperature at zero annual amplitude: No significant warming.	2000-2007	
		Permafrost temperature at zero annual amplitude: Warming of permafrost resumed at many locations predominantly near Arctic coasts.	2007-2008	
	Russia, East of Urals (Asian Arctic)	***Average erosion rate of coastline:*** 0.27-0.87 m/year	-	Lantuit *et al.*, 2012
	Russia, East of Urals (Ural Mountains)	***Area of glaciers:*** Decreased by 20-30% in total	1953-1981	Anisimov *et al.*, 2008
	Russia, East of Urals (Kodar Mountains)	***Area of glaciers:*** Exposed ice area (EIA) declined by c. 44%	ca. 1963-2010	Stokes *et al*., 2013
		Area of glaciers: EIA declined by c. 40%, from 11.72 ± 0.72 km^2 to 7.01 ± 0.23 km^2	1995-2010	
	Russia, East of Urals (Suntar Khayata Range)	***Area of glaciers:*** Decreased by19.3%	Mid. 20th C.-2003	Ananicheva *et al*., 2005, 2006
	Russia, East of Urals (Chersky Range)	***Area of glaciers:*** Decreased by 28 %	1970-2003	Anisimov *et al*., 2008
	Russia, East of Urals (Kamchatka)	***Area of glaciers:*** Decreased for some glaciers, increased for others	Since Mid 19th C.	Anisimov *et al*., 2008
South Asia	India (Upper Indus Basin)	***Water stress:*** No strong evidence for marked reduction in water resources	1961-2004	Archer *et al*., 2010
	India (Headwater of Kosi River)	***Water resources:*** Reducion in groundwater recharge, 36% of springs have dried, heads of perennial streams have dried and water discharge in springs and streams have decreased considerably	1990-2010	Tiwari & Joshi, 2012
	India (Andaman Islands)	***Coral health:*** Mass bleaching	2010	Krishnan *et al.*, 2011
	Nepal (Himalayan region)	***Water resources:*** Significantly moving snowline		Karki *et al.* 2009;
	Nepal (Shorong, Khumbu, Langtang, Dhaulagiri, Kanchenjunga)	***River discharge:*** Decreasing trend in Karnali and Sapta Koshi; increasing trend in Narayani. No trend in southern rivers.	1970s-2000s	Shrestha & Aryal 2011
	Pakistan, India, Nepal, Bhutan (Himalayas)	***Start of plant growth in spring:*** Earlier start by 1.9 days per decade	1982-2006	Shrestha *et al.*, 2012
		Livelihoods: Leave farming due to repeated droughts	-	Kulkarni & Rao, 2008
Southeast Asia	Republic Cambodia	***Poverty:*** Loss of crops, income and fallows	-	Kulkarni & Rao, 2008
	Indonesia (Province of Papua)	***Area of mountain glaciers Puncak Jaya, Central Cordillera, New Guinea Island:*** Reduced from 19.3 km^2 to 7.3 km^2 (Mid 19th C.-1972), Reduced from 7.3 km^2 to 2.1 km^2 (1972-2002)	Mid 19th C. - 2002	Prentice & Glidden, 2010; Allison, 2011
	Malaysia (Mt Kinabalu, Sabah)	***Altitudinal distributions of moth species:*** Uphill shifts by average 83 m (upper) and 86 m (lower)	1965-2007	Chen *et al.*, 2011
	Indonesia, Malaysia, Singapore	***Coral health:*** Mass bleaching and subsequent mortality	2010	Guest *et al*., 2012
West Asia	Jordan	***Wheat and barley yield*****:** In 1999, total production and average yield for wheat and barley were lowest among years due low rainfall which was 30% of average.	1996-2006	Al-Bakri *et al*., 2010
	Azerbaijan, Georgia (Southern macroslope of Greater Caucasus Range)	***Area of glaciers:*** Decreased by 31.2% in total	1895-2000	Anisimov *et al*., 2008
	Iran, Iraq, Kuwait, Qatar, Saudi Arabia, UAE	***Coral health:*** Mass bleaching and subsequent mortality	1996-2012	Coles & Riegl, 2013
Kazakhstan, Kyrgyzstan, Tajikistan, China, Mongolia, Russia (East of Urals), Afghanistan (Altai-Sayan, Pamir, and Tien Shan Mountains)		***Area of glaciers:*** Decreased on average by 10%, accuracy of area loss estimate: 0.7%	1960-2009	Aizen, 2011; Aizen *et al.*, 2006, 2007
		Ice volume of glaciers: Decreased on average by15%, accuracy of volume loss estimate: 0.21%		
East and South Asia		***Poverty:*** Disproportionately impacts by climate related hazards	-	Kim, 2011
East and Southeast Asia (Mekong region)		***Livelihoods:*** Increased migration due to environmental (e.g. rapid onset disasters), social and economic reasons	-	Warner, 2010; Black *et al.*, 2011

Table 24-6: Summary of key future climate change impacts in Asia.

Sub-Region	Countries/Regions (Area)	***Parameters*: Projected impacts**	Scenario/GCM (RCM)/Period (Base year)	Reference
Central Asia	N. & E. Kazakhstan	***Crop yield (cereal):*** Benefit from longer growing season, warmer winters and slight increase in winter precipitation		Lioubimtseva & Henebry, 2009
	W. Turkmenistan & Uzbekistan	***Crop yield (cotton):*** Negative impacts by frequent droughts		
East Asia	Japan (Tohoku and Hokuriku)	***River discharge:*** 200% higher in Feb., 50-60% lower in May.	A1B/AGCM/2080-2099 (1980-99)	Sato, Y. *et al*., 2012
	Japan	***Rice transplanting date:*** Northward shift of isochrones of safe transplanting dates for rice seedlings.	A2/MRI-CGCM2 (RCM20) /2081-2100 (1971–2000)	Ohta & Kimura, 2007
	China (Tarim River Basin)	***Flow:*** Positive change 1.3-12.8% in BYBLK and 17.7-29.7% in DSK	A2, A1B, B1/18GCMs/2046-65 (1979-98)	Liu *et al*., 2011
	China (Poyang Lake)	***Annual catchment inflow:*** Increased by 2.9% (A1B) and 6.5% (B1), decreased by 5.2% (A2).	A1B, B1, A2/ ECHAM5/ 2011-50 (1961-2000)	Ye *et al*., 2011
	China (Qinghai-Tibet Plateau)	***Permafrost area:*** Decrease by <19% (20-50 years since 1996), Decrease by 58% (2099)	+1°C in air temp. in 30 years since 1996/HADCM2/20-50 years since 1996, 2099 (1996)	Results of Li & Cheng (1999) after Cheng & Wu (2007)
	China (Tibetan Plateau)	***Alpine vegetation:*** Most replaced by forest and shrubland	A1B/Pattern-scaled output of multiple models/2070-2099 (1931-1960)	Wang *et al*., 2013
	China (Huang-Hai Plain in northeast China)	***Winter wheat yield:*** Increase by 0.2 Mg/ha (2015-45), Increase by 0.8 Mg/ha (2070-99)	A2, B2/HadCM3/2015-45,2070-99 (1961-90)	Thomson *et al*., 2006
	China (Huang-Huai-Hai (3H) Plain)	***Wheat-maize relative yield change (RYC):*** a. +2ºC & +5ºC in temp., +15 & -30% in prec., 500 & 700 ppmv CO_2: Decreased on average by -10.33%. b. a. with CO_2 fertilization: +4.46±14.83% (2ºC), -5.78±25.82% (5ºC). Base year: 1996-2004.		Liu *et al*., 2010
	South Korea (Han, Nakdong, Gum, Sumjin, Youngsan River Basin)	***Runoff:*** Four major river basins decrease 10% by 2030	A2/ ECO-G (MM5)/ 2001-30, 2016-45 (1961-2001)	Chang *et al*., 2007
	South Korea	***Paddy irrigation requirements:*** Decrease by 1-8%	A2, B2/HadCM3(RCMs)/ 2010-2039, 2040-2069, 2070-2099 (1961-90)	Chung *et al*., 2011
		Volumetric irrigation demand: Decrease by 4-10%		
	South Korea (Soyang, Chungju, Daecheong Basins)	***Annual mean streamflow:*** Reduced by 7.6%	2×CO_2/YONU GCM (WGEN)/ 2031-50 (1961-80)	Kim *et al*., 2007
	China, Taiwan province (Upstream catchment of Shihmen reservoir)	***Runoff:*** Future runoff may be higher during wet season and lower during dry season.	A2, B2/CCSR, CGCM2, CSIRO, ECHAM4, GFDL, HADCM3/2010-39; 2040-69; 2070-99 (1973-2000)	Yu & Wang, 2009
	China (Taiwan province)	***Annual renewable water resource:*** Drop by 12.3%	A1B/JAM/MRI TL 959L60/2080-99 (1949-2000)	Tsai & Huang 2012; Li *et al*., 2010
		Water resource condition for Five levels: good (L1), good (L2), fair(L3), poor (L4), very poor (L5): No change in northern and eastern parts with L2; visibly deteriorate in southern part with L3 to L4; central part will be L4	A1B/ JAM/MRI TL 959L60/2080-99 (1979-98)	Tsai, et al., 2011
North Asia	Russia, East of Urals (Siberia)	***Tundra area:*** Decrease by 93% as result of boreal forest expansion	+1% GHG per year/HADCM3 (GGa1)/2090-2100 (1964)	Tchebakova *et al.*, 2010
		Steppe area: Increase by 27%		
	Russia, East of Urals (Asian Russia)	***Tundra area:*** Decrease by 3% as result of boreal forest expansion	+1°C in annual mean global surface temp./ECHAM4/OPYC3, HadCM3a, IAP RAS CM/Late 2030s - early 2050s (1961-90)	Golubyatnikov & Denisenko, 2007
		Steppe area: Decrease by < 65%		
	Russia, East of Urals (Asian Arctic)	***Coast recession rate:*** Increase by 1.5- to 2.6-fold	+2°C in annual mean global surface temp. over 21st C., /2100 (c. 2000)	Pavlidis *et al.*, 2007
	Russia, East of Urals (Arctic)	***Ice-dependent mammals*:** Population declines in some species	Various/Various/21st C.	Kovacs *et al*., 2011
	Russia (East of Urals)	***Frequency of shortfalls:*** +3-4 years/decade in 2070s	A2, B2/ECHAM, HadCM3/2070s (1961-90)	Alcamo *et al*., 2007
South Asia	India(All)	***Forests:*** 34-39% of forests to change forest type	A2, B2/HadRM3/2085 (1931-60)	Chaturvedi *et al*., 2011
	India (Indo-Gangetic Plains,	***Sorghum winter grain yield:*** Reduced by up to 7% by 2020, up to 11% by	A2a/HadCM3/2020, 2050, 2080 (1970-95)	Srivastava *et al*., 2010

	Indore, Hyderabad, Dharwad)	2050 and up to 32% by 2080		
	Pakistan(Swat & Chitral districts)	***Wheat yield:*** -7% & -24% (Swat district), +14% & -23% (Chitral district).	1.5 & 3°C in temp./ (1976-2000)	Hussain & Mudasser, 2007
Southeast Asia	Indonesia (Java & Bali)	***Date of rice planting:*** Shift with marked increase in probability of a 30-day delay in monsoon onset in 2050	A2, B1/Ensamble/2050 (1979-2004)	Naylor *et al*., 2007
West Asia	Iran (all)	***Deep aquifer recharge:*** Decreases by 50-100% in groundwater recharge in earstern	A1B; B1; A2/CGCM 3.1/2010-40, 2070-2100 (1980-2002)	Abbaspour *et al*., 2009
	Jordan (Upper Jordan; Wadi Faynan)	***Stream flows, flood flow and numbers:*** Decrease by 12%	A2/(HadRM3)/ 2071-2100 (1961–1990)	Wade *et al*., 2010
	Jordan (Yarmouk basin)	***Wheat and barley yield:*** a. Reduction of rainfall by 10-20%: - 4 to -8% (barley), -10 to -20% (wheat). b. Increase of rainfall by 10–20%: +3 to +5% (barley), +9 to +18% (wheat). c. Increase of air temp. by 1, 2, 3, 4°C: +14%, +28%, +38%, +46% (barley), +17%, +4%, +43%, +113% (wheat)	DSSAT/CSIROMK3, ECHAM5OM, HADGEM1/2050 (1960–2005)	Al-Bakri *et al*., 2010
Eastern Mediterranean and Middle East region		***Internal water resource:*** Decreases from 464 to 419 and 412km^3	A1B /HadCM3 (PRECIS)/2040-69, 2070-99 (1961-90)	Chenoweth *et al*., 2011
		Runoff: -9.5% & -10% (Tigris-Euphrates River), -22% & -30% (Jordan River)		
North Asia, East Asia, Central Asia	Asian Russia, China, Mongolia, Kazakhstan (Permafrost area in Asia)	***Permafrost degradation:*** Spread from southern and low-altitude margins, advancing northwards and upwards	Multiple scenarios/Multiple GCMs/21st C.	Multiple references, see section 24.4.2.3.
North, East Asia	Asian Russia, China (Siberia and Tibet)	***Permafrost distribution:*** Permafrost will remain only in Central and Eastern Siberia and in part of Tibet	A1B, A2/IAP RAS CM/Late 21st C.	Eliseev *et al.*, 2009
West, South, Southeast Asia (all countries with tropical coasts)		***Coral health:*** Large declines in structure and diversity	Several/Several/2050	Hoegh-Guldberg, 2011; Burke *et al*., 2011
Asia		***Poverty:*** Negative impact on rice crop, increase in food price and cost of living, increased poverty, projections for 2030 by GTAP Model under three scenarios resulting low, medium and high productivity		Hertel *et al*., 2010
Central, East, South, Southeast Asia (Tibet/Himalayas)		***Livelihoods:*** Loss of livelihoods to indigenous people from declining alpine biodiversity		Salick *et al*., 2009; Xu *et al*., 2009

Table 24-7: Summary of adaptation options for agriculture in Asia.

Crop	Country/ Regions	Recommended/ Potential Adaptation strategies	Benefits/ Co-Benefits	References
Wheat	General	Conservation agriculture (reductions in tillage, surface retention of adequate crop residues, and diversified, economically viable crop rotations)	Improve rural incomes and livelihoods by reducing production costs, managing agroecosystem productivity and diversity more sustainably, and minimizing unfavorable environmental impacts	Ortiz *et al.*, 2008
Wheat	Pakistan	Development of short duration and high yield varieties of wheat.	Can withstand climatic anomalies expected in future	Hussain & Mudasser 2007
Wheat	Indo- Gangetic Plains, India	Development of heat-tolerant wheat germplasm, as well as cultivars.	Better adapted to heat and conservation agriculture	Ortiz et al., 2008
Barley; wheat	Jordan	Soil water conservation. Selection of drought tolerant genotypes with shorter growing seasons.	Increase available water to crop	Al-Bakri *et al*., 2010
Sorghum	India	Changing variety and sowing date	Reduce impacts on monsoon sorghum to about 10%, 2% and 3% in 2020 scenario. Reduced impacts on winter crop to 1–2% in 2020, 3–8% in 2050 and 4–9% in 2080.	Srivastava *et al.*, 2010
Rice	Sri Lanka	Traditional approaches for resolving water stress, such as increasing water use efficiency, water harvesting and/or reducing cropped areas. Earlier planting and shorter duration varieties to avoid impacts of less rainfall in January and February.		De Silva *et al.*, 2007.
Rice	China	Shifts in planting dates and automatic application of irrigation and fertilization. Selection for more temperature-tolerant cultivars and later-maturing cultivars to take advantage of longer growing seasons		Tao *et al.*, 2008
Corn	China	Using high-temperature sensitive varieties Early planting, fixing variety growing duration, and late planting	Using high-temperature sensitive varieties, maize yield could averagely increase by 1.0-6.0%, 9.9-15.2%, and 4.1-5.6%, by adopting adaptation options of early planting, fixing variety growing duration, and late planting, respectively	Tao & Zhang, 2010
General	India	Water harvesting		Kelkar *et al*., 2008
General	South Asia	Increasing livestock production relative to crops Selection of crop varieties Livelihood diversification		Morton, 2007
General	Central Asia	Replacement of existing network of open irrigation canals by more efficient drip irrigation systems Development of early warning systems, such as drought forecast, pest and epidemic disease forecasts, and water quality monitoring systems.	Could significantly reduce evaporative water loss, while simultaneously improving crop productivity, reducing soil salinization, and decreasing risks of water contamination and transmission of vector-borne and waterborne diseases.	Lioubimtseva & Henebry, 2009
General	West Asia	Changing of cropping systems and patterns, switching from cereal-based systems to cereal–legumes and diversifying production systems into higher value and greater water use efficient options. Using supplementary irrigation systems, more efficient irrigation practices and adaptation and adoption of existing and new water harvesting technologies. Development of more drought and heat tolerant germplasm using traditional and participatory plant breeding methodologies and better predictions of extreme climatic events.		Thomas, 2008
General	Russia	Crop substitution Diversification of crops Expanding irrigated agricultural areas Strategic food reserves, Improving management, Monitoring and early warning systems, Food imports from abroad.		Alcamo *et al.*, ,2007,
General	Philippines	Crop diversification; change of crop varieties, use of water conservation pratices		Peras *et al.*, 2008; Lasco *et al.*, 2011
General	General	Cultivars with multiple resistance to insects and diseases		Sharma *et al.*, 2010

Table 24-8: Summary of adaptation options for securing livelihoods in Asia.

Aspect/ Issues	Country/ Regions	Recommended/ Potential Adaptation strategies	Benefits/ Co-Benefits	References
Delay and shortfall in rainfall	Indonesia	Access to credit and public works project	Able to protect food expenditure in the face of weather shocks	Skoufias *et al.*, 2011

Executive Summary

The regional climate is changing (***very high confidence***). The region continues to demonstrate long term trends toward higher surface air and sea-surface temperatures, more hot extremes and fewer cold extremes, and changed rainfall patterns. Over the past 50 years, increasing greenhouse gas concentrations have contributed to rising regional average temperature *(high confidence)* and changes to rainfall in far south-west Australia (*medium confidence*). [25.2, Table 25-1]

Warming is projected to continue through the 21st century (*virtually certain*) along with other changes in climate. Warming is expected to be associated with more frequent hot extremes and less frequent cold extremes (*high confidence*), and increasing extreme rainfall and flood risk in many locations (*medium confidence*). Annual average rainfall is expected to decrease in south-western Australia (*high confidence*) and elsewhere in southern Australia and the north-east South Island and northern and eastern North Island of New Zealand, and to increase in other parts of New Zealand (*medium confidence*). Tropical cyclones are projected to increase in intensity but decrease in numbers (*low confidence*), and fire weather is projected to increase in most of southern Australia (*high confidence*) and many parts of New Zealand (*medium confidence*). Regional sea level rise will *very likely* exceed the historical rate (1971-2010), consistent with global mean trends. [25.2, Table 25-1, Box 25-6, WGI 13.6]

Uncertainty in projected rainfall changes remains large for many parts of Australia and New Zealand, which creates significant challenges for adaptation. For example, projections for average annual runoff in far south-eastern Australia range from little change to a 40% decline for 2°C global warming. The dry end of these scenarios would have severe implications for agriculture, rural livelihoods, ecosystems and urban water supply, and would increase demands for transformative adaptation (*high confidence*). [25.2, 25.5.1, 25.6.1, 25.7.2, Box 25-2, Box 25-5]

Recent extreme climatic events show significant vulnerability of some ecosystems and many human systems to current climate variability (*very high confidence*), and the frequency and/or intensity of such events is projected to increase in many locations (*medium* to *high confidence*). For example, high sea surface temperatures have repeatedly bleached coral reefs in north-eastern Australia (since the late 1970s) and more recently in western Australia. Recent floods in Australia and New Zealand caused severe damage to infrastructure and settlements and 35 deaths in Queensland alone (2011); the Victorian heat wave (2009) increased heat-related morbidity and caused 374 excess deaths, and intense bushfires destroyed over 2,000 buildings and led to 173 deaths; widespread drought in south-east Australia (1997-2009) and many parts of New Zealand (2007-2009) resulted in economic losses (approximately A$7.4b in south-east Australia in 2002-03 and NZ$3.6b in direct and off-farm output in 2007-09) and mental health problems in some areas of Australia. [Table 25-1, 25.6.2, 25.8.1, Box 25-5, Box 25-6, Box 25-8]

Without adaptation, further changes in climate, atmospheric CO_2 and ocean pH are projected to affect water resources, coastal ecosystems, infrastructure, agriculture, and biodiversity substantially (*high confidence*). Freshwater resources are projected to decline in far south-west and far south-east mainland Australia (*high confidence*) and for rivers originating in the eastern and northern parts of New Zealand (*medium confidence*); rising sea levels and increasing heavy rainfall are projected to increase erosion and inundation, with consequent damages to many low-lying ecosystems, infrastructure and housing; rainfall changes and rising temperatures will shift agricultural production zones; and many endemic species will suffer from range contractions and some may face local or even global extinction. [25.5.1, 25.6.1, 25.6.2, 25.7.1, 25.7.2, 25.7.4, Box 25-1, Box 25-5, Box 25-8]

Some sectors in some locations have the potential to benefit from projected changes in climate and increasing atmospheric CO_2 (*high confidence*). Examples include reduced morbidity from winter illnesses and reduced energy demand for winter heating in New Zealand and southern parts of Australia, and forest growth in cooler regions except where soil nutrients or rainfall are limiting. Spring pasture growth in cooler regions would also increase and be beneficial for animal production if it can be utilized. [25.7.1, 25.7.2, 25.7.4, 25.8.1]

Adaptation is already occurring and adaptation planning is becoming embedded in planning processes, albeit mostly at the conceptual rather than implementation level (*high agreement, robust evidence*). Many solutions for reducing energy and water consumption in urban areas with co-benefits for climate change adaptation (e.g. greening cities and recycling water), are already being implemented. Planning for sea-level rise and, in Australia, reduced water availability, is becoming widely adopted, although implementation of specific policies remains piecemeal, subject to political changes, and open to legal challenges. [25.4, Box 25-1, Box 25-2, Box 25-9]

Adaptive capacity is generally high in many human systems, but implementation faces major constraints especially for transformative responses at local and community levels (*high confidence*). Efforts to understand and enhance adaptive capacity and adaptation processes have increased since AR4, particularly in Australia. Constraints on implementation arise from: uncertainty of projected impacts; limited financial and human resources to develop and implement effective policies and rules; limited integration of different levels of governance; lack of

binding guidance on principles and priorities; different values and beliefs relating to the existence of climate change, objects and places at risk; and, attitudes towards risk. [25.4, 25.10.3, Box 25-1]

Indigenous peoples in both Australia and New Zealand have higher than average exposure to climate change due to a heavy reliance on climate-sensitive primary industries and strong income and social connections to the natural environment, and face particular constraints to adaptation (*medium confidence*). Social status and representation, health, infrastructure and economic issues, and engagement with natural resource industries constrain adaptation and are only partly offset by intrinsic adaptive capacity (*high confidence*). Some proposed responses to climate change may provide economic opportunities, particularly in New Zealand related to forestry. Torres Strait communities are vulnerable even to small sea level rises (*high confidence*). [25.3, 25.8.2]

We identify eight *regional key risks* during the 21st century based on the severity of potential impacts for different levels of warming, uniqueness of the systems affected, and adaptation options (*high confidence*). These risks differ in the degree to which they can be managed via adaptation and mitigation, and some are more likely to be realized than others, but all warrant attention from a risk-management perspective.

- Some potential impacts can be delayed but now appear very difficult to avoid entirely, even with combined globally effective mitigation and planned adaptation:
  - ***significant change in community structure of coral reef systems in Australia***, driven by increasing sea-surface temperatures and ocean acidification; the natural ability of reefs to adapt to projected changes is limited [Box CC-CR, 25.6.2, 30.5]
  - ***loss of montane ecosystems and some endemic species in Australia***, driven by rising temperatures, increased fire risk and drying trends; fragmentation of landscapes, limited dispersal and evolutionary capacity limit adaptation options [25.6.1]
- Some impacts have the potential to be severe but can be moderated or delayed significantly by globally effective mitigation combined with adaptation, with an increasing need for transformative adaptation for greater rates and magnitude of change:
  - ***increased frequency and intensity of flood damage to settlements and infrastructure in Australia and New Zealand***, driven by increasing extreme rainfall although the amount of change remains uncertain; in many locations, continued reliance on increased protection alone would become progressively less feasible [Table 25-1, 25.4.2, 25.10.3, Box 25-8]
  - ***systematic constraints on water resource use in southern Australia***, driven by rising temperatures and reduced cool-season rainfall; integrated responses encompassing management of supply, recycling, water conservation and increased efficiency across all sectors are available but face implementation constraints [25.2, 25.5.1, Box 25-2]
  - ***increasing morbidity, mortality and infrastructure damages during heat waves in Australia***, resulting from increased frequency and magnitude of extreme temperatures; vulnerable populations include the elderly, children and those with existing chronic diseases; ageing trends and prevailing social dynamics constrain effectiveness of adaptation responses [25.8.1]
  - ***increased damages to ecosystems and settlements, economic losses and risks to human life from wildfires in most of southern Australia and many parts of New Zealand***, driven by drying trends and rising temperatures; building codes, design standards, local planning mechanisms and public education can assist with adaptation and are being implemented in regions that have experienced major events [25.2, Table 25-1, 25.6.1, 25.7.1, Box 25-6]
- Some potential impacts have a low or currently unknown probability but cannot be ruled out entirely even under mitigation scenarios; these impacts would present major challenges if realized:
  - ***widespread damages to coastal infrastructure and low-lying ecosystems in Australia and New Zealand* if *sea level rise exceeds 1m***; managed retreat is a long-term adaptation strategy for human systems but options for some natural ecosystems are limited due to the rapidity of change and lack of suitable space for inland migration. Risks from sea level rise *very likely* continue to increase beyond 2100 even if temperatures are stabilised. [AR5 *WGI 13.ES;* Box 25-1, Table 25-1, 25.4.2, 25.6.1-2]
  - ***significant reduction in food production in the Murray-Darling Basin, far south-eastern Australia and some eastern and northern areas of New Zealand* if *scenarios of severe drying are realised;*** more efficient water use, allocation and trading would increase the resilience of systems in the near term but

cannot prevent significant reductions in agricultural production and severe consequences for ecosystems and some rural communities at the dry end of the projected range [25.2, 25.5.1, 25.7.2, Box 25-5]

Significant synergies and trade-offs exist between alternative adaptation responses, and between mitigation and adaptation responses; interactions occur both within Australasia and between Australasia and the rest of the world (*very high confidence*). Increasing efforts to mitigate and adapt to climate change imply an increasing complexity of interactions, particularly at the intersections among water, energy and biodiversity, but tools to understand and manage these interactions remain limited. Flow-on effects from climate change impacts and responses outside Australasia have the potential to outweigh some of the direct impacts within the region, particularly economic impacts on trade-intensive sectors such as agriculture (*medium confidence*), but they remain amongst the least explored issues. [25.7.5, 25.9.1, 25.9.2, Box 25-10]

Understanding of future vulnerability of human and mixed human-natural systems to climate change remains limited due to incomplete consideration of socio-economic dimensions (*very high confidence*). Future vulnerability will depend on factors such as wealth and its distribution across society, patterns of ageing, access to technology and information, labour force participation, societal values, and mechanisms and institutions to resolve conflicts. These dimensions have received only limited attention and are rarely included in vulnerability assessments, and frameworks to integrate social and cultural dimensions of vulnerability with bio-physical impacts and economic losses are lacking. In addition, conclusions for New Zealand in many sectors, even for bio-physical impacts, are based on limited studies that often use a narrow set of assumptions, models and data and hence have not explored the full range of potential outcomes. [25.3, 25.4, 25.11]

25.1. Introduction and Major Conclusions from Previous Assessments

Australasia is defined here as lands, territories, offshore waters and oceanic islands of the exclusive economic zones of Australia and New Zealand. Both countries are relatively wealthy with export-led economies. Both have Westminster-style political systems and have a relatively recent history of non-indigenous settlement (Australia in the late 18th, New Zealand in the early 19th century). Both retain significant indigenous populations.

Principal findings from the IPCC Fourth Assessment Report (AR4) for the region were (Hennessy *et al*., 2007):

- Consistent with global trends, Australia and New Zealand had experienced warming of 0.4 to 0.7°C since 1950 with changed rainfall patterns and sea-level rise of about 70 mm across the region; there had also been a greater frequency and intensity of droughts and heat waves, reduced seasonal snow cover and glacial retreat.
- Impacts from recent climate changes were evident in increasing stresses on water supply and agriculture, and changed natural ecosystems; some adaptation had occurred in these sectors but vulnerability to extreme events such as fire, tropical cyclones, droughts, hail and floods remained high.
- The climate of the 21st century would be warmer (*virtually certain*), with changes in extreme events including more intense and frequent heat waves, fire, floods, storm surges and droughts but less frequent frost and snow (*high confidence*), reduced soil moisture in large parts of the Australian mainland and eastern New Zealand but more rain in western New Zealand (*medium confidence*).
- Significant advances had occurred in understanding future impacts on water, ecosystems, Indigenous people and health together with an increased focus on adaptation; potential impacts would be substantial without further adaptation, particularly for water security, coastal development, biodiversity, and major infrastructure, but impacts on agriculture and forestry would be variable across the region, including potential benefits in some areas.
- Vulnerability would increase mainly due to an increase in extreme events; human systems were considered to have a higher adaptive capacity than natural systems.
- Hotspots of high vulnerability by 2050 under a medium emissions scenario included:
  - significant loss of biodiversity in areas such as alpine regions, the Wet Tropics, the Australian south-west, Kakadu wetlands, coral reefs and sub-Antarctic islands;
  - water security problems in the Murray-Darling basin, south-western Australia and eastern New Zealand;
  - potentially large losses in areas of rapid coastal development in south-eastern Queensland and in New Zealand from Northland to the Bay of Plenty.

25.2. Observed and Projected Climate Change

Australasia exhibits a wide diversity of climates including moist tropical monsoonal, arid and moist temperate, including alpine conditions. Key climatic processes are the Asian-Australian monsoon and the southeast trade winds over northern Australia, and the subtropical high pressure belt and the mid-latitude storm tracks over southern Australia and New Zealand. Tropical cyclones also affect northern Australia, and, more rarely, the northernmost areas of New Zealand. Natural climatic variability is very high in the region, especially for rainfall and over Australia, with the El Nino-Southern Oscillation (ENSO) being the most important driver (McBride and Nicholls, 1983; Power *et al.*, 1998). The southern annular mode, Indian Ocean Dipole and the Pacific Decadal Oscillation are also important regional drivers (Thompson and Wallace, 2000; Cai *et al.*, 2009b). This variability poses particular challenges for detecting and projecting anthropogenic climate change and its impacts in the region. For example, changes in ENSO in response to anthropogenic climate change are uncertain (AR5 WGI Ch14) but could significantly influence rainfall and temperature extremes, droughts, fire danger, tropical cyclones, marine conditions and glacial mass balance.

Understanding of observed and projected climate change has received significant attention since AR4, particularly in Australia, with a focus on better understanding the causes of observed rainfall changes and more systematic analysis of projected changes from different models and approaches. Climatic extremes have also been a research focus. Table 25-1 presents an assessment of this body of research for observed trends and projected changes for a range of climatic variables (including extremes) relevant for regional impacts and adaptation, including examples of the magnitude of projected change where possible. Most studies are based on CMIP3 models and SRES scenarios, but CMIP5 model results are considered where available (see also AR5 WGI Chap 14 and Atlas, WGII Chapter 21).

The region has exhibited warming to the present (*very high confidence*) and is *virtually certain* to continue to do so (Table 25-1). Observed and CMIP5-modelled past and projected future annual average surface temperatures are shown in Figures 25-1 and 25-2. For further details see WGI Atlas, Figures AI.82-85.

Changes in precipitation have been observed with *very high confidence* in some areas, such as the autumn/winter decline since 1970 in south-western Australia and, since the 1990s, in south-eastern Australia, and over 1950-2004 increases in annual rainfall in the south and west of both islands of New Zealand with decreases elsewhere. Based on multiple lines of evidence, annual average rainfall is projected to decrease with at least *medium confidence* in southern Australia and in the north-east South Island and eastern and northern North Island of New Zealand, and increase in other parts of New Zealand. The direction and magnitude of rainfall change in eastern and northern Australia remains a key uncertainty (Table 25-1).

This pattern of projected rainfall change is reflected in CMIP5 model results (Figure 25-1; WGI Atlas Figures AI 86-87). Examples of the magnitude of projected annual change from 1990 to 2090 under RCP8.5 from CMIP5 are -2±21% in the Murray Darling Basin, -5±22% in Queensland and -20±13% in south-western Australia. Changes during winter and spring are more pronounced and consistent across models in many areas (see Figure 25-3), e.g. drying in the Murray Darling Basin (-16±22%, June to August) but an increase by 15% or more in the west and south of the South Island of New Zealand (Irving *et al.*, in press). Downscaled CMIP3 model projections for New Zealand indicate a stronger drying pattern in the south-east of the South Island and eastern and northern regions of the North Island in winter and spring (Reisinger *et al.*, 2010) than seen in the raw CMIP5 data; based on similar broader scale changes this pattern is expected to hold once CMIP5 data are also downscaled (Irving *et al.*, in press).

Other projected changes of at least *high confidence* include regional increases in sea surface temperature, the occurrence of hot days, extreme rainfall, mean and extreme sea level, fire danger in southern Australia, and decreases in cold days and snow extent and depth. Although changes to tropical cyclone occurrence and that of other severe storms are potentially important for future vulnerability, regional changes to these phenomena cannot be projected with at least *medium confidence* as yet.

[INSERT FIGURE 25-1 HERE
Figure 25-1: Observed and projected change in annual temperature and precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

[INSERT FIGURE 25-2 HERE
Figure 25-2: Observed and simulated variations in past and projected future annual average temperature over land areas of Australia (left) and New Zealand (right). Black lines show several estimates from measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Chapter 21.]

[INSERT FIGURE 25-3 HERE
Figure 25-3: Projected CMIP5 multi-model mean change in rainfall for 2080-2099 relative to 1980-1999, under RCP 8.5. Dots [carets] indicate where the models agree (>90% red; >67% black) that there will [will not] be a substantial increase (>10%) or decrease (< -10%). White areas indicate where the models agree (> 67%) that there will be a substantial change in rainfall (larger in magnitude than 10%) however <67% agree on the direction of this substantial change (Figure from Irving *et al*., in press).]

[INSERT TABLE 25-1 HERE
Table 25-1: Observed and projected changes in key climate variables, and (where assessed) the contribution of human activities to observed changes. For further relevant information see WGI Chapters 3, 6 (ocean changes, including acidification), 11, 12 (projections), 13 (sea level) and 14 (regional climate phenomena).]

25.3. Socio-Economic Trends Influencing Vulnerability and Adaptive Capacity

25.3.1. Economic, Demographic and Social Trends

The economies of Australia and New Zealand rely on natural resources, agriculture, minerals, manufacturing and tourism, but the relative importance of these sectors differs between the two countries. Agriculture and mineral/energy resources accounted, respectively, for 11% and 54% (Australia) and 56% and 5% (New Zealand) of the value of total exports in 2009/2010 (ABARES, 2010; Stats NZ, 2011c). Australia and New Zealand abstracted an estimated 930 and 940 m^3 of water per capita in 2007, with about half used for irrigation (OECD, 2011). Between 1970 and 2011, GDP grew by an average of 3.2% p.a. in Australia and 2.4% p.a. in New Zealand, with annual GDP per capita growth of 1.8% and 1.2%, respectively (Stats NZ, 2011a; ABS, 2012b; Stats NZ, 2012). GDP is projected to grow on average by 2.5-3.5% p.a. in Australia and about 1.9% p.a. in New Zealand to 2050 (Australian Treasury, 2010; Bell *et al*., 2010) subject to significant short-term fluctuations.

The populations of Australia and New Zealand are projected to grow significantly over at least the next several decades (*very high confidence*) due to immigration and changes in mortality and fertility (ABS, 2008; Stats NZ,

2011b); Australia's population from 22.4 million in 2011 to 31-43 million by 2056 and 34-62 million by 2101 (ABS, 2008); New Zealand's population from 4.4 million in 2011 to 4.8-6.7 million by 2061 (Stats NZ, 2011b). The number of people aged 65 and over is projected to double in the next two decades (Australian Treasury, 2010; Stats NZ, 2011b). More than 20% of Australian and New Zealand residents were born overseas (OECD, 2011). More than 85% of the Australasian population lives in urban areas and their satellite communities (Stats NZ, 2004; ABS, 2008), mostly in coastal areas (DCC, 2009; Stats NZ, 2010b). Urban concentration and depletion of remote rural areas is expected to continue (Mendham and Curtis, 2010; Stats NZ, 2010c), but some coastal non-urban spaces also face increasing development pressure (Freeman and Cheyne, 2008; Gurran, 2008).

Poverty rates and income inequality in New Zealand and Australia are in the upper half of OECD countries. Both measures increased significantly in New Zealand between the mid-1980s and mid-2000s (OECD, 2011). Measurement of poverty and inequality, however, is highly contested and anticipating future changes and effects on adaptive capacity remain difficult (Peace, 2001; Scutella *et al*., 2009).

Indigenous peoples constitute about 2% and 15% of the Australian and New Zealand populations, respectively, but are growing faster than the average and, in Australia, constitute a much higher percentage of the population in remote and very remote regions (ABS, 2009; Biddle and Taylor, 2009; ABS, 2010a; Stats NZ, 2010a). Indigenous peoples in both countries have lower than average life expectancy, income and education, implying that changes in socio-economic status and social inclusion could strongly influence their future adaptive capacity (25.8.2).

25.3.2. Use and Relevance of Socio-Economic Scenarios in Adaptive Capacity/Vulnerability Assessments

Demographic, economic and socio-cultural trends influence the vulnerability and adaptive capacity of individuals and communities (see Chapters 2, 11-13, 16). A limited but growing number of studies in Australasia have attempted to incorporate such information, e.g. changes in the number of people and percentage of elderly people at risk (Preston *et al*., 2008; Baum *et al*., 2009; Preston and Stafford-Smith, 2009; Roiko *et al*., 2012), the density of urban settlements and exposed infrastructure (Preston and Jones, 2008; Preston *et al*., 2008; Baynes *et al*., 2012), population-driven pressures on water demand (CSIRO, 2009a), and economic and social factors affecting individual coping, planning and recovery capacity (Dwyer *et al*., 2004; Khan, 2012; Khan *et al*., 2012; Roiko *et al*., 2012).

Socio-economic considerations are used increasingly to understand adaptive capacity of communities (Preston *et al*., 2008; Smith *et al*., 2008; Fitzsimons *et al*., 2010; Soste, 2010; Brunckhorst *et al*., 2011; Cradock-Henry, in press) and to construct scenarios to help build regional planning capacity (CSIRO, 2006; Frame *et al*., 2007; Pride *et al*., 2010; Pettit *et al*., 2011; Taylor *et al*., 2011). Such scenarios, however, are only beginning to be used to quantify vulnerability to climate change (except e.g. Bohensky *et al*., 2011; Baynes *et al*., 2012; Low Choy *et al*., 2012).

Apart from these emerging efforts, most vulnerability studies from Australasia make no or very limited use of socio-economic factors, consider only current conditions, and/or rely on postulated correlations between generic socio-economic indicators and climate change vulnerability. In many cases this limits confidence in conclusions regarding future vulnerability to climate change and adaptive capacity of human and mixed natural-human systems.

25.4. Cross-Sectoral Adaptation: Approaches, Effectiveness, and Constraints

25.4.1. Frameworks, Governance, and Institutional Arrangements

Adaptation to climate change is motivated by experienced and expected changes in climate but also influenced by non-climate pressures, social and cultural values, perceptions of risk, and economic and political considerations. Adaptation responses depend heavily on institutional and governance arrangements that enable decision-makers to consider climate change information (see Chapters 2, 14, 15, 16, 20; Downing, 2012).

Responsibility for development and implementation of adaptation policy in Australasia is largely devolved to local governments and, in Australia, to State governments and Natural Resource Management bodies. Federal/central

government supports adaptation mostly via provision of information, tools, legislation, policy guidance and (in Australia) support for pilot projects. A standard risk management paradigm has been promoted to embed adaptation into decision-making practices (AGO, 2006; MfE, 2008d; Standards Australia, 2012).

The Council of Australian Governments agreed a national adaptation policy framework in 2007 (COAG, 2007). This included establishing the collaborative National Climate Change Adaptation Research Facility (NCCARF) in 2008, which complements CSIRO's Climate Adaptation Flagship. The federal government supported a first-pass national coastal risk assessment (DCC, 2009; DCCEE, 2011), and reports addressing impacts and management options for natural and managed landscapes (Campbell, 2008; Steffen *et al*., 2009; Dunlop *et al*., 2012), National and World Heritage areas (ANU, 2009; BMT WBM, 2011), and indigenous and urban communities (Green *et al*., 2009; Norman, 2010). In New Zealand, the central government updated and expanded tools to support impact assessments and adaptation responses consistent with regulatory requirements (MfE, 2008a, d, c, 2010a), and revised key directions for coastal management (Minister of Conservation, 2010). No cross-sectoral adaptation policy framework or national-level risk assessments exist, but some departments commissioned high-level impacts assessments after the AR4 (e.g. on agriculture and on biodiversity; Wratt *et al*., 2008; McGlone and Walker, 2011).

Public and private sector organisations are potentially important adaptation actors but exhibit large differences in preparedness, linked to knowledge and belief about climate change, economic opportunities, external connections, size, familiarity with strategic planning and planning horizons (Gardner *et al*., 2010; Johnston *et al*., 2012; Murta *et al*., 2012; Taylor *et al*., 2012a). This creates challenges for achieving holistic societal outcomes (see also 25.7-25.9).

Several recent policy initiatives in Australia, while responding to broader socio-economic and environmental pressures, include goals to reduce vulnerability to climate variability and change. These include establishing the Murray-Darling Basin Authority to address over-allocation of water resources (Connell and Grafton, 2011; MDBA, 2011), removal of the interest rate subsidy during exceptional droughts (Productivity Commission, 2009), and management of bush fire risk (VBRC, 2010). These may be seen as examples of mainstreaming adaptation (Dovers, 2009), but they also demonstrate lag times in policy design and implementation and windows of opportunity presented by crises (e.g. the Millennium Drought 1997-2009, the Victorian bushfires 2009), and the challenges arising from competing interests in managing finite water resources (Botterill and Dovers, 2013; Box 25-2).

25.4.2. Constraints on Adaptation and Emerging Leading Practice Models

A rapidly growing literature since the AR4 confirms, with *high confidence,* that while the adaptive capacity of society in Australasia is generally high, there are formidable environmental, economic, informational, social, attitudinal and political constraints, especially at the community level, and for small or highly fragmented industries. Reviews of public- and private-sector adaptation plans and strategies in Australia demonstrate strong efforts in institutional capacity building, but differences in assessment methods and weaknesses in translating goals into specific policies (White, 2009; Gardner *et al*., 2010; Measham *et al*., 2011; Preston *et al*., 2011; Kay *et al*., 2013). Similarly, local governments in New Zealand to date have mostly focused on impacts and climate-related hazards but few have committed to specific climate change responses (e.g. O'Donnell, 2007; Britton, 2010; Fitzharris, 2010; HRC, 2012; KCDC, 2012; Lawrence *et al*., submitted-b).

Table 25-2 lists key constraints and corresponding enabling factors for effective institutional adaptation processes identified in Australia and New Zealand. Scientific uncertainty and resources limitations are reported consistently as important constraints, particularly for smaller councils. Ultimately more powerful constraints arise, however, from current legislative, institutional and governance arrangements and the lack of consistent tools to deal with dynamic risks and uncertainty or to evaluate the success of adaptation responses (*high agreement, robust evidence*; Britton, 2010; Mukheibir *et al*., 2013; Lawrence *et al*., submitted-b; Webb *et al*., submitted; see also Chapter 16).

[INSERT TABLE 25-2 HERE
Table 25-2: Constraints and enabling factors for institutional adaptation processes in Australasia.]

Some constraints exacerbate others. There is *high confidence* that the absence of a consistent information base and binding guidelines that clarify governing principles and liabilities is a challenge particularly for small and resource-limited local authorities, which need to balance special interest advocacy with longer term community resilience. This heightens reliance on individual leadership subject to short-term political change (Smith *et al*., 2008; Brown *et al*., 2009; Norman, 2009; Britton, 2010; Preston and Kay, 2010; Rouse and Norton, 2010; Smith *et al*., 2010; Abel *et al*., 2011; McDonald, 2011; Rive and Weeks, 2011; Corkhill, 2013). In these situations, planners tend to rely more on single numbers for climate change projections that can be argued in court (Reisinger *et al*., 2011; Lawrence *et al*., submitted-b), which increases the risk of maladaptation given the uncertain and dynamic nature of climate risk (McDonald, 2010; Stafford-Smith *et al*., 2011b; Gorrdard *et al*., 2012; McDonald, 2013; Reisinger *et al*., 2013).

Vulnerability assessments that take mid- to late-century impacts as their starting point can inhibit actors from implementing adaptation actions, as distant impacts are easily discounted and difficult to prioritise in competition with near-term non-climate change pressures (Productivity Commission, 2012). Emerging leading practice models in Australia (Balston, 2012; HCCREMS, 2012; SGS, 2012a, b) and New Zealand (MfE, 2008e; Britton *et al*., 2011) recommend a high-level scan of sectors and locations at risk and emphasise a focus on near-term decisions that influence current and future vulnerability (which could range from early warning systems to strategic and planning responses). More detailed assessment can then focus on this more tractable subset of issues, based on explicit and iterative framing of the adaptation issue (Webb *et al*., submitted) and taking into account the full lifetime (lead- and consequence time) of the decision/asset in question (Stafford-Smith *et al*., 2011b).

Participatory processes help balance societal preferences with robust scientific information and ensure ownership by affected communities (*high confidence*), but rely on human capital and political commitment (Hobson and Niemeyer, 2011; Rouse and Blackett, 2011; Weber *et al*., 2011; Leitch and Robinson, 2012). Realising widespread and equitable participation is challenging where policies are complex, debates polarised, legitimacy of institutions contested and potential transformational changes threaten deeply held values (Gardner *et al*., 2009a; Gorrdard *et al*., 2012; Burton and Mustelin, 2013; see also 25.4.3). Regional approaches that engage diverse stakeholders, government and science providers and support the co-production of knowledge can help overcome some of these problems but require long-term institutional and financial commitments (e.g. Britton *et al*., 2011; DSEWPC, 2011; CSIRO, 2012; IOCI, 2012; Low Choy *et al*., 2012; Webb and Beh, 2013).

An emerging literature questions whether incremental adjustments of existing planning instruments, institutions and decision-making processes can deal adequately with the dynamic and uncertain nature of climate change and support transformative responses (Kennedy *et al*., 2010; Preston *et al*., 2011; Park *et al*., 2012; McDonald, 2013; Stafford-Smith, 2013; Lawrence *et al*., submitted-b). Recent studies suggest a greater focus on flexibility and matching decision-making frameworks to specific problems (Hertzler, 2007; Nelson *et al*., 2008; Dobes, 2010; Howden and Stokes, 2010; Randall *et al*., 2012). Limitations of mainstreamed and autonomous adaptation (Dovers and Hezri, 2010) and the potential need for more proactive government intervention are being explored in Australia (see Productivity Commission, 2012, including submissions), but have not yet resulted in new policy frameworks.

_____ START BOX 25-1 HERE _____

Box 25-1. Coastal Adaptation – Planning and Legal Dimensions

Sea level rise is a significant risk to Australia and New Zealand (*very high confidence*) due to intensifying coastal development and the location of population centres and infrastructure (Freeman and Cheyne, 2008; DCC, 2009; see also 25.3). Local case studies in New Zealand (Fitzharris, 2010; Reisinger *et al*., 2013) and national reviews in Australia (DCC, 2009; DCCEE, 2011) demonstrate risks to large numbers of residential and commercial assets as well as key services. In Australia, sea level rise of 1.1 m would affect over A$226 billion of assets, including up to 274,000 residential and 8,600 commercial buildings (DCCEE, 2011), with additional intangible costs related to stress, health effects and service disruption (HCCREMS, 2010). Under expected future settlement patterns, exposure of the Australian road and rail network will increase significantly once sea level rise exceeds about 0.5 m (Baynes *et al*., 2012). While the magnitude of sea level rise during the 21st century remains uncertain, its persistence over many centuries implies that realization of these risks is only a question of time (AR5 WGI Chapter 13).

Responsibility for adapting to sea level rise in Australasia rests principally with local governments through spatial planning instruments. Western Australia, South Australia and Victoria have mandatory State planning benchmarks for 2100, with local governments determining how they should be implemented. Long-term benchmarks in NSW and Queensland have either been suspended or revoked, so local authorities now have broad discretion to develop their own adaptation plans. The New Zealand Coastal Policy Statement (Minister of Conservation, 2010) mandates a minimum 100-year planning horizon for assessing hazard risks, discourages protection of existing development and recommends avoidance of new development in vulnerable areas. Non-binding government guidance recommends a risk based approach, using a base value of 0.5 m sea level rise by the 2090s and at least considering implications of greater rises of 0.8 m, and 0.1 m per decade beyond 2100, where relevant (MfE, 2008c).

The incorporation of climate change impacts into local planning has evolved considerably over the past 20 years, but remains piecemeal and shows a diversity of approaches (Gibbs and Hill, 2012; Kay *et al*., 2013). Many local governments lack the resources for hazard mapping and policy design. Political commitment is variable, and legitimacy of approaches and institutions is often strongly contested (Gorrdard *et al*., 2012), including pressure on State governments to modify adaptation policies and on local authorities to compensate developers for restrictions on current or future land uses (LGNZ, 2008; Berry and Vella, 2010; McDonald, 2010; Reisinger *et al*., 2011). There is *limited evidence* but *high agreement* that incremental local coastal adaptation responses can generate a path-dependency that becomes increasingly difficult to overcome (Gorrdard *et al*., 2012; McDonald, 2013), with appreciating land values supporting ever greater emphasis on protection (Fletcher *et al*., submitted). Strategic regional-scale planning initiatives in rapidly growing regions, like southeast Queensland, allow climate change adaptation to be addressed in ways that are not typically achieved by locality- or sector-specific plans, but require effective coordination across different scales of governance (Low Choy *et al*., 2013; Smith *et al*., 2013).

Courts in both countries have played an important role in evaluating planning measures. Results of litigation have varied and, in the absence of clearer legislative guidance, more litigation is expected as rising sea levels affect existing properties and adaptation responses constrain development on coastal land (MfE, 2008c; Rive and Weeks, 2011; Verschuuren and McDonald, 2012; Corkhill, 2013).

In addition to raising minimum floor levels and creating coastal set-backs to limit further development in areas at risk, several councils have attempted to implement managed retreat policies, such as Byron Shire Council, Australia (BSC, 2010), Environment Canterbury and Kapiti Coast District Council, New Zealand (ECAN, 2005; KCDC, 2012). These policies remain largely untested in New Zealand, but experience in Australia has shown high litigation potential and opposing priorities at different levels of government, undermining retreat policies (Parliament of Australia, 2009; DCC, 2010; Abel *et al*., 2011). Mandatory disclosure of information about future risks, community engagement and policy stability are critical to support retreat, but existing-use rights, liability concerns, special interests, community resources, place attachment and divergent priorities at different levels of government present powerful barriers (*high agreement, robust evidence*; Hayward, 2008a; Berry and Vella, 2010; McDonald, 2010; Abel *et al*., 2011; Alexander *et al*., 2012; Leitch and Robinson, 2012; Reisinger *et al*., 2013).

_____ END BOX 25-1 HERE _____

25.4.3. Socio-cultural Factors Influencing Impacts of and Adaptation to Climate Change

Adapting to climate change relies on individuals accepting and understanding changing risks, implications, and opportunities, and responding to these risks and changes both psychologically and behaviourally within their respective spheres of influence (see Chapters 2, 16). The majority of Australasians accept the reality of climate change and less than 10% fundamentally deny its existence (high confidence; ShapeNZ, 2009; Leviston *et al*., 2011; Lewandowsky, 2011; Lewandowsky *et al*., 2012; Milfont, 2012; Reser *et al*., 2012b, c). Australians generally perceive themselves to be at higher risk from climate change than New Zealanders and citizens of many other countries, which may reflect recent climatic extremes and their impacts (Gifford *et al*., 2009; Agho *et al*., 2010; Ashworth *et al*., 2011; Milfont *et al*., 2012; Reser *et al*., 2012b). However, beliefs about climate change and the risks posed vary over time, are uneven across society and reflect media coverage and bias, political preferences, and gender (ShapeNZ, 2009; Bacon, 2011; Leviston *et al*., 2012; Milfont, 2012), which can influence the willingness of

communities and businesses to consider adaptation (Gardner *et al*., 2010; Gifford, 2011; Reser *et al*., 2011; Alexander *et al*., 2012; Raymond and Spoehr, 2013).

Surveys in Australia between 2007 and 2011 show moderate to high levels of climate change concern, distress, frustration, resolve, motivation, psychological adaptation, and carbon-reducing behavioural engagement (high agreement, medium evidence; Agho *et al*., 2010; Reser *et al*., 2012b, c). About two thirds of respondents perceived global warming as likely to worsen, with about half very or extremely concerned that they or their family would be directly affected. Direct personal experience with environmental changes or events attributed to climate change, reported by 45% of respondents, was particularly significant and influential, but concern about global warming was also linked to general psychological distress levels. The extent to which distress and concern about climate change impacts translate into actual support for proactive adaptation responses has not yet been fully assessed.

Perceived levels of risk and potential losses from climate change depend on values attributed and invested by individuals to specific places, activities and objects. Examples from Australia include the value placed on winter snow cover in the Snowy Mountains (Gorman-Murray, 2008, 2010), risks to biodiversity and recreational values in coastal South Australia (Raymond and Brown, 2011), conflicts between human uses and environmental priorities in national parks (Wyborn, 2009; Roman *et al*., 2010), and alternative uses of limited water resources in rural areas (Alston, 2010; Hurlimann and Dolnicar, 2011; Kingsford *et al*., 2011). These and additional studies in Australasia addressing place connection and environmental change (e.g. Rogan *et al*., 2005; McCleave *et al*., 2006; Collins and Kearns, 2010; Gosling and Williams, 2010; Raymond *et al*., 2011) confirm the importance of place attachment in understanding psychological dimensions of climate change impacts.

Acceptable adaptation responses are similarly influenced and often constrained by social and cultural values and norms. Place attachment and differing values relating to near- versus long-term, private versus public costs and benefits, and legitimacy of institutions influence adaptation preferences, e.g. in the coastal zone (Hayward, 2008b; Agyeman *et al*., 2009; King *et al*., 2010; Gorrdard *et al*., 2012; Hofmeester *et al*., 2012) and acceptance of water recycling or pricing (Pearce *et al*., 2007; Miller and Buys, 2008; Hurlimann and Dolnicar, 2010; Kouvelis *et al*., 2010; Mankad and Tapsuwan, 2011). On the other hand, place attachment, connection, and identity can also offer substantial benefits and support with respect to adaptation challenges and impacts, including stress reduction, restoration, recreation, and continuity, and enhancement of environmental quality, subjective well being, and mental health, especially for disadvantaged and indigenous communities (Berry *et al*., 2010; see also 25.9.2).

These studies indicate that the threat of and direct and indirect experience of climate change and extreme climatic events are having appreciable psychological impacts, but also result in psychological and subsequent behavioural adaptations, reflected in high levels of acceptance and realistic concern, motivational resolve, self-reported changes in thinking, feeling and understanding of climate change and its implications, and behavioural engagement (Reser and Swim, 2011; Reser *et al*., 2012a; Reser *et al*., 2012b, c). However, adequate ongoing and standardised impact assessment strategies and systems are lacking to monitor trends and to compare impacts with bio-physical and economic impacts that dominate the climate change vulnerability literature.

25.5. Freshwater Resources

25.5.1. Projected Impacts

Impact of climate change on water resources and river flow characteristics is a cross-cutting issue affecting people, agriculture, industries and ecosystems. The challenge of satisfying multiple demands with a limited resource is exacerbated by the high inter-annual and inter-decadal variability of river flows (Chiew and McMahon, 2002; Peel *et al*., 2004; Verdon *et al*., 2004; McKerchar *et al*., 2010) particularly in Australia.

Figure 25-4 shows estimated changes to mean annual runoff across Australia for a 1°C global average warming (Chiew and Prosser, 2011; Teng *et al*., 2012). The range of estimates arises mainly from uncertainty in projected precipitation (Table 25-1). Hydrological modelling based on CMIP3 climate models indicates that freshwater resources in far south-eastern and far south-west Australia will decline (*high confidence;* by 0-40% and 20-70%,

respectively, for 2°C warming) due to the reduction in winter half-year precipitation (Table 25-1 and Figure 25-3) when most of the runoff in southern Australia occurs. The percent change in mean annual precipitation in Australia is generally amplified as a 2–3 times larger percent change in mean annual streamflow (Chiew, 2006; Jones *et al.*, 2006). This can vary, however, with unprecedented declines in flow in far south-eastern Australia in the 1997–2009 drought (Cai and Cowan, 2008; Potter *et al.*, 2010; Chiew *et al.*, 2011; Potter and Chiew, 2011). Higher temperatures and associated evaporation, tree re-growth following more frequent bushfires (Kuczera, 1987; Cornish and Vertessy, 2001; Marcar *et al.*, 2006; Lucas *et al.*, 2007), interception activities like farm dams (Van Dijk *et al.*, 2006; Lett *et al.*, 2009) and reduced surface-groundwater connectivity in long dry spells (Petrone *et al.*, 2010; Hughes *et al.*, 2012) can further accentuate declines. In the longer-term, water availability will also be affected by changes in vegetation and surface-atmosphere feedbacks from a warmer and higher CO_2 environment (Betts *et al.*, 2007; Donohue *et al.*, 2009; McVicar *et al.*, 2010).

[INSERT FIGURE 25-4 HERE
Figure 25-4: Estimated changes in mean annual runoff for a 1°C global average warming. Maps show changes in annual runoff (percentage change; top row) and runoff depth (millimetres; bottom row), for median, dry and wet (10^{th} and 90^{th} percentile) range of estimates, based on hydrological modelling using CMIP3 models (Chiew *et al.*, 2009; CSIRO, 2009b; Petheram *et al.*, 2012; Post *et al.*, 2012). Projections for 2°C global average warming are about twice that shown in the maps (Post *et al.*, 2011). (Figure adapted from Chiew and Prosser, 2011; Teng *et al.*, 2012).]

In New Zealand, projected precipitation changes (Table 25-1) will generally lead to increased runoff in the west and south of the South Island and reduced runoff in the north-east of the South Island, and the east and north of the North Island (*medium confidence*). Annual flows of eastward flowing rivers with headwaters in the Southern Alps (Clutha, Waimakariri, Rangitata) are projected to increase by 5-10 % (median projection) by 2040 (Bright *et al.*, 2008; Poyck *et al.*, 2011; Zammit and Woods, 2011b, a) in response to higher alpine precipitation. Most of the projected increases occur in winter and spring, as more precipitation falls as rain and snow melts earlier. In contrast, the Ashley River, slightly north of this region, is projected to have little change in annual flows, with the increase in winter flows offset by reduced summer flows (Woods *et al.*, 2008). The retreat of glaciers is expected to have only a minor impact on river flows in the first half of the century (Chinn, 2001; Anderson *et al.*, 2008). Limited modelling studies show reduced mean annual streamflow in the east and north of the North Island: for example by 14% (median projection) by 2040 in the Waipaoa River, in response to projected precipitation decline and higher temperature (Zemansky, 2010; Collins, 2012).

Climate change will affect groundwater through changes in recharge rates and the relationship between surface waters and aquifers. Dryland diffuse recharge in most of western, central and southern Australia is projected to decrease because of the decline in precipitation, with increases in the north and some parts of the east because of projected increase in extreme rainfall intensity (*medium confidence*; Crosbie *et al.*, 2010; McCallum *et al.*, 2010; Crosbie *et al.*, 2012). There has been little research in New Zealand, with one study projecting groundwater recharge in the Canterbury Plains to decrease by about 10% by 2040 (Bright *et al.*, 2008).

25.5.2. Adaptation

The 1997-2009 ‘Millennium’ drought in south-eastern Australia and projected declines in future water resources in southern Australia are already stimulating adaptation (Box 25-2). In New Zealand, there is little evidence of this. Water in New Zealand is not as scarce generally and water policy reform is driven more by pressure to maintain water quality while expanding agricultural activities, with an increasing focus on collaborative management (Memon and Skelton, 2007; Memon *et al.*, 2010; Lennox *et al.*, 2011; Weber *et al.*, 2011) within national guidelines (LWF, 2010; MfE, 2011). Impacts of climate change on water supply, demand and infrastructure have been considered by several local authorities and consultancy reports (Jollands *et al.*, 2007; Williams *et al.*, 2008; Kouvelis *et al.*, 2010), but no explicit management changes have yet resulted.

_____ START BOX 25-2 HERE _____

Box 25-2. Adaptation through Water Resources Policy and Management in Australia

Water policy and management in Australia is focused on allocating an often scarce resource exhibiting high seasonal, annual and decadal variability (Chiew and Prosser, 2011; Prosser, 2011). Widespread drought and projections of a drier future in south-eastern and far south-west Australia (Bates *et al*., 2010; CSIRO, 2010; Potter *et al*., 2010; Chiew *et al*., 2011) saw extensive policy and management change in both rural and urban water systems (Hussey and Dovers, 2007; Bates *et al*., 2008; Melbourne Water, 2010; DSE, 2011; MDBA, 2011; NWC, 2011; Schofield, 2011). These management changes provide examples of adaptations, building on previous policy reforms dealing with climate variability but less explicitly with climate change (Botterill and Dovers, 2013).

The broad policy framework is set out in the 2004-2014 National Water Initiative and the 2007 Commonwealth Water Act. The establishment of the National Water Commission (2004) and the Murray-Darling Basin Authority (2008) were major institutional reforms. The National Water Initiative explicitly recognises climate change as a constraint on future water allocations. Official assessments (NWC, 2009, 2011) and critiques (Connell, 2007; Grafton and Hussey, 2007; Byron, 2011; Crase, 2011; Pittock and Finlayson, 2011) have discussed progress and shortcomings of the initiative, but assessment of its overall success is made difficult by other factors such as on-going revisions to allocation plans and time lags to observable impacts.

Rural water reform in south-eastern Australia, focused on the Murray-Darling Basin, is still unfolding. The first draft Murray-Darling Basin Plan (MDBA, 2011) aims to return 2750 GL/year of consumptive water (about one fifth of current entitlements) to riverine ecosystems and develop flexible and adaptive water sharing plans to cope with current and future climates, although climate change is not factored in explicitly. The Plan recommends more than A$10 billion be spent on public buyback of entitlements, upgrading infrastructure, and improving water use efficiency. Water markets are a key policy instrument, allowing water use patterns to adapt to shifting availability and move toward higher value water (NWC, 2010; Kirby *et al*., 2012). For example, the two-thirds reduction in irrigation water use over the 1997-2009 drought in the Basin resulted in only 20% reduction in agricultural returns, mainly because water use shifted to more valuable enterprises (Kirby *et al*., 2012). Elsewhere, catchment management authorities and state agencies throughout south-eastern Australia develop water management strategies to cope with prolonged droughts and climate change (e.g. DSE, 2011). Nevertheless, if the extreme dry end of future water projections is realized (25.5.1, Figure 25-4), agriculture and ecosystems across south-eastern Australia would be threatened even with comprehensive adaptation (see 25.6.2, 25.7.2; Connor *et al*., 2009; Kirby *et al*., in press).

Many capital cities in Australia are reducing their reliance on catchment runoff and groundwater as these sources are most sensitive to climate change and drought, and are diversifying supplies by investing in desalinisation plants, water re-use and integrated water cycle management. Concurrently, demand is being reduced through water conservation and water sensitive urban design and, during severe shortfalls, through implementation of restrictions. In Melbourne, for example, planning has centred on securing new supplies that are more resilient to major climate shocks, increasing use of alternative sources like sewage recycling and stormwater for non-potable water, programs to reduce demand, and integrated planning that also considers integration with climate change impacts on flood risk and on urban stormwater and wastewater infrastructures (DSE, 2007; Skinner, 2010; DSE, 2011; Rhodes *et al*., 2012). Melbourne's water augmentation program includes a desalinisation plant with a 150 GL/year capacity (about one third of the current demand), following the lead of Perth in far south-west Australia where a desalinisation plant was established in 2006 following declining inflows since the mid-1970s (Hennessy *et al*., 2007; Bates and Hughes, 2009). Melbourne's water conservation strategies include water efficiency and rebate programs for business and industry, water smart gardens, dual flush toilets, grey water systems, rainwater tank rebates, free water-efficient showerheads and voluntary residential use targets. These conservation measures, together with water restrictions since the early 2000s, have reduced Melbourne's total per capita use by 40% (Fitzgerald, 2009; Rhodes *et al*., 2012). Similar recent programs reduced Brisbane's per capita use by about 50% (Shearer, 2011), while adoption of water recycling and rainwater harvesting resulted in up to 60% water savings in some parts of Adelaide (Barton and Argue, 2009; Radcliffe, 2010).

The success of urban water reforms in the face of drought and climate change can be interpreted in different ways. Increasing supply through desalinisation plants and water reuse schemes reduces the risk of future water shortages and helps cities cope with increasing population. Uptake of household-scale adaptation options has been significant in some locations, but their long-term sustainability or reversibility in response to changing drivers and societal attitudes is an open question (Troy, 2008; Brown and Farrelly, 2009; Mankad and Tapsuwan, 2011). In addition, desalinisation plants can be maladaptive in that they are energy intensive, and the enhancement of traditional mass supply could create a disincentive for reducing demand or increasing resilience by diversifying supply (Barnett and O'Neill, 2010; Taptiklis, 2011).

_____ END BOX 25-2 HERE _____

25.6. Natural Ecosystems

25.6.1. Terrestrial and Inland Freshwater Ecosystems

Terrestrial and freshwater ecosystems have suffered high rates of habitat loss and degradation, and species extinctions since European settlement (Kingsford *et al.*, 2009; Bradshaw *et al.*, 2010; McGlone *et al.*, 2010; Lundquist *et al.*, 2011; SoE, 2011); many reserves are small and isolated, and some key ecosystems and species under-represented (Walker *et al.*, 2006; Sattler and Taylor, 2008; MfE, 2010b; SoE, 2011). Freshwater ecosystems in both countries are pressured from over-allocation, agriculture and pollution (e.g. Ling, 2010). Additional stresses include erosion, changes in nutrients and fire regimes, mining, invasive species, grazing and salinity (Kingsford *et al.*, 2009; McGlone *et al.*, 2010; SoE, 2011). These increase vulnerability to rapid climate change and provide challenges for both autonomous and managed adaptation (Burbidge *et al.*, 2008).

25.6.1.1. Observed Impacts

In Australian terrestrial systems, some recently observed changes in the distributions, genetics and phenology of individual species, and in the structure and composition of some ecological communities can be attributed to recent climatic and atmospheric trends (*medium* to *high confidence*; see Box 25-3). Uncertainty remains regarding the role of non-climatic drivers, including changes in fire management, grazing and land-use. The 1997-2009 drought had severe impacts in freshwater systems in the eastern States and the Murray Darling Basin (Pittock and Finlayson, 2011) but in many freshwater systems, direct climate impacts are difficult to detect above the strong signal of over-allocation, pollution, sedimentation, exotic invasions and natural climate variability (Jenkins *et al.*, 2011). In New Zealand, few if any impacts have been directly attributed to climate change rather than variability (Box 25-3; McGlone *et al.*, 2010; McGlone and Walker, 2011). Alpine treelines in New Zealand have remained roughly stable for several hundred years (*high confidence*) despite 0.9°C average warming (McGlone *et al.*, 2010; McGlone and Walker, 2011; Harsch *et al.*, 2012).

25.6.1.2. Projected Impacts

Existing environmental stresses will interact with, and in many cases be exacerbated by, shifts in mean climatic conditions and associated increase in the frequency or intensity of extreme events, especially fire, drought and floods (*high confidence*; Steffen *et al.*, 2009; Bradstock, 2010; Murphy *et al.*, 2012). Recent drought-related mortality of amphibians in south-east Australia (Mac Nally *et al.*, 2009); savannah trees in north-east Australia (Fensham *et al.*, 2009; Allen *et al.*, 2010); eucalypts in sub-alpine regions in Tasmania (Calder and Kirkpatrick, 2008); and mass die-offs of flying foxes and cockatoos during heatwaves (Welbergen *et al.*, 2008; Saunders *et al.*, 2011) provide *high confidence* that extreme heat combined with reduced water availability will be a significant driver of future population loss and increase the risk of local species extinctions (e.g. McKechnie and Wolf, 2010; see also Figure 25-5).

Species distribution modelling (SDM) consistently indicates future range contractions for Australia's native species even assuming optimistic rates of dispersal, e.g. WA *Banksia* spp. (Fitzpatrick *et al*., 2008), koalas (Adams-Hosking *et al*., 2011), northern macropods (Ritchie and Bolitho, 2008), native rats (Green *et al*., 2008b), greater gliders (Kearney *et al*., 2010b), quokkas (Gibson *et al*., 2010), platypus (Klamt *et al*., 2011) and fish (Bond *et al*., 2011). In some studies, complete loss of climatically suitable habitat is projected for some species within a few decades, and therefore increased risk of local and, perhaps, global extinction (*medium confidence*). SDM has limitations (e.g. Elith *et al*., 2010; McGlone and Walker, 2011) but is being improved through integration with physiological (Kearney *et al*., 2010b) and demographic models (Keith *et al*., 2008; Harris *et al*., 2012), and incorporation into broader risk assessments (e.g. Williams *et al*., 2008; Crossman *et al*., 2012).

In Australia, assessments of ecosystem vulnerability have been based on observed changes, coupled with projections of future climate in relation to known biological thresholds and assumptions about adaptive capacity (e.g. Laurance *et al*., 2011; Murphy *et al*., 2012). There is *very high confidence* that one of the most vulnerable Australian ecosystems is the alpine zone, from loss of snow cover, with flow on impacts such as exotic species invasions and changed species interactions (Pickering *et al*., 2008). There is also *high confidence* in substantial risks to coastal wetlands such as Kakadu National Park subject to saline intrusion (BMT WBM, 2011); tropical savannas subject to changed fire regimes (Laurance *et al*., 2011); inland freshwater and groundwater systems subject to drought, over-allocation and altered timing of floods (Lake and Bond, 2007; Pittock, 2008; Pittock *et al*., 2008; Nielsen and Brock, 2009; Balcombe *et al*., 2011; Jenkins *et al*., 2011; Morrongiello *et al*., 2011; Pratchett *et al*., 2011; Kroon *et al*., 2012); peat-forming wetlands along the east coast (Keith *et al*., 2010); and biodiversity-rich regions such as southwest Western Australia (Yates *et al*., 2010a; Yates *et al*., 2010b) and rainforests in Queensland (Stork *et al*., 2007; Shoo *et al*., 2011; Murphy *et al*., 2012).

The very few studies of climate change impacts on biodiversity in New Zealand suggest that on-going impacts of invasive species (Box 25-4) and habitat loss will dominate climate change signals in the short- to medium-term (McGlone *et al*., 2010), but that atmospheric and climatic change have the potential to exacerbate existing stresses (McGlone and Walker, 2011). There is *limited evidence but high agreement* that the rich biota of the alpine zone is at risk through increasing shrubby growth and loss of herbs, especially if combined with increased establishment of invasive species (McGlone *et al*., 2010; McGlone and Walker, 2011). Some cold water-adapted freshwater fish and invertebrates are vulnerable to warming (August and Hicks, 2008; Winterbourn *et al*., 2008; Hitchings, 2009; McGlone and Walker, 2011) and increased spring flooding may increase risks for braided-river bird species (MfE, 2008d). For some restricted native species, suitable habitat may increase with warming (e.g. native frogs; Fouquet *et al*., 2010) although limited dispersal ability will limit range expansion. Tuatara populations are at risk as warming increases the ratio of males to females (Mitchell *et al*., 2010), although the lineage has persisted during higher temperatures in the geological past (McGlone and Walker, 2011).

25.6.1.3. Adaptation

High levels of endemism in both countries (Lindenmayer, 2007; Lundquist *et al*., 2011) are associated with narrow geographic ranges and associated climatic vulnerability, although there is greater scope for adaptive dispersal to higher elevations in New Zealand than in Australia. Anticipated rates of climate change, together with fragmentation of remaining habitat and limited migration options in many regions (Steffen *et al*., 2009; Morrongiello *et al*., 2011), will limit *in situ* adaptive capacity and distributional shifts to more climatically suitable areas for many species (*high confidence*). Significant local and global losses of species and ecosystem services, and large scale changes in ecological communities, are anticipated (e.g. Dunlop *et al*., 2012; Murphy *et al*., 2012).

There is increasing recognition in Australia that rapid climate change has fundamental implications for traditional conservation objectives (e.g. Steffen *et al*., 2009; Prober and Dunlop, 2011; Dunlop *et al*., 2012; Murphy *et al*., 2012). Research on impacts and adaptation in terrestrial and freshwater systems has been guided by the National Adaptation Research Plans (Hughes *et al*., 2010; Bates *et al*., 2011). Climate change adaptation plans developed by many levels of government and Natural Resource Management (NRM) bodies, supported by substantial federal government funding, have identified priorities that include: identification and protection of climatic refugia (Shoo *et al*., 2011); restoration of riparian zones to reduce stream temperatures (Davies, 2010; Jenkins *et al*., 2011);

construction of levees to protect wetlands from saltwater intrusion (Jenkins *et al*., 2011); reduction of non-climatic threats such as invasive species to increase ecosystem resilience (Kingsford *et al*., 2009); ecologically-appropriate fire regimes (Driscoll *et al*., 2010); restoration of environmental flows in major rivers (Kingsford and Watson, 2011; Pittock and Finlayson, 2011); protecting and restoring habitat connectivity in association with expansion of the protected area network (Dunlop and Brown, 2008; Mackey *et al*., 2008; Taylor and Philp, 2010; Prowse and Brook, 2011); and active interventionist strategies such as assisted colonisation (Burbidge *et al*., 2011; McIntyre, 2011). The effectiveness of these measures cannot yet be assessed. Biodiversity research and management in New Zealand to date has taken little account of climate change-related pressures and continues to focus largely on managing pressures from invasive species and predators, freshwater pollution, exotic diseases, and halting the decline in native vegetation, although a number of specific recommendations have been made to improve ecosystem resilience to future climate threats (McGlone *et al*., 2010; McGlone and Walker, 2011).

Climate change responses in other sectors may have beneficial as well as adverse impacts on biodiversity, but few tools to assess risks from an integrated perspective have been developed (25.9.1, Box 25.10).

25.6.2. Coastal and Ocean Ecosystems

Australia's 60,000 km coastline spans tropical waters in the north to cool temperate waters off Tasmania and the sub-Antarctic islands with sovereign rights over ~8.1 million km^2, excluding the Australian Antarctic Territory (Richardson and Poloczanska, 2009). New Zealand has ~18,000 km of coastline, spanning subtropical to sub-Antarctic waters, and the world's fifth largest Exclusive Economic Zone at 4.2 million km^2 (Gordon *et al*., 2010). The marine ecosystems of both are considered hotspots of global marine biodiversity with many rare, endemic and commercially important species (Hoegh-Guldberg *et al*., 2007; Blanchette *et al*., 2009; Gordon *et al*., 2010; Gillanders *et al*., 2011; Lundquist *et al*., 2011). The increasing density of coastal populations (25.3) and stressors such as pollution and sedimentation from settlements and agriculture will intensify non-climate stressors in coastal areas (*high confidence*; e.g. Russell *et al*., 2009). Coastal habitats also store carbon, particularly seagrass, saltmarsh and mangroves, which could become increasingly important for mitigation (e.g. Irving *et al*., 2011). Coastal ecosystems occupy <1% of the land mass but may account for 39% of Australia's average national annual carbon burial (estimated total: 466 millions tonnes CO_2-eq per year; Lawrence *et al*., 2012).

25.6.2.1. Observed Impacts

There is *high confidence* that climate change is already affecting the oceans around Australia (Pearce and Feng, 2007; Poloczanska *et al*., 2007; Lough and Hobday, 2011) and warming the Tasman sea in northern New Zealand (Sutton *et al*., 2005; Lundquist *et al*., 2011); average climate zones have shifted south by more than 200 km along the northeast and about 100 km along the northwest Australian coasts (Lough, 2008). The rate of warming is even faster in southeast Australia, with a poleward advance of the East Australia Current of ~350 km over the past 60 years (Ridgway, 2007; Wu *et al*., 2012). Based on elevated rates of ocean warming, southwest and southeast Australia are recognized as global warming hotspots (Wernberg *et al*., 2011; Wu *et al*., 2012).

Observed impacts on marine species around Australia have been reported from a range of trophic levels (Box 25-3) and include changes in phytoplankton productivity (Thompson *et al*., 2009; Johnson *et al*., 2011); species abundance of macroalgae (Johnson *et al*., 2011); growth rates of abalone (Johnson *et al*., 2011), southern rock lobster (Pecl *et al*., 2009; Johnson *et al*., 2011), coastal fish (Neuheimer *et al*., 2011) and coral (De'ath *et al*., 2009); life cycles of southern rock lobster (Pecl *et al*., 2009) and seabirds (Cullen *et al*., 2009; Chambers *et al*., 2011); and distribution of subtidal seaweeds (Johnson *et al*., 2011; Wernberg *et al*., 2011; Smale and Wernberg, 2013), plankton (McLeod *et al*., 2012), fish (Figueira *et al*., 2009; Figueira and Booth, 2010; Last *et al*., 2011; Madin *et al*., 2012), sea urchins (Ling *et al*., 2009) and intertidal invertebrates (Pitt *et al*., 2010).

Habitat-related impacts are more prevalent in northern Australia (Pratchett *et al*., 2011), while distribution changes are reported more often in southern waters (Madin *et al*., 2012), particularly south-east Australia, where warming has been greatest. The 2011 marine heat wave in Western Australia caused the first-ever reported bleaching at

Ningaloo reef, as well as reports of southern range extensions of many marine species, and declines in local abundance (Wernberg *et al*., 2013). About 10% of the observed 50% decline in coral cover on the Great Barrier Reef has been attributed to bleaching, the remainder to cyclones and predators (De'ath *et al*., 2012). Changes in distribution and abundance of marine species in New Zealand are primarily linked to ENSO-related variability that dominates in many time series (Clucas, 2011; Lundquist *et al*., 2011; McGlone and Walker, 2011; Schiel, 2011), although water temperature is also important (e.g. Beentjes and Renwick, 2001). New Zealand fisheries export some $1.4 billion worth of product and variability in ocean circulation and temperature plays an important role in local fish abundance (e.g. Chiswell and Booth, 2005; Dunn *et al*., 2009), but no climate change impacts have been reported at this stage (Dunn *et al*., 2009).

25.6.2.2. Projected Impacts

Even though evidence to date of climate impacts on coastal habitats is limited, *confidence* is *high* that negative impacts will arise with continued climate change (Lovelock *et al*., 2009; McGlone and Walker, 2011; Traill *et al*., 2011). Some coastal habitats such as mangroves are projected to expand further landward, driven by sea-level rise and exacerbated by soil subsidence if rainfall declines (*medium confidence*; Traill *et al*., 2011), although this may be at the expense of saltmarsh and constrained in many regions by the built environment (DCC, 2009; Lovelock *et al*., 2009; Rogers *et al*., 2012). Estuarine habitats will be affected by changing rainfall or sediment discharges, as well as connectivity to the ocean (*high confidence*; Gillanders *et al*., 2011). Loss of coastal habitats and declines in iconic species will result in substantial impacts on coastal settlements and infrastructure from direct impacts such as storm surge, and tourism (*medium confidence*; 25.7.5).

Change in temperature and rainfall, and sea level rise, are expected to lead to secondary effects, including erosion, landslips, and flooding, affecting coastal habitats and their dependent species, e.g. loss of habitat for nesting birds (*high confidence*; Chambers *et al*., 2011). Increasing ocean acidification is expected to affect many taxa (*medium confidence*; see also Box CC-OA) including corals (Fabricius *et al*., 2011), coralline algae (Anthony *et al*., 2008), calcareous plankton (Richardson *et al*., 2009; Thompson *et al*., 2009; Hallegraeff, 2010), reef fishes (Munday *et al*., 2009; Nilsson *et al*., 2012), bryozoans and other benthic calcifiers (Fabricius *et al*., 2011). Deep-sea scleractinian corals off New Zealand and Australia are also expected to decline with ocean acidification (Miller *et al*., 2011).

The AR4 identified the Great Barrier Reef (GBR) as highly vulnerable to warming and acidification (Hennessy *et al*., 2007). Recent observations of bleaching and reduced calcification in both the GBR and other reef systems (Cooper *et al*., 2008; De'ath *et al*., 2009; Cooper *et al*., 2012), along with model and experimental studies (Hoegh-Guldberg *et al*., 2007; Anthony *et al*., 2008; Veron *et al*., 2009) confirm this vulnerability (see also Box CC-CR). There is *high confidence* that the combined impacts of warming and acidification associated with atmospheric CO_2 concentrations in excess of 450-500 ppm will be associated with increased frequency and severity of coral bleaching, disease incidence and mortality, leading to dominance by macroalgae (Hoegh-Guldberg *et al*., 2007; Veron *et al*., 2009). Bleaching frequency is expected to increase and become decoupled from the 4-7 year El Niño cycle (Veron *et al*., 2009). Other stresses, including rising sea levels, increased cyclone intensity, and nutrient-enriched runoff, will exacerbate these impacts (*high confidence*; Hoegh-Guldberg *et al*., 2007; Veron *et al*., 2009). Thermal thresholds and the ability to recover from bleaching events vary geographically and between species (e.g. Diaz-Pulido *et al*., 2009) but evidence of the ability of corals to adapt to rising temperatures and acidification is limited and appears insufficient to offset the detrimental effects of warming and acidification (*robust evidence, medium agreement*; Hoegh-Guldberg et al., 2007; Veron et al., 2009).

Under all SRES scenarios and a range of CMIP3 models, pelagic fishes such as sharks, tuna and billfish are projected to move further south on the east and west coasts of Australia (*high confidence*; Hobday, 2010). These changes depend on sensitivity to water temperature, and may lead to shifts in species-overlap with implications for by-catch management (Hartog *et al*., 2011). Poleward movements are also projected for coastal fish species in Western Australia (Cheung *et al*., 2012). A strengthening East Auckland Current in northern New Zealand is expected to promote establishment of tropical or sub-tropical species that currently occur as vagrants in warm La Niña years (Willis *et al*., 2007). Such shifts suggest potentially substantial changes in production and profit of both wild fisheries (Norman-Lopez *et al*., 2011) and aquaculture species such as salmon, mussels and oysters (*medium*

confidence; Hobday *et al*., 2008; Hobday and Poloczanska, 2010). Ecosystem models also project changes to habitat and fisheries production (*low confidence*; Fulton, 2011; Watson *et al*., 2012).

25.6.2.3. Adaptation

In Australia, research on marine impacts and adaptation has been guided by the National Adaptation Research Plan for Marine Biodiversity and Resources (Mapstone *et al*., 2010). Planned adaptation options include removal of human barriers to landward migration of species, beach nourishment, management of environmental flows to maintain estuaries (Jenkins *et al*., 2010), habitat provision (Hobday and Poloczanska, 2010), translocation of seagrass and species such as turtles (e.g. Fuentes *et al*., 2009) and burrow modification for nesting seabirds (Chambers *et al*., 2011). For southern species on the continental shelf, options are more limited because suitable habitat will not be present – the next shallow water to the south is Macquarie Island. There is *low confidence* about the adequacy of autonomous rates of adaptation by species, although recent experiments with coral reef fish suggest that some species may adapt to the projected climate changes (Miller *et al*., 2012).

Management actions to increase coral reef resilience include reducing fishing pressure on herbivorous fish, protecting top predators, managing runoff quality, and minimizing other human disturbances, especially through marine protected areas (Hughes *et al*., 2007; Veron *et al*., 2009; Wooldridge *et al*., 2012). There is *high confidence* that such actions will slow, but not prevent, long-term degradation of reef systems once critical thresholds of ocean temperature and acidity are exceeded, and so novel options, including translocation and shading critical reefs, have been proposed (Rau *et al*., 2012). Forecasting can also prepare managers for bleaching events (Spillman, 2011).

Adaptation by the fishing industry to shifting distributions of target species is considered possible by most stakeholders (e.g. southern rock lobster fishery; Pecl *et al*., 2009). Translocation to maintain production in the face of declining recruitment may also be possible for some high value species, and has been trialled for the southern rock lobster (Green *et al*., 2010a). Options for aquaculture include disease management, alternative site selection, and selective breeding (Battaglene *et al*., 2008), although implementation is only in preliminary stages for both Australia and New Zealand. Marine protected area planning is not explicitly considering climate change in either country, but reserve performance will be affected by the projected environment shifts and novel combinations of species, habitats and human pressures (Hobday, 2011).

_____ START BOX 25-3 HERE _____

Box 25-3. Impacts of a Changing Climate in Natural and Managed Ecosystems

Observed changes in species, and in natural and managed ecosystems (25.6.1, 25.6.2, 25.7.2) provide multiple lines of evidence of the impacts of a changing climate[1]. Examples of observations published since the AR4 are shown in Table 25-3. At present only one study describes a climate-related change in a managed ecosystem (wine grape ripening in Australia; Webb *et al*., 2012a). It remains unclear whether this imbalance is due to confounding factors or a lack of published research.

[INSERT TABLE 25-3 HERE
Table 25-3: Examples of detected changes in species, natural and managed ecosystems, consistent with a climate change[1] signal, published since the AR4. Confidence in detection of change is based on the length of study, and the type, amount and quality of data in relation to the natural variability in the particular species or system. Confidence in the role of climate as a major driver of the change is based on the extent to which the detected change is consistent with that expected under climate change, and to which other confounding or interacting non-climate factors have been considered and been found insufficient to explain the observed change.]

[FOOTNOTE 1: Consistent with the IPCC definition, a change in climate refers to any statistically detectable signal, it does not necessarily imply a human cause. See Glossary, Table 25-1 and 25.2.]

_____ END BOX 25-3 HERE _____

25.7. Major Industries

25.7.1. Production Forestry

Australia has about 149 Mha forests (includes woodlands, 2 Mha plantations, 9.4 Mha multiple-use native forests; MPIGA, 2008; Gavran and Parsons, 2010), and forestry contributes around $7 billion annually to GDP (ABARES, 2011a). New Zealand's plantation estate comprises about 1.7 Mha (90% *Pinus radiata*), with recent contractions due to increased profitability of dairying (MfE, 2008b; NZPFI, 2012).

25.7.1.1. Observed and Projected Impacts

Existing climate variability and other confounding factors have so far prevented the detection of climate change impacts on forests. Modelled projections are based on ecophysiological responses of forests to CO_2, water and temperatures. In Australia, potential changes in water availability will be most important (*very high confidence*). Modelling future distributions or growth rates indicate that plantations in south-west Western Australia are most at risk due to declining rainfall, and there is *high confidence* that plantation growth will be reduced by temperature increases in hotter regions, especially where species are grown at the upper range of their temperature tolerances (Medlyn *et al*., 2011a). There is *limited evidence* and *medium agreement* that moderate reductions in rainfall and increased temperature could be offset by fertilisation from increasing CO_2 (Simioni *et al*., 2009). In cool regions where water is not limiting, higher temperatures could benefit production (Battaglia *et al*., 2009). In New Zealand, temperatures are mostly sub-optimal for forest growth and water relations are generally less limiting (Kirschbaum and Watt, 2011). Warming is expected to increase *P. radiata* growth in the cooler south (*very high confidence*). In the warmer north, temperature increases can reduce productivity, but CO_2 fertilisation may offset this (*medium confidence*; Kirschbaum *et al*., 2012).

Modelling studies are limited by their reliance on key assumptions which are difficult to verify experimentally, e.g. either no or strong down-regulation of photosynthesis under elevated CO_2 (Battaglia *et al*., 2009). Most studies also exclude impacts of pests, diseases, weeds, fire and wind damage that may change adversely with climate. Fire, for instance, poses a significant threat in Australia and is expected to worsen with climate change (see Box 25.6), especially for the commercial forestry plantations in the southern winter-rainfall regions (Williams *et al*., 2009; Clarke *et al*., 2011). In New Zealand, changes in biotic factors are particularly important as they already affect plantation productivity. *Dothistroma* blight, for instance, is a serious pine disease with a temperature optimum that coincides with New Zealand's warmer, but not warmest, pine-growing regions (Watt *et al*., 2011a). Under climate change, its severity is, therefore, expected to reduce in the warm central North Island but increase in the cooler South Island (*high confidence*) where it could offset temperature-driven improved plantation growth. There is *medium evidence* and *high agreement* of similar future southward shifts in the distribution of existing plantation weed, insect pest and disease species in Australia (see review in Medlyn *et al*., 2011b).

25.7.1.2. Adaptation

Adaptation strategies include changes to species or provenance selection, and adopting different silvicultural options, e.g. fertilizer management or modified stand stocking (White *et al*., 2009; Booth *et al*., 2010). Depending on the extent of climate changes, and plant responses to increasing CO_2, the above studies (25.7.1.1) provide *limited evidence* but *high agreement* of potential net increased productivity in many areas, but only where soil nutrients are not limiting. The rotation time of plantation forests of about 30 years or more makes proactive adaptation important but also challenging. There is *medium evidence* and *high agreement* that the greatest barriers to long-term adaptation planning are incomplete knowledge of plant responses to CO_2 concentration and uncertainty in regionally-specific climate change scenarios (Medlyn *et al*., 2011b).

25.7.2. Agriculture

Australia produces 93% of its domestic food requirements yet still exports 76% of agricultural production (11.9% of total exports; DAFF, 2010). New Zealand agriculture contributes about 56% of total export value of which dairy products contribute 30% (Stats NZ, 2011c); 95% of all New Zealand dairy products are exported and these account for about 35% of world trade. Agricultural production is sensitive to climate (in particular to drought; see Box 25-5) but also to many non-climate factors, which thus far has limited detection or attribution of climate-related changes (7.2, although see Webb et al., 2012a). In New Zealand, the importance of agriculture makes the economy very sensitive to climate, for example an increase in soil moisture deficit has an immediate negative effect on domestic output and a consequent effect on GDP (Buckle *et al*., 2002)

25.7.2.1. Projected Impacts and Adaptation – Livestock Systems

Livestock grazing dominates land use by area in the region. At the Australian national level, the net effect of a 3°C temperature increase is expected to be a 4% reduction in gross value of the beef, sheep and wool sector due to declining rainfall and rising temperatures (McKeon et al., 2008). Dairy output is projected to decline in all regions of Australia other than Tasmania under a 1°C increase by 2030 (Hanslow *et al*., submitted). Projected changes in national pasture production for dairy, sheep and beef pastures in New Zealand range from an average reduction of 4% across climate scenarios for the 2030s (Wratt et al., 2008) to increases of up to 4% for two scenarios in the 2050s (Baisden *et al*., 2010), with increases based on more recent process-based models that incorporate CO_2 fertilisation and nitrogen feedbacks. An analysis of the impact of a 0.9-1.2°C increase on dairy systems across five sites in New Zealand found little change in operating profit over the period 2030-2049 (Lee et al., 2012).

Studies modelling seasonal (rather than annual average) changes in fodder supply show greater sensitivity in animal production to climate change and elevated CO_2 than previously anticipated and are expected to occur even under modest warming (*high confidence*) in both New Zealand (Lieffering *et al*., 2012) and Australia (Moore and Ghahramani, 2013). Across 25 sites in southern Australia (an area covering 85% of sheep and 40% of beef production regions), modelled profitability declined at most sites by the 2050s because of a shorter growing season (Moore and Ghahramani, 2013). Increasing soil fertility (largely using phosphate fertiliser) was an adequate adaptation until about 2050 but, thereafter, transformational change, such as enterprise choice, would be required to maintain incomes (Ghahramani and Moore, submitted). In New Zealand, projected changes in seasonal pasture growth drove changes in animal production at four sites representing the main areas of sheep production (Lieffering *et al*., 2012). In Hawke's Bay, changes in stock number were able to maintain farm income for a period in the face of variable forage supply but transformational adaptation would be required to maintain farm income in the longer term. In Southland and Waikato, projected increases in early spring pasture growth posed management problems in maintaining pasture quality, yet, if these were met, animal production could be maintained or increased.

Rainfall is a key determinant of inter-annual variability in production and profitability of pastures and rangelands (Radcliffe and Baars, 1987; Steffen *et al*., 2011) yet remains the most uncertain change. Savannahs that are currently water-limited are expected to show greater sensitivity to temperature and rainfall changes than nitrogen-limited ones (Webb *et al*., 2012b). The 'water-sparing' effect of elevated CO_2 (offsetting reduced water availability through reduced rainfall and increased temperatures) is invoked in many impact studies but reduced stomatal conductance does not always translate into production benefits (Kamman *et al*., 2005; Newton *et al*., 2006; Stokes and Ash, 2007; Wan *et al*., 2007). The impacts of elevated CO_2 on forage production, quality, nutrient cycling and water availability remains the major uncertainty in modelling system responses (McKeon *et al*., 2009). New Zealand agro-ecosystems are subject to erosion processes strongly driven by climate; greater certainty in projections of rainfall, particularly storm frequency, are needed to better understand climate change impacts on erosion (Basher et al., 2012).

25.7.2.2. Projected Impacts and Adaptation – Cropping

Experiments (Fitzgerald *et al*., 2010) and modelling for wheat in Australia (Crimp *et al*., 2008; Luo *et al*., 2009; O'Leary *et al*., 2010) and New Zealand (Teixeira *et al*., 2012) support the AR4 conclusion (Hennessy *et al*., 2007)

that adaptation, particularly altering sowing dates and cultivars, can sustain or increase yields past 2050 except under the most extreme low rainfall scenarios (*high confidence*). Although yields may increase in New Zealand with current management (Teixeira *et al*., 2012), adaptation will be essential in Australia to avoid yield reductions in some regions (Luo *et al*., 2009). Under the more severe climate scenarios and without adaptation, Australia could become a net importer of wheat (Howden *et al*., 2010).

Rice production in Australia is largely dependent on irrigation and climate change impacts will strongly depend on water availability and price (Gaydon *et al*., 2010). Sugarcane is also strongly water dependent (Carr and Knox, 2011); yields may increase where rainfall is unchanged or increased, but rising temperatures could drive up evapotranspiration and increase water use (*medium confidence*; Park *et al*., 2010).

Observed trends and modelling for wine-grapes suggest that climate change will lead to earlier budburst, ripening and harvest for most regions and scenarios (*high confidence*; Grace *et al*., 2009; Sadras and Petrie, 2011; Webb *et al*., 2012a). Without adaptation, reduced quality is expected in all Australian regions (*high confidence*; Webb *et al*., 2008). Change in cultivar suitability in specific regions is expected (Clothier *et al*., 2012), with potential for development of cooler or more elevated sites within some regions (Tait, 2008; Hall and Jones, 2009) and/or expansion to new regions, with some growers in Australia already relocating (e.g. to Tasmania; Smart, 2010).

Climate change and elevated CO_2 impacts on weeds, pests and diseases are highly uncertain (see Box 25.4). Future performance of currently effective resistance mechanisms under elevated CO_2 and temperature is particularly important (Melloy *et al*., 2010; Chakraborty *et al*., 2011) as is the future efficacy of biocontrol (Gerard *et al*., 2012), which is widely used in the region. Australia is ranked second and New Zealand fourth in the world in the number of biological control agent introductions (Cock *et al*., 2010).

25.7.2.3. Integrated Adaptation Perspectives

Future water demand by the sector is critical for planning (Box 25.2). Even though dryland agriculture dominates in Australia (DAFF, 2010), irrigation takes 50% of total water consumption (70% in the Murray-Darling Basin; Quiggin *et al*., 2008), and generates 30% of the gross value of Australian agriculture (Robertson, 2010). Reduced inflow under a non-mitigation scenario is predicted to reduce the value of agricultural production in the Basin by 12-44% to 2030 and 49-72% to 2050 (A1FI; Garnaut, 2008). Water availability also constrains agricultural expansion: 17 Mha in northern Australia could support cropping but only 1% has appropriate water availability (Webster *et al*., 2009). In New Zealand, the irrigated area has risen by 82% since 1999 to over 1 Mha; 76% is on pasture (Rajanayaka *et al*., 2010). The New Zealand dairy herd doubled between 1980-2009 moving from high rainfall zones (>2000 mm annual) to drier, irrigation-dependent areas (600-1000 mm annual); this dependence will increase with expansion (Robertson, 2010), which is being supported by the Government's Irrigation Acceleration Fund.

Many adaptation options such as flexible water allocation, irrigation and seasonal forecasting support managing risk in the current climate (Howden *et al*., 2008; Botterill and Dovers, 2013) and adoption is often high (Hogan *et al*., 2011a; Kenny, 2011). However, incremental on-farm adaptation has limits (Stafford-Smith *et al*., 2011a; Park *et al*., 2012) and may hinder transformational change such as diversification of land use or relocation (see Box 25-5) if it encourages persistence where climate change may take current systems beyond their response capacity (Marshall, 2010; Park *et al*., 2012; Rickards and Howden, 2012). In many cases, transformational change requires a greater level of commitment, access to more resources, and greater integration across levels of decision-making that encompass both on- and off-farm knowledge, processes and values (Marshall, 2010; Rickards and Howden, 2012).

_____ START BOX 25-4 HERE _____

Box 25-4. Biosecurity

Biosecurity is a high priority for Australia and New Zealand given the economic importance of biologically-based industries and risks to endemic species and iconic ecosystems. There is *high confidence* that the biology and

potential risk from invasive and native pathogenic species will be altered by climate change (Roura-Pascual *et al.*, 2011), but impacts may be positive or negative depending on the particular system.

[INSERT TABLE 25-4 HERE
Table 25-4: Examples of potential consequences of climate change for invasive and pathogenic species relevant to Australia and New Zealand, with consequence categories based on Hellman et al. (2008).]

_____ START BOX 25-5 HERE _____

Box 25-5. Climate Change Vulnerability and Adaptation in Rural Areas

Rural communities in Australasia have higher proportions of older and unemployed people than urban populations (Mulet-Marquis and Fairweather, 2008). Employment and economic prospects depend heavily on the physical environment and hence are highly exposed to climate (averages, variability and extremes) as well as changing commodity prices. These interact with other economic, social and environmental pressures, such as changing government policies (e.g. on drought, carbon pricing; Productivity Commission, 2009; Nelson *et al.*, 2010) and access to water resources. The vulnerability of rural communities differs within and between countries reflecting differences in financial security, environmental awareness, policy and social support, strategic skills and capacity for diversification (Bi and Parton, 2008; Marshall, 2009; Nelson *et al.*, 2010; Hogan *et al.*, 2011b; Kenny, 2011).

Climate change will affect rural industries and communities through impacts on resource availability and distribution, particularly water. Decreased availability and/or increased demand, or price, in response to climate change will increase tensions among agricultural, mining, urban and environmental water users (*very high confidence*), with implications for governance and participatory adaptation processes to resolve conflicts (see 25.4.2, 25.4.3, 25.6.1, 25.7.2, 25.7.3, Box 25-2, Box 25-10). Communities will also be affected through direct impacts on primary production, extraction activities, critical infrastructure, population health and recreational and culturally significant sites (see 25.7, 25.8; Kouvelis *et al.*, 2010; Balston *et al.*, 2012).

Altered production and profitability risks and/or land use will translate into complex and interconnected effects on rural communities, particularly income, employment, service provision, and reduced volunteerism (Stehlik *et al.*, 2000; Bevin, 2007; Kerr and Zhang, 2009). The prolonged drought in Australia during the early 2000s, for example, had many interrelated negative social impacts in rural communities, including farm closures, increased poverty, increased off-farm work and, hence, involuntary separation of families, increased social isolation, rising stress and associated health impacts, including suicide (especially of male farmers), accelerated rural depopulation and closure of key services (*high agreement, robust evidence*; Alston, 2007; Edwards and Gray, 2009; Alston, 2010, 2012; Hanigan *et al.*, 2012). Positive social change also occurred, however, including increased social capital through interaction with community organisations (Edwards and Gray, 2009). While social and cultural changes have the potential to undermine the adaptive capacity of communities (Smith *et al.*, 2011b), robust ongoing engagement between farmers and the local community can contribute to a strong sense of community and enhance potential for resilience (McManus *et al.*, 2012).

The economic impact of droughts on rural communities and the entire economy can be substantial. The 2002-03 drought in Australia, for example, significantly reduced agricultural income and employment and subtracted around 1% from GDP (equivalent to A$7.4 billion; ABS, 2004), but the full impact may have been as high as 1.6% when indirect impacts are included (Horridge *et al.*, 2005). Widespread drought in New Zealand during 2007-2009 affected many regions not traditionally impacted by drought, such as the Waikato, resulting in an estimated reduction of NZ$3.6 billion in direct and off-farm output (Butcher, 2009). Drought frequency and severity are projected to increase in many parts of the region (Table 25-1).

The decisions of rural enterprise managers have significant consequences for and beyond rural communities (Pomeroy, 1996; Clark and Tait, 2008). Many current responses are incremental, responding to existing climate variability (Kenny, 2011), but transformational change has occurred where industries and individuals are relocating

part of their operations, e.g. rice (Gaydon *et al*., 2010), wine-grapes (Park *et al*., 2012), peanuts (Thorburn *et al*., 2012) or changing and diversifying land use *in situ* (e.g. the recent switch from grazing to cropping in South Australia; Howden *et al*., 2010) in response to recent and/or expectations of future climate or policy change (Kenny, 2011; see also Box 25-10). Such transformational changes are expected to become more frequent and widespread with a changing climate (*high confidence*; 25..6.2), with positive or negative implications for the wider communities in origin and destination regions.

Although stakeholders within rural communities differ in their vulnerabilities and adaptive capacities, they are bound by similar dependence upon critical infrastructure and resources, economic conditions, government policy direction, and societal expectations (Loechel *et al*., 2013). Consequently, adaptation to climate change will require an approach that devolves decision-making to the level where the knowledge for effective adaptations resides, using open communication, interaction and joint-planning (Nelson *et al*., 2008).

_____ END BOX 25-5 HERE _____

_____ START BOX 25-6 HERE _____

Box 25-6. Climate Change and Fire

Fire during hot, dry and windy summers in southern Australia can cause loss of life and substantial property damage (Cary *et al*., 2003; Adams and Attiwill, 2010). The 'Black Saturday' bushfires in Victoria in February 2009, for example, burnt over 4,500 km^2, caused 173 deaths, destroyed over 2,000 buildings and caused damages of A$4billion (Cameron *et al*., 2009; VBRC, 2010). This fire occurred toward the end of a 13-year drought (CSIRO, 2010) and after an extended period of consecutive days over 40°C (Tolhurst, 2009).

Climate change is expected to increase the number of days with very high and extreme fire weather (Table 25-1), with greater changes where fire is weather-constrained (most of southern Australia; many, in particular eastern and northern, parts of New Zealand) than where it is constrained by fuel load and ignitions (tropical savannas in Australia). Fire season length will be extended in many already high-risk areas (*high confidence*) and so reduce opportunities for controlled burning (Lucas *et al*., 2007). Higher CO_2 will also generally enhance fuel loads except where moisture is limiting (Donohue *et al*., 2009; Williams *et al*., 2009; Bradstock, 2010; Hovenden and Williams, 2010; King *et al*., 2011).

Climate change and fire will have complex impacts on vegetation communities and biodiversity, with negative or positive implications in different regions (Williams *et al*., 2009). The greatest impacts on biodiversity in Australia are expected in the sclerophyll forests of the south-east and south-west (Williams *et al*., 2009). Most New Zealand native ecosystems have limited exposure but also limited adaptation to fire (Ogden *et al*., 1998; McGlone and Walker, 2011). There is *high confidence* that increased incidence of fires in southern Australia will increase risk to people, property and infrastructure such as electricity transmission lines (Parsons Brinkerhoff, 2009; O'Neill and Handmer, 2012; Whittaker *et al*., 2013) and in parts of New Zealand where urban margins expand into rural areas (Jakes *et al*., 2010; Jakes and Langer, 2012); exacerbate some respiratory conditions such as asthma (Johnston *et al*., 2002; Beggs and Bennett, 2011); and increase economic risks to plantation forestry (Watt *et al*., 2008; Pearce *et al*., 2011). Forest regeneration following wildfires also reduces water yields (Brown *et al*., 2005; MDBC, 2007), while reduced vegetation cover increases erosion risk and material washoff to waterways with implications for water quality (Shakesby *et al*., 2007; Wilkinson *et al*., 2009; Smith *et al*., 2011a).

In Australia, fire management will become increasingly challenging under climate change (*high confidence*; O'Neill and Handmer, 2012; Whittaker *et al*., 2013). Current initiatives centre on planning and regulations, building design to reduce flammability, fuel management, early warning systems, and fire detection and suppression (Handmer and Haynes, 2008; Preston *et al*., 2009; VBRC, 2010; O'Neill and Handmer, 2012). Some Australian authorities are taking climate change into account when rethinking approaches to managing fire to restore ecosystems while protecting human life and properties (Preston *et al*., 2009; Adams and Attiwill, 2010). Improved understanding of climate-drivers of fire risks is assisting fire management agencies, landowners and communities in New Zealand

(Pearce *et al*., 2008; Pearce *et al*., 2011), although changes in management to date show little evidence of being driven by climate change.

_____ END BOX 25-6 HERE _____

25.7.3. Mining

Australia is the world's largest exporter of coking coal and iron ore and has the world's largest resources of brown coal, nickel, uranium, lead and zinc (ABS, 2012a). Recent events demonstrated significant vulnerability to climate extremes: the 2011 floods reduced coal exports by 25-54 million tonnes and led to A$5-9bn in lost revenue in that year (ABARES, 2011b; RBA, 2011). Impacts were exacerbated by regulatory constraints on mine discharges, highlighting tensions among industry, social and ecological management objectives (QRC, 2011).

Projected changes in climate extremes imply increasing sector vulnerability without adaptation (*high confidence*; Hodgkinson *et al*., 2010a; Hodgkinson *et al*., 2010b). Stakeholders perceive the adaptive capacity of the industry to be high (Hodgkinson *et al*., 2010a; Loechel *et al*., 2010; QRC, 2011), but costs and broader benefits are yet to be explored along the value-chain and evaluated for community support. On-going and open challenges include competition for energy and water, climate scepticism, avoiding maladaptation, and mining-community relations regarding response options, acceptable mine discharges and post-mining rehabilitation (Loechel *et al*., 2013).

25.7.4. Energy Supply, Demand and Transmission

Primary energy demand is projected to grow by 0.5-1.3% per annum in Australasia over the next few decades (MED, 2011; Syed, 2012). Australia's predominantly thermal power generation is vulnerable to drought-induced water restrictions, which could require dry-cooling and increased water use efficiency where rainfall declines (Graham *et al*., 2008; Smart and Aspinall, 2009). Depending on carbon price and technology costs, renewable electricity generation in Australia is projected to increase from 10% in 2010/11 to 19-50% by 2030 (Hayward *et al*., 2011; Stark *et al*., 2012; Syed, 2012), but few studies have explored the climate vulnerability of these new energy sources (Bryan *et al*., 2010; Crook *et al*., 2011; Odeh *et al*., 2011).

New Zealand's predominantly hydroelectric power generation is vulnerable to precipitation variability. Increasing winter precipitation and snow melt, and a shift from snowfall to rainfall will reduce this vulnerability (*medium confidence*) as winter/spring inflows to main hydro lakes are projected to increase by 5-10% over the next few decades (McKerchar and Mullan, 2004; Poyck *et al*., 2011). Further reductions in seasonal snow and glacial melt as glaciers diminish, however, would compromise this benefit (Chinn, 2001; Renwick *et al*., 2009; Srinivasan *et al*., 2011). Increasing wind power generation (MED, 2011) would benefit from projected increases in mean westerly winds but face increased risk of damages and shut-down during extreme winds (Renwick *et al*., 2009).

Climate warming would reduce annual average peak electricity demands by 1-2% per °C across New Zealand and 2(±1)% in New South Wales, but increase by 1.1(±1.4) and 4.6(±2.7)% in Queensland and South Australia due to air conditioning demand (Stroombergen *et al*., 2006; Jollands *et al*., 2007; Thatcher, 2007; Chen and Lie, 2010). Increased summer peak demand (see also Figure 25-5) will place additional stress on networks, particularly in Australia (*very high confidence*; Jollands *et al*., 2007; Thatcher, 2007; Howden and Crimp, 2008; Wang *et al*., 2010a). During the 2009 Victorian heat wave, for example, demand rose by 24% but electrical losses from transmission lines increased by 53% due to higher peak currents (Nguyen *et al*., 2010), and successive failures of the overloaded network temporarily left more than 500,000 people without power (QUT, 2010). Various adaptation options to limit increasing urban energy demand exist and some are being implemented (see Box 25-9).

There is *limited evidence* but *high agreement* that without additional adaptation, distribution networks in most Australian states will be at high risk of failure by 2031-2070 under non-mitigation scenarios due to increased bushfire risk and potential strengthening and southward shift of severe cyclones in tropical regions (Maunsell and CSIRO, 2008; Parsons Brinkerhoff, 2009). Adaptation costs have been estimated at A$2.5 billion to 2015, with

more than half to meet increasing demand for air conditioning and the remainder to increase resilience to climate-related hazards; underground cabling would reduce bushfire risk but has large investment costs (not included above; Parsons Brinkerhoff, 2009). Decentralised ownership of assets constitutes a significant adaptation constraint (ATSE, 2008; Parsons Brinkerhoff, 2009). In New Zealand, increasing high winds and temperatures have been identified qualitatively as the most relevant risks to transmission (Jollands *et al*., 2007; Renwick *et al*., 2009).

25.7.5. Tourism

Tourism contributes 2.6-4% of GDP to the economies of Australia and New Zealand (ABS, 2010b; Stats NZ, 2011a). The net present value of the Great Barrier Reef alone over the next 100 years has been estimated at A$51.4 billion (Oxford Economics, 2009). Most Australasian tourism is exposed to climate variability and change, and some destinations are highly sensitive to extreme events (Becken and Hay, 2012). The 2011 floods and Cyclone Yasi, for example, cost the Queensland tourism industry about A$590 million, mainly due to cancellations and damage to the Great Barrier Reef (PWC, 2011), and drought in the Murray-Darling Basin caused an estimated A$70 million loss in 2008 due to reduced visitor days (TRA, 2010).

25.7.5.1. Projected Impacts

Future impacts on tourism have been modelled for several Australian destinations. The Great Barrier Reef is expected to degrade under all climate change scenarios (Box CC-CR, 25.6.2, 30.5), reducing its attractiveness (Marshall and Johnson, 2007; Bohensky *et al*., 2011; Wilson and Turton, 2011). Ski tourism is expected to decline in the Australian Alps due to snow cover reducing more rapidly than in New Zealand (Pickering *et al*., 2010; Hendrikx *et al*., in press) and greater perceived broad attractiveness of New Zealand (Hopkins *et al*., 2012). Higher temperature extremes in the Northern Territory are projected with *high confidence* to increase heat stress and incur higher costs for air conditioning (Turton *et al*., 2009). Sea level rise places pressures on shorelines and long-lived infrastructure but implications for tourist resorts have not been quantified (Buckley, 2008).

Economic modelling suggests that the Australian alpine region would be most negatively affected in relative terms due to limited alternative activities (Pham *et al*., 2010), whereas the competitiveness of some destinations (e.g. Margaret River in Western Australia) could be enhanced by higher temperatures and lower rainfall (Jones *et al*., 2010; Pham *et al*., 2010). An analogue-based study suggests that, in New Zealand, warmer and drier conditions mostly benefit but wetter conditions and extreme climate events undermine tourism (Wilson and Becken, 2011). *Confidence* in outcomes is *low* due to uncertain future tourist behaviour (Scott *et al*., 2012; also 25.9.2).

25.7.5.2. Adaptation

Both New Zealand and Australia have adaptation strategies for tourism (Becken and Clapcott, 2011; Zeppel and Beaumont, 2011); promoted preparation for extreme events (Tourism Queensland, 2007, 2010; Tourism Victoria, 2010); and are strengthening ecosystem resilience to maintain destination attractiveness (GBRMPA, 2009). Snow-making is already broadly adopted to increase reliability of skiing (Bicknell and McManus, 2006; Hennessy *et al*., 2008b), but its future effectiveness depends on location. In New Zealand, even though warming will significantly reduce the number of days suitable for snow-making (Hendrikx and Hreinsson, 2012), sufficient snow could be made in all years until the end of the 21st century to maintain current minimum operational skiing conditions. Options for resorts in Australia's Snowy Mountains are far more limited (Hendrikx *et al*., in press), where maintaining skiing conditions until at least 2020 would require A$100 million in capital investment into 700 snow guns and 2.5-3.3 GL of water per month (Pickering and Buckley, 2010).

Short investment horizons, high substitutability and a high proportion of human capital compared with built assets give *high confidence* that the adaptive capacity of the tourism industry is high overall, except for destinations where climate change is projected to degrade core natural assets and diversification opportunities are limited (Evans *et al*., 2011; Morrison and Pickering, 2011). Strategic adaptation decisions are constrained by uncertainties in regional

climatic changes (Turton *et al*., 2010), limited concern (Bicknell and McManus, 2006), lack of leadership and limited coordinated forward planning (Sanders *et al*., 2008; Turton *et al*., 2009; Roman *et al*., 2010; White and Buultjens, 2012). An integrated assessment of tourism vulnerability in Australasia is not yet possible due to limited understanding of future changes in tourism and community preferences (Scott *et al*., 2012), including the flow-on effects of changing travel behaviour and tourism preferences in other world regions (see 25.9.2).

25.8. Human Society

25.8.1. Human Health

25.8.1.1. Observed Impacts

Life expectancy in Australasia is high, but shows substantial ethnic and socio-economic inequalities (Anderson *et al*., 2006b). There is *high agreement and robust evidence* that mortality increases in hot weather (Bi and Parton, 2008; Vaneckova *et al*., 2008) with air pollution exacerbating this association. Exceptional heatwave conditions in Australia have been associated with substantial increases in mortality and hospital admissions in several capital cities (*high confidence*; Khalaj *et al*., 2010; Loughnan *et al*., 2010; Tong *et al*., 2010a; Tong *et al*., 2010b). In January and February 2009, for example, south-eastern Australia experienced record maximum temperatures and consecutive hot days in many locations (BoM, 2009). Over this period, total emergency cases increased by 25% and by 46% over the three hottest days. Direct heat-related health problems increased 34-fold, 61% of these being people aged 75 years or older. There were 374 excess deaths, a 62% increase in all-cause mortality (Victorian Government, 2009a). Mental health admissions increased by 7.3% in metropolitan South Australia during heatwaves (1993-2006), with increases across all age groups (Hansen *et al*., 2008). Mortality attributed to mental and behavioural disorders increased in the 65 to 74-year age group and in persons with schizophrenia, schizotypal, and delusional disorders (Hansen *et al*., 2008). Experience of extreme events also correlates strongly with general concern about climate change and psychological well-being (see 25.4.3).

25.8.1.2. Projected Impacts

Projected increases in heatwaves (see Figure 25-5) will increase both heat-related deaths and hospitalizations, especially among the elderly, compounded by population growth and ageing (*high confidence*). This may be partly offset by reduced deaths from cold at least for modest rises in temperature in the southern states of Australia and parts of New Zealand (*low confidence*; Bambrick *et al*., 2008; Kinney, 2012). Relative to a baseline that allowed for demographic change but no climate change after 2005, the annual net change across Australia was 943 (-11%) *fewer* deaths in 2070 and 924 (-11%) fewer in 2100 in a strongly mitigated 450 ppm scenario, or an *additional* 1250 (+14%) deaths in 2070 and 8628 (+100%) in 2100 in a hot, dry A1FI scenario (Bambrick *et al*., 2008). In this study, which accounted for changes in the mean but not variability of temperatures, net results were driven almost entirely by increased mortality in the north, especially Queensland, consistent with Huang *et al*., (2012) who projected temperature-related years of life lost in Brisbane. In a separate study, which did account for increased daily temperature variability, a substantial increase in heat-related deaths was estimated for Sydney (Gosling *et al*., 2009): using the HadCM3 climate model for both recent past and future climates, without adaptation, annual heat-related deaths per 100,000 people were projected to increase nearly threefold, from 2.5 in 1961-1990 to 7.4 in 2070-2099 for the A2 emissions scenario, and from 2.6 to 6.8 for the B2 scenario. The annual number of temperature-related hospital admissions in South Australia under the A1FI scenario is projected to increase 110% by 2100 (Bambrick *et al*., 2008). The number of hot days when physical labor in the sun becomes dangerous is also projected to increase substantially in Australia by 2070, leading to economic costs from lost productivity, increased hospitalisations and occasional deaths (*medium confidence*; Hanna *et al*., 2011; Maloney and Forbes, 2011).

Water- and food-borne diseases are projected to increase, but the complexity of their relationship to climate and non-climate drivers means there is *low confidence* in specific projections. For Australia, 205,000-335,000 new cases of bacterial gastroenteritis by 2050, and 239,000-870,000 cases by 2100, were projected under a range of emission scenarios (Bambrick *et al*., 2008; Harley *et al*., 2011). Water-borne zoonotic diseases such as cryptosporidiosis have

more complex relationships with climate (Lal *et al*., 2012), while water treatment systems help to prevent outbreaks related to heavy rainfall or flooding (Britton *et al*., 2010b, a).

Current empirical models assess the combined effects of climate change and socio-economic development on the distribution of vector borne diseases. The area climatically suitable for transmission of dengue is projected to expand under A1FI scenarios in Australia (*high confidence*; Bambrick *et al*., 2008). This expansion may be limited or even reversed depending on socio-economic development (*low confidence*; Åström *et al*., 2013). Australasia is projected to remain malaria free under the A1B emission scenario until at least 2050 (Béguin *et al*., 2011) and sporadic cases could be treated effectively. The impacts of climate change on Ross River and other arboviruses with more complex transmission cycles that involve multiple host species have not been modelled in this region. However, the combined effects of climate change, frequent travel within and outside the region, and recent incursions of exotic mosquito species suggest that the geographic range of arboviruses could expand (*medium confidence*; Derraik and Slaney, 2007; Derraik *et al*., 2010).

A growing literature since the AR4 has focused on the psychological impacts of climate change, based on impacts of recent climate variability and extremes (Doherty and Clayton, 2011; 25.4.3). These studies indicate significant mental health risks associated with climate-related disasters, in particular persistent and severe drought, floods and storms, and that impacts may be especially acute in rural communities where climate change places additional stresses on livelihoods (*high confidence*; Edwards *et al*., 2011; see also Box 25.5). Projected population growth and urbanization could further increase health risks indirectly via climate-related stress on housing, transport and energy infrastructure and water supplies (*low confidence*; Howden-Chapman, 2010).

[INSERT FIGURE 25-5 HERE
Figure 25-5: Projected changes in exposure to heat under a high emissions scenario (A1FI). Maps show the average number of days with peak temperatures >40°C for Australian statistical local areas, for ~1990 (based on available meteorological station data for the period 1975-2004), ~2050 and ~2100. Bar charts show the change in population heat exposure, expressed as person-days exposed to peak temperatures >40°C, aggregated by State/Territory and including projected population growth for a default scenario. Future temperatures are based on simulations by the GFDL-CM2 global climate model (Meehl *et al*., 2007), re-scaled to the A1FI scenario; simulations based on other climate models could give higher or lower results. Data from Baynes *et al*. (2012).]

25.8.1.3. Adaptation

Research since the AR4 has mainly focused on health impacts. Some adaptation strategies have received attention in Australia, however, including reshaping government policy, improving healthcare services, social support for those most at risk, improving community awareness to reduce adverse exposures, and developing early warning and emergency response plans (Wang and McAllister, 2011). In New Zealand, central Government health policies show no specific measures to adapt to climate change (Wilson, 2011).

A review of the southern Australian heatwave of 2009 identified communication failures with no clear public information or warning strategy, no clear thresholds for initiating public information campaigns or incident response resulting in mixed messages to the media and public (Kiem *et al*., 2010). Emergency and services infrastructure were underprepared and relied on reactive solutions (QUT, 2010). Charging more for energy during peak times would reduce risk to infrastructure overload (see 25.7.4), but leave low-income residents more vulnerable to heat waves (Strengers and Maller, 2011). The Victorian government has since developed a heatwave plan to coordinate a state-wide response, maintain consistent community-wide understanding through a Heat Health alert system, build capacity of councils to support communities most at risk from heat-related impacts, support and fund health services and a Heat Health Intelligence surveillance system, and distribute public health information (Victorian Government, 2009b). As a longer term strategy, greening cities reduces the urban heat island effect which in turn reduces heat health risks (Bambrick *et al*., 2011; see Box 25-9). The increased risk of dengue from domestic water tanks suggests a risk of maladaptive outcomes unless climate-related risks are taken into account in their installation and maintenance (Kearney *et al*., 2009).

25.8.2. Indigenous Peoples

25.8.2.1. Aboriginal and Torres Strait Islanders

Australia's Indigenous population is small (2.5%), widely dispersed and rapidly growing (ABS 2009) yet controls more than 25% of the Australian land area (Altman *et al*., 2007; NNTT, 2013). Key work since the AR4 includes a national Indigenous adaptation research action plan (Langton *et al*., 2012), regional risk studies (Green *et al*., 2009; DoNP 2010; TSRA 2010) and scrutiny from an Indigenous rights perspective (ATSISJC 2009).

Socio-economic disadvantage and poor health (SCRGSP 2011) indicate a disproportionate climate change vulnerability of Indigenous Australians (McMichael *et al*., 2009) although there are no detailed assessments. In urban and regional areas, where 75% of the Indigenous population lives, assessments have not specifically addressed risks to Indigenous people (e.g. Guillaume *et al*., 2010). In other regions, all remote, there is limited empirical evidence of vulnerability (Maru *et al*., 2012). However, there is *high agreement* and *medium evidence* for significant future impacts from increasing heat stress, extreme events and increased disease (Campbell *et al*., 2008; Spickett *et al*., 2008; Green *et al*., 2009).

There is also *high agreement* but *limited evidence*, that: natural resource dependence (e.g. Bird *et al*., 2005; Gray *et al*., 2005a; Kwan *et al*., 2006; Buultjens *et al*., 2010) increases Indigenous exposure and sensitivity to climate change (Green *et al*., 2009); climate change-induced dislocation, attenuation of cultural attachment to place and loss of agency will disadvantage Indigenous mental health and community identity (Fritze *et al*., 2008; Hunter, 2009; McIntyre-Tamwoy and Buhrich, 2011); and, housing, infrastructure, services and transport, often already inadequate for Indigenous needs especially in remote Australia (ABS 2010c), will be further stressed (Taylor and Philp, 2010). Torres Strait island communities and livelihoods are vulnerable to major impacts from even small sea level rises (*high confidence*; DCC, 2009; Green *et al*., 2010b; TSRA 2010).

Little adaptation of Indigenous communities to climate change is apparent to date (but see Burroughs, 2010; GETF 2011). Institutions external to Indigenous communities can constrain their adaptive capacity (Ellemor, 2005; Petheram *et al*., 2010; Veland *et al*., 2010; Langton *et al*., 2012) and designing and communicating adaptation strategies is challenged by multiple stressors. Adaptation planning would benefit from a robust typology (Maru *et al*., 2011) across the diversity of Indigenous life experience (McMichael *et al*., 2009). Indigenous re-engagement with environmental management (e. g. Hunt *et al*., 2009; Ross *et al*., 2009) can promote health (Burgess *et al*., 2009) and may increase adaptive capacity (Berry *et al*., 2010; Davies *et al*., 2011). There is emerging interest in integrating Indigenous observations of climate change (Green *et al*., 2010c; Petheram *et al*., 2010) and developing inter-cultural communication tools (Prober *et al*., 2011; Woodward *et al*., 2012). Extensive land ownership in northern and inland Australia and land management traditions mean that Indigenous people are well situated to provide greenhouse gas abatement and carbon sequestration services that may also support their livelihood aspirations (Whitehead *et al*., 2009; Heckbert *et al*., 2012).

25.8.2.2. New Zealand Māori

The projected impacts of climate change on Māori society are expected to be highly differentiated reflecting complex economic, social, cultural, environmental and political factors (*high confidence*). Since the AR4, studies have been either sector-specific (e.g. Insley, 2007; Insley and Meade, 2008; Harmsworth *et al*., 2010; King *et al*., 2012) or more general, inferring risk and vulnerability based on exploratory engagements with varied stakeholders and existing social, economic, political and ecological conditions (e.g. MfE, 2007b; Te Aho, 2007; King *et al*., 2010).

The Māori economy depends on climate-sensitive primary industries with vulnerabilities to climate conditions (*high confidence*; Packman *et al*., 2001; NZIER, 2003; Cottrell *et al*., 2004; TPK, 2007; Tait *et al*., 2008b; Harmsworth *et al*., 2010; King *et al*., 2010; Nana *et al*., 2011a). Much of Māori-owned land is steep (>60%) and susceptible to damage from high intensity rainstorms, while many lowland areas are vulnerable to flooding and sedimentation (Harmsworth and Raynor, 2005; King *et al*., 2010). Land in the east and north is also drought prone, and this

increases uncertainties for future agricultural performance, product quality and investment (*medium confidence*; Cottrell *et al*., 2004; Harmsworth *et al*., 2010; King *et al*., 2010). The fisheries and aquaculture sector faces substantial risks (and uncertainties) from changes in ocean temperature and chemistry, potential changes in species composition, condition and productivity levels (*medium confidence*; King *et al*., 2010; see also 25.6.2). At the community and individual level, Māori regularly utilize the natural environment for hunting and fishing, recreation, the maintenance of traditional skills and identity, and collection of cultural resources (King and Penny, 2006; King *et al*., 2012). Many of these activities are already compromised due to resource-competition, degradation and modification (Woodward *et al*., 2001; King *et al*., 2012). Climate change driven shifts in natural ecosystems will further challenge the capacities of some Māori to cope and adapt (*medium confidence*; King *et al*., 2012).

Māori organizations have sophisticated business structures, governance (e.g. trusts, incorporations) and networks (e.g. Iwi leadership groups) across the state and private sectors (Harmsworth *et al*., 2010; Insley, 2010; Nana *et al*., 2011b), critical for managing and adapting to climate change risks (Harmsworth *et al*., 2010; King *et al*., 2012). Some tribal organizations are developing options in response to the New Zealand Government's Emissions Trading Scheme (Insley, 2010). Future opportunities will depend on partnerships in business, science, research and government (*high confidence*; Harmsworth *et al*., 2010; King *et al*., 2010) as well as innovative technologies and new land management practices to better suit future climates (Carswell *et al*., 2002; Harmsworth, 2003; Funk and Kerr, 2007; Insley and Meade, 2008; Tait *et al*., 2008b; Penny and King, 2010).

Māori knowledge of environmental processes and hazards (King *et al*., 2005; King *et al*., 2007) as well as strong social-cultural networks are vital for adaptation and on-going risk management (King *et al*., 2008); however, choices and actions continue to be constrained by insufficient resourcing, shortages in social capital, and competing values (King *et al*., 2012). Combining traditional ways and knowledge with new and untried policies and strategies will be key to the long-term sustainability of climate-sensitive Māori communities, groups and activities (*high confidence*; Harmsworth *et al*., 2010; King *et al*., 2012).

_____ START BOX 25-7 HERE _____

Box 25-7. Insurance as Climate Risk Management Tool

Insurance helps spread the risk from extreme events across communities and over time and therefore enhances the resilience of society to disasters (see 10.7). In Australia, insured losses are dominated by meteorological hazards, including the 2011 Queensland floods and the 1999 Sydney hailstorm (ICA, 2012) with estimated claims of A$3 billion p.a. (IAA, 2011a). In New Zealand, floods and storms are the second most costly natural hazards after earthquakes (ICNZ, 2013). Even though the number of damaging insured events (up to a certain loss value) has increased significantly in the Oceania region since 1980 (Schuster, 2013), normalised insured losses in Australia show no significant trend from 1967 to 2006 (Crompton and McAneney, 2008; see also Table 10.4).

There is *high confidence* that without adaptive measures, projected increases in extremes (Table 25-1) and uncertainties in these projections will lead to increased insurance premiums, exclusions and non-coverage in some locations (IAG, 2011), which will reshape the distribution of vulnerability, e.g., through unaffordability or unavailability of cover in areas at highest risk (IAA, 2011a, b; NDIR, 2011; Booth and Williams, 2012). Restriction of cover occurred in some locations following recent flood events in Queensland (Suncorp, 2013).

Insurance can positively contribute to risk reduction by providing incentives to policy holders to reduce their risk profile (O'Neill and Handmer, 2012), e.g. through resilience ratings given to buildings (TGA, 2009; Edge Environment, 2011; IAG, 2011). Apart from constituting an autonomous private sector response to extreme events, insurance can also be framed as a form of social policy to manage climate risks, similar to New Zealand's government insurance scheme to manage geological risk (Glavovic *et al*., 2010); government measures to reduce or avoid risks also interact with insurance companies' willingness to provide cover (Booth and Williams, 2012). Insurance can also act as a barrier to adaptation, however, where those living in climate-risk prone localities pay discounted or cross-subsidised premiums, or if policies fail to encourage betterment after damaging events by requiring replacement of 'like for like', constituting a missed opportunity for risk reduction (NDIR, 2011; QFCI, 2012; Reisinger *et al*., 2013; see also 10.7).

_____ END BOX 25-7 HERE _____

_____ START BOX 25-8 HERE _____

Box 25-8. Changes in Flood Risk and Management Responses

Floods are the most costly natural disaster in Australia (BTE, 2001) and the second-most costly insured disaster in New Zealand, after earthquakes (ICNZ, 2013). Nonetheless, flood damages across eastern Australia and both main islands of New Zealand in 2010 and 2011 revealed a significant adaptation deficit (ICA, 2012; ICNZ, 2013). For example, the Queensland floods in January 2011 resulted in 35 deaths, three quarters of the State including Brisbane declared a disaster zone, and damages in excess of AUD$2 billion (Queensland Government, 2011). These floods were associated with a strong monsoon and the strongest La Niña on record (Cai *et al*., 2012; CSIRO and BoM, 2012; Evans and Boyer-Souchet, 2012). Floods exhibit strong decadal variability in their frequency and severity but no significant long-term trend to date (Kiem *et al*., 2003; Smart and McKerchar, 2010; Ishak *et al*., in press).

Flood risk is projected to increase in many regions due to more intense extreme rainfall events driven by a warmer and wetter atmosphere (*medium confidence*; Table 25-1). High resolution downscaling (Griffiths, 2007; Carey-Smith *et al*., 2010), and dynamic catchment hydrological and river hydraulic modelling in New Zealand (Gray *et al*., 2005b; McMillan *et al*., 2010; MfE, 2010a; Ballinger *et al*., 2011; Duncan and Smart, 2011; McMillan *et al*., 2012) indicate that the 50-year and 100-year flood peaks for rivers in many parts of the country will increase by 10-20% by 2050 and more (and greater variation between models and scenarios) by 2100, with a corresponding decrease in return periods for design floods. Studies for Queensland show similar results (DERM *et al*., 2010). In Australia, flood risk is expected to increase more in the north (driven by convective rainfall systems) than in the south (where more intense extreme rainfall may be compensated by drier antecedent moisture conditions), consistent with confidence in heavy rainfall projections (Table 25-1; Alexander and Arblaster, 2009; Rafter and Abbs, 2009a).

Flood risk near river mouths will be exacerbated by storm surge associated with higher sea level and potential change in wind speeds (McInnes *et al*., 2005; MfE, 2010a; Wang *et al*., 2010b). Higher rainfall intensity and peak flow will also increase erosion and sediment loads in waterways (Nearing *et al*., 2004) and exacerbate problems from aging stormwater and wastewater infrastructure in cities (Howe *et al*., 2005; Jollands *et al*., 2007; CCC, 2010; WCC, 2010). However, moderate flooding also has benefits through filling reservoirs, recharging groundwater and replenishing natural environments (Hughes, 2003; Chiew and Prosser, 2011; Oliver and Webster, 2011).

Adaptation to increased flood risks from climate change is starting to happen (Wilby and Keenan, 2012) through updating guidelines for design flood estimation (MfE, 2010a; Westra, 2012), improving flood risk management (O'Connell and Hargreaves, 2004; NFRAG, 2008; Queensland Government, 2011), enhancing coping capacity for buildings in flood prone areas (options include raising floor levels, using strong piled foundations, using water-resistant insulation materials and ensuring weather tightness), and risk reduction and avoidance through spatial planning and managed relocation (Trotman, 2008; Glavovic *et al*., 2010; LVRC, 2012; QFCI, 2012). Adaptation options in urban areas include retaining floodplains and floodways and retrofitting existing systems to attenuate flows (Box 25.9; Howe *et al*., 2005; Skinner, 2010; WCC, 2010).

The recent flooding in eastern Australia and the projected increase in future flood risk have resulted in changes to reservoir operations to mitigate floods (van den Honert and McAneney, 2011; QFCI, 2012) and insurance practice to cover flood damages (NDIR, 2011; Phelan, 2011). However, the magnitude of potential future changes in flood risks and limits to incremental adaptation responses in urban areas suggest that more transformative and structural approaches based on altering land-use and avoidance of exposure to future flooding may be needed in some locations, especially if changes in the upper range of projections are realised (*high confidence*; Lawrence and Allan, 2009; DERM *et al*., 2010; Glavovic *et al*., 2010; Wilby and Keenan, 2012; Lawrence *et al*., submitted-a).

_____ END BOX 25-8 HERE _____

_____ START BOX 25-9 HERE _____

Box 25-9. Opportunities, Constraints, and Challenges to Adaptation in Urban Spaces

Considerable opportunities exist for Australasian cities and towns to reduce climate change impacts and, in some regions, benefit from projected changes such as warmer winters and more secure water supply (Fitzharris, 2010; Australian Government, 2012). Many tools and practices developed for sustainable resource management or disaster risk reduction in urban areas are co-beneficial for climate change adaptation, and vice versa, and can be integrated with mitigation objectives (Hamin and Gurran, 2009). Despite the abundance of potential adaptation options, however, social, cultural, institutional and economic factors frequently constrain their implementation (*robust evidence* and *high agreement*; see also 25.4.2). The form and longevity of cities and towns, with their concentration of hard and critical infrastructure such as housing, transport, energy transmission, waste, telecommunications and public facilities provide additional challenges (see also Chapters 8 and 10, Boxes 25-1, 25-2, 25-8, 25.7.4, 25.8.1). Table 25-5 summarises some adaptation options, co-benefits and constraints on their adoption in Australasia.

Overall, the implementation of climate change adaptation policy for urban settlements in Australia and New Zealand has been mixed. The Australian National Urban Policy encourages adaptation, and many urban plans include significant adaptation policies (City of Melbourne, 2009; City of Port Phillip, 2010; e.g. ACT Government, 2012; City of Adelaide, 2012). New Zealand also promotes urban adaptation through strategies, plans and guidance documents (MfE, 2008a; CCC, 2010; WCC, 2010; Auckland Council, 2012). Many examples of incremental urban adaptation exist already (see Box 25-2, Table 25-5), particularly where these include co-benefits and respond to other stressors, like prolonged drought in southern Australia and recurrent floods. Experience is much scarcer with transformative changes, such as managed relocation or more flexible land-uses that could disrupt existing settlement patterns and development trends, and where maintaining flexibility to address long-term climate risks can run against near-term development pressures (see Boxes 25-2, 25-8). Decision-making models that support adaptive and transformative change (25.4.2) have not yet been implemented widely in urban contexts; increased coordination among different levels of government may be required to spread costs and balance public and private, near- and long-term and local and regional benefits (Norman, 2009; Britton, 2010; Norman, 2010; Abel *et al.*, 2011; McDonald, 2013; Palutikof *et al.*, 2013; Reisinger *et al.*, 2013; Lawrence *et al.*, submitted-a).

[INSERT TABLE 25-5 HERE
Table 25-5: Examples of co-beneficial climate change adaptation options for urban areas and barriers to their adoption. Options in italics are already widely implemented in Australia and New Zealand urban areas.]

_____ END BOX 25-9 HERE _____

25.9. Interactions among Impacts, Adaptation, and Mitigation Responses

The AR4 found that individual adaptation responses can entail synergies or trade-offs with other adaptation responses and with mitigation, but that integrated assessment tools were lacking in Australasia (Hennessy *et al.*, 2007). Subsequent studies provide detail on such interactions and can inform a balanced portfolio of climate change responses, but evaluation tools remain limited, especially for local decision-making (Park *et al.*, 2011). A review of 25 specific climate change-associated land-use plans from Australia, for example, found that 12 exhibited potential for conflict between mitigation and adaptation (Hamin and Gurran, 2009).

25.9.1. Interactions among Local-Level Impacts, Adaptation, and Mitigation Responses

Table 25-6 shows examples of adaptation responses that are either synergistic or entail trade-offs with other impacts and/or adaptation responses and goals. Adapting proactively to projected climate changes, particularly extremes such as floods or drought, can increase near-term resilience to climate variability and be a motivation for adopting adaptation measures (Productivity Commission, 2012). However, exclusive reliance on near-term benefits can increase trade-offs and result in long-term maladaptation (*high confidence*). For example, enhancing protection

measures after major flood events, combined with rapid re-building, accumulates fixed assets that can become increasingly costly to protect as climate change continues, with attendant loss of amenity and environmental values (Glavovic *et al.*, 2010; Gorrdard *et al.*, 2012; McDonald, 2013). Similarly, deferring adoption of increased design wind speeds in cyclone-prone areas delays near-term investment costs but also reduces the long-term benefit/cost ratio of the strategy (Stewart and Wang, 2011).

[INSERT TABLE 25-6 HERE
Table 25-6: Examples of interactions between impacts and adaptation measures in different sectors. In each case, impacts or responses in one sector have the potential to cause negative impacts or have co-benefits with impacts or responses in another sector, or with another type of response in the same sector.]

Mitigation actions can contribute to but also counteract local adaptation goals. Energy efficient buildings, for example, reduce network and health risks during heat waves, but urban densification to reduce transport energy demand intensifies urban heat islands and, hence, heat-related health risks (25.7.4, 25.8.1). Specific adaptations can also make achievement of mitigation targets harder or easier. Increased use of air conditioning, for example, increases energy demand, but reducing heat exposure through energy efficiency and building design reduces demand (25.7.4, Box 25-9). Table 25-7 gives further examples, and Box 25-10 explores the multiple and complex benefits and trade-offs in changing land-use simultaneously to adapt to and mitigate climate change.

[INSERT TABLE 25-7 HERE
Table 25-7: Examples of interactions between adaptation and mitigation measures (green rows denote synergies where multiple benefits may be realized, orange rows denote potential tradeoffs and conflicts; grey row gives an example of complex, mixed interactions). The primary goal may be adaptation or mitigation.]

_____ START BOX 25-10 HERE _____

Box 25-10. Land-based Interactions Among Climate, Energy, Water, and Biodiversity

Climate, water, biodiversity, food and energy production and use are intertwined through complex feedbacks and trade-offs (see also Box CC-WE). This could make alternative uses of natural resources within rural landscapes increasingly contested, yet decision support tools to manage competing objectives are limited (PMSIEC, 2010).

Various policies in Australasia support increased biofuel production and biological carbon sequestration via, for example, mandatory renewable energy targets and incentives to increase carbon storage. Impacts of increased biological sequestration activities on biodiversity depend on their implementation. Benefits arise from reduced erosion, additional habitat, and enhanced ecosystem connectivity, while risks or lost opportunities are associated with large-scale monocultures especially if replacing more diverse landscapes (Brockerhoff *et al.*, 2008; Giltrap *et al.*, 2009; Steffen *et al.*, 2009; Todd *et al.*, 2009; Bradshaw *et al.*, submitted).

Photosynthesis transfers water to the atmosphere, so increased sequestration is projected to reduce catchment yields particularly in southern Australia and affect water quality negatively (Botkin *et al.*, 2007; CSIRO, 2008; Schrobback *et al.*, 2011; Bradshaw *et al.*, submitted). Accounting for this water use in water allocations for sequestration activities would increase their cost and limit the potential of sequestration-driven land-use change (Polglase *et al.*, 2011; Stewart *et al.*, 2011). Large-scale land-cover changes also affect regional climate through changing albedo, evapotranspiration and surface roughness, but these feedbacks have rarely been integrated with direct water demands (McAlpine *et al.*, 2009; Kirschbaum *et al.*, 2011b).

Biological carbon sequestration in New Zealand is less water-challenged than in Australia, except where catchments are projected to become drier and/or are already completely allocated (MfE, 2007a; Rutledge *et al.*, 2011). Carbon sequestration would mostly improve water quality through reduced erosion (Giltrap *et al.*, 2009). Policies to protect water quality by limiting nitrogen discharge from agriculture have reduced livestock production and greenhouse gas emissions in the Lake Taupo catchment and supported land-use change towards sequestration (Yeo *et al.*, 2012).

Trade-offs between biofuel and food production and ecosystem services depend strongly on the type of sequestration activity and their management relies on use of consistent principles to evaluate externalities and benefits of alternative land-uses (PMSIEC, 2010). First-generation biofuels have been modelled in Australia as directly competing with agricultural production (Bryan *et al*., 2010). In contrast, production of woody biofuels in New Zealand is projected to occur on marginal land, not where the most intense agriculture occurs (Todd *et al*., 2009). Falling costs and increasing efficiency of solar energy may limit future biofuel demand, given the limited efficiency of plants in converting solar energy into usable fuel (e.g. Reijnders and Huijbregts, 2007).

_____ END BOX 25-10 HERE _____

25.9.2. Intra- and Inter-Regional Flow-On Effects Among Impacts, Adaptation and Mitigation

Recent studies strengthen conclusions from the AR4 (Hennessy *et al*., 2007) that flow-on effects from climate change impacts occurring in other world regions can exacerbate or counteract projected impacts in Australasia.

Modelling suggests Australia's terms of trade would deteriorate by about 0.23% in 2050 and 2.95% in 2100 as climate change impacts reduce economic activity and demand for coal, minerals and agricultural products in other world regions (A1FI scenario; Harman *et al*., 2008). As a result, Australian Gross National Product (GNP) is expected to decline more strongly than GDP due to climate change, especially towards the end of the 21st century (Gunasekera *et al*., 2008). These conclusions, however, merit only *medium confidence*, because they rely on simplified assumptions about global climate change impacts, economic effects and policy responses.

For New Zealand, there is *limited evidence* but *high agreement* that higher global food prices driven by adverse climate change impacts on global agriculture and some international climate policies would increase commodity prices and hence producer returns. Agriculture and forestry producer returns, for example, are estimated to increase by 14.6% under the A2 scenario by 2070 (Saunders *et al*., 2010) and real gross national disposable income by 0.6-2.3% under a range of non-mitigation scenarios (Stroombergen, 2010) relative to baseline projections in the absence of global climate change. Some climate policies such as biofuel targets and agricultural mitigation in other regions would also increase global commodity prices and hence returns to New Zealand farmers (Saunders *et al*., 2009; Reisinger *et al*., 2012). Depending on global implementation, these could more than offset projected average domestic climate change impacts on agriculture (Tait *et al*., 2008a). In contrast, higher international agricultural commodity prices appear insufficient to compensate for the more severe effects of climate change on agriculture in Australia (see 25.7.2; Gunasekera *et al*., 2007; Garnaut, 2008).

Climate change could affect international tourism to Australasia through international destination and activity preferences (Kulendran and Dwyer, 2010; Rosselló-Nadal *et al*., 2011; Scott *et al*., 2012), climate policies, and oil prices (Mayor and Tol, 2007; Becken, 2011; Schiff and Becken, 2011). These potentially significant effects remain poorly quantified, however, and are not well integrated into local vulnerability studies (Hopkins *et al*., 2012).

Climate change has the potential to change migration flows within Australasia, particularly due to coastal changes (e.g. from the Torres Straits islands to mainland Australia), although reliable estimates of such movements do not yet exist (see Chapter 12.4; Green *et al*., 2010b; McNamara *et al*., 2011; Hugo, 2012). Migration within countries, and from New Zealand to Australia, is largely economically driven and sustained by transnational networks, though the perceived more attractive current climate in Australia is reportedly a factor in migration from New Zealand (Goss and Lindquist, 2000; Green *et al*., 2008a; Poot, 2009). The impacts of climate change in the Pacific may contribute to an increase in the number of people seeking to move to nearby countries (Bedford and Bedford, 2010; Hugo, 2010; McAdam, 2010; Farbotko and Lazrus, 2012) and affect political stability and geopolitical rivalry within the Asia-Pacific region, although there is no clear evidence of this to date and causal theories are scarce (Dupont, 2008; Pearman, 2009; see Chapter 12.5). There is *high agreement* and *robust evidence* that increasing climate-driven disasters, disease and border control will stimulate operations other than war for Australasia's armed forces, and that integration of security into adaptation and development assistance for Pacific island countries can play a key role in moderating the influence of climate change on forced migration and conflict (Dupont and Pearman, 2006; Bergin and Townsend, 2007; Dupont, 2008; Sinclair, 2008; Barnett, 2009; Rolfe, 2009).

25.10. Synthesis and Regional Key Risks

25.10.1. Economy-wide Impacts and the Potential of Mitigation to Reduce Risks

Globally effective mitigation could reduce or delay some of the risks associated with climate change and make adaptation more feasible beyond about 2050, when projected climates begin to diverge substantially between mitigation and non-mitigation scenarios (see also 19.7). However, literature quantifying these benefits for Australasia is sparse. Economy-wide net costs for Australia are modelled to be substantially greater in 2100 under unmitigated climate change (A1FI; GNP loss 7.6%) than under globally effective mitigation (GNP loss less than 2% for stabilization at 450 or 550 ppm CO_2-eq, including residual impacts and costs of mitigation; Garnaut, 2008). These estimates, however, are highly uncertain and depend strongly on valuation of non-market impacts, treatment of potentially catastrophic outcomes, and specific assumptions about autonomous adaptation, global changes and flow-on effects for Australia, and effectiveness and implementation of global mitigation efforts (Garnaut, 2008). No integrated estimates of climate change costs across the entire economy exist for New Zealand.

The benefits of mitigation in terms of reduced risks have been quantified for some individual sectors in Australia, e.g. for irrigated agriculture in the Murray-Darling Basin (Quiggin *et al*., 2008; Quiggin *et al*., 2010; Valenzuela and Anderson, 2011; Scealy *et al*., 2012) and for net health outcomes (Bambrick *et al*., 2008). Although quantitative estimates from individual studies are highly assumption-dependent, multiple lines of evidence (see 25.7-8) give *very high confidence* that globally effective mitigation would significantly reduce many long-term risks from climate change to Australia. Benefits differ, however, between States for some issues, e.g. heat and cold mortality (Bambrick *et al*., 2008). Few studies consider mitigation benefits explicitly for New Zealand, but scenario-based studies give *high confidence* that mitigating emissions from a high (A2) to at least a medium-low (B1) emissions scenario would markedly lower the projected increase in flood risks (Ballinger *et al*., 2011; McMillan *et al*., 2012) and reduce risks to livestock production in the most drought prone regions (Tait *et al*., 2008a; Clark *et al*., 2011b). Mitigation would also reduce the projected benefits to production forestry, however, though amounts depend on the response to CO_2 fertilization (Kirschbaum *et al*., 2011a; 25.7.1).

25.10.2. Regional Key Risks as a Function of Mitigation and Adaptation

The Australia/New Zealand Chapter of the AR4 (Hennessy *et al*., 2007) concluded with an assessment of aggregated vulnerability for a range of sectors as a function of global average temperature. Building on recent additional insights, Table 25-8 shows eight key risks within those sectors that can be identified with *high confidence* for the 21st century, based on the multiple lines of evidence presented in the preceding sections and selected using the framework for identifying key risks set out in Chapter 19. This combines consideration of biophysical impacts, their likelihood, timing and persistence, with vulnerability of the affected system, based on exposure, magnitude of harm, significance of the system and its ability to cope with or adapt to projected biophysical changes. These key risks differ in the extent to which they can be managed through adaptation and mitigation, and some are more likely than others, but all warrant attention from a risk-management perspective.

[INSERT TABLE 25-8 HERE
Table 25-8: Key regional risks during the 21st century from climate change for Australia and New Zealand. Colour bars indicate risk as a function of global mean temperature relative to pre-industrial, based on the studies assessed and expert judgment, for the current (top bar) and a hypothetical fully adapted state (bottom bar). For each risk, relevant climate variables and trends are indicated by symbols, in approximate order of priority. Where relevant climate projections span a particularly wide range even for a given amount of global mean temperature change, risks are shown in two pairs for low and high end projections, each without and with effective adaptation.]

One set of risks comprises damages to natural ecosystems (significant change in coral reefs and decline of some montane and low-lying ecosystems) that can be moderated by globally effective mitigation but to which some damage now seems inevitable. For some species and ecosystems, there is *high confidence* that climatically

constrained ecological niches, fragmented habitats and limited adaptive movement collectively present hard limits to adaptation to further climate change (see also 25.10.3). A second set of key risks (increase in wild fire, heat waves, water scarcity and flood risk) comprises damages that could be severe but can be moderated or delayed by a portfolio of adaptation measures together with mitigation, and where the need for transformative adaptation increases with the rate and amount of climate change (see also 25.10.3). A third set of key risks (coastal damages from sea level rise, and loss of food production from severe drying) comprises potential impacts that are particularly uncertain within the 21st century, even for a given global temperature change, and where alternative scenarios for changes in other climate drivers materially affect levels of concern and adaptation needs. Even though scenarios of severe drying or rapid sea level rise have low or currently unknown probabilities, the associated impacts would so severely challenge adaptive capacity, including transformational changes, that they constitute important risks.

A first comparative assessment of exposure and damages from different hazards for Australia up to 2100 indicates that inland flooding will continue to be the most costly source of direct damages to infrastructure, even though the largest value of assets is exposed to bush fire. Exposure to and damages from coastal inundation are currently smaller, but would rise most rapidly beyond mid-century once sea level rise exceeds 0.5 m (Baynes *et al*., 2012).

An *emerging risk* is the compounding of extreme events, none of which would constitute a *key* risk in its own right, but that collectively and cumulatively across space, time and governance scales could stretch emergency response and recovery capacity and hamper regional economic development, including through impacts on insurance markets or multiple concurrent needs for major infrastructure upgrades (NDIR, 2011; Phelan, 2011; Baynes *et al*., 2012; Booth and Williams, 2012; Karoly and Boulter, 2013). Efforts are underway to better understand the potential importance of cumulative impacts and responses (CSIRO, 2011; Leonard *et al*., submitted) but evidence is as yet too limited to identify this as a *key risk* consistent with the definitions adopted in this report (see Chapter 19).

Climate change is projected to bring benefits to some sectors and parts of Australasia, at least under limited warming scenarios associated with globally effective mitigation (*high confidence*). Examples include an extended growing season for agriculture and forestry in cooler parts of New Zealand and Tasmania, reduced winter energy demand and illnesses in most of New Zealand and southern States of Australia, and increased winter hydropower potential in New Zealand's South Island (25.7.1, 25.7.2, 25.7.4, 25.8.1).

The literature supporting this assessment of key risks is uneven among sectors and between Australia and New Zealand; for the latter, conclusions in many sectors are based on limited studies that often use a narrow set of assumptions, models, and data and which, accordingly, have not explored the full range of potential outcomes.

25.10.3. Challenges to Adaptation in Managing Key Risks, and Limits to Adaptation

Two key and related challenges for regional adaptation are apparent: to identify when and where a move from incremental to transformative adaptation measures is needed; and, where specific interventions are needed to overcome adaptation constraints, in particular to support proactive and transformative responses that require coordination across different spheres of governance and decision-making (Palutikof *et al*., 2013). The magnitude of climate change, especially under scenarios of limited mitigation, and constraints to adaptation suggest that incremental and autonomous responses will not deliver the full range of adaptation options available, or to ensure natural and human systems can still function even if some key risks are realized (*high confidence*; see also 25.4).

Most incremental adaptation measures in natural ecosystems focus on reducing other non-climate stresses (25.6.1, 25.6.2) but, even with scaled-up efforts, conserving the current state and composition of natural ecosystems most at risk appears increasingly infeasible. Maintenance of key ecosystem functions and services and individual species requires a radical reassessment of conservation values and practices related to translocation of species and the values placed on "introduced" species (Steffen *et al*., 2009). Divergent views regarding intrinsic and service values of individual species and ecosystems imply that a proactive discussion is necessary to enable effective decision-making and resource allocation. In human systems, incremental adjustments of current tools, planning approaches and early warning systems for floods, fire, drought, water resources and coastal hazards will increase resilience to climate variability and could be sufficient under scenarios of limited climate change (*medium confidence*; Stafford-Smith,

2013). A purely incremental approach, however, which generally aims to preserve current management objectives, governance and institutional arrangements, creates a path-dependency that becomes increasingly constraining and costly to overcome once more transformative changes are needed (*high agreement, medium evidence*; e.g. Howden *et al.*, 2010; Park *et al.*, 2012; McDonald, 2013, and 25.4.2). Examples include: managed retreat from eroding coasts that are increasingly difficult or costly to protect; the transformation of some rural and remote communities; translocation of some industries and economic activities in response to increasing drought, flood and fire risks or water scarcity; and re-balancing protection from and accommodation or avoidance of flood risk (Boxes 25-1, -2, 5-9; Linnenluecke *et al.*, 2011; Kiem and Austin, 2012; O'Neill and Handmer, 2012; Fletcher *et al.*, submitted).

Consideration of transformative adaptation becomes critical where long life- or lead-times are involved, and where high up-front costs or multiple interdependent actors across a range of scales create barriers that require coordinated and proactive interventions (Stafford-Smith *et al.*, 2011b; Palutikof *et al.*, 2013). In these situations, deferring adaptation decisions due to limited knowledge about the future will not necessarily minimize costs or ensure adequate flexibility for future responses (Stewart and Wang, 2011; Gorrdard *et al.*, 2012; McDonald, 2013).

Nonetheless, thresholds and any need for policy support for transformative adaptation inevitably depend upon social, institutional and cultural values and objectives. Whether transformative responses are seen as success or failure of adaptation depends on the extent to which actors accept a change in, or wish to maintain current activities and management objectives, and the degree to which the values and institutions underpinning the transformation are shared or contested across stakeholders (Park *et al.*, 2012; Stafford-Smith, 2013). These views will differ not only between communities and industries but also from person to person depending on their individual value systems, perceptions of and attitude to risk, and ability to capitalize on opportunities (see also 25.4.3).

25.11. Filling Knowledge Gaps to Improve Management of Climate Risks

The wide range of projected rainfall changes (averages and extremes) and their hydrological amplification are key uncertainties affecting the scale and urgency of adaptation in agriculture, forestry, water resources, some ecosystems, and wildfire and flood risks. For ecosystems, agriculture and forestry, these uncertainties are compounded by limited knowledge of responses of vegetation to elevated CO_2, changes in ocean pH, and interactions with changing climatic conditions. The uncertainties in future impacts are most critical for decisions with long lifetimes, such as capital infrastructure investment or large-scale changes in land- and water-use. Uncertainties about the rate of sea level rise, and changes in storm paths and intensity, add to challenges for infrastructure design. The use of multi-model means and a narrow set of emissions scenarios in many past studies implies that the full set of climate-related risks and management options remains incompletely explored.

Understanding of ecological and physiological thresholds that, once exceeded, would result in rapid changes in species, ecosystems and their services, is still very limited. The literature is noticeably sparse in New Zealand and for arid Australia. These knowledge gaps are compounded by limited information about the effect of global climate change on patterns of natural climate variability, such as ENSO. Better understanding the effect of evolving natural climate variability and long-term trends on both invasive species and native and managed ecosystems could support more robust ecosystem-based adaptation strategies.

Vulnerability of human and managed systems depends critically on future socio-economic characteristics. Research into psychological, social and cultural dimensions of vulnerability, adaptive capacity and underpinning values remains limited and poorly integrated with bio-physical studies, which reduces confidence in conclusions regarding future vulnerabilities and the feasibility and effectiveness of adaptation strategies.

These multiple, persistent and structural uncertainties imply that, in most cases, adaptation requires an iterative risk management process. While decision-support frameworks are being developed, it remains unclear to what extent existing governance and institutional arrangements will be able to support more transformational responses, particularly where competing public and private interests and particularly vulnerable groups are involved. The enabling or constraining influences on adaptation from interactions among market forces, institutions, governance, policy and regulatory environments have only recently begun to attract research attention, mostly in Australia.

Climate change impacts, adaptation and mitigation responses in other world regions will affect Australasia, but our understanding of this remains very limited. Existing studies suggest transboundary effects, mediated mostly via trade but potentially also migration, can be of similar if not larger scale than direct domestic impacts of climate change for economically important sectors such as agriculture and tourism. However, scenarios used in such studies tend to be highly simplified. Effective management of risks and opportunities in these sectors would benefit from better integration of relevant global scenarios of climatic and socio-economic changes into studies of local impacts, vulnerabilities and adaptation options.

Frequently Asked Questions

FAQ 25-1: How can we adapt to climate change while projected future changes remain so uncertain?

A focus on distant impacts and their uncertainties can make adaptation to climate change appear an impossible task. However, a different approach can mitigate this perceived problem (Figure 25-6). First, many climate changes are reasonably certain, especially in the short to medium term (i.e. to mid-century). Examples include rising air and sea surface temperatures (including a related increase in heatwaves and moisture evaporation), rising atmospheric CO_2, increasing ocean acidification, and rising sea-levels. These changes are no more uncertain than other changes such as future population, economic development or exchange rates that also concern decision-makers.

Second, for adaptation, our attention should focus on decisions that can and will be made in the near future, on the 'lifetime' of those decisions, and the risk posed by climate change during that lifetime. Thus the choice of next year's annual crop, even though it is greatly affected by climate, only matters for a year or two and can be adjusted within a few years. When the adaptation challenge is reframed as implications for near-term decisions, many decisions are not greatly affected by climate change, or do not require a dedicated adaptation response. Third, there are, of course, decisions such as those about long-lived infrastructure and spatial planning which must take longer-term climate change into account, and in some cases these do need to be addressed in light of significant uncertainty. Even then, techniques exist and are widely used in other areas to reduce challenges for decision-making – including the precautionary principle, real options, adaptive management, no regrets strategies, or risk hedging. These can be matched to the type of uncertainty.

Last, adaptation is not a one-off action; change will be on-going and adaptation will take place along an evolving pathway, in which decisions are updated and revisited as the future unfolds and more information comes to hand (see Figure 25-6). While this creates an opportunity for learning, successive short-term decisions need to be monitored to avoid unwittingly creating an adaptation path that is not be sustainable as climate change continues, also referred to as maladaptation. Changing pathways (e.g. from a paradigm that favours protection from risks, to one that seeks to accommodate or avoid risks) can be challenging and may require new collaborations and interactions between decision-makers at various levels and the people affected by those decisions.

[INSERT FIGURE 25-6 HERE

Schematic illustration of adaptation as an iterative risk management process. Each individual adaptation decision comprises well known aspects of risk assessment and management (top left panel). Each such decision occurs within and exerts its own sphere of influence, determined by the lead- and consequence time of the decision, and the broader regulatory and societal influences on the decision (top right panel). A sequence of adaptation decisions creates an adaptation pathway (bottom panel). There is no single correct adaptation pathway, although some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but the judgment of outcomes depends strongly on societal values, expectations and goals.]

FAQ 25-2: Why and where does climate change matter to Australia and New Zealand?

Climate change will produce rises in temperatures, atmospheric CO_2 and sea levels as well as changes in rainfall and other precipitation patterns and some extreme weather events. Ecosystems have developed and many aspects of human society, including large-scale infrastructure, been designed to function under *current* climate conditions. The projected changes, accordingly, will affect water resources, coasts, infrastructure, agriculture, health and biodiversity in Australia and New Zealand.

For the range of plausible climate changes over the 21st century, key risks exist for Australia and New Zealand. These differ both in their likelihood and the degree to which they can be managed by adaptation and mitigation.

Some potential impacts, such as significant change in coral reef systems and loss of higher-altitude ecosystems, are very difficult to avoid entirely even if climate change is limited by mitigation. Some impacts, such as increased flood damage to settlements and infrastructures, increased health impacts, and infrastructure failure during heat waves, increasing water scarcity in some regions and increased damages to ecosystems and risk to human life, properties and infrastructure from wildfires, have the potential to be severe but can be moderated by effective mitigation combined with regional adaptation measures - although the degree and nature of adaptation required will depend on the amount of climate change. Other impacts are very uncertain but could arise even if global mitigation actions are effective. These include significant region-wide damages to coastal infrastructure and low-lying ecosystems from sea level rise, or a severe decline in water availability resulting in significant reduction in food production, e.g. in the Murray-Darling Basin. In spite of their uncertainty, the severe consequences of such extreme scenarios warrants their consideration in current risk management.

Cross-Chapter Box

Box CC-WE. The Water-Energy-Food Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Ken Strzepek (UNU/USA), FerencToth (IAEA/Hungary), Blanca Elena Jimenez Cisneros (Mexico), Taikan Oki (Japan)]

Water, energy, and food are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure CC-WE-1. The depth and intensity of those linkages vary enormously between regions and production systems. Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Chapter 3.7.2, 7.3.2, 10.2,10.3.4, McMahon and Price, 2011, Macknick et al, 2012a, Cary and Weber 2008). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Kahn and Hajra 2009, Gertenet al. 2011). While food production and transport require large amounts of energy (Pelletier et al 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (7.3.2, Diffenbaugh et al 2012, Skaggs et al, 2012).

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change.]

Most energy production methods require significant amounts of water, either directly (e.g. crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Chapter 10.2.2 and 10.3.4, and Davies et al 2013, van Vliet et al 2012). Water is also required for mining, processing, and residue disposal of fossil fuels. Water for biofuels, for example, has been reported by Gerbens-Leenes et al. 2012 who computed a scenario of water use for biofuels for transport in 2030 based on the Alternative Policy Scenario of the IEA. Under this scenario, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water for energy currently ranges from a few percent to more than 50% of freshwater withdrawals, depending on the region and future water requirements will depend on electric demand growth, the portfolio of generation technologies and water management options employed (WEC 2010, Sattler et al., 2012). Future water availability for energy production will change due to climate change (Chapter 3.5.2.2).

Water may require significant amounts of energy for lifting, transport and distribution, treatment or desalination. Non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced or reclaimed wastewater vs. desalinated seawater (Plappally and Lienhard 2012, Macknick et al, 2012b). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user, Döll et al. 2012) is generally more energy intensive than surface water – in some countries, 40% of total energy use is for pumping groundwater. Pumping from greater depth (following falling groundwater tables) increases energy demand significantly– electricity use ($kWhr/m^3$) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard 2012). A lack of

water security can lead to increasing energy demand and vice versa, e.g. over-irrigation in response to electricity or water supply gaps.

Other linkages through land use and management, e.g. afforestation, can affect water as well as other ecosystem services, climate and water cycles (4.4.4, Box 25-10). Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security (3.7.2, 4.4.4). Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water (McCornick *et al.,* 2008, Bazilian *et al.,* 2011, Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy demand, bioproductivity and other factors (see Figure WE-1 and Wise et al, 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this Assessment Report.

(eds.)]. Adelaide, SA.

Table 25-1: Observed and projected changes in key climate variables, and (where assessed) the contribution of human activities to observed changes. For further relevant information see WGI Chapters 3, 6 (ocean changes, including acidification), 11, 12 (projections), 13 (sea level), and 14 (regional climate phenomena).

(*) *medium confidence*, (**) *high confidence*, (***) *very high confidence*, (****) *virtually certain*

Climate variable	***Observed change***	***Direction of projected change***	***Examples of projected magnitude of change*** *(relative to 1990, unless otherwise stated)*	***Additional comments***
Mean air temperature	***Aus:*** Increased by 0.09 ± 0.03°C per decade since 1911[1] (***) ***NZ:*** Increased by 0.09 ± 0.03°C per decade since 1909[2] (***)	***Aus and NZ:*** Increase [3-7](****); greatest over inland Aus and least in coastal areas and NZ[3, 4, 7, 8] (***)	***Aus:*** 0.5-1.5°C (2030 A1B), 1.0-2.5°C (2070 B1), 2.2-5.0°C (2070 A1FI)[5] ***NZ:*** 0.3-1.4°C (2040 A1B), 0.7-2.3°C (2090 B1), 1.6-5.1°C (2090 A1FI)[7] *CMIP5 RCP4.5, rel. to 1995[9]:* ***N Aus:*** 0.2-1.9°C (2035), 0.9-3.4°C (2065) ***S Aus & NZ:*** 0.1-1.2°C (2035), 0.6-2.2°C (2065)	***Aus:*** A significant contribution to observed change attributed to anthropogenic climate change[10] (**) with some regional variations attributed to atmospheric circulation variations[11, 12] ***NZ:*** Observed change partially attributed to anthropogenic climate change[13](*)
Sea surface temperature	***Aus:*** Increased by about 0.12°C per decade for NW&NE Aus and by about 0.2°C per decade for E Aus since 1950[14-16](***) ***NZ:*** Increased by about 0.07°C per decade from 1909-2009[2] (***)	**Aus and NZ:** Increase[3-5, 17](***) with greater increase in the Tasman sea region (*) [3-5, 17]	***Aus:*** 0.6-1.0°C (2070 B1) and 1.6-2.0°C (2070 A1FI) for southern coastal and 1.2-1.5°C (2070 B1) and 2.2-2.5°C (2070 A1FI) elsewhere[5] ***NZ:*** Similar to projected changes in mean air temperature for coastal waters[7, 18]	
Air temperature extremes	***Aus and NZ:*** Significant trend since 1950: cool extremes have become rarer and hot extremes more frequent and intense[19-22] (**)	***Aus and NZ:*** Hot days and nights more frequent and cold days and cold nights less frequent during the 21st century[5, 7, 18, 23-25](**)	***Aus:*** Hot days in Melbourne (>35°C max.) increase by 20-40% (2030 A1B), 30-90% (2070 B1) and 70-190% (2070 A1FI)[5] ***NZ:*** Spring and autumn frost-free land to increase by around 16% by 2080s; up to 60 more hot days (>25°C max.) for northern areas by 2090[7]	***Aus:*** Observed trend partly attributable to anthropogenic climate change[21-23, 26](**), although other factors may have contributed high extremes during droughts[27-29]
Precipitation	***Aus:*** Late autumn/winter decreases in SW Aus since the 1970s and in SE Aus since the mid 1990s, and annual increases in NW Aus since the 1950s[30-32](***) ***NZ:*** Mean annual rainfall increased over 1950-2004 in the south and west of both islands and decreased elsewhere[33] (***)	***Aus:*** Annual decline in SW Aus (**) and elsewhere in southern Aus (*) with the reductions strongest in the winter half year[5, 6, 34-36] (**). Direction of annual change elsewhere is uncertain[5, 36, 37] (Figure 25.2) (**) ***NZ:*** In the South Island, annual increase in the west and south and decrease in north-east. In the North Island, increase in the west and decrease in eastern and northern regions [7, 35, 38] (Figure 25.2) (**)	***Aus:*** For 2030 A1B, annual changes of-15% to +10% (N&E Aus) and -10% to 0% (S Aus), for 2070 B1, -15% to +7.5% (N&E Aus) and -15% to 0% (S Aus), and for 2070 A1FI, -30% to +20% (N&E Aus) and -30% to +5% (S Aus), with larger changes seasonally[5] ***NZ:*** For 2040 A1B, -5 to +15% (S&W) and -15% to +10% (N&E) and for 2090 A1B, -10% to +25% (S&W) and -20% to +15% (N&E) based on downscaled projections with larger changes seasonally[7, 38]	***Aus:*** Observed decline in SW is related to atmospheric circulation changes[39-41] (***), other factors[42], and partly attributable to anthropogenic climate change[41-44](***). The recent SE rainfall decline is also related to circulation changes[32, 45-47] (**), with some evidence of an anthropogenic component[48] ***NZ:*** Observed trends related to increased westerly winds[33]. Projected annual trends dominated by winter and spring trends related to increased westerlies[7]
Precipitation extremes	***Aus:*** Indices of annual daily extremes (e.g. 95th and 99th percentile rainfalls) show mixed or insignificant trends[23, 49], but significant increase is evident in recent decades for shorter duration (sub-daily) events[50, 51] (**). ***NZ:*** Extreme annual 1-day rainfall decrease in north and east and increase in west since 1930 (*).	***Aus and NZ:*** Increase in most regions in the intensity of rare daily rainfall extremes (i.e. current 20 year return period events) and in short duration (sub-daily) extremes (*) and an increase in the intensity of 99 percentile daily extremes (*low confidence*)[4, 7, 23, 52-56]	***Aus:*** For 2090 A2, CMIP3 give increases in the intensity of the 20 year daily extreme of +200% to -25% depending on region and model[53] ***NZ:*** Increases of daily extreme rainfalls of 8% per degree C are projected but with significant regional variations[7, 57]	***Aus and NZ:*** The sign of observed trends mostly reflects trends in mean rainfall (e.g. there is a decrease in mean and daily extremes in SW Aus)[23, 33, 50]. Similarly, future increases in intensity of extreme daily rainfall are more likely where mean rainfall is projected to increase[5]

Drought	***Aus:*** Defined using rainfall only, drought occurrence over the period 1900-2007 has not changed significantly[58](**) ***NZ:*** Defined using a soil water balance model, there has been no trend in drought occurrence since 1972[59] (*)	***Aus and NZ:*** Drought frequency is projected to increase in southern Australia [4, 55, 58, 60, 61](*) and in eastern and northern New Zealand[59, 62] (*)	***Aus:*** Occurrence under 2070 A1B ranges from a halving to 3 times more frequent in N. Aus, and 0-5 times more frequent in southern Aus[61] ***NZ:*** Time spent in drought in eastern and northern New Zealand is projected to double or triple by 2040[62]	***Aus:*** Regional warming may have led to an increase in hydrological drought (*low confidence*)[63, 64]
Winds	***Aus:*** Significant decline in storminess over SE Aus since 1885[65](*), but inconsistent trends in wind observations since 1975[66, 67] ***NZ:*** Mean westerly flow increased during the late 20th century (1978–1998), associated with the positive phase of the IPO[68, 69]	***Aus:*** Increases in winds in 20-30°S band, with little change to decrease elsewhere, except for winter increases over Tasmania. Decrease to little change in extremes (99th percentile) over most of Australia except Tasmania in winter[70] (*). ***NZ:*** Mean westerly winds and extreme winds (based on projected changes in circulation patterns) are projected to increase, especially in winter[7, 71](*)	***Aus:*** Magnitude of simulated changes are around 10% under A1B for 2081-2100 relative to 1981-2000[70] ***NZ:*** Westerlies to increase by approximately 10% by 2090[7]	***Aus and NZ:*** Many of past and projected changes in mean wind speed can be related to changes in atmospheric circulation[44, 68, 69] ***NZ:*** Extreme westerlies and southerlies have slightly increased while extreme easterlies have decreased since 1960[13, 72]
Mean sea level	***Aus:*** From 1920-2011 the average rate of relative sea level rise (SLR) was 1.6±0.1.4 mm/yr[73] (***) ***NZ:*** The average rate of relative SLR was 1.7±0.1 mm/yr over 1900-2009[74](***)	***Aus and NZ:*** Regional sea level rise will *very likely* exceed the 1971-2000 historical rate, consistent with global mean trends[75]. Mean sea level will continue to rise for at least several more centuries[75] (***).	***Aus and NZ:*** Off shore eastern Australian regional sea level rise, may exceed 10% more than global SLR, see AR5 WGI Chap13, Figure 13.15[75]	***Aus:*** Satellite estimates of regional SLR for 1993-2009 are significantly higher than those for 1920-2000, partly reflecting atmospheric circulation changes[73, 74, 76, 77] ***NZ:*** Allowing for glacial isostatic adjustment, absolute observed SLR is around 2.0mm/yr[74, 78]
Extreme sea level	***Aus:*** Extreme sea levels have risen at a similar rate to global SLR[79]	***Aus and NZ:*** Projected mean SLR will lead to large increases in the frequency of extreme sea level events (***), with changes in storm surges playing a lesser role[80-83]	***Aus:*** An increase of mean sea level by 0.1m increases the frequency of an extreme sea level event by a factor of between 5 and 10[80-82], depending on location	
Fire weather	***Aus:*** Increased since 1973(**) with 24 out of 38 sites showing increases in the 90th percentile of the McArthur Forest Fire Danger index[84]	***Aus:*** Fire weather is expected to increase in most of southern Australia due to hotter and drier conditions (**), based on explicit model studies carried out for SE Australia [85-88] , and change little or decrease in NE[88] (*) ***NZ:*** Fire danger is projected to increase in many areas[89](*)	***Aus:*** Very high and extreme fire danger increase 2-30% (2020), 10-100% (2050) (using B1 and A2 and two climate models, and 1973-2007 base)[85] ***NZ:*** Very high and extreme fire danger days increase 0 to 400% (2040), 0 to 600% (2090) (using A1B,16 CMIP3 GCMs)[89]	***Aus:*** For the example of Canberra, the projected changes represent the current 17 days per year increasing to 18-23 days in 2020 and 20-33 days in 2050[85]
Tropical cyclones and other severe storms	***Aus:*** No regional change in the number of tropical cyclones (TCs) or in the proportion of intense TCs over 1981-2007[90](*), but landfall in NE Aus has declined significantly since the 19th Century[91] and east-west distribution changed since 1980[92]	***Aus:*** Tropical cyclones are projected to increase in intensity, but stay similar or decrease in numbers[9, 93] (*low confidence*) ***NZ:*** Projected increase in the average intensity of cyclones in the south during winter, but a decrease elsewhere[71] (*)	***Aus:*** Modelling study shows a 50% reduction in TC occurrence for 2051-2090 relative to 1971-2000 but increases in intensity of the modelled storms[93] ***NZ:*** Occurrence of conditions conducive to convective storm development is projected to increase by 3–6% by 2070-2100 (A2), relative to 1970-2000, with the largest increases over the South Island[71]	***Aus:*** Single studies project decreased cool-season tornadoes in southern Australia[94], and hail increases in Sydney[95]
Snow and ice	***Aus:*** Late season significant snow depth decline at three out of four Snowy mountain sites over 1957-2002[96](**) ***NZ:*** Ice volume declined by almost 50% during the 20th century, with glacier volume reducing by at least 25% since 1950[97-100] (**).	***Aus:*** Both snow depth and area are projected to decline[96] (***) ***NZ:*** Snowline elevations are projected to rise, and winter snow volume and the duration of days with low elevation snow lying are projected to decrease[7, 101, 102] (**)	***Aus:*** Area with at least 30 days cover annually projected to decline 14-54% (2020) and 30-93% (2050) [96] ***NZ:*** By 2090, peak snow accumulation is projected to decline by 32-79% at 1000m and by 6-51% at 2000m[102]	***NZ:*** Atmospheric circulation variations can enhance or outweigh multi-decadal trends in ice volume over time scales of up to two decades[103, 104]

Table 25-2: Constraints and enabling factors for institutional adaptation processes in Australasia.*

Constraint	Enabling factors	References
Uncertainty of projections	Improved guidance and tools to manage uncertainty and support adaptive management Increased focus on lead and consequence time of decisions and link with current climate variability Increased communication between practitioners and scientists to identify and provide decision-relevant data	(Reisinger *et al.*, 2011; Stafford-Smith *et al.*, 2011b; Johnston *et al.*, 2012; Murta *et al.*, 2012; Park *et al.*, 2012; Productivity Commission, 2012; Randall *et al.*, 2012; Verdon-Kidd *et al.*, 2012; Stafford-Smith, 2013; Webb *et al.*, submitted)
Availability and cost of data and models	Central provision of relevant core climate and non-climate data, including regional scenarios projected changes National first-pass risk assessments	(DCC, 2009; Smith *et al.*, 2010; DCCEE, 2011; Baynes *et al.*, 2012; Roiko *et al.*, 2012; Mukheibir *et al.*, 2013; Webb and Beh, 2013; Lawrence *et al.*, submitted-b)
Limited financial and human capability and capacity; time lag in developing expertise	Support for pilot projects Building capacity through institutional commitment and learning Central databases on guidance, tools, methodologies, case studies Regional partnerships and collaborations, knowledge networks	(Smith *et al.*, 2008; Gardner *et al.*, 2010; Preston and Kay, 2010; DSEWPC, 2011; Johnston *et al.*, 2012; Low Choy *et al.*, 2012; Murta *et al.*, 2012; Park *et al.*, 2012; Yuen *et al.*, 2012; Webb and Beh, 2013; Lawrence *et al.*, submitted-b; Mustelin *et al.*, submitted; Webb *et al.*, submitted)
Unclear problem definition and goals; unclear standards for choices in risk assessment methodologies and decision support tools; limited monitoring and evaluation	Explicit but iterative framing and scoping of adaptation challenge, to reflect alternative entry points for stakeholders while meeting expectations of project sponsors to ensure long-term support Tailoring decision-making frameworks to specific problems Criteria and tools to monitor and evaluate adaptation success	(Nelson *et al.*, 2008; Preston *et al.*, 2008; Preston and Stafford-Smith, 2009; Rouse and Norton, 2010; Britton *et al.*, 2011; Maru *et al.*, 2011; Fünfgeld *et al.*, 2012; Randall *et al.*, 2012; Verdon-Kidd *et al.*, 2012; Mukheibir *et al.*, 2013; Webb and Beh, 2013; Webb *et al.*, submitted)
Unclear or contradictory legislative frameworks and responsibilities, unclear liabilities	Clear and coordinated legislative frameworks Defined responsibilities for public and private actors, including liabilities from acting and failure to act Legally binding guidance on the incorporation of climate change in planning mechanisms	(Smith *et al.*, 2008; Norman, 2009; Parliament of Australia, 2009; McDonald, 2010; Minister of Conservation, 2010; Rouse and Norton, 2010; Abel *et al.*, 2011; McDonald, 2011; Rive and Weeks, 2011; Corkhill, 2013; McDonald, 2013; Lawrence *et al.*, submitted-b)
Static planning mechanisms and practice; competing mandates and fragmentation of policies; disciplinary voids or single approaches	Whole-of-council approach to climate adaptation Long-term policy commitments and implementation support Increased policy coherence across sectors Strengthening multi-disciplinarity across professional fields	(Smith *et al.*, 2008; CSIRO, 2011; Measham *et al.*, 2011; Preston *et al.*, 2011; Reisinger *et al.*, 2011; Rive and Weeks, 2011; Webb and Beh, 2013; Lawrence *et al.*, submitted-b; Mustelin *et al.*, submitted)
Lack of political leadership; short election cycles; limited community support, participation and awareness for adaptation	Legally binding guidance and clarification of liabilities and duty of care to reduce dependence on individual leadership Consistent communication of current and potential future vulnerability and implications for community values Comprehensible communication of and access to response options, and their consistency with wider development plans Clearly identified entry points for public participation	(Smith *et al.*, 2008; Gardner *et al.*, 2009a; Britton *et al.*, 2011; Hobson and Niemeyer, 2011; Rouse and Blackett, 2011; Alexander *et al.*, 2012; Burton and Mustelin, 2013; Keys *et al.*, 2013)

* Note: The relevance of each constraint varies among organisations, sectors and location. Some enabling factors are only beginning to be implemented or have only been suggested in the literature, hence their effectiveness cannot yet be evaluated. Entries exclude issue-specific responses, such as early warning systems and their funding and operation, or funding mechanisms for capital infrastructure upgrades or retreat schemes.

Table 25-3: Examples of detected changes in species, natural and managed ecosystems, consistent with a climate change[1] signal, published since the AR4. Confidence in detection of change is based on the length of study, and the type, amount and quality of data in relation to the natural variability in the particular species or system. Confidence in the role of climate being a major driver of the change is based on the extent to which the detected change is consistent with that expected under climate change, and to which other confounding or interacting non-climate factors have been considered and been found insufficient to explain the observed change.

Type of change and nature of evidence	Examples	Time scale of observations	Confidence in the detection of biological change	Potential climate change driver(s) [1]	Confidence in the role of climate vs other drivers
Morphology *Limited evidence* (1 study)	Declining body size of southeast Australian passerine birds, equivalent to ~7º latitudinal shift (Gardner *et al*., 2009b)	~100 years	***medium*** trend significant for 4 out of 8 species, two other species show same trend but not statistically significant	Warming air temperatures ~1.0ºC over same period	***medium*** Nutritional cause discounted
Geographic distribution *High agreement, robust evidence* for many marine species & mobile terrestrial species	Southerly range extension of the barrens-forming sea urchin *Centrostephanus rodgersii* from the NSW coast to Tasmania; flow on impacts to marine communities including lobster fishery; shift of 160 km per decade over 30 years (Ling, 2008; Ling *et al*., 2008), (Ling *et al*., 2009; Banks *et al*., 2010)	~30-50 years (first recorded in Tasmania late 1970s)	***high***	Increased sea surface temperature (SST), Ocean warming in SE Australia, increased southerly penetration of the East Australian Current (EAC), 350 km over 60 years	***high***
	Forty-five fish species, representing 27 families (about 30% of the inshore fish families occurring in the region), exhibited major distributional shifts in Tasmania (Last et al 2011)	distributions from late 1880s, 1980s and present (1995-now)	***high***	Increased SST SE Australia, increased southerly penetration of EAC	***medium*** Changed fishing practices have potentially contributed to trends
	Southward range shift of intertidal species (average minimum distance 116 km) off west coast of Tasmania; 55% species recorded at more southerly sites, only 3% species expanded to more northerly sites (Pitt *et al*., 2010)	~50 years Sites resampled 2007-2008, compared with 1950s	***medium***	Increased SST in SE Australia (average 0.22ºC per decade), increased southerly penetration of the EAC, 350 km over 60 years	***medium***
Life cycles *Robust evidence, medium agreement*; increasing documentation of	Significant advance in mean emergence date of 1.5 days per decade (1941-2005) in the Common Brown butterfly *Heteronympha merope* in Australia (Kearney *et al*., 2010a)	65 years	***high***	Increase in local air temperatures of 0.16ºC per decade (1945-2007)	***high*** Advance consistent with physiologically based model of temperature influence on development

advances in phenology in some species (mainly migration and reproduction in birds, emergence in butterflies, flowering in plants) but also significant trends towards later life cycle events in some taxa	Earlier wine-grape ripening at 9 of 10 sites in Australia (Webb *et al*. 2012)	Multiple time periods up to 64 years (average 41 years)	***high***	Increased length of growing season, increased average temperature and reduced soil moisture	***medium*** Changed husbandry techniques, resulting in lower crop yields, may have contributed to trend
	Timing of migration of glass eels, *Anguilla* spp. advanced by several weeks in Waikato River, North island, New Zealand (Jellyman *et al*., 2009)	30 years (2004-2005 compared to 1970s)	***medium***	Warming water temperatures in spawning grounds	***low*** Changes in discharge discounted as contributing factor
Marine productivity *Limited evidence, medium agreement*	Otolith ("ear stone") analyses in long-lived Pacific fish indicates significantly increased growth rates for shallow-water species (<250 m) (3 of 3 species), reduced growth rates of deep-water (>1000 m) species (3 of 3 species); no change observed in the 2 intermediate-depth species (Thresher *et al*., 2007)	Birth years ranged 1861-1993 (fish 2-128 years old)	***high***	Increasing growth rates in species in top 250m associated with warming SST, declining growth rates in species >1000m associated with long-term cooling (as indicated by Mg/Ca ratios and delta^{18}O in deep water corals)	***medium*** Changed fishing pressure may have contributed to trend
	~50% decline in growth rate and biomass of spring phytoplankton bloom in western Tasman Sea (Thompson *et al*., 2009)	60 years (1997-2007)	***high***	Increased SST and extension EAC associated with reduced nutrient availability	***medium***
Vegetation change *Limited agreement & evidence*; interacting impacts of changed land practices, altered fire regimes, increasing atmospheric CO_2 concentration and climate trends difficult to disentangle	Expansion of monsoon rainforest at expense of eucalypt savanna and grassland in Northern Territory, Australia (Banfai and Bowman, 2007) (Bowman *et al*., 2010)	~40 years	***medium***	Increases in rainfall and atmospheric CO_2	***medium*** Changes in fire regimes and land management practices may have contributed to trend
	Net increase in mire wetland extent (10.2%) and corresponding contraction of adjacent eucalypt woodland in seven sub-catchments in south east Australia (Keith *et al*., 2010)	Weather data covers 40 years; vegetation mapping from 1961-1998	***medium***	Decline in evapo-transpiration	***low*** Resource exploitation, fire history and autogenic mire development discounted

Freshwater communities *Limited evidence* (1 study)	Decline in families of macroinvertebrates that favour cooler, faster-flowing habitats in NSW streams and increase in families favouring warmer and more lentic conditions (Chessman, 2009)	13 years (1994-2007)	***medium***	Increasing water temperatures and declining flows	***low*** Variation in sampling, changes in water quality, impacts of impoundment and water extraction may have contributed to trends
Disease *Limited evidence, robust agreement*	Emergence and increased incidence of coral diseases including white syndrome (since 1998), and black band disease (since 1993-4) (Bruno *et al.*, 2007), (Sato *et al.*, 2009), (Dalton *et al.*, 2010)	1998 onwards	***medium***	Increasing SST	***high***
Coral reefs *Robust evidence & high agreement*	Multiple mass bleaching events since 1979 (see 25.6.2, 30.5)	1979 onwards	***high***	Increasing SST	***high***
	Calcification of *Porites* on GBR declined 21% (1971-2003) (n=4 reefs); (Cooper *et al.*, 2008), 14.2% (1990-2005) (n=69 reefs) (De'ath *et al.*, 2009)	1971-2003; 1961-2005	***high***	Increasing SST	***high*** Changes in water quality discounted

Table 25-4: Examples of potential consequences of climate change for invasive and pathogenic species relevant to Australia and New Zealand, with consequence categories based on Hellman et al. (2008).

Consequence	Projected	Organism/Ecosystem affected	Reference
altered mechanisms of transport and introduction	Increased risk of introduction of Asiatic Citrus Psyllid, (*Diaphorina citri*), vector of the disease huanglongbing	Australian citrus industry and native citrus and other rutaceaous species and endemic psyllid fauna	(Finlay *et al.*, 2009)
altered distribution of existing invasive & pathogenic species	*Nassella neesiana* (Chilean needle grass): increased droughts favour establishment	Managed pasture in New Zealand	(Bourdôt *et al.*, 2012)
	Warming and drying may encourage the spread of existing invasives such as *Pheidole megacephala* and provide suitable conditions for other exotic ant species if they invade	Human health and potentially agricultural and natural ecosystems	(Harris and Barker, 2007)
	Reduced climatic suitability for exotic invasive grasses in Australia (11 species including *Nassella* sp.)	Australian rangeland	(Gallagher *et al.*, 2012)
	Range of the invasive weed *Lantana camara* (lantana) projected to extend from Northern Australia to Victoria, South Australia and Tasmania.	Multiple	(Taylor *et al.*, 2012b)
	Projected increases in the range of three recently naturalised sub-tropical plants (*Archontophoenix cunninghamiana*, *Psidium guajava*, *Schefflera actinophylla*)	Native ecosystems in New Zealand	(Sheppard, 2012)
altered climatic constraints on invasive & pathogenic species	Queensland fruit fly (*Bactrocera tryoni*) moving southwards	Horticulture	(Sutherst *et al.*, 2000)
	Significant association between amphibian declines in upland rainforests of North QLD and three consecutive years of warm weather suggests future warming could increase the vulnerability of frogs to chytridiomycosis caused by the chytrid fungus *Batrachochytrium dendrobatadis*	Native frogs	(Laurance, 2008)
altered impact of existing invasive & pathogenic species	*Fusarium pseudograminearum* causing crown rot increases under elevated CO_2	Wheat	(Melloy *et al.*, 2010)
	Increased abundance of the root-feeding nematode *Longidorus elongatus* under elevated CO_2	New Zealand pasture	(Yeates and Newton, 2009)
	Increased severity of Swiss needle cast disease caused by *Phaeocryptopus gaeumannii*	Douglas fir plantations in New Zealand, impact more severe in North Island	(Watt *et al.*, 2011b)
altered effectiveness of management strategies	Light brown apple moth, *Epiphyas postvittana* (Walker) (Lepidoptera:Tortricidae) reduction in natural enemies due to asynchrony and loss of host species	Australian horticulture	(Thomson *et al.*, 2010)
	Projected changes in the efficacy of five biological control systems demonstrating a range of potential disruption mechanisms	Pastoral and horticultural systems in New Zealand	(Gerard *et al.*, 2012)

Table 25-5: Examples of co-beneficial climate change adaptation options for urban areas and barriers to their adoption. Options in italics are already widely implemented in Australia and New Zealand urban areas.

Climate impact	**Adaptation options**	**Co-benefits**	**Barriers to adoption**	**References**
Hot days and heatwaves	Greening cities/roofs; *more green spaces*; well-designed energy efficient buildings; occupant behavioural change; standards for new and retrofitting of existing infrastructure and assets	Energy efficiency; reduced risk of blackouts; fewer health impacts; resilient infrastructure and assets	Lack of standards; high installation costs; limited understanding of benefits; high individual discount rate; split of private costs and public benefits	(BRANZ, 2007; Coutts *et al.*, 2010; Stephenson *et al.*, 2010; Williams *et al.*, 2010; Tables 25-5, 25-6; Moon and Han, 2011; Ren *et al.*, 2012)
Decreased water supply and drought	Supply augmentation (*water recycling*, *rainwater harvesting*, *increased storage*, desalinisation); *demand management*; *infrastructure upgrades*; *integrated urban sensitive design*	Water self-sufficiency for current and future demand/population; less pipe/storage leakage; reduced environmental impacts from abstraction	Potential health impacts of recycled water; lower than expected uptake of demand options and relaxation after crises; trade-offs between supply and demand management	See Box 25-2 for more detail; also Table 25-5
River and local flooding, coastal erosion and inundation	*Building and infrastructure (e.g. drainage) improvements*; *upgrades of protection systems*; buffers from hazard-prone areas; *raising minimum floor levels*; rezoning/ relocation; integrated urban sensitive design	Reduced damages to homes and infrastructure and loss of life; decreased insurance premiums	High implementation cost especially if retrospective on existing stock; rezoning/ relocation can affect property prices and are highly contested	See Boxes 25-1 and 25-8 for more detail
Severe storms and tropical cyclones	New building design to withstand higher wind pressures; rezoning/relocation	Reduced damages to homes and infrastructure and loss of life; decreased insurance premiums	High implementation cost; rezoning/ relocation can affect property prices and are highly contested	(Mason and Haynes, 2010; Wang *et al.*, 2010b; Stewart and Wang, 2011; Mason *et al.*, 2013)
Corrosion from increased atmospheric CO_2 levels	Improved standards for construction using concrete; application of coatings for existing building stock	Reduced rates of carbonation-induced corrosion of concrete	Effectiveness of coatings varies with age and condition of concrete	(Stewart *et al.*, 2012; Wang *et al.*, 2012)

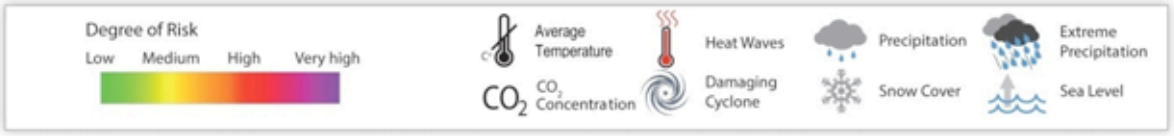
Table 25-6: Examples of interactions between impacts and adaptation measures in different sectors. In each case, impacts or responses in one sector have the potential to conflict (cause negative impacts) or be synergistic (have co-benefits) with impacts or responses in another sector, or with another type of response in the same sector.

Primary goal	Sector(s) affected	Examples of interactions between impacts and adaptation responses
Reduction of bushfire risk in natural landscapes	Biodiversity, tourism	Potential for greater conflict between conservation managers and other park users in Kosciuszko National Park if increasing fire incidence causes park closures, either to reduce risk, or to rehabilitate vegetation after fires (Wyborn, 2009), e.g. Objectives of the Wildfire Management Overlay (WMO) in Victoria conflicts with vegetation conservation (Hughes and Mercer, 2009).
Reduction of risk to energy transmission from bushfires	Biodiversity, energy	Underground cabling would reduce both the susceptibility of transmission networks to fire and ignition sources for wild fires, thus reducing risks to ecosystems and settlements; constraints include significant investment cost, diverse ownership of assets and lack of an overarching national strategy (ATSE, 2008; Parsons Brinkerhoff, 2009; Linnenluecke *et al.*, 2011).
Protection of coastal infrastructure	Biodiversity, tourism	Seawalls may provide habitat but these communities have different diversity and structure to those developing on natural substrates (Jackson *et al.*, 2008); groynes potentially alter beach fauna diversity and community structure (Walker *et al.*, 2008); continuing hard protection against sea level rise results in long-term loss of coastal amenities (Gorrdard *et al.*, 2012).
Avoidance of risks from sea level rise via relocation	Indigenous communities	Relocation can avoid increasing local pressures on communities from sea level rise but raises complex cultural, land rights, legal and economic issues, e.g. potential relocation of Torres Strait islander communities (Green *et al.*, 2010b; McNamara *et al.*, 2011).
Allocating scarce water resources via market instruments	Rural areas, agriculture, mining	Market based instruments such as water trading help allocation of scarce water resources to the highest value uses. The negative implications of this include potential loss of access to lower value users, which in some areas includes agriculture and drinking water supplies, with potentially significant social, environmental and wider economic consequences (Kiem and Austin, 2012).
Increased water security via water storage and irrigation for urban and agricultural systems	Biodiversity, water demand management	Water storage can buffer urban settlements and agricultural systems via irrigation against low runoff and high variability in river flow. Altered flow regimes have significant negative impacts on freshwater ecosystems (Bond *et al.*, 2008; Pittock *et al.*, 2008; Kingsford, 2011). Discharge from desalination plants (e.g. in Perth and Sydney) can lead to substantial local increases in salinity and temperature, and the accumulation of metals, hydrocarbons and toxic anti-fouling compounds in receiving waters (Roberts *et al.*, 2010) and reduce the effectiveness of measures to reduce water demand (Barnett and O'Neill, 2010).

Table 25-7: Examples of interactions between adaptation and mitigation measures (green rows denote synergies where multiple benefits may be realized, orange rows denote potential tradeoffs and conflicts; grey row gives an example of complex, mixed interactions). The primary goal may be adaptation or mitigation.

Primary goal	Sector(s) affected	Examples of interactions between adaptation and mitigation responses
Adaptation to decreasing snowfall	Biodiversity, energy use, water use	Snowmaking in the Australian Alps would require large additional energy and water resources by 2020 of 2500-3300 ML of water per month, more than half the average monthly water consumption by Canberra in 2004-05. Increased snowmaking negatively affects vegetation, soils and hydrology of subalpine-alpine areas (Pickering and Buckley, 2010; Morrison and Pickering, 2011; ABS, 2012c).
Air conditioning for heat stress	Health, energy use	Rising temperatures degrade building energy efficiency (Wang *et al*., 2010a) and increase energy demand and associated CO_2 emissions if summer cooling needs are met by increased air conditioning (Stroombergen *et al*., 2006; Thatcher, 2007; Wang *et al*., 2010a).
Renewable wind energy production	Biodiversity	Wind-farms can have localised negative effects on bats and birds. However, risk assessment of the potential negative impacts of wind turbines on threatened bird species in Australia indicated low to negligible impacts on all species modelled (Smales, 2006).
Urban densification	Biodiversity, water, health	Higher urban density to reduce energy consumption from transport and infrastructure can result in loss of permeable surfaces and tree cover, intensify flood risks, and exacerbate discomfort and health impacts of hotter summers (Hamin and Gurran, 2009).
Water supply from desalination	Energy demand	Meeting increasing urban water demand via desalination plants increases energy demand and CO_2 emissions if this demand is met by increased fossil fuel energy generation (Barnett and O'Neill, 2010; Stamatov and Stamatov, 2010).
Secure food production in a warming climate	Nitrous oxide and methane emissions	Net greenhouse gas emissions intensity from dairy systems in southern Australia have been estimated to increase in future in several locations due to a changing climate and management responses (Cullen and Eckard, 2011; Eckard and Cullen, 2011). A shift towards perennial C4 grasses would increase methane emissions from grazing ruminants due to lower feed quality, but studies in south-west Australia suggest this could be more than offset by increased soil carbon storage (Thomas *et al*., 2012; Bradshaw *et al*., submitted).
Housing design to reduce peak energy demand	Energy use, infrastructure, health	Reducing peak energy demand through building design and demand management reduces vulnerability of electricity networks and transmission losses during heat waves (Parsons Brinkerhoff, 2009; Nguyen *et al*., 2010), reduces heat stress during summer and provides health benefits during winter (Strengers, 2008; Howden-Chapman, 2010; Strengers and Maller, 2011; Ren *et al*., 2012).
Energy from second-generation biofuels	Biodiversity, rural areas, agriculture	New crops such as oil mallees or other eucalypts may provide multiple benefits, especially in marginal areas, displacing fossil fuels or sequestering carbon, generating income for landholders (essential oils, charcoal, bio-char, biofuels), and providing ecosystem services including reducing erosion (Cocklin and Dibden, 2009; Giltrap *et al*., 2009; McHenry, 2009).
Reduction of emissions from fires	Biodiversity, livelihoods	Improved management of savanna fires to reduce the extent of high intensity late season fires could substantially reduce emissions as well as having significant benefits for biodiversity and indigenous employment (Russell-Smith *et al*., 2009; Bradshaw *et al*., submitted).
Reduce methane emissions from feral camels	Biodiversity, agriculture	Feral camels in Australia are projected to double from 1 to 2 million by 2020. Control of exotic vertebrate pests to reduce methane emissions could have significant biodiversity benefits (NRMMC, 2010; Bradshaw *et al*., submitted). Economic benefits of reduced grazing competition, infrastructure damage and greenhouse gases could outweigh costs of camel reductions (Drucker *et al*., 2010).

Table 25-8 | Key regional risks during the 21st century from climate change for Australia and New Zealand. Colour bars indicate risk as a function of global mean temperature relative to pre-industrial, based on the studies assessed and expert judgement, for the current (top bar) and a hypothetical fully adapted state (bottom bar). For each risk, relevant climate variables and trends are indicated by symbols, in approximate order of priority. Where relevant climate projections span a particularly wide range even for a given amount of global mean temperature change, risks are shown in two pairs for high and low end projections, each without and with effective adaptation*.



Arrows show projected future changes in key drivers under a range of climate and mitigation scenarios. Arrows pointing in both directions indicate that the direction of change (indicated by red and blue colours) is uncertain. Narrow horizontal bars indicate the range of potential changes, with more bars indicating greater uncertainty. Thick bars are used where the direction of change is highly certain and some amount of further change over the 21st century is virtually unavoidable even under mitigation scenarios.

Key Regional Risk		Risk for current and hypothetical fully adapted state	Key Climate Drivers and Trends	Key adaptation issues / prospects
Impacts that can be delayed but now appear very difficult to avoid entirely, even with globally effective mitigation and proactive adaptation	Significant change in community structure of coral reef systems in Australia [25.6.2, 30.5, Box CC-CR]			Limited evidence for autonomous genetic adaptation of corals; other adaptation options are limited to reducing other stresses, mainly enhancing water quality and limiting pressures from tourism and fishing
	Loss of montane eco-systems and some endemic species in Australia [25.6.1]			Direct adaptation options are limited, but reducing other stresses such as pests, diseases and predator control and enhancing connectivity of habitats provides immediate co-benefits; need to consider translocation and migration
Impacts that have the potential to be severe but can be moderated or delayed significantly by globally effective mitigation and a portfolio of available adaptation measures	Wild fire damages to ecosystems and settlements and risks to human life in southern Australia and many parts of New Zealand [Table 25-1, Box 25-6]			Part of integrated landscape management; trade-offs exist between different management objectives and settlement patterns and goals
	Systematic constraints on water resource use in southern Australia [25.5.1, Box 25-2, 25-9]			Water resources already struggling to meet unlimited demand in many locations and exacerbated by projected population growth; effective adaptation relies on combination of demand and supply mechanisms
	Increase in morbidity and mortality and infrastructure failure during heat waves in Australia [25.7.4, 25.8.1]			Linked to social dynamics and ageing population in cities; transport and power infrastructure already at coping limit in many regions, with significant financial costs from future upgrades
	Increased frequency and intensity of flood damage to infrastruc-ture and settlements in Australia and New Zealand [25.2, Table 25-1, Box 25-8, 25-9]			Significant adaptation deficit in some regions to current flood risk; effective adaptation includes land-use controls and relocation as well as protection and accommodation of increased risk to ensure flexibility
Impacts that have a low or currently unknown probability but cannot be ruled out even with globally effective mitigation, and would present major challenges if realized	Significant reduction in food production in the Murray-Darling Basin, far south-east Australia and eastern and northern parts of New Zealand [25.2, Table 25-1, 25.6.1, 25.7.2, Box 25-2, 25-5]			Immediate co-benefits from improved management of over-allocated water resources and balancing competing demands, but the extreme dry end would threaten agricultural production as well as ecosystems and some rural communities
	Widespread damages to coastal infrastructure and low-lying ecosys-tems in Australia and New Zealand [Table 25-1, 25.6.1, 25.6.2, Box 25-2, 25-9]			Adaptation deficit in some locations to current coastal erosion and flood risk; successive building and protection cycles constrain flexible responses; effective adaptation includes land-use controls and ultimately relocation as well as protection and accommodation

* For rainfall and its impact on food production, wet and dry scenarios represent approximately the 10 and 90 percentile range of current model projections and RCP emissions scenarios. For sea level, the low scenario is a 0.39 m rise by 2100 (mid-range model projections, RCP 2.6); the high scenario is a 1.5 m rise by 2100 (semi-empirical models, RCP 8.5). See AR5 WGI Chap 13 for more details. Under either scenario, sea level would continue to rise beyond 2100, but the focus of the risk assessment here is for risks that could be realised during the 21st century.

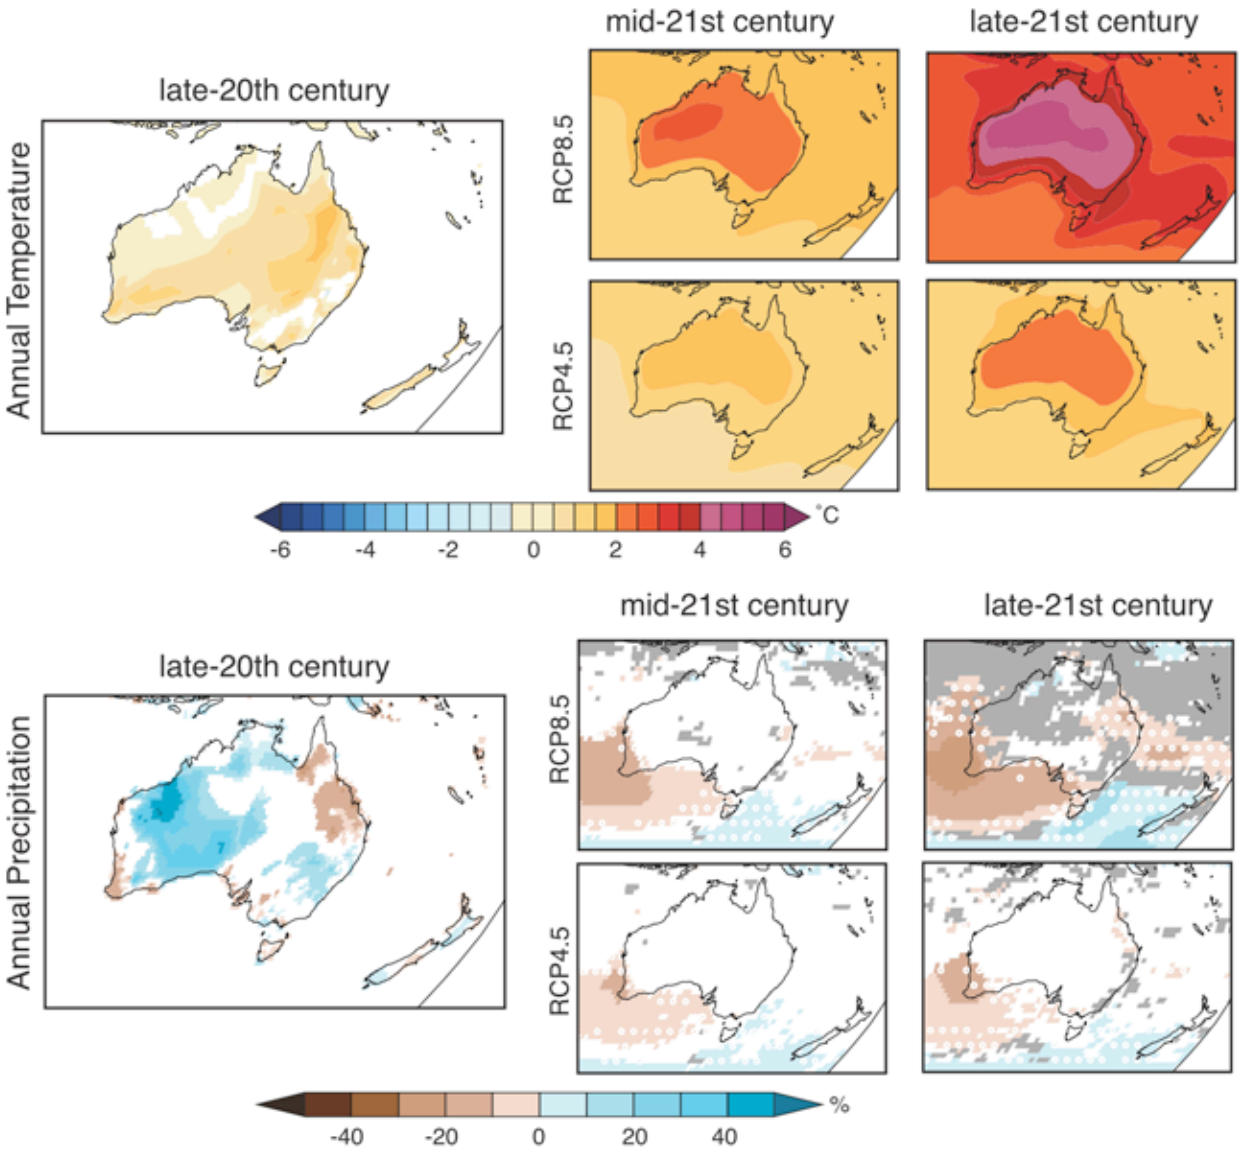


Figure 25-1: Observed and projected change in annual temperature and precipitation.

Maps: Change in annual temperature and precipitation. For the CRU observations, differences are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

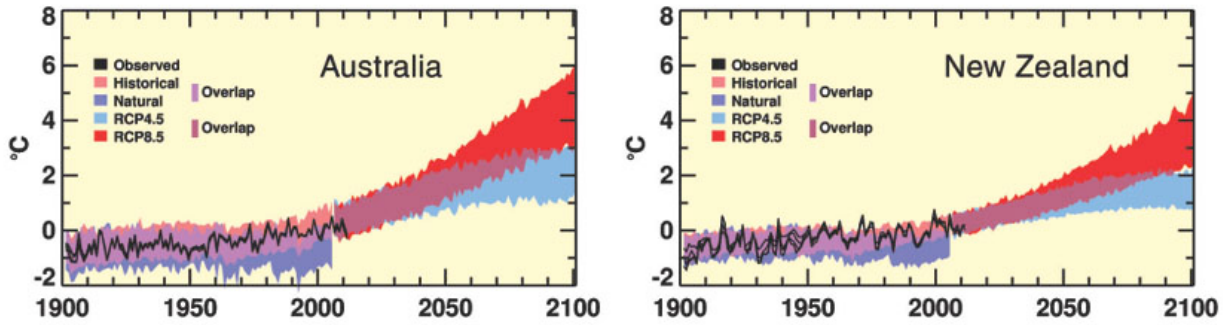

Figure 25-2: Observed and simulated variations in past and projected future annual average temperature over land areas of Australia (left) and New Zealand (right). Black lines show several estimates from measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Chapter 21.

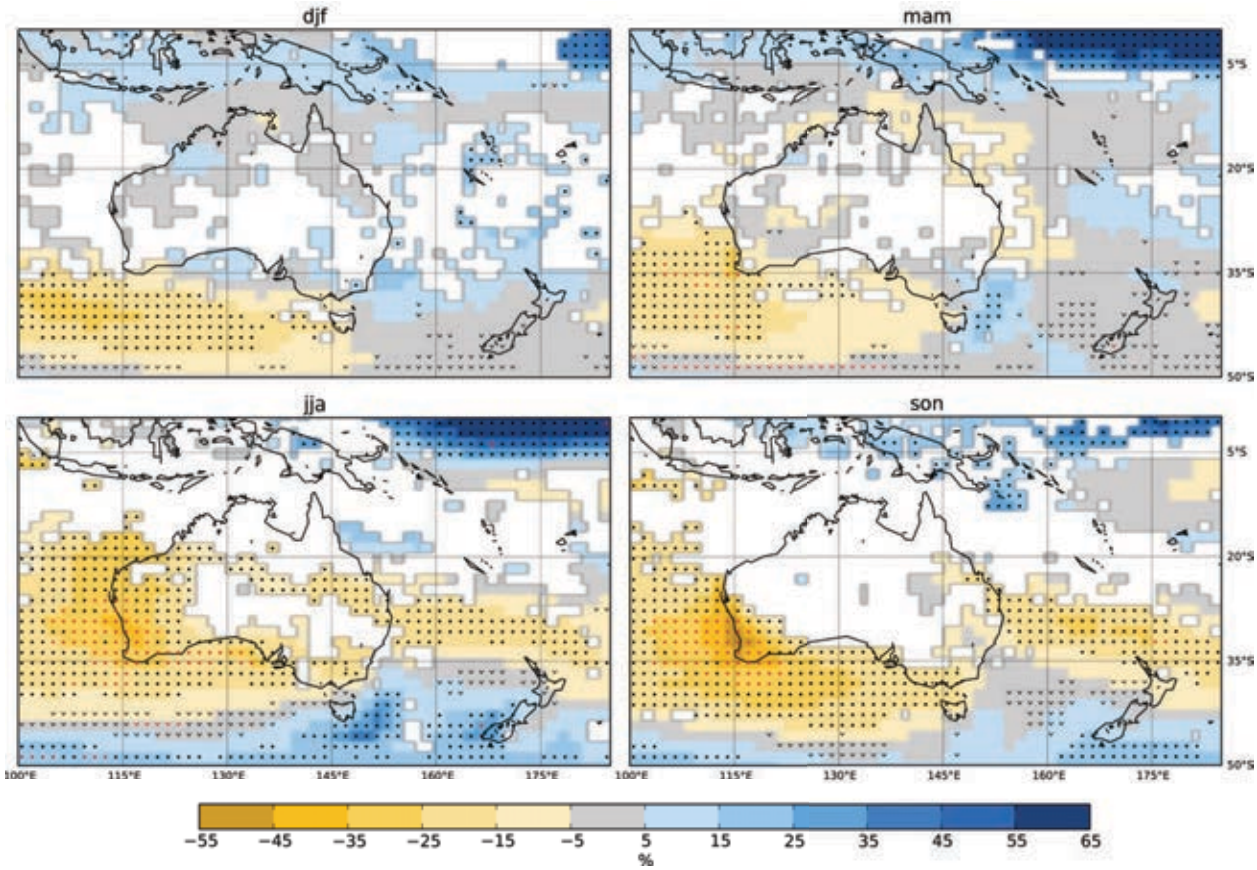

Figure 25-3: Projected CMIP5 multi-model mean change in rainfall for 2080-2099 relative to 1980-1999, under RCP 8.5. Dots [carets] indicate where the models agree (>90% red; >67% black) that there will [will not] be a substantial increase (>10%) or decrease (< -10%). White areas indicate where the models agree (> 67%) that there will be a substantial change in rainfall (larger in magnitude than 10%) however <67% agree on the direction of this substantial change (Figure from Irving *et al.*, in press).

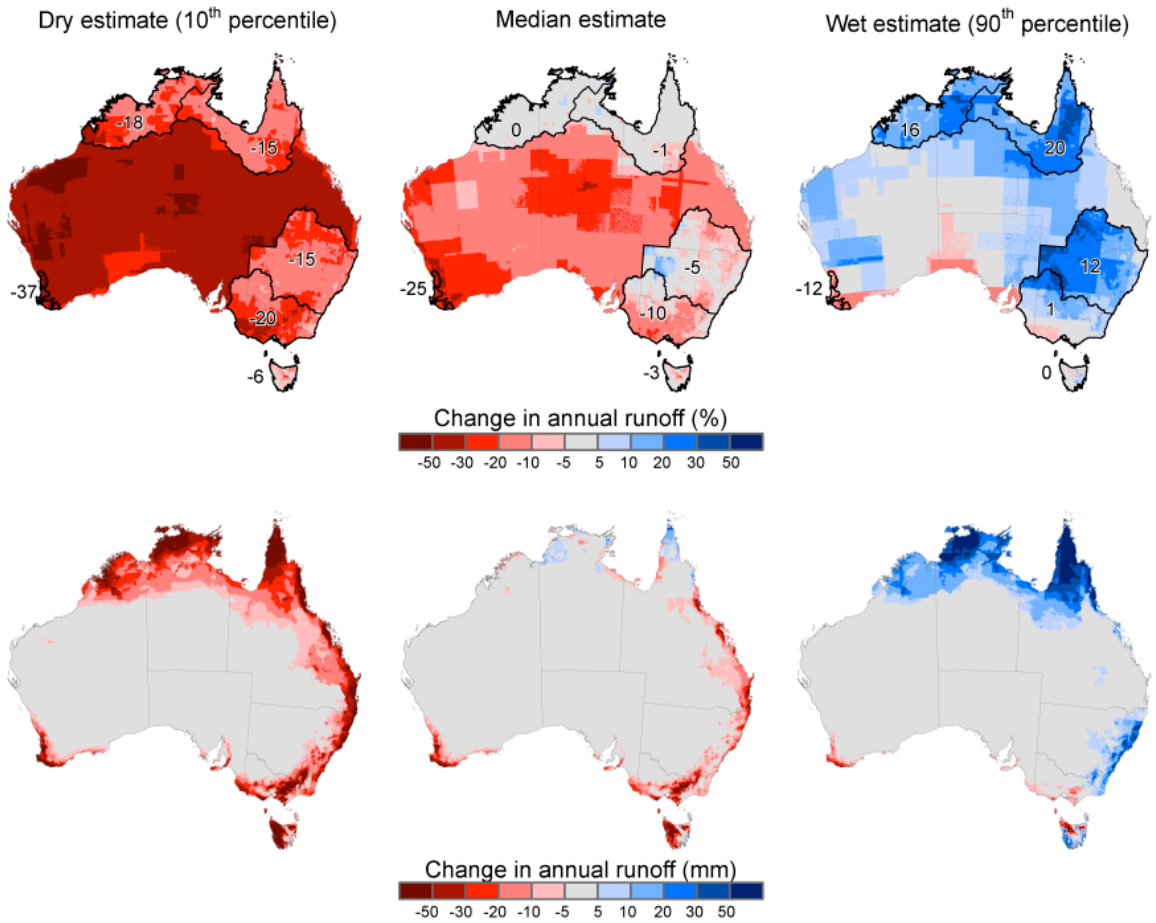

Figure 25-4: Projected changes in mean annual runoff for a 1°C global average warming. Figures show changes in annual run-off (percentage change; top row) and run-off depth (millimetres; bottom row), for median, dry and wet (10th and 90th percentile) range of estimates, based on hydrological modelling using catchment-scale climate data downscaled from AR4 GCMs (Chiew *et al.*, 2009; CSIRO, 2009b; Petheram *et al.*, 2012; Post *et al.*, 2012). Projections for a 2°C global average warming are about twice that shown in the plots (Post *et al.*, 2011). Figure adapted from (Chiew and Prosser, 2011; Teng *et al.*, 2012).

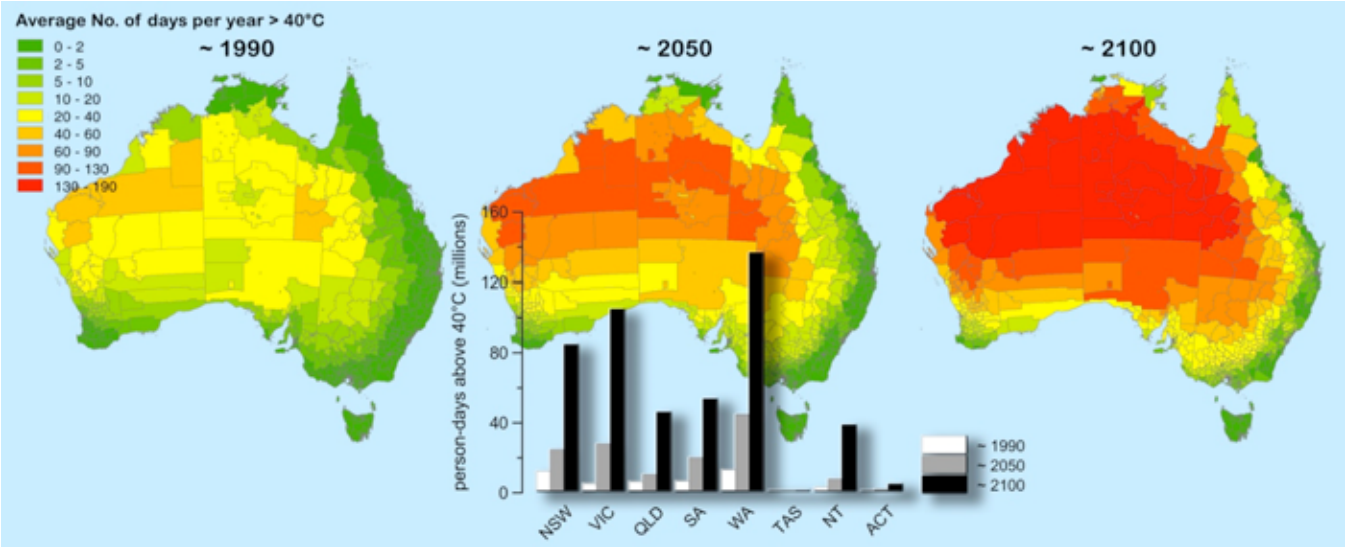

Figure 25-5: Projected changes in exposure to heat under a high emissions scenario (A1FI). Maps show the average number of days with peak temperatures >40°C for Australian statistical local areas, for ~1990 (based on available meteorological station data for the period 1975-2004), ~2050 and ~2100. Bar charts show the change in population heat exposure, expressed as person-days exposed to peak temperatures >40°C, aggregated by State/Territory and including projected population growth for a default scenario. Future temperatures are based on simulations by the GFDL-CM2 global climate model (Meehl *et al*., 2007), re-scaled to the A1FI scenario; simulations based on other climate models could give higher or lower results. Data from Baynes *et al*. (2012).

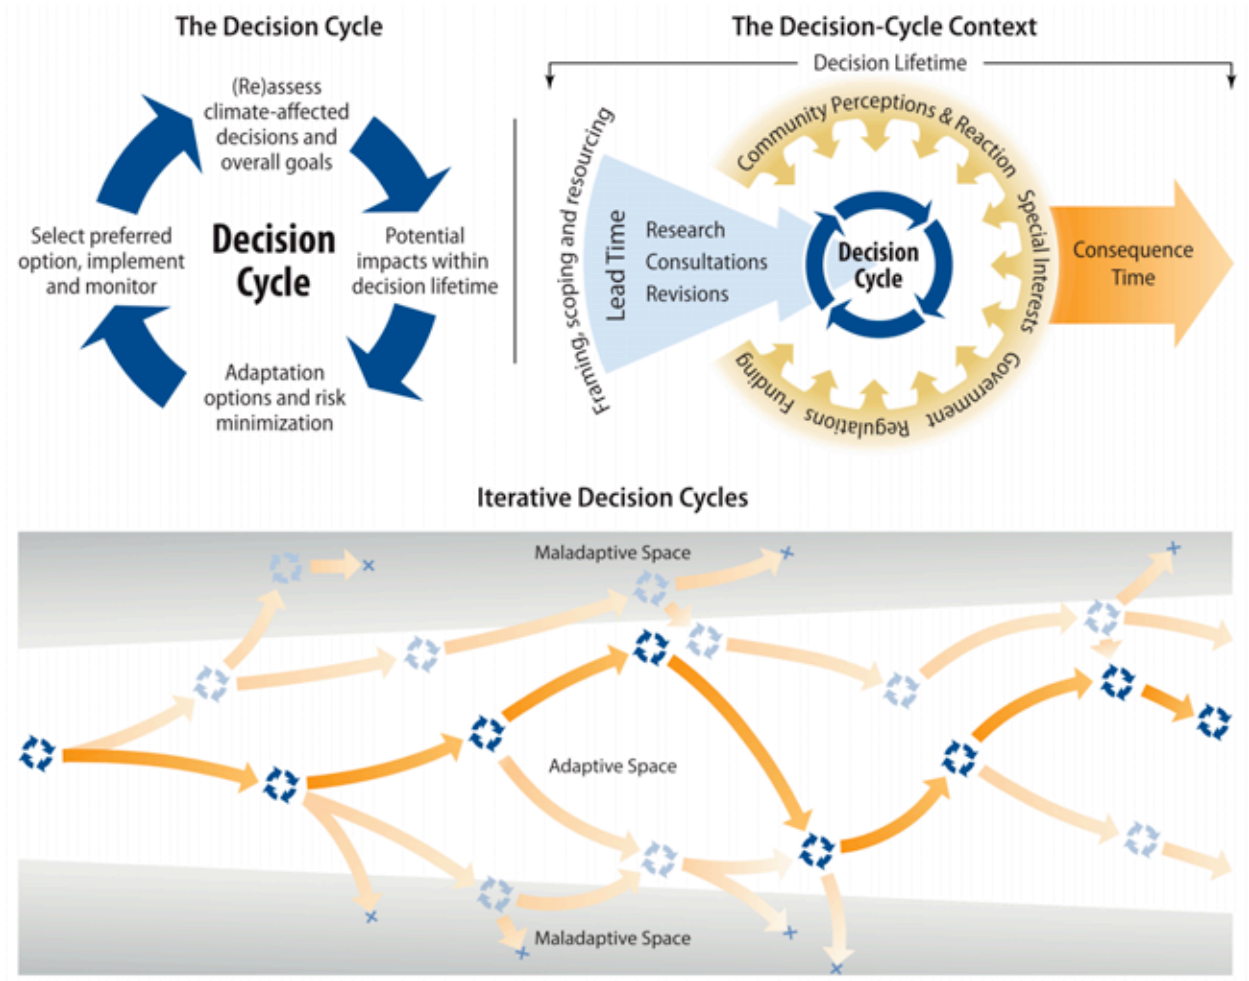

Figure 25-6: Schematic illustration of adaptation as an iterative risk management process. Each individual adaptation decision comprises well known aspects of risk assessment and management (top left panel). Each such decision occurs within and exerts its own sphere of influence, determined by the lead- and consequence time of the decision, and the broader regulatory and societal influences on the decision (top right panel). A sequence of adaptation decisions creates an adaptation pathway (bottom panel). There is no single correct adaptation pathway, although some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but the judgment of outcomes depends strongly on societal values, expectations and goals.

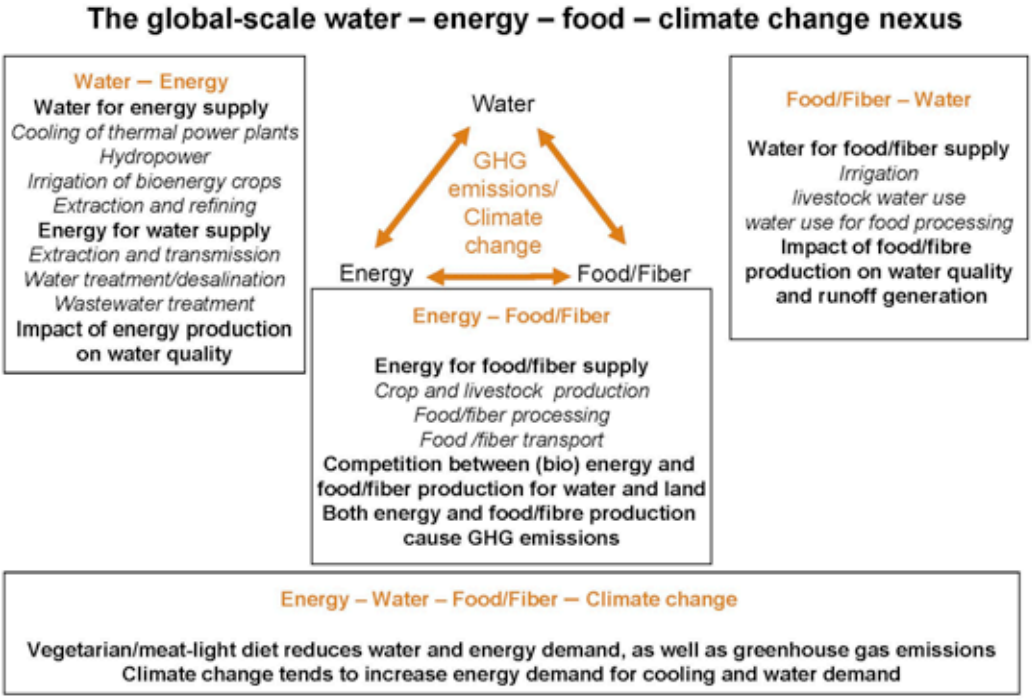

Figure WE-1: The water-energy-food nexus as related to climate change.

Frequently Asked Questions
26.1: What makes North America especially unique compared with other continents when it comes to climate vulnerabilities?
26.2: Will changing patterns of precipitation be experienced in NA and if so, in what ways?
26.3: What sectors/regions are more vulnerable? What factors/drivers contribute to a vulnerable situation?
26.4: What lessons can be drawn from existing adaptation actions on the factors shaping effective responses?

References

Executive Summary

Changes in climate trends in North America include **i**ncreased occurrence of severe hot weather events over much of the U.S., decreases in frost days, increases in heavy precipitation over much of North America, and reductions in spring snowpack along with an earlier peak runoff over many areas (*very high confidence*). **It is *highly likely* that global average increases in temperatures of at least 2°C (above the pre-industrial baseline) will lead North America to experience a frequent occurrence of**:

- **Extreme heat** during the summer in most areas
- **Low snow years and shifts towards earlier snowmelt runoff** in areas where seasonal snow cover is present in the current climate. [26.2]

It is *likely* that global warming of approximately 4°C will cause increases in annual precipitation in northern North America and decreases in annual precipitation in southern North America.

Attribution of observed changes in North America to anthropogenic climate change has been established for some physical systems (e.g., snowpack) and some ecosystems (e.g., forests dieback and pests distribution) (*very high confidence*). Evidence of anthropogenic climatic influence on agriculture, water, and human settlements is less clearly established.

Impacts of climate variability such as floods, decreased water availability, and increased salinity of coastal water supplies, which are exacerbated by other anthropogenic drivers, are observed in most areas of North America (*high confidence*). Water supply deficits are conducive to adaptive response, with many hard and soft approaches to adaptation currently available; adaptive responses to flooding and water quality concerns are more limited (*high confidence*). [26.3] **It is *very likely* that the 21st century will witness:**

- **Decreases in water quality, and increases in flooding and droughts, throughout most of North America** under climate change, and these impacts exacerbated by other anthropogenic drivers.
- **Decreases in water supplies for urban areas and irrigation in selected areas** of North America with confounding effects of development, except in general for *southern Mexico*; the northwest and northeast coastal USA; and west and east Canada. [26.3, 26.8]

Climate change is already affecting many ecosystems across North America. A global increase of 2°C would have widespread adverse impacts on those ecosystems (*high confidence*). Forests are being affected by fire, drought, pests, and other climate-related stresses. Coastal zones are being affected by multiple and often interacting climate stresses including higher temperatures, ocean acidification, coral reef bleaching, sea level rise, storm surges, and storms. Climate stresses will *likely* reduce biodiversity and ecosystem services. [26.4]

Without adaptation, projected changes in temperature, precipitation, and extreme events would result in notable productivity declines in major North American crops by the end of the 21st Century (*very high confidence*). Given that North America is a significant source of global food supplies, if projected productivity declines here are not addressed with substantial investments in adaptation, there will likely be a negative effect on global food security (*medium confidence*). Adaptation may ameliorate many climate impacts to North American agriculture, but the institutional support mechanisms currently in place are insufficient to ensure effective, equitable and sustainable adaptation strategies (*medium confidence*). [26.5]

Human *health impacts* from extreme events have been observed. Heat extremes currently result in increases in mortality and morbidity in North America, with impacts that vary by age and socioeconomic factors (*very high confidence*). Coastal storm events periodically cause excess mortality and morbidity via a range of direct and indirect pathways in North America, particularly along the east coast of the United States, and the gulf coast of both Mexico and the United States (*high confidence*). The effect of increasing heat extremes on human health will depend on the pace of adaptation, which is unknown. Given current levels of adaptation, there are *likely* to be increased health impacts from heat extremes among vulnerable communities, populations, and individuals. Conditional on an increase in storm severity under a changing climate, there are likely to be continued human health risks in the absence of specific adaptation planning. [26.6]

Several social and economic impacts observed in North American human settlements have been attributed, with different degrees of certainty, to climate-related processes (*high confidence*). These processes include but are not limited to sea level rise, changes in temperature and precipitation, and occurrences of such extreme events as droughts and storms. [26.8]

Differences in the severity of climate impacts on human settlements are strongly influenced by context-specific social and environmental factors and processes (*high confidence*). Some of these processes (e.g., the legacy of previous and current stresses) are common to urban and rural settlements, while others are more pertinent to some types of settlements than others. For example, concentrations of populations, economic activities, cultural amenities, and built environments in highly exposed urban locations such as coastal and dry areas creates higher hazard risks in cities; whereas, for many small rural areas, geographic isolation and institutional deficits are key sources of vulnerability. **Among the most vulnerable are indigenous peoples** due to their unique history and relationship to the land, and Mexico City due to the high density of population combined with several socio-economic and environmental sources of vulnerability (*high confidence*). [26.8]

Many infrastructural elements across North America are currently vulnerable to extreme weather events and, unless investments are made to strengthen them, would be more vulnerable to climate change (*medium confidence*). Infrastructures, particularly in water resources and transportation, are in many cases deteriorating, thus more vulnerable to extremes than strengthened ones. Extreme events have caused significant damage to infrastructure in many parts of North America. Risks to infrastructure are particularly acute in Mexico. [26.7]

Most sectors of the North American economy have been affected by and responded to extreme weather, including hurricanes, flooding, and intense rainfall (*high confidence*). There are, however, few examples of proactive adaptation anticipating future climate impacts, and these are largely found in sectors with longer term decisionmaking, including energy and public infrastructure. Lessons learned are not well-documented in the literature. [26.7]

There is an emerging concern that dislocation in one sector of the economy may have an adverse impact on other sectors due to supply chain interdependency (*medium confidence*). [26.7]

Slow onset perils – like sea level rise, drought, and permafrost melt – are another emerging concern for some sectors, with large regional variation in awareness (*medium confidence*). There is little published literature about impacts and adaptation experience. [26.7]

Different economic and demographic sectors are responding to climate change (e.g., purchasing additional insurance, reinforcing homes to withstand extreme weather). **While different tiers of government are assessing their climate vulnerabilities and designing adaptation actions and programs**, **there has been more** l**eadership in adaptation planning at the local level.** Many governmental responses are in diagnosis and planning stage and have not yet moved into implementation (*high confidence*). [26.8, 26.9]

Important barriers exist to effective adaptation such as path dependency**,** lack of assets and options, lack of funding and staff, lack of horizontal and vertical coordination, asymmetries in access to information, lack of social capital, and top-down decisionmaking (*high confidence*). [26.8, 26.9]

Climate change impacts can hamper progress towards sustainability and have the potential to exacerbate existing challenges such as deficits in infrastructure or in institutional capacity to promote the health and well-being of human populations (*high confidence*). [26.7, 26.9]

Adaptation actions at the local level throughout North America have the potential to result in synergies, conflicts, or tradeoffs with mitigation and other development actions and goals (*high confidence*). For example, reductions in greenhouse pollutant emissions will in many cases bring proximal benefits for human health by reducing health-damaging air pollution concentrations. Conversely, sea walls can protect coastal properties, yet may negatively affect the structure and function of coastal ecosystems. [26.8]

26.1. Introduction

This chapter assesses literature on observed and projected impacts, vulnerabilities and risks as well as on adaptation practices and options in three North American countries: Canada, Mexico and USA. (The North American Arctic region is assessed in Chapter 28: Polar Regions). North America ranges from the tropics to frozen tundra, and contains a diversity of topography, ecosystems, economies, governance structures and cultures. As a result, risk and vulnerability to climate variability and change may differ considerably across the continent depending on geography, scale, hazard, social, socio-ecological or ecological systems, demographic sectors, cultural values and institutional settings (Table 26-1). This chapter seeks to take account of this diversity and complexity as it affects and is predicted to affect vulnerability and risk across North America.

No single chapter would be adequate to cover the range and scope of the literature about climate change impacts, vulnerabilities and adaptations in our three focus countries. (Interested readers are encouraged to review the following reports: Canadian Climate Report; (SEMARNAT-INECC, 2012; NCADAC, 2013). We, therefore, attempt to take a more integrative and innovative approach. In addition to describing current and future climatic and socioeconomic trends of relevance to understanding risk and vulnerability in North America (section 26.2), we contrast climate impacts, vulnerabilities and adaptations across and within the three countries in the following key sectors: water resources and management (section 26.3); ecosystems and biodiversity (section 26.4); agriculture and food security (section 26.5); human health (section 26.6); and infrastructures and other economic sectors (section 26.7). We use a comparative approach to explore the factors and processes associated with differences and commonalities in vulnerability, risk and adaptation between urban and rural settlements (section 26.8); and to illustrate and contrast the nuanced challenges and opportunities adaption entails at the city, the state and the national level (sections 26.8.4 and 26.9; Box 26-3). We highlight two case studies that cut across sectors, systems or national boundaries. The first, on wildfires (Box 26-2), explores some of the connections between climatic and physical process (e.g., decadal climatic oscillation, droughts, wildfires and pests) and across systems and sectors (e.g., fires direct and indirect impacts on local economies, livelihoods, built environments and human health). The second takes a look at the world's longest border between a high-income (US) and middle income country (Mexico) and briefly reflects on the challenges and opportunities of responding to climate change in a transboundary context (Box 26-1).

We close with a section (26.10) summarizing key multi-sectoral risks and uncertainties at the regional level and discussing some of the knowledge gaps that will need to be filled by future research.

Findings from the Fourth Assessment Report

This section summarizes key findings on North America, as identified in chapters 13 and 14 of the Fourth IPCC assessment focused on Mexico (Magrin *et al*., 2007) *and Canada and the USA respectively* (Field *et al*., 2007). Over the past decades, economic damage, from severe weather has increased dramatically, due largely to the high value of infrastructures at risk in Canada and the US (14.2) (*very high confidence*). Increases in the frequency of very heavy rains were identified in central Mexico [13.2.4.1] (*high confidence*).

Although Canada and the US have considerable adaptive capacity, their vulnerability depends on the effectiveness and timing of adaptation and the distribution of capacity, which vary spatially and among sectors [14.2.6, 14.4] (*very high confidence*). Mexico has early warning systems and risk analysis in such areas as agriculture, human health and water resources, yet it faces planning and management barriers (*high confidence*). In Canada and the US, based upon long standing traditions and institutions, a decentralized response framework has resulted in adaptation that tends to be reactive, unevenly distributed, and focused on coping with rather than preventing problems [14.5] (*very high confidence*).

Coastal communities and habitats in the three countries will be stressed by sea level rise, storm-surge flooding and other climate change impacts interacting with developmental and environmental stresses, such as salt intrusion, pollution, population growth and the rising value of infrastructure in coastal areas (Mexico: [13.4.4]) (*high confidence*); (US and Canada: [14.2.3; 14.4.3) (*very high confidence*).

Land use changes in Mexico have intensified land degradation, and increased the vulnerability of coastal mangroves and estuaries [13.2.3] (*high confidence*). Significant species extinctions in many tropical areas of Mexico are projected [13.4.1] (*high confidence*). While increases in grain yields in U.S. and Canada are likely [14.4.4], in Mexico the picture is mixed for wheat and maize, whose behavior is more erratic depending on the scenario that plays out [13.4.2] (*medium confidence*).

Millions in Mexico are projected to be at risk from the lack of adequate water supplies [13.4.3] (*medium confidence*), while in the US and Canada rising temperatures will diminish snowpack and increase evaporation, thus affecting seasonal availability of water [14.2.1] (*very high confidence*). Together with higher demand from economic development, agriculture and population growth will impose further constrains to over-allocated water resources, increasing competition among agricultural, municipal, industrial and ecological uses [14.4.1; 14.4.6] (*very high confidence*).

Changes in geographical distribution and transmission of diseases have been projected for the three countries. Mexico will likely face changes in the geographical distribution of dengue [13.4.5], while the US and Canada are likely to see an increase in risk and geographic distribution of vector-borne infectious diseases, including Lyme disease and West Nile virus. Warming and climate extremes are also likely to increase respiratory illness, including exposure to pollen and ozone [14.4]. Hot temperatures and extreme weather in Canada and the US are likely to increase adverse health impacts from heat-related mortality. Climate change impacts on infrastructure and human health and safety in urban centers of Canada and the US will be compounded by aging infrastructure, maladapted urban form and building stock, urban heat islands, air pollution, population growth and an aging population [14.4; 14.5] (*very high confidence*).

A warmer future with drier soils and longer growing seasons will also likely increase and intensify wildfire and insect outbreaks in Canada and the US. Pressure for species to shift north and to higher elevations will fundamentally rearrange North American ecosystems. Differential capacities for range shifts and constraints from development, habitat fragmentation, invasive species, and broken ecological connections will alter ecosystem structure, function and services [14.2; 14.4] (*very high confidence*).

Without increased investments in such countermeasures as early warning and surveillance systems, air conditioning, access to health care, pollution, storm-related fatalities and injuries, and infectious diseases, hot temperatures and extreme weather in Canada and the US are likely increase adverse health impacts from heat-related mortality. Furthermore, climate change impacts on infrastructure and human health and safety in urban centers of Canada and the US will be compounded by aging infrastructure, maladapted urban form and building stock, urban heat islands, air pollution, population growth and an aging population [14.4; 14.5] (*very high confidence*).

How vulnerable North America is depends upon the effectiveness of adaptation and the distribution of capacity. Both of these are unevenly distributed [14.5]. While both chapters see 'mainstreaming' climate issues into decision making as key to successful adaptation [14.5; 13.5], chapter 13 suggests mainstreaming adaptation strategies with national / regional sustainable development plans [13.5] as a key step towards meeting adaptation needs.

26.2. Key Trends

26.2.1. Demographic and Socioeconomic Trends

26.2.1.1. Current Trends

Canada, Mexico and USA share commonalities but also differ in key dimensions shaping vulnerability and adaptation such as population dynamics, economic development, and institutional capacity. Population growth has been slower in Canada and USA than in Mexico (United Nations, 2011). Yet population growth in Mexico also decreased from 3.4 percent during 1970-1980 to 1.5 percent during the last decade due to lower birth rates, which were offset by gains in life expectancy. All three countries have aging populations. In 2010, 20% of the population in Canada was 60 years and older, compared to 18% in the USA, and 9% in Mexico (United Nations, 2011). Urban populations have grown faster than rural populations resulting in a North America that is highly urbanized (Canada 84.8%, Mexico 82.8% and USA 85.8%). These urban populations are also expanding into peri-urban spaces, producing rapid changes in *population patterns* and land use that can exacerbate climate risks (Eakin *et al*., 2010; Romero-Lankao *et al*., 2012).

Similarly, while concentrations of growing populations, infrastructures and sectors in urban areas can be a source of risk, geographic isolation of rural populations can be a source of sensitivity that is aggravated by high dispersion levels (Figure 26-1; section 26.8). Rural populations might experience an increased sensitivity to climate events, as they face smaller labor markets, lower income levels and reduced access to public services. Rural poverty could also be aggravated by agricultural changes, particularly in Mexico where 65% of the rural population is poor, agricultural production is seasonal and most households lack insurance (Scott, 2007). Food price increases, which may also result from climate events, would contribute to poverty levels in urban and rural areas (Lobell *et al*., 2011; World Bank, 2011).

[INSERT FIGURE 26-1 HERE
Figure 26-1: Current and future populations in North America. While concentrations of growing populations, infrastructures, and sectors in urban areas can be a source of risk, geographic isolation of rural populations can be a source of sensitivity that is aggravated by high dispersion levels. Source: Lutz, 2007.]

The three countries have become more economically integrated following the 1994 North American Free Trade Agreement. For instance, prior to a 2007-2008 reduction in trade, the US-Mexico border was a region of dynamic growth in industry, employment and global trade of agricultural and manufactured goods (Robertson *et al*., 2009). However, differences in such determinants of adaptive capacity as levels of human development within and across countries, institutional asymmetry and fragmentation can be a source of risks and opportunities in managing trans-border environmental resources and vulnerability issues (Scott and Banister, 2008; Wilder *et al*., 2010) (Box 26-1).

_____ START BOX 26-1 HERE _____

Box 26-1. Adapting in a Transboundary Context: the Mexico-US Border Region

Extending over 3169 km (1969 miles), the border between the United States and Mexico is one of the longest between a high-income and middle income country, and offers both challenges and opportunities to respond to climate change in a transboundary context. Sharing common climate regimes, natural resources, regional economies and urban areas (Wilder *et al*., 2013), in recent years the region has been subject to severe droughts, and floods, and these events are likely to become more frequent and intense as climate change progresses (Wilder *et al*., 2013). Additionally, there is a prevalence of incipient or actual conflict, given by currently or historically contested land boundaries or natural resources (Udall and Varady, 1993) and management of shared resources by distinct entities (Megdal and Scott, 2011).Climate change, therefore, as it interplays with socio-economic changes in the area, will most likely bring significant consequences for water resources, ecosystems, human health, and rural and urban settlements.

Changing Socio-Economic and Physical Conditions

The population of the Mexico-US Border Region is rapidly growing and urbanizing, with population increasing from just under 7 million in 1983 to over 15 million in 2012. Since 1994, rapid growth in the area has been fueled by a fast-paced economic change resulting from the passage of the North American Free Trade Agreement (NAFTA) (U.S. EPA and Secretaría de Medio Ambiente y Recursos Naturales, 2011; U.S. EPA, 2012). Between 1990 and 2001 the number of maquiladoras in Mexico had more than doubled, from 1700 to nearly 3,800, *with* 2,700 in the border area. By 2004, it was estimated that more than one million Mexicans were employed in the more than 3,000 *maquiladoras* located along the border.

Notwithstanding this explosive growth in economic activity and population in the region, challenges to adaptive capacity include high rates of poverty in a landscape of uneven economic development (Wilder *et al*., 2013). Large sections of the urban population live in informal housing lacking the health and safety standards needed to respond to hazards, and with no insurance (Collins *et al*., 2011). Any effort to increase regional adaptive capacity needs to take existing gaps into account.

Climate change is projected to put additional stresses to the region (Wilder *et al*., 2013), currently characterized by high temperatures and aridity, with about half of its precipitation coming in the summer monsoon and that has experienced particularly dry conditions in recent years. For example, the current drought, affecting large areas on both sides of the border is the most extreme in over a century of recorded precipitation patterns for the area (Cayan *et al*., 2010; Seager and Vecchi, 2010b; Nielsen-Gammon, 2011). Streamflow in already oversubscribed rivers such as the Colorado and Rio Grande has also decreased, threatening water resources. Climatological conditions for the area have been particularly unprecedented, with sustained high temperatures that may exceed any experienced for 1,200 years. While these changes cannot conclusively be attributed to anthropogenic climate change, they are consistent with climate change projections (Woodhouse *et al*., 2010).

Ecosystems

Population growth, economic development and urbanization are already fragmenting and degrading the region's highly diverse habitats, species and ecosystems, such as the California saga and chaparral, the Sonoran and Chihuahuan deserts, sensitive wetlands and the Tamaulipan mezquital (Wilder *et al*., 2013). Of the region's over 6,500 animal and plant species, 235 on the Mexican side are classified in a risk category and 85 are considered endangered under Mexico's law. While on the U.S. side, 148 species are listed as endangered under the U.S. Endangered Species Act. (U.S. EPA and Secretaría de Medio Ambiente y Recursos Naturales, 2011).

Human Health

In the absence of adequate policies and governance structures, upward trends in population growth and economic activity have brought with them more pollution sources, including motor vehicles, industries and power plants (Varady *et al*., 2002; Sarnat *et al*., 2012). Heavy diesel trucking is also concentrated along several highways and border crossings, creating local hotspots for fine particle pollution (Svendsen *et al*., 2012). Border monitoring stations show that there were some days with violations of ozone or PM10 air quality standards in the past five years, but with variations from year to year (World Health Organization, 2007).

As climate change enters the equation, it may impact human health in the region in diverse ways: For instance, long-term draught in the region increases respiratory impacts from wind-blown dust. Rising temperatures increase ozone levels (U.S. EPA and Secretaría de Medio Ambiente y Recursos Naturales, 2011). As climate change interacts with socio-economic factors in the region, the human health stressors may be compounded.

Adaptation Challenges

In the fragile ecosystems of this region, opportunities and challenges, resources and environmental and health impacts are shared across international borders, creating the need for cooperation among local, national and international actors. Although there are examples of efforts to manage trans-border environmental problems (Wilder *et al*., 2010; Megdal and Scott, 2011), barriers to effective cooperation and collaboration exist such as different governance structures —centralized (Mexico) versus decentralized (United States); institutional fragmentation; asymmetries in the use and dissemination of information, and language (Wilder *et al*., 2013).

_____ END BOX 26-1 HERE _____

26.2.1.2. Future Trends

Population in North America is projected to keep growing over the next decades and reach between 531.8 and 660.1 million by 2050 based on respective B2 and A2 scenarios (Lutz *et al*., 2007). The aging of population is also projected to progress, particularly in Mexico, so that by 2050, between 26.9% and 23.4% of the population in Canada, 18.4 % and 12.4% Mexico and 20.9% and 17.3% in the USA is projected to be elderly under respective B2 and A2 scenarios (Lutz *et al*., 2007). The elderly are more sensitive to extreme weather events (heat waves in particular, Figure 26-2) and the risks are still greater for those living alone (Martiello and Giacchi, 2010; Diffenbaugh and Scherer, 2011; Romero-Lankao, 2012; White-Newsome *et al*., 2012). Increases in the numbers of single-person households and female-headed households may also exacerbate the vulnerability of populations. Institutional capacity may also be limited by challenges posed by aging populations and a resulting stress on health and economic performance.

[INSERT FIGURE 26-2 HERE
Figure 26-2: Projected changes in the intensity of the worst heat events, as simulated by CLMU for urban grid cells: a) near term (2020-2039) relative to present-day climate (1980-1999); b) end of the 21st century (2080-2099) relative to present-day climate (1980-1999). Source Wilhelmi et al. (forthcoming).]

While many demographic factors have bearing on impacts and adaptation, three other shifts are projected to influence impacts, vulnerabilities and adaptation to climate change in North America: urbanization, migration, and economic disparity. With small differences between countries, both the concentration of growing populations in some urban areas and the dispersion of rural populations in many smaller settlements are projected to continue to define North America by 2050 (Figure 26-1b). For instance, according to projections, giving no consideration to global warming, between 2005 and 2030 the population of Mexico-City-Metro-Area will increase by 17.5%, while between 2007 and 2030 available water will diminish by 11.2% (Romero-Lankao, 2010). Conversely, education, a key determinant of adaptive capacity, is expected to expand to low-income households, minorities, and women, which could increase the capcity of households to cope with environmental risks and have a positive impact on economic growth (Goujon and Lutz, 2004). However, a continued growth in economic disparity and poverty could hinder such improvements. Inequality in Mexico is larger, having a Gini index (a measure of economic disparity) of 0.56, in contrast to 0.317 for Canada and 0.389 for USA (OECD, 2010b). Limited economic growth expected in the short run for the region would not help to reduce the income gap across and within countries (OECD, 2010a). Mexico, which already has a markedly higher poverty rate than Canada or the U.S., is one of five developing countries in the world that is projected to experience the highest increases in poverty due to climate-induced extreme events (52% increase in rural households; 95.4% in urban wage-labor households) (CMIP3, A2) (Ahmed *et al*., 2009).

Migration can be influenced by multiple factors, and isolating climate change as a cause is difficult. However, changes in climate can influence decisions to migrate, and migration flows themselves have implications for climate

change impacts and vulnerability. This because the arrival migrants can increase pressure on climate sensitive urban regions (Hugo, 2011). In North America, one of the most significant migration flows that was influenced, in part, by climate change was the outmigration of many in the Mexican agrarian sector (Saldaña-Zorrilla and Sandberg, 2009). Lack of capital has been the key inducement for migration in response to historic Mexican droughts (Fraser, 2007; Gilbert and McLeman, 2010). However, current outmigration from regions in Mexico experiencing recurrent disasters outpaces migration from regions with lower socio-economic status (Saldaña-Zorrilla, 2006) pointing to concerns for health and safety as another driver of migration resulting from changes in climate.

26.2.2. Physical Climate Trends

Some processes important for climate change in North America are assessed in other Chapters of AR5, including WGI Chapter 2 (*Observations: Atmosphere and Surface*), WGI Chapter 14 (*Climate Phenomena and their Relevance for Future Regional Climate Change*), WGI Annex I (*Atlas of Global and Regional Climate Projections*), and WGII Chapter 21 (*Regional Context*). In addition, comparisons of emissions, concentrations, and radiative forcing in the RCPs and SRES scenarios can be found in WGI Annex II (*Climate System Scenario Tables*).

26.2.2.1. Current Trends

Chapter 2 of WGI assesses observations of the climate system. Observations show increases in the occurrence of severe hot events over the U.S. over the late 20th century (Kunkel *et al.*, 2008, WGI 2.6.1), a result in agreement with observed late-20th-century increases in extremely hot seasons over a region encompassing northern Mexico, the U.S. and parts of eastern Canada (Diffenbaugh and Scherer, 2011). These increases in hot extremes have been accompanied by observed decreases in frost days over much of North America (Alexander et al., 2006; Brown *et al.*, 2010b, WGI 2.6.12), decreases in cold spells over the U.S. (Kunkel *et al.*, 2008, WGI 2.6.1), and increasing ratio of record high to low daily temperatures over the U.S. (Meehl *et al.*, 2009). However, relative cooling has occurred over central North America and the eastern USA (e.g., Alexander et al., 2006; Peterson *et al.*, 2008, WGI 2.6.1), with more pronounced contrast seen in trends over the past century than in trends over the last three decades (WGI Figure 2.22, Figure 26-3). It is possible that this "warming hole" has been influenced by changes in the hydrologic cycle (e.g., Pan *et al.*, 2004; Portmann *et al.*, 2009), as well as by decadal-scale variability in the ocean (e.g., Kumar *et al.*, 2012; Meehl *et al.*, 2012).

[INSERT FIGURE 26-3 HERE
Figure 26-3: Changes in annual temperature and precipitation. White indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.]

WGI notes that observations show increases in heavy precipitation over Mexico, the U.S. and Canada between the mid-20th century and the early 21st century (WGI 2.6.2, DeGaetano, 2009; Peterson and Baringer, 2009; Pryor *et al.*, 2009). Observational analyses of changes in drought are more equivocal over North America, with mixed sign of trend in dryness over Mexico, the U.S. and Canada (WGI 2.6.2 and Figure 2.42, Dai, 2011; Sheffield *et al.*, 2012). WGI notes evidence for earlier occurrence of peak flow in snow-dominated rivers globally (Rosenzweig, 2007, WGI 2.6.2). Observed snowpack and snow-dominated runoff have been extensively studied in the western U.S. and western Canada, with observations showing primarily decreasing trends in the amount of water stored in spring snowpack from 1960-2002 (with the most prominent exception being the central and southern Sierra Nevada)

(Mote, 2006) and primarily earlier trends in the timing of peak runoff over the 1948-2000 period (Stewart *et al.*, 2006). WGI also assess observed changes in extreme storms in North America, noting that observational limitations prohibit conclusions about trends in severe thunderstorms (WGI 2.6.2) and tropical cyclones (WGI 2.6.3). The most robust trends in extratropical cyclones over North America are determined to be towards more frequent and intense storms over the northern Canadian Arctic and towards less frequent and weaker storms over the southeastern and southwestern coasts of Canada over the 1953-2002 period(WGI 2.7.4, Wang *et al.*, 2006).

WGI concludes that it is "*virtually certain* that globally mean sea level (GMSL) has risen at a mean rate between 1.4 to 2.0 mm yr^{-1} over the 20th Century and between 2.7 and 3.7 mm yr^{-1} since 1993." (WGI 3 Executive Summary). In addition, WGI concludes that observed changes in extreme sea level have been caused primarily by increases in mean sea level (WGI 3.7.5). WGI also concludes that regional variations in the observed rate of sea level rise can result from processes related to atmosphere and ocean variability (such as lower rates along the west coast of the U.S.) or vertical land motion (such as high rates along the U.S. Gulf Coast), but that the persistence of the observed regional patterns is unknown (WGI 3.7.3).

26.2.2.2. Climate Change Projections

Chapter 14 of the WGI contribution to the AR5 assesses processes important for regional climate change, with section 14.7.3 focused on North America. Many of the WGI conclusions are drawn from Annex I of the WGI contribution to the AR5.

The CMIP5 ensemble projects very likely annual warming over North America, with very likely increases in temperature over all land areas in the mid- and late-21st-century periods of RCP4.5 and RCP8.5 (Figure 26-4). Mean warming across climate models exceeds 2°C over most land areas of all three countries in the mid-21st-century period of RCP8.5 and the late-21st century period of RCP4.5, and exceeds 4°C over most land areas of all three countries in the late-21st-century period of RCP8.5. The largest mean warming occurs over the high latitudes of the United States and Canada, as well as much of eastern Canada, including greater than 6°C of annual warming in the late-21st-century period of RCP8.5. The smallest mean warming occurs over areas of southern Mexico, the Pacific Coast of the United States, and the southeastern United States.

[INSERT FIGURE 26-4 HERE
Figure 26-4: Observed and simulated variations in past and projected future annual average precipitation and temperature over land areas of Canada, the contiguous United States, and Mexico. Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.]

Most land areas north of 45°N exhibit likely increases in annual precipitation in the late-21st-century period of RCP8.5, including very likely increases over the high latitude areas of North America (Figure 26-3). In contrast, much of Mexico and the southcentral and southwestern United States exhibit likely decreases in annual precipitation in the late-21st-century period of RCP8.5. Likely changes in annual precipitation are much less common at lower levels of forcing, with few areas of Mexico exhibiting changes that exceed the baseline variability in the mid- or late-21st-century periods of RCP4.5 or the mid-21st-century period of RCP8.5. Likewise, likely changes in annual precipitation in the United States are primarily confined to increases over the northern latitudes during the mid- and late-21st-century periods of RCP4.5, and the mid-21st-century period of RCP8.5. Very likely changes in annual precipitation are confined primarily to increases over the high latitude areas of North America throughout the illustrative RCP periods, with very likely increases occurring in the mid-21st-century period of RCP4.5 and becoming generally more wide-spread at higher levels of forcing.

The CMIP5 ensemble projects warming in all seasons over North America beginning as early as the 2016-2035 period of RCP2.6, with the greatest warming occurring in winter over the high latitudes (WGI Annex I and Figure

26-4; Diffenbaugh and Giorgi, 2012). An important measure of the robustness of climate change is the magnitude of the change ("signal") relative to the background climate variability ("noise"). From the perspective of impacts, adaptation and vulnerability, the "signal-to-noise ratio" helps to quantify the magnitude of climate changes relative to the background variability to which natural and human systems are accustomed in the recent climate. The CMIP5 and CMIP3 ensembles suggests that the response of warm-season temperatures to elevated radiative forcing exhibits higher signal-to-noise ratio than the response of cold-season temperatures (Diffenbaugh and Scherer, 2011; Kumar *et al.*, 2012), and the CMIP3 ensemble suggests that the response of temperature in low-latitude areas of North America exhibits higher signal-to-noise ratio than the response of temperature in high-latitude areas (Diffenbaugh and Scherer, 2011). In addition, CMIP3 and a high-resolution climate model ensemble suggest that the signal-to-noise ratio of 21st century warming is far greater over the western U.S., northern Mexico and the northeastern U.S. than over the central U.S. (Diffenbaugh *et al.*, 2011).

CMIP5 projects increases in winter precipitation over Canada and Alaska, consistent with projections of poleward shift in the dominant cold-season stormtracks (WGI 14.7.3, Yin, 2005), extratropical cyclones (Trapp *et al.*, 2009) and areas of moisture convergence (WG1 14.7.3), as well as with projections of shift towards positive North Atlantic Oscillation (NAO) trends (WGI 14.7.3, Hori *et al.*, 2007). CMIP5 also projects decreases in winter precipitation over the southwestern U.S. and much of Mexico associated with the poleward shift in the dominant stormtracks and the expansion of subtropical arid regions (WGI14.7.3, Seager and Vecchi, 2010b). However, there are uncertainties in hydroclimatic change in western North America associated with the response of the tropical Pacific sea surface temperatures (SSTs) to elevated radiative forcing (particularly given the influence of tropical SSTs on the Pacific North American pattern (PNA) and north Pacific storm tracks) (WGI 14.7.3, Cayan *et al.*, 1999; Findell and Delworth, 2010; Seager and Vecchi, 2010a), and not all CMIP5 models simulate the observed recent hydrologic trends in the region (Kumar *et al.*, 2012)

Mexico and the western U.S. emerge as prominent areas of aggregate climate change in both RCP4.5 and RCP8.5, primarily as result of extreme heat in all seasons and extreme dry conditions in winter and spring (Diffenbaugh and Giorgi, 2012). CMIP5 projects substantial increases in the occurrence of extremely hot seasons over North America in early, middle and late 21st century periods of RCP8.5, including greater than 80% of summers exceeding the late 20th century maximum during the 2070-2099 period (Diffenbaugh and Giorgi, 2012). The CMIP5 ensemble also projects substantial decreases in snow accumulation over the U.S. and Canada, including greater than 80% of years with March snow amount below the late 20th century median – and greater than 30% of years below the late 20th century minimum – over much of the western U.S. and western Canada beginning the middle 21st century period of RCP8.5 (Diffenbaugh *et al.*, 2012). These decreases in spring snow amount are associated with substantial changes in the timing of total surface runoff, including greater than 30% of years above (below) the baseline winter (spring) runoff over the high elevation areas of the western U.S. and western Canada during the 2070-2099 period, greater than 50% of years below the summer maximum runoff over the high elevations of northwestern Canada, and greater than 30% of years above the baseline winter maximum runoff over most of central Canada during the 2070-2099 period (Diffenbaugh *et al.*, submitted) .

26.3. Water Resources and Management

26.3.1. Observed Impacts on Water Resources

Drought: Although no evidence has yet been found indicating trends of increased drought occurrence at the North American continental scale (section 26.2.2.1.1., USCCSP, 2008), local trends over the past approximately 40 years have been observed in east and southwest USA, north and northwest Mexico, and the Canadian Prairies (Barnett *et al.*, 2008; Groisman and Knight, 2008; Ellis *et al.*, 2010; SEMARNAT-INECC, 2012, section 26).

Floods: Changes in the magnitude or frequency of flood events are difficult to attribute to climate change. Floods are generated by multiple mechanisms affected by numerous influences such as land use change, urbanization and flow regulation (section 26.2.2.1, Villarini *et al.*, 2011; SEMARNAT-INECC, 2012). For instance, in the eastern USA, the relationship between heavy rainfall and flooding shows a large annual variability that is not easily associated with changing climate (Smith *et al.*, 2011).

Mean Annual Streamflow: While annual precipitation and runoff increases have been found in the Midwestern and Northwestern United States, decreases have been observed in southern states (Georgakakos *et al*., 2013).

26.3.2. Water Use

Water withdrawals are already exceeding stressful levels (exceeding 40 percent of supply) in many regions of North America such as the southwest US, northern and central Mexico (particularly Mexico City), southern Ontario and the southern Canadian Prairies (National Water Commission of Mexico, 2010; Romero-Lankao, 2010; Sosa-Rodriguez, 2010; Averyt *et al*., 2011; Environment Canada, 2013a).

10 % to 30 % of the water quality monitoring sites in Mexico have polluted or heavily polluted water, depending upon the parameter monitored (National Water Commission of Mexico, 2010), and about 44% of assessed stream miles, and 64% of assessed lake areas in the US were not clean enough to support uses such as fishing and swimming (U.S. EPA, 2004). Conversely the stations in Canada's 16 most populated drainage basins reported at least fair quality, with many basins reporting good or excellent quality (Environment Canada, 2013b).

As noted in Section 26.7, the water resources management infrastructure in most areas of North America is in need of repair, replacement or expansion.

26.3.3. Projected Impacts and Risks

26.3.3.1. Water Supply

Most of the discussion focuses on surface water as there are few groundwater studies (Tremblay *et al*., 2011; Georgakakos *et al*., 2013).

In arid and semi-arid western USA and Canada and in most of Mexico, except the southern tropical area, water supplies are predicted to be further stressed by climate change (IMTA, 2010; MacDonald, 2010b; Montero Martinez *et al*., 2010), with expected changes varying based upon climate models, time frames and regions studied. For instance, along the United States-Mexico border under A2, A1B, and B1 scenarios for 2050 and 2080s, reduced water availability is anticipated to result from increasing temperatures and high degree of annual precipitation variability (Cayan *et al*., 2010; IMTA, 2010), resulting in possible surface and groundwater overexploitation (CONAGUA, 2011). Similarly, with scenarios A2 and A1B in 2039, the northeastern coast of Mexico will probably face high water stress due to the decreased availability and increased demand for water leading to overexploitation of groundwater even though the region already has many reservoirs (CONAGUA, 2011). Compounding factors will include salt water intrusion, and increased groundwater and surface water pollution (Leal *et al*., 2008).

In the US southwest and southeast, ecosystems and irrigation are projected to be particularly stressed by decreases in water availability and growing water demand, or by water transfers to urban and industrial users with greater economic productivity (Seager *et al*., 2009; Georgakakos *et al*., 2013) . In the Colorado River Basin crop irrigation requirements for pasture grass are projected to increase by 20% by 2040 and by 31 % by 2070 (AECOM, 2010). In the Rio Grande basin, New Mexico, runoff is projected to be reduced by nearly 30% by 2080. Water transfers entail significant transaction costs associated with adjudication and potential litigation. In addition, transferring water reduces ecological, environmental, social, and cultural attributes (Hurd and Coonrod, 2012).

Other parts of North America are projected to have different climate risks. For instance, while no vulnerability of water resources is projected for 2050 over the tropical southern region of Mexico, greater precipitation is projected after 2050, increasing the possibility of destroying hydropower and water storage dams by floods (IMTA, 2010). Throughout the 21st century, the cities of Seattle, Everett, and Tacoma, Washington, are projected to have drawdown of average seasonal reservoir storage in the absence of demand reduction because of less snowpack even though annual streamflows increase. Without accounting for demand increases, reliability of all systems can remain

above 98% for Seattle, Everett and Tacoma through mid and late century (Vano *et al.*, 2010a). Throughout eastern USA, water supply systems will be negatively impacted if groundwater recharge lessens and snowpack storage is lost as well as by rising sea levels, increased storm intensities, salt water intrusion, lower flows, land use, population changes, and other stresses (Sun *et al.*, 2008; Obeysekera *et al.*, 2011). Southern Alberta, where approximately two-thirds of Canadian irrigated land is found (Poirier and de Loë, 2012) is projected to experience declines in mean annual streamflow, especially during the summer (Shepherd *et al.*, 2010.). Decreases of 5% annual average runoff of the Chaudière River watershed, in Québec, Canada, were simulated for 2010-2039 relative to the reference period 1970-1999 using a variety of downscaling methods (Quilbe *et al.*, 2008; Chen *et al.*, 2011).

26.3.3.2. Water Quality

Reduced flow conditions can result in quality impacts due to increased temperature, increased concentrations of dissolved substances, and dissolved oxygen level changes (Novotny and Stefan, 2007; Delpla *et al.*, 2009.; Daley *et al.*, 2009; Benotti *et al.*, 2010). Increased wildfires linked to a warming climate are expected to affect water quality downstream of forested headwater regions (Emelko *et al.*, 2011). Model simulation of lakes under a range of plausible higher air temperatures (Tahoe, Great Lakes, Lake Onondaga and shallow polymictic lakes), depending on the system, predict a range of impacts such as increased phytoplankton, fish and cyanobacteria biomass, lengthened stratification periods with risks of significant hypolimnetic oxygen deficits in late summer with solubilization of accumulated phosphorous and heavy metals with accelerated reaction rates, and decreased lake clarity (Dupuis and Hann, 2009.; Trumpickas *et al.*, 2009; Sahoo *et al.*, 2010; Taner *et al.*, 2011). Model simulations have found seasonal climate change impacts on nonpoint source pollution loads, while others have found no impact (Marshall and Randhir, 2008; Tu, 2009; Praskievicz and Chang, 2011; Taner *et al.*, 2011). Tu (2009), Praskievicz and Chang (2011), Daley et al (2009), Tong et al (2012), and Wilson and Weng (2011) find the combined impacts of climate change and development will result in poorer water quality. However, where investigated, climate change impacts were greater than those of land use changes.

Delpla (2009), Carriere et al. (2010), and Emelko (2011) found that changes in physical-chemical-biological parameters and micropollutants will negatively affect drinking water treatment and distribution systems. Wastewater treatment plants will be more vulnerable as increases in rainfall and wet weather lead to higher rates of inflow and infiltration (King County Department of Natural Resources and Parks, 2008; NYCDEP., 2008; Flood and Cahoon, 2011). These plants will also face reduced hydraulic capacities due to higher sea levels and increased river and coastal flooding (Flood and Cahoon, 2011), with higher sea levels also threatening the sewage collection systems (Rosenzweig *et al.*, 2007; King County Department of Natural Resources and Parks, 2008)

26.3.3.3. Flooding

Projected increases in flooding (Georgakakos *et al.*, 2013) may affect sectors ranging from agriculture and livestock in southern tropical Mexico (National Water Commission of Mexico, 2010) to urban and water infrastructure in areas such as Dayton, Ohio, metro Boston and the Californian Bay-Delta region (National Research Council, 1995; Kirshen *et al.*, 2006; California Department of Water Resources, 2009; Wu, 2010). Floods could begin earlier, have earlier peaks and longer durations (e.g., southern Quebec basin . Urbanization can compound the impacts of increased flooding due to climate change, particularly in the absence of flood management infrastructures that take climate change into account (Hejazi and Markus, 2009; Mailhot and Duchesne, 2010; Ntelekos *et al.*, 2010; Sosa-Rodriguez, 2010) estimate that annual riverine flood losses in the USA could increase from approximately $2 billion now to $7-$19 billion annually by 2100 under the business as usual scenario.

26.3.3.4. Instream Uses

Projections of climate impacts on instream uses vary by region and time-frame. Hydropower generation, affected by reduced lake levels, is projected to decrease in arid and semi-arid areas of Mexico (SEMARNAT, 2009; Sosa-Rodriguez, 2013) and in the Great Lakes (Buttle *et al.*, 2004; Mortsch *et al.*, 2006; Georgakakos *et al.*, 2013). In the

US Pacific Northwest it is projected to increase in 2040 by 5% in the winter and decrease by 13% in the summer, with annual reductions of about 2.5%. Larger decreases of 17% to 21% in summer hydropower production are projected by 2080 (Hamlet *et al.*, 2010). On the Peribonka River system in Quebec, annual mean hydropower production would decrease by 1.8% for 2010-2039 and increase by 9.3% and 18.3% respectively during the periods 2040-2069 and 2070-2099 (Minville *et al.*, 2009). Navigation on the Great Lakes, Mississippi River and other inland waterways may benefit from less ice cover but will be hindered by increased floods and droughts (Georgakakos *et al.*, 2013).

26.3.3.5. Energy-Water Nexus

Energy demands for water supply and wastewater treatment are projected to increase under climate change due to increases in pumping and treatment requirements, partly due to increased surface water temperatures (CH2M Hill, 2009; Skaggs *et al.*, 2012). Cooling of USA thermoelectric power plants is predicted to be affected; it accounts for approximately 50% of the nation's water withdrawals (Kenny *et al.*, 2009). The vulnerability of these power plants will vary regionally depending on differences in water availability and temperature due to climate impacts (Wilbanks *et al.*, 2008). Carbon pricing policies may decrease thermoelectric power plant freshwater withdrawals and consumption in the continental USA compared to business as usual policies (Chandel *et al.*, 2011). Total freshwater consumption for national energy production (including thermoelectric power, biofuels, and fossil fuels) in the United States is estimated at 11% (Elcock, 2010; Mekonnen and Hoekstra, 2011; Spang *et al.*, 2013). However, energy production mitigation measures such as carbon capture, nuclear power, and some biofuels will exacerbate stresses on water supplies and quality (Engelhaupt, 2007; Delucchi, 2010; Stone *et al.*, 2010; Powers *et al.*, 2011; Cooper and Sehlke, 2012)

26.3.4. Adaptations

Most of the project-level adaptation actions are no-regret policies. For instance, in preparation for more intense storms, New York City is using green infrastructure to capture rainwater before it can flood the combined sewer system and is elevating boilers and other equipment above ground (Bloomberg, 2012). The Mexican cities of Monterrey, Guadalajara, Mexico City and Tlaxcala are reducing leaks from water systems (SEMARNAT, 2009; National Water Commission of Mexico, 2010; Romero-Lankao, 2010; Sosa-Rodriguez, 2010). Regina, SK has increased urban water conservation efforts (Lemmen *et al.*, 2008).

The 540-foot high, 1300-foot long concrete Ross Dam in the state of Washington, USA was built on a special foundation so it could later be raised in height (Jay Lund, personal communication). Dock owners in the Trent-Severn Waterway in the Great Lakes have moved their docks into deeper water to better manage impacts on shorelines (Coleman *et al.*, 2013). The South Florida Water Management District is assessing the vulnerability to sea level rise of its aging coastal flood control system and exploring adaptation strategies, including a strategy known as forward pumping (Obeysekera *et al.*, 2011). In Cambridge, Ontario, extra capacity culverts are being installed in anticipation of larger runoff (Scheckenberger *et al.*, 2009).

Water meters have been installed to reduce water consumption by different users such as Mexican (also installing drip irrigation) and Canadian farmers and several Canadian cities (INE (National Institute of Ecology), 2006; Lemmen *et al.*, 2008). Agreements and regulations are underway, such as the "shortage sharing agreement" signed in 2007 for the management of the Colorado River, USA and driven by concerns about water conservation, shortage planning, better reservoir coordination, and preserving flexibility to respond to climate change (http://www.usbr.gov/lc/region/programs/strategies.html, accessed January 27, 2013). Quebec Province is also requiring dam safety inspections each 10 years to also account for new knowledge on climate change impacts (http://www.cehq.gouv.qc.ca/loisreglements/barrages/reglement/index-en.htm).

26.4. Ecosystems and Biodiversity

Recent research has documented gradual changes in physiology, phenology and distributions in North American ecosystems (Dumais and Prévost, 2007). Concomitant with 20th century temperature increases, shifts in plant, mammal, bird, lizard, and insect species' distributions have been documented extensively in the western United States and eastern Mexico (Parmesan, 2006; Kelly and Goulden, 2008; Moritz *et al*., 2009; Tingley *et al*., 2009; Sinervo *et al*., 2010). These gradual climate-induced distribution shifts interact with other existing environmental changes such as land-use change, hindering the ability of species to respond.

Different techniques have been applied to assess the vulnerability of North American ecosystems to changes in climate (Loarie *et al*., 2009). A global risk analysis based on dynamic global vegetation models identified boreal forest in Canada as notably vulnerable to ecosystem shift(Scholze *et al*., 2006). Building upon results presented in the AR4, studies have identified a more prominent role of extreme events such as droughts and floods on vegetation mortality, increased infestation by fungi, sea levels rise, hurricanes and other increasingly severe impacts facing North American ecosystems (Chambers *et al*., 2007; IPCC, 2012). Although North American forests were a net carbon sink between 1990-2007 (Pan *et al*., 2011), current measurements suggest a reduction in the global net primary production of 0.55 petagrams of carbon due to large-scale droughts between 2000 to 2009 (Zhao and Running, 2010).

Climatic changes are expected to affect North American terrestrial and coastal ecosystems in significant and in many cases adverse ways. The responses of biological systems depend on organizational level and can differ across communities, populations or species. Changes in temperature, precipitation amount, carbon dioxide concentrations can have differential effects across species and ecological communities (Parmesan, 2006; Matthews *et al*., 2011). Risk studies on 134 species in U.S. and 16 forest species in Mexico estimated shifts in potential habitat under climate scenarios (Iverson *et al*., 2008; Gómez *et al*., 2011; Iverson *et al*., 2012). These studies have contributed to planning management strategies for adaptation of these ecosystems (USDA Forest Service, 2010; Leichenko, 2011; Comisión Intersecretarial de Cambio Climático, 2012).

The following section focuses in more depth on climate vulnerabilities in forests and coastal ecosystems and transboundary ecosystems across all three North American countries where research advances since AR4 justify further exploration. Additional synthesis on climate impacts on ecosystems in general and terrestrial, coastal and ocean in particular can be found in Chapter 8 of the (Groffman *et al*., 2013) and chapters 4, 5 and 6 of AR5.

26.4.1. Tree Mortality and Forest Infestation

26.4.1.1. Observed Impacts

Droughts of unusual severity, extent, and duration have affected large parts of western and southwestern North America and resulted in regional-scale forest dieback in Canada, US and Mexico. Extensive tree mortality has been related to exacerbated drought by higher summertime temperatures mainly in quaking aspen (*Populus tremuloides*), pinyon pine (*Pinus edulis*) and lodgepole pine (*Pinus contorta*) (Breshears *et al*., 2005; Hogg *et al*., 2008; Raffa *et al*., 2008; Worral *et al*., 2008; Michaelian *et al*., 2011; Anderegg *et al*., 2012). Similarly, in 2011 and 2012 oak forest dieback in Northern and central Mexico was associated with extreme temperatures and severe droughts (Conafor, 2012).Widespread forest-mortality events triggered by extreme climate events can alter ecosystem structure, function, and severely impact biodiversity (Phillips *et al*., 2009; Allen *et al*., 2010; Anderegg *et al*., 2013). Similarly, multi-decadal changes in demographic rates, particularly mortality, indicate climate-mediated changes in forest communities over longer periods (Hogg and Bernier, 2005; Williamson *et al*., 2009a). Increases in the average mortality rate of 4.7% yr –1 between 1963 and 2008 were reported for Canada's boreal forests (Peng *et al*., 2011), and in western US forests as well (van Mantgem *et al*., 2009).

The influences of climate change on ecosystem disturbance, such as insect outbreaks have become increasingly salient and suggest that these disturbances could have a major influence on North American ecosystems and

economy in a changing climate. In terms of carbon stores these outbreaks can turn forests into carbon sources (Kurz *et al*., 2008a; Kurz *et al*., 2008b; Hicke *et al*., 2012).

Warm winters in Western Canada and U.S. have allowed the larvae of mountain pine beetle to overwinter, causing the "largest and most severe [outbreak] in history" from Alaska to Colorado (Bentz, 2008), with massive die-offs in some regions. An estimated 18,177 km2 of U.S. forests is affected (Williams *et al*., 2010). British Columbia, Canada had the largest impact (Brown *et al*., 2010a), with mortality in over 7 million hectares (Aukema *et al*., 2006).

26.4.1.2. Projected Impacts and Risks

Projected increases in drought severity in southwestern United States and northwestern Mexico suggest that these ecosystems may be more vulnerable to rapid changes, such as vegetation mortality (Seager *et al*., 2007; Overpeck and Udall, 2010; Williams *et al*., 2010), and an increase of biological agents such as beetles, borers, pathogenic fungi, budworms and other pests (Drake *et al*., 2005). An index of forest drought stress calibrated on tree rings indicates that projected drought stress by the 2050s will exceed the most severe droughts of the past 1,000 years (Park Williams *et al*., 2013).

Major changes are projected towards the end of the century in forest soils in southern Quebec in 2040-2069 and 2070-2099 projected with subsequent decrease between 20-40% in the growing season of trees due to elevated evapotranspiration rates (Houle *et al*., 2012). More frequent droughts in tropical forests may change forest structure and regional distribution, favoring a higher prevalence of deciduous species in the forests of Mexico (Drake *et al*., 2005; Trejo *et al*., 2011).

Shifts in climate are expected to lead to changes in forest infestation, including expansion into higher latitudes and elevations (Bentz *et al*., 2010). Predicted climate warming is expected to have effects on bark beetle population dynamics in the southwestern United States and Northern part of Mexico that may include increases in developmental rates, generations per year, and changes in habitat suitability (Waring *et al*., 2009). As a result, the impacts of *Dendroctonus frontalis* and *Dendroctonus mexicanus* on forest resources are likely subject to amplification (Waring *et al*., 2009).

26.4.2. Coastal Ecosystems

Highly productive estuaries, wetlands and mangrove ecosystems are present in the East and West coasts of North America. These fragile ecosystems are vulnerable to sea level rise, increase in sea surface temperature, acidification of water, and hurricanes. Coastal zones are subject to many other stressors as well, including urban and tourist developments and the indirect effects of overfishing *(*Bhatti, 2006); (Mortsch *et al*., 2006; CONABIO-CONANP-TNC-PRONATURA, 2007; Lund *et al*., 2007)

26.4.2.1. Observed Impacts

Sea level rise, which has not been uniform across the coasts of North America (Crawford *et al*., 2007; Kemp *et al*., 2008; Leonard *et al*., 2009; Zavala-Hidalgo *et al*., 2010; Sallenger *et al*., 2012), is directly related to flooding and loss of coastal dunes, oyster beds, seagrass and mangroves affectations (Feagin *et al*., 2005; Cooper *et al*., 2008; Najjar *et al*., 2010; Martinez Arroyo *et al*., 2011; McKee, 2011). Influenced by rising sea levels, severe flooding and salinity movement inward in deltas have been detected in Sacramento-San Joaquin area, which can severely alter vegetation and species habitat (Lund *et al*., 2007).

Increases in sea surface temperature in estuaries threaten species, especially cold water fish and the metabolism of many organisms (Crawford *et al*., 2007). Historical warm periods have coincided with low salmon abundance and restriction of fisheries in Alaska (Crozier *et al*., 2008; USGCRP, 2009). In addition, some fisheries currently support

sardine fishing where they once fished for anchovy (Chavez *et al*., 2003). North Atlantic mammals, and tropical coral reefs in the Gulf of California, and the Caribbean are affected by increase in transmission diseases associated with warming of waters and low water quality(ICES, 2011; Mumby *et al*., 2011).

There is *very high confidence* about acidification in oceans and coasts (Box CC-OA). The increased CO2 contributes to acidification and affects mainly calcareous organisms colonial mussel beds temperate coastal and indirectly influences food webs of benthic species (Wootton *et al*., 2008). The acidity in conjunction with high temperatures have been identified as a serious threat to coral reefs and other marine ecosystems (Doney *et al*., 2009; Hernández *et al*., 2010; Mumby *et al*., 2011).

The ecological effects of tropical storms and hurricanes can alter coastal wetland hydrology, geomorphology (erosion), biotic structure in reefs and nutrient cycling. Hurricanes impacts on the coastline change dramatically the marine habitat of sea turtles reducing feeding habitats, like coral reefs, areas of seaweed and nesting places. (Liceaga-Correa *et al*., 2010; Márquez, R. and Jiménez, Ma. del C., 2010).

26.4.2.2. Projected Impacts and Risks

Projected increases in sea levels, particularly along the coastlines of Florida, Louisiana, North Carolina, and Texas(Kemp *et al*., 2008; Leonard *et al*., 2009; Weiss *et al*., 2011a), are projected to reduce flood tolerance of many plants in coastal ecosystems and their recovery almost impossible; result in a loss of wetlands and mangroves of between 20% (in Tamaulipas) to 94% (in Veracruz) for the Gulf of Mexico coast by the end of the 21st century (Flores Verdugo *et al*., 2010); and lead to large losses in tidal marshes in San Francisco Bay (Stralberg *et al*., 2011).

Projected impacts of increased water temperatures include contraction of coldwater fish habitat and expansion of warm-water fish habitat, which can increase the presence of invasive species threatening resident populations (Janetos *et al*., 2008). Up to 40 % of Northwest salmon populations may be lost by 2050 due to climate change (Battin *et al*., 2007; Crozier *et al*., 2008). Future restrictions are expected in productivity and abundance at the southern end while doing the opposite at the northern end of their range (Azumaya *et al*., 2007).

The progressive onset of ocean acidification will cause damage and reduction of coral growth with consequent extinctions and declines in biodiversity (Veron *et al*., 2009). Increases of CO2 alter calcification of bivalve and other organisms with shells, oyster larvae reared with levels between 560 to 480ppm were held in Chesapeake Bay and found slower calcification than in the current environmental conditions (Najjar *et al*., 2010).

The projected increase in the frequency of category 4 and 5 storms by the end of the 21st century (Bender *et al*., 2010; Knutson *et al*., 2010) might directly affect the mangroves over a period of at least 25 years and completely change their structure and age (Kovacs *et al*., 2004).

26.4.3. Ecosystems Resilience, Adaptation, and Mitigation

The resilience of the ecosystems to climate change depends on different and context specific factors: the biodiversity and conservation of habitats and food chains (Thompson *et al*., 2010) the interactions between relatively rapid rate of climate change and the land-use changes that can reduce species capacity to adapt or to be resilient (Bhatti et al 2006); (Magrin *et al*., 2007). The uncertain implications of these changes on productivity of fisheries and forestry (ICES, 2011; Okey *et al*., 2012) can force rural and indigenous population (whose economies depend on this resources) to migrate (Perry *et al*., 2010, section 26.6).

Some adaptation measures have been implemented to respond to climate change impacts on ecosystems: increases in plant community composition and biological diversity to reduce Canadian forest infestations (Johnston *et al*., 2010); breeding programs for resistance to diseases and insect pests (Yanchuk and Allard, 2009); selection by forest or fisheries managers of productive activities that are more adapted to new climatic conditions (chapter 4 Canadian Assessment); effective planning and regulations on other human activities such as commercial fishing and mass

tourism(Pratchett *et al*., 2008); for wetlands in the Great Lakes, Canada and coastal areas in San Joaquin and San Francisco, California, enforcement mechanisms for using water regulation technologies and maintain quantity and quality of water bodies (Mortsch *et al*., 2006; Okey *et al*., 2012).Human-assisted migration has been proposed as a potential management option to maintain optimal health and productivity of forests; yet the technique has logistical and feasibility challenges (Keel, 2007; Winder *et al*., 2011).

Adaptation research suggests that improving climate resilience and adaptation requires changes in the approach to protected area planning, establishment and management (CONABIO-CONANP-TNC-PRONATURA, 2007; March *et al*., 2011), and that it will be much more difficult and, in some cases, not sufficient if global temperature rise exceeds 2ºC above preindustrial levels (Mansourian *et al*., 2009). One of the more notable short-term changes in the policy arena is the discussion of GHG emissions reduction through CDM and REDD+ and management, conservation and restoration of forest carbon stocks. There are manifold ways through which forests influence the climate both biogeochemically (e.g. carbon sequestration) and biophysically (e.g. albedo and roughness)(Anderson and Bell, 2009; Anderson *et al*., 2011). Managers face challenges in adjusting management practices in favor of carbon accumulation, while at the same time maintaining biodiversity, recognizing the rights of indigenous people and contributing to local economic development (FAO, 2012).

_____ START BOX 26-2 HERE _____

Box 26-2. Wildfires

North America's large wildfire activity has markedly increased since the mid-1980s, and large wildfires have occurred with increased frequency and durations, within longer wildfire seasons (Westerling *et al*., 2006; Williamson *et al*., 2009b). The great conflagrations that have occurred in western Canada, the U.S. and Mexico in recent years are related to long and warm spring and summer droughts in those years, particularly when they have been, accompanied by wind events. (Holden *et al*., 2007; CONAFOR, 2011). Legacies of forest management also play a substantial role in wildfire risk across systems.

Socio-Ecological Impacts

Although fire-adapted ecosystems exist, increasing summer wildfires could lead to changes in dominant vegetation types and community structure. In places like Sierra Nevada, mixed conifer forests, which have a natural cycle of small, non-crown fires, will have an increased likelihood of massive crown-fires. Human use of fires in forests not prone to fires, such as tropical forests can have devastating impacts, and is strongly related to the frequency of fires (Bond and Keeley, 2005; CONANP and TNC, 2009).

While healthy forests provide carbon sequestration that benefits climate change mitigation, forests affected by pests and fires are less effective carbon sinks, and wildfires themselves are a source of emissions. Furthermore, fires pose a direct threat to human lives, property and health. The expansion of human habitation or productive activities in peri-urban areas or near forested areas, alongside legacies of forest management, has undoubtedly increased the probability of ignitions, causing severe fires and increasing human exposure (Radeloff *et al*., 2005; Peter *et al*., 2006; Fischlin *et al*., 2007; Theobald and Romme, 2007; Gude *et al*., 2008; Hammer *et al*., 2009). Wildfires pose direct health threats as well. According to the EM-DAT disaster database, over the last 30 years, 155 people were killed in wildfires across North America, including 103 in the United States, 50 in Mexico and 2 in Canada (CRED, 2012). Direct effects include injury and respiratory effects from smoke inhalation, with firefighters at increased risk (Naeher *et al*., 2007; Reisen and Brown, 2009; Reisen *et al*., 2011). Contingent on shifting fire regime, there is *high confidence* that wildfire activity will cause health impacts at the individual and neighborhood levels.

Climate Variability and Extremes

Drought conditions are strongly associated with wildfire occurrence, as dead fuels such as needles and dried stems promote the incidence of firebrands and spot fires (Keeley and Zedler, 2009) (Liu, et al.2012). Drought periods in Alberta and Idaho coincide with large burned areas (Pierce and Meyer, 2008; Kulshreshtha, 2011). Decadal climatic oscillations also contribute to drought conditions, and thus to wildfires. The areas burned in the North American boreal forest and in northwest and central Mexico are strongly related to the dynamics of these large-scale climatic patterns (Macias Fauria and Johnson, 2006; Skinner *et al*., 2006; Villers-Ruíz and Hernández-Lozano, 2007; Macias

Fauria and Johnson, 2008), which are already shifting toward hotter temperatures and longer droughts with the advance of climate change.

Southern and western Canada, Alaska and Mexico have all experienced a trend toward drier conditions since the 1950s (Kunkel *et al*., 2008), and augmented drought conditions are projected for a large proportion of the Western interior, Florida, and Mexico by 2100. Drought index projections and climate change regional models carried out in the USA show increases in the potential for fires, mainly in summer and fall, on the southeast Pacific coast, Northern Plains and the Rocky Mountains (Liu, et al 2012).

Adaptation Strategies

Further research on the relationships between climate and wildfire should include attention to population growth, land-use planning and forest structure as important aspects for adaptation planning. Prescribed fire may be an important tool for managing fire risk in Canada and the US (Hurteau and North, 2010; Wiedinmyer and Hurteau, 2010; Hurteau *et al*., 2011). Managers in the U.S. have encouraged reduction of flammable vegetation around structures with some success (Stewart *et al*., 2006). However, such efforts depend largely on the socio-economic capacity of communities at risk, the extent of resource dependence, community composition, and the risk perceptions, attitudes and beliefs of decision-makers, private property owners, and the public (McFarlane, 2006; Repetto, 2008; Collins and Bolin, 2009; Martin *et al*., 2009; Trainor *et al*., 2009; Brenkert-Smith, 2010).

Forest management also requires stakeholder involvement and investment. The provision of adequate information on smoke, managed fire/fire-use, pest management, and forest thinning is crucial, as is building trust between stakeholders and land managers (Dombeck *et al*., 2004; Flint *et al*., 2008; Chang *et al*., 2009). However, institutional shifts from reliance on historical records toward incorporation of climate forecasting in forest management will also be crucial to developing resilience in these areas (McKenzie *et al*., 2004; Millar *et al*., 2007; Kolden and Brown, 2010).

_____ END BOX 26-2 HERE _____

26.5. Agriculture and Food Security

Climate change is projected to cause food price increases and declines in caloric availability globally (Nelson *et al*., 2009); and changes in supply and price from diversion of production into biofuels (Searchinger *et al*., 2008; Valero-Gil and Valero, 2008; Liverman and Kapadia, 2010). Canada and the U.S. are relatively food secure, although households living in poverty and unengaged in food production are vulnerable. Mexico has high levels of food insecurity, where food constitutes a higher proportion of household budget (Juarez and Gonzalez, 2010). Indigenous peoples are also sensitive. Because North America is a major exporter (FAO, 2009; Schlenker and Roberts, 2009), shifts in agricultural productivity here may have implications for global food security.

26.5.1. Observed Impacts

There is strong evidence of the climate sensitivity of North American agricultural productivity. Historic increases in crop yield are attributed in part to increasing temperatures in Canada and high precipitation in the U.S. (Pearson *et al*., 2008; Nadler and Bullock, 2011; Sakurai *et al*., 2011), but optimum temperature ranges are narrow for many crops, and in many cases have already been reached (Hatfield *et al*., 2008). Yields of grains, forage, livestock and dairy decline significantly above temperature thresholds (Wolfe *et al*., 2008; Schlenker and Roberts, 2009; Craine *et al*., 2010). Increasing temperatures unless accompanied by increased precipitation result in soil organic content declines (Smith *et al*., 2009; Lin and Zhang, 2012), and increases in salinity (Sabo *et al*., 2010). Climate change affects product quality as well (e.g. coffee (Lin, 2007), wine grapes (Hayhoe *et al*., 2004; Jones *et al*., 2005), wheat (Porter and Semenov, 2005), fruits and nuts (Lobell *et al*., 2006), and cattle forage (Craine *et al*., 2010).

Yield variances over time have been attributed to climate variability (Cabas *et al*., 2010) (Almaraz et al 2008). Events such as drought, extreme heat and storms have also had a notable negative effect on economic returns (Chen and McCarl, 2009; Costello *et al*., 2009) (Swanson, Hiley and Venema 2007), particularly in Mexico, where the

agricultural sector accounted for 80% of weather-related financial losses over the past 20 years (Saldaña-Zorrilla, 2008).

26.5.2. Projected Impacts

Studies project productivity gains in northern regions and where water is not projected to be a limiting factor, due to longer and warmer growing seasons (Hatfield *et al*., 2008; Pearson *et al*., 2008; Costello *et al*., 2009; Wheaton *et al*., 2010; Nadler and Bullock, 2011). Overall, net declines in yields of major crops in North America are projected without adaptation, particularly for grains and perennials, although certain regions and crops may experience gains in the absence of extreme events, and projected yields vary widely by climate model (e.g., Paudel and Hatch, 2012). Yield declines combined with increased production costs would affect the economic health of the industry as well as food prices (Kiely *et al*., 2005), although the effects on profitability are difficult to forecast, and can be expected to be nonlinear. Aggregate profits have been projected to decline by up to 58% by 2099 (CCSM, A2) (Deschenes and Kolstad, 2011) in California's agriculture industry. In northwest Montana, Net Farm Income and average returns per acre are projected to decline by 57% and 24% respectively by 2050 (A1B, B1, A2, CMIP3) (Prato *et al*., 2010).

Among studies projecting yield declines, two factors stand out: exceedance of temperature thresholds and water availability. Projected temperature increases may affect yield negatively as early as 2020, with a growing number of studies indicating sharp declines in several major crops by 2099 (e.g., Schlenker and Roberts, 2009) (Hadley III) (Figure 26-5), and increased inter-annual variability over the next century (Sakurai *et al*., 2011; Urban *et al*., 2012). Projected temperature increases in California would result in declines in wine grape yields, where current conditions are already at temperature optimums (Jones *et al*., 2005), cotton and sunflower, (A2,B1, DAYCENT model) (Lee, de Gryze and Six 2009), and nut-bearing trees (Lobell *et al*., 2006). Even in northern regions, such as Quebec, projected temperature increases are higher than optimum for some major crops (Brassard and Singh, 2008) and result in productivity declines for fruit-bearing trees (Wolfe *et al*., 2008).

[INSERT FIGURE 26-5 HERE
Figure 26-5 Nonlinear relation between temperature and yields. Source: Schlenker, 2009.]

The effect of temperature on yield is moderated by changes in precipitation, projections of which are more variable by region, time frame, and climate model. Increases in precipitation would off-set but not necessarily entirely compensate for temperature-related declines in productivity (Kucharik and Serbin 2008). In regions projected to experience increasing temperatures combined with declining precipitation, declines in yield and quality are more acute (Craine *et al*., 2010; Monterroso Rivas *et al*., 2011a). The direct effects of increasing average temperatures on livestock stress, combined with reduced forage quality, would reduce significantly milk production and weight gain in cattle (Wolfe *et al*., 2008; Hernandez *et al*., 2011).

Agriculture is likely to be affected by soil moisture deficits and declining water availability in the U.S. Western/Southwest, the Western Prairies in Canada, and central and northern Mexico (Pearson *et al*., 2008; Cai *et al*., 2009; USGCRP, 2009; Esqueda *et al*., 2010; Vano *et al*., 2010b; Kulshreshtha, 2011). Current sectoral competition for limited water supplies is likely to become more intense (USGCRP, 2009; MacDonald, 2010a; Vano *et al*., 2010a; Lal *et al*., 2011). In the western U.S. and Canadian Prairies, projected earlier Spring snowmelt and higher proportions of precipitation falling as rain would negatively affect agricultural productivity regardless of precipitation levels, as water availability in Summer and Fall are reduced (Forbes *et al*., 2011); (Schlenker *et al*., 2007)(Kienzle et al 2011).

Projected increases in extreme heat, drought andstorms are other factors with negative effects on productivity (Chen and McCarl, 2009; Kulshreshtha, 2011), even in regions in which beneficial impacts in response to projected changes in average conditions are anticipated (Sushama *et al*., 2010). Projected changes in temperature and precipitation would also affect the prevalence and variety of pests, fungi and diseases (Wolfe *et al*., 2008; Jackson *et al*., 2009); (Wu et al 2011). Weeds are generally more responsive to increasing temperatures and CO_2 fertilization than crops (USGCRP, 2009), and the variety of weeds prevalent for a particular region is projected to change (McDonald *et al*., 2009). Organic producers would be particularly affected (Jackson and Wheeler 2010).

Responsiveness to CO_2 varies by crop, and positive growth response ceases when plants reach a CO_2 saturation point; thus CO_2 fertilization may not compensate for the negative impacts of temperature rise (Hatfield et al 2011). Elevated CO_2 can result in reduced nitrogen and protein content in grains and forage grasses (Brassard and Singh, 2008; Karl *et al*., 2009), and weeds are more responsive to CO_2 than crop species (Wolfe *et al*., 2008; USGCRP, 2009).

A Closer Look at Mexico

While agriculture in Canada and the U.S. is largely commercial, in Mexico it is comprised primarily of subsistence farmers (2.1 million) (Claridades Agropecuarias 2006). The negative effects to productivity of projected changes in climate here may be particularly acute, in part because a large proportion of Mexico's landbase is already marginal for two of the country's major crops: corn and beef (Monterroso-Rivas et al 2011b); (Buechler, 2009). Water deficits for Northwestern Mexico, the primary region of irrigated grain farming, may be substantial due to projected larger temperature increases and reductions in precipitation up to 30% greater than the rest of the country by 2050 (mean of ensemble of 18 models, A2 and A1B)(Magana *et al*., 2012). Irrigation, an important source of mitigation during water deficits, is limited in Mexico (Skoufias *et al*., 2011).

Although projected increases in precipitation may contribute to an overall increase in the productivity of rangeland in some regions (Monterroso Rivas *et al*., 2011b)2011a, the direct effects of temperature on livestock stress is expected to reach the dangerous zone by 2020 and continue to rise in Veracruz (A2 and B2, three GCMs) (Hernandez *et al*., 2011). Reduced frost threat in some regions would enhance corn yields (Conde *et al*., 2006). However, decreases from 6.2% currently to between 3% and 4.3% are projected in the land classified as "suitable" for rain-fed corn production (UKHadley B2) (ECHAM5/MPI A2) by 2050 (Monterroso-Rivas et al 2011b). The distribution of most races of corn is expected to be reduced and some eliminated by 2030 (A2, three climate models) (Ureta et al 2012). Coffee, an economically important crop supporting 500,000 primarily indigenous households (Gonzalez Martinez 2006), is projected to decline 34% by 2020 in Veracruz (Gay *et al*., 2006) and from 265400 ha today to 6000 ha by 2050 in Chiapas (A2a, mean of 15 models) (Schroth *et al*., 2009).

26.5.3. Adaptation

Adaptation can off-set projected declines in yields and capitalize on emerging opportunities. Importantly, adaptation imposes both costs and risks onto producers (Wolfe *et al*., 2008), and in some cases will be insufficient (Boyd and Ibarraran, 2009; Prato *et al*., 2010). Technological improvements can increase yield under normal conditions but do not protect harvests from extreme events (USGCRP, 2009; Wittrock *et al*., 2011). Some adaptation strategies may be economically precluded for low-value crops, or maladaptive for other sectors (depletion of groundwater supplies and increased energy consumption). Strong promotion of capital-intensive adaptation strategies may be beyond the means of smallholders (Mercer et al 2012).

26.5.3.1. Adaptation Options

Coping mechanisms, such as insurance, the purchase of livestock feed during droughts, or increased application of herbicides (Craine *et al*., 2010), may be necessary but insufficient, and certainly not optimal. Consideration of the potential for broad application, co-benefits, and unintended consequences of adaptation options will enhance adaptation planning (Belliveau *et al*., 2006). Planting varieties better suited to future climate conditions has high potential (Bootsma *et al*., 2005; Eakin and Appendini, 2008; Coles and Scott, 2009; Paudel and Hatch, 2012), and has been in use by farmers in the past (Conde *et al*., 2006; Nadler and Bullock, 2011).

Other options have multiple co-benefits. Low- and no-till practices that significantly reduce soil erosion and runoff also protect crops from extreme precipitation (Zhang and Nearing, 2005), retain soil moisture, and reduce greenhouse gas emissions (Suddick *et al*., 2010). Strategies to maintain productivity of grazing lands, such as

planting legumes and weed management, enhance soil carbon sequestration (Follett and Reed, 2010). Shade-producing perennials greatly enhances soil moisture retention (Lin, 2010), and contributes to local cooling (Georgescu *et al*., 2011). Increasing crop diversity, an historic risk management strategy that mediates the impacts of climate and market shocks (Eakin and Appendini, 2008), enhances management flexibility (Chhetri *et al*., 2010), and is more conducive to organic practices, which produce lower greenhouse gas emissions (Jackson and Wheeler 2010).

26.5.3.2. Criteria for Adaptation Observed in Existing Practices

High prices may motivate investments in adaptation(Li *et al*., 2011). However, market forces and technical feasibility alone are unlikely to lead to sectoral-level adaptation (Kulshreshtha, 2011), thus institutional support is key, found to be inadequate in many contexts (Klerkx and Leeuwis, 2009; Jacques *et al*., 2010; Tarnoczi and Berkes, 2010; Brooks and Loevinsohn, 2011; Alam *et al*., 2012; Anderson and McLachlan, 2012)(Bryant *et al*. 2008). Small Mexican farmers face limited access to credit and insurance (Eakin, 2006; Wehbe *et al*., 2008; Saldaña-Zorilla and Sandberg, 2009; Walthall *et al*., 2012). In some sectors we are seeing investments in adaptation. International coffee retailers and non-governmental organizations are engaged in enhancing coffee farmers' adaptive capacity (Schroth *et al*., 2009; Soto-Pinto and Anzueto, 2010).

Other key criteria are access to and quality of information (Tarnoczi and Berkes, 2010; Tarnoczi, 2011; Baumgart-Getz *et al*., 2012; Tambo and Abdoulaye, 2012) and the social networks needed to exchange that information and offer mutual support, particularly stronger ties among producers (Chiffoleau, 2009; Wittrock *et al*., 2011; Baumgart-Getz *et al*., 2012). Social networks may be especially important to the level of awareness and concern farmers hold about climate change, which in turn has motivated adaptation (Sánchez-Cortéz and Chavero 2011)(Eakin *et* al., forthcoming)(Frank *et al*., 2010).

26.6. Human Health

North America has been an important source of research on climate-related health impacts and vulnerability. Large national assessments of climate and health have been carried out in both the US and Canada (see reference to them in section 26.1). These have highlighted the potential for changes in impacts of extreme storm and heat events, air pollution, pollen, and infectious diseases, drawing from a growing NA research base analyzing observed and projected relationships among weather variables, vulnerability factors and health outcomes. The causal pathways leading from climate to health are complex, and can be modified by intervening factors including economic status, pre-existing illness, age, other health risk factors, access to health care, built and natural environments, adaptation actions and others. Human health is an important dimension of adaptation planning at the local level, much of which has so-far focused on warning and response systems to extreme heat events (New York State CAC, 2012).

26.6.1. Observed Impacts

26.6.1.1. Storm-Related Impacts

The magnitude of health impacts of extreme storms depends on the interaction between hazard exposure and characteristics of the affected communities (Keim, 2008). Coastal and other low-lying infrastructure and populations can be vulnerable due to flood-related interruptions in communications, healthcare access, and mobility. Health impacts include direct effects on traumatic death and injury (e.g., drowning; impacts of blowing and falling objects; contact with power wires) as well as indirect, longer-term effects related to contamination of water and soil, vector-borne diseases, respiratory diseases and mental health (Gamble *et al*., 2008). Infectious disease impacts from flooding include creation of breeding sites for vectors (Ivers and Ryan, 2006) and bacterial transmission through contaminated water and food sources causing gastrointestinal disease. Chemical toxins can be mobilized from industrial or contaminated sites (Euripidou and Murray, 2004) . Elevated indoor mold levels associated with flooding of buildings and standing water are identified as risk factors for cough, wheeze and childhood asthma

(Bornehag *et al.*, 2001; Jaakkola *et al.*, 2005). Mental health impacts of extreme storms have received relatively little study to date (Berry *et al.*, 2010). Stress of evacuation, property damage, economic loss, and household disruption are some of the mental health triggers (Weisler *et al.*, 2006; Gamble *et al.*, 2008). In the period of recent warming, i.e., 1970 to 2010, there has been no clear trend in US hurricane deaths, once the singular Katrina event is set aside (National Hurricane Center).

26.6.1.2. Extremes of Temperature

A large body of literature in North America has associated high temperatures with increased mortality and morbidity (e.g., Medina-Ramon and Schwartz, 2007; Anderson and Bell, 2009; Deschenes *et al.*, 2009; Knowlton *et al.*, 2009; O'Neill and Ebi, 2009; Cueva-Luna *et al.*, 2011; Hurtado-Díaz *et al.*, 2011; Romero-Lankao *et al.*, 2012). Extremely cold temperatures have also been associated with increased mortality (Medina-Ramon and Schwartz, 2007) , an effect separate from the seasonal phenomenon of excess winter mortality, which does not appear to be directly related to cold temperatures (Kinney, 2012). Most available NA evidence derives from the US and Canada, though one recent study reported significant heat- and cold-related mortality impacts in Mexico City (McMichael *et al.*, 2008).

26.6.1.3. Air Quality

Ozone and particulate matter (e.g., PM2.5 and PM10) have been associated with adverse health effects in many locations in North America (Romero-Lankao *et al.*, 2013). Weather and climate affect concentrations of air pollution over multiple scales in time and space. Emissions, transport, dilution, chemical transformation, and eventual deposition of air pollutants all can be influenced by meteorological variables such as temperature, humidity, wind speed and direction, and mixing height (Kinney, 2008). However, long-term trends in anthropogenic air pollution in NA are more influenced by trends in emission from sources than by climate, and to-date, there has been no discernible climate-induced trend in outdoor air quality in NA. Forest fires are an important source of particle emissions in NA, and can lead to increased cardiac and respiratory diseases incidence, as well as direct mortality (Rittmaster *et al.*, 2006; Ebi *et al.*, 2008). The indoor environment also can affect health in many ways, e.g., via penetration of outdoor pollution, emissions or pollutants indoors, moisture-related problems, and transmission of respiratory infections. Indoor moisture leads to mold growth, a problem that is exacerbated in colder regions such as northern NA in the winter. Climate variability and change is *likely* to affect indoor air quality, but with direction and magnitude that remains largely unknown (IOM, 2011).

26.6.1.4. Pollen

Exposure to pollen has been associated with a range of allergic outcomes, including exacerbations of allergic rhinitis (Cakmak *et al.*, 2002; Villeneuve *et al.*, 2006) and asthma (Delfino, 2002). Temperature and precipitation in the months prior to the pollen season affects production of many types of tree and grass pollen (Reiss and Kostic, 1976; Minero *et al.*, 1998; Lo and Levetin, 2007; U.S. EPA, 2008). Ragweed pollen production is responsive to temperatures and concentrations of atmospheric carbon dioxide (Ziska and Caulfield, 2000; Wayne *et al.*, 2002; Ziska *et al.*, 2003; Singer *et al.*, 2005). Because pollen production and release can be affected by temperature, precipitation, and CO_2 concentrations, it is possible that pollen exposure and allergic disease morbidity could change in response to climate change. However, to date, the only evidence for observed climate-related impacts are for the timing of the pollen season. Many studies have indicated that pollen seasons are beginning earlier (Emberlin *et al.*, 2002; Rasmussen, 2002; Clot, 2003; Teranishi *et al.*, 2006; Frei and Gassner, 2008; Levetin and Van, 2008; Ariano *et al.*, 2010). Evidence of an earlier start to the pollen season has recently been reported in the United States; some pollen types, such as ragweed, also have shown an increase in season length (Ariano *et al.*, 2010; Ziska *et al.*, 2011). Research on trends in NA has been hampered by the lack of long-term, consistently collected pollen records (U.S. EPA, 2008).

26.6.1.5. Waterborne Diseases

Waterborne infections are an important source of morbidity and mortality in North America. Commonly reported infectious agents in recent US and Canadian outbreaks include legionella bacterium, the cryptosporidium parasite, campylobacter, and giardia (CDC, 2011), (Séguin 2008). Cholera remains an important agent in Mexico (Greer *et al.*, 2008). Risk of waterborne illness is greater among the poor, infants, elderly, pregnant women, and immunocompromised individuals (Rose *et al.*, 2001; Gamble *et al.*, 2008) . In Mexico City, declining water quality has led to ineffective disinfection of drinking water supplies (Mazari-Hiriart *et al.*, 2005; Sosa-Rodriguez, 2010).

Changes in the temperature and the hydrological cycle can influence the risk of waterborne diseases (Curriero *et al.*, 2001; Greer *et al.*, 2008; Harper *et al.*, 2011). Floods enhance the potential for runoff to carry sediment and pollutants to water supplies (Karl *et al.*, 2009). Disparities in access to treated water were identified as a key determinant of under age-5 morbidity due to water borne illnesses in the central State of Mexico (Jimenez-Moleon and Gomez-Albores, 2011).

26.6.1.6. Vectorborne Diseases

The extent to which climate change has altered, and will alter, the geographic distribution of vectors of infectious disease remains uncertain because of the inherent complexity of the ecological system. Spatial and temporal distribution of disease vectors depend not only on climate factors, but also on land use/change, socio-economic and socio-cultural factors, prioritization of vector control, access to health care and human behavioral responses to perception of disease risk, among other factors (Lafferty, 2009; Wilson, 2009). Although temperature drives important biological processes in these organisms, variability in climate on a daily, seasonal or interannual scale may result in organism adaptation and a shift in geographic range, not necessarily an expansion in range (Lafferty, 2009; Tabachnick, 2010; McGregor, 2011). This shift may alter the incidence of disease depending on host receptiveness and immunity, as well as the ability of the pathogen to evolve so that strains are more effectively and efficiently acquired (Reiter, 2008; Beebe *et al.*, 2009; Rosenthal, 2009; Russell, 2009; Epstein, 2010).

North Americans are currently at risk from a number of vector-borne diseases, including Lyme disease (Ogden *et al.*, 2008; Diuk-Wasser *et al.*, 2010), dengue fever (Jury, 2008; Ramos *et al.*, 2008; Johansson *et al.*, 2009; Degallier *et al.*, 2010; Kolivras, 2010; Lambrechts *et al.*, 2011; Riojas-Rodriguez *et al.*, 2011; Lozano-Fuentes *et al.*, 2012), West Nile virus (Morin and Comrie, 2010; Gong *et al.*, 2011) and Rocky Mountain spotted fever, to name a few. There is increasing risk from invasive vector-borne pathogens, such as chikungunya (Ruiz-Moreno *et al.*, 2012) and Rift Valley fever viruses 8(Greer *et al.*, 2008).

26.6.2. Projected Impacts

Projecting future public health consequences of gradual climate warming is challenging, due in large part to uncertainties in the nature and pace of adaptations that populations and societal infrastructure will undergo in response to long-term climate change (Kinney *et al.*, 2008). Additional uncertainties arise from changes over time in population demographics, economic well-being, and underlying disease risk, as well as in the model-based predictions of future climate and our understanding of the exposure-response relationship for heat-related mortality. However, climate warming will lead to continuing health stresses related to extreme high temperatures, particularly for the northern parts of North America. The health implications of warming winters remain uncertain (Kinney, 2012).

There is a large literature examining future climate influences on outdoor air quality in North America, particularly for ozone (Kunkel *et al.*, 2007; Tao *et al.*, 2007; Holloway *et al.*, 2008; Lin *et al.*, 2008; Nolte *et al.*, 2008; Wu *et al.*, 2008; Avise *et al.*, 2009; Chen *et al.*, 2009; Liao *et al.*, 2009; Racherla and Adams, 2009; Lin *et al.*, 2010; Tai *et al.*, 2010). This work suggests with *medium confidence* that ozone concentrations could increase under future climate change scenarios if emissions of precursors were held constant (Jacob and Winner, 2009a). The literature for PM2.5 is more limited than that for ozone (Liao *et al.*, 2007; Tagaris *et al.*, 2008; Avise *et al.*, 2009; Pye *et al.*, 2009;

Mahmud *et al.*, 2010). Several recent studies have projected future health impacts due to air pollution in a changing climate (Bell *et al.*, 2007; Tagaris *et al.*, 2009; Chang *et al.*, 2010; Tagaris *et al.*, 2010). Using a range of climate/air quality models and scenarios as well as a range of health and demographic projections, Post and colleagues (2012) found that future mortality effects of ozone tended to increase in a changing climate. Similar findings were previously reported for the eastern and northeastern US (Knowlton *et al.*, 2004; Bell *et al.*, 2007). Future changes in seasonal timing of pollen release are *likely*. Another driver of future pollen might be changing patterns of vegetation, which are projected to change in the future.

Regarding clean water supplies, extreme precipitation can overwhelm combined sewer systems and lead to overflow events that can threaten human health (Patz *et al.*, 2008). Conditional on a future increase in such events, we can anticipate increasing risks related to water-borne diseases.

Whether future warmer winters in the United States and Canada will promote transmission of diseases like dengue and malaria is uncertain, in part, because of access to amenities such as screening and air-conditioning that provide barriers to human-vector contact. Socio-economic factors also play important roles in determining risks. Better longitudinal datasets and empirical models are needed to address knowledge gaps in research on climate-sensitive infectious diseases, as well as to provide a better mechanism for weighting the roles of external drivers such as climate change on a macro/micro scale, human-environmental changes on a regional to local scale and extrinsic factors in the transmission of vector-borne infectious diseases (Wilson, 2009; McGregor, 2011).

26.6.3. Adaptation Responses

Early warning and response systems can be developed to build resilience to severe climate-relate events (Ebi, 2011) and protect susceptible populations, which include infants, children, the elderly, individuals with pre-existing diseases, and those living in socially and/or economically disadvantaged conditions (Pinkerton *et al.*, 2012). At the urban and regional level, adaptation planning to build resilience for health systems in the face of changing climate is a growing priority (Kinney *et al.*, 2011).

Adaptation to heat events can occur via physiologic mechanisms, indoor climate control, urban-scale cooling initiatives, and as a result of warning and response systems. Additional research is needed on the extent to which warning systems prevent deaths (Harlan and Ruddell, 2011). Efforts to reduce GHG emissions could provide health co-benefits, including reductions in heat-related and respiratory illnesses (Health Chapter, US National Climate Assessment). Tree planting initiatives in cities are often motivated by climate adaptation goals. Health benefits related to pollen can be promoted by careful species selection.

26.7. Infrastructures and Other Economic Sectors

This section covers the following economic sectors not addressed elsewhere in the chapter: manufacturing, mining, energy, and services and infrastructures (insurance, construction, housing, and transportation). Available research typically focuses on the direct impact of climate on economic activity, although recent studies have begun to assess the indirect impacts resulting from, for example, scarce supplies during droughts or disruption of transportation and other infrastructure services from storms or floods.

There is mounting evidence that many sectors across North America are adapting to the risk of loss and damage from weather perils. The limited literature available largely reports a range of adaptive practices and adaptation responses to experience with extreme events, and only an emerging consideration of proactive adaptation in anticipation of future global warming.

26.7.1. Manufacturing

26.7.1.1. Observed Impacts

There is little literature focused on climate change and manufacturing, although one study suggested that manufacturing is among the most sensitive sectors to weather in the United States (Lazo *et al.*, 2011). Weather affects, for example, the supply of raw material (e.g. agricultural inputs for food manufacturing), the production process (e.g. water availability and energy demands for cooling/heating), the transportation of goods (e.g. storm delays can close roads and affect travel time), and the demand for certain products. In 2011, automobile manufacturers in North America experienced production losses associated with shortages of components due to flooding in Thailand (Newswire, 2011). In 2013, reduced cattle-supply and higher feed prices associated with several years of drought in Texas led to a decision to close a beef processing plant (Beef Today Editors, 2013). Other major storms, like Hurricanes Sandy, Katrina and Andrew, significantly disrupted manufacturing activity across North America This included delays in production when plants were forced to shutdown due to direct damages and/or loss of electricity and supply disruptions due to unavailability of parts, as well as difficulties delivering products associated with compromised transportation networks. (Baade *et al.*, 2007; Dolfman *et al.*, 2007).

26.7.1.2. Projected Impacts

The drier conditions projected for many regions of North America (Sun *et al.*, 2008; Seager and Vecchi, 2010a; Wehner *et al.*, 2011) would present challenges, especially for manufacturers located in regions already experiencing water stress. This could lead to increased conflicts over water between sectors and regions, and affect the ability of regions to attract new facilities or retain existing manufacturing operations. A modeling study which considered the impact of projected changes in precipitation on 70 industries in the United States between 2010 and 2050 suggested the potential for losses in production and employment due to declines in water availability and the interconnected nature of different industries (Backus *et al.*, 2013). For instance, costs incurred by chemical companies responding to water deficits could translate to reduced supply or higher costs of chemical products needed by other industries, such as construction, textiles and agriculture (Backus *et al.*, 2013). Declining water levels in the Great Lakes would increase shipping costs by restricting vessel drafts and reducing vessel cargo volume (Millerd, 2011).

For manufacturers dependent on raw materials from mining, the impacts on transportation (*see* section 26.7.5.2) could be high. Another potential concern for manufacturing relates to impacts of heat on worker safety and productivity. Several studies suggest that higher temperatures and humidity would lead to decreased productivity and increased health risks (e.g., Kjellstrom *et al.*, 2009; Hanna *et al.*, 2011; Kjellstrom and Crowe, 2011).

26.7.1.3. Adaptation

There is evidence that some companies are beginning to recognize the risks climate change presents to their manufacturing operations, and consider strategies to build resilience to these risks (National Round Table on the Environment and the Economy, 2012). Air conditioning is a viable and effective adaptation option to address some of the impacts of warming across much of North America, though it does incur additional costs (Scott *et al.*, 2008a). Coca Cola has a water stewardship strategy focusing, among other things, on improving water use efficiency at its manufacturing plants, while Rio Tinto Alcan is assessing climate change risks for their operations and infrastructure, which include vulnerability of transport systems, increased maintenance costs, and disruptions due to extreme events (National Round Table on the Environment and the Economy, 2012 (National Round Table on the Environment and the Economy, 2012).

26.7.2. Mining

26.7.2.1. Observed Impacts

Climatic sensitivities of mining activities (including exploration, extraction, processing, operations, transportation and site remediation) have been noted in the limited literature (Chiotti and Lavender, 2008; Furgal and Prowse, 2008; Meza-Figueroa *et al*., 2009; Ford *et al*., 2010; Gómez-álvarez *et al*., 2011; Kirchner *et al*., 2011; Locke *et al*., 2011; Pearce *et al*., 2011; Stratos Inc, 2011). Drought-like conditions have affected the mining sector by limiting water supply for operations (Pearce *et al*., 2011), enhancing dust emissions from quarries (Pearce *et al*., 2011) and increasing concentrations of heavy metals in sediments (Gómez-álvarez *et al*., 2011). Heavy precipitation events have caused untreated mining wastewater to be flushed into river systems (Pearce *et al*., 2011). High loads of contamination (metals, sulfate and acid) at three mine sites in the United States were measured during rainstorm events following dry periods (Nordstrom, 2009).

26.7.2.2. Projected Impacts

An increase in heavy precipitation events and more intense and/or frequent droughts projected for much of North America is likely to affect mining (Warren and Egginton, 2008; Nordstrom, 2009; Gutzler and Robbins, 2011). Although climate change is perceived as an emerging risk, and in some cases, a potential opportunity by Canadian mine practitioners (Ford *et al*., 2010; Ford *et al*., 2011; Pearce *et al*., 2011; National Round Table on the Environment and the Economy, 2012), potential impacts on transportation are perceived as a key issue for Canadian mines (Ford *et al*., 2011), as is limited water availability (Acclimatise, 2009) from projected drier conditions (Sun *et al*., 2008; Seager and Vecchi, 2010a).

A study on acid rock damage drainage in Canada concluded that while the mining sector could minimize the impacts of incremental change to 2050, an increase in heavy precipitation events presented a greater risk of both environmental impacts and economic costs (Stratos Inc, 2011) Climate change impacts that affect the bottom-line of mining companies (through direct impacts or associated costs of adaptation), would have consequences for employment, for both the mining sectors and local support industries (Backus *et al*., 2013).

26.7.2.3. Adaptation

Despite awareness of the potential role of adaptation within the mining industry, there is presently little evidence of proactive adaptation planning within the mining sector (Acclimatise, 2009; Ford *et al*., 2010; Ford *et al*., 2011). However, adjustments to management practices to deal with short-term water shortages, including reducing water intake, increasing water recycling and establishing infrastructure to move water from tailing ponds, pits and quarries, have worked successfully in the past (Chiotti and Lavender, 2008). Climate change is now considered in the design phase of mines in Canada, as a requirement of the Canadian environmental assessment process (Prowse *et al*., 2009). Integrating climate change considerations at the mine planning and design phase increases the opportunity for effective and cost-efficient adaptation (Stratos Inc, 2011).

26.7.3. Energy

26.7.3.1. Observed Impacts

The energy is particularly sensitive to climate change though literature is unequally distributed among countries. Across the United States, energy demand for cooling has increased over the last 40 years, while demand for heating has decreased.(Dell et al.) (2013), note that recent extreme weather events such as hurricanes have disrupted energy production and distribution.

26.7.3.2. Projected Impacts

In Canada, a net decrease in annual energy demand is projected by 2050 and by 2100 (Isaac and Van Vuuren, 2009). The net change in United States energy demand by 2080 is estimated to range from -15 to +4% (Wilbanks *et al.*, 2008), , with peak demand for electricity increasing more than the average demand for electricity, and capacity expansion required in many areas.

Rising temperatures (which reduce thermal power plant efficiencies) and limited water supplies (which affect power plant cooling) are projected to affect both energy production and hydropower and renewable energy sources. Changing cloud cover affects solar energy resources, changes in winds affect wind power potentials, and temperature change and water availability can affect biomass production (for instance, water requirements for biofuel production) (Wilbanks *et al.*, 2008).

The magnitude of projected impacts on hydropower potential will vary significantly between regions and within drainage basins, as flow regimes shift in response to changing climate (Desrochers *et al.*, 2009; Kienzle *et al.*, 2012; Shrestha *et al.*, 2012). Annual mean hydropower production in the St. Lawrence and Great Lakes region of Canada is estimated to decrease by 1.8% in the period 2010–2039 and then increase by 9.3% and 18.3% during the periods 2040–2069 and 2070–2099, respectively (Minville *et al.*, 2009). Regionally in the United States, major concerns include effects of increased cooling demands and water scarcity in the west; effects of extreme weather events, sea-level rise, and seasonal droughts in the southeast; effects of increased cooling demands in the northern regions; effects of warming on energy production and transportation in Alaska; and effects of climate policy on regions whose economies are closely tied to fossil energy production and conversion (Wilbanks *et al.*, 2008).

26.7.4. Insurance

26.7.4.1. Observed Impacts

Property insurance and reinsurance companies across North America experienced a significant increase in severe weather damage claims paid over the past three or four decades(Cutter and Emrich, 2005; Bresch and Spiegel, 2011; Munich Re, 2011). Most of the increase in insurance costs has been attributed to increasing exposure of people and assets in areas of risk (Pielke Jr *et al.*, 2008; Barthel and Neumayer, 2012). A role for climate change has not been excluded, but the increase to date in damage claims is largely due to growth in wealth and population(Field *et al.*, 2012).

Severe weather and climate risks have emerged over the past decade as the leading cost for property insurers across North America, resulting in significant change in industry practices. The price of insurance increased in regions where the risk of loss and damage has increased, and discounts were introduced where risks have been reduced.

26.7.4.2. Projected Impacts

Without adaptation, there is an expectation that severe weather insurance damage claims will increase significantly over the next several decades across North America (World Bank, 2010). The risk of damage is expected to rise due to continuing growth in wealth, the population living at risk, and climate change. There is also an expectation that some weather perils in North America will increase in severity, including Atlantic hurricanes and the area burned by wildfire (Karl *et al.*, 2008), and frequency, including intense rainfall events (Field *et al.*, 2012).

26.7.4.3. Adaptation

Most adaptation in the insurance industry, one of the most studied sectors with respect to adaptation to present and future weather and climate impacts (Mills and Lecomte, 2006; Mills, 2007; Mills, 2009; Autorite des Marches

Financiers, 2011; Leurig, 2011), has been in response to an increase in severe weather damage, with little evidence of proactive adaptation in anticipation of future climate change.

Catastrophe models were developed to help insurers manage the risk of insolvency, their capital needs and the appropriate use of reinsurance. In addition to pricing decisions based on an actuarial analysis of historic loss experience, many insurance companies now use model information to help determine the prices they charge and discounts they offer. Most insurance companies have established specialized claims handling procedures for responding to catastrophic events (Kovacs, 2005; Mills, 2009).

A recent Bank of International Settlements study of more than 2,000 major catastrophes since 1960 found that insurance is a critical adaptive tool available to help society minimize the adverse economic consequences of natural disasters. In the United States and Canada homeowners make extensive use of insurance to manage a broad range of risks, and those with insurance recover quickly following most extreme weather events. However the majority of public infrastructure is not insured and it frequently takes more than a decade before government services fully recover. In contrast Mexico has a well-developed program for financing the rebuilding of public infrastructure following a disaster (FONDEN) but insurance markets are only beginning to emerge for homeowners and businesses. (In 2010, per capita spending on property and casualty insurance was US$2,112.80 in the United States, US$1,870.60 in Canada and US$92.90 in Mexico (Bevere *et al*., 2012).)
Insurance companies are also working to influence the behavior of their policyholders to reduce the risk of damage from climate extremes (Kovacs, 2005; Anderson *et al*., 2006; Mills, 2009). For example, the industry supports the work of the Insurance Institute for Business and Home Safety in the United States, and the Institute for Catastrophic Loss Reduction in Canada working to champion change in the building code and communicate to property owners, governments and other stakeholders best practices for reducing the risk of damage from hurricanes, tornadoes, winter storms, wildfire, flood and other extremes.

26.7.5. Other Service Industries

Most service industries are less climate-sensitive than goods-producing industries, except insurance and tourism (Ford *et al*., 2010; Ford *et al*., 2011). Three broad categories of impacts of climate extremes can affect tourism destinations, competitiveness, and sustainability. The first relates to direct impacts on hotels, access roads and other tourist infrastructures; on such operating costs as heating/cooling, snowmaking, irrigation, food and water supply, evacuation, and insurance; on emergency preparedness requirements; and on business disruption (e.g., sun-and-sea or winter sports holidays). The second category refers to indirect environmental change impacts of extreme events on biodiversity and landscape change (e.g., coastal erosion), which may negatively affect the quality and attractiveness of tourism destinations. Particular tourist regions can suffer as a result of tourism-adverse perception after occurrence of the extreme event itself (Scott *et al*., 2008a).

26.7.5.1. Construction and Housing

26.7.5.1.1. Observed impacts

The risk of damage from climate perils is a significant issue for the housing and construction industries, though little research has systematically explored the topic (Morton *et al*., 2011).
There are no public sources of data that track damage to the built environment from weather events in North America. Private data from insurance companies report a significant increase in severe weather damage to buildings and other insured infrastructure over several decades. Studies indicate that the increase in reported damage is largely due to rising wealth and populations living at risk.

26.7.5.1.2. Projected impacts

Most studies project a significant further increase in damage to homes, buildings and infrastructure. Affordable adaptation in design and construction practices could reduce much of the risk of climate damage for new buildings and infrastructure, likely involving reform in Building Codes and other standards. However, adaptation best practices in design and construction are often prohibitively expensive to apply to existing buildings and infrastructure, so much of the projected increase in climate damage risk involves existing buildings and infrastructure.

26.7.5.1.3. Adaptation

Engineering and construction knowledge exists to design and construct new buildings to accommodate the risk of damage from historic extremes and anticipated changes in severe weather (Kelly, 2010; Ministry of Municipal Affairs and Housing, 2011; Institute for Business and Home Safety, 2012). Older buildings may be retrofit to increase resilience, but these changes are often more expensive to introduce into an existing structure than if they were included during initial construction.

The housing and construction industries have made advances toward climate change mitigation by incorporating energy efficiency in building design (Heap, 2007). Less progress has been made in addressing the risk of damage from extreme weather events (Kenter, 2010). In some markets, like the Gulf Coast of the United States, change is under way in the design and construction of new homes in reaction to recent hurricanes, but in most markets across North America there has been little change in building practices. The cost of adaptation measures combined with limited long-term liability for future buildings influenced some builders to take a wait-and-see attitude (Morton *et al.*, 2011). Exploratory work is under way to consider implementation of building codes that would focus on historic weather experience and also introduce expected future weather risks (Auld *et al.*, 2010; Ontario Ministry of Environment, 2011).

26.7.5.2. Transportation

26.7.5.2.1. Observed impacts

Transportation infrastructure across North America is aging, or inadequate (Mexico) which may make it more vulnerable to damage from extreme events, like intense rainfall washing away roads or rails, and slow onset perils like sea level rise and melting permafrost. The American Society for Civil Engineers estimates that more than US$2 trillion is needed to bring infrastructure in the United States up to “good condition” (ASCE, 2009, p.6). The U.S. Department of Transportation estimated that between US$100 and US$175 billion would be needed in the next 20 years to upgrade U.S. highways (Federal Transit Administration, 2008). Canadian infrastructure had an investment deficit of C$125 billion in the 1980s and 1990s (Mirza and Haider, 2003).

26.7.5.2.2. Projected impacts

Scholarship on projected climate impacts on transportation infrastructure focuses mostly on US and Canada. The Transportation Research Board found that increases in high temperature events, intense precipitation, drought, sea level, and storm surge could affect transportation across the United States. The greatest risks would be to coastal transportation infrastructure, but there could be benefits to marine and lake transportation in high latitudes from shorter period with ice cover (Transportation Research Board, 2008). A one meter sea level rise combined with a 7 meter storm surge could inundate over half of the highways, arterials, and rail lines in the United States Gulf coast (Savonis *et al.*, 2008). While in southern Canada by the 2050s, low temperature cracking from either the B2 or A2 scenarios would decrease, structures would freeze later and thaw earlier, and higher extreme temperatures would increase the potential for rutting (Mills *et al.*, 2009) and related maintenance and rehabilitation costs (Canadian Council of Professional Engineers, 2008).

A 1 to 1.5°C increase in global mean temperature would increase the costs of keeping paved and unpaved roads in the United States in service by, respectively, US$1.9 to US$2.8 billion per year by 2050 (Chinowsky *et al.*, Submitted). Up to 100,000 bridges in the United States crossing rivers and streams could be made vulnerable by increasing peak flows in the mid- and late-21st Century under the A1B and A2 scenarios. Currently deficient bridges, about one-fourth of the current bridges, would be most vulnerable. Strengthening the vulnerable bridges to be more resilient to climate change is estimated to cost US$138 to US$247 billion, but the costs could be reduced by 27 to 28% if currently deficient bridges are strengthened (Wright *et al.*, 2012).

26.8. Urban and Rural Settlements

26.8.1. Weather and Climate Impacts

Observed impacts in North American settlements such as livelihood stresses and changes in access to essential services have been attributed, *with different degrees of certainty,* to climate variability and change including but not limited to: changes in mean climate conditions (SLR, temperature and precipitation) and in extreme events.

26.8.1.1. Changes in Mean Conditions

In coastal zones, SLR and storm surges have reduced development options and increased hazard risk. This process was observed dramatically in New York in 2012, but it is also affecting other settlements along the mid-Atlantic, the Gulf of Mexico, and the St. Lawrence (Kirshen *et al.*, 2008; Friesinger and Bernatchez, 2010; Zavala-Hidalgo *et al.*, 2010; Rosenzweig *et al.*, 2011; Tebaldi *et al.*, 2012).

During the 20th century temperatures increased faster in cities compared to rural areas, due mainly to the urban heat island (UHI) (Harlan and Ruddell, 2011) resulting from land and energy use patterns.

26.8.1.2. Extreme Events

Droughts are among the more notable extreme events affecting North American settlements recently, with severe occurrences in the Canadian Prairies (2001-2) (Wheaton *et al.*, 2007) and Southwestern US - Northern Mexico (2010-2012)—argued to be the most severe in a century (MacDonald, 2010a). The 2012 drought affected 80% of agricultural land in the U.S., with 2,000 counties designated disaster zones by September (USDA Economic Research Service, 2012), http://www.ers.usda.gov/topics/in-the-news/us-drought-2012-farm-and-food-impacts.aspx, accessed November 25, 2012). Road pavement in Chicago buckled under temperatures over 100oF (CBS Chicago, 2012). In Colorado two wildfires burned over 600 homes (NCDC (National Climate Data Center), 2013). Among the most severely affected were indigenous peoples, such as the Rarámuri of Chihuahua (Imison, 2012)

Pest outbreaks such as the Mountain Pine Beetle infestation that emerged across western North America early in the 21st Century, describe another significant recent event attributed to climate change, affecting rural and peri-urban settlements (Kurz *et al.*, 2008a). *Wildfires* have also had notable effects (Box 26-2).

Extreme storms have also had their effect, although changes in their frequency are difficult to attribute to anthropogenic climate change. While immediate health and safety threats associated with such events have been minimized in most cases, impacts on the built environment have been costly. Heavy precipitation, storm surges, flash-floods and wind have compromised homes and business (Comfort, 2006; Kirshen *et al.*, 2008; Jonkman *et al.*, 2009; Romero-Lankao, 2010), including flooding in the U.S. Midwest (2011), and hurricanes in southern Mexico (2004-5). Hurricane Wilma alone caused $1.8 billion in damage, among the biggest insurance losses in Latin American history (Galindo *et al.*, 2009).

Lives and livelihoods have been affected by extreme events. Examples include:

- A relationship between heat and excess mortality in cities, with city-specific thresholds varying with latitude and hazard magnitude (O'Neill and Ebi, 2009; Romero-Lankao *et al*., 2012).
- The Canadian forest sector has shed 100,000 jobs since 2005, attributed in part to the mountain pine beetle (Parkins and MacKendrick, 2007; Parkins, 2008; Holmes, 2010; MacKendrick and Parkins) identified 30 communities and 25,000 families in British Columbia directly affected.
- Observed shifts in Pacific Northwest marine ecosystems attributed to climate change have restricted fisheries; northeast fisheries are projected to follow suit (USGCRP, 2009).
- Loss of 3.2 million tons of maize placing 2.5 million Mexicans at risk of food insecurity (DGCS, 2012), http://www.dgcs.unam.mx/boletin/bdboletin/2012_053.html, accessed November 25, 2012).
- Drought-related economic and employment losses in the Canadian Prairies (Wheaton *et al*., 2007; Kulshreshtha, 2011).
- Intensified inequalities in vulnerability to wildfire between amenity migrants and low-income residents in peri-urban areas (Collins and Bolin, 2009).

Human settlements are differentially affected by impacts to ecological services. Among the most essential human services, changes in water supplies have immediate implications for economies and health (section 26.3).

26.8.2. Observed Factors and Processes Associated with Vulnerability

Differences in severity of climate impacts are strongly influenced by context-specific factors and processes exacerbating or ameliorating vulnerability (Table 26-1; Cutter *et al*., 2013), each of which is more pertinent to some types of settlements than others. Human settlements simultaneously face a multilevel array of non-climate-related risks (e.g., economic, industrial, technological) that contribute to climate change vulnerability (McGranahan *et al*., 2007; Satterthwaite *et al*., 2007; Romero-Lankao and Dodman, 2011). In the following we highlight key sources of vulnerability for urban and rural systems.

[INSERT TABLE 26-1 HERE
Table 26-1: Dimensions of vulnerability. Source: Romero-Lanka, 2012.]

26.8.2.1. Urban Settlements

Geography: The concentration of populations, economic activities, cultural amenities and built environments characteristic of urban areas in highly-exposed locations such as coastal and arid areas creates hazard risks. Of particular concern are Canadian prairie cities; US-Mexico border cities; major U.S. urban areas including Boston, New York, Chicago, Washington, DC, Los Angeles, and Mexico City (Bin *et al*., 2007; Collins, 2008; Kirshen *et al*., 2008; Collins and Bolin, 2009; Gallivan *et al*., 2009; Hayhoe *et al*., 2010; Romero-Lankao, 2010; Rosenzweig *et al*., 2010; Wittrock *et al*., 2011). Without effective policies, environmental impacts such as poor urban air quality can exacerbate climate impacts (Romero-Lankao *et al*., 2013).

Interactive causes and effects: As with all complex systems, the interaction of multiple processes (e.g., disaster management, economic stratification, high-magnitude hazards) can contribute to urban vulnerability. Research increasingly emphasizes the interrelated nature of economic, social and ecological impacts (Gasper *et al*., 2011). For instance, under current local financial constraints, climate-related economic losses can reduce resources available to address social issues, thus threatening institutional capacity and urban livelihoods (Kundzewicz *et al*., 2008).

Urbanization changes land-use and land-surface physical characteristics (e.g., surface albedo, Chen *et al*., 2011). A 34% increase in U.S. urban land development (Alig *et al*., 2004) between 1982 and 1997 had implications for water supplies and extreme event impacts. Effects on water are of special concern, as urbanization can enhance or reduce precipitation, depending on climate regime, geographical location and regional patterns of land, energy and water use (Cuo *et al*., 2009). Urbanization also has significant impacts on flood climatology through atmospheric processes tied to the Urban Heat Island (UHI), the Urban Canopy Layer (UCL), and aerosol composition of airsheds

(Ntelekos *et al*., 2010) . The UHI, which varies across and within cities (Harlan *et al*., 2008; Miao *et al*., 2011), can increase health risks (health section).

Urbanization imposes path dependencies that can amplify or attenuate vulnerability (Romero Lankao and Qin, 2011). For example, the overexploitation of Mexico City's aquifer by 19.1 - 22.2 m^3/s has reduced groundwater levels and caused subsidence, undermining building foundations and infrastructure and increasing residents' vulnerability to earthquakes and heavy rains (Romero-Lankao, 2010).

The Built Environment: Housing stock, urban form, condition of water and power infrastructures, and changes in urban and ecological services also affect vulnerability. Large, impermeable surfaces and buildings disrupt drainage channels and accelerate run-off (Walsh *et al*., 2005). Damage from floods can be much more catastrophic if drainage or waste collection systems are inadequate to accommodate peak flows (Richardson, 2010; Sosa-Rodriguez, 2010). While infrastructures in many Canadian and US cities are in need of adaptation upgrades (Doyle *et al*., 2008; Conrad, 2010), Mexican cites are additionally faced with infrastructure deficits (Niven *et al*., 2010; Hardoy and Romero Lankao, 2011), and high levels of socio-spatial segregation (Smolka and Larangeira, 2008).

Institutional capacity: Although cities have comparatively higher revenue pools than rural municipalities, barriers to urban adaptation planning persist, including fragmented governance, asymmetries in information access and communication, fiscal constraints to support public services including emergency personnel, and top-down decision making (Carmin *et al*., 2012b; Romero-Lankao *et al*., 2013).

Differences in human and social capital: Cities are better endowed than rural populations with individual and neighborhood assets such as income, education, quality of housing and access to infrastructures and services that offer protection from climate hazards. However, socio-spatial differences in access shape response capacities (Harlan and Ruddell, 2011; Romero-Lankao *et al*., 2013). Social networks, family bonds and other forms of social capital differentially influence individual-level vulnerability (Romero-Lankao *et al*., 2012).

Economic Sensitivity: Climate hazards affect the economic activities and highly-valued physical capital of cities (real estate, transportation infrastructure); some urban areas are particularly exposed to key resource constraints (e.g., water in the US-Mexico Border); others are dependent upon climate-sensitive sectors (e.g., tourism) (Lal *et al*., 2011). Disruptions to production, services and livelihoods, and changes in the costs of raw materials and inputs also impact the economic performance of cities (Hunt and Watkiss, 2011).

Risk Distribution: Class and socio-spatial segregation are key determinants vulnerability. Economic elites are better positioned to access the best land and enjoy the rewards of environmental amenities such as clean air, safe drinking water, open space, and tree shade (Morello-Frosch *et al*., 2002; Harlan *et al*., 2006; Harlan *et al*., 2008; Ruddell *et al*., 2009). Although wealthy sectors are moving into risk prone coastal and forested areas (Collins, 2008), and certain hazards (air pollution) affect both rich and poor alike (Romero-Lankao *et al*., 2013), climate risks tend to be disproportionally borne by the poor or otherwise marginalized populations (Cutter *et al*., 2008; Collins and Bolin, 2009; Romero-Lankao, 2010; Wittrock *et al*., 2011). Marginalized populations are moving to peri-urban areas with inadequate services, a portfolio of precarious livelihood mechanisms, and inappropriate risk-management institutions (Collins and Bolin, 2009; Eakin *et al*., 2010; Monkkonen, 2011; Romero-Lankao *et al*., 2012); (Colton, 2008).

26.8.2.2. Rural Settlements

Geography: Geographic isolation can be a key source of vulnerability, for rural communities, with long commutes to essential services like hospitals, and non-redundant transportation corridors that can be compromised during extreme events (Chouinard *et al*., 2008). Many Indigenous communities are isolated, raising the costs and limiting the diversity of imported food, fuel and other supplies, rendering the ability to engage in subsistence harvesting especially critical for wellbeing (Andrachuk and Pearce, 2010; Hardess *et al*., 2011).

Interactive causes and effects: The legacy of previous and current stresses contributing to rapid population growth or loss, reduced employment, or degradation of local knowledge systems, can increase vulnerability (Brklacich *et al*., 2008; Coles and Scott, 2009; McLeman, 2010). Engagement in export markets presents opportunity but also exposure to economic volatility (Eakin, 2006; Saldaña-Zorilla and Sandberg, 2009), and economic downturns take attention away from climate change adaptation. Many indigenous peoples maintain strong cultural attachment to ancestral lands, and thus are especially sensitive to declines in the ability of that land to sustain their livelihoods and cultural wellbeing (Downing and Cuerrier, 2011).

The Built Environment: Rural physical infrastructure is often inadequate to meet service needs or is in poor condition (McLeman and Gilbert, 2008; Krishnamurthy *et al*., 2011), especially for Indigenous communities (section 26.9, Brklacich *et al*., 2008; Hardess *et al*., 2011; Lal *et al*., 2011). The lack of redundant power and communication services compromises hazard response capacity.

Economic Sensitivity: Rural economies have less diversity, and higher dependence on climate-sensitive sectors (Johnston *et al*., 2008; Lemmen *et al*., 2008; Molnar, 2010), and are sensitive to climate-induced reductions in resource supply and productivity, in addition to direct exposure to climate hazards (Daw *et al*., 2009). Single-sector economic dependence contributes significantly to vulnerability (Cutter *et al*., 2003). Farming and fishing provide both economic and food security, the impacts of climate thus posing a double threat to livelihood (Badjek *et al*., 2010), particularly among women (Bee *et al*., 2013). Inter-related factors affecting vulnerability in forestry and fishing communities include over-harvesting, and the cumulative environmental effects of multiple land use activities (Brklacich *et al*., 2008). Many tourism-based communities are dominated by low-wage, service-based employment (Tufts, 2010), and small businesses that lack resources for emergency planning (Hystad and Keller, 2006; Hystad and Keller, 2008). Non-renewable resource industries are sensitive to power and water supply and transportation disruptions associated with hazards.

Institutional capacity: Small revenue pools translate into fiscal constraints necessary to support public services, including emergency personnel and health care (Lal *et al*., 2011).

Differences in human capital and social capital: North American rural communities have a higher proportion of lower income and unemployed populations and higher poverty than cities (Whitener and Parker, 2007; Lal *et al*., 2011; Skoufias *et al*., 2011). 55% of Mexico's rural residents live in poverty, and the livelihood of 72% of these is in farming (Saldaña-Zorrilla, 2008). U.S. and Canadian rural communities have older populations (McLeman, 2010) and lower education levels (Lal *et al*., 2011). Indigenous communities have lower education levels, and high levels of poverty, but are younger than average populations (Downing and Cuerrier, 2011). The legacy of their colonial history, furthermore, has stripped Indigenous communities of many sources of social and human capital (Brklacich *et al*., 2008; Hardess *et al*., 2011).

Conversely, rural and indigenous community members espouse valuable local and experiential knowledge regarding regional ecosystem services (Nakashima *et al*., 2011).

26.8.3. Projected Climate Impacts on Human Settlements

Urbanization, migration, economic disparity, and institutional capacity are likely to influence future impacts and adaptation to climate change in North America.

Projected SLR is *very likely* to alter regional land development differentially, depending on regional shifts in ocean circulation (U.S. GAO, 2007; Yin *et al*., 2009; Conrad, 2010; Sobel *et al*., 2010; Millerd, 2011), making some areas particularly vulnerable to inundation (Cooper and Sehlke, 2012). SLR also exacerbates vulnerability to extreme events such as hurricanes(Frazier *et al*., 2010).

Temperatures increases are *very likely* lead to additional health hazards in cities. Baseline warmer temperatures in cities are expected to be further elevated by extreme heat events whose intensity and frequency is projected to increase during the 21st century (section 26.2) and impair the health of urban populations (section 26.6), particularly

in northern mid-latitude cities (Jacob and Winner, 2009b). Participation in outdoor activities would also increase as a result of projected increases in warm days (Scott and McBoyle, 2007); winter sports face shorter seasons. Projected snowfall declines Canada and the Northeast U.S. would reduce length of winter sport seasons (McBoyle *et al.*, 2007; Scott *et al.*, 2008b).

Extreme Events, such as intense precipitation, flooding and prolonged dry periods are *likely* to affect settlements on coasts, flood-prone deltas and arid regions (Kirshen *et al.*, 2008; Nicholls *et al.*, 2008; Richardson, 2010; Weiss *et al.*, 2011b). Using an operational hurricane-prediction model (NOAA-GFDL) Bender et al. (2010) project an almost doubling in frequency of category 4 and 5 hurricanes by 2100. By the end of this century, New York City is projected to experience nearly twice as many extreme precipitation days compared to today (A2, mean ensemble of 17 models, (Cayan *et al.*, 2010; Ntelekos *et al.*, 2010) project increased number and duration of droughts in the southwest U.S., with most droughts expected to last over five years by 2050 (GDFL CM2.1 and CNRM CM3, A2 and B1). Wildfire vulnerability in the southwest has been elevated with peri-urban growth (Collins and Bolin, 2009; Brenkert-Smith, 2010) .

Climate impacts on *Lives and Livelihoods* have been relatively less studied. Projected shifts in forest productivity indicate potential substantial shifts in livelihood options without adaptation. Sohngen and Sedjo (2005) estimate losses from climate change in the Canadian/U.S. timber sector of $1.4 – $2.1 billion per year over the next century. Anticipated future supply reductions in British Columbia as a consequence of the pine beetle outbreak vary from 10 to 62% (Patriquin *et al.*, 2007). Forecast substantial declines in suitable habitat for valued tree species in Mexico have been projected (Gómez-Mendoza and Arriaga, 2007; Diaz *et al.*, 2011).

Essential Services: Increased occurrence of drought is projected for southwestern U.S./Northern Mexico, the southern Canadian Prairies and central Mexico, combined with projected increases in water demand due to rapid population growth and agriculture (MacDonald, 2010a; Lal *et al.*, 2011); (Schindler and Donahue 2006). In the Mexico City Metropolitan Area, due to population growth alone, available water per capita is projected to diminish by 11.2% between 2007 and 2030 (Partida and Anzaldo, 2009). Sea-level rise threatens water and electricity infrastructure with inundation and increasing salinity (Sharp, 2010).

26.8.4. Adaptation

26.8.4.1. Evidence of Adaptation

26.8.4.1.1. What are populations doing? Autonomous adaptation

Individuals in North America have been responding to climate change impacts in several ways, for example by purchasing additional insurance, or reinforcing homes to withstand extreme weather (Simmons and Sutter, 2007; Romero-Lankao *et al.*, 2012). When climate change poses significant livelihood impacts, individuals respond by diversifying livelihoods (Newland *et al.*, 2008; Rose and Shaw, 2008) or migrating (Black *et al.*, 2011). Migration can have maladaptive effects at higher levels: many regions experiencing rapid influxes of in-migrants are also among the most vulnerable to climate change impacts (Hugo, 2011).

The propensity to engage in adaptation is strongly influenced by perceived risks of climate change. Residents of the U.S. stand out in international research as holding lower levels of perceived risk of climate change (AXA Ipsos, 2012), which may limit involvement in household-level adaptation.

26.8.4.1.2. What are authorities doing? Planned adaptation

Overall, leadership in adaptation planning is far more evident locally than at other governance levels (Richardson, 2010; Vasseur, 2011; Vrolijks *et al.*, 2011; Carmin *et al.*, 2012a; Henstra, 2012). Many local authorities have not yet moved into the implementation stage, and most of the adaptation programs are in the process of problem diagnosis and adaptation planning (Perkins *et al.*, 2007; Moser and Satterthwaite, 2009; Romero-Lankao and Dodman,

2011).Climate change policies have been motivated by concerns for local economic or energy security and the desire to play leadership roles (Rosenzweig *et al*., 2010; Anguelovski and Carmin, 2011; Romero-Lankao *et al*., 2013). Some of these constitute "integrated" strategies (New York) (Perkins *et al*., 2007; Rosenzweig *et al*., 2010), and in some cases entail coordinated participation of multiple municipalities (Vancouver) (Richardson, 2010). Sector-specific climate risk management plans have also emerged (e.g., water conservation in Phoenix, US and Regina, Canada; wildfire protection in Kamloops, Canada and Boulder, US). Municipalities affected by the mountain pine beetle have taken many steps toward adaptation (Parkins, 2008), and coastal communities in eastern Canada are investing in saltwater marsh restoration to adapt to rising sea levels (Marlin *et al*., 2007). Green roofs, forest thinning and urban agriculture have all been expanding (Chicago, New York, Kamloops, Mexico City), as have flood protection (New Orleans, Chicago), private and governmental insurance policies (section 26.10, Browne and Hoyt, 2000; Ntelekos *et al*., 2010), safe saving schemes (common in Mexico), air pollution controls (Mexico City), and hazard warning systems (Collins and Bolin, 2009; Coffee *et al*., 2010; Romero-Lankao, 2010; Aguilar and Santos, 2011).

Many municipalities are engaged in problem diagnosis and adaptation planning (Perkins *et al*., 2007; Moser and Ekstrom, 2011; Carmin *et al*., 2012b; Romero-Lankao *et al*., 2013). However, few have reached the implementation stage or are comprehensive in scope; and systematic assessments of vulnerability are rare, particularly in relation to population groups (Vrolijks *et al*., 2011). Surveys of municipal leaders showed adaptation is rarely incorporated into planning, due to lack of resources, information and expertise (Horton and Richardson, 2011), and the prevalence of other issues considered higher priority (United States Government Accountability Office, 2009; Romero-Lankao *et al*., 2013), suggesting the need for state- and federal-level facilitation.

26.8.4.2. Opportunities and Constraints

26.8.4.2.1. Adaptation is path-dependent

Adaptation options are influenced by past settlement patterns and decisions. The evolution of cities as economic hubs, for example, affects vulnerability and resilience (Leichenko, 2011). Urban expansion into mountain, agricultural, protected and otherwise risk-prone areas (Boruff *et al*., 2005; McGranahan *et al*., 2007; Collins and Bolin, 2009; Conrad, 2010) invariably alters regional environments. Development histories foreclose some resilience pathways, such as irreversible overexploitation and degradation of water resources (Mexico City) (Romero-Lankao, 2010). Local cultures can pose barriers to adaptation. While strong attachment to place and occupation may motivate willingness to support incremental change, they have been found to serve as barriers to transformational change (Marshall *et al*., 2012). Those same processes, however, may enhance coping capacity and foster learning and adaptation (Collins and Bolin, 2009; Romero-Lankao, 2010; Aguilar and Santos, 2011; Wittrock *et al*., 2011).

26.8.4.2.2. Institutional capacity

Effective adaptation is influenced by access to resources, and the capacity for institutional-level attention and coordination (Burch, 2010; Romero-Lankao *et al*., 2013). Levels of adaptation knowledge and prioritization can be low among some institutional actors, such as municipal planners (Picketts *et al*., 2012), and industries and governmental actors (Spittlehouse, 2008; Brown, 2009). Research has also shed light on the following attributes:

- *Economic Resources:* Rural communities face limited revenues combined with higher costs of supplying adaptation services (Williamson *et al*., 2008; Posey, 2009). Although large cities tend to have greater fiscal capacity, most do not receive financial support for adaptation (Carmin *et al*., 2012b), yet face the risk of higher economic losses.
- *Information and social capital:* Differences in access and use of information, and capacity for learning and innovation, affect adaptive capacity (Romero-Lankao *et al*., 2013). Information access can be limited, even among environmental planners (Picketts *et al*., 2012). The relationship between trust and participation in support networks (social capital) and adaptive capacity is generally positive, however strong social bonds may support narratives that under-estimate risk (Wolf *et al*., 2010; Romero-Lankao *et al*., 2013).

- *Participation:* Long-term effectiveness of adaptation strategies hinges upon the ability to integrate the needs, concerns, and deliberations of all stakeholders, and complementarity with sustainability goals, involving forward-thinking analysis and continuous learning and adjustment (Swanson *et al*., 2010). Considering the overlap among impacts and sources of vulnerability, adaptation planning for human settlements demands an integrative approach. Stakeholder involvement lengthens planning time frames, may elicit conflicts, and power relationships can constrain access (Few *et al*., 2007; Colten *et al*., 2008). But effective stakeholder engagement has tremendously enhanced adaptation planning, eliciting key sources of information regarding social values, and securing legitimacy (Aguilar and Santos, 2011).
- *Multilevel coordination:* Enhancement of vertical inter-governmental coordination for improved resource delivery is key, especially for rural communities (Brklacich *et al*., 2008; Brown, 2009; Sander-Regier *et al*., 2009; Sydneysmith *et al*., 2010). Integrative planning requires horizontal coordination: careful assessment of the layers involved in land-use planning, emergency responses, housing, health and other sectors and their effects on vulnerability at the municipal, neighbourhood and individual levels (Table 26-1). Traditionally, environmental or engineering agencies are responsible for managing climate issues (e.g., Mexico City, Edmonton and London, Canada), but have neither the decision making power nor the resources to address all the dimensions involved. Adaptation planning requires long-term investments by government, business, grassroots organizations and individuals (e.g., Romero-Lankao, 2007; Croci *et al*., 2010; Richardson, 2010; Sarah, 2010).

26.8.4.3. Maladaptation, Trade-Offs, and Co-Benefits

Adaptation strategies may introduce trade-offs or maladaptive effects for policy goals in mitigation, industrial development, energy security, and health (Hamin and Gurran, 2009; Laukkonen *et al*., 2009). Snow-making equipment, for example, mediates snowpack reductions, but is expensive and has high water and energy requirements (Scott *et al*., 2007). Irrigation and air conditioning have immediate adaptive effects, but are energy-consumptive. Sea walls protect coastal properties, yet negatively affect the structure and functioning of coastal ecosystems (Richardson, 2010).

Conventional sectoral approaches to risk management and adaptation planning undertaken at different temporal and spatial scales have exacerbated vulnerability in some cases (Eakin *et al*., 2010; Romero-Lankao, 2012)(Doves 2009). Approaches that delegate response planning to residents in the absence of effective knowledge exchange have resulted in maladaptive effects (Friesinger and Bernatchez, 2010).

Other strategies offer potential synergies and co-benefits. Policies addressing air pollution (Harlan and Ruddell, 2011) or housing for the poor (Colten *et al*., 2008) can often be adapted at low or no cost to fulfill adaptation and sustainability goals simultaneously (Badjek *et al*., 2010). Efforts to temper declines in production or competitiveness in rural communities could involve mitigation innovations, including carbon sequestration forest plantations (Holmes, 2010). Painting roofs white reduces the effects of heat and lowers energy demand for cooling (Akbari *et al*., 2009).

Adaptation planning can be greatly enhanced by incorporating region-specific vulnerability information, so socio-economic vulnerabilities can be targeted (Clark *et al*., 1998). Methods for mapping environmental and socio-economic vulnerability have been improved and widely utilized (Romero-Lankao *et al*., 2013). Similarly, strategies supporting cultural preservation and subsistence livelihood needs among indigenous peoples would enhance effectiveness (Ford *et al*., 2010), as would integrating traditional culture with other forms of knowledge, education and economic development (Hardess *et al*., 2011).

Box 26-3. Responding to Climate Change in Three North American Cities

With growing populations of 20.5, 14 and 2.3 million people, respectively, the metropolitan areas of Mexico City, New York and Vancouver are facing multiple risks climate change is predicted to aggravate. These risks range from

sea level rise, coastal flooding and storm surges in New York and Vancouver to heat waves, heavy rains and associated flooding, air pollution, and heat-island effects in all the three cities (Leon and Neri, 2010; Magana, 2010; Rosenzweig and Solecki, 2010; City of Vancouver, 2012). Many of these risks result not only from long-term global and regional processes of environmental change, but also from local changes in land and water uses and in atmospheric emissions induced by urbanization (Magana, 2010; Romero-Lankao, 2010; Kinney *et al*., 2011; Solecki, 2012).

Despite the compound risks they are facing, the three cities have shown promise as innovators of climate relevant actions as they have moved to institutionalize their climate agendas. In Mexico City, the Program of Climate Action 2008–2012 (PAC) and the 2011 Law for Mitigation and Adaptation to Climate Change are parts of a larger 15-year "Green Agenda", which focuses mainly on reducing 7 million tonnes of CO2 equivalent between 2008-2012 through mitigation actions, with these efforts accounting for 94.3% of its total budget expenditures between 2008 and 2012 (Romero-Lankao *et al*., 2012). Similarly, in 2005 New York City's Plan to reduce GHG by 30% from 2005 levels is mitigation centered, as is Vancouver' 2007 Greenest City Plan calling for a 33% reduction in GHG emissions below 2007 levels by 2020. However, mitigation became in 2007 part of New-York's long-term sustainability plan that included adaptation concerns with climate actions intended to protect city's infrastructures and buildings (Solecki, 2012; Ray *et al*., 2013), while Vancouver launched the first comprehensive municipal adaptation plan in Canada in July 2012. The shifts in focus from mitigation to adaptation have followed as it has become increasingly clear that even if mitigation efforts are wholly successful, some adverse impacts due to climate change are probably unavoidable.

City mayors and other urban actors have often played key roles in launching climate policies. Mayor Michael Bloomberg of New York and Mayor Marcello Ebrard of Mexico City have, respectively, chaired the C40 and World Mayors Council on Climate Change. Scientists, private sector actors and nongovernmental organizations have been of no lesser importance. To take advantage of a broad based interaction between various climate change actors, Mexico City has set up a Virtual Climate Change Center, a boundary organization intended to serve as a repository of knowledge, models and data on climate change impacts, vulnerability and risks (Romero-Lankao *et al*., 2012). Information sharing by climate change actors has also taken place in New York, where scientists, and insurance and risk management experts have served on the Panel on Climate Change to advise the city on the science of climate change impacts and "protection levels specific to the city's critical infrastructure" (Solecki, 2012): 564).

Notwithstanding these positive pressures, however, climate policies in the three cities are faced with many challenges. Inconsistencies among the three tiers of government approaches (or lack thereof) to climate change are a barrier to effective responses in Vancouver (Burch, 2010). Fragmented governance structures in Mexico City and New York prevent these cities from having jurisdictional control over how their three regionally interdependent states (i.e., Federal District, Mexico and Hidalgo for Mexico City and Connecticut, New Jersey and New York for New York) respond to climate change (Romero-Lankao *et al*., 2012; Solecki, 2012). There are also conflicts in priorities and objectives between various actors and sectors moving city policy. For instance, authorities in Mexico City are concerned with avoiding growth into risk-prone areas and into conservation areas providing ecosystems-services (Aguilar and Santos, 2011). However, these priorities compete for regulatory space within a policy agenda that is already coping with a very wide range of economic and developmental imperatives (Romero-Lankao *et al*., 2012). Cultural barriers across stakeholders in the Vancouver region, lack of leadership and of strategies facilitating the effective use of existing resources are notable constraints to effective adaptation (Burch, 2010).

The climate plans of the three cities are far reaching and include mitigation and adaptation strategies that are related to their sustainable development goals. However, few of the proposed actions will result in immediate effects, and instead call for additional planning. This highlights the significant effort that is necessary for comprehensive responses. There are also differences in what the three cities emphasize in their climate action plans. For instance, the three cities differ in their levels of emphasis on infrastructural protection. Mexico City seeks to reduce water and transportation emissions through such actions as improvements in infrastructure and changes in transportation mode-share. Vancouver has prioritized the separation of sanitary and stormwater, yet this adaptation is not expected to be complete until 2050 (City of Vancouver, 2012). It will also take New York much time, money and energy to expand adaptation strategies beyond the protection of water supply, sewer, and wastewater treatment systems to include all essential city infrastructures (Ray *et al*., 2013);

Climate responses require new types of scientific information at very local scales, e.g., vulnerability analyses, flood risk assessments, health impacts analyses, and these are not always available (Romero-Lankao *et al*., 2012; Ray *et al*., 2013). Little is known, for instance, about how to predict and respond to common and differential levels of risk experienced by different populations within cities. Although some scholarship exists on disparities in household or population level vulnerability and adaptive capacity (Cutter *et al*., 2003; Villeneuve and Burnett, 2003; Douglas *et al*., 2012; Romero-Lankao *et al*., 2013), equity concerns in all three cities have gotten little attention as the cities have focused on reducing emissions (Mexico City), or protecting critical infrastructures (New York and Vancouver). Yet, even when local needs are identified, such as the need to protect higher risk homeless and low-income populations, they are often not addressed in action plans, as risk planning and long term adaptation strategies give way to shorter term priorities and economic imperatives.

_____ END BOX 26-3 HERE _____

26.9. Federal and State Level Adaptation

Besides adaptations at the city level (section 25.7), governments at the federal, state/provincial, and local levels across North America are developing climate change adaptation plans. These initiatives, which began at the provincial (e.g., Nunavut (Nunavut Department of Sustainable Development, 2003)) and municipal (e.g., Keene, New Hampshire (City of Keene, New Hampshire and ICLEI - Local Governments for Sustainability, 2007)) levels, appear to be preliminary and relatively little has been done to implement specific measures.

26.9.1. Federal Level

All three national governments are addressing adaptation to some extent, with a national strategy and a policy framework (Mexico), a federal policy framework (Canada), and the United States having all federal agencies develop adaptation plans.

In 2005, the Mexican government created the *Inter-Secretarial Commission to Climate Change* (CICC – Comisión Inter-Secretarial de Cambio Climático) to coordinate national public policy on climate change (Comisión Inter-Secretarial de Cambio Climático, 2005; SEMARNAT, 2010; Sosa-Rodriguez, 2013).The government's initiatives are being delivered through the *National Strategy for Climate Change 2007-2012* (Intersecretarial Commission on Climate Change, 2007) and, the *Special Programme on Climate Change 2009-2012*, which identify priorities in research, cross-sectoral action such as developing early warning systems, and capacity development to support mitigation and adaptation actions (Comisión Inter-Secretarial de Cambio Climático, 2009). The *Policy Framework for Medium Term Adaptation* (Consejo Intersecretarial de Cambio Climático, 2010)aims at framing a single national public policy approach on adaptation with a time-horizon up to 2030. The General Law of Climate Change requires state governments to implement mitigation and adaptation actions (Diario Oficial de la Federación, 2012).

Canada is working towards creating a Federal Adaptation Policy Framework intended to mainstream climate risks and impacts into programs and activities to help frame government priorities (Government of Canada, 2011). In 2007, the federal Government made a four-year adaptation commitment to develop six Regional Adaptation Collaboratives (RAC) in provinces across Canada, ranging in size and scope, from flood protection and drought planning, to extreme weather risk management; and assessing the vulnerability of Nunavut's mining sector to climate change (Natural Resources Canada, 2011). In 2011, the federal government renewed financial support for Environment Canada's Climate Change Prediction and Scenarios Program and Canada's Heat Alert and Response System, and provided new funding to create a Climate Adaptation and Resilience Program for Aboriginals and Northerners, and to finance the integration of adaptation into National Codes and Standards (Environment Canada, 2011).

The U.S. government embarked in 2009 on a federal government wide effort to have all federal agencies address adaptation; to apply understanding of climate change to agency missions and operations; to develop, prioritize, and

implement actions; and to evaluate adaptations and learn from experience (The White House, 2009; Bierbaum *et al.*, 2012). The U.S. Government provides technical and information support for adaptation by non-federal actors, but does not provide direct financial support for adaptation (Parris *et al.*, 2010).

Some federal agencies took steps to address climate change adaptation prior to this broader interagency effort. In 2010, the U.S. Department of Interior created Climate Science Centers to integrate climate change information and management strategies in eight regions and 21 Landscape Conservation Cooperatives (Secretary of the Interior, 2010), while the U.S. Environmental Protection Agency's Office of Water developed a climate change strategy (U.S. Environmental Protection Agency National Water Program, 2011).

26.9.2. State and Provincial Levels

A number of states and provinces in all three countries have developed adaptation plans. For example, Ontario's 2011-2014 adaptation strategy and action plan identifies 37 measures, including requiring that building codes be revised to increase resilience and increase water and energy conservation (Government of Ontario, 2011). Quebec updated their plan which covers a number of managed sectors and ecosystems (Government of Quebec, 2012). British Columbia is modernizing its *Water Act* to alter water allocation during drought to reduce agricultural crop, livestock loss and community conflict, while protecting aquatic ecosystems (British Columbia Ministry of the Environment, 2010).

In the U.S. California was the first state to publish an adaptation plan calling for a 20% reduction in per capita water use by 2020 (California Natural Resources Agency, 2009). Maryland first developed a plan on coastal resources and then broadened it to cover human health, agriculture, ecosystems, water resources, and infrastructure (Maryland Commission on Climate Change Adaptation and Response Working Group, 2008; Maryland Department of the Environment on behalf of the Maryland Commission on Climate Change, 2010). The State of Washington is addressing environment, infrastructure, and communities; human health and security; ecosystems, species, and habitat; and natural resources (Washington State Built Environment: Infrastructure & Communities Topic Advisory Group (TAG), 2011; Washington State TAG 4 Natural Resources Working Lands and Waters, 2011; Washington State Topic Advisory Group (TAG) Report- TAG 2 Human Health and Security, 2011; Washington State Topic Advisory Group 3 Species, Habitats and Ecosystems, 2011).

In Mexico, Veracruz, Mexico City, Nuevo León, Guanajuato, Puebla, Tabasco, and Chiapas, have all developed their *State Programmes for Climate Change Action* (Programas Estatales de Acción ante el Cambio Climático - PEACC), while Baja California Sur, Hidalgo, and Campeche are in the final stage and 17 states are still in the planning and developing stage (Instituto de Ecología del Estado de Guanajuato, 2011). The proposed adaptation actions focus mainly on: 1) reducing physical and social vulnerability of key sectors and populations; 2) conservation and sustainable management of ecosystems, biodiversity, and ecosystem services; 3) developing risk management strategies; 4) strengthening water management; 5) protecting human health, and; 6) improving current urban development strategies, focusing on settlements and services, transport and land use planning.

26.9.3. Barriers to Adaptation

Of the three national governments, only Mexico requires that states develop adaptation plans. Most adaptation activities have only involved planning for climate change and few measures have been implemented (Preston *et al.*, 2010; Bierbaum *et al.*, 2012).

Even though Canada and the U.S. are relatively well-endowed in their capacity to adapt, there are significant constraints on adaptation (Chapter 16), with financing being a significant constraint in all three countries(Carmin *et al.*, 2012a). Barriers include legal constraints (e.g., Jantarasami *et al.*, 2010) lack of coordination across different jurisdictions (Smith *et al.*, 2009; National Research Council, 2010; INECC-SEMARNAT, 2012), leadership (Smith *et al.*, 2009; Moser and Ekstrom, 2010), and divergent perceptions about climate change (Bierbaum *et al.*, 2012). Although obtaining accurate scientific data was ranked less important by (Carmin *et al.*, 2012a), an important

constraint is lack of access to scientific information and capacity to manage and use it (Moser and Ekstrom, 2010; INECC-SEMARNAT, 2012). Adaptation activities in the U.S. tend to address hazards and propose adaptations that tend to protect current activities rather than facilitate long term change. In addition, the adaptation plans generally do not attempt to increase adaptive capacity (Eakin and Patt, 2011).

26.10. Key Multi-Sectoral Risks, Uncertainties, Knowledge Gaps, and Research Needs

26.10.1. Key Multi-Sectoral Risks

We close this chapter with our assessment of key current and future regional risks (Figure 26-6). These figures illustrate how *relative* risks within a sector can change based on increases in the magnitude and rate of climate change and adaptation levels. However, the assignment of *absolute* risk by sector/system and relative risk across sectors/systems and regions should be interpreted with much caution for different reasons. Risks in *terrestrial ecosystems* and *coastal systems* lend themselves better to *predictions* based on models that mix historical and theoretical information. That is not the case with the complexity of key risks in such systems and sectors as water resources and management, food security, and urban and rural settlements, where differences in the severity of climate risks are likely to be strongly influenced by context-specific societal and environmental factors and processes (e.g., population and economic growth, governance, land use change, etc.) whose future trajectories are inherently unpredictable, or unknown. That can be the reason why it was harder for team authors to assign risk levels in the areas of human security, livelihoods and poverty.

[INSERT FIGURE 26-6 HERE
Figure 26-6: Estimated climate risk to key sectors and systems in North America, for different time frames (2030-2040 and 2080-2100), under two levels of global warming (2°C and 4°C), and diverse assumptions about anticipated adaptation. Levels of risk and levels of anticipated adaptation are differentiated by colored shading and ranges from low to high. They represent the judgment of North American individual authors who have different approaches or "ways of knowing" and assessing risks, and realize that generalizations over an area as heterogeneous as North America can be difficult to interpret.]

This figure assigns a single score to sectors and systems that contain a wide array of risks amongst their components. Consider for example agriculture. Although projected changes in temperature, precipitation and extreme events are predicted to result in notable productivity declines in major North American crops, vulnerability to climate varies considerably depending on the extent to which farmers and communities have access to financial resources, technology, institutional support mechanisms and social networks. Risk in rural and urban settlements and economy sectors can vary considerably depending on context-specific social and physical factors faced by different communities, individuals, and firms. Even in biophysical coastal and terrestrial ecosystems, vulnerability varies widely across individual species and landscapes. Furthermore, the rate of change matters in ecosystems (e.g., 2C by 2040 is more risky than 2C by 2080). In short the judgments on risk in this figure are intended to apply to each sector as a whole, but should *not* be interpreted to mean that all components of the sector face the same level of risk.

A further key consideration is that the judgments about risk conveyed by these figures were made by experts living under current socio-economic conditions, not being able as such to fully anticipate potential future changes. Yet over the course of the 21st century, socioeconomic conditions will very likely change considerably for many sectors, systems and places. The dynamics of wealth generation and distribution, technological innovations, institutions, even culture, can substantially affect what level of risk can be absorbed by the North American systems and sectors considered in Figure 26-6. Under the conditions and estimations of risk depicted in the figure it is, hence, highly likely that in the near term (*the era of climate responsibility*), risks associated with committed climate changes can be managed primarily through adaptation actions. However, current mitigation actions can help reduce risks during the second half of the century (*the era of climate options*).

26.10.2. Uncertainties, Knowledge Gaps, and Research Needs

The literature on climate impacts, adaptation and vulnerability in North America has grown considerably, as has the diversity of sectors and topics covered (e.g., urban and rural settlements, food security, and adaptation at local, state and national levels). However, limitations in the topical and geographical scope of this literature are still a challenge (e.g., more studies have focused on insurance than on economic sectors such as industries, construction and transportation). It is also challenging to summarize results across many studies and identify trends in the literature when there are differences in methodology, theoretical frameworks and causation narratives (e.g., between outcome and contextual approaches) making it hard to compare "apples to oranges" (Romero-Lankao *et al.*, 2012) While the US and Canada have produced large volumes of literature, Mexico lags well behind. It was, therefore, difficult to devote equal space to observed and projected impacts, vulnerabilities and adaptations in Mexico in comparison with its Northern neighbors. With its large land area, population and important, albeit understudied, climate change risks and vulnerabilities, more climate change research focusing on Mexico is direly needed.

The literature on North America tends to be dominated by sector level analyses. Yet, climate change interacts with other physical and social processes to create differential risk and impact levels. These differences are mediated by context-specific physical and social factors shaping the vulnerability of exposed systems and sectors. Furthermore, while studies often focus on isolated sectorial effects, impacts happen in communities, socio-ecologic systems and regions, and shocks and dislocations in one sector or region often affect other sectors and regions due to social and physical interdependencies. This point is illustrated by our border region and wildfire boxes and the human settlements section, which discuss place-based impacts, vulnerabilities and adaptations. Unfortunately, literature using placed-based or integrated approaches to these complexities is limited. Indeed although in early drafts the authors of this chapter attempted to put more emphasis on place-based analysis and comparisons, the literature was inadequate to support such an effort. The IPCC includes chapters on continents and large regions to make it possible to assess how multiple climate change impacts can affect these large areas. However, this macro view gives insufficient detail on context specific local impacts and risks, missing the on-the-ground reality that the effects of climate change are and will be experienced at much smaller scales, and those smaller scales are often where meaningful mitigation and adaptation actions can be generated. In order to give local actors relevant information on which to base these local actions, more research is needed to better understand the local and regional effects of climate change across sectors.

Frequently Asked Questions

FAQ 26.1: What makes North America especially unique compared with other continents when it comes to climate vulnerabilities?

North America is unique in the very broad diversity of geography, climate, economic development, social fabric and governance systems which can be found across its broad landmass, and result in different vulnerabilities and capacities to adapt across sectors and regions. Layered on top of this broad diversity is a similarly broad range of climate trends and projections. For example rapid observed and projected further warming of northern NA will lead to major changes in transportation, agriculture, and native livelihoods. Meanwhile, strong drying trends in the western US and Mexico are leading to major stresses on water supplies, agriculture, and ecological services.

FAQ 26.2: Will changing patterns of precipitation be experienced in NA and if so, in what ways?

Future projections over NA suggest increases in annual precipitation in Canada and Alaska. However decreases in the southwestern US and much of Mexico are projected. These average trends will be accompanied by increasing intensity of precipitation events along with longer, more intense periods of draught. Thus, variability in precipitation appears to be a hallmark of future climate in NA. Extreme storm events can have significant impacts on local infrastructure and human health when they exceed the intensity for which these systems have been developed over many decades. The large concentration of human and infrastructure resources in the Gulf of Mexico and other coastal regions can exacerbate this vulnerability.

FAQ 26.3: What sectors/regions are more vulnerable? What factors/drivers contribute to a vulnerable situation?

- *Water supplies and quality in many regions*: Runoff throughout most of Mexico, except the south, much of the western United States and southwestern Canada is likely to decrease. These areas are already facing stress from limited water supply and lower future runoff is likely to result in increased competition for water supplies, decreased agricultural production, and harm to aquatic ecosystem.
- *Agriculture in Mexico*, particularly among smallholders: Higher temperatures, a decrease in runoff, and lower soil moisture, which are all considered to be likely for many agricultural-producing areas of Mexico, will likely decrease agricultural production. Only a small proportion of cultivated land is irrigated, furthermore, and the availability of insurance to small-holders in particular is limited. This risks reducing food security, and increasing social instability and migration. Mention something about the wet tropical south
- *Many ecosystems*: In particular, wildfire and pest outbreaks have increased in North America and both of these trends have been linked to climate change. Forest ecosystems, forest-based industries, and human settlements have been impacted negatively by recent wildfire and pest events. Forecasts indicating increasing frequency and intensity of both processes suggest a high likelihood for further reductions in biodiversity, loss of habitat, decreases in ecosystem services, challenges for forest-based industries, and increased economic and health consequences for local communities

FAQ 26.4: What lessons can be drawn from existing adaptation actions on the factors shaping effective responses?

Different economic and demographic sectors and tiers of government are starting to assess their climate change vulnerabilities and designing adaptation programs. Many responses are in diagnosis and planning stage and have not yet moved into the implementation.

Engaging stakeholders in adaptation has proved effective in gaining legitimacy for public decisions and helping capture local realities. The use of scientific information in participatory exercises has also been crucial. However, potential issues might arise: delays in decision making; tensions and conflicts among stakeholder groups embedded in power relationships that can constrain the access of the general population to decision making processes. In addition, adaptation may be constrained by a general unwillingness to address long-term changes (e.g., many decision makers have relatively short term planning and management horizons).

Adapting to climate change is complicated by the fact that it is undertaken at different temporal, spatial and sectoral scales, thus requiring a careful assessment of the different sectoral and spatial layers involved (e.g., land-use planning, emergency responses, housing, and health). Often, environmental or engineering agencies are responsible for managing climate issues, but do not have the decision making power nor the resources available to address all the dimensions involved. Adaptation requires not only shorter term actions, but also longer term measures and perspectives by the different tiers of governmental, businesses, grassroots organizations and individuals.

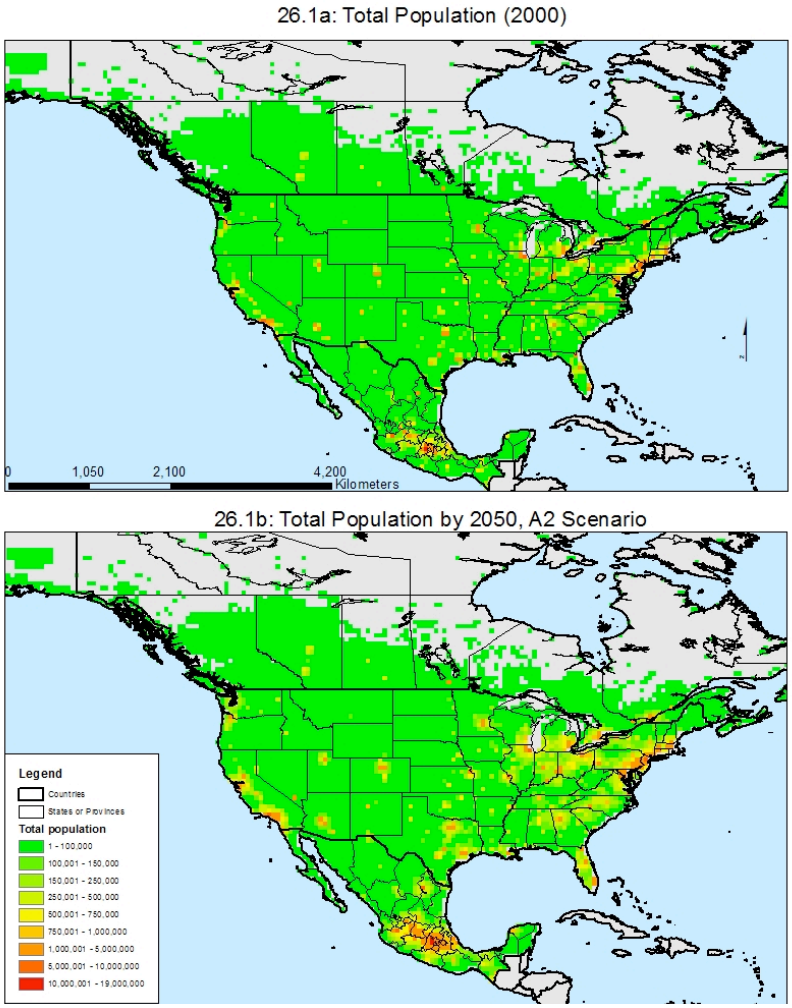

Figure 26-1: Current and future populations in North America. While concentrations of growing populations, infrastructures, and sectors in urban areas can be a source of risk, geographic isolation of rural populations can be a source of sensitivity that is aggravated by high dispersion levels. Source: Lutz, 2007.

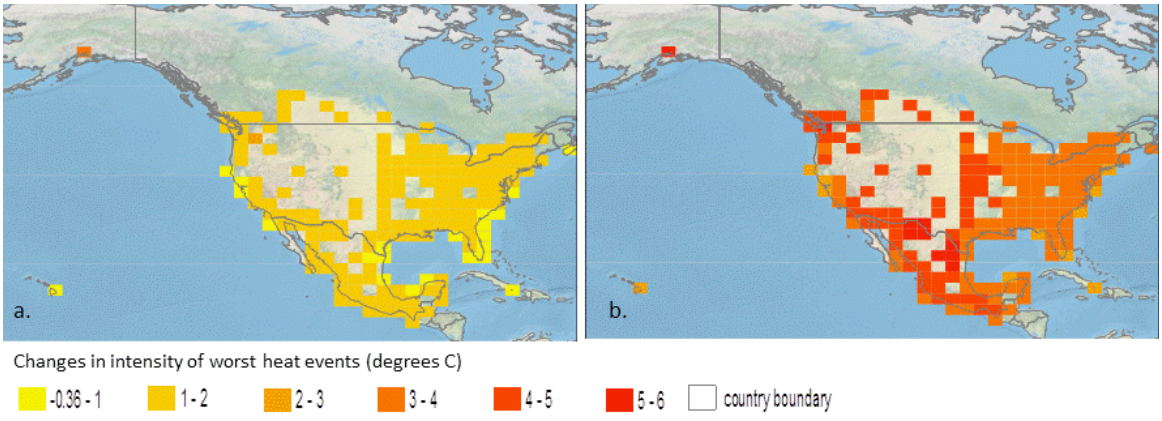

Figure 26-2: Projected changes in the intensity of the worst heat events, as simulated by CLMU for urban grid cells: a) near term (2020-2039) relative to present-day climate (1980-1999); b) end of the 21st century (2080-2099) relative to present-day climate (1980-1999). Source Wilhelmi et al. (forthcoming).

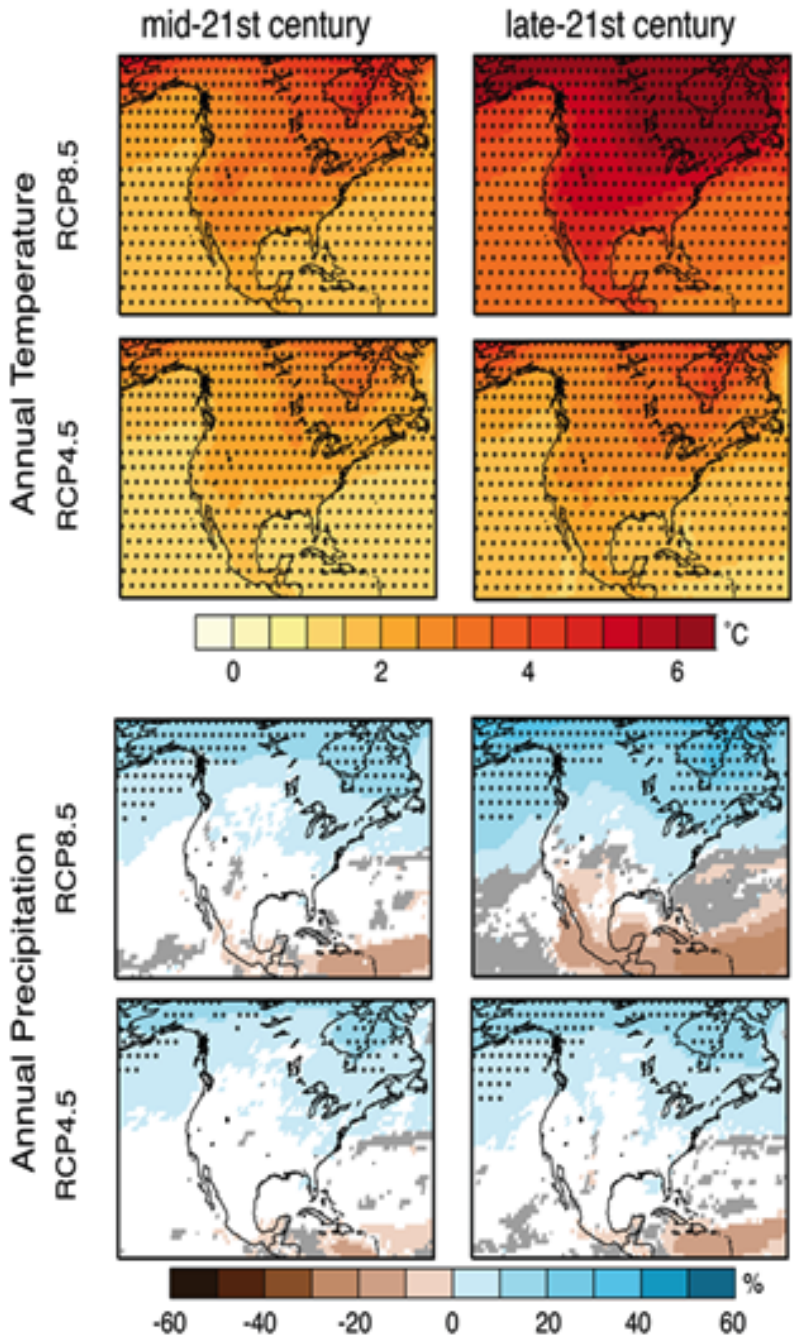

Figure 26-3: Changes in annual temperature and precipitation. White indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Gray indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st century period is 2081-2100. The mid-21st century period is 2046-2065.

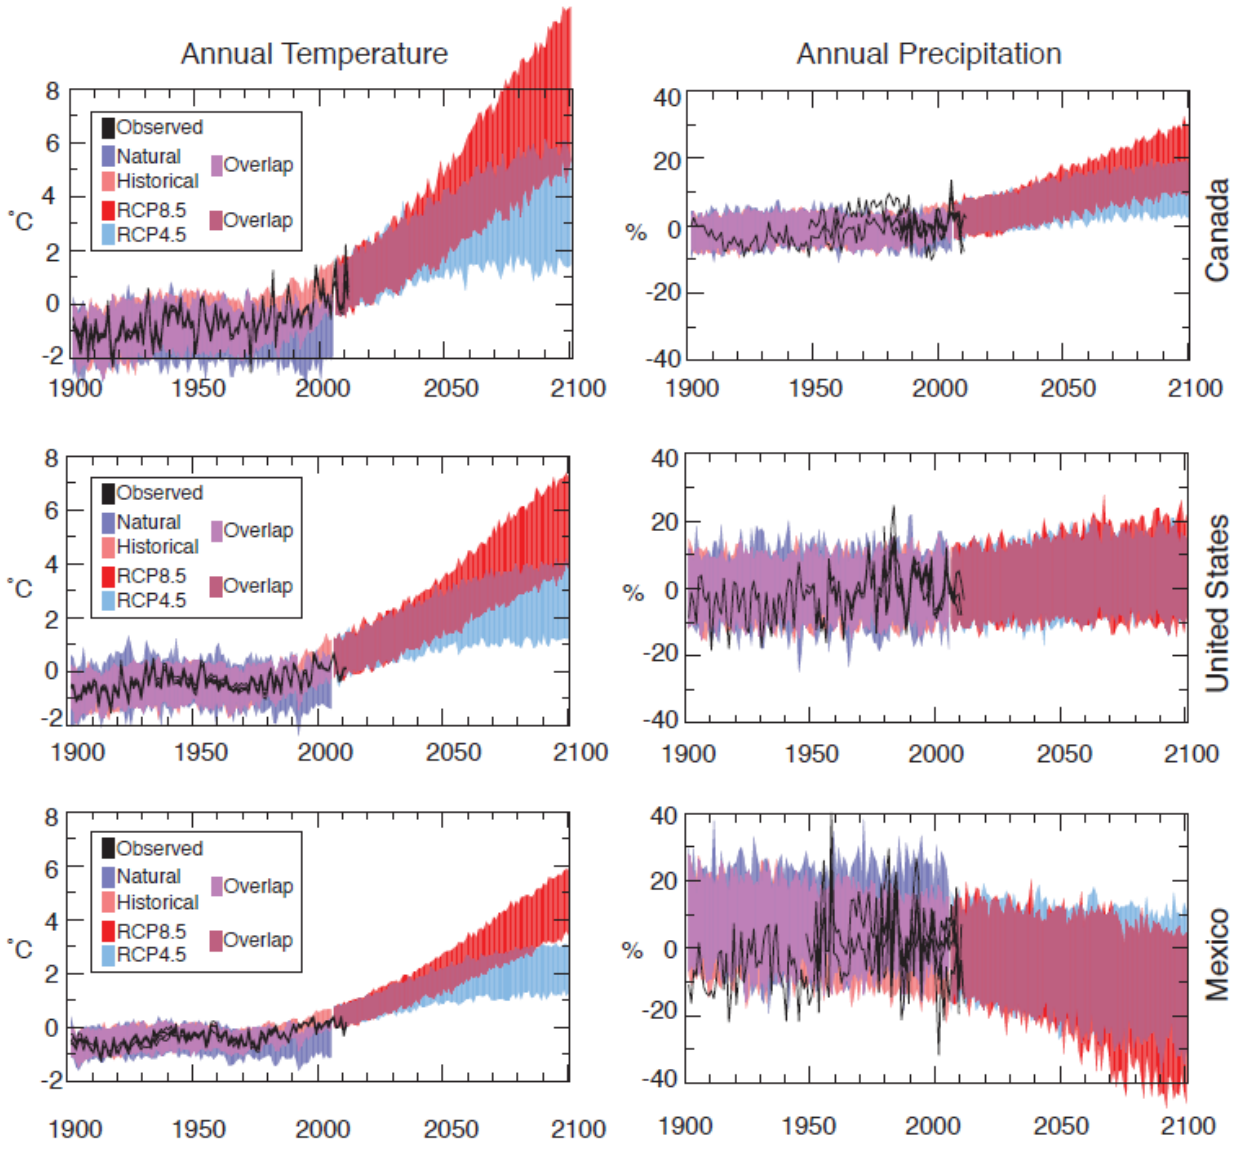

Figure 26-4: Observed and simulated variations in past and projected future annual average precipitation and temperature over land areas of Canada, the contiguous United States, and Mexico. Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.

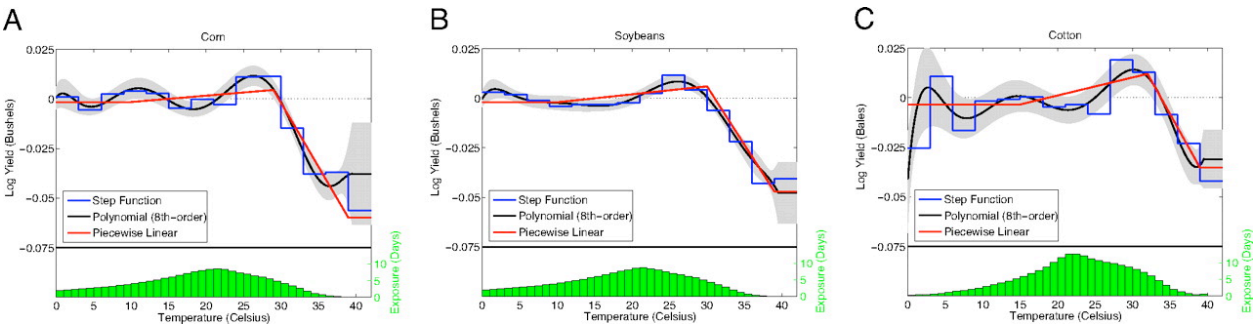

Figure 26-5 Nonlinear relation between temperature and yields. Source: Schlenker, 2009.

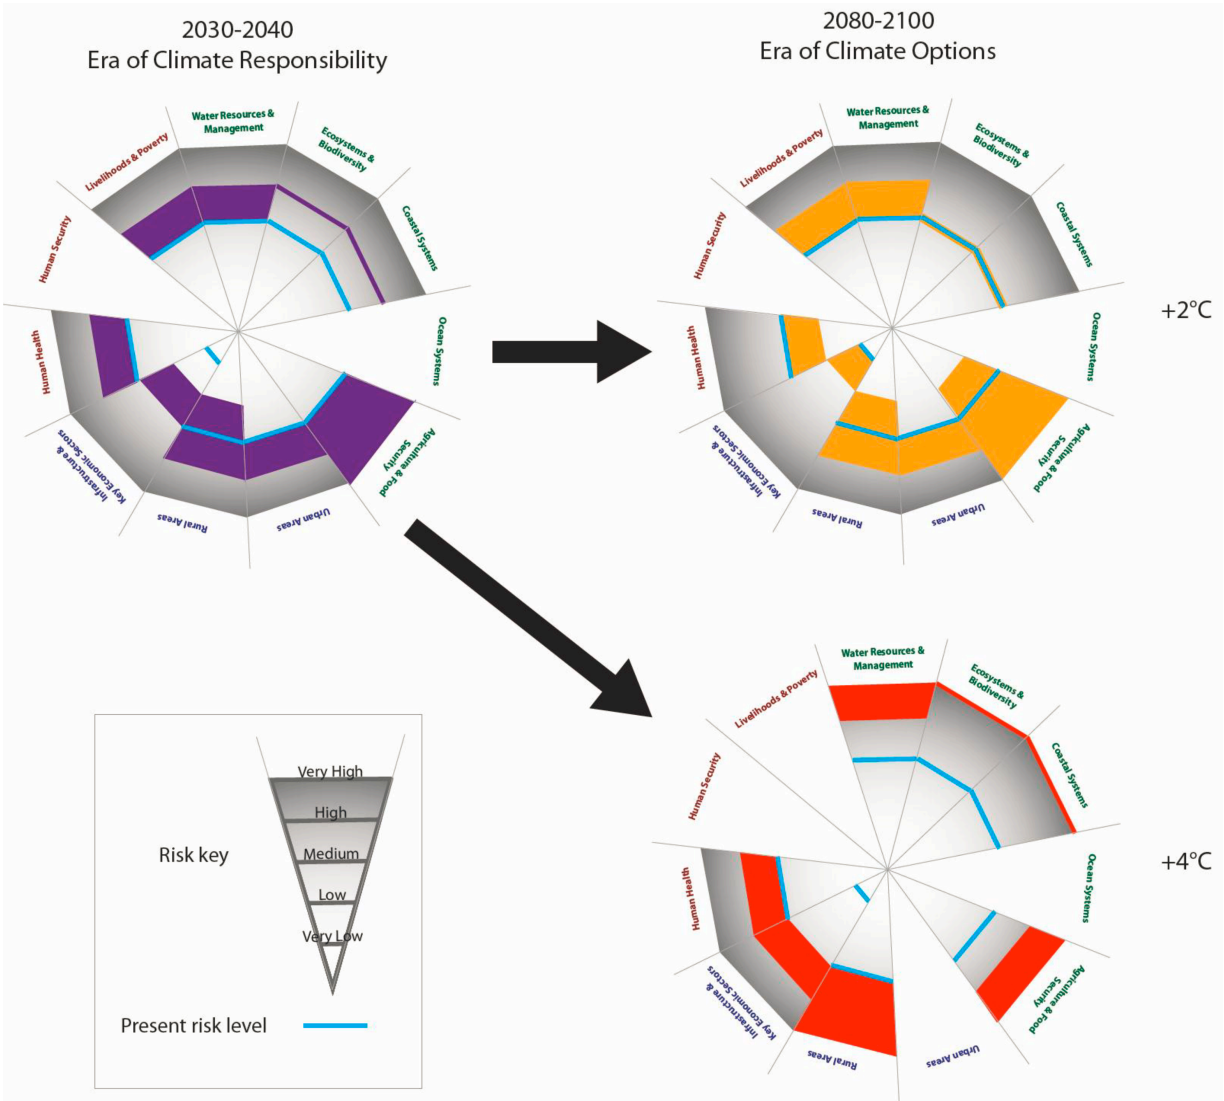

Figure 26-6: Estimated climate risk to key sectors and systems in North America, for different time frames (2030-2040 and 2080-2100), under two levels of global warming (2°C and 4°C), and diverse assumptions about anticipated adaptation. Levels of risk and levels of anticipated adaptation are differentiated by colored shading and ranges from low to high. They represent the judgment of North American individual authors who have different approaches or "ways of knowing" and assessing risks, and realize that generalizations over an area as heterogeneous as North America can be difficult to interpret.

Executive Summary

Changes in climate variability and in extreme events have been severely affecting Central America (CA) and South America (SA) during the last 60 years. Increases in observed warm days and decreases in cold days and nights have been identified in CA, Northern SA, Northeast Brazil (NEB), Southeastern South America (SESA) and the West Coast of SA (medium-lower confidence). More frequent and intense rainfall extremes in SESA have favored an increase in the occurrence of landslides and flash floods (low confidence). On seasonal scales, it is likely that changes in hydrometeorological extremes in regions such as Amazonia, La Plata basin and Northern South America observed during the last 10 years have been related to changes in natural climate variability, determining changes in extreme streamflow variability in the La Plata and Amazon Rivers (27.1.2.2, 27.2.1.1).

The projected mean warming for CA by the end of the century, according to different global and regional climate models from the CMIP3 and CMIP5 ranges from 1.5°C to 4.0 °C, while rainfall tends to decrease between 5 and 10% by 2100. SA shows a warming between 1.0°C to 5.0 °C, with rainfall reduction up to 10% in tropical SA and an increase of about 10-15% in SESA. Projections for the 21st century from CMIP3 global models suggest a weakening of the North American Monsoon System NAMS and precipitation reduction in June-July, accompanied by projected warming in most of CA (medium confidence). Analyses from global and regional models in SA show common patterns of projected climate in some sectors of the continent, with a very likely increase of precipitation in SESA, Northwest of Peru and Ecuador and western Amazonia, while decreases are projected for northern SA,

Eastern Amazonia, central eastern Brazil, NEB, the Altiplano and southern Chile. With lower-medium confidence, heavy precipitation is likely projected to increase in SESA, while dry spells would increase in northeastern South America. Increases in warm days and nights are very likely to occur in most of SA (27.2.1.2).

In CA and SA there is evidence of changing conditions in terms of geophysical variables (cryosphere and runoff) that affect streamflow and finally water availability (high confidence). Since AR4, there is growing evidence that glaciers (both tropical and extratropical) are retreating and the cryosphere in the Andes is changing according to the warming trends. These changes affect streamflow availability in different seasons of the year. Robust trends are apparent associated with changes in precipitation such as increasing runoff in the SESA region (La Plata basin), and reducing runoff in the Central Andes (Chile, Argentina) and Central America. In contrast to these findings, no robust trend in streamflow in the Amazon Basin has been detected (27.3.1.1).

Land cover change is a key driver of environmental change with significant impacts that may increase the potential negative impacts from climate change. Deforestation and land degradation are mainly attributed to increased extensive and intensive agriculture, both from traditional export activities such as beef and soy production, but more recently from biomass for biofuel production. The agricultural expansion has affected fragile ecosystems such as the edges of the Amazon forest and the tropical Andes increasing the vulnerability of communities to extreme climate events, particularly floods, landslides and droughts. Even though deforestation rates in the Amazon have decreased substantially in the last eight years to a current value of 0.29%, the lowest for all forest biomes in Brazil, other regions like the Cerrado and the Chaco forests still present high levels of deforestation with rates as high as 1.33% (27.2.2.1).

Socioeconomic development shows a high level of structural heterogeneity and a very unequal income distribution resulting in high vulnerability of the region to climate change. There is still a high and persistent level of poverty in most countries of the region (45% for CA and 30% for SA for year 2010) in spite of the sustained economic growth observed in the last decade. In terms of human development, the performance of different countries varied greatly from Chile and Argentina at the high end of human development, and Guatemala and Nicaragua with the lowest indices. The economic inequality translates into inequality in access to water, sanitation and adequate housing, particularly for the most vulnerable groups: indigenous peoples, Afro-descendants and women living in poverty which translates into low adaptive capacities to climate change for these groups (27.2.2.2).

Coastal and marine ecosystems have been undergoing significant transformations that pose threats to fish stocks, corals, mangroves, places for recreation and tourism, and controls of pests and pathogens. Frequent coral bleaching events have been recently reported for the Mesoamerican Coral Reef. In CA and SA, some of the main drivers of mangrove loss are deforestation and land conversion, agriculture and shrimp ponds to an extent that the mangroves of the Atlantic and Pacific coasts of CA are some of the most endangered in the planet. Changes over 2 mm/yr of sea-level rise (SLR) have been found in CA and SA, which is reason for concern since 3/4 of the population of the region live within the range of 200 km of the coast (27.3.3.1). In Brazil, fisheries' co-management - a participatory process involving local fishermen communities, government, academia and NGOs - favors a balance between conservation of marine fisheries, coral reefs and mangroves, and the improvement of livelihoods, as well as the cultural survival of traditional populations (27.3.3.2).

Conversion of natural ecosystems is the main proximate cause of biodiversity and ecosystem loss in the region, and in parallel is a driver of anthropogenic climate change. Plant species are rapidly declining in CA and SA; the highest percentage of rapidly declining amphibian species occurs also in CA and SA; with Brazil being among the countries with most threatened bird, mammal species and freshwater fish. However, the region has still large extensions of natural vegetation cover for which the Amazon is the main example. Ecosystem-based Adaptation practices, such as conservation agreements and community management of natural areas, begin to multiply across the region (27.3.2.2).

Although there is high uncertainty in terms of climate change projections for regions with high vulnerability in terms of current water availability, this vulnerability is expected to increase in the future due to climate change impacts (high confidence). Already vulnerable regions in terms of water supply, like the semi-arid zones in Chile-Argentina, North Eastern Brazil and Central America and the tropical Andes, are expected to increase even further their

vulnerability due to climate change. Glacier retreat is expected to continue, and a reduction in water availability due to expected precipitation reduction and increase evapotranspiration demands is expected in the semi-arid regions of CA and SA. These scenarios would affect water supply for large cities, small communities, hydropower generation and the agriculture sector (27.3.1.1, 27.3.1.2, 27.6.1). Current practices to reduce the mismatch between water supply and demand could be used to reduce future vulnerability. Constitutional and legal reforms towards more efficient and effective water resources management and coordination among relevant actors in many countries in the region (e.g. Honduras, Nicaragua, Ecuador, Peru, Uruguay, Bolivia and Mexico) also represent an adaptation strategy to climate variability and change (27.3.1.2).

Changes in agricultural productivity attributed to climate change are expected to have a great spatial variability**.** In SESA, where projections indicate more rainfall, average productivity could be sustained or increased until the mid-century (SRES: A2, B2) (medium confidence). In CA, northeast of Brazil and parts of the Andean region increases in temperature and decreases in rainfall could decrease the productivity in the short-term (before 2025), threatening the food security of the poorest population (medium confidence). The great challenge for CA and SA will be to increase the food and bioenergy production and at the same time to sustain the environmental quality in a scenario of climate change (27.3.4.1).

Renewable energy (RE) has a potential impact on land use change and deforestation, but at the same time will be an important means of adaptation, with the region, mainly SESA being key in this process. Hydropower is currently the main source of RE in CA and SA, followed by biofuels, notably bioethanol from sugarcane and biodiesel from soy. SESA is one of the main sources of production of the feedstocks for biofuels' production. Sugarcane and soy are likely to respond to the elevation of CO_2 and temperature with an increase in growth, which might lead to an increase in productivity and production. However, the drought effects expected for some regions in CA and SA will be critical and scientific knowledge has to advance in this area. Advances in second generation bioethanol from sugarcane and other feedstocks will be important as a measure of adaptation, as they have the potential to increase biofuels productivity in the region. In spite of the large amount of arable land available in the region, the expansion of sugarcane and soy, related to biofuels production, might have some indirect land use change effects, producing teleconnections that could lead to deforestation in the Amazon and loss of employment in some countries. This is especially derived from the expansion of soy, which is used for biodiesel production inclusively (27.3.6.).

Climate variability and climate change are negatively affecting human health in CA and SA, either by increasing morbidity, mortality, and disabilities (very high confidence), and through the emergence of diseases in regions previously non-endemic, or the re-emergence of diseases in areas where they have previously been eradicated or controlled (high confidence). Climate-related drivers have been recognized for respiratory and cardiovascular diseases, vector- and water-borne diseases (malaria, dengue, yellow fever, leishmaniasis, cholera, and other diarrheal diseases), Hantaviruses and Rotaviruses, pregnancy-related outcomes, diabetes, chronic kidney diseases, and psychological trauma (27.3.7.1). Vulnerabilities vary with geography, age, gender, race, ethnicity, and socio-economic status, and are rising in large cities (27.3.7.2). It is very likely that Climate change and variability may exacerbate current and future risks to health, given the region's vulnerabilities in existing health, water, sanitation and waste collection systems, nutrition, and pollution.

The best way to be prepared to adapt to future climate change is by assisting people to cope with current climate variability. Long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the CA and SA population. Such conditions weaken the importance of adaptation planning to climate change on the political agenda. Various examples demonstrate possible synergies between development, adaptation and mitigation planning, which can help local communities and governments to allocate efficiently available resources in the design of strategies to reduce vulnerability (27.3.4, 27.4.1, 27.4.2, 27.4.3, 27.4.4, 27.5).

27.1. Introduction

27.1.1. The Central and South America Region

The CA and SA region harbours unique ecosystems and maximum biodiversity, has a variety of eco-climatic gradients, and it is rapidly developing. Agricultural and beef production is quickly increasing mostly by expanding agricultural frontiers; accelerated urbanization and demographic changes are remarkable; poverty and inequality are decreasing continuously, but at a low pace; while adaptive capacity is improving related to poverty alleviation.

The region has multiple stressors being climate variability/climate change and land cover change two of the most remarkable drivers of changes. Climate variability at various time scales has been affecting social and natural systems, and extremes in particular have affected large regions. During 2000-2010, almost 630 weather and climate extreme events ocurred in CA and SA, leaving near to 16,000 fatalities and 46.6 million people affected; and generating economical losses amounting to US$ 208 million (CRED, 2011). Land is facing increasing pressure from competing uses like cattle ranching, food production and bioenergy.

CA and SA are thought to have some key roles in the future because some countries, especially in SA, are rapidly developing and becoming economically important in the world scenario. The region is bound to be exposed to the pressure related to increasing land use and industrialization. Therefore, it is likely to have to deal with increasing emission potentials. Therefore, science-based decision-making is thought to be an important tool to control innovation and development of the countries in the region.

Two other important contrasting features characterize the region: having the biggest tropical forest of the planet on the one side, and possessing the largest potential for agricultural development during the next decades on the other. This is the case because the large countries of SA, especially, would have a major role in food and bioenergy production in the future, as long as policies towards adaptation to global climate change (GCC) will be strategically designed. The region is already one of the top producers and user of bioenergy and this experience will serve as an example to other developing regions as well as developed regions.

27.1.2. Summary of the AR4 and SREX Findings

27.1.2.1. AR4 Findings

During the last decades of the 20th century, unusual extreme weather events have been severely affecting the LA region contributing greatly to the strengthening of the vulnerability of human systems to natural disasters. In addition, increases in precipitation were observed in SESA, northwest Peru and Ecuador; while decreases were registered in southern Chile, southwest Argentina, southern Peru and western CA since 1960. Mean warming was near to 0.1ºC/decade. The rate of SLR has accelerated over the last 20 years reaching 2-3mm/year. The glacier-retreat trend has intensified, reaching critical conditions in the Andean countries. Rates of deforestation have been continuously increasing mainly due to agricultural expansion, and land degradation has been intensified for the entire region.

Mean warming for LA at the end of 21st century could reach 1ºC to 4ºC (SRES B2) or 2ºC to 6ºC (SRES A2). Rainfall anomalies (positive or negative) will be larger for the tropical part of LA.The frequency and intensity of weather and climate extremes is likely to increase.

Future impacts include: “Significant species extinctions, mainly in tropical LA” (high confidence). “Replacement of tropical forest by savannas, and semi-arid vegetation by arid vegetation” (medium confidence). “Increases in the number of people experiencing water stress” (medium confidence). “Probable reductions in rice yields and possible increases of soy yield in SESA; and increases in crop pests and diseases” (medium confidence). “Some coastal areas affected by sea level rise, weather and climatic variability and extremes” (high confidence).

Some countries have made efforts to adapt to climate change and variability, for example through the conservation of key ecosystems, the use of early warning systems and climate forecast, and the implementation of disease surveillance systems. However, several constraints like the lack of basic information, observation and monitoring systems; the lack of capacity-building and appropriate political, institutional and technological frameworks; low income; and settlements in vulnerable areas, outweigh the effectiveness of these efforts.

27.1.2.2. SREX Findings

As reported by the IPCC SREX (IPCC, 2012), a changing climate leads to changes in the frequency, intensity, spatial extent or duration of weather and climate extremes, and can result in unprecedented extremes. Levels of confidence in historical changes depend on the availability of high quality and homogeneous data, and relevant model projections. This has been a major problem in CA and SA, where a lack of long-term homogeneous and continuous climate and hydrological records, and of complete studies on trends have not allowed for an identification of trends in extremes, particularly in CA. Recent studies and projections from global and regional models suggest changes in extremes. With medium confidence, increases in warm days and decreases in cold days, as well as increases on warm nights and decreases in cold nights have been identified in CA, Northern SA, NEB, SESA and west coast of SA. In CA, there is low confidence that any observed long-term increase in tropical cyclone activity is robust, after accounting for past changes in observing capabilities. In other regions, such as the Amazon region, insufficient evidence, inconsistencies among studies and detected trends result in low confidence of observed rainfall trends. While it is likely that there has been an anthropogenic influence on extreme temperature in the region, there is low confidence in attribution of changes in tropical cyclone activity to anthropogenic influences.

Projections for the end of the 21st century for differing emissions scenarios (SRES A2 and A1B) show that for all CA and SA, models project substantial warming in temperature extremes. It is likely that increases in the frequency and magnitude of warm daily temperature extremes and decreases in cold extremes will occur in the 21st century on the global scale. With medium-high confidence, it is very likely that the length, frequency and/or intensity of heat waves will experience a large increase over most of SA, with weaker tendency towards increasing in SESA. With low to medium confidence, the models also project an increase of the proportion of total rainfall from heavy falls for SESA and the West coast of SA; while for Amazonia and the rest of SA and CA there are not consistent signals of change. In some regions, there is low confidence in projections of changes in fluvial floods. Confidence is low due to limited evidence and because the causes of regional changes are complex. There is medium confidence that droughts will intensify along the 21st century in some seasons and areas due to reduced precipitation and/or increased evapotranspiration in Amazonia and NEB.

The character and severity of the impacts from climate extremes depend not only on the extremes themselves but also on exposure and vulnerability. These are influenced by a wide range of factors, including anthropogenic climate change, natural climate variability, and socioeconomic development. Disaster risk management and adaptation to climate change focuses on reducing exposure and vulnerability and increasing resilience to the potential adverse impacts of climate extremes, even though risks cannot be fully eliminated.

27.2. Major Recent Changes and Projections in the Region

27.2.1. Climatic Stressors

27.2.1.1. Climate Trends, Long-term Variability, and Extremes

In CA and SA, decadal variability and changes in extremes have been affecting large sectors of the population, especially those more vulnerable and exposed to climate hazards. Observed changes in some regions have been attributed to natural climate variability while human influences (changes in extremes due to urbanization, for instance) have been attributed to land use change. Table 27-1 summarizes observed trends in the region's climate.

[INSERT TABLE 27-1 HERE
Table 27-1: Regional observed changes in temperature, precipitation and climate extremes in various sectors of CA and SA. Additional information on changes in observed extremes can be found in the IPCC SREX Chapter 3 (IPCC, 2012) and in WGI AR5 [2.4, 2.5, 2.6]]

Many areas in the Intra American Seas region that includes tropical and subtropical western North Atlantic Ocean encompassing the Gulf of Mexico, the Caribbean Sea, the Bahamas and Florida, the northeast coast of SA, and the juxtaposed coastal regions, including the Antillean Islands, show severe anomalies in rainfall. In CA and the North American Monsoon System (NAMS), rainfall has been starting increasingly later and has become more irregular in space and time, while the intensity of rainfall has been increasing during the onset season (see references in Table 27-1) since around 1950. Arias *et al*. (2012) found decadal rainfall variations in NAMS.

In SA, the West coast has shown a prominent but localized coastal cooling during the past 30-50 years extending from central Peru down to central Chile. Presumably, this occurs in connection with an increased upwelling of coastal waters favored by the trade winds (Narayan *et al*., 2010), that are associated with a negative trend in the sea surface temperature (SST) over a large oceanic region off the coast of northern Chile during the same period (Schulz *et al*., 2011). In the extremely arid northern coast of Chile, rainfall, temperature and cloudiness show strong interannual and decadal variability, and since the mid-70s, the minimum daily temperature, cloudiness and precipitation have decreased. In central Chile, a negative trend in precipitation was observed over the period 1935-1976, and an increase after 1976, while further south, the negative trend in rainfall that prevailed since the 1950s has intensified by the end of the 20th century (Quintana and Aceituno, 2012).

Towards the east of the Andes, NEB exhibits large interannual rainfall variability and a slight decrease since the 1970s. Although droughts in this region (e.g. 1983, 1987, 1998) have been associated with El Niño, the recent extremely intense drought in 2012-2013 occurred during La Niña (Marengo *et al*., 2013). In the La Plata Basin, various studies have documented interannual and decadal scale circulation changes that have led to decreases in the frequency of cold nights in austral summer, as well as to increases in warm nights and minimum temperatures during the last 40 years (see references in Table 27-1). Simultaneously, a reduction in the number of dry months in the warm season is found since the mid-1970s (see references in Table 27-1). Heavy rain frequency is increasing in SESA (references in Table 27-1).

In the central Andes, in the Mantaro Valley (Peru), precipitation shows a strong negative trend, while warming is also detected (SENAMHI, 2007). In the southern Andes of Peru, minimum air temperatures have increased during 1964-2006, while the number of frost days during September-April has also increased, but no clear signal on precipitation changes has been detected (Marengo *et al*., 2009a). In the northern Andes (Colombia, Ecuador), changes in temperature and rainfall in 1961-90 have been identified by Villacís (2008). In the Patagonia region, Masiokas *et al*. (2008) have identified an increase of temperature together with precipitation reductions during 1950-90.

For the Amazon basin, Marengo (2004), Marengo *et al*. (2009a; 2010), Satyamurty *et al*. (2010), and Buarque *et al*. (2010) concluded that no systematic unidirectional long-term trends towards drier or wetter conditions in both the northern and southern Amazon have been identified since the 1920s. Rainfall fluctuations are more characterized by inter-annual scales linked to ENSO or decadal variability. Analyzing a narrower time period, Espinoza *et al*. (2009a; 2009b) found that mean rainfall in the Amazon basin for 1964–2003 has decreased, with stronger amplitude after 1982, especially in the Peruvian western Amazonia (Lavado *et al*., 2012), consistent with reductions in convection and cloudiness in the same region (Arias *et al*., 2011). Recents studies by Donat *et al*. (2013) suggest that heavy rains are increasing in frequency in Amazonia. Regarding seasonal extremes in the Amazon region, two major droughts and three floods have affected the region from 2005 to 2012, although these events have been related to natural climate variability rather than to deforestation (Marengo *et al*., 2008; Espinoza *et al*., 2011; Lewis *et al*., 2011; Espinoza *et al*., 2012; Marengo *et al*., 2012a). On the impacts of land use changes on changes in the climate and hydrology of Amazonia, Zhang *et al*. (2009) suggest that biomass-burning aerosols can work against the seasonal monsoon circulation transition, thus re-inforce the dry season rainfall pattern for Southern Amazonia, while Wang *et al*. (2011) suggests the importance of deforestation and vegetation dynamics on decadal variability of

rainfall in the region. Costa and Pires (2010) have suggested a possible decrease in precipitation due to soybean expansion in Amazonia, mainly as a consequence of its very high albedo.

In the SAMS region in the last 50 or 60 years, positive trends in rainfall extremes have been identified (see Table 27-1). These studies suggest a pattern of increasing frequency and intensity of heavy rainfall events, with a tendency for early onsets and late demise of the rainy season.

Collini *et al*. (2008) and Saulo *et al*. (2010) find the SESA precipitation to be more responsive to changes in soil moisture, and although feedback mechanisms are present at all scales, the atmosphere influence is more significant at large scales. Moreover, land use change studies in the Brazilian southern Amazonia for the last decades showed that the impact on the hydrological response is time lagged at larger scales (Rodriguez *et al*., 2010)

27.2.1.2. Climate Projections

Since the AR4, substantial additional regional analysis has been carried out using the CMIP3 model ensemble. In addition, projections from CMIP5 models, and new experiences using regional models (downscaling) have allowed for a better description of future changes in climate and extremes in CA and SA. Using CMIP3 and CMIP5 models, Giorgi (2006), Diffenbaugh *et al*. (2008), Xu *et al*. (2009) and Diffenbaugh and Giorgi (2012) have identified areas of CA/western North America and the Amazon as persistent regional climate change hotspots throughout the 21st century of the RCP8.5 and RCP4.5. Table 27-2 summarizes projected climatic changes derived from global and regional models for the region, indicating the projected change, models, emission scenarios, time spans and references.

[INSERT TABLE 27-2 HERE
Table 27-2: Regional projected changes in temperature, precipitation, and climate extremes in different sectors of CA and SA. Various studies used A2 and B2 scenarios from CMIP3 and various RCPs scenarios for CMIP5, and different time slices from 2010 to 2100. In order to make results comparable, the CMIP3 and CMIP5 at the time slice ending in 2100 are included. Additional information on changes in projected extremes can be found in the IPCC SREX (see IPCC, 2012), and WG1 AR5 Chapter 9 and 14 [9.5, 9.6 and 14.2, 14.7]]

In CA and Northern Venezuela, projections from CMIP3 models and from downscaling expriments suggest precipitation reductions and warming together with an increase in evaporation, and reductions in soil moisture for most of the land during all seasons by the end of the 21th century (see references in Table 27-2). However, the spread of projections is high for future precipitation.

Analyses from global and regional models in tropical and subtropical SA show common patterns of projected climate in some sectors of the continent. Projections from CMIP3 regional and high resolution global models show by the end of the 21st century for a high emission scenario A2, a consistent pattern of increase of precipitation in SESA, Northwest of Peru and Ecuador and western Amazonia, while decreases are projected for northern SA, Eastern Amazonia, central eastern Brazil, NEB, the Altiplano and southern Chile (see references in Table 27-2). For some regions, projections show mixed results in rainfall projections, for the Amazonia and the SA monsoon region (see references in Table 27-2).

As for extremes, CMIP3 models and downscaling experiments show increases in dry spells are projected for Eastern Amazonia and NEB, while rainfall extremes are projected to increase in SESA, in western Amazonia, Northwest Peru and Ecuador, while over southern Amazonia, northeastern Brazil and eastern Amazonia, the maximum number of consecutive dry days tends to augment, suggesting a longer dry season. Increases in warm nights throughout SA are also rojected by the end of the 21st century (see references in Table 27-2). Shiogama *et al*. (2011) suggest that although the CMIP3 ensemble mean assessment suggested wetting across most of SA, the observational constraints indicate a higher probability of drying in the eastern Amazon basin.

The CMIP5 models project an even larger expansion of the monsoon regions in NAMS and SAMS in the future scenarios (Kitoh *et al*., 2012; Jones and Carvalho, 2013). A comparison from eight models from CMIP3 and CMIP5

identifies some improvements in the new generation models. For example, CMIP5 inter-model variability of temperature in summer was lower over northeastern Argentina, Paraguay and northern Brazil, in the last decades of the 21st century, as compared to CMIP3. Although no major differences were observed in both precipitation datasets, CMIP5 inter-model variability was lower over northern and eastern Brazil in summer by 2100 (Blázquez and Nuñez, 2012).

The projections from the CMIP5 models at regional level for CA and SA (using the same regions from the IPCC SREX) are shown in Figure 27-1, and update some of these previous projections based on SRES A2 and B2 emission scenarios from CMIP3. Figure 27-1 shows that in relation to the baseline period 1986-2005, for CA and northern South America-Amazonia, temperatures are projected to increase approximately by 1.8 °C and 3 °C for the RCP4.5 scenario, and by 4 C and 5 °C for the RCP8.5 scenario. For the rest of South America, increases by about 1.8 to 2 °C are projected for the RCP4.5 and by about 4 C to 5 C for the RCP8.5 scenario. The observed records show increases of temperature from 1900 to 1986 by about 1 °C. For precipitation, while for CA and northern South America-Amazonia precipitation is projected to decrease by about 10% (with large spread among models). For Northeast Brazil, there is a spread among models between +20 to -20% making hard to identify any projected change. This spread is much lower in the western coast of South America and SESA, where the spread is between +10 and -10%, and in SESA, the tendency is for an increase of precipitation that may reach 30%.

[INSERT FIGURE 27-1 HERE
Figure 27-1: Observed and simulated variations in past and projected future annual average temperature over land areas of the Central and South American "SREX regions". Black lines show several estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (68 simulations), historical changes in "natural" drivers only (30), the "RCP4.5" emissions scenario (68), and the "RCP8.5" (68). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.]

27.2.2. Non-Climatic Stressors

27.2.2.1. Trends and Projections in Land Use and Land Use Change

Land use and land cover change are key drivers of environmental change for the region with significant impacts that may increase the potential negative impacts from climate change (Sampaio *et al*., 2007; Lopez-Rodriguez and Blanco-Libreros, 2008). The high levels of deforestation observed in most of the countries have been widely discussed in the literature as a deliberate development strategy based on the expansion of agriculture to satisfy the growing world demand for food, energy and minerals (Benhin, 2006; Grau and Aide, 2008; Mueller *et al*., 2008). Land is facing increasing pressure from competing uses, among them cattle ranching, food and bioenergy production. The enhanced competition for land increases the risk of land use changes, which may lead to negative environmental and socio-economic impacts. Agricultural expansion has relied in many cases on government subsidies, which have often resulted in lower land productivity and more land speculation (Bulte *et al*., 2007; Roebeling and Hendrix, 2010). Some of the most affected areas due to the expansion of the agricultural frontier are fragile ecosystems such as the edges of the Amazon forest in Brazil, Colombia, Ecuador and Peru, and the tropical Andes, where activities such as deforestation, agriculture, cattle ranching and gold mining are causing severe environmental degradation (ECLAC, 2010d), and the reduction of environmental services provided by these ecosystems.

Deforestation rates for the region remain high in spite of a reducing trend in the last decade (Ramankutty *et al*., 2007; Fearnside, 2008). Brazil is by far the country with the highest area of forest loss in the world according to the latest FAO statistics (2010): 21,940 km² per year -39% of world deforestation for the period 2005-2010. Bolivia, Venezuela and Argentina follow in deforested area (Figure 27-2) with all four countries accounting for 54% of the forest loss in the world for the same period. The countries of CA and SA lost a total of 38,300 km² of forest per year in that period (69% of the total world deforestation) (FAO, 2010). These numbers are limited by the fact that many countries do not have comparable information through time, particularly for recent years.

[INSERT FIGURE 27-2 HERE
Figure 27-2: Area deforested per year for selected countries in CA and SA (2005-2010). Notice three countries listed with a positive change in forest cover (based on data from FAO, 2010).]

Deforestation in the Amazon forest has received much international attention in the last decades, both because of its high rates, and its rich biodiversity. Brazilian Legal Amazon is now one of the best-monitored ecosystems in terms of deforestation since 1988 (INPE, 2011; see Figure 27-3). Deforestation rates for this region peaked in 2004 and have steadily declined since then currently exhibiting the lowest rates during the entire record. Such reduction results from a series of integrated policies to control illegal deforestation particularly enforcing protected areas, which now shelter 54% of the remaining forests of the Brazilian Amazon (Soares-Filho *et al.*, 2010). Deforestation in Brazilian Amazon for the period 2005-2010 accounted for 41% of the total deforestation for that country and showed the lowest rate for all forest biomes in Brazil (0.29%), with the Cerrado forest (drier ecosystem south of Amazon) presenting the forest biome with the highest deforestation rates (1.33%), accounting for 37% of Brazil's total deforestation (FAO, 2009).

[INSERT FIGURE 27-3 HERE
Figure 27-3: Deforestation rates in the Brazilian Amazonia (km^2/year) based on measurements by the PRODES INPE project (see also INPE, 2011).]

The amount of forest loss in CA is considerably less than in SA, owing to smaller country sizes. When deforestation rates are considered, Honduras and Nicaragua show the highest values for the area (Carr *et al.*, 2009). At the same time, CA includes three countries where forest cover shows a recovery trend in the last years: Costa Rica, El Salvador and Panama. This forest transition is the result of: (1) economies less dependent on agriculture, and more on industry and services (Wright and Samaniego, 2008); (2) processes of international migration with the associated remittances (Hecht and Saatchi, 2007), and (3) a stronger emphasis on the recognition of environmental services of forest ecosystems (Kaimowitz, 2008). The same positive trend is observed in some SA countries (Figure 27-2). However, a substantial amount of forest is gained through (single-crop) plantations, most noticeably in Chile (Aguayo *et al.*, 2009), which has a much lower ecological value than natural forests (Izquierdo *et al.*, 2008).

Land degradation, is also an important process compromising extensive areas of CA and SA very rapidly. According to data from the Global Land Degradation Assessment and Improvement (GLADA) project of the Global Environmental Facility (GEF), additional degraded areas reached 16.4% of the entire territory of Paraguay, 15.3% of Peru and 14.2% of Ecuador for the period 1982-2002. In CA, Guatemala shows the highest proportion of degraded land, currently at 58.9% of the country's territory, followed by Honduras (38.4%) and Costa Rica (29.5%); only El Salvador shows a reversal of the land degradation process, probably due to eased land exploitation following intensive migratory processes (ECLAC, 2010d).

Deforestation and land degradation are mainly attributed to increased extensive and intensive agriculture. Two activities have traditionally dominated the agricultural expansion: soy production (only in SA) and beef; but more recently, biomass for biofuel production has become as important (Nepstad and Stickler, 2008) with some regions also affected by oil and mining extractions. Deforestation by small farmers, mainly coming from families who migrate in search for land and using shifting agriculture techniques is relatively low. In this line, Oliveira *et al.* (2007) found that only 9% of the deforestation in the Peruvian Amazon between 1999 and 2005 happened in indigenous territories. Pasture for livestock production is the predominant land use in deforested areas of tropical and subtropical Latin America (Wassenaar *et al.*, 2007). More than 2/3 of the total deforested areas in Colombia (Etter *et al.*, 2006) and in the Brazilian Amazon (Nepstad *et al.*, 2006) are converted to cattle ranching. Forest conversion to pasture for livestock is also the major land use change driver in eastern Bolivia (Killeen *et al.*, 2008).

In recent years, soybean croplands have expanded continuously in SA, becoming increasingly more important in the agricultural production of the region. Soybean-planted area in Amazonian states (mainly Mato Grosso) in Brazil expanded 12.1% per year during the 1990s, and 16.8% per year from 2000 to 2005 (Costa *et al.*, 2007). This landscape-scale conversion from forest to soy and other large-scale agriculture can alter substantially the water

balance for large areas of the region resulting in important feedbacks to the local climate (Hayhoe *et al.*, 2011; Loarie *et al.*, 2011) (see section 27.3.4.1).

Soybean and beef production have also impacted other ecosystems next to the Amazon, such as the Cerrado (Brazil) and the Chaco dry forests (Bolivia, Paraguay, Argentina and Brazil). Gasparri *et al.* (2008) estimated carbon emissions from deforestation in Northern Argentina and concluded that deforestation in the Chaco forest has accelerated in the past decade from agricultural expansion and is now the most important source of carbon emission for that region. In northwest Argentina (Tucumán and Salta provinces) 1.4 Mha of dry forest were cleared from 1972 to 2007 as a result of technological improvements and increasing rainfall (Gasparri and Grau, 2009). Deforestation continued during the 1980s and 1990s resulting in cropland area covering up to 63% of the region by 2005 (Viglizzo *et al.*, 2011). In central Argentina (northern Córdoba province), cultivated lands have increased from 3% to 30% (between 1969 and 1999); and the forest cover has decreased from 52.5% to 8.2%. This change has also been attributed to the synergistic effect of climatic, socioeconomic, and technological factors (Zak *et al.*, 2008). Losses in the Atlantic forest are estimated in 29% of the original area in 1960, and in 28% of the Yunga forest area, mainly due to cattle ranching migration from the Pampas and Espinal (Viglizzo *et al.*, 2011).

Oil palm is a significant biofuel crop also linked to recent deforestation in tropical CA and SA. Its magnitude is still small compared with deforestation related to soybean and cattle ranching, but it is considerable for specific countries and expected to increase due to increasing demands for biofuels (Fitzherbert *et al.*, 2008). The main forest regions where oil palm has recently expanded are the Chocó region in Colombia and the Sucumbios region of Ecuador. Oil palm production is also important in Brazil (with 75% of the area planted in the state of Bahia) and emerging in the Amazonian region of Peru, where 72% of new plantations have expanded into forested areas (Gutiérrez-Vélez *et al.*, 2011).

However, forests are not the only important ecosystems threatened in the region. An assessment of threatened ecosystems in SA by Jarvis *et al.* (2010) concluded that grasslands, savannas and shrublands are more threatened than forests, mainly from fires and grazing pressure. An estimation of burned land in Latin America by Chuvieco *et al.* (2008) also concluded that, proportionally, the most affected ecosystems were the savannas of Colombia and Venezuela. In the Río de la Plata region (Central-East Argentina, southern Brazil, and Uruguay), grasslands decreased from 67.4% to 61.4% between 1985 and 2004. This reduction was associated with an increase in annual crops, mainly soybean, sunflower, wheat, and maize (Baldi and Paruelo, 2008).

Even with technological changes that might result in agricultural intensification, the expansion of pastures and croplands is expected to continue in the coming years (Wassenaar *et al.*, 2007; Kaimowitz and Angelsen, 2008), particularly fom an increasing global demand for food and biofuels (Gregg and Smith, 2010) with the consequent increase in commodity prices. This agricultural expansion will be mainly in Latin America and Sub-Saharan Africa as these regions hold two-thirds of the global land with potential to expand cultivation (Nepstad and Stickler, 2008). It is important to consider enforceable policy and legal reforms to keep this process of large-scale change under control as much as possible; these reforms should aim to reduce the impact on poor households who depend directly on the natural resources being depleted (Takasaki, 2007). Indigenous groups require particular attention in this respect; there is a growing acknowledgment that recognizing the land ownership and authority of indigenous groups can help central governments to better manage many of the natural areas remaining in the region (Oltremari and Jackson, 2006; Larson, 2010). Many indigenous groups are important drivers of land use change in the region and their well-being should be considered when designing responses to pressures on the land by a globalized economy (Gray *et al.*, 2008; Killeen *et al.*, 2008).

27.2.2.2. Trends and Projections in Socioeconomic Conditions

Development in the region has traditionally displayed four characteristics: low growth rates, high volatility, structural heterogeneity and a very unequal income distribution (ECLAC, 2008; Bárcena, 2010). This combination of factors has generated high and persistent poverty levels (45% for CA and 30% for SA for year 2010), with the rate of poverty being generally higher in rural than urban areas (ECLAC, 2009c). SA has based its economic growth in natural resource exploitation (mining, energy, agricultural), which involves direct and intensive use of land and

water, and in energy-intensive and, in many cases, highly polluting natural-resource-based manufactures. In turn, CA has exploited its proximity to the North American market and its relatively low labor costs (ECLAC, 2010e). The region shows a marked structural heterogeneity, where modern production structures coexist with large segments of the population with low productivity and income levels (ECLAC, 2010g). The GDP per capita in SA is twice that of CA; in addition, in the latter poverty is 50% higher (see Figure 27-4).

[INSERT FIGURE 27-4 HERE
Figure 27-4: Evolution of GDP per capita and poverty (income below US$ 2 per day) from 1990-2011: CA and SA (US-Dollars per inhabitant at 2005 prices and percentages) (ECLAC on the basis of CEPALSTAT (2012)and ECLAC (2011c))]

The 2008 financial crisis reached CA and SA through exports and credits, remittances and worsening expectations by consumers and producers (Bárcena, 2010; Kacef and López-Monti, 2010). This resulted in the sudden stop of six consecutive years of robust growth and improving social indicators, which contributed to higher poverty in 2009 after six years where poverty had declined by 11%. Poverty rates fell from 44% to 33% of the total population, leaving 150 million people in this situation while extreme poverty diminished from 19.4% to 12.9% (which represents slightly more than 70 million people) (ECLAC, 2010e).

In the second half of 2009 industrial production and exports began to recover and yielded a stronger economic performance (GDP growth of 6.4% in SA and 3.9% in CA in 2010) (ECLAC, 2012). SA benefited the most because of the larger size of their domestic markets and the greater diversification of export markets. Conversely, slower growth was observed in CA with more open economies and a less diversified portfolio of trading partners and a greater emphasis on manufacturing trade (ECLAC, 2010g).

The region is expected to continue to grow in the short term, albeit at a pace that is closer to potential GDP growth, helped by internal demand as the middle class becomes stronger and as credit becomes more available. In SA, this could be boosted by external demand from the Asian economies as they continue to grow at a rapid pace. The macroeconomic challenge is to act counter cyclically creating conditions for productive development that is not based solely on commodity exports (ECLAC, 2010f).

In spite of its economic growth, the region still displays high and persistent inequality: most countries have Gini coefficients between 0.5 and 0.6, whereas the equivalent figures in a group of 24 developed countries vary between under 0.25 and around 0.40. The average per capita income of richest 10% of households is approximately 17 times that of the poorest 40% of households. Nevertheless, during the first decade of the century, prior to the financial crisis, the region has shown a slight but clear trend towards a more equitable distriburion of income and a stronger middle class population resulting in a higher demand for goods (ECLAC, 2010g; UN, 2010; ECLAC, 2011b). Latin American countries also reported gains in terms of human development, although these gains have slowed down slightly over recent years. In comparative terms, the performance of countries as measured by the Human Development Index (HDI) varied greatly (from Chile with 0.878 and Argentina with 0.866 to Guatemala -0.704- and Nicaragua -0.699-) although those with lower levels of HDI showed notably higher improvements than countries with the highest HDI (UNDP, 2010).

Associated with inequality are disparities in access to water, sanitation and adequate housing for the most vulnerable groups - for example indigenous peoples, Afro-descendants, children and women living in poverty- and in their exposure to the effects of climate change. The strong heterogeneity of subnational territorial entities in the region takes the form of high spatial concentration and persistent disparities in the territorial distribution of wealth (ECLAC, 2010g; UN, 2010; ECLAC, 2011b).

The region faces significant challenges in terms of environmental sustainability and adaptability to a changing climate (UN, 2010), reflecting the specific characteristics of its population and economy already discussed and added to a significant deficit in infrastructure development. The stakeholders - the State, private sector and civil society- have made progress in incorporating environmental protection into decision-making processes, and particularly in terms of environmental institutions and legislation. Difficulties, however, remain in effectively mainstreaming the environment into public policies (UN, 2010). While the global economic and financial crises

together with climate change impose new challenges, they also provide an opportunity to shift development and growth patterns towards a more environmentally friendly economy.

27.3. Impacts, Vulnerabilities, and Adaptation Practices

27.3.1. Freshwater Resources

CA and SA are regions with a high average but unevenly distributed water resources availability (Magrin *et al.*, 2007a). The main user of water is agriculture, accounting for 70% of all withdrawals used to feed more than 20 Mha of irrigated land (14% of the world's total cultivated area) (ECLAC *et al.*, 2010). The second use is composed by the region's 580 million inhabitants (including the Caribbean), of which 86% had access to water supply by 2006 (ECLAC, 2010b), although in rural areas only 51% of the population have access to those services. In terms of non-consumptive water uses, according to the International Energy Agency (IEA), the region meets 60% of its electricity demand through hydropower generation, which contrast with the 20% average contribution of other regions (see case study 27.6.1).

27.3.1.1. Observed and Projected Impacts

In CA and SA there are many evidences of changing conditions in terms of hydro-geophysical variables (cryosphere and runoff) that affect streamflow and finally water availability.

The most robust trend for major rivers is found in the sub-basins of the La Plata River basin (***high agreement, robust evidence***). This basin, second only to the Amazon in size, and third in streamflow (21,500 m^3/s) (Pasquini and Depetris, 2007), shows a positive trend in streamflow in the second half of the 20th century at different sites (Pasquini and Depetris, 2007; Krepper *et al.*, 2008; Saurral *et al.*, 2008; Amsler and Drago, 2009; Conway and Mahé, 2009; Dai *et al.*, 2009; Krepper and Zucarelli, 2010a; Dai, 2011; Doyle and Barros, 2011). An increase in precipitation and a reduction in evapotranspiration from land use changes have been associated with the trend in streamflows (Saurral *et al.*, 2008; Doyle and Barros, 2011), with the former being more important in the southern sub-basins and the latter in the northern ones (Doyle and Barros, 2011) (see section 27.2.1). Increasing trends in streamflows have also been found in the Laguna Mar Chiquita (a closed lake), and in the Santa Fe Province, both in Argentina, with ecological and erosive consequences (Pasquini *et al.*, 2006; Rodrigues Capítulo *et al.*, 2010; Troin *et al.*, 2010; Venencio and García, 2011; Bucher and Curto, 2012). The effect of reservoirs on changing hydrologic conditions has been reported for the San Francisco River basin in Northeast Brazil (Andrade e Santos *et al.*, 2012; Genz and Luz, 2012).

There is no clear long-term trend for the Amazon River, owing to its strong interannual and decadal variability. Extremely low levels were experienced during the droughts of 2005 and 2010, while record high levels for the same rivers were detected during the 2009 and 2012 floods (see section 27.2.1). Espinoza *et al.* (2009a; 2011) showed that the 1974-2004 apparent stability in mean discharge at the main stem of the Amazon in Obidos is explained by opposing regional features of Andean rivers (e.g. increasing trends in the Peruvian Amazons, Lavado *et al.*, 2012) (see section 27.2.1). Major Colombian rivers draining to the Caribbean Sea (Magdalena and Cauca) exhibit decreasing trends along their main channels (Carmona and Poveda, 2011), while significant trends are absent for all other major large rivers in the Brazilian North East, and northern SA (Dai *et al.*, 2009). The only study done for rivers in CA is that of Dai (2011) who showed a drying trend in this region.

Water resources are threatened by the rapid retreat and melting of the Andean cryosphere, which has been further reported following the IPCC AR4, through diverse techniques such as aereal photography, satellite imagery, ice coring, and lichens in the tropical glaciers of Venezuela, Colombia, Ecuador, Peru and Bolivia (see reviews in Vuille *et al.*, 2008a ; Jomelli *et al.*, 2009; Bradley *et al.*, 2009; Poveda and Pineda, 2009; Rabatel *et al.*, 2012) and specific papers in Table 27-3a). A synthesis of the studies recognizes with ***high confidence*** (based on ***high agreement, and robust evidence***) that tropical glaciers' retreat has accelerated since the middle of the 20th century (Table 27-3a). In early stages of glacier retreat runoff tends to increase due to an acceleration of glacier melt, but after a peak in

discharge as the glacierized water reservoir gradually empties, runoff tends to decrease, as evidenced in the Cordillera Blanca of Peru (Chevallier *et al*., 2011; Baraer *et al*., 2012), where seven out nine river basins have probably crossed a critical threshold, exhibiting a decreasing dry-season discharge (Baraer *et al*., 2012). In general, runoff tends to decrease during the period in the year when precipitation is at its lowest level. Likewise, glaciers and icefields in the extra tropical Andes located in Central-South Chile and Argentina face significant reductions (see Table 27-3b), with their effect being compounded by changes in snowpack extent, thus magnifying changes in hydrograph seasonality by reducing flows in dry seasons and increasing them in wet seasons.

[INSERT TABLE 27-3 HERE
Table 27-3: Observed trends related to Andean cryosphere.
a) Andean tropical glacier trends since the Little Ice Age (LIA) maximum and, particularly, during the last decades
b) Extra tropical Andean cryposphere (glaciers, snowpack, runoff effects) trends]

Some regions in Central-South Chile and Argentina also face significant reductions in precipitation (section 27.2.1), which has contributed to runoff reductions in the last decades of the 20th century (Seoane and López, 2007; Rubio-Álvarez and McPhee, 2010; Urrutia *et al*., 2011), contrasted with long-term trends found through dendrochronology (Lara *et al*., 2007; Urrutia *et al*., 2011). Trends in precipitation and runoff are less evident in the Central-North region in Chile (Fiebig-Wittmaack *et al*., 2012; Souvignet *et al*., 2012).

Assessment on future impacts (see Table 27-4) show a large range of uncertainty across the spectrum of climate models. It is hard to make conclusive statements in terms of trends on some particular regions/rivers. Nohara *et al*. (2006) studied climate change impacts on 24 of the main rivers in the world (considering an uncertainty analysis driven by use of 19 GCMs), and found no robust change for the Paraná (La Plata Basin) and Amazon Rivers. Nevertheless, in both cases the average change showed a positive value consistent at least with observations for the La Plata Basin. On top of such climatic uncertainty, future streamflows and water availability projections are confounded by the potential effects of deforestation (Moore *et al*., 2007; Coe *et al*., 2009).

[INSERT TABLE 27-4 HERE
Table 27-4: Synthesis of projected climate change impacts on hydrologic variables in large South American basins and major glaciers.]

CA shows a consistent runoff reduction, Maurer *et al*. (2009) studied climate change projections for the Lempa River basin, one of the largest basins in CA, covering portions of Guatemala, Honduras and El Salvador. They showed that future climate projections imply a reduction of 20% in inflows to major reservoirs in this system (see Table 27-4). Imbach *et al*. (2012) found similar results using a modeling approach that also considered potential changes in vegetation. These effects could have large hydropower generation implications as discussed in the case study (see section 27.6.1).

Since the AR4 several studies have been developed to associate future climate scenarios with the evolution of glaciers, especially in the tropical Andes. Juen *et al*. (2007) and Chevallier *et al*. (2011) developed "regression" type of analysis relating glacier evolution (manifested as downstream streamflow) to changes in temperature. Similarly, Poveda and Pineda (2009) performed linear extrapolations on historic glacier retreat rates to estimate the fate of the six remaining glaciers in Colombia. In general, these studies indicate that glaciers may continue their retreat (Vuille *et al*., 2008a) as glacier Equilibrium Line Altitudes rises, with larger hydrological effects during the dry season (Kaser *et al*., 2010; Gascoin *et al*., 2011). This is expected to happen during the next 20-50 years (Juen *et al*., 2007; Chevallier *et al*., 2011) (see Table 27-4). After that period water availability during the dry months is expected to diminish. A forecast, for instance, by Baraer *et al*. (2012) for the Santa River in the Peruvian Andes finds that once the glaciers are completely melt, annual discharge would decrease by 2%–30%, depending on the watershed.

Significant effects are foreseen in the energy balances of the Andes, through changes in temperature and albedo, thus influencing hydrologic regimes. In Central Chile, Vicuña *et al*. (2011) project changes in the seasonality of streamflows of the upper snowmelt-driven watersheds of the Limarí River, associated with temperature increases and reductions in water availability owing to a reduction (increase) in precipitation (evapotranspiration) (see Table 27-4). Similar conclusions are derived across the Andes on the Limay River in Argentina by Seoane and López

(2007). Projected changes in the cryosphere conditions of the Andes could affect the occurrence of extreme events, such as the Glacial-lake outburst floods occurring in the icefields of Patagonia (Dussaillant *et al.*, 2010), volcanic collapse and debris flow associated with accelerated glacial melting in the tropical Andes (Carey, 2005; Carey *et al.*, 2012b; Fraser, 2012), and with volcanoes in southern Chile and Argentina (Tormey, 2010), as well as scenarios of water quality pollution by exposure to contaminants owing to glaciers retreat (Fortner *et al.*, 2011).

27.3.1.2. Vulnerability and Adaptation Practices

Vulnerability for the region considers both 'future/outcome vulnerability' (related to impacts associated with climate change) and 'actual/contextual vulnerability' (depending on social, political, economic, cultural, and institutional factors) (O'Brien *et al.*, 2007). Current highly vulnerable regions include the semi-arid regions in Chile-Argentina and North East Brazil, certain regions in CA, and communities along the tropical Andes.

Semiarid regions are characterized by pronounced climatic variability and often by water scarcity and related social stress (Krol and Bronstert, 2007; Scott *et al.*, 2012). The semiarid regions of Central Chile-Argentina are expected to face streamflow reductions and changes in seasonality, with potentially significant effects on already vulnerable and highly populated regions (e.g. Santiago, Chile) and extensive agriculture irrigation demands (ECLAC, 2009a; Souvignet *et al.*, 2010; Fiebig-Wittmaack *et al.*, 2012). The need to develop special adaptation tools to face the threats of climate change is particularly special for the most vulnerable communities in this region (Young *et al.*, 2010), such as those located in the transition between the semiarid and arid climates (Debels *et al.*, 2009) (see Table 27-4).

Another semiarid region that has been studied thoroughly is the Northeast Brazilian (Hastenrath, 2012). De Mello *et al.* (2008), Gondim *et al.* (2008), Souza *et al.* (2010) and Montenegro and Ragab (2010) have shown that future climate change scenarios would decrease water availability for agriculture irrigation owing to reductions in precipitation and increases in evapotranspiration. Krol and Bronstert (2007) and Krol *et al.* (2006) presented an integrated modeling study that linked projected impacts on water availability for agriculture with economic impacts that could potentially drive full-scale migrations in the Brazilian northeast region.

In CA, Benegas *et al.* (2009), Manuel-Navarrete *et al.* (2007) and Aguilar *et al.* (2009) provide different frameworks to understand vulnerability and adaptation strategies to climate change and variability in urban and rural contexts, although no specific adaptation strategies are suggested.

The retreat of Andean glaciers can exacerbate water resources vulnerability (Bradley *et al.*, 2006; Casassa *et al.*, 2007; Vuille *et al.*, 2008b; Mulligan *et al.*, 2010). Glacier retreat diminishes the mountains' water regulation capacity, making it more expensive and less reliable the supply of water for diverse purposes, as well as for ecosystems integrity (Buytaert *et al.*, 2011). Impacts on economic activities associated with conceptual scenarios of glacier melt reduction have been monetized (Vergara *et al.*, 2007), representing about US$100 million in the case of water supply for Quito, and between US$212 million to US$ 1.5 billion in the case of the Peruvian electricity sector due to losses of hydropower generation (see case study 27.6.1). Andean communities face an important increase in their vulnerability, as documented by Mark *et al.* (2010), Pérez *et al.* (2010) and Buytaert and De Bièvre (2012). Different issues have been addressed in the assessment of adaptation strategies for these communities such as the role of governance and institutions (Young and Lipton, 2006; Lynch, 2012), technology (Carey *et al.*, 2012a), and the dynamics of multiple stressors (McDowell and Hess, 2012).

A series of policies have been developed to reduced vulnerability to climate variability as faced today in different regions and settings of CA and SA. In 1997, Brazil instituted the National Water Resources Policy and created the National Water Resources Management System under the shared responsibility between the States and the Federal government. Key to this new regulation has been the promotion of decentralization and social participation through the creation of National Council of Water Resources and their counterparts in the states, the States Water Resources Councils. The challenges and opportunities dealing with water resources management in Brazil in the face of climate variability and climate change have been well studied (Abers, 2007; Kumler and Lemos, 2008; Medema *et al.*, 2008; Engle *et al.*, 2011; Lorz *et al.*, 2012). Other countries in the region are following similar approaches. In the last five

years, there have been constitutional and legal reforms towards more efficient and effective water resources management and coordination among relevant actors in Honduras, Nicaragua, Ecuador, Peru, Uruguay, Bolivia and Mexico; although in many cases, these innovations have not been completely implemented (Hantke –Domas, 2011). Institutional and governance improvements are required to assure an effective implementation of these adaptation measures (e.g. Halsnæs and Verhagen, 2007; Engle and Lemos, 2010; Lemos *et al*., 2010; Zagonari, 2010; and Pittock, 2011).

The particular experience in Northeast Brazil provides other examples of adaptation strategies. Broad *et al*. (2007) and Sankarasubramanian *et al*. (2009) studied the potential benefits of streamflow forecast in this region as a way to reduce the impacts of climate change and climate variability on water distribution under stress conditions. An historical review and analysis of drought management in this region are provided by Campos and Carvalho (2008). Souza Filho and Brown (2009) studied different water distribution policy scenarios finding that the best option depended on the degree of water scarcity. The study by Nelson and Finan (2009) provides a critical perspective of drought-related policies, arguing that they constitute an example of maladaptation as they do not try to solve the causes of vulnerability and instead undermine resilience. Tompkins *et al*. (2008) are also critical of risk reduction practices in this region because they have fallen short of addressing the fundamental causes of vulnerability needed for efficient longer-term drought management.

Other types of adaptation options that stem from studies on arid and semiarid regions are related to: a) increase in water supply from groundwater pumping (Döll, 2009; Kundzewicz and Döll, 2009; Zagonari, 2010; Burte *et al*., 2011); fog interception practices (Holder, 2006; Klemm *et al*., 2012), and reservoirs and irrigation infraestructure (Fry *et al*., 2010; Vicuña *et al*., 2010; 2012); b) improvements in water demand management associated with increased irrigation efficiency and practices (Geerts *et al*., 2010; Montenegro and Ragab, 2010; Van Oel *et al*., 2010; Bell *et al*., 2011; Jara-Rojas *et al*., 2012), and changes towards less water intensive crops (Montenegro and Ragab, 2010).

Flood management practices also provide a suite of options to deal with actual and future vulnerabilities related to hydrologic extremes, such as the management of ENSO-related events in Peru via participatory (Warner and Oré, 2006) or risk reduction approaches (Khalil *et al*., 2007), the role of land use management (Bathurst *et al*., 2010; 2011; Coe *et al*., 2011), and flood hazard assessment (Mosquera-Machado and Ahmad, 2006).

27.3.2. Terrestrial and Inland Water Systems

27.3.2.1. Observed and Projected Impacts and Vulnerabilities

CA and SA house the largest biological diversity and several of the world's megadiverse countries (Mittermeier *et al*., 1997; Guevara and Laborde, 2008). However, land use change has led to the existence of six biodiversity hotspots, i.e. places with a great species diversity that show high habitat loss and also high levels of species endemism: Mesoamerica, Chocó-Darien-Western Ecuador, Tropical Andes, Central Chile, Brazilian Atlantic forest, and Brazilian Cerrado (Mittermeier *et al*., 2005). Thus, conversion of natural ecosystems is the main proximate cause of biodiversity and ecosystem loss in the region (Ayoo, 2008). Tropical deforestation is the second largest driver of anthropogenic climate change on the planet, adding up to 17%-20% of total greenhouse gas emissions during the 1990s (Gullison *et al*., 2007; Strassburg *et al*., 2010). In parallel, the region has still large extensions of wilderness areas for which the Amazon is the most outstanding example. Nevertheless, some of these areas are precisely the new frontier of economic expansion. For instance, between 1996 and 2005 Brazil deforested about 19,500 km^2 per year, which represented 2% to 5% of global annual CO_2 emissions (Nepstad *et al*., 2009). Between 2005 and 2009, deforestation in the Brazilian Amazon dropped by 36%, which is partly related to the network of protected areas that now covers around 45.6% of the biome in Brazil (Soares-Filho *et al*., 2010). Using LandSHIFT modeling framework for land use change and the IMPACT projections of crop/livestock production, Lapola *et al*. (2011) projected that zero deforestation in the Brazilian Amazon forest by 2020 (and of the Cerrado by 2025) would require either a reduction of 26%–40% in livestock production until 2050 or a doubling of average livestock density from 0.74 to 1.46 head per hectare. Thus, climate change may imply reduction of yields and entail further deforestation.

Local deforestation rates or rising greenhouse gases globally drive changes in the regional SA that during this century might lead the Amazon rainforest into crossing a critical threshold at which a relatively small perturbation can qualitatively alter the state or development of a system (Cox *et al*., 2000; Salazar *et al*., 2007; Sampaio *et al*., 2007; Lenton *et al*., 2008; Nobre and Borma, 2009). Various models are projecting a risk of reduced rainfall and higher temperatures and water stress, that may lead to an abrupt and irreversible replacement of Amazon forests by savanna-like vegetation, under a high emission scenario (A2), from 2050-2060 to 2100 (Betts *et al*., 2004; Cox *et al*., 2004; Salazar *et al*., 2007; Sampaio *et al*., 2007; 2008; Malhi *et al*., 2008; Sitch *et al*., 2008; Malhi *et al*., 2009; Nobre and Borma, 2009; Marengo *et al*., 2011c). The possible 'savannization' or 'die-back' of the Amazon region would potentially have large-scale impacts on climate, biodiversity and people in the region. The possibility of this die-back scenario occurring, however, is still an open issue and the uncertainties are still very high (Rammig *et al*., 2010; Shiogama *et al*., 2011).

Plant species are rapidly declining in CA, SA, Central and West Africa, and Southeast Asia (Bradshaw *et al*., 2009). Risk estimates of plant species extinction in the Amazon, which do not take into account possible climate change impacts, range from 5%-9% by 2050 with a habitat reduction of 12%-24% (Feeley and Silman, 2009) to 33% by 2030 (Hubbell *et al*., 2008). The highest percentage of rapidly declining amphibian species occurs in CA and SA. Brazil is among the countries with most threatened bird and mammal species (Bradshaw *et al*., 2009).

A similar scenario is found in inland water systems. Among the components of aquatic biodiversity, fish are the best-known organisms (Abell *et al*., 2008) with Brazil accounting for the richest icthyofauna of the planet (Nogueira *et al*., 2010). For instance, the 540 Brazilian small microbasins host 819 fish species with restrict distribution. However, 29% of these microbasins have historically lost more than 70% of their natural vegetation cover and only 26% show a significant overlap with protected areas or indigenous reserves. Moreover, 40% of the microbasins overlap with hydrodams (see 27.6.1 and Chapter 3) or have few protected areas and high rates of habitat loss (Nogueira *et al*., 2010).

The faster and more severe the rate of climate change, the more severe the biological consequences such as species decline (Brook *et al*., 2008). Vertebrate fauna in North and South America is projected to suffer species losses until 2100 of at least 10%, as forecasted in over 80% of the climate projections based on low emissions scenario (Lawler *et al*., 2009). Vertebrate species turnover until 2100 will be as high as 90% in specific areas of CA and the Andes Mountains for emission scenarios varying from low B1 to mid-high A2 (Lawler *et al*., 2009). Elevational specialists, i.e. a small proportion of species with small geographic ranges restricted to high mountains, are most frequent in the Americas (e.g. Andes and Sierra Madre) and might be particularly vulnerable to global warming because of their small geographic ranges and high energetic and area requirements, particularly birds and mammals (Laurance *et al*., 2011). In Brazil, projections for Atlantic forest birds (Anciães and Peterson, 2006), endemic bird species (Marini *et al*., 2009), and plant species (by 2055, scenarios HHGSDX50 and HHGGAX50; Siqueira and Peterson, 2003) of the Cerrado indicate that distribution will dislocate towards the South and Southeast, precisely where fragmentation and habitat loss are worse. Global climate change is also predicted to increase negative impacts worldwide, including SA, on freshwater fisheries due to alterations in physiology and life histories of fish (Ficke *et al*., 2007).

In addition to climate change impacts at individual species level, biotic interactions will be affected. Modifications in phenology, structure of ecological networks, predator-preys interactions and non-trophic interactions among organisms have been forecasted (Brooker *et al*., 2008; Walther, 2010). The outcome of non-trophic interactions among plants is expected to shift along with variation in climatic parameters, with more facilitative interactions in more stressful environments, and more competitive interactions in more benign environments (Brooker *et al*., 2008; Anthelme *et al*., 2012). These effects are expected to have a strong influence of community and ecosystem (re-) organization given the key engineering role played by plants on the functioning of ecosystems (Callaway, 2007). High Andean ecosystems, especially those within the tropics, are expected to face exceptionally strong warming effects during the 21th century because of their uncommonly high altitude (Bradley *et al*., 2006). At the same time they provide a series of crucial ecosystem services for millions people (Buytaert *et al*., 2011). For these reasons shifts in biotic interactions are expected to have negative consequences on biodiversity and ecosystem services in this region.

Although in the region biodiversity conservation is largely confined to protected areas, with the magnitude of climatic changes projected for the century, it is expected that many species and vegetational types will lose representativeness inside such protected areas (Heller and Zavaleta, 2009).

27.3.2.2. Adaptation Practices

The sub-set of practices that are multi-sectoral, multi-scale, and based on the premise that ecosystem services reduce the vulnerability of society to climate change are known as Ecosystem-based Adaptation (EbA) (Vignola *et al.*, 2009; see also Glossary). Schemes such as the payment for environmental services (PES) and community management fit the concept of EbA that begins to spread in CA and SA (Vignola *et al.*, 2009). The principle behind these schemes is the valuation of ecosystem services that should reflect both the economic and cultural benefits derived from the human-ecosystem interaction and the capacity of ecosystems to secure the flow of these benefits in the future (Abson and Termansen, 2011).

Since PES schemes have developed more commonly in CA and SA than in other parts of the world (Balvanera *et al.*, 2012), this topic will be covered as a case study (see 27.6.2 in this Chapter).

Ecological restoration can be an important tool for adaptation. A meta-analysis of 89 studies by Benayas *et al.* (2009) (with timescale of restoration varying from <5 to 300 years), including many in SA, showed that ecological restoration enhances the provision of biodiversity and environmental services by 44% and 25%, respectively, as compared to degraded systems (Benayas *et al.*, 2009) Moreover, ecological restoration increases the potential for carbon sequestration and promotes community organization, economic activities and livelihoods in rural areas (Chazdon, 2008), as seen in examples of the Brazilian Atlantic Forest (Calmon *et al.*, 2011; Rodrigues *et al.*, 2011). Chazdon *et al.* (2009) also highlight the potential of restoration efforts to build ecological corridors (see Harvey *et al.*, 2008, for example in Central America).

Community management of natural areas is another efficient tool to adapt to climate change and to reconcile biodiversity conservation with socio-economic development. Porter-Bolland *et al.* (2012) compared protected areas with areas under community management in different parts of the tropical world, including CA and SA, and found that protected areas have higher deforestation rates than areas with community management. Similarly, Nelson and Chomitz (2011) found for the region that (i) protected areas of restricted use reduced fire substantially, but multi-use protected areas are even more effective; and that (ii) in indigenous reserves the incidence of forest fire was reduced by 16% as compared to non-protected areas. This somehow contrasts with the findings of Miteva *et al.* (2012) that found protected areas more efficient in constraining deforestation than other schemes. Other good examples of adaptive community management in the continent include community forest concessions (e.g., Guatemala; Radachowsky *et al.*, 2012), multiple-use management of forests (Guariguata *et al.*, 2012 ; see also examples in Brazil – Klimas *et al.*, 2012, Soriano *et al.*, 2012, and Bolívia – Cronckleton *et al.*, 2012); and local communities where research and monitoring protocols are in place to pay the communities for collecting primary scientific data (Luzar *et al.*, 2011).

27.3.3. Coastal Systems and Low-Lying Areas

27.3.3.1. Observed and Projected Impacts and Vulnerabilities

Climate change is altering coastal and marine ecosystems (Hoegh-Guldberg and Bruno, 2010). Coral reefs, seagrass beds, mangroves, rocky reefs and shelves, and seamounts have few to no areas left in the world that remain unaffected by human influence (Halpern *et al.*, 2008). Anthropogenic drivers associated with climate change decreased ocean productivity, altered food web dynamics, reduced abundance of habitat-forming species, shifting species distributions, and greater incidence of disease (Hoegh-Guldberg and Bruno, 2010). Coastal and marine impacts and vulnerability are often associated with collateral effects of climate change such as sea-level rise, ocean warming and ocean acidification. Overfishing, habitat pollution and destruction, and the invasion of species also negatively impact biodiversity and the delivery of ecosystem services (Guarderas *et al.*, 2008; Halpern *et al.*, 2008).

Such negative impacts lead to losses that pose significant challenges and costs for societies, particularly in developing countries (Hoegh-Guldberg and Bruno, 2010). For instance, the Ocean Health Index (Halpern *et al.*, 2012) that measures how healthy the coupling of the human-ocean system is for every coastal country (including parameters related to climate change), indicates that CA countries rank amongst the lowest values. For SA, Suriname stands out with one of the highest scores.

Since the coastal states of Latin America and the Caribbean have a human population of more than 610 million, 3/4 of whom live within 200 km of the coast, marine ecosystems have been undergoing significant transformations (Guarderas *et al.*, 2008). Fish stocks, places for recreation and tourism, and controls of pests and pathogens are all under threat (Guarderas *et al.*, 2008; Mora, 2008). Moreover, changes over 2 mm yr^{-1} of sea-level rise have been found in CA and SA. The Western equatorial border, influenced by the ENSO phenomenon, shows a lower variation (of about 1 mm yr^{-1}) and a range of variation under El Niño events of the same order of magnitude that the sustained past changes. The distribution of population is a crucial factor for inundation impact, with coastal areas being non-homogeneously impacted. A scenario of 1m SLR would affect some coastal populations in Brazil and the Caribbean islands (see Figure 27-5). (ECLAC, 2011a)

[INSERT FIGURE 27-5 HERE
Figure 27-5: Current and predicted coastal impacts and coastal dynamics in response to climate change (elaborated by Iñigo Losada, ECLAC)]

The greatest flooding levels (hurricanes not considered) in the region are found in Rio de La Plata area, which combine a 5 mm yr^{-1} change in storm surge with SLR changes in extreme flooding levels (ECLAC, 2011a). Extreme flooding events may become more frequent since return periods are decreasing, and urban coastal areas in the eastern coast will be particularly affected, while at the same time beach erosion is expected to increase in southern Brazil and in scattered areas at the Pacific coast. (ECLAC, 2011a)

The majority of literature concerning climate change impacts for coastal and marine ecosytems consideres coral reefs, mangroves and fisheres. Coral reefs are particularly sensitive to climate-induced changes in the physical environment (Baker *et al.*, 2008) to an extent that 1/3 of the more than 700 species of reef-building corals worldwide are already threatened with extinction (Carpenter *et al.*, 2008). Coral bleaching and mortality are often associated with ocean warming and acidification (Baker *et al.*, 2008). If extreme sea surface temperatures are to continue, the projections of scenario SRES A1F indicate that it is possible that the Mesoamerican coral reef will collapse by mid-century, causing major economic losses (Vergara *et al.*, 2009). Extreme high sea surface temperatures have been increasingly documented in the western Caribbean near the coast of CA and have resulted in frequent bleaching events (1993, 1998, 2005, and again in 2010) of the Mesoamerican coral reef, located along the coasts of Belize, Honduras and Guatemala (Eakin *et al.*, 2010). Reef but also mangrove ecosystems are estimated to contribute greatly to goods and services in economic terms. In Belize, for example, this amount is approximately US$395-US$559 million annually, primarily through marine-based tourism, fisheries and coastal protection (Cooper *et al.*, 2008). In the Eastern Tropical Pacific, seascape trace abundance of cement and elevated nutrients in upwelled waters are factors that help explain high bioerosion rates of local coral reefs (Manzello *et al.*, 2008). In the southwestern Atlantic coast, eastern Brazilian reefs might suffer a massive coral cover decline in the next 50 years. Francini-Filho *et al.* (2008) pointed out that coral diseases intensified between 2005 and 2007 based on qualitative observations since the 1980s and regular monitoring since 2001. They have also predicted that *Mussismilia braziliensis*- a major reef-building coral species that is endemic in Brazil- will be nearly extinct in less than a century if the current rate of mortality due to disease is not reversed (Francini-Filho *et al.*, 2008).

Mangroves are largely affected by anthropogenic activities whether or not they are climate driven. All mangrove forests, along with important ecosystem goods and services, could be lost in the next 100 years if the present rate of loss continues (1-2% a year) (Duke *et al.*, 2007). Moreover, estimates are that climate change may lead to a maximum global loss of 10–15% of mangrove forest by 2100 (Alongi, 2008). In CA and SA, some of the main drivers of loss are deforestation and land conversion, agriculture and shrimp ponds (Polidoro *et al.*, 2010). The Atlantic and Pacific coasts of CA are some of the most endangered in the planet with regards to mangroves, since approximately 40% of the present mangroves' species are threatened with extinction (Polidoro *et al.*, 2010). Approximately 75% of the mangrove extension of the planet is concentrated in 15 countries, among which Brazil is

included (Giri *et al*., 2011). The rate of survival of original mangroves lies between 12.8% and 47.6% in the Tumaco Bay (Colombia), resulting in ecosystem collapse, fisheries reduction and impacts on livelihoods (Lampis, 2010). Gratiot *et al*. (2008) project for the current decade an increase of mean high water levels of 6 cm followed by 90m shoreline retreat implying flooding of thousands of hectares of mangrove forest along the coast of French Guiana.

Peru and Colombia are two of the eight most vulnerable countries to climate change impacts on fisheries, due to the combined effect of observed and projected warming, the relative importance of fisheries to national economies and diets, and limited societal capacity to adapt to potential impacts and opportunities (Allison *et al*., 2009). Fisheries production systems are already pressured by overfishing, habitat loss, pollution, invasive species, water abstraction and damming (Allison *et al*., 2009). In Brazil, a decadal rate of 0.16 trophic level decline has been detected through most of the northeastern coast, between 1978 and 2000, which is one of the highest rates documented in the world (Freire and Pauly, 2010).

Despite the focus in the literature on corals, mangroves and fisheries, there is evidence that other benthic marine invertebrates that provide key services to reef systems, such as nutrient cycling, water quality regulation, and herbivory, are also threatened by climate change (Przeslawski *et al*., 2008). The same applies for seagrasses for which a worldwide decline has accelerated from a median of 0.9% yr^{-1} before 1940 to 7% yr^{-1} since 1990, which is comparable to rates reported for mangroves, coral reefs, tropical rainforests and place seagrass meadows among the most threatened ecosystems on earth (Waycott *et al*., 2009).

A major challenge of particular relevance at local and global scales will be to understand how these physical changes will impact the biological environment of the ocean (e.g., Gutiérrez *et al*., 2011b), as the Humboldt Current system -flowing along the west coast of SA- is the most productive upwelling system of the world in terms of fish productivity.

27.3.3.2. Adaptation Practices

Designing marine protected areas (MPAs) that are resilient to climate change is a key adaptation strategy in coastal and marine environments (McLeod *et al*., 2009). By 2007, Latin America and the Caribbean (which includes CA and SA countries) had over 700 MPAs established covering around 1.5% of the coastal and shelf waters, most of which allow varying levels of extractive activities (Guarderas *et al*., 2008). This protected area cover, however, is insufficient to preserve important habitats or connectivity among populations at large biogeographic scales (Guarderas *et al*., 2008).

In Brazil, a protected area type known as “Marine Extractive Reserves” currently benefits 60,000 small-scale fishermen along the coast (Moura *et al*., 2009). Examples of fisheries’ co-management, a form of a participatory process envolving local fishermen communities, government, academia and NGOs, are reported to favor a balance between conservation of marine fisheries, coral reefs and mangroves on the one hand (Francini-Filho and Moura, 2008), and the improvement of livelihoods, as well as the cultural survival of traditional populations on the other (Moura *et al*., 2009; Hastings, 2011).

In addition to marine protected areas that include mangroves and functionally linked ecosystems, Gilman *et al*. (2008) list a number of other relevant adaptation practices: coastal planning to facilitate mangrove migration with sea-level rise, management of activities within the catchment that affect long-term trends in the mangrove sediment elevation, better management of non-climate stressors, and the rehabilitation of degraded areas.

Significant financial and human resources are expended annually in the marine reserves to support reef management efforts. These actions, including the creation of marine reserves to protect from overfishing, improvement of watershed management, and protection or replanting of coastal mangroves, are proven tools to improve ecosystem functioning. However, they may also actually increase the thermal tolerance of corals to bleaching stress and thus the associated likelihood of surviving future warming (Carilli *et al*., 2009).

Adaptations to sea level rise involve redirecting new settlements to better-protected locations and to promote investments in appropriate infrastructure. This shall be required in the low elevation coastal zones (LECZ) of the region, particularly in lower income countries with limited resources, which are especially vulnerable. The same applies to countries with high shares of land (e.g., Brazil ranking 7th worldwide of the total land area in the LECZ) and/or population (e.g., Guyana and Suriname rank 2nd and 5th by the share of population in the LECZ, having respectively 76% and 55% of their populations in such areas (McGranahan *et al*., 2007). Adaptation will demand effective and enforceable regulations and economic incentives, all of which require political will as well as financial and human capital (McGranahan *et al*., 2007).

27.3.4. Food Production Systems and Food Security

27.3.4.1. Observed and Projected Impacts and Vulnerabilities

Increases in the global demand for food, forage, fiber and biofuels promoted a sharp increase in agricultural production in SA and CA mainly associated with the expansion of planted areas (see Chapter 7). This trend is predicted to continue since SA accounts for 40% of the global potential arable land (Nellemann *et al*., 2009). Agro-ecosystems are being and will be affected in isolation and synergistically by climate variability/change and land use changes, which are comparable drivers of environmental change. According to projections based on 30 GCMs (under SRES A1B and B1) by the end of 21th century (2070-2099), SA could lose between 1% and 21% of its arable land due to climate change and population growth (Zhang and Cai, 2011).

In the future, SA will face both the great challenge of fulfilling the growing food and biofuels demand and the impact of climate change, trying to preserve natural resources. Although optimal land management could combine efficient agricultural and biofuels production with ecosystem preservation under climate change conditions, current practices are far from optimal, leading to a deterioration of ecosystems throughout the continent (see section 27.3.2). Examples for this are, e.g., in southern Brazilian Amazonia water yields were near four times higher in soy than forested watersheds, and showed greater seasonal variability (Hayhoe *et al*., 2011). In the Argentinas Pampas current land use changes disrupt water and biogeochemical cycles and may result in soil salinization, altered C and N storage, surface runoff and stream acidification (Nosetto *et al*., 2008; Berthrong *et al*., 2009; Farley *et al*., 2009). In central Argentina flood extension was associated with the dynamics of groundwater level that, in turn, has been influenced by precipitation and land use change (Viglizzo *et al*., 2009).

Observed impacts: The SESA region has shown significant increases in precipitation and wetter soil conditions during the 20th century (Giorgi, 2002) (see Table 27-1). Rainfall increases benefited summer crops and pastures productivity, and contributed to a significant expansion of agricultural areas, mainly in climatically marginal regions of Argentina (Barros, 2010; Hoyos *et al*., 2012). Comparing the periods 1930-60 and 1970-2000, maize and soybean yields increased between 9% and 58% in Argentina, Uruguay and South Brazil (Magrin *et al*., 2007b) mainly due to precipitation increases. However, current agricultural production systems, which evolved partially in response to wetter conditions, could be threatened if climate reverts to a drier situation, putting at risk the the viability of continuous agriculture in marginal regions of the Argentina's Pampas (Podestá *et al*., 2009). During the 1930s-1940s, dry and windy conditions together with deforestation, overgrazing, overcropping and non-suitable tillage technology produced devastating results including severe dust storms, cattle mortality, crop failure, farmer bankruptcy and rural migration (Viglizzo and Frank, 2006).

At the global scale, warming since 1981 has reduced wheat, maize and barley productivity, although the impacts were small compared with the technological yield gains over the same period (Lobell and Field, 2007). In central Argentina, simulated potential wheat yield has been decreasing at increasing rates since 1930 (1930-2000: -28 kg/ha/year; 1970-2000: -53 kg/ha/year) in response to increases in minimum temperature during October-November (1930-2000: +0.4°C/decade; 1970-2000: +0.6°C/decade) (Magrin *et al*., 2009). Lobell *et al*. (2011) showed that the observed changes in the growing season temperature and precipitation between 1980 and 2008 have slowed the positive yield trends due to improved genetics in Brazilian wheat, maize and soy, as well as Paraguayan soy. In contrast, rice in Brazil and soybean in Argentina have benefited from precipitation and temperature trends. In

Argentina, increases in soybean yield may be associated with weather types that reduce thermal stress during flowering and pod set stages and favour stability at harvest time (Bettolli *et al*., 2009).

Projected impacts: In SESA climate change could benefit some crops until mid-21st-century if CO_2 effects are considered (see Table 27-5), although interannual and decadal climate variability coul provoke important damages. In Uruguay, productivity could increase steadily until the 2030s-2050s depending on the SRES scenario.(ECLAC, 2010c). In Argentina average yields of soy, maize and wheat could increase or remain almost stable. Increases in temperature and precipitation may benefit crops towards the southern and western zone of the Pampas (Magrin *et al*., 2007c; ECLAC, 2010c). In South Brazil, irrigated rice yield (Walter *et al*., 2010) and bean productivity (Costa *et al*., 2009) is expected to increase. If technological improvement is considered, the productivity of common bean and maize could increase between 40% and 90% (Costa *et al*., 2009). Sugarcane production could benefit as warming could allow the expansion of planted areas towards the south, where low temperatures are a limiting factor (Pinto *et al*., 2008). Increases in crop productivity could reach 6% in São Paulo state towards 2040 (Marin *et al*., 2009). In Paraguay the yields of soybean and wheat could remain almost stable or increase slightly until 2030 (ECLAC, 2010a).

In Chile and western Argentina, yields could be reduced by water limitation. In central Chile (30ºS to 42ºS) temperature increases, reduction in chilling hours and water shortages may reduce productivity of winter crops, fruits, vines and radiata pine. Conversely, rising temperatures, more moderate frosts and more abundant water will *very likely* benefit all species towards the South (Meza and Silva, 2009; ECLAC, 2010a). In northern Patagonia (Argentina) fruit and and vegetable growing could be negatively affected because of a reduction in rainfall and in average flows in the Neuquén River basin. At the same time in the region, in specific in the north of the Mendoza basin, increases in water demand, because of population growth, may compromise the availability of subterranean water for irrigation, pushing up irrigation costs and forcing many producers out of farming towards 2030. Also, water quality could be reduced by the worsening of existing salinization processes (ECLAC, 2010a).

In CA, northeastern Brazil and parts of the Andean region (Table 27-5) climate change could affect crop yields, local economies and food security. Results from 23 GCMs suggest a high probability (>90%) that growing season temperatures in parts of tropical SA, east of the Andes and CA will exceed the extreme seasonal temperatures documented from 1900 to 2006 at the end of this century, affecting regional agricultural productivity and human welfare (Battisti and Naylor, 2009). For NEB, declining crop yields in subsistence crops such as beans, corn and cassava are projected (Lobell *et al*., 2008; Margulis *et al*., 2010). In addition, increases in temperature could reduce the areas currently favorable to cowpea bean (Silva *et al*., 2010). The warming up to 5.8 °C foreseen for 2070 could make the coffee crop unfeasible in Minas Gerais and São Paulo (SE Brazil) if no adaptation action is accomplished. By 2070 the coffee crop may have to be transferred to southern regions where frost risk will be much lower (Camargo, 2010). A Great increases in Arabica coffee production (principally in the Uruguayan border and North of Argentina) are expected in low climatic risks areas with 3ºC increases in mean temperature (Zullo *et al*., 2011). Brazilian potato production could be restricted to a few months in currently warm areas, which today allow potato production all around the year (Lopes *et al*., 2011). Large losses of suitable environments for the “Pequi” tree (*Caryocar brasiliense*; an economically important Cerrado fruit tree) are projected by 2050, mainly affecting the poorest communities in Central Brazil (Nabout *et al*., 2011). Climate change in the Amazon region may also have a critical impact on the yields of commonly cultivated crops. Lapola *et al*. (2011) showed that by 2050 soybean yields would be reduced by 44% in the worst-case scenario (HadCM3 climate and no CO_2 fertilization).

Teixeira *et al*. (2011) identified hot spots for heat stress towards 2071-2100 under the A1B scenario and suggest that rice in South East Brazil, maize in CA and SA, and soybean in Central Brazil will be the crops and zones most affected by increases in temperature.

In CA, warming conditions combined with more variable rainfall are expected to reduce maize, bean and rice productivity endangering the food security of many people and increasing poverty (ECLAC, 2010c) (see Table 26-7). According to Lobell *et al*. (2008), rice and wheat yields could decrease up to 10% by 2030. In Panamá, maize production could modestly increase over the century because of accelerated development helping the grain-filling period to be completed before the worst water stresses occur, although the large interannual climate variations will continue to be the dominant influence on seasonal maize yield into the coming decades (Ruane *et al*., 2011).

One of the uncertainties associated with the impacts of climatic change is the effect of CO_2 on plant physiology. According to DaMatta *et al.* (2010), many crops (such as soybean, common bean, maize and sugarcane) can probably respond with an increasing productivity as a result of higher growth rates and better water use efficiency. However, food quality could decrease due to higher sugar contents in grain and fruits, and decreases in the protein content in cereals and legumes.

Uncertainties associated with climate and crop models, as well as with the uncertainty in human behavior, potentially lead to large error bars on any long-term prediction of food output. However, the trends presented here represent the current available information (see Table 27-5).

[INSERT TABLE 27-5 HERE
Table 27-5: Impacts on agriculture.]

Climate change may also alter the current scenario of plant diseases and their management, having effects on productivity (Ghini *et al*., 2011). In Argentina, years with severe infection of late cycle diseases in soybean could increase; severe outbreaks of the Mal de Rio Cuarto virus in maize could be more frequent; and wheat head fusariosis will increase slightly in the south of the Pampas region, and decrease in the north by the end of the century (ECLAC, 2010a; Martínez *et al*., 2011). Potato late blight (*Phytophtora infestans*) severity is expected to increase in Perú (Giraldo *et al*., 2010). However, there is uncertainty related to how plants will respond to diseases because of a potential increase in plants' photosynthesis and accelerates in their metabolism under the effect of elevated CO_2 and higher temperature (Sage, 2002), possibly offsetting many of the diseases' effects in the future.

The impacts of climate change on livestock production would vary by species and climate scenarios. By 2060, under a hot and dry scenario, beef and dairy cattle, pigs and chickens could decrease between 0.9 and 3.2%, while sheep could increase by 7% mainly in the Andean mountain countries. Dairy cattle could increase only in Uruguay and Argentina. Under a milder and wetter scenario, beef cattle choice declines in Colombia, Ecuador, and Venezuela, but increases in Argentina and Chile. Sheep increase in Colombia and Venezuela, but decrease in the high mountains of Chile where chickens are chosen more frequently Seo *et al.* (2010). Future climate could strongly affect milk production and feed intake in dairy cattle in Brazil. Furthermore, substantial modifications in the Brazilian areas at present suitable for livestock, particularly in the main Pernambuco region are expected (Silva *et al*., 2009).

Climate change impact on regional welfare will depend not only on changes in yield, but also in international trade. By 2030, global cereal price could change between +32% (low-productivity scenario) and -16% (optimistic yield scenario). A rise in prices could benefit net exporting countries like Brazil, where gains from terms of trade shifts could outweigh the losses due to climate change. Despite experiencing significant negative yield shocks, some countries tend to gain from higher commodity prices (Hertel *et al*., 2010). Increases in prices during 2007-2009 led to rising poverty in Nicaragua, but decreasing poverty in Peru (see chapter 7).

27.3.4.2. Adaptation Practices

Genetic advances and suitable soil and technological management may induce an increase in some crops' yield despite unfavorable future climate conditions. In Argentina, genetic techniques, specific scientific knowledge and land-use planning are viewed as promising sources of adaptation (Urcola *et al*., 2010). Adjustments in sowing dates and fertilization rates could reduce negative impacts in maize and wheat crops in Argentina and Chile (Magrin *et al*., 2009; Meza and Silva, 2009; Travasso *et al*., 2009b). Furthermore, in central Chile and southern Pampas in Argentina warmer climates could allow performing two crops per season increasing productivity per unit land (Monzon *et al*., 2007; Meza *et al*., 2008). In Brazil, adaptation strategies for coffee crops include: planting at high densities, vegetated soil, accurate irrigation and breeding programs, and shading management system (arborization) (Camargo, 2010). Shading is also used in Costa Rica and Colombia. In South Brazil, a good option for irrigated rice could be to plant early cultivars (Walter *et al*., 2010).

Several adaptation practices have been oriented towards water management (see section 27.3.1), especially in irrigated crops for a needed better preparedness regarding water scarcity. Adaptive strategies might need to look at the harvest, storage, temporal transfer and efficient use of rainfall water (Quiroga and Gaggioli, 2011). Adaptation to water scarcity can be improved by taking into account a well-known set of agronomic practices like: fallowing, crop sequences, groundwater management, no-till operations, cover-crops and fertilization. Deficit irrigation could be an effective measure for water savings in dry areas such as the Bolivian Altiplano (quinoa), central Brazil (tomatoes) and northern Argentina (cotton) (Geerts and Raes, 2009).

The best way to be prepared to adapt to future climate change is by assisting people to cope with current climate variability (Baethgen, 2010), for which the use of climatic forecasts in agricultural planning presents a measure. Increased access to scientific forecasts, and increased availability of improved forecast information would greatly enhance the ability of the farmers in the Brazilian Amazon to cope with El Niño events (Moran *et al*., 2006). Other climatic indices such as the SOI (Southern Oscilation Index) for maize and the SSTSA (Sea Surface Temperature South Atlantic) for soybean and sunflower were the best indicators of annual crop yield variability in Argentina (Travasso *et al*., 2009a). Another possibility to cope with extreme events, consists in transferring weather-related risks by using different types of rural insurance (Baethgen, 2010). Index insurance is one mechanism that has been recently introduced to overcome obstacles to traditional agricultural and disaster insurance markets (see chapter 15). For the support of such a parametric agricultrual insurance, a Central American climate data base was recently established (CRRH-SICA, 2010).

Local and indigenous knowledge have the potential to bring solutions even in the face of rapidly changing climatic conditions (Folke *et al*., 2002; Alteri and Koohafkan, 2008), Crop diversification is used in the Peruvian Andes to suppress pest outbreaks and dampen pathogen transmission (Lin, 2011). In Honduras, Nicaragua and Guatemala traditional practices such as soil and water conservation, cover cropping, organic fertilizer and integrated pest management have proven more resilient to erosion and runoff and have helped retain more topsoil and moisture during periods of droughts (Holt-Gimenez, 2002). A case study with indigenous farmers in highland Bolivia indicates that constraints on access to key resources must be addressed for reducing vulnerability over time (McDowell and Hess, 2012). Otherwise, adaptation measures may include an orientation towards non-farming activites as was the case for NEB. In that case, vulnerability has been increasing since the late 1990s due mainly to the overuse of natural resources to which smallholders responded with off-farm activities to sustain their livelihoods (Sietz, 2011). In El Salvador, if local sustainability efforts continue the future climate vulnerability index could only slightly increase by 2015 (Aguilar *et al*., 2009).

Shifting in agricultural zoning has been an autonomous adaptation observed in SA. In Argentina e.g., increases in precipitation promoted the expansion of the agricultural frontier to the West and North of the traditional agricultural area, resulting in environmental damage that could be aggrevated in the future (Barros, 2007; República Argentina, 2007). Adjustment of production practices, like farmers in the semi-arid zones of mountain regions of Bolivia have begun as they noticed strong changes in the climate since the 1980s, including upward migration of crops, selection of more resistant varieties and water capturing, presents a further adaptation measure (PNCC, 2007).

Organic systems are highly adaptive to climate change due to the application of traditional skills and farmers' knowledge, soil fertility-building techniques and a high degree of diversity (ITC, 2007). A controversial, but important issue in relation to adaptation is the use of genetically modified plants to produce food, with biotech crops being likely to be key to cope with the needed food productivity increase considiering global population trend (see Chapter 7) Brazil and Argentina are the 2nd and 3rd fastest growing biotech crop producers in the world after the US (Marshall, 2012).

Two of the main challenges to maintain food quality and food security in most regions of the world will be 1) the integration of agriculture based in breeding and biotech with organic strategies and 2) the integration between food and bioenergy production. These two issues have to be addressed by increasing the production of scientific knowledge in agriculture, which according to Nivia *et al*. (2009) in CA and SA is the one that receive the lowest investments when compared to the rest of the world.

27.3.5. Human Settlements, Industry, and Infrastructure

According to the World Bank database (The World Bank, 2012) CA and SA are the geographic regions with the second largest urbanization rate (79%), only behind North America (82%) and clearly above the world average (50%). It is therefore of high relevance the assessment of the literature on climate change impacts and vulnerability of *urban* human settlements in this region as presented in this section. The information provided should be complemented with other sections of the chapter (see 27.2.2.2; 27.3.1; 27.3.3; and 27.3.7)

27.3.5.1. Observed and Projected Impacts and Vulnerabilities

Urban human settlements suffer from many of the vulnerabilities and impacts already presented in several sections of this chapter. The provision of critical resources and services as already discussed in the chapter –water, health and energy– and of adequate infrastructure and housing remain factors of urban vulnerability *likely* to be enhanced by climate change (Smolka and Larangeira, 2008; Winchester, 2008; Roberts, 2009; Romero-Lankao, 2012).

Water resource management for example (see section 27.3.1), is a major concern for many cities in view of both controlling flooding while retaining water for other uses (Henríquez Ruiz, 2009). More than 20% of the population in the region tends to be concentrated in the largest city of each country (The World Bank, 2012), and hence water availability for human consumption in the region's megacities (e.g. São Paulo, Santiago, Lima, Buenos Aires) is of great concern. In this regards, reduction in glacier and snowmelt related runoff in the Andes poses important adaptation challenges for many cities, e.g. the metropolitan areas of Lima, La Paz/El Alto and Santiago de Chile (Bradley *et al*., 2006; Hegglin and Huggel, 2008; Melo *et al*., 2010). The excess of water is also a preoccupation in several cities. In São Paulo for example, according to Marengo *et al*. (2009b; 2012b) the number of days with rainfall above 50 mm were almost absent during the 1950s and now they occur between 2 to 5 times per year (2000-2010). The increase in precipitation is one of the expected vulnerability issues affecting the city of São Paulo as presented in Box 27-1. Increases in flood events during 1980-2000 have been observed also in the Buenos Aires province and Metropolitan Area (Andrade and Scarpati, 2007; Barros *et al*., 2008; Hegglin and Huggel, 2008; Nabel *et al*., 2008). There are also the combined effects of climate change impacts, human settlements' features and other stresses, such as more intense pollution events (Moreno, 2006; Nobre *et al*., 2011; Nobre, 2011; Romero-Lankao *et al*., 2013b) and more intense hydrological cycles from urban heat-island effects.

_____START BOX 27-1 HERE_____

Box 27-1. Vulnerability of South American Megacities to Climate Change: The Case of the Metropolitan Region of São Paulo (MRSP)

Research in the Metropolitan Region of São Paulo (MRSP), between 2009 and 2011, reveals a very comprehensive and interdisciplinary project on the impacts of climate variability and change, and vulnerability of Brazilian megacities. Studies derived from this project (Nobre *et al*., 2011; Marengo *et al*., 2012b) identify the impacts of climate extremes on the occurrence of natural disasters and the impacts on human health. These impacts are linked to a projected increase of 38% in the extension of the urban area of the MRSP by 2030, accompanied by a projected increase in rainfall extremes. These may induce an intensification of urban flash floods and land slides, affecting larges areas of the population that is already vulnerable to climate extremes and variability. The urbanization process in the MRSP has been affecting the local climate, and the intensification of the heat island effect to a certain degree may be responsible for the 2°C warming detected in the city during the last 50 years (Nobre *et al*., 2011). This warming has been further accompanied by an increase in heavy precipitation as well as more frequent warm nights (Marengo *et al*., 2012b; Silva Dias *et al*., 2012). By 2100, climate projections based on data from 1933-2010 show an expected warming between 2-3°C in the MRSP, together with a possible doubling of the number of days with heavy precipitation in comparison to the present (Marengo *et al*., 2012b; Silva Dias *et al*., 2012).

With the projected changes in climate and in the extension of the MRSP (Marengo *et al*., 2012b) more than 20% of the total area of the city could be potentially affected by natural disasters. Related, more frequent floods may increase the risk of leptospirosis, which together with increasing air pollution and worsening environmental

conditions that trigger the risk of respiratory diseases would leave the population of the MRSP more vulnerable. Potential adaptation measures include a set of strategies needed to be developed by the MRSP and its institutions to face environmental changes. Among them are a better building control to avoid construction in risk areas, investment in public transportation, protection of the urban basins and the establishment of forest corridors in the collecting basins and slope regions. The lessons learned suggest that the knowledge on the observed and projected environmental changes, as well as on the vulnerability of populations living in risk areas is of great importance on the definition of adaptation policies as a first step towards improving the quality of life and building resilient cities in Brazil.

_____END BOX 27-1 HERE_____

Changes in prevailing urban climates have led to changing patterns of disease vectors, also water-borne disease issues linked to water availability and subsequent quality (see section 27.3.7). The influence of climate change on particulate matter and other local contaminants is also relevant in this regard (Moreno, 2006). The relationship between the two factors – water and disease – is important to highlight given the on-going problems of water stress, also intense precipitation events. Both give rise to changing disease risks, as well as wider problems of event-related mortalities and morbidity, and infrastructure and property damage. For low-income groups concentrated in settlements with little or no service provision, e.g. waste collection, piped drinking water, sanitation, these risks are compounded (ECLAC, 2008). Existing cases of flooding, air pollution and heat waves reveal that not only low-income groups are at risk, but also that wealthier sectors are not spared. Factors such as high-density settlement (Barros *et al.*, 2008) and the characteristics of some hazards explain this – e.g., poor and wealthy alike are at risk from air pollution and temperature in Santiago de Chile and Bogota (Romero-Lankao *et al.*, 2012; 2013b).

There are also other climate change risks in terms of economic activity location and impacts on urban manufacturing and service workers, e.g. thermal stress (Hsiang, 2010), and the forms of urban expansion or sprawl into areas where ecosystem services may be compromised and risks enhanced, e.g. floodplains. Both processes are also related to rising motorisation rates; the number of light vehicles in Latin America and the Caribbean is expected to double between 2000 and 2030, and be three times the 2000 figure by 2050 (ECLAC, 2009b).

While urban populations face diverse social, political, economic and environmental risks in daily life, climate change adds a new dimension to these risk settings (Pielke Jr *et al.*, 2003; Roberts, 2009; Romero-Lankao and Qin, 2011). Since urban development remains fragile in many cases, with weak planning responses, climate change is *likely* to compound existing challenges. The probabilities and magnitudes of these events in each urban center will differ signigicantly according to socioeconomic, institutional and physical context.

27.3.5.2. Adaptation Practices

Given high regional urbanization rates in CA and SA, the direct (e.g. flooding, heat islands) and indirect effects (e.g. food insecurity, watershed management) of climate change present an urban set of challenges and opportunities for mainstreaming flood management, warning systems and other adaptation responses with sustainability goals (Bradley *et al.*, 2006; Hegglin and Huggel, 2008; Hardoy and Pandiella, 2009; Romero-Lankao, 2012; Romero-Lankao *et al.*, 2013a).

Increasingly the links between adaptation and a wide variety of local development issues are being highlighted and brought into urban and regional planning in SA and CA. These issues include connections with natural hazards and risk assessment, disease transmission, resource availability, land use considerations, poverty linked to vulnerability, and with appropriate governance frameworks. (Barton, 2009; Luque *et al.*, 2013)

Population, economic activities and authorities have a long experience of responding to climate related hazards, particularly through disaster risk management (e.g., Tucuman and San Martin, Argentina (Plaza and Pasculi, 2007; Sayago *et al.*, 2010)) and land use and economic develop planning to a limited extent (Barton, 2009). Climate policies can build on these. Several adaptation plans have been generated over the last five years in São Paulo, Buenos Aires, Quito, Esmeraldas, Santiago and other large cities (Romero-Lankao, 2007b; Carmin *et al.*, 2009;

Romero-Lankao, 2012; Luque *et al*., 2013; Romero-Lankao *et al*., 2013a). Local administrations participate in the ICLEI, C40 and other networks demonstrating their engagement towards climate resilient cities. In smaller settlements, there is lower capacity to respond (e.g., climate change and vulnerability information (Hardoy and Romero-Lankao, 2011). These policies, plans and programs are required to reduce social vulnerability, and identify and reduce potential economic effects of climate on the local economy. Rio de Janeiro, for example, with its coastline property and high dependence on tourists (and their perceptions of risk), cannot ignore these climate related hazards (Gasper *et al*., 2011).

Poverty and vulnerability, as interlinked elements of the adaptation challenge in CA and SA, remain pivotal to understanding urban responses and provoke the need for 'pro-poor' responses that engage with broader development issues and not solely the capacity to respond to climate change (Hardoy and Pandiella, 2009; Winchester and Szalachman, 2009; Hardoy and Romero-Lankao, 2011). These broader links are part of the complexity of defining and operationalizing vulnerability concepts, and the need to develop these alongside more dominant infrastructural responses to adaptation, as with mitigation (Romero-Lankao, 2007a; Romero-Lankao and Qin, 2011). Within these response options, a focus on social assets has been highlighted by Rubin and Rossing (2012), rather than a, purely, physical asset focus.

Much urbanisation involves in-migrating or already resident, low-income groups and their location in risk-prone zones (Costa Fereira *et al*., 2011). The need to consider land use arrangements, particularly risk-prone zones, as part of climate change adaptation have highlighted the role of public space in order to increase vegetation, thus mitigate the heat island effect, also to reduce risks from landslides and flooding (Rodríguez Laredo, 2011).

In the case of governance frameworks, there is clear evidence that incorporation of climate change considerations into wider city planning is still a challenge, as are more inter-sectoral and participative processes that have been linked to more effective policies (Barton, 2009; De Oliveira, 2009; Romero-Lankao *et al*., 2013a). Several metropolitan adaptation plans have been generated over the last five years, although these have been largely restricted to the largest conglomerations, and are included as an addition to principally mitigation plans, e.g. São Paulo and Buenos Aires.

27.3.6. Renewable Energy

27.3.6.1. Observed and Projected Impacts and Vulnerabilities

Table 27-6 shows the relevance of RE in the Latin America energy matrix as compared to the world for 2009 according to the International Energy Agency statistics (IEA, 2012). Hydropower is the most representative source of RE in the region and therefore analyzed separately from this section and all other RE sources (see case study in section 27.6.1.). At the same time, geothermal energy will be not discussed as it is assumed that there is no impact of climate change on the effectiveness of this energy type (Arvizu *et al*., 2011).

[INSERT TABLE 27-6 HERE
Table 27-6: Comparison of consumption of different energetics in Latin America and the world (in thousand tonnes of oil equivalent (ktoe) on a net calorific value basis).]

Lucena *et al*. (2009) demonstrated that hydro and wind energy, as well as biodiesel production might be particularly sensitive to climate change in Brazil. With the vital role that RE plays in mitigating the effects of GCC, this sensitivity translates into the importance of accounting with knowledge on the implementation of RE projects as well as on the crops providing bioenergy, being by far the most important sources of non-hydro RE in SA and CA.

For historical reasons, CA and SA developed sugarcane as bioenergy feedstock, as sugarcane has been considered advantageous for its high sugar contents. Brazil accounts for the most intensive RE production in the form of bioethanol, which is used by 90% of the cars in the country (Goldemberg, 2008) whereas biodiesel comprises 5% of all diesel nationwide. In 2011, countries like Colombia and Chile have started efforts to increase their bioenergy production from sugarcane and eucalyptus, respectively. With the continent's long latitudinal length, the expected

impacts of climate changes on plants are very complex due to a wide variety of climate conditions, imposing the problem of using different crops in different regions. For biodiesel, in Brazil 80% is produced from soybeans, but there are promising new sources such as the African palm dendê (Lucena *et al*., 2009). As mentioned in the section 27.2.2, the development of palm oil as well as soybean are important factors that induce land use change, with a potential to influence stability of forests in certain key regions in SA, such as the Amazon.

Biofuels are promising sources of RE that can help CA and SA to decrease emissions from energy production and use. At the same time, RE might imply potential problems such as those related to positive net emissions of greenhouse gases, threats to biodiversity, an increase in food prices and competition for water resources (see also 27.2.3), some of which can be reverted or attenuated (Koh and Ghazoul, 2008). For example, the sugarcane agro industry in Brazil, besides producing bioethanol, combusts the bagasse to produce electricity, in a process called cogeneration, providing power for the bioethanol industry and increasing sustainability. The excess heat energy is then used to generate bioelectricity, thus allowing the biorefinery to be self-sufficient in energy utilization (Amorim *et al*., 2011; Dias *et al*., 2012). In 2005/2006 the production of bioelectricity was estimated to be 9.2 kWh per ton of sugarcane (Macedo *et al*., 2008), approximately 2% of Brazil's total energy generation production.

Most bioenergy feedstocks at present in production in CA and SA are grasses. In the case of sugarcane, the responses to the elevation of CO_2 concentration up to 720ppmv have been shown to be positive in terms of biomass production and principally regarding water use efficiency (Souza *et al*., 2008).

The production of energy from renewable sources such as hydro- and wind power are greatly dependent on climatic conditions and therefore may be impacted in the future by GCC. The analysis by Lucena *et al*. (2010a), related to liquid biofuels and hydropower, suggests an increasing energy vulnerability of the poorest regions of Brazil to GCC together with a possible negative influence on biofuels production and electricity generation, mainly biodiesel and hydropower respectively.

Expansion of biofuel plantations in Brazil might cause both direct and indirect land use changes (e.g., biofuel plantations replacing rangelands, which previously replaced forests) with the direct land use changes, according to simulation performed by Lapola *et al*. (2010) of the effects for 2020. The same study shows that sugarcane ethanol and biodiesel derived from soybean each contribute with about one half of the indirect deforestation projected for 2020 (121.970 km^2) (Lapola *et al*., 2010). Thus, indirect land use changes, especially those causing the rangeland frontier to move further into the Amazonian forests, might potentially offset carbon savings from biofuels production.

The increase in global ethanol demand, driven by global concern for addressing climate change, is leading to the development of new hydrolytic processes which aim at converting cellulose and hemicelluloses into ethanol (Santos *et al*., 2011). The expected increase in the hydrolysis technologies is *likely* to balance the requirement of land for biomass crops. Thus, the development of these technologies has a strong potential to diminish social (e.g. negative health effects due the burning process, poor labor conditions) and environmental impacts (e.g. loss of biodiversity, water and land uses) whereas at the same time it can improve the economic potential of sugarcane. One adaptation measure will be to increase the productivity of bioenergy crops due to planting in high productivity environments with highly developed technologies, in order to use less land. As one of the main centers of biotech agriculture application in the world (Gruskin, 2012), the region accounts with a great potential to achieve this goal.

As the effects previously reported on crops growing in SESA might prevail (see 27.3.4.1), i.e. that an increase in productivity may happen due to increasing precipitation, future uncertainty will have to be dealt with by preparing adapted varieties of soybean in order to maintain food and biodiesel production, mainly in Argentina as it is one of the main producers of biodiesel from soybean in the world (Chum *et al*., 2011).

Other renewable energy sources—such as wind power generation—may also be vulnerable, raising the need for further research. According to Lucena *et al*. (2009; 2010b) the projections of changes in wind power in Brazil, may not negatively influence the use of this kind of energy in the future.

Minimization of the impact of sugarcane on biodiversity and the environment is expected to improve its sustainability. As the demand for bioethanol increases, improvement of productivity will result in a greater demand of land for sugarcane production. In this context, an expansion of land under sugarcane production is *likely*, especially in Brazil's Central-South region (Lapola *et al*., 2010). However, this region also includes the cerrado (savannah) biome, which requires protection from expanding agriculture (Sawyer, 2008). It is important to ensure the protection of this unique region of Northern Brazil and Colombia as sugarcane grows into a commodity and policy is formed (Sawyer, 2008).

Initiatives such as the soy moratorium in the Amazon have an inhibitory effect over deforestation rates. Rudorff *et al*. (2011) showed that from 2008 to 2010 soybean was planted only on 0.25% of deforested land, which represents 0.027% of the total soybean cover in Brazil. Therefore, increased protection of natural areas in species-rich areas is necessary to preserve biodiversity in the face of these pressures (Brooks *et al*., 2009).

27.3.6.2. Adaptation Practices

RE will, in general, become increasingly more important over time as this is closely related with the emissions of GHG (Fischedick *et al*., 2011). Thus, RE could have an important role as adaptation means to provide sustainable energy for development in the region. However, it has to be noted that the production of RE requires large available areas for agriculture, which is the case of Argentina, Bolivia, Brazil, Chile, Colombia, Peru and Venezuela, that together represent 90% of the total area of CA and SA. However, for small countries it might not be possible to use bioenergy. Instead, they could benefit in the future from other types of RE, such as geothermal, eolic, photovoltaic etc, depending on policies and investment in different technologies. This is important because economic development is thought to be strongly correlated with an increase in energy use (Smil, 2000), which is itself associated with an increase in emissions (Sathaye *et al*., 2011).

Latin America is second to Africa in terms of technical potential for bioenergy production from rain-fed lignocellulosic feedstocks on unprotected grassland and woodlands (Chum *et al*., 2011). Some of the most important adaptation measures regarding RE are: (1) management of land use change (LUC); (2) modeling indirect land use change (ILUC); and (3) development of policies for financing and management of science and technology for all types of RE in the region.

If carefully managed, biofuel crops can be used as a means to regenerate biodiversity as proposed by Buckeridge *et al*. (2012) who pointed the fact that the technology for tropical forest regeneration has become available to the present, and that forests could share land with biofuel crops (such as sugarcane) taking advantage of forests' mitigating potential. A possible adaptation measure could be to expand the use of reforestation technology to other countries in CA and SA.

One of the main adaptation issues is the one of food *vs*. fuel, i. e. the possibility that bioenergy crops would compete for land with food crops (Valentine *et al*., 2012). This issue is important because an uncontrolled increase in bioenergy feedstocks might threaten primary food production in a scenario expected to feed future populations with an increase of 50% to 70% in production (Gruskin, 2012; Valentine *et al*., 2012). This issue is particularly important in the region as it has one of the highest percentages of arable land available for food production in the world (Nellemann *et al*., 2009). As CA and SA develop new strategies to produce more RE in the region, LUC may push ILUC so that the pressure for more acreage to produce bioenergy, for instance, might be put forward on food crops on the one hand and on biodiversity and ecosystem services on the other hand. As climate change will affect bioenergy and food crops at the same time, their effects, as well as the adaptation measures related to agriculture will be similar in both cases. The main risks identified by Arvizu *et al*. (2011) are: (1) business as usual; (2) un-reconciled growth, and (3) environment and food *vs*. fuel. Thus, the most important adaptation measures will probably be the ones related to the control of economic growth, environmental management and agriculture production. These three factors will have to be carefully managed so that their sustainability levels should be the highest possible. With this, lower emissions and consequently lower impacts of the GCC will be expected. The choice for lignocellulosic feedstocks (eg. sugarcane second generation technologies) will be quite important because these feedstocks do not compete with food (Arvizu *et al*., 2011). In the case of sugarcane, for instance, an increase

of ca. 40% in the production of bioethanol is expected as a result of the implantation of second generation technologies coupled with the first generation ones already existent in Brazil (Buckeridge *et al*., 2012; Dias *et al*., 2012).

Biodiesel production has the lowest costs in Latin America (Chum *et al*., 2011), probably due to the high production of soybean in Brazil and Argentina. The use of biodiesel to complement oil-derived diesel is a productive choice for adaptation measures regarding this bioenergy source. Also, the cost of ethanol, mainly derived from sugarcane, is the lowest in CA, SA and Latin America (Chum *et al*., 2011) and as an adaptation measure, such costs, as well as the one of bioediesel, should be lowered even more by improving technologies related to agricultural and industrial production of both. Indeed, it has been reported that in LA the use of agricultural budgets by governments for investment in public goods induces faster growth, decreasing poverty and environmental degradation (López and Galinato, 2007). One issue that may become important in the future is that the pressure of soy expansion due to biodiesel demand can lead to land use change and consequently to economic teleconnections, as suggested by Nepstad *et al*. (2006). For example, these teleconnections may link Amazon deforestation derived from soy expansion to the economic growth in China due to changes in the demand of soy. The effects of such teleconnections may possibly mean a decrease in jobs related to small to big farms in agriculture in Argentina (Tomei and Upham, 2009) on the one hand, and deforestation in the Amazon due to the advance of soybean cropping in the region on the other (Nepstad and Stickler, 2008) (see Figure 27-6).

[INSERT FIGURE 27-6 HERE
Figure 27-6: Soy teleconnections and major effects in SA. Economic growth giant consumers as China pressurize the soy production system in SA, increasing the production of biodiesel, but demanding more energy in general. (partly based on Nepstad and Stickler (2008), and Tomei and Upham (2009).]

27.3.7. Human Health

27.3.7.1. Observed and Projected Impacts and Vulnerability

Climate variability and climate change (CV/CC) are negatively affecting human health in CA and SA, either by increasing morbidity, mortality, and disabilities (very high confidence), and through the emergence of diseases in regions previously non-endemic, or the re-emergence of diseases in areas where they have previously been eradicated or controlled (high confidence) (Winchester and Szalachman, 2009; Rodríguez-Morales, 2011). Heat waves and cold spells are affecting mortality rates in cities (McMichael *et al*., 2006; Bell *et al*., 2008; Hardoy and Pandiella, 2009; Muggeo and Hajat, 2009; Hajat *et al*., 2010). Outbreaks of leptospirosis, malaria, dengue fever, and cholera were triggered in CA by hurricane Mitch in 1998 (Costello *et al*., 2009; Rodríguez-Morales *et al*., 2010). The 2010-2012 floods in Colombia (Poveda *et al*., 2011a) caused hundreds of deaths and thousands of displaced people. Dengue fever outbreaks followed floods in Brazil in the last decade (Teixeira *et al*., 2009).

Indices of malaria have increased in the last five decades, along with air temperatures, in Colombia (Poveda *et al*., 2011b; Arevalo-Herrera *et al*., 2012), as well as in urban and rural areas of Amazonia, concomitantly with large environmental changes (Gil *et al*., 2007; Tada *et al*., 2007; Cabral *et al*., 2010; Da Silva-Nunes *et al*., 2012). Malaria vector densities have increased in northwestern Argentina along with climate variables (Dantur Juri *et al*., 2010; 2011). Besides, El Niño is a major driver of malaria outbreaks in Colombia (Mantilla *et al*., 2009; Poveda *et al*., 2011b), amidst drug resistance of the parasite (Restrepo-Pineda *et al*., 2008), and human migration (Rodríguez-Morales *et al*., 2006; Osorio *et al*., 2007). Linkages between ENSO and malaria have been also reported in Ecuador and Peru (Anyamba *et al*., 2006; Kelly-Hope and Thomson, 2010), French Guiana (Hanf *et al*., 2011), Amazonia (Olson *et al*., 2009), and Venezuela (Moreno *et al*., 2007), including unheard malaria in the Andes up to 2200 m a.s.l. (Benítez and Rodríguez-Morales, 2004).

Dengue fever (DF) and dengue hemorrhagic fever (DHF) have risen in tropical America in the last 25 years, posing an annual toll of US$ 2.1+[1 to 4] billion (Torres and Castro, 2007; Tapia-Conyer *et al*., 2009; Shepard *et al*., 2011). Environmental and climatic variability affect DF and DHF incidence in Honduras and Nicaragua (Rodríguez-Morales *et al*., 2010), in Costa Rica (Fuller *et al*., 2009; Mena *et al*., 2011), in French Guiana being concurrent with

malaria (Carme *et al*., 2009; Gharbi *et al*., 2011), in cities of Colombia (Arboleda *et al*., 2009) and Venezuela. In Caracas, DF increases (decreases) during La Niña (El Niño) (Rodríguez-Morales and Herrera-Martinez, 2009; Herrera-Martinez and Rodríguez-Morales, 2010). Weather and climate variability are also associated with DF in southern SA (Honório *et al*., 2009; Costa *et al*., 2010; De Carvalho-Leandro *et al*., 2010; Degallier *et al*., 2010; Lowe *et al*., 2011). A study in Rio de Janeiro found that a 1°C (10-mm) increase in monthly minimum temperature (rainfall) led to a 45% (6%) increase in DF in the following month (Gomes *et al*., 2012). Despite large vaccination campaigns, the risk of major Yellow Fever (YF) outbreaks has increased in tropical America amidst changes in climate and environmental conditions (Jentes *et al*., 2011), mainly in densely populated poor urban settings (Gardner and Ryman, 2010).

Schistosomiasis (SCH) is an endemic Neglected Tropical Disease (NTD) in rural areas, including Brazil (Igreja, 2011), Suriname, Venezuela, and the Andean highlands, while uncontrolled peripheral urbanisation and environmental degradation increase its incidence in Brazil (Barbosa *et al*., 2010; Kelly-Hope and Thomson, 2010). It is possible that the incidence of SCH will increase as a result of increasing temperatures (Mangal *et al*., 2008; Mas-Coma *et al*., 2009; Lopes *et al*., 2010), while vegetation indices (e.g. Normalized Difference Vegetaion Index), which are directly related to climate conditions, are associated with human fascioliasis in the Andes (Fuentes, 2004).

Hantaviruses (HV) have been reported in Honduras, Panama, Costa Rica, Venezuela, Argentina, Chile, Paraguay, Bolivia, Peru, and Brazil (Jonsson *et al*., 2010; MacNeil *et al*., 2011). There is evidence that El Niño and climate change enhance the prevalence of HV (Dearing and Dizney, 2010). In Venezuela, RVs are more frequent, more severe, and more (less) common in cities with minimal (marked) seasonality (Kane *et al*., 2004). The seasonal peak of RV in Guatemala coincides with the dry season, being responsible for 60% of diarrhoea cases (Cortes *et al*., 2012).

In spite of its rapid decline, Chagas disease is still a major public health issue, in which climate and environmental changes play an important role (Abad-Franch *et al*., 2009; Araújo *et al*., 2009; Moncayo and Silveira, 2009), as in Panama and Argentina (Tourre *et al*., 2008; Gottdenker *et al*., 2011). Ciguatera fish poisoning (CFP) is a tropical disease correlated with water temperature, and thus climate change could increase its incidence across the Caribbean (Tester *et al*., 2010). Climate is an important factor of Paracoccidioidomycosis, Latin America's most prevalent mycosis (Barrozo *et al*., 2009), while ENSO is associated with recent outbreaks of bartonellosis in Peru (Payne and Fitchett, 2010).

Cutaneous leishmaniasis (CL) is correlated with climate in LA, with highest incidence in Bolivia, where it increases (decreases) during La Niña (El Niño) (Gomez *et al*., 2006; García *et al*., 2009). CL is affected in Costa Rica by temperature, forest cover, and ENSO indices (Chaves and Pascual, 2006; Chaves *et al*., 2008). Land use, altitude, and diverse climatic variables are associated with increasing trends of CL in Colombia (Valderrama-Ardila *et al*., 2010), which also increases (decreases) during El Niño (La Niña) (Cárdenas *et al*., 2006; 2007; 2008). The situation of CL in Colombia is aggravated by the internal conflict (Beyrer *et al*., 2007). In Venezuela, CL increased (67%) during a weak La Niña (Cabaniel *et al*., 2005). CL is a seasonal disease in Suriname peaking during the March dry season (35%) (Van der Meide *et al*., 2008), while in French Guiana it is intensified after the October-December dry season (Rotureau *et al*., 2007). The incidence rates of visceral leishmaniasis (VL) have been increasing in Brazil (the highest in LA) owing to deforestation (Cascio *et al*., 2011; Sortino-Rachou *et al*., 2011), and to the occurrence of El Niño (Ready, 2008), as is also the case in Argentina, Paraguay, and Uruguay (Bern *et al*., 2008; Dupnik *et al*., 2011; Salomón *et al*., 2011; Fernández *et al*., 2012). VL transmission in western Venezuela is also associated with the bimodal annual rainfall regime (Feliciangeli *et al*., 2006; Rodríguez-Morales *et al*., 2007). On the other hand, the incidence of skin cancer in Chile has increased in recent years, which is statistically correlated to climatic and geographic variables (Salinas *et al*., 2006).

Onchocerciasis (river blindness) is another climate-related disease (Botto *et al*., 2005), whose vector exhibits clear-cut wet-dry seasonal biting rates (Rodríguez-Pérez *et al*., 2011). Leptospirosis is particularly prevalent in warm and humid tropical regions of CA (Valverde *et al*., 2008). Other climate-driven infectious diseases are ascariasis and gram-positive cocci in Venezuela (Benítez *et al*., 2004; Rodríguez-Morales *et al*., 2010), and Carrion's disease in Peru (Huarcaya *et al*., 2004)

Sea water temperature affects the abundance of the bacteria responsible for cholera (Koelle, 2009; Jutla *et al*., 2010; Marcheggiani *et al*., 2010; Hofstra, 2011), and thus high correlations exist between El Niño and cholera in Peru, Ecuador, Colombia, Mexico and Venezuela (Cerda Lorca *et al*., 2008; Martínez-Urtaza *et al*., 2008; Salazar-Lindo *et al*., 2008; Holmner *et al*., 2010; Gavilán and Martínez-Urtaza, 2011; Murugaiah, 2011). Extreme temperatures and changes in rainfall may also increase food safety hazards along the food chain (Sivakumar *et al*., 2005; Tirado *et al*., 2010).

Air pollution and higher temperatures exacerbate chronic respiratory and cardiovascular problems. Dehydration from heatwaves increases hospitalizations for chronic kidney diseases (Kjellstrom *et al*., 2010), mainly affecting construction workers, and CA sugarcane and cotton workers (Crowe *et al*., 2009; 2010; Kjellstrom and Crowe, 2011; Peraza *et al*., 2012). In the region, atmospheric pollutants are associated with artherosclerosis, respiratory and cardiovascular diseases, pregnancy-related outcomes, cancer, cognitive deficit, otitis, and diabetes (Olmo *et al*., 2011). The worsening of air quality in large cities is increasing allergic respiratory diseases, and morbidity from asthma and rhinitis (Grass and Cane, 2008; Martins and Andrade, 2008; Gurjar *et al*., 2010; Jasinski *et al*., 2011; Rodriguez *et al*., 2011).

Extreme weather and climate events affect mental health by exposure to psychological trauma (Higginbotham *et al*., 2006; Berry *et al*., 2010). Drought-prone areas in NEB are vulnerable to lower socioeconomic and educational levels, in turn associated with depression, psychological distress, and anxiety (Coêlho *et al*., 2004). Hospital admissions for mania and bipolar disorder are associated with climate seasonality in Brazil. Extreme weather, meager crop yields, and low GDP are also linked with increased violence (McMichael *et al*., 2006). All these problems may be exacerbated by climate change (Schulte and Chun, 2009).

Many factors increase CA and SA's vulnerability to climate change: precarious health systems, socio-economic factors, inadequate water and sanitation services, poor waste collection and treatment systems, air, soil and water pollution, lack of social participation, and inadequate governance (Luber and Prudent, 2009; Rodríguez-Morales, 2011; Sverdlik, 2011). Human health vulnerabilities exhibit serious biases with geography, age (Perera, 2008; Martiello and Giacchi, 2010; Graham *et al*., 2011; Åstrom *et al*., 2011), gender (Oliveira *et al*., 2011), race, ethnicity, and socio-economic status (Diez Roux *et al*., 2007; Martiello and Giacchi, 2010). Malnutrition due to crop failure and drought adds up to vulnerability (Schmidhuber and Tubiello, 2007). NTDs cause 1.5-5.0 million disability-adjusted life years (DALYs- a measure of disease burden, expressed as the number of years lost owing to disability, ill-health or early death) in LA, many of which are climate-sensitive diseases (Hotez *et al*., 2008; Allotey *et al*., 2010). Mega-cities' vulnerability (see 27.3.5) is aggravated by the provision of drinking water and by the rapid spread of diseases. It further is increasing due to migration from rural areas forced by environmental degradation and disasters (Campbell-Lendrum and Corvalán, 2007; Borsdorf and Coy, 2009; Hardoy and Pandiella, 2009), and in turn mega-cities are vulnerable to natural disasters (earthquakes, fires, storms etc.) that might change in frequency and intensity in the context of global climate change. The provision of drinking water and the spread of diseases make mega-cities vulnerable to global environmental change (Borsdorf and Coy, 2009). Diverse vulnerability assessments to the impacts of climate change on human health have been developed in Brazil at national, regional and municipal scales. The approach uses composite indicators, which included downscaled climate scenarios, epidemiological variables, economic and demographic projections and the status of natural ecosystems (Confalonieri *et al*., 2009; 2011; Barbieri and Confalonieri, 2011; FIOCRUZ, 2011). The Andes and CA are among the regions of highest predicted losses [1% to 27%] in labor productivity from future climate scenarios (Kjellstrom *et al*., 2009). Argentina and Chile (under the sub-Antarctic atmospheric circulation) might suffer serious health effects from impacts to water and food availability, and extreme weather (Team and Manderson, 2011).

27.3.7.2. Adaptation Strategies and Practices

Despite the attempt to implement adaptation strategies in CA and SA ((Blashki *et al*., 2007; Costello *et al*., 2011), several factors hamper their effectiveness, such as: a lack of political commitment, gaps in scientific knowledge, and institutional weaknesses of health systems (Keim, 2008; Lesnikowski *et al*., 2011; Olmo *et al*., 2011) (see section 27.4.3)

Research priorities and current strategies must be reviewed to achieve better disease control (Halsnæs and Verhagen, 2007; Romero and Boelaert, 2010; Karanja *et al*., 2011). The low adaptive capacity of rural communities associated with poor health systems and limited resources exacerbate human health stressors from climate change, and thus regional responsive systems must be put in place in key operational areas (Bell, 2011), involving adaptive capacity building, and implementation of adaptation actions (Huang *et al*., 2011), which in turn require considering the potential magnitude and uncertainty of the hazards, and the effectiveness, costs, and risks of the proposed responses (Campbell-Lendrum and Bertollini, 2010).

Diverse human wellbeing indices must be explicitly stated as climate change policies of adaptation and mitigation in LA, along with the Millennium Development Goals (Franco-Paredes *et al*., 2007; Halsnæs and Verhagen, 2007; Mitra and Rodriguez-Fernandez, 2010). South-south cooperation and multidisciplinary research is required to study the health impacts of climate change and to identify resilience, adaptation, and mitigation strategies (Tirado *et al*., 2010; Team and Manderson, 2011). Colombia is starting to develop a pilot human health adaptation program, to cope with climate-driven changes in malaria transmission and exposure (Poveda *et al*., 2011b). The city of São Paulo has implemented diverse local pollution control measures, with the co-benefit of reducing GHG emissions, such as the 11% reduction of methane by landfills (De Oliveira, 2009; Nath and Behera, 2011).

27.4. Adaptation Opportunities, Constraints, and Limits

27.4.1. Adaptation Needs and Gaps

During the last years, the study of adaptation to climate change has progressively switched from an impact-focused approach (mainly climate-driven) to a vulnerability-focused vision (Boulanger *et al*., 2011). While different frameworks and definitions of vulnerability exist, a general tendency aims at studying vulnerability to climate change especially in SA and CA using a holistic or systemic approach (Ison, 2010; Carey *et al*., 2012b), where climate drivers are actually few with respect to all other drivers related to human and environment interactions including physical, economic, political and social context, as well as local characteristics such as occupations, resource uses, accessibility to water, etc. (Manuel-Navarrete *et al*., 2007; Young *et al*., 2010).

In developing and emergent countries, there exists a general consensus that the adaptive capacity is low, strengthened by the fact that poverty is a limit to resilience (Pettengell, 2010) leading to a “low human development trap” (UNDP, 2007). Although this is true, Magnan (2009) suggests that this analysis is biased by a “relative immaturity of the science of adaptation to explain what are the processes and the determinants of adaptive capacity”. Increasing research efforts on the study of adaptation is therefore of great importance to improve our understanding of the actual societal, economical, community and individual drivers defining the adaptive capacity. Especially, a major focus on traditions and their transmission (Young and Lipton, 2006) may actually indicate potential adaption potentials in remote and economically poor regions of SA and CA. Such a potential does not dismiss the fact that the nature of future challenges may actually not be compared to past climate variability (e.g. glacier retreat in the Andes).

Coping with new situations may require new approaches such as a multilevel risk governance (Young and Lipton, 2006; Corfee-Morlot *et al*., 2011) somehow associated with decentralization in decision-taking and responsibility. While the multilevel risk governance and the local participatory approach are interesting frameworks for strengthening adaptation capacity, their major counterpart is that at all levels it requires (from local to national levels) capacity-building and information transmission on future risks, major challenges and possible methodologies to plan adaptation strategies to climate change. At present, despite an important improvement during the last years, there still exists a certain lack of awareness of environmental changes and mainly their implications for livelihoods and businesses (Young *et al*., 2010). Moreover, considering the limited financial resources of some states in CA and SA, long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the population. This situation weakens the importance of adaptation planning to climate change in the political agenda, and requires therefore international involvement as one facilitating factor in natural hazard management and climate change adaptation (Carey *et al*., 2012b). However, as pointed out by McGray *et al*. (2007), development, adaptation and mitigation issues are not separate issues. Especially,

development and adaptation strategies should be tackled together in developing countries sch as SA and CA, focusing on strategies to reduce vulnerability. The poor level of adaptation of present-day climate in SA and CA countries is characterized by the fact that responses to disasters are mainly reactive rather than preventive. Some early warning systems are being implemented, but the capacity of responding to a warning is often limited, particularly among poor populations. Finally, actions combining public communication (and education), public decision-maker capacity-building and a synergetic development-adaptation funding will be key to sustain the adaptation process that CA and SA require to face future climate change challenges.

27.4.2. Practical Experiences of Adaptation, including Lessons Learned

Adaptation processes have been in many cases initiated a few years ago, and there is still a lack of literature to evaluate their efficiency in reducing vulnerability and building resilience of the society against climate changes. However, some lessons have already been learned on these first experiences (see section 27.3). In CA and SA, many societal issues are strongly connected to development goals and are often considered priority in comparison to adaptation efforts to climate change. However, according to the 135 case studies analyzed by McGray *et al.* (2007), 21 of which were in CA and SA, the synergy between development and adaptation actions allows to ensuring a sustainable result of the development projects.

Vulnerability and disaster risk reduction may not always lead to long-term adaptive capacity (Tompkins *et al.*, 2008; Nelson and Finan, 2009), except when structural reforms based on good governance (Tompkins *et al.*, 2008) and negotiations (Souza Filho and Brown, 2009) are implemented. While multi-level governance can help to create resilience and reduce vulnerability (Roncoli, 2006; Young and Lipton, 2006; Corfee-Morlot *et al.*, 2011), capacity-building (Eakin and Lemos, 2006), good governance and enforcement (Lemos *et al.*, 2010; Pittock, 2011) are key components.

Local adaptation to climate and non-climate drivers may undermine long-term resilience of social-ecological systems when local, short-term strategies designed to deal with specific threats or challenges do not integrate a more holistic and long-term vision of the system at threat (Adger *et al.*, 2011). Thus, policy should identify the sources of and conditions for local resilience and strengthen their capacities to adapt and learn (Adger *et al.*, 2011; Eakin *et al.*, 2011), as well as to integrate new adapted tools (Oft, 2010). This sets the question of convergence between the local-scale/short-term and broad scale/long-term visions in terms of perceptions of risks, needs to adapt and appropriate policies to be implemented (Eakin and Wehbe, 2009; Salzmann *et al.*, 2009). Even if funding for adaptation is available, the overarching problem is the lack of capacity and/or willingness to address the risks, especially those threatening lower income groups (Satterthwaite, 2011). Adaptation to climate change cannot eliminate the extreme weather risks, and thus efforts should focus on disaster preparedness and post-disaster response (Sverdlik, 2011). Migration is the last resort for rural comunities facing water stress problems in CA and SA (Acosta-Michlik *et al.*, 2008).

In natural hazard management contributing to climate change adaptation, specific cases such as the one in Lake 513 in Peru (Carey *et al.*, 2012b) clearly allowed to identify facilitating factors for a successful adptation process (technical capacity, disaster events with visible hazards, institutional support, committed individuals, and international involvement) as well as impediments divergent risk perceptions, imposed government policies, institutional instability, knowledge disparities, and invisible hazards).

In certain cases, forward-looking learning (anticipatory process), as a contrast to learning by shock (reactive process), has been found as a key element for adaptation and resilience (Tschakert and Dietrich, 2010) and should be promoted as a tool for capacity-building at all levels (stakeholders, local and national governments). Its combination with role-playing game and agent-based models (Rebaudo *et al.*, 2011) can strengthen and accelerate the learning process.

27.4.3. Observed and Expected Barriers to Adaptation

It is usually considered that a major barrier to adaptation is the perception of risks and many studies focused on such an issue (Bonatti *et al*., 2012). However, new studies (Adger *et al*., 2009) identified social limits to possible adaptation to climate change in relation with issues of values and ethics, risk, knowledge and culture, even though such limits can evolve in time. Indeed, while being a necessary condition, perception may not be the main driver for initiating an adaptation process. As pointed out by Tucker et al. (2010), exogenous factors (economic, land tenure, cost, etc.) may actually strongly constrain the decision-making process involved in possible adaptation process.

Moreover, it is difficult to describe adaptation without defining at which level it is thought. Indeed, while a lot of efforts are invested in national and regional policy initiatives, most of the final adaptation efforts will be local. National and international (transborder) governance is key to build adaptive capacity (Engle and Lemos, 2010) and therefore to strengthen (or weaken) local adaptation through efficient policies and delivery of resources. At a smaller scale (Agrawal, 2008), local institutions can strongly contribute to vulnerability reduction and adaptation. However, at all levels, the efficiency in national and local adaptation activities strongly depend on the capacity-building and information transmission to decision-makers (Eakin and Lemos, 2006).

27.4.4. Planned and Autonomous Adaptation

Autonomous adaptation strategies are mainly realized at local levels (individual or communitarian), but not always respond to climate forcing. For instance, the agricultural sector adapts rapidly to economic stressors, while, despite a clear perception of climate risks, it may last longer before responding to climate changes (Tucker *et al*., 2010). In certain regions or communities, such as Anchioreta in Brazil (Bonatti *et al*., 2012), adaptation is part of a permanent process and is actually tackled through a clear objective of vulnerability reduction, maintaining and diversifying a large set of natural varieties of corn allowing the farmers to diversify their planting. Another kind of autonomous adaptation is the southward displacement of agriculture activities (e.g. wine, coffee) though the purchase of lands, which will become favorable for such agriculture activities in a warmer climate. In Argentina, the increase of precipitacion observed during the last 30 years contributed to a westward displacement of the crop frontier.

Planned adaptation is by definition associated to government policies and planning. During the last years, there has been a growing awareness of CA and SA governments on the need to integrate climate change and future climate risks in their policies. Up to date, in total 18 regional Non-Annex countries, including Argentina, Belize, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, Guatemala, Honduras, Nicaragua, Guyana, Panama, Paraguay, Peru, Suriname, Uruguay and Venezuela, have already responded through their initial and most cases second National Communication to the UNFCCC from 1997 until 2012 (see UNFCCC, 2012) allowing to measure the country's emissions and to assess its present and future vulnerability. In addition, for instance Argentina, Brazil and Uruguay among others, created specific Secretaries in the government organizations specifically dedicated to climate change in order to coordinate actions between different ministries and secretaries of state. Finally, most of the countries in the region (Keller *et al*., 2011) are now involved in international networks focused on adaptation to climate change, or in international projects aiming at capacity-building and design of adaptation strategies. As an example, the 'CentroAmerican Integration System' (see SICA, 2013 gathers every three months climate experts for regional institutions as well as sectorial experts (agriculture, energy, etc.) in order to discuss climate trends, increase capacity-building and anticipate major climate threats. It is of course too early to evaluate the actual impact of such new initiatives on regional or national adaptation to climate change. However, new tools (Debels *et al*., 2009) or international platforms for CA and SA may help to prioritize adaptation policies according to their efficiency and the limited financial resources in the future (Kok *et al*., 2007).

Table 27-7 presents programs, projects and initiatives with focus on current and past practical adaptation measures maintained in the data collection by the UNFCCC under the Nairobi Work Programme (NWP) (distinguishing Private Sector Initiatives (PSI); Local Coping Strategies (LCP) (UNFCCC, 2012b); EbA approaches; and Adaptation Practices (AP); complemented with international projects from the weAdapt database (weAdapt, 2012).

[INSERT TABLE 27-7 HERE
Table 27-7: Overview on local, regional, national and international adaptation programs, projects and initiatives relevant for the region]

27.5. Interactions between Adaptation and Mitigation

As demonstrated in 'The SouthSouthNorth Capacity Building Module on Poverty Reduction" (see SSN, 2006), a synergy between adaptation and mitigation strategies can be reached especially when the community organizes itself in a cooperative. In many examples, mitigation strategies based on a cooperative system, which manages recycling or renewable energy production, actually lead to an increase in energy availability, crucial to increase production capacity and thus to create new financial resources for the community. As also pointed out by (Venema and Cisse, 2004), the growth of renewable energy in CA and SA (see also section 27.3.6) should not be limited to large infrastructure projects, and should also encompass the development of decentralized renewable energy solutions. In spite of their smaller size (individual or communitarian), these solutions offer adaptation and mitigation benefits. On one hand, fossil-based energy consumption is reduced, while energy availability is increased. On the other hand, reduction of energy precariousness is key in any development strategy. Thus, it allows local community and individuals to growing socially and economically; and therefore to reducing its vulnerability avoiding the poverty trap (UNDP, 2007), and to initiating an adaptation process based on non-fossil fuel energy sources. Such initiatives also depend on local and organizational leaderships (UN-Habitat, 2011).

At national and regional scales, CA and SA countries will require the allocation of human and financial resources to adapt to climate change. While resources are limited, too large an economic dependence of these countries to fossil fuels will reduce their adaptive capacity. The reduction in energy consumption and the integration of renewable energies in their energetic matrix is therefore a key issue for all these countries in order to sustain their development and growth and therefore increase their adaptive capacity (see also section 27.3.6).

27.6. Case Studies

27.6.1. Hydropower

Hydropower is the main source of renewable energy in CA and SA (see section 27.3.6). Although there is debate about GHG emissions from hydropower reservoirs (especially in tropical environments, Fearnside and Pueyo, 2012) this form of electricity generation is often seen as a major contributor to mitigating GHG emissions worldwide (see IPCC SRREN [5]; Kumar *et al*. (2011). On the other hand, hydropower is also a climate-related (water) sector, thus making it prone to serious efects from climate change (see section 27.3.1.1).

The CA and SA region constitute a unique example to study these relations between climate change mitigation and adaptation in relation to hydropower generation. According to the Special Report on Renewable Energy Sources and Climate Change Mitigation (see Table 5.1 SRREN; IPCC, 2011) CA and SA are second to Asia in terms of hydropower energy generation in the world, displaying a 20% share of total annual generation. The quality of water resources availability in CA and SA is the largest in the world with an average regional capacity factor of over 50%. As a result, the region has by far the largest proportion of electricity generated through hydropower facilities (Table 27-6 in section 27.3.6.1). The hydropower proportion of total electricity production is over 40% in the region, and in some cases is near or close to 80%, as in the case of Brazil, Colombia and Costa Rica.

Diverse studies have analyzed the potential impacts of climate change on hydropower generation (see details in Table 27-4 in section 27.3.1.1). Maurer *et al*. (2009) studied future hydrologic conditions for the Lempa River basin across El Salvador, Honduras and Guatemala, which feeds major hydroelectric facilities. Assesmment of projections including uncertainty analysis show a reduction in hydropower capacity of 33% to 53% by 2070-2099. A similar loss is expected for the Sinu-Caribe basin in Colombia were, despite a general projection of increased precipitation, losses due to evaporation enhancement reduces inflows to hydroelectric systems, thus reducing electricity generation up to 35% compared to base conditions (Ospina-Noreña *et al*., 2009a). Further studies (Ospina-Noreña *et al*., 2011a;

2011b) have estimated vulnerability indices for the hydropower sector in the same basin, and identified reservoir operation strategies to reduce this vulnerability. Overall reductions in hydropower generation capacity are also expected in Chile for the main hydropower generation river basins: Maule, Laja and Biobio (ECLAC, 2009a; McPhee *et al*., 2010; Stehr *et al*., 2010), and also in the Argentinean Limay River basin (Seoane and López, 2007). Ecuador, on the other hand, faces an increase in generation capacity associated with an increment in precipitation on its largest hydroelectric generation Paute River basin (Buytaert *et al*., 2010). In Brazil, the country with the largest installed hydroelectric capacity in the region, continuous efforts are made to improve the management of the system under variable climatic conditions (Lima and Lall, 2010). There is still unused generation capacity in sub-basins of the Amazon River (Soito and Freitas, 2011), but future climate conditions plus environmental concerns pose an important challenge for the expansion of the system (Freitas and Soito, 2009; Finer and Jenkins, 2012). According to Lucena *et al*. (2009), hydropower systems in southern Brazil (most significantly the Parana River system) could face a slight increase in energy production under an A2 scenario. However, the rest of the country's hydropower system, and especially those located in the North East region, could face a reduction in power generation, thus reducing the reliability of the whole system (Lucena *et al*., 2009).

An obvious implication of the mentioned impacts is the need to replace the energy lost due to climate change impacts. In this regard, a typical adaptation measure would be to increase alterantive energies (see 27.3.6.2). Lower cost of adaptation measures have been studied for Brazil (Lucena *et al*., 2010a), with results implying an increase in natural gas and sugarcane bagasse electricity generation in the order of 300 TWh, increase in operation costs in the order of 7 billion USD annually and 50 billion USD in terms of investment costs by 2035. In the case of Chile, ECLAC (2009a) assumed that the loss in hydropower generation would be compensated by the least operating cost source available (not used probably at full capacity), which is a coal-fired power plant. In this case, the amount of average electricity that needs to be replaced for the 2011-2040 period is around 18 TWh of electricity, a little over 10% of actual total hydropower generation capacity in the country (ECLAC, 2009a). According to the same study (ECLAC, 2009a), this implies an increase in operating costs of the order of 100 million USD annually and an increase of 2 $MTCO_2e$ (total emissions from the electricity generation subsector in Chile are around 25 $MTCO_2e$ in 2009). Ospina-Noreña (2011a; 2011b) studied some adaptation options, such as changes in water use efficiency or demand growth that could mitigate the expected impacts on hydropower systems in the Colombian Sinú-Caribe River basin.

Some other implications are, for instance, changes in the seasonality of inflows to hydropower generation systems such as those projected for Peru (Juen *et al*., 2007), Chile (ECLAC, 2009a), and Argentina (Seoane and López, 2007), that could affect the relationship between different water users within a basin. In Chile for example, hydrologic impacts of climate change could affect water supply to agriculture irrigation triggering economic and social conflicts between this and the hydropower sector that share water resources from the same river basin. It is worth noting that those regions which are projected to face an increase in streamflow and associated generation capacity, such as Ecuador or Costa Rica, also share difficulties in managing deforestation, erosion and sedimentation which limits the useful life of reservoirs (see section 27.3.1.1). In these cases it is important to consider these effects in future infrastructure operation (Ferreira and Teegavarapu, 2012) and planning, and also enhance the on-going process of recognizing the value of the relation between ecosystem services and hydropower system operations (Leguía *et al*., 2008) (see more on PES in section 27.3.2.2).

27.6.2. Payment for Ecosystem Services

Payment for ecosystem services (PES) is commonly described as a set of transparent schemes for securing a well-defined ecosystem service (or a land use capable to secure that service) through conditional payments or compensations to voluntary providers (Engel *et al*., 2008; Tacconi, 2012). Van Noordwijk *et al*. (2012) provides a broader definition to PES by arguing that it encompasses three complementary approaches, (i) the one above, i.e., commodification of pre-defined ecosystem services so that prices can be negotiated between buyers and sellers; plus (ii) compensation for opportunities forgone voluntarily or by command and control decisions; and (iii) coinvestment in environmental stewardships. Therefore, the terms ´conservation agreements´, ´conservation incentives´ and ´community conservation´ are often used as synonyms or as something different or broader than PES (Milne and

Niesten, 2009; Cranford and Mourato, 2011). For simplicity, we refer to PES in its broadest sense (sensu van Noordwijk *et al*., 2012).

Services subjected to such types of agreements often include regulation of freshwater flows, carbon storage, provision of habitat for biodiversity, and scenic beauty (De Koning *et al*., 2011; Montagnini and Finney, 2011). Since the ecosystems that provide the services are mostly privately owned, policies often aim at supporting landowners to maintain the provision of services over time (Kemkes *et al*., 2010). Irrespective of the debate of as to whether payments or compensations should be designed to focus on actions or results (Gibbons *et al*., 2011), experiences in Colombia, Costa Rica and Nicaragua show that PES can finance conservation, ecosystem restoration, and better land use practices (Montagnini and Finney, 2011; see also Table 27-5). However, based on examples from Ecuador and Guatemala, Southgate *et al*. (2010) argue that uniformity of payment for beneficiaries can be inefficient if recipients accept less compensation in return for conservation measures, or if recipients that promote greater environmental gains receive only the prevailing payment. Other setbacks to PES schemes might include cases where there is a perception of commoditization of nature and its intangible values (e.g. Bolivia, Cuba, Ecuador and Venezuela), cases where mechanisms are inefficient to reduce poverty, slowness to build trust between buyers and sellers, as well as gender and land tenure issues that might arise (Asquith *et al*., 2008; Peterson *et al*., 2010; Balvanera *et al*., 2012; van Noordwijk *et al*., 2012).

Table 27-8 lists selected examples of PES schemes in Latin America, but a more complete and detailed list is given in Balvanera *et al*. (2012).

[INSERT TABLE 27-8 HERE
Table 27-8: Cases of government-funded PES schemes in CA and SA.]

The PES concept (or ´fishing agreements´) also applies to coastal and marine areas, although only a few cases have been reported. Begossi (2011) argues that this is due to three factors: origin (the mechanism was originally designed for forests), monitoring (marine resources such as fish are more difficult to monitor than terrestrial resources) and definition of resource boundaries in offshore water. One example of a compensation mechanism in the region is the so-called *defeso*, in Brazil. It consists of a period (reproductive season) when fishing is forbidden by the government and fishermen receive a financial compensation. It applies to shrimp, lobster and both marine and freshwater fisheries (Begossi *et al*., 2011).

27.7. Data and Research Gaps

The lack of high quality and continuous climate, oceanic and hydrological records, together with the very few complete regional studies, poses challenges for the region to address climate variability and the identification of trends in climatic extremes, in particular for CA. The non-availability of high resolution climatic and hydrological data also hampers studies on frequency and variability of extremes. This situation affects the studies of related impacts and vulnerability analyses in present climates, and the development of vulnerability assessments and adaptation actions for the future.

Related with observed impacts in most of the sectors, there is a great difference in information availability between countries, While more studies have been performed for the SESA region, much less are available for CA and for some regions of tropical SA. The problem is not only the lack of studies of observed impacts, but also the lack or poor dissemination of results in peer-reviewed publications. There is a need for studies focused on current impacts and vulnerabilities in all the sectors throughout CA and SA, potentially with a certain emphasis on extremes in order to improve risk management assessments.

The complex interactions between climate and non-climate drivers can challenge impacts assessment and projections, as can for instance be the case for water availability and streamflow when looking at current and potential deforestation; or overfishing and pollution regarding the impacts on fisheries, or impacts on hydroenergy production. In this sense, the lack of interdisciplinary integrated studies limits the knowledge of such complex processes that involve not only physical but also socioeconomical factors.

In addition, the accelerated changes in some issues like deforestation and changes in land use, as well as economic conditions, demand continuous and detailed studies to update available information to be made available to the research community.

To address the global challenge of food secturity and food quality, being important issues in CA and SA, investments in the production of scientific agricultural knowledge will be reinforced in relation to: integration of agriculture with organic production; and the integration of food and bioenergy production. With the important interlinakges of renewable energy, adaptation and mitigation, sufficient knowledge on RE project implementation and on crops is requested.

Also, a better understanding is needed of potential adverse effects of bioenergy production and indirect land use changes. Equally, further research is needed on future projections of renewable energy, e.g. wind power. However, it is indispensable that the competition for food and bioenergy production considers ethical aspects; identifying which activity is most important and whether bioenergy production would affect food security.

Sea level rise and costal erosion are also relevant issues, and the lack of comparable measurements of sea level rise in CA and SA makes integrated assessments on sea level rise and impacts on the region difficult, both for the present and future. Of local and global importance will be an enhancement of the understanding of the physical processes on the ocean, in specific the Humboldt Current system flowing along the West Coast of SA, being the most fish productive system worldwide.

While the majority of the coastal section literature focuses on fisheries, there is a recognized need for research on how corals reefs, mangroves and benthic marine invertebrates, that are key to reef systems as well, could be impacted upon by climate change.

There is still a need for more research and information about the impacts of climate variability and change on human health, mainly in CA. One problem is the difficulty to accessing health data that are not always archived and ready to be used in integrated studies. Another need refers to building the necessary critical mass of transdisciplinary scientists to tackle the climate change-human health problems in the region. The prevailing gaps in scientific knowledge hamper the implementation of adaptation strategies, thus demanding a review of of research priorities towards better disease control. With the aim of further studying the health impacts of climate change and identifying resilience, mitigation and adaptation strategies, South-South cooperation and multidisciplinary research are considered to be relevant priorities.

In despite of the uncertainty that stems from global and regional climatic projections, the region needs to act. In this sense it is usseful to promote research activities leading to assist people to cope with current climate variability, as for example, risk assessment and risk management. Other important aspect is the improvement of climate modeling that can be done in the region, thus lowering uncertaintities. Since the AR4, experiences on model development and the generation of high resolution climate scenarios have allowed for the production of the first integrated regional studies on impacts and vulnerability assessments of climate change, for sectors such as agriculture, energy and human health.

Research on adaptation and the scientific understanding of the various processes and determinants of adaptive capacity is also key to the region, with particular potential in increasing adaptation capacity when focusing on traditions and how they are transmitted. Linking indigenous knowledge with scientific knowledge is also needed. Although adaptation processes have mostly been intiated in the past years, still their efficiency is difficult to determine owing to a lack of literature to evaluate them.

There is a need for change in the research agenda in order to address vulnerability and foster adaptation in the region; encompassing an inclusion of the regions' researchers and focusing also on governance structures and action-oriented research that also addresses resource distribution inequities.

Regional and international partnerships, networks, research programs have allowed a linkage of those programs with local strategies for adaptation and mitigation, also providing opportunities to address research gaps and exchange among researchers. Examples are the Ibero-American Network of Climate Change Offices- RIOCC; the European Union funded projects CLARIS LPB in SESA and AMAZALERT in Amazonia. Other important initiaves come from the WHO, GEF, IDB, ECLAC (CEPAL), La Red, BirdLife International. The same holds for local international networks such as ICLEI or C40, of which CA and SA cities form part. The weADAPT initiative is a good example on how practitioners, researchers and policy makers for CA and SA can have access to credible, high quality information and to share experiences and lessons learnt in other regions of the world.

27.8. Conclusions

In CA and SA there is ample evidence of increases in extreme climate events and on their impacts on natural and human systems. Changes in climate variability and in extreme events have been severely affecting CA and SA since the second half of the 21st century. Since the AR4, unusual extreme weather and climate events have occurred in most countries: drought/flood episodes in Amazonia in 2010/2009, 2012, the drought in NE Brazil in 2012, cold waves and floods in the Andes from 2010-2012, among others. Temperature increases have been identified in most of CA and SA, with the exception of the southern coast of South America that has experienced cooling during the last decades. Changes in observed warm days and cold nights have been identified in CA, and some sectors of SA, while more frequent and intense rainfall extremes in SESA have favored an increase in the occurrence of landslides and flash floods. Since the AR4, there is growing evidence that glaciers (both tropical and extratropical) are retreating and the cryosphere in the Andes is changing according to the warming trends, affecting the hydrometeorological regimes in SA.

Land cover change is a key driver of environmental change with significant impacts on climate change. Deforestation and land degradation are mainly attributed to increased extensive and intensive agriculture, both from traditional export activities such as beef and soy production, but more recently from biomass for biofuel production. Even though deforestation rates in the Amazon have decreased substantially in the last eight years, other regions like the Cerrado and the Chaco forests still present high levels of deforestation with rates as high as 1.33%. In Argentina, Bolivia, Brazil and Paraguay, agricultural expansion, mainly soybean, has exacerbated deforestation and has intensified the process of land degradation. The agricultural expansion has affected fragile ecosystems such as the edges of the Amazon forest and the Pampas region; or the tropical Andes, increasing the vulnerability of communities to extreme climate events, particularly floods, landslides and droughts.

Socioeconomic development shows a high level of structural heterogeneity and a very unequal income distribution resulting in the high vulnerability of the region to climate variability and change. There is still a high and persistent level of poverty in most countries in spite of the sustained economic growth observed in the last decade. The economic inequality translates into inequality in access to water, sanitation and adequate housing; particularly for the most vulnerable groups living in poverty. However, high vulnerability can be found in regions with high income.

Coastal and marine ecosystems have been undergoing significant transformations that pose threats to marine excosystems and to the services they offer. Frequent coral bleaching events have been recently reported for the Mesoamerican Coral Reef. In CA and SA, some of the main drivers of mangrove loss are deforestation and land conversion, agriculture and shrimp ponds, to an extent that the mangroves of the Atlantic and Pacific coasts of CA are some of the most endangered in the planet. Changes over 2 mm/yr of sea-level rise have been found in CA and SA, which is reason for concern since 3/4 of the population of the region live within the range of 200 km of the coast.

Conversion of natural ecosystems is the main proximate cause of biodiversity and ecosystem loss in the region, and in parallel is a driver of anthropogenic climate change. Plant species are rapidly declining in CA and SA; the highest percentage of rapidly declining amphibian species occurs also in CA and SA; with Brazil being among the countries with most threatened bird, mammal species and freshwater fish. However, the region has still large extensions of natural vegetation cover for which the Amazon is the main example. Ecosystem-based Adaptation practices, such as

conservation agreements, community management of natural areas, and payment for ecosystem services, begin to appear across the region.

Figure 27-7 presents a summary of some of the main observed trends in global environmental change drivers across different representative regions of CA and SA. The figure presents changes in climate and non climate drivers and has to be compounded with other socioeconomic related trends, such as the rapid urbanization process experienced the region.

[INSERT FIGURE 27-7 HERE
Figure 27-7: Summary of observed changes in climate and other environmental factors in representative regions of CA and SA. The boundaries of the regions in the map are conceptual (not precise geographic nor political) and follow those developed in Figure 3-1 of the IPCC SREX (IPCC, 2012). Information and references to changes provided are presented in different sections of the chapter.]

In terms of attribution to climate change, some of the observed impacts on human and natural systems detected and reported in the literature are shown in Figure 27-8. Some of them can be directly or indirectly attributed to human influences, and can be summarized as:

- Reduction in tropical glaciers and icefields in tropical and extra tropical Andes over the second half of the 20th century that can be attributed to an increase in temperature.
- There have changes identified in river flows in SA. Extreme streamflow in the Amazon River have changed during the last two decades, robust positive trends in streamflow in different sites have been detected in sub-basins of the La Plata River basin and increased dryness for most of the river basins in west coast of South America have been detected during the last 50 years.
- Mangrove degradation in the Northern South American coast and reduction in fisheries stock.
- Increase in agricultural yield in SESA, and shifting in agricultural zoning: significant expansion of agricultural areas, mainly in climatically marginal regions.
- Increase in frequency and extension of dengue fever, yellow fever and malaria.

However, the fact that in some impacts the number of studies is still insufficient leads to extreme low levels of confidence for attribution to human influences.

[INSERT FIGURE 27-8 HERE
Figure 27-8: Observed impacts of climate variations and attribution of causes in CA and SA.]

By the end of the century, the projected mean warming for CA ranges from 1.5°C to 4.0 °C, while rainfall tends to decrease between 5 and 10%. SA shows a warming between 1.0°C to 5.0 °C, with rainfall reduction up to 10% in tropical SA and an increase of about 10-15% in SESA, and in other regions of the continent. Heavy precipitation is projected to increase in SESA, while dry spells would increase in northeastern South America. Increases in warm days and nights are very likely to occur in most of SA. Projections for CA show summertime precipitation reduction, accompanied by projected warming in most of the region. However, there is some degree of uncertainty on climate change projections for regions, particularly for rainfall.

In present climates, there are regions that experience vulnerability in terms of current water availability, and this vulnerability is expected to increase in the future due to climate change impacts. Already vulnerable regions in terms of water supply, like the semi-arid zones in SA and CA and the tropical Andes, are expected to increase even further their vulnerability due to climate change. This would be complicated by the expected glacier retreat, and a reduction in water availability due to expected precipitation reduction and increase evapotranspiration demands as expected in the semi-arid regions of CA and SA. These scenarios would affect water supply for large cities, small communities, hydropower generation and the agriculture sector.

This results in a need for re-assessing current practices to reduce the mismatch between water supply and demand. Thiscould be used to reduce future vulnerability, and to implement constitutional and legal reforms towards more efficient and effective water resources management in the region, as part of adaptation strategies to cope with

climate variability and change. Changes in agricultural productivity as a consequence of climate change are expected to have a great spatial variability, and while in SESA projections show that average productivity could be sustained or increased until the mid-century (SRES: A2, B2), in other regions increases in temperature and decreases in rainfall could decrease the productivity in the short-term (before 2025), threatening the food security of the poorest population. The great challenge for CA and SA will be to increase the food and bioenergy production and at the same time sustain the environmental quality in a scenario of climate change.

Renewable energy has a great potential for adaptation and mitigation. Hydropower is currently the main source of RE in CA and SA, followed by biofuels, notably bioethanol from sugarcane and biodiesel from soy. SESA is one of the main sources of production of the feedstocks for biofuels' production, mainly with sugarcane and soybean, and future climate conditions may lead to an increase in productivity and production. Advances in second generation bioethanol from sugarcane and other feedstocks will be important as a measure of adaptation, as they have the potential to increase biofuels productivity in the region. In spite of the large amount of arable land available in the region, the expansion of sugarcane and soy, related to biofuels production, might have some indirect land use change effects, producing teleconnections that could lead to deforestation in the Amazon and loss of employment in some countries. This would also also affect food security.

Climate variability and climate change are negatively affecting human health in CA and SA, either by increasing morbidity, mortality, and disabilities and through the emergence of diseases in regions previously non-endemic, or the re-emergence of diseases in areas where they have previously been eradicated or controlled. Climate-related drivers have been recognized for respiratory and cardiovascular diseases, vector- and water-borne diseases, mainly malaria, dengue and yellow fever. Vulnerabilities vary with geography, age, gender, race, ethnicity, and socio-economic status, and climate change and variability may exacerbate current and future risks to health.

Climate change would bring new environmental conditions resulting from modifications in space and time, and in the frequency and intensity, of weather and climate processes. The best way to be prepared to adapt to future climate change is by assisting people to cope with current climate variability, particurly to weather and climate extremes. Long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the CA and SA population. Such conditions weaken the importance of adaptation planning to climate change on the political agenda. In the present, there are few experiences on synergies between development, adaptation and mitigation planning, which can help local communities and governments to allocate available resources in the design of strategies to reduce vulnerability and to develop adapation measures. Facing a new climate system and, in particular, the exacerbation of extreme events, will call for new ways to manage human and natural systems for achieving ustainable development.

Frequently Asked Questions

FAQ 27.1: What is the impact of receding glaciers on natural and human systems in the tropical Andes?

Andean tropical glaciers retreat, with some fluctuations, started after the Little Ice Age (16^{th} to 19^{th} centuries) but the rate of retreat has accelerated since the middle of the 20^{th} century. Depending on the size and phase of glacier retreat there is an expected effect in terms of changes in runoff in basins fed from these glaciers. In an early phase of the glacier retreat runoff tends to increase due to an acceleration of glacier melt, but after a peak in discharge as the glacierized water reservoir gradually empties, runoff tends to decrease. This reduction in runoff is more evident during dry months when glacier melt is the major contribution to runoff. A reduction in runoff could reduce water related benefits and intensify conflicts among different users of water in high elevation Andean tropical basins which concentrates highly vulnerable populations. Glacier retreat has also been associated with disasters such as glacial lake outburst floods (GLOFS) that are a continuous threat in the region. And finally glacier retreat could have impacts on activities that rely on these high mountainous ecosystems such as alpine tourism, mountaineering and adventure tourism.

FAQ 27.2: Can PES be used as an effective way for helping local communities to adapt to climate change?

PES can be used as an effective way to help local communities to adapt to climate change. It can simultaneously help protect natural areas, while improving livelihoods and human well-being. However, during design and

planning, a number of factors at local level need to be taken into consideration in order to avoid potentially negative side effects. Reported setbacks include: poor definition if design should focus on actions or results, perception of commoditization of nature and its intangible values, inneficiency in reducing poverty, difficulties in building trust between parts involved in agreements, and eventual gender or land tenure issues.

FAQ 27.3: Are there emerging and re emerging human diseases as a consequence of climate variability and change in the region?

Climate variability and climate change (CC/CV) are negatively affecting human health in CA and SA, either by increasing morbidity, mortality, and disabilities (very high confidence), or by the emergence of diseases in previously non-endemic regions, or the re-emergence of diseases in areas where they have previously been eradicated or controlled (high confidence). Climate-related drivers have been recognized for respiratory and cardiovascular diseases, vector- and water-borne diseases (malaria, dengue, yellow fever, leishmaniasis, cholera, and other diarrheal diseases), Hantaviruses and Rotaviruses, pregnancy-related outcomes, diabetes, chronic kidney diseases, and psychological trauma. It is very likely that CC/CV together augment current and future risks to health, amidst the region's vulnerabilities in existing health, water, sanitation and waste collection systems, nutrition, and pollution.
