Important categories of extreme events causing negative impacts in rural areas include tropical storms and droughts: Hurricane Stan in October 2005 affected nearly 600,000 people on the Chiapas coast as a consequence of flooding and sudden river overflows (Saldaña-Zorrilla, 2008). Droughts produce severe economic distress in rural areas. Employment reduction as a consequence of lower agricultural productivity and ultimate migration are two of the most common responses (Gray and Muller, 2012). Ericksen *et al*. (2012) review a variety of livestock mortality rates, up to 80% of livestock in some areas, for recent droughts in the Horn of Africa

Climate change impacts on agriculture and ecosystems run through rising temperature and changes in rainfall variability and seasonality as well as through extreme events. Lobell *et al*. (2011) adopt a different approach to and scale of analysis by examining global yields of the four major agricultural commodities, from 1980 to 2008, in relation to temperature trends and in relation to a counterfactual without climate trends. Yields of maize and wheat declined by 3.8 and 5.5% respectively relative to the counterfactual, which offset in some countries some of the gains from improved agricultural technology. Badjeck *et al*. (2010) discuss current and future impacts on fisherfolk across the world. Many local-level studies are subject to the attribution problems mentioned above, but Wellard *et al*. (2012) cautiously note a convergence of climate data with the perceptions of farmers and officials to the effect that over the last 30 years the rainfall in Malawi has become less predictable, that the rainy season is arriving later in the year causing delays in planting of the main crops, and that damaging dry spells during the rainy season have become more likely.

Glacial retreat in Latin America is one of the best evidenced current impacts on rural areas. In highland Peru there have been rapid observed declines since 1962 in glacier area and dry-season stream flow, on which local livelihoods depend, which accord well with local perceptions of changes that are necessitating adaptation (Orlove, 2009). Other studies of the area focus both on observed changes in water availability and on glacial lake outburst floods, which are attributable to climate change (Bury *et al*., 2009; Carey, 2010, Carey *et al*. 2012). There is also a rich specialized literature on the impacts of shrinking sea-ice and changing seasonal patterns of ice formation and melt on Inuit in circumpolar regions (Ford, 2009; Beaumier and Ford, 2010).

Migration associated with weather-related extremes or longer-term climate trends is discussed in Chapter 12, Table 12-3, with empirical examples of migrations linked to droughts, coastal storms, floods and sea level rise. Attribution of migration to climate change is extremely complex, as recognized by Black *et al*. (2011). Life in rural areas across the world typically involves complex patterns of rural-urban and rural-rural migration, which are modified or exacerbated by climate events and trends rather than solely caused by them. Black *et al*. (2011) see environmental drivers of migration as operating in combination with economic, political, social and demographic drivers. MacLeman and Hunter (2010), argue that analogies of historical migration trends associated with environmental change though not with global climate processes, such as the 1930s Dustbowl in the USA (Reuveny (2007) allow closer examination of such multiple causality.

9.3.3. Future Impacts

This section will examine the major impacts of climate change identified or projected for rural areas, under the headings of: economic base and livelihoods; landscape and regional interconnections, including migration, trade, investment and knowledge; and second-order impacts of climate policy. The following section, 9.3.4, assesses literature on impact through a different and specific lens, that of economic valuation, though there is some overlap. The biophysical impacts of climate change on food crops are dealt with primarily in Chapter 7; but also here and in section 9.3.4 insofar as they affect rural economies. Biophysical impacts on non-food cash crops, in particular beverage crops, are discussed below.

As with the observed impacts in section 9.3.2, the future impacts of climate change described here, and quantified in section 9.3.4, are at the latter stages of complex causal chains that flow through changing patterns of extreme events and/or effects of climate change on biophysical processes in agriculture and less-managed ecosystems. This increases the uncertainty associated with any particular impact on the economic base, on land-use or on regional interconnections.

Some of the discussion here will involve issues of vulnerability, particularly contextual vulnerability, but this is discussed more fully in section 9.4 below.

9.3.3.1. Economic Base and Livelihoods

Climate change will affect rural livelihoods, or "the capabilities, assets (stores, resources, claims and access) and activities required for a means of living" (Chambers and Conway, 1992).This is because many rural livelihoods are dependent on natural resources (e.g. agriculture, fishing and forestry), and their availability will vary in a changing climate. This may have effects on human security and wellbeing (Kumssa and Jones, 2010).

The livelihoods framework allows analysis of livelihoods outcomes as embedded within an external context of multiple stresses and dynamics, all of which change over time (Kepe, 2008). Climate variability and change interacts with, and sometimes compounds, existing livelihood pressures in rural areas, such as economic policy, globalization, environmental degradation and HIV/AIDS, as has been shown in Tanzania (Hamisi *et al*., 2012), Ghana (Westerhoff and Smit, 2009), South Africa (O'Brien *et al*., 2009; Ziervogel and Taylor, 2008; Reid and Vogel, 2006), Malawi (Casale *et al*., 2010), Kenya, (Oluoko-Odingoa, 2011), Senegal (Mbow *et al*., 2008) and India (O'Brien *et al*., 2004).

Especially for agriculture and other traditional livelihoods in developing countries, the concept of the "centrality of the social" (Fairhead and Leach, 2006) is important: social relations within households (particularly gender relations) and between households, profoundly affect production decisions, management of knowledge, and marketing (Morton, 2007). Similarly access to diversification as an adaptation to climate extremes depends on gender, age, governance and institutions, as shown in studies in South Africa, Tanzania and Uganda (Goulden *et al*., 2009).

Morton (2007), adapting findings from AR4, suggests that the impacts of climate change on smallholder and subsistence farmers can be conceptualized as a combination of: biological processes affecting crops and animals at organism or field level; environmental and physical processes affecting production at a landscape, watershed or community level; and other impacts, including those on human health and on non-agricultural livelihoods. This schema is developed by Anderson *et al*. (2010), with a cross-cutting dimension of extreme events, increased variability and shifts in average temperature and rainfall, as well as introducing indirect impacts, for example through trade and food prices, and through climate mitigation policies.

An additional dimension is effects of climate change on water supply which in turn affect rural livelihood bases, whether through a decrease or increase. In South Africa, for example, most of the climate change models predict a reduction in freshwater availability by 2050, and a computable general equilibrium approach shows that this will adversely affect household welfare (Juana *et al*., 2008). In the Mount Kenya region, in contrast, the NRM3 Streamflow Model under the TGICA climate change projection will result in an increase of annual runoff by 26%, with a severe increase in flood flows, and a reduction of the lowest flows to about a tenth of the current value (Notter *et al*., 2007). Changing rainfall levels will also affect groundwater levels, which play a role in rural livelihoods. At the continental level in Africa, analysis of existing rainfall and recharge studies suggests that climate change will not lead to widespread catastrophic failure of improved rural groundwater supplies (Macdonald *et al*., 2009). However, at higher resolution groundwater resources are threatened (e.g. in South Africa, Knüppe, 2011), and water crises are expected to multiple resulting from the increasing demand, and this will further affect the people in rural areas who fetch water (Nkem *et al*., 2011).

Water availability plays a key role in the viability of agricultural livelihoods, alongside changes in temperature. Climate change is expected to impact water resources in the Asian region in a major way. A study by the World Bank (2010a) argues that diminishing Himalayan glaciers would impact the agricultural water supply and food security of more than one billion people in Asia. There are some regional and country studies, which support this view. Likewise, Immerzeel *et al*. (2010) in a study of major river basins of the region viz. Indus, Ganges, Brahmaputra, Yangtze and Yellow rivers conclude that different river basins would experience different impacts on water availability and food security due to climate change. They further argue that the Brahmaputra and Indus basins

would be more susceptible to changes in water availability affecting the food security of 60 million people (ibid). ADB (2009a) argues that climate change would increase water stress in four south East Asian countries of Indonesia, Philippines, Thailand and Vietnam.

In assessing the impacts of climate change on water resources in rural areas of Europe, it is predicted that Mediterranean climates will experience more pressure on water resources from reduced rainfall and meltwater from glacial ice and snow. Schroter *et al*. (2005) predict that in the Mediterranean region summer water supply could fall by 20 to 30% following global warming of 2ºC and 40 -50% for 4ºC . These declines would increase the costs of production and living in the South (Falloon and Betts, 2010). Drought could threaten biodiversity and traditional ecosystems particularly in Southern Europe with problems exacerbated by declining water quality. Decline in economic activity may increase rural depopulation and harm the development of rural communities in Southern Europe (Westhoek *et al*., 2006). Given the rapid population growth, economic development and hence increasing completion over water resources (for both agricultural and non-agricultural uses) in the Middle East, the per capita availability of water will be reduced significantly for rural populations (see also Chapter 22) (Chenoweth J, *et al*., 2011; Rochdane *et al*., 2012; Iglesias *et al*., 2010; Hanafi *et al*., 2011, Sowers *et al*., 2011; Verner, 2012: 166). According to MacDonald *et al*. (2009) climate change will not lead to a widespread failure of improved rural groundwater supply in Africa, but it could affect a population of up to 90 million people, as they live in rural areas where annual rainfall is between 200 and 500mm per year, and where decreases in annual rainfall, changes in intensity or seasonal variations may cause problems for groundwater supply.

Various studies conclude a decline in crop yield of agriculture due to climate change over the next three to four decades in different parts of the world (Section 7.2.1, Chapter 7, AR5). For the Asia –Pacific region several studies have concentrated on impacts emanating from the agricultural sector (ADB & IFPRI, 2009; ADB, 2009a; Srivastava *et al*., 2010; De Silva *et al*., 2007; Xiong *et al*., 2009, 2010; Ramirez-Villegas *et al*., 2011) *S*imilarly, studies on the adverse impacts of climatic changes on yields in different parts of North America, Australia and Europe have been conducted (Warren *et al*., 2006; Olesena *et al*., 2011; Anwar *et al*., 2007; COPA COGECA, 2003; Schlenker and Roberts, 2009; Roberts and Schlenker, 2010; Niemi *et al*. 2009; Wolfe *et al*. 2008). The impacts of climate change on the smallholder and rain-fed dominated (96% of all agricultural land is rain-fed) agricultural sector are considered to be very significant to the economies and livelihoods in Africa (Müller *et al*., 2011; Kotir, 2011; Collier *et al*., 2008; Hassan, 2010). These results emerge across a range of scenarios. Several other studies also map declines in net revenues from crops and the associated links with food security and poverty (Molua, 2009; Thurlow *et al*., 2009; Reid *et al*., 2008; World Bank, 2010a; Thurlow and Wobst, 2003. Yield patterns are expected to present spatial differences in South America, as projected by various studies with some losing such as bean growers in Central America and some gaining such as sugarcane cultivators in Brazil. Such country case studies are based on climate projections for SRES A2 and B2 scenarios derived by Hadley Center HadRM3P model (Pinto and Assad, 2008; ECLAC, 2009; ECLAC, 2010a). Adverse impacts on yield derived on the basis of simulations of the above mentioned scenarios imply that since bean growers in Central America are small, low-income farmers, climate change may have large repercussion throughout the region, endangering the food security of large segments of the population (ECLAC, 2010b).

There will also be impacts on non-food cash crops, (or industrial crops), which represent an important source of livelihood in many rural areas. However they have received less attention than traditional agricultural crops when assessing the impacts of climate change. Relevant crops include cotton and other fibres, wine grapes, beverage crops, and a wide variety of others. Yields of several cash crops in the Middle East such as olives, apples and pistachios may decline if winter temperatures are too high (Verner, 2012). Literature on biofuels such as jatropha focuses on the impacts of biofuels on climate change rather than on the effects of climate on yields and other relevant variables in these agricultural systems. Where crops have dual use as food and biofuel (for example oilseeds, sugarcane, sugar beet, maize and wheat) impacts can be inferred from studies that focus on their use for food.

The findings of Easterling *et al*., (2007), that cotton yields are likely to decrease as changes in temperature and precipitation overcome potential benefits of increasing carbon dioxide have been corroborated in other studies, where yield reductions have been estimated the order of 10% (Lee *et al*., 2001) causing substantial economic losses. It is reported that the cotton cultivation in Israel will declined by 52% and 38% under the A2 and B2 scenarios, and

that the net revenue will also decrease by 240% and 173% in the scenarios (Haim *et al*., 2008: 433). Few systematic assessments have been done on other fibre crops such as jute, kenaf, and flax.

Climate change impacts on wine grapes have been extensively studied and documented. Climate impacts such as increasing number of hot days and decreasing frost risk may benefit some varieties. Lobell *et al*. (2006) assess the impacts of climate change on yields of six perennial crops in California by 2099. This paper presents that the production of wine grapes will experience relatively small changes compared to other commodities during the concerned period. The uncertainty analysis shows the yield variations are limited within 10% although Gatto et al. (2009) argue that the revenue of the industry in Napa, California could declined by 2034. Jones *et al*. (2005) indicate that future climate change will exceed climatic thresholds affecting ripening for existing varieties grown at the margins of their climatic limits. Warmer conditions could also lead to more poleward locations potentially becoming more conducive to grape growing and wine production.

The case of tropical beverage crops, in particular coffee, is discussed in Box 9-1, and projected changes in area suitable for all three tropical beverage crops are set out in Table 9-4.

____ START BOX 9-1 HERE ____

Box 9-1. Impacts of Climate Change on Tropical Beverage Crops

The major traded beverage crops coffee, tea and cocoa support the livelihoods of several million small-scale producers in over 60 countries of the tropics of Africa, Asia and Latin America. Coffee production has long been recognized as sensitive to climate variability with global production and prices sensitive to occasional frosts in Brazil – the world's largest producer. Likewise the livelihoods of millions of small producers are dependent both on stability of production and stability in world prices. During the last crash in coffee prices from 2000-2003 poverty levels in the coffee growing regions of Nicaragua increased, while they fell in the rest of the country (World Bank, 2003); subsequently during the drought associated with El Nino in 2005 coffee productivity fell to between a third and half of normal similarly leading to severely reduced income for small producers (Haggar, 2009).

Analysis of the effects of recent climate change on coffee producing areas in Mexico by Gay *et al*. (2006) show that in Veracruz between 1969 and 1998 rainfall has decreased by 40mm and temperatures have increased by 0.02ºC per year. They developed econometric models of the relationship between coffee productivity and fluctuations in temperature and precipitation, which gave an R-squared of 0.69 against historical data. Extrapolating the historical tendencies in temperature and precipitation to 2020 and applying their econometric model they predict that coffee production could decline by 34%, but most importantly this decline in production takes producers from making net profits of on average around US$200 per acre, to less than $20 per acre. This has led to a series of studies projecting the effects of climate change on the distribution of Arabica coffee growing areas of the coming decades summarized below.

For Brazil, Pinto *et al*., (2004) have mapped the changes in area suitable for coffee production in the four main coffee producing states. A 3ºC increase in temperature and 15% increase in rainfall (taken from the general prediction of climate change for Southern Brazil in the IPCC 2001 report) would lead to major changes in the distribution of coffee producing zones. In the main coffee producing states of Minas Gerais and Sao Paulo the potential area for production would decline from 70-75% of the state to 20-25%, production in Gioas would be eliminated, but only a 10% reduction in area in Parana. New areas suitable for production in Santa Catarina and Rio Grande do Sul will only partially compensate the loss of area in other states (Pinto and Assad, 2008). The economic impacts of a rise in temperature of 3ºC would cause a 60% decline coffee production in the state of Sao Paulo equal to nearly 300 million dollars income (Pinto *et al*., 2007).

Models developed by CIAT predict the distribution of coffee under the A2a climate scenario using a statistical downscaling of the climate change data from 20 different GCM models used in the IPCC Fourth Assessment. They use WorldClim data to characterize the current distribution of coffee using 19 climatic variables and then use the climate data downscaled to 1, 5 and 10 km resolution to map where those conditions may occur in the future (2020 or 2050). This method has been applied to coffee distribution in Kenya (CIAT 2010), Central America and Mexico

(Laderach *et al*., 2010), tea production in Kenya (CIAT, 2011b) and Uganda (CIAT, 2011b), and cocoa production in Ghana and Ivory Coast (CIAT, 2011c) (Table 9-4). Only one similar study appears to have been done for Robusta coffee (Simonett, 2002) in Uganda, which appears to show similarly drastic changes in both distribution and total area suitable for coffee production. At a minimum climate change will cause considerable changes in the distribution of these crops disrupting the livelihoods of millions of small-holder producers, in many cases the total area suitable for production would decrease considerably with increases of temperature of only 2-2.5ºC. Although some local areas may have improved conditions for coffee production, e.g. high altitude areas of Guatemala, the overall predictions are for a reduction in area suitable for coffee production by 2050 in all countries studied.

[INSERT TABLE 9-4 HERE
Table 9-4: Projected changes in areas suitable for production of tropical beverage crops by 2050.]

Food security, which is also discussed in Chapters 7 and 13, is now known to reflect a broader range of factors than merely food production (Sen, 1992). In three countries in Africa – Ethiopia, Malawi and Niger - mass mortality food crises since 2000 -were triggered by a moderate decline in crop and/or livestock production, exacerbated by "exchange entitlement failures" – food price spikes and asset price collapses (Devereux, 2009).). For example, the food crisis of 2007-2008 exposed the vulnerability of rural livelihoods to external price shocks. Review of the evidence shows that price rises have a disproportionate impact on the welfare of the poorest of the poor in rural areas - female-headed households (which tend to be poorer than male-headed households) and those who have limited access to land, modern agricultural inputs, infrastructure and education (Ruel *et al*., 2009: 3). This has illustrated that the vulnerability of rural livelihoods is affected by not only ecological, but also social and economic factors that mediate or hinder people's access to different assets and capacities to adapt (Ericksen, 2008a, b; Ellis, 2000: 290-91). However, changes in production will play a role in affecting food security and resultant increases in malnutrition (Ringler, 2010).

Post-harvest aspects of agriculture – storage on farm and commercially, handling and transport – have been relatively neglected in discussions of climate change, but will be affected by changes in temperature, rainfall, humidity, and by extreme events. Many adaptation opportunities are already understood by postharvest service providers, but getting postharvest knowledge into use at scale is a significant challenge (Stathers *et al*. submitted).

Rural food security is discussed extensively in the regional chapters of this report. Major themes include: for Africa the range of contributing factors including globalization (22.3.3.1.5), and the adaptation responses of farmers (22.3.3.16); for Asia (24.4.4) the regional variation in yields across crops and countries, and potential for adaptation; for North America the high food insecurity in Mexico and the vulnerability to climate change of food security in indigenous communities (26.6, 26.7); for Central and South America (27.3.4) the threats to the food security of the poor in specific agricultural regions, and the inter-linkages between food and bioenenergy and farmers' responses. Links between food security and agriculture trade are also discussed in 9.3.3.3 below.

Agricultural livelihoods are not restricted to crops, but also involve livestock in a variety of farming systems (Devendra *et al*. 2005). Thornton *et al*. (2009) view the impacts on livestock of climate change as a neglected research area, complicated by other drivers of change, broader development trends, rapid change in livestock systems, spatial heterogeneity and social inequality between livestock-keepers. Drawing on livestock science, range ecology and projected climate trends, they review some possible future impacts through quantity and quality of feeds, heat stress, water, disease and others. Impacts through drought will be significant, as will heat stress, particularly of *Bos taurus* cattle. Impacts through animal health and disease will be even harder to predict than other categories of impact (Thornton *et al*., 2009). Aggregating at the level of one country, Kabubo-Mariara (2009) shows that livestock production in Kenya is highly sensitive to climate change, whereby increased mean precipitation of 1% could reduce revenues by 6%.

Pastoralists, who are dependent on livestock grazed in arid, semi-arid or mountainous areas, represent a specific case, display very specific combinations of adaptive capacity, especially through mobility, and vulnerability, as discussed in 9.3.5 below. Ericksen *et al*. (2012), with particular reference to East Africa, discuss possibilities of loss

of rangeland productivity, changes in rangeland composition towards browse species, and changes in herd dynamics through more frequent droughts as possible impacts. In the Middle East, rangelands will be under substantial climate stress which may reduce their carrying capacity, in light of the growing demand for meat products and the region's growing size livestock population (Verner, 2012: 166). Little *et al*. (2001) discuss impacts of floods, directly and through disease, on pastoral herds. Six SRES scenarios generated by six GCMs were used by Hein *et al* .(2009) for the Ferlo Region in Northern Senegal, where livestock keeping is the main economic activity of the rural population. A modest reduction in rainfall of 15% in combination with a 20% increase in rainfall variability could have considerable effects on livestock stocking density and profits, reducing the optimal stocking density by 30%.

As extensive livestock production is associated with semi-arid areas marginal for cropping, some authors project shifts toward livestock production under climate change. Jones and Thornton (2009) identify major transition zones across Africa where increased probability of drought between now and 2050 will create conditions for shifts from cropping to livestock. Data from over 9000 African livestock farmers in 10 countries shows that farmers are more likely to have livestock as temperatures increase and as precipitation decreases, based on logit analysis to estimate whether farmers adopt livestock, followed by three econometric models to determine species choice. These analyses predict a decrease in the probability of beef cattle and an increase in the probability of sheep and goats, and more heat-tolerant animals will dominate the future in Africa (Seo and Mendelsohn, 2007a). A development of the Ricardian method shows that these choices relate to the net income of different animal species. On this basis, large-scale commercial beef cattle farmers are most vulnerable to climate change in Africa, particularly since they are less likely to have diversified (Seo and Mendelsohn, 2007b). To Sallu *et al*. (2010), investment in and accumulation of physical assets, including land and livestock, can be a strategy to decrease vulnerability

Livelihoods dependent on fisheries will also experience vulnerability to climate change. Impacts of climate change on aquatic ecosystems will have adverse consequences for the world's 36 million fisherfolk as well as the nearly 1.5 billion consumers who rely on fish for more than 20% of their dietary animal protein (Badjeck *et al*., 2010). An indicator approach showed that economies with the highest vulnerability of capture fisheries to climate change were in Central and Western Africa (e.g. Malawi, Guinea, Senegal, and Uganda), Peru and Colombia in north-western South America, and four tropical Asian countries (Bangladesh, Cambodia, Pakistan, and Yemen)(Allison *et al*., 2009). This vulnerability arises from the combined effect of predicted climate change on fish stocks, the relatively high share of fisheries as a source of income (including export earnings) and diets, and limited societal capacity to adapt due to the prominence of poverty in these societies (Allison *et al*., 2009). In another study of changes in climate and social systems in north eastern Asia on fisheries development, Kim (2010) argues that in countries like China, Japan and South Korea these changes could have a negative impact on fisheries adversely affecting livelihoods and food security of the region. (Chapter 7, AR5, provides an assessment of the impacts of climate change on the biological and ecological processes in aquatic ecosystems and on livelihoods that depend on the fisheries and aquaculture sector).

Diversification into non-farm incomes might accelerate if climate-related risks of farm income failure increase as a result of climate change, although it is also determined by other factors such as poverty, income distribution, farm output, gender, labour and credit markets (Ellis, 2000). Such diversification would help households achieve low risk correlations between their livelihood components (Ellis, 2000).

9.3.3.2. Infrastructure

Assessments of the impacts of climate change on infrastructure take a general or urban perspective and do not focus on rural areas, though rural impacts can be inferred. For example, river flooding and sea level rise will produce temporary loss of land and land activities, and transportation infrastructure particularly on coastal areas (Kirshen et al 2008). Climate change will affect current water management practices and the operation of existing water infrastructures, which are very likely to be inadequate to overcome the negative impacts of climate change on water supply reliability (Kundzewicz *et al*., 2008). Some documented impacts on dams, reservoirs and irrigation infrastructure are: reduction of sediment load due to reductions in flows (associated with lower precipitation), this positively affects infrastructure operation (Wang *et al*., 2007); impacts of climate variability and change on storage capacity that creates further vulnerability (Lane *et al*., 1999); and failures in the reliability of water allocation

systems (based on water use rights) due to reductions of streamflows under future climate scenarios (Meza *et al.*, 2012).

9.3.3.3. Spatial and Regional Interconnections

In both developing and developed countries, rural areas have been increasingly integrated with the rest of world. The main channels through which this rapid integration process takes place are migration (permanent and cyclical), commuting, transfer of public and private remittances, regional and international trade, inflow of investment and diffusion of knowledge through new information and communication technologies (IFAD, 2010), as well as the spatial intermingling of rural and urban economic activities, labelled as desakota systems and discussed in Section 9.1.3 above. A trend to increase in urban areas can be associated with different spatial patterns, reflecting alternative development processes, e.g. periurbanisation versus counter-urbanisation (Rounsevell *et al.*, 2007). In this context, changes in the occurrence of some types of extreme events due to climate change, increased variability, and changing mean climate parameters are *likely* to have significant implications for regional and global integration trends in rural areas.

9.3.3.3.1. Migration

Growing efforts are researching environmental migration, building on the AR4 conclusion that extreme events might lead to changed patterns of migration (Boko *et al.*, 2007). Though the impacts of climate change are *likely* to affect population distribution and mobility, it is difficult to establish a causal relationship between environmental degradation and migration, which is still termed "complex and unpredictable" (Brown, 2008). Hence, the link between internal migration and environmental stresses is contested. One school of thought shows migration (and particularly rural out-migration) increasing during times of environmental stresses (e.g. Afifi, 2011; Gray and Mueller, 2012), with projections that these trends will continue under climate change (Kniveton et al, 2011). This may also affect human security (Brown and Crawford, 2008). Growing vulnerability to environmental change may also lead to an increase in abandonment of settlements (McLeman, 2011).

However, some estimates and forecasts of the potential number of displaced people because of climate change are being challenged by another body of literature which argues that migration rates are no higher under conditions of environmental or climate stress (Black, 2011; van der Geest, 2011; van der Geest and de Jeu, 2008; Tacoli, 2009; McLeman and Hunter, 2010; Gemenne, 2011; Foresight, 2011; Cohen, 2004; Brown, IOM, 2008). Some studies have ascertained (Mertz *et al.,* 2007; Parnell and Walawege, 2011) that climatic variabiity is certainly one of the most significant catalyst for migration toward urban areas, as has been the case during the severe droughts occurred in the Sahel in the 70s and the 90s, but the current alarmist predictions of massive flows of refugees (so called ''environmental refugees'' or ''environmental migrants''), are not supported by past experiences of responses to droughts and extreme weather events and predictions for future migration flows are tentative at best (C. Tacoli, 2009; M'bow 2011). Similarly, a recent survey by Mertz *et al.* (2010) has argued that climate factors play a limited role in past adaptation options of sahelian farmers.

There have also been attempts to understand the nexus between migration and climate change through examining analogous experiences in the past and present in which climate variability is associated with particular kinds of population movements (McLeman and Hunter 2010). For example, in Ghana the causality of migration was established to be relatively clear in the case of sudden-onset environmental perturbations such as floods, whereas in case of slow-onset environmental deterioration, there was usually a set of overlapping causes - political and socioeconomic factors – which come into play (van der Geest, 2011). Given the multiple drivers of migration (Black *et al.*, 2011) and the complex interactions which mediate migratory decision-making by individual or households (Raleigh, 2008; McLeman and Smit, 2006; Kniveton and Al., 2011, Blake and Al, 2011), the detection of the effects of climate change on intra-rural and rural-to-urban migration remains a major challenge.

9.3.3.3.2. Trade

Although agricultural exports accounted for only one sixth of world agricultural production and consumption (Anderson, 2010), it is the sector for which most data is available, and is the focus here. Between 2000 and 2008, the value of global agricultural exports rose from US$ 551 billion to US$ 1,342 billion, representing an average annual growth of 5 percent (WTO, 2009). In addition to trade in primary crops, trade in processed food, fish and forest products has also been expanding (WTO, 2009). However, the fundamentals of agricultural trade have changed significantly in the late 2000s. There was a major agricultural price spike, and historically high degree of price volatility towards the end of the period. Some cyclical and structural factors – such as droughts in several major producers, including Australia, Ukraine and the United States, creating shortage of cereals in international markets, the expansion of bio-fuels at the expense of food crop production, export controls, growing demand by emerging economies for secondary agricultural products such as meat, energy and feed crops, financial speculation – have led to a volatile and unpredictable trading environment (FAO, 2008; Timmer, 2010; Schmidhuber and Matuschke, 2010; Karapinar and Haberli, 2010; Headey , 2011).

Against this backdrop, climate change is expected to affect the pattern and volume of international agricultural trade flows. At the sectoral and product levels, it may alter the comparative advantage of countries and regions through its potential impacts on their agricultural supply capacities. These effects will be reflected on agricultural prices – which are the signals of economic scarcity or abundance. Recent studies produce even more pessimistic projections of climate change on food prices differentiated at the crop level than did AR4 (Easterling *et al.,* 2007). For example, simulations results of two climate models —the National Centre for Atmospheric Research, US (NCAR) and the Commonwealth Scientific and Industrial Research Organization, Australia (CSIRO) —based on A2 scenario inputs — suggested that climate change might result in additional price increases in 2050, ranging from 30-37 percent for rice, 52-55 percent for maize to 94-111 percent for wheat (Nelson *et al*., 2009). If CO_2 fertilization is taken into account, the 2050 price increases are expected to be smaller (for example, by 15-17 percent for rice relative to no CO_2 fertilization). It is important to note that these price increases are projected in addition to the price increases (62 percent in rice, 63 percent maize, and 40 percent in wheat) that are expected under no-climate-change scenario, which are largely driven by population and income growth projected to be greater than productivity and area growth (Nelson *et al*., 2009a). Other studies, using different models and scenario combinations, produce significantly different results in relation to price projections. For example, IFPRI using the International Model for Policy Analysis of Agricultural Commodities and Trade (IMPACT) estimates additional price increases for 2050 (relative to no-climate change) of 32- 34 percent for maize (with baseline and pessimistic scenarios in relation to population and income growth (e.g. human well-being)), 18-20 percent for rice (with optimistic and pessimistic human well-being scenarios) and 23-24 percent for wheat (with baseline and pessimistic human well-being scenarios) (Rosegrant, *et al.,* 2008; Nelson *et al*., 2010). This reflects the high level of uncertainty on price predictions (Rivera-Ferre and Ortega-Cerdà, 2011) and the caution needed to develop food policies.

The prices of beef, pork and poultry are also projected to increase significantly under A2 inputs simulated in CSIRO and NCAR models. Accordingly, in addition to the projected price increases, under no-climate-change scenario, of 33%, 36%, 35% for beef, pork and poultry respectively, 20%, 18%, 21% increases are projected for 2050 under climate change scenario for these three commodities respectively, without taking into account CO2 fertilization ((Nelson *et al*., 2009a).

The projected production and price changes across regions will affect trade flows substantially. Without climate change, net developed-country exports (of rice, wheat, maize, millet, sorghum, and other grains) to developing countries are expected to increase by 22.4 million mt, from 83.4 million mt to 105.8 million mt between 2000 and 2050, representing a growth of 27 percent (Nelson *et al*., 2009b). Climate change might lead to an additional export volume of 0.9 million mt (with wetter NCAR scenario) to 39.9 million mt (with drier CSIRO scenario) (Nelson *et al*., 2009b). Developed-country exports are projected to increase by an additional 12 to 18 percent relative to no climate change if CO2 fertilization is taken into account (Nelson *et al*., 2009b). Regions such as South Asia, East Asia and Pacific are projected to increase their imports substantially over this period. For example, South Asia which exported around 15 million mt in 2000 is expected to import up to 54 million mt (with drier CSIRO scenario) (Nelson *et al*., 2009b). By 2050, the Middle East and North Africa region and Sub-Saharan Africa which are already net importers of cereals are estimated to increase the volumes of cereals imports by 29 and 30 percent, respectively

(Nelson *et al*., 2009b). In addition, due to climate impacts on prices, trade flow values will increase even at higher rates than trade volumes.

However, there are other models producing substantially different projections for developed country cereals exports. For example, MIROC scenario (produced by the Center for Climate System Research, University of Tokyo) with A1B-induced production effects on U.S. maize production project a radical decline in net maize exports by up to 70 percent by 2050 (Nelson *et al*., 2010). This is in sharp contrast to the projection that U.S. exports would double under no-climate change scenario (Nelson *et al*., 2010). These different projections underline the high degree of uncertainty in the climate scenarios.

The literature highlights the potential role of international trade in managing the effects of climate change on agricultural productivity (Nelson *et al*., 2009; Huang *et al*., 2011:12; Jankowska, et al 2012). Models show that world trade volumes would need to increase substantially to offset the negative welfare effects of climate-change induced crop yield variability (Reimer and Li, 2009). This would also allow some countries to capitalize on new export opportunities arising from higher achievable yields, for example in Argentina (Asseng *et al*., 2013) or increasing heterogeneity of climate impacts on yields, for example in Tanzania (Ahmed *et al*., 2012). Similarly, it is projected that climate-induced food deficits occurring in low income developing countries will be supplied, fully or partly through food aid. Hence food aid agencies, which have already been struggling to deliver aid in an environment of growing scale of poverty and malnutrition due to the recent price hikes and of historical volatility in food aid supplies might face additional operational challenges (Barrett and Maxwell, 2006; Harvey *et al*., 2010). Staple food trade might also save water resources, and hence contribute to adaptation efforts in rural areas, as the total volume of embedded water ("virtual water") in trade is projected to decrease under climate change (Konar *et al.,* 2013).

The potential role that trade could play in managing the impacts of climate change will inevitably be affected by countries' trade policies. For example, during the 'food crisis' of 2007–2008, dozens of countries instituted various forms of export restrictions on food staples, in order to maintain domestic availability of supplies, which created additional volatility in global markets (Anderson and Nelgen, 2012; Headey, 2011; Karapinar, 2011, 2012). Low-income countries are particularly vulnerable to such volatilities (FAO, 2008; Reimer and Li, 2009).
The emerging literature on the subjects illustrates that deepening agricultural markets through trade reform, improved market access, and institutional efforts to improve the predictability and the reliability of the world trading system as well as by investing in additional supply capacity of small-scale farms in developing countries could help reduce market volatility and offset supply shortages which might be caused by climate change (UNEP, 2009; WTO, 2009; Nelson *et al*., 2009a and 2009b; Reimer and Li, 2009; Ahmed *et al*., 2012).

9.3.3.3.3. Investment

Climate change may also affect investment patterns in rural areas. On the one hand, countries, regions and sectors that are expected to be affected adversely by climate change may have difficulty attracting investment. On the other hand, ecological zones that will become favourable due to climate change are expected to see increasing inflow of investment. For example the recent price hikes in agricultural commodities have led to new initiatives of foreign direct investment (FDI) in the form of large-scale crop production in poor countries (Anseeuw *et al*., 2012; World Bank, 2010). This type of FDI seems to follow a new pattern whereby capital-endowed countries with high imports of food or feed crops are preparing to invest in large production projects in low-income countries endowed with low-cost labour force, land and water resources. Climate change may lead to similar investment patterns. However, there is a risk that these new investments might not be integrated into local structures and the local populations becoming increasingly vulnerable as they might lose access to vital assets such as land and water (Anseeuw *et al*., 2012). On the other hand, if FDI comes with a basket of new technology, business connections, infrastructure and human capital, and if such investments lead to local business development and employment generation, they could bring substantial benefits to the host country (World Bank, 2010).

9.3.3.3.4. Knowledge

Rural areas, as never before, are exposed to diffusion of knowledge through migration, trade and investment flows, technology transfers, and improved communication and transport facilities (IFAD, 2010), although differentials n knowledge access between rural and urban areas remain. Future impacts of climate change on these channels of integration will affect the pace and intensity of knowledge transfers. For example, increased transport and communication connectivity can reduce disaster risk by providing a greater diversity of livelihood options and improving access to education (Pelling and Mustafa 2010). If trade, migration and investment flows will be intensified as a result of climate change, this will inevitably have a positive impact on knowledge transfer both from and to rural areas.

Traditional Ecological Knowledge (TEK and also known by a variety of other terms), developed to adapt to past climate variability and change, can both be impacted by climate change and used and transformed in adaptation (Nyong, *et al.,* 2007). Ettenger (2012) discusses how seasonal hunting camps among the Cree of Northern Quebec that were the occasion for intergenerational knowledge transfer have been disrupted by changing bird migrations, while new technologies such as the internet, GPS and satellite phones have been integrated into livelihood strategies. Climate-change induced migration can threaten LTK transfer (Valdivia *et al*., 2010; Giles *et al*., 2013). Disaster management by cental government may undermine decentralization efforts, disfavouring TEK transfer (Dekens, 2008).

9.3.3.4. Second-Order Impacts of Climate Policy

Policy responses to climate change impact on rural people and can affect their livelihoods and environment. The need to work towards increasing energy supply from renewable resources as responses to climate change, will in time manifest themselves in landscape changes, whether it be through the granting of planning consents for wind farms, the creation of a market for energy crops, structural changes in coastal defences, etc. (Dockerty *et al*., 2006), or increased employment opportunities (del Río and Burguillo, 2008).

Social responses to these changes are expected (Molnar 2010) while some impacts have already been documented. One of the most analysed is the promotion of biofuel crops, which have been an extremely controversial issue in the last decade. Delucchi (2010) concludes that biofuels produced from conventional intensive agriculture will exacerbate stresses on water supplies, water quality, and land use, and thus will have impacts on rural areas (land-use change) and agriculture. Concerns have already been expressed about the impact of biofuel production on food security due to increase in food prices, increasing land concentration (and landgrabs), and competition for water (Eide, 2008; Müller *et al*., 2008). Gurgel *et al*. (2007) modeled potential production and implications of a global biofuels industry: estimated production at the end of the century will reach 220-270 exajoules in a reference scenario, and 320-370 exajoules under a global effort to mitigate greenhouse gas emissions. They recognise the need for a high land conversion rate to achieve this. Delucchi (2010) suggests developing biofuels programs with low inputs of fossil fuels and chemicals, that do not require irrigation, and that use land with little or no economic or ecological value in alternative uses (Plevin *et al*., 2010). This implies analysing each case in its context, including production for both local and global markets.

Another relevant climate-policy developed in the last few years under the UNFCCC umbrella has been the REDD mechanisms. Major criticisms of this instrument arise from the difficulties posed for the participation of communities in REDD programs and its potential in undermining a general decentralization of forest management (Phelps, Webb, and Agrawal 2010), which is shown to be essential for a sustainable management of forests and reducing vulnerability of forest-dependent communities. Campbell (2009) notes the presence of some ssynergies between mitigation through REDD and adaptation, but also trade-offs between REDD, rural incomes, and rural equity. To address these problems Sikor *et al*., (2010) suggest the recognition and operationalizing of forest peoples' rights through participation of communities in decision-making, equitable distribution of forest benefits, and recognition of their particular identities. This will require the implementation of a polycentric approach implying a nested forest and climate governance.

9.3.4. Valuation of Climate Impacts

This section assesses literature on climate change impacts through studies that have adopted various economic methods for valuation of impact. Valuation of impacts of climate change on rural areas is a difficult task and should reflect the significance of the ecological service categories for different stakeholders, including women (Kennet 2009) and minority groups, and ideally the valuations of unit changes in the levels of those services across management options. Valuations can be made at individualistic or communal levels (Farber *et al*., 2006). different understandings of value may exist (Spangenberg and Settele, 2010; Kosoy and Corbera, 2010), as well as different philosophical approaches to address it (from positivists to ethicists) (Weisbach and Sunstein, 2008), which makes more difficult to agree on valuation methodologies. The impacts of climate change are expected to be unequally distributed across the globe, with developing countries at a disadvantage, given their geographical position, low adaptive capacities (Stern, 2007; World Bank, 2010a) and the significance of agriculture and natural resources to the economies and people (World Bank, 2010b; Collier *et al*., 2008). Both direct and indirect impacts have been projected, such as lower agricultural productivity, increase in prices for major crops and rise in poverty (Hertel *et al.,*2010), which have implications for rural areas and rural communities. This section discusses literature on the valuation of impacts as relevant for rural areas and arising from climate change, with reference to agriculture, fisheries and livestock, water resources, GDP and rural economy, extreme weather events and sea level rise and health. There are various channels through which changes in economic values may occur in rural areas, such as through changes in profitability, crop and land values and loss of livelihoods of specific communities through changes in fisheries and tourism values. Losses and gains in health status and nutrition, and wider economy-wide impacts such as changes in job availability and urbanization also impact economic values that accrue to rural communities, the opportunities and the constraints that rural communities experience and changes that rural landscapes undergo. The impact on availability of fresh water resources is another major area of concern for the developing regions in particular. Climate change can adversely impact poverty through multiple channels (Section 10.9, chapter 10, AR5).

Viewing impacts regionally, despite the ongoing debates around the uncertainty and limitations of valuation studies, scholars generally agree that African countries could experience relatively high losses compared to countries in other regions (World Bank, 2010b; Watkiss *et al*., 2010; Collier *et al.,* 2008). These conclusions emerge across a range of climate scenarios and models used by researchers. For instance, Watkiss *et al*. (2010) use the FUND model for a business as usual scenario and a mitigation 450ppm 2 degrees scenario as generated by using the PAGE2002 model, while the World Bank uses a range of country specific models for calculating costs. Overall negative consequences are seen for Africa and Asia, due to changes in rainfall patterns and increases in temperature (Müller *et al*., 2011). Though climate change and climate variability would impact a range of sectors, water and agriculture are expected to be the two most sensitive to climatic changes in Asia (Cruz *et al*., 2007, Chapter 3 AR5) and for droughts in particular for Australia (Nelson *et al.,* 2007, Meinke and Stone 2005). In South American countries, higher temperatures and changes in precipitation patterns associated with climate change affect the process of land degradation, compromising extensive agricultural areas in LAC countries. Research on climate change impacts in rural North America has largely focused on the effects on agricultural production and on indigenous population, many of whom rely directly on natural resources. Developed countries in Europe will be less affected than the developing world (Tol *et al.,* 2004), with most of the climate sensitive sectors located in rural areas.

Valuation and costing of climate impacts, draws upon both monetary and non-monetary metrics. Most studies use models that estimate aggregated costs or benefits from impacts to entire economies, or to a few sectors, expressed in relation to a country's gross domestic product (GDP) (Stage, 2010; Watkiss, 2011). Values which are aggregated across sectors generalise across multiple contexts and could mask particular circumstances that could be significant to specific locations, while expressing outcomes in aggregated GDP terms. This is a matter of concern for economies in Africa and Asia, where subsistence production continues to play a key role in rural livelihoods. Valuation of non marketed ecosystem services poses further methodological and empirical concerns (Dasgupta, 2008; Dasgupta *et.al*., 2009; Watkiss, 2011; Stage, 2010). Würtenberger *et al*. (2006) developed a methodology to estimate environmental and socio-economic impacts of agricultural trade regarding virtual land use, and Adger *et al*. (2011) use qualitative methodologies to consider non-market and non-instrumental metrics of risk, based on

principles of justice and recognition of individual and community identity, which they suggest should be considered in decision-making.

Integrated assessment models and cost-benefit tools have been criticised for not being a valid tool to assess intergenerational events, processes with high levels of uncertainty and irreversibility, for not considering equity concerns, power structures, or for assigning monetary values on the basis of incomplete information or assuming speculative judgments regarding the monetary value of, e.g. natural resources (Ackerman et al. 2009; Toman 2006; Kuik *et al*., 2008), not recognising incommensurability (Aldred 2012). In recent years, various perspectives for valuing the economic impacts of climate change have come into focus including the feminist (Nelson 2008; Power 2009), deliberative (Zografos and Howarth 2010) or behavioural economics (Brekke and Johansson-Stenman 2008; Gowdy 2008), and the integration of economics with moral and political philosophy (Dietz *et al*., 2008). Some common characteristics of these new approaches include transdisciplinarity, acknowledging the diversity of views and maintaining complexity in models. Research in this area although relatively recent, shows promise.

Illustrative regional and sub-regional estimates for the value of impacts of climate change are presented here. Estimates for agriculture in most cases relate directly to rural lives. A range of other impacts on which available information exists is also considered, since these values and costs concern significant proportions of livelihoods and assets in rural areas. It is also to be noted that available literature concentrates on certain sectors and a few countries. For instance, research on specific rural populations is less developed than for particular sectors that are largely located in rural spaces such as agriculture. Limited information is available on West Asia and Pacific islands, on health impacts for both Africa and Asia, small and poor communities of the Arctic (Furgal and Seguin 2006, Furgal and Prowse, 2008; Ford and Pearce, 2010).

9.3.4.1. Agriculture

Changes in agricultural production will have corresponding impacts on incomes and wellbeing of rural peoples. The largest known economic impact of climate change is upon agriculture because of the size and sensitivity of the sector, particularly in the developing world and to a lesser extent in parts of the developed world. A large number of studies to evaluate the impacts on the agricultural sector and its ramifications for communities have been conducted at various scales, ranging from micro level farm models to large scale regional and country level climate cum socio-economic scenario modeling exercises. Some of these also report values for associated economic losses. Since models are simplifications of complex real world phenomena, different models tend to highlight different aspects of impacts and their consequent economic values. For instance, in estimating economic losses the Ricardian method has been used widely to study climate change impacts in agriculture and inbuilt adaptation. However, often such analysis does not incorporate features like technological progress, relative price changes, agricultural policy and other dynamic characteristics. Similarly on the bio-physical impacts side, changes in the El Niño/Southern Oscillation (ENSO) statistics may also have serious economic implications for the agricultural sector in certain countries such as in Latin America and Australia (Kokic *et al.,* 2007). However, ENSO responses differ strongly across climate models, and at the current stage of understanding do not allow conclusions to be drawn on how global warming will affect the Tropical Pacific climate system (Latif and Keenlyside, 2009). A sample of the available studies is provided in Table 9-5.

[INSERT TABLE 9-5 HERE
Table 9-5: Illustrative sample of studies on economic value and changes in value from climate change.]

9.3.4.2. Other Rural Sectors: Water, Fisheries, Livestock, Mining

The changes in valuation of water resources due to climate change arise from expected impacts on populations dependent on these water resources and these will be felt in several parts of the world (Sections 3.4.9, 3.5 and 3.8, Chapter 3, AR5). Monetary estimates of losses due to impacts on water resources are not generalizable. Among alternative approaches to value water resources, use of the water footprint tool (Hoekstra and Mekonnen, 2012) and

the concept of virtual water has been suggested for informing policy-makers in water-scarce countries, such as Egypt.

Analysis of intergenerational valuation has shown to provide some interesting results in valuation of marine fisheries (Ainsworth and Sumaila 2005). For fisheries in rural coastal areas, some of the challenges faced include the valuation of environmental externalities such as breeding habitats, or mangroves, that might be lost due to climate change or other forces (Hall 2011). It has also been argued that the true worth of livelihoods dependent on fisheries in developing countries, where these constitute part of a diversified livelihood or subsistence strategy, requires a different set of metrics from those used in the developed world (Mills et al. 2011). Climate change can also have significant impacts on livestock keeping (Section 9.3.3.1 current chapter). Franco *et al*. (2011) reveal significant declines in forage for ranching in California under SRES scenarios B1 and A2. The dairy sector in California is predicted to lose $287-902 million annually to climate impacts by the end of the century (Lal *et al.,* 2011).

A relatively less researched area which may impact the livelihoods of rural communities is mining (Section 26.11.1.2). Pearce *et al*. (2011) highlight the current and ongoing vulnerability of mining and mining communities in Canada, often rural and with few other economic activities, to climate change. Current and past infrastructure for mines was built under a no-climate change presumption and economic and ecological vulnerabilities as a result are substantial, and industry actors are unprepared to deal with this. As with other industrial sectors, the extent of loss would vary depending on the importance of the sector in the local economy (Backus *et al*., 2012).

9.3.4.3. GDP and Economy-Wide Impacts

In a regional review of economics of climate change in four south East Asian countries of Indonesia, Philippines, Thailand and Vietnam, ADB suggests that climate change would result in a mean annual loss of 2.2% of GDP by 2100 if only market related impact is accounted. If non market impacts related to health and ecosystems are also accounted for, then it would result in 5.7% annual loss of GDP for the same period (ADB, 2009a). Bigano *et al*. (2008) suggest that a predicted 25cm rise in sea level alone would result in a GDP loss of 0.1% in southeast Asia by 2050. Another estimate suggests that four Asian countries of Bangladesh, India, Philippines and Vietnam had a cumulative loss of $20billion due to natural disasters in the last decade, which makes them quite sensitive to climate risks (ADB, 2009 b). In case of Bangladesh, which is extremely vulnerable to climate change because of a large area less than 5 metres above sea level, a single severe cyclone could result in damages worth $9 billion by 2050 accounting for 0.6% of the country's GDP (ADB, 2009b). Most of the impacted regions are rural, and coastal. Thus the implied losses in GDP become relevant for the rural communities in these countries.

Coastal and island rural communities throughout North America are less able to afford major infrastructure improvements and will thus be more vulnerable to the effects of sea level rise, including waterborne and food borne diseases, water table salinity, and diminished storm protection from affected reefs and wetlands, but detailed costs are very site-specific (Hess *et al.,* 2008). Cordalis *et al*. (2007) discuss the climate vulnerabilities and policy complexities facing Native American tribes and note that moving villages where needed could cost billions of dollars.

In Arctic Canada and Alaska, infrastructure built for very cold weather will deteriorate as the air and ground warm. Larsen *et al*. (2008) estimate increases in public infrastructure costs of 10-20 percent through 2030 and 10% through 2080 for Alaska, amounting to several billion dollars, much of it to be spent outside of urban centers. The climate models used were part of the IPCC's coordinated AOGCM model inter-comparison project and the underlying model assumptions are based on a middle-of-the-road ''A1B'' emissions and growth scenario defined by the IPCC. Lemmen *et al*. (2007) reports that foundation fixes alone in the largely rural Northwest Territories could cost up to CAN$420 million, and that nearly all of Northern Canada's extensive winter road network, which supplies rural communities and supports extractive industries which bring billions of dollars to the Canadian economy annually, is at risk. Replacing it with all-weather roadways is estimated to cost CAN$85,000/km.

9.3.4.4. Extreme Weather Events, Sea-Level Rise

The climate change related extreme events that may cause changes in economic values in rural areas include heat waves and droughts, storms, inundation and flooding (Stern 2007; Handmer *et al*., 2012; Section 3.4.9, Chapter 3, AR5). A detailed discussion on the costs of climate extremes and disasters is set out by Handmer *et al*., 2012. Costs can be of two kinds: losses or damage costs and costs of adaptation. While some of the costs lend themselves to monetary valuation (such as infrastructure costs) others cannot be easily estimated such as the value of lives lost and the value of eco system services lost (for discussion on the methodologies for valuing costs refer to Handmer *et al*., 2012: Section 4.5.3).

Damage costs of floods and droughts (Section 10.3.1, chapter 10, AR5) and from rise in water levels in Europe (Swiss Re, 2009a) demonstrate the cost implications for rural communities in the developed regions of the world. Studies mapping the adverse impacts in UK and Europe show a range of sectors that are impacted in rural areas particularly due to drought in Europe and flooding in UK. For instance, major impacts hit farming and forestry with an estimated $15 billion production lost through drought, heat stress and fire (Munich Re 2004), the worst effect being on summer crops in Mediterranean regions (Giannakoupoulos *et al*., 2009). Longer term adaptation could reduce the severity of losses but could include displacement of agricultural and forestry production from Southern Europe to the North. The UK Government's Foresight Programme (2004) estimates that global warming of 3 to 4 ºC could increase flood damage from 0.1% up to 0.4% of GDP. In Europe costs could rise from $10 billion today to $120-150 billion by 2100. With strengthened flood defences these costs may only double. Much of the investment in flood defences and coastal protection would be in rural coastal areas.

Several studies from the developing countries provide evidence on the substantial costs rural communities in particular face in these countries. Salinity and salt water intrusion have implications for rural livelihoods as they impact both fisheries and agriculture (Section 5.5.3, Chapter 5, AR5). Sea level rise also leads to wetland loss and coastal erosion. A few illustrations of the range of impacts of relevance for the rural economy are provided here. Loss of agricultural land and changes in the saline-freshwater interface is estimated to impact the economies of Africa adversely (SEI, 2009, S. Dasgupta *et al.,* 2007). Ahmed *et al*., (2009) suggest that climate volatility from increase in extreme events, increases poverty in developing countries, particularly Bangladesh, Mexico, Indonesia and in Africa. They also find that on simulating the effect of climate extremes on poverty in Mexico using the SRES A2 scenario as generated by CMIP3 multi-model dataset, rural poverty increases by 43-52% following a single climate shock. Kronik and Verner (2010) note that some 12% of Mexico's population is indigenous and that these rural subsistence communities are vulnerable to extreme weather events and often depend on climate-sensitive crops like coffee. Studying extreme events Boyd and Ibarrarán (2009) use a CGE model to simulate the effects of a long drought on the Mexican economy and find declines in production of 10-20% across a variety of agricultural sectors. Scenario-based stakeholder engagement has been tested for coastal management planning under climate change threats (Tompkins *et al*., 2008) and to determine impacts and responses of extreme-events in coastal areas (Toth and Hizsnyik, 2008).

9.3.4.5. Recreation and Tourism; Forestry

Studies assessing the changes in economic value of recreation and tourism due to climate change are relatively fewer in number (coastal tourism is discussed in Section 5.4.4.2, Chapter 5, AR5). While some studies locate an increase in values for certain regions others estimate shifts in tourism and losses (Bigano *et al*., 2007; Hamilton *et al*., 2005; Beniston, 2010), methodological challenges and contrasting findings for the short and long run pose problems in generalizing findings (economic values for recreation and tourism are discussed in Section 10.6, Chapter 10, AR5). Change in economic values will impact rural communities (Lal *et al*., 2011), with the linkages between biodiversity, tourism and rural livelihoods and rural landscapes being an established one both for developing and developed countries (Nyaupane and Poulde 2011, Scott *et al*., 2007, Hein *et al*., 2009).

It has been argued that climate change would have adverse impacts on various ecosystems, including forests and biodiversity in many regions of the world (AR4; Stern, 2007; Eliasch, 2008; Ogawa-Onishi *et al.,* 2010; ADB, 2009a; Tran *et al.,* 2010; Preston *et al*., 2006) and these will have implications for rural livelihoods and economies

(Chopra and Dasgupta, 2008; Safranyik and Wilson, 2006; Kurz *et al*., 2008; Walton, 2010). However, monetary valuation of changes in non-marketed ecosystem services due to climate change continue to pose a challenge to researchers. To overcome some of the limitations, multicriteria analysis has been used for forest management (Fürstenau *et al*., 2007).

9.3.4.6. Health

Some studies have looked at the health impacts in various regions of the world, however for the most part these do not by and large distinguish the rural from the urban sector . Studies have examined the linkages between health and climate change in terms of the implications for vector-borne and waterborne diseases for Asia and Africa. No comprehensive assessment of climate change effects on health in Africa or Asia has been conducted so far, and there remain considerable gaps in knowledge (Costello *et al*., 2009; Byass, 2009). In general it appears that the region of Africa could be seriously affected if counter measures are not put in place (Byass, 2009; Costello *et al*., 2009; Ebi, 2008; SEI, 2009) and that most climate change related health impacts are in children of rural areas in Sub-Saharan Africa and Asia. As there is a lack of studies which consider rural areas specifically, the interested reader is referred to chapter 11 for current sources of vulnerability (Section 11.3.1, Chapter 11, AR5) and major climate sensitive health outcomes (section 11.2, Chapter 11, AR5). A discussion on the additional costs of treatment due to climate related health outcomes is available in Section 10.8.2, chapter 10, AR5. For region specific health concerns from climate change, the reader is referred to the following sections: North America (26.8, chapter 26); Central and South America (27.3.7, chapter 27); Small islands (29.3.3, chapter 29); Australia (25.6.9, Chapter 25); Asia (24.4.6, chapter 24); Europe (23.5.1 and 23.5.2, Chapter 23); Africa (22.3.3.2, chapter 22).

9.3.5. Key Vulnerabilities and Risks

9.3.5.1. Competing Definitions of Vulnerability

Discussions on climate vulnerability in rural areas is necessarily related to discussion on competing conceptualizations and terminologies of vulnerability, much of which arises from research based on case-studies located in rural areas. Different conceptualizations are important, because the policy prescriptions for rural areas derived from each are different (O'Brien *et al.,* 2007), or even contradictory. Two main concepts of vulnerability exist (O'Brien *et al.,* 2007; R. Nelson *et al.,* 2010; Füssel, 2007):

- Vulnerability viewed as a combination of exposure to hazards, sensitivity and adaptive capacity, as used in the Fourth Assessment Report of the IPCC, also called end-point or outcome vulnerability. The resulting policy options derived strongly emphasise new technologies as options to reduce vulnerability and enhance adaptive capacity. One important consequence of this is a downplaying of factors such as gender (V. Nelson *et al.,* 2002) or the status of indigenous people (O'Brien *et al*., 2009).
- Vulnerability viewed as arising from pre-existing socio-economic factors that make populations vulnerable to extreme events (or climate change), also called starting-point or contextual vulnerability, emphasizing climate change interactions with multiple processes of change and thus widening the It is assumed that vulnerability arises less from physical sensitivities of the resource base that supports the human system than from the social, economic and political facts that affect how the human system interacts with the resource base. The resulting policy options have a strong focus on diversity and local knowledge (Brondizio and Moran, 2008). This type of assessment has grown in the last few years.

In line with these interpretations different methodologies exist to measure vulnerability (inductive and deductive methods (Nelson *et al*., 2010); vulnerability variable, unicriterial or econometric assessment, e.g. centered on examining changes in agricultural yield, and vulnerability indicator or multicriterial approach. Recent discussions in this field also relate to whether studies should be centered on the analysis of vulnerability or resilience. Vulnerability implies a key role for targeted international development assistance in helping the rural poor while resilience research emphasises more bottom-up forms of assistance that allow adaptive capacities and flexible governance structures, and considers that conventional development assistance can exacerbate vulnerability before and after shocks (McSweeney and Coomes, 2011a). Cannon and Muller-Mahn (2010) however, suggest that resilience as a

focus is overly associated with the natural sciences while important social issues can be left behind in the assessments.

9.3.5.2. Drivers of Vulnerability and Risk

In this chapter we use vulnerability as a starting point, in which different trends can be observed in different situations, while we consider risk to be the product of impact, exposure and vulnerability. The most commonly used approaches to analyzing causes of vulnerability, use the concepts of entitlements or livelihoods in evaluating the multi-scale factors shaping people's assets. The importance and impact of drivers affecting vulnerability are seen as context and scale-dependent, although vulnerability is experienced locally, its causes and solutions occur at different social, geographic, and temporal scales (Ribot, 2010). Vulnerability in rural areas can be aggravated by non-climate factors which can operate at both individual and community levels (Eakin and Wehbe, 2009), and include the following:

- Physical geography, e.g. desert or semi-desert conditions (Lioubimtseva and Henebry, 2009), remoteness (Horton *et al*., 2010), level of dependence on climate conditions (Brondizio and Moran 2008))
- Economic constraints and poverty (Ahmed *et al*., 2011; Macdonald *et al*., 2009; Mertz, Halsnæs *et al*., 2009; Mertz, Mbow *et al*., 2009)
- Gender inequalities (V. Nelson *et al*., 2002)
- Social, economic and institutional shocks and trends (e.g. urbanization, industrialization, prevalence of female-headed households, landlessness, short-time policy horizons, low literacy, high share of agriculture in GDP), as well as demographic changes, HIV/AIDS, access and availability of food, density of social networks, memories of past climate variations, knowledge and long-term residence in the region (Macdonald *et al*., 2009; Mougou *et al*., 2011; Ruel *et al*., 2010; Sallu *et al.,* 2010; Simelton *et al.,* 2009; Mertz, Halsnæs *et al*., 2009; Parks and Roberts, 2006; Gbetibouo *et al*., 2010; Ahmed *et al.,* 2011; Cooper *et al*., 2008; Brondizio and Moran, 2008).

The adoption of different approaches in the analyses can result in contradictory findings regarding vulnerability in rural areas. Further, vulnerability being highly context-dependent, there are low levels of agreement on the direction in which some key factors may affect vulnerability or resilience in rural areas, including rainfed as opposed to irrigated agriculture, small-scale and family-managed farms, integration into world markets, or poverty. For instance, poverty has traditionally been considered a clear factor increasing vulnerability to climate change, but McSweeney and Coomes (2011a) found that climate-related disasters can change the structural factors, fostering local capacities for endogenous institutional changes that enhance community resilience, intergenerational equity and long-term ecological sustainability. Brouwer *et al*. (2007) contrary to expectations found that vulnerability to flooding in Bangladesh in terms of damage suffered was lower for households that fully depended on natural resources than those who did not fully depend on natural resources. Also Osbahr *et al*. (2008) found that diversification in rural areas does not always reduce vulnerability and can increase inequity within communities if it is not accompanied by reciprocity.

There is greater agreement on the importance for resilience of drivers such as access to land and natural resources, flexible local institutions and knowledge and information, and the association of gender inequalities with vulnerability. This section focuses on the following drivers of vulnerability to climate change: water, market orientation, institutions, access to resources, gender, migration and access to information and knowledge.

9.3.5.2.1. Acces to water

Access to drinking and irrigation water is considered an important factor driving vulnerability to climate change of rural populations. Availability of water is also linked to other indicators such as income, agricultural employment and nutritional status in the household (Halsnæs and Trærup, 2009). Reducing vulnerability requires a reduction of the multiple non-climate-related pressures on freshwater resources (e.g. water pollution, high water withdrawals) together with improvement of water supply and sanitation in developing countries (Kundzewicz *et al*., 2008). It is agreed that water supply will be adversely affected by climate change, but vulnerability of populations will also be

determined by other elements, such as the role of institutions in facilitating the access to water, or people's demand, which in turn is influenced by local cultural norms (Wutich *et al*., 2012) and perceptions of vulnerability which may differ between men and women Larson, Ibes,and White 2011. Improvements in technologies can reduce the perception of water scarcity and increase water demand without reductions in underlying vulnerability (El-Sadek, 2010; Sowers *et al*., 2011). Where appropriate water management institutions exist and are effective, their role in improving rural livelihoods has been demonstrated, for example in Tanzania's Great Ruaha basin (Kashaigili *et al*., 2009).

Past research has tended to agree that rain-fed agriculture is more vulnerable to climate change (Bellon *et al*., 2011) and that irrigation is needed to decrease that vulnerability (Gbetibouo *et al*., 2010). More recent findings suggest that this is context-dependent and irrigation has been found to increase vulnerability in certain cases (Lioubimtseva and Henebry, 2009; Eakin, 2005). Cooper *et al*. (2008) concluded that in rainfed Sub-Saharan Africa the focus should be on improving productivity of rain-fed agriculture instead of irrigation as irrigation schemes are also being threatened by drought, and Ahmed *et al*. (2011) emphasised the role of drought-tolerant crops. It is important, both for rain-fen and irrigated agriculture, to promote water harvesting strategies, including storage and conservation.

9.3.5.2.2. Market orientation

Some authors argue that opening markets to international trade increases vulnerability of small farmers and poor people. However, linkages among international, regional and local markets are not clear, including how global prices affect regional and local prices in the long term (Ulimwengu *et al*., 2009). Market integration reduces the capacity of indigenous systems for dealing with climate risk in Bolivia (Valdivia *et al*., 2010) and Mozambique (Eriksen and Silva, 2009), and in the Sahel favours a shift towards cash-cropping a narrow range of commodities that increased dryland degradation (Fraser *et al*., 2011) as in Honduras (McSweeney and Coomes, 2011a), by accelerating socioeconomic stratification or focusing incomes in a single crop. Ruel *et al*. (2010) suggest that excessive dependence on cash income increases vulnerability of the urban poor compared with the rural poor, who can have access to other type of assets. According to Brooks *et al*. (2009) the dominant development paradigm favouring transitions from tradition to modernization, economic growth and globalization, does not favour action under uncertainty. They suggest the need for new models of development built *around* environmental constraints and opportunities which search for a balance between productivity and resilience.

On the other hand, Jones and Thorton (2009) estimated that rainfed mixed crop/livestock areas in sub-Saharan Africa which are far from large markets have higher poverty rates and thus, conclude they are more vulnerable to climate change. Also Gbetibou *et al*. (2010) proposed increased market participation as a valid measure to reduce vulnerability of vulnerable regions in South Africa as calculated by a vulnerability index. Thus, each case needs to be analysed within its complexity considering interactions among all factors that can affect vulnerability, to avoid magic recipes which can work in one place but not in other (Rivera-Ferre *et al*., submitted).

Regarding the scale of farms, some authors suggest that high reliance on small-scale farming increases the vulnerability of communities in rural areas (Bellon *et al*., 2011; Gbetibouo *et al*., 2010) although it is suggested that their resilience capacity (stemming from factors such as indigenous knowledge, family labour, livelihood diversification) should not be underestimated. On the contrary, Brondizio and Moran (2008) indicate that small farmers are less vulnerable than large, monocropp farmers when climatic variations make an area inappropriate for a particular crop, because they tend to cultivate multiple crops. However, they recognize that small farmers tend to suffer from technological limitations, low access to extension services, and market disadvantages. Mertz *et al*. (2009) suggest that history demonstrates small farmers are highly resilient as they face numerous changes and that the value of local knowledge in climate change studies has received little attention. For Eakin (2005), the shift in support to agriculture from subsistence to commercial agriculture in Mexico reduced smallholders resilience for climatic variations.

9.3.5.2.3. Institutions, access to resources, and governance

Vulnerability and livelihood security are closely linked to the institutional environment. Institutions and their networks can increase (Eakin, 2005) or reduce vulnerability to climate change. For that reason it is important to foster research on the role of local institutions in influencing vulnerability (Agrawal and Perrin 2008; Berman *et al.*, 2012). According to Agrawal and Perrin (2008) local institutions (as organizations) influence livelihoods in three manners: through distribution of risks related to climate hazards they can structure how particular social groups will be affected by them; they determine the incentive structures for household and community level adaptation responses; and they mediate external interventions (e.g. finances, knowledge and information, skills training) into local contexts, and articulate between local and extra-local social and political processes through which adaptation efforts unfold. In that manner, rural institutions structure risk and sensitivity in the face of climate hazards by enabling or disabling individual and collective action (Ribot, 2010). Governance structures and communication flows are important, as shown in a Swiss mountain region vulnerable to climate change (Ingold *et al.*, 2010). The knowledge and perceptions of decision-makers are important. Romsdahl *et al.*(2013) show that local government decision-makers in the US Great Plains resist seeing climate change as within their responsibilities, which has contributed to low levels of planning for either adaptation or mitigation, and thus to greater vulnerability, but that a reframing of issues around current resource management priorities could allow proactive planning.

According to Leach *et al.* (1999) institutions (as the rules of the game in society) mediate vulnerability by shaping access to resources as composed by endowments, entitlements and capabilities of different social actors. Anderson *et al.* (2010) associate flexible local institutions in dryland societies, primarily for resource management, with resilience to climate change and vulnerability reduction. Lack of access to assets, among which land is an important one, is accepted to be an important factor increasing vulnerability in rural people (McSweeney and Coomes, 2011a). The breakdown of traditional land tenure systems increases vulnerability (Fraser *et al.*, 2011; Dougill *et al.*, 2010) in many different ways. Lack of access to land is a multi-causal process, among which climatic change is just but one. For instance, Dougill *et al.* (2010) shows that land privatization in Bostwana has increased vulnerability of poorer communal pastoralist, although it has helped the wealthier farmers, remaining a route to enhance resilience as this private land-owning group has become less vulnerable. Brouwer *et al.* (2007) found that individuals with less access to natural productive resources are more vulnerable to flooding, being even higher when disparities of distribution at the community level are also higher. Lack of access to productive land is also linked to migration and conflicts. Obioha (2008) shows how reduction of access to productive land due to climatic changes increases communal civil violent conflicts in Nigeria.

9.3.5.2.4. Migration

The relationship of vulnerability to migration is complex. Vulnerable people can migrate, both as a coping and as an adaptive strategy, depending on the temporal scale of that migration. Areas of out-migration can experience reduced vulnerability if migrants send remittances, or increased vulnerability if the burden of work, usually for women, also increases. Social networks, essential to reduce vulnerability, are also affected reducing the transmission of traditional knowledge (Valdivia *et al.*, 2010). Furthermore, those places receiving migrants can experience an excessive demographic growth, which increases pressure over scarce resources, as it is being experienced in the semiarid tropics (Cooper *et al.*, 2008) or Africa (Obioha, 2008). Brondizio and Moran (2008) found that in-migration in the Amazon brought people with knowledge that is ill-adapted to the local environment.

9.3.5.2.5. Gender

Gender was a “latecomer” to the climate debate (Denton, 2004), but patterns of vulnerability reflects gender-related inequalities, of special relevance to rural areas in the developing world (Denton, 2002; Vincent *et al.,* 2010; V. Nelson and Stathers, 2009). Gender differences in roles, responsibilities and capabilities mean that climate change may actually reinforce disparities between men and women (Vincent *et al.*, 2010), in crucial key dimensions for coping with climate-related change, including inequalities in access to wealth, new technologies, education,

information, and other resources such as land. The major issues concerning gender and climate change in rural areas, not only in terms of vulnerability but also of enabling adaptation, are reviewed in Box 9-2.

_____ START BOX 9-2 HERE _____

Box 9-2. Gender and Climate Change in Rural Areas

Differences in access to resources between men and women can create gender inequalities, which in turn leads to differential vulnerabilities and capacities to adapt (Nelson *et al*., 2002; Adger, 2006; O'Brien *et al*., 2007). Whilst recognised in AR4 (Adger *et al*., 2007) and SREX (IPCC, 2012), evidence since then has become stronger, with additional case studies on the gendered dimensions of climate change (e.g. Nelson and Stathers, 2009; Vincent *et al*., 2010). The social constructions of gender roles and responsibilities mean that women are typically disadvantaged relative to men. Due to greater levels of out-migration by men, women are disproportionately represented in rural areas, and globally women in rural areas make up one quarter of global population (Inter-Agency Task Force on Rural Women, 2012). As a result, it is essential that a chapter on rural areas be gender-sensitive. This box summarises the gender elements of vulnerability, impacts, and adaptation in rural areas.

Gendered differences exist in experiences of the multiple stresses that affect rural areas. Access to land shows strong differences between men and women, as do labour markets (FAO, 2010) and access to non-farm entrepreneurship (Rijkers and Costa, 2012). Less than 20% of the world's landholders are women, but women still play a disproportionate role in agriculture. On average women make up around 43% of the agricultural labour force in developing countries; in South Asia almost 70% of employed women work in agriculture, and more than 60% in sub-Saharan Africa (Inter-Agency Task Force on Rural Women, 2012). Climate change increases vulnerability through male out-migration that increases the work to women; cropping and livestock changes that affect gender division of labour; increased difficulty in accessing resources (fuelwood and water) and increased conflicts over natural resources. These factors can make rural women more vulnerable than men, in terms of reductions in resources, potential loss of employment and raised food prices (e.g. Tandon, 2007; Rossi and Lambrou, 2008; Ruel et al, 2009). Evidence for gendered vulnerability to climate change in rural areas exists in Africa (e.g. Omolo, 2011; Huisman, 2005).

In additional to differential access to resources and property rights, gender-ascribed social roles and responsibilities can also mean that women are differentially affected by climate extremes. Women are generally more vulnerable to the impacts of extreme events, such as floods and tropical cyclones. This occurs due to a combination of being close to the homestead, not having access to information (such as early warnings), and lacking the skills to survive, such as swimming. As well as differential immediate effects of extreme events, women are typically disadvantaged relative to men in the relief and recovery period (Alam and Collins, 2010). Lack of gender-sensitivity in emergency camps (e.g. different sanitation facilities) can put women's personal security at risk; and as social constructions of gender determine that they should be responsible for taking care of other household members; although there have been calls to add nuances to these differences (Cupples, 2007). Although there is little agreement in the role of environmental migration in response to climate change, women are disadvantaged in accessing this option (Foresight: Migration and Global Environmental Change, 2011).

Enabling adaptation of men and women requires a gender-sensitive approach that recognises and addresses the differential vulnerabilities. Not taking a gender-sensitive perspective can risk reinforcing existing vulnerabilities (Figueiredo and Perkins, 2012; Arora-Jonsson, 2011). However it is also important to move beyond generic gender differences and examinegender alongside other factors (Tschakert, 2013). Government interventions to improve production through cash-cropping and non-farm enterprises, for example, typically advantage men over women since cash income is seen as a male activity in rural areas (Gladwin et al, 2001); whilst rainwater and conservation-based adaptation initiatives may require additional labour which women do not necessarily have (Baiphethi et al, 2008). Encouraging gender-equitable access to education and strengthening of social capital are among the best means of improving adaptation of rural women farmers (Below et al, 2012; Goulden et al, 2009; Vincent et al, 2010). Similarly recognising preferences in accessing adaptation-enabling information is important: in South Africa, for example, it was observed that women preferred to hear seasonal forecasts through extension agents, as opposed

to over the radio like men (Archer, 2003); whilst in Ghana information is broadcast over the radio, but women only hear it if they happen to be in the company of men who are listening (Nab and Korenteng, 2012).

_____ END BOX 9-2 HERE _____

9.3.5.2.6. Knowledge and information

Knowledge and information debates are very much linked to institutions, since knowledge is in itself is a component of institutions. Lack of access to information and knowledge of rural people is suggested as a factor that increases vulnerability, mostly among poor people, which can also affect the above mentioned drivers. What is not so much agreed in the literature is what type of knowledge is best to reduce vulnerability. Some authors suggest the need for local responses and indigenous knowledge to reduce vulnerability (Valdivia *et al*., 2010), and call for an integration of local knowledge into climate policies (Nyong *et al*., 2007), while Bellon *et al*., (2011) state that local knowledge and traditional institutions are too local, and in some contexts gathering information from further away is important. They find that to face the forecasted climatic changes, the geographical area of exchange of seeds should be larger than the one covered by the traditional systems of seed exchange.

Access to information is also important, shared knowledge and lessons learned from previous climatic stresses provide vital entry points for social learning and enhanced adaptive capacity (Tschakert, 2007). However, access to information is not always a guarantee of success. Coles and Scott (2009) found that in Arizona, despite ample access to weather forecasting, ranchers did not rely on such information, implying that changes are required to make more attractive information to users, as well as to understand prevailing local cultures and norms.

It is also important in the debate how knowledge is produced, managed, and disseminated within the formal institutional structure to address vulnerability issues. A local case-study in Sweden shows that limited co-operation between local sector organisations, lack of local co-ordination, and an absence of methods and traditions to build institutional knowledge exist, posing barriers to manage vulnerability (Glaas *et al*., 2010). To address this it is suggested that local institutional structure must be flexible and encourage institutional learning and knowledge transfer, implementing communication mechanisms between public authorities, other knowledge producers, and civil society to favour more reliable assessments of local vulnerabilities (Glaas *et al*., 2010). Moumouni and Idrissou (2013 and forthcoming) examine the lack of co-ordination in Benin between climate policies and the policies and practices which govern agricultural research and extension, while good practice at project level could be harnessed to foster collective learning of farmers and other agricultural stakeholders, and thus adapataion to climate change.

The importance of access to knowledge and information has also been addressed with other drivers, suggesting that the combined pressure of climate change–induced decreased access to resources, the institutional vacuum, the loss of esteem for authorities, and the loss of trust in cultural knowledge accentuates the need to address governance to improve access to resources, access to information, mutual understanding of the role of knowledge systems for the interpretation of climate change and variability, and relevant institutional capacities (Kronik and Verner, 2010). In this direction, an alternative mode of interaction to the science and practice one-way interaction often used to address vulnerability, adaptation and resilience, in which different experts, risk-bearers, and local communities are involved and knowledge and practice is contested, co-produced and reflected upon it (Vogel *et al.,* 2007).

9.3.5.3. Outcomes

The outcome of vulnerability is the result of and interaction of the driving forces that determine vulnerability. This section analyses how different drivers may affect specific vulnerable groups in rural areas, that is pastoralists, mountain farmers and artisanal fisherfolk. Box 9-3 takes a specific economic sector important in rural areas, and demonstrates the interplay of vulnerability and exposure.

_____ START BOX 9-3 HERE _____

Box 9-3. Tourism and Rural Areas

The three major market segments of tourism most likely to be affected by climate change are rural-based, namely, coastal tourism, nature-based tourism and winter sports tourism) (Scott *et al*., 2012). Tourism is a significant rural landuse in many parts of the world, yet compared to other economic sectors in rural areas, the impacts of climate change are typically under-researched. In the Caribbean, for example, tourism has overtaken agriculture in terms of economic importance, with several regional states (including the Bahamas, the Cayman Islands and St Lucia) receiving more than 60 percent of their GDP from this industry (Meyer, 2006). Coastal environments elsewhere in the world are also characterised by dependence on rural tourism, and are known to be vulnerable to cyclones and sea level rise (Klint *et al.,* 2011; Payet, 2007).

Terrestrial natural resource-based tourism is also a significant foreign exchange earner in many countries. In sub-Saharan Africa, between 25 and 40% of mammal species in national parks are likely to become endangered by 2080, assuming no species migration (and 10-20% with the opportunity for migration) (Thuiller *et al.,* 2006). There are also many rural environments viewed as "iconic" or having cultural significance that are vulnerable to climate change. In South Africa, for example, the Cape Floral (fynbos) ecosystem has a high level of species endemism which will be vulnerable to the projected increase in dry conditions (Midgley *et al*., 2002; Boko *et al*., 2007). The projected increase in climate change-related hazards, such as glacial lake outbursts, landslides, debris flows and floods, will likely affect trekking in the Nepali Himalayas (Nyaupune and Chhetri, 2009).

The development of tourism has, in many cases, increased levels of exposure to climate change impacts. In the Caribbean, for example, tourism has led to considerable coastal development in the region (Potter, 2000), which may exacerbate vulnerability to sea-level rise. In many cases, the carbon emissions resulting from participating in rural tourism threaten the very survival of the areas being visited. This is often the case for very remote locations, for example polar bear tourism in Canada (Dawson *et al*., 2010), dive tourism in Vanuatu (Klint *et al*., 2012). Although on aggregate resource consumption of tourists and locals has been shown to be similar in developed county contexts (e.g. in Italy – Patterson *et al*., 2007); in many developing countries resources used by tourists are much higher than locals (e.g. in Nepal - Nepal, 2008).

Despite the potential impacts of climate change on rural tourism, there is little evidence of significant concern, which impedes adaptive responses. Surveys in both the upper Norrland area of northern Sweden and New Zealand showed that climate change is not perceived to pose a major threat in the short term, relative to other business risks perceived by small business owners and tourism operators (Broudera and Landmarka, 2011; Hall, 2006).

That said, there is evidence that, with planned adaptation, tourism can flourish in rural areas under climate change. In the Costa Brava region of Spain, for example, although the increasing temperatures and reduced water availability is projected to negatively impact tourism in the current high seasons, there is scope to shift to the current shoulder seasons, namely April, May, September and October (Ribas *et al*., 2010). Recognition of the opportunities for adaptation have also necessitated reassessment of the extent of the potential impacts of climate change on the tourism industry in rural areas. Using snowmaking as an adaptation in the eastern North American ski industry suggests that even the warmest scenario only poses a minor risk to four out of six areas (Scott *et al*., 2006).

_____ END BOX 9-3 HERE _____

9.3.5.3.1. Pastoralists

Pastoralists have developed successful strategies for responding to climate variability, especially what Krätli *et al.* (2013) refer to as "strategic mobility" in pursuit of high-quality grazing, in combination with shorter-term coping strategies (Morton, 2006), for example in the Afar region of Ethiopia (Davies and Bennett, 2007). These strategies suggest that a strong adaptive capacity is intrinsic to pastoralism (Davies and Nori, 2008). However, traditional practices such as pastoral mobility are declining , which increases the vulnerability of people in arid and semiarid

regions (Lioubimtseva and Henebry, 2009; Fraser *et al*., 2011). Drought may become famine because of privatization policies that limit pastoral mobility making pastoralists dependent on rainfed agriculture (Smucker and Wisner 2008). Furthermore, the lack of other alternatives in certain marginal areas where animals are the only secure assets can lead to overstocking and overgrazing, and thus, to increased vulnerability of pastoralism (Cooper *et al*., 2008).

These constraints arise from a range of social, economic, environmental and political pressures external to pastoralism that bring about "induced vulnerability" (Krätli *et al.,* 2013): especially encroachment on rangelands, inappropriate land policy, undermining of pastoral culture and values, and economic policies promoting uniformity and competition over diversity and complementarity. Other authors list as constituents of increased vulnerability: population growth; increased conflict over natural resources; changed market conditions and access to services under liberalisation; concentration of political power in national centres; and perceptions that pastoralists are backward (Dougill *et al*., Fraser, and Reed, 2010; Rivera-Ferre and López-i-Gelats, 2012; Smucker and Wisner, 2008; Dong *et al,*. 2011). These in turn can be seen as results of what Reynolds *et al*., (2007) conceptualise as two key features of dryland populations: remoteness, and distance from the centres and priorities of decision-makers or "distant voice". However Dong *et al*. (2011) and Sietz *et al*. (2011) stress the geographic differentiation of pastoral systems (and more broadly of dryland systems with which they overlap).

9.3.5.3.2. Mountain farmers

Mountain ecosystems have been identified as extremely vulnerable to climate change (IPCC 2007), and thus populations have a high exposure to climate change. A detailed understanding of climate change impacts in mountain areas is difficult because of physical inaccessibility and scarcity of resources for research in mountain states and regions (Singh *et al.,* 2011), as well as more generic uncertainties relating to climate projection. However, agreement exists that impacts will include melting of glaciers, flooding or increasing probability of fires (Nogués-Bravo *et al*., 2007; Beniston, 2003). This will in turn have strong impacts on agriculture and livestock-based activities in these areas (e.g., changes in plants, pastures and water availability; slope instability; new diseases) as well as on tourism-based activities (Scott, 2006). But mountain dwellers, as pastoralists in drylands, are adapted to live in steep and harsh and variable conditions, and thus have a variety of strategies to adapt and foster resilience to changing climatic conditions. However, to develop their strategies they need to overcome other drivers that can affect their vulnerability in different contexts. For instance, in most developed countries, mountains are becoming depopulated (Gellrich *et al*., 2007; López-i-Gelats, 2013; Gehrig-Fasel *et al*., 2007) given the extreme climatic conditions, their remoteness and subsequent isolation, while in developing countries there is a trend towards increasing population (e.g. tropical mountain areas) (Lama and Devkota, 2009; Huber *et al*., 2005). The impacts of the projected warming on mountain farming, as well as their adaptation strategies, differ spatially because the socioeconomic role of mountains varies significantly between industrialized and industrializing or non-industrialized countries (Nogués-Bravo *et al*., 2007). Mountain grasslands in developed countries are usually managed via a sub-exploitation model that involves the intensive use of the most productive areas and the abandonment of those regions where production is economically less viable (López-i-Gelats *et al*., 2011). In contrast, mountain grasslands in developing countries remain centers of fodder and livestock production. Thus, two general trends are identified in world mountain grasslands, while temperate grasslands tend to suffer from conversion to agriculture, and land abandonment where livestock raising is less feasible (Gellrich *et al*., 2008); in tropical grasslands the main cause of degradation is overgrazing, linked to processes of demographic growth. Land privatization, loss of grazing rights, or changes in land use (e.g., development of infrastructure) also affect mountain farmers both in developed and developing countries (Tyler *et al*., 2007; Xu *et al*., 2008).

9.3.5.3.3. Artisanal fisherfolk

Small coastal and riparian rural communities face several drivers that increase their vulnerability, which remain largely ignored by mainstream fisheries policy analysts; for example, the likely impact of demographic, health and disease trends, or of wider development policy trends (Hall, 2011), pressure from other resources (e.g. water, agriculture, coastal defense), unbalanced property-rights; lack of adequate health systems, potable water, or sewage

and drainage (Badjeck *et al*., 2010). The most important drivers affecting small-scale fisheries can be grouped into: international trade and globalization of markets; technology; climate and environment; health and disease; demography; development patterns and aquaculture; for instance, freshwater fisheries are threatened by increasing irrigation, while vulnerability of coastal fisheries increases with mangrove loss to aquaculture facilities in response to growing markets for prawns (Hall, 2011). Another difficulty faced by fisheries-based livelihoods is the neglect of governments and researchers, which is more centred on industrial fishing leaving aside artisanal ones (Mills *et al*., 2011). Management systems, property rights and institutions are extremely important in fisheries. Given the complexity of fisheries management and the particular open ecosystem in which this activity is carried out, the existing discussions about fisheries management are complex but also advanced in terms of introducing ecosystem rights and participation principles into management (Andrew and Evans, 2011; Charles, 2011), which in other fields are essential for reducing vulnerability, adapting to climate change and favouring sustainable societies.

9.4. Adaptation and Managing Risks

9.4.1. Framing Adaptation

As the previous sections outlined, it is virtually certain that there will be impacts of climate change in rural areas in both developed and developing countries for which adaptation is required. AR4 stated with very high confidence that adaptation to climate change is already taking place, but on a limited basis. Since then, evidence has increased such that there is very high confidence that adaptation is taking place in rural areas. Many adaptations build on examples of responses to past variability in resource availability, and it has been suggested that the ability to cope with current climate variability is a prerequisite for adapting to future change (Cooper *et al*., 2008). At the same time, however, it cannot be assumed that past response strategies will be sufficient to deal with the range of projected climate change. In some cases, existing coping strategies may increase vulnerability to future climate change, by prioritising short–term resource availability (O'Brien *et al*., 2008; Adepetu and Berthe, 2007). In developing countries, there is high confidence that adaptation could be linked to other development initiatives aiming for poverty reduction or improvement of rural areas (Nielsen *et al*., 2012; Hassan, 2010; Eriksen and O'Brien, 2007). In Ethiopia, for example,"low regrets" measures to respond to current variability are important to shift the trajectory from disaster-focused to longer-term vulnerability reduction (Conway and Schipper, 2011).

9.4.2. Decisionmaking for Adaptation

Decision-making for adaptation takes place at a variety of levels, and can be public or private. At the national and local levels, law and policies can enable planned adaptation (Stuart-Hill and Schulze, 2010). Evidence for policies to support adaptation exists from across the world, but tends to be greater in developed countries. In Australia, the Queensland government has set policies in anticipation of sea level rise, and in New Zealand the revised Coastal Policy Statement requires a minimum 100-year time frame for coastal planning (see Box 25-2). Australia also has a comprehensive water resources policy designed to deal with scarcity (see Box 25-3). In northern Canada, some territorial governments in Northern Canada have developed climate change strategies that promote further adaptation such as providing hunter support programs (Ford et. al., 2010)(see also chapter 26). However, in the Great Plains of the US, less than 20% of jurisdictions have developed plans on either climate adaptation or climate mitigation (Romsdahl *et al*., 2013).

At the local level, many adaptations are examples of private decisions for adaptation. As shown with very high confidence in AR4, such adaptation decisions are embedded in the inter-relationship of a variety of social factors in which climate drivers are only one consideration (Crane *et al*., 2011). An example of where public policy can support private adaptation is in index-based insurance schemes. In Africa where understanding of insurance is low, participation rates can be improved by using simulation games, as trialed in Ethiopia and Malawi, or by more conventional training methods (Patt *et al*., 2010). Data from India, Africa and South America shows that the trust that people have in the insurance product and the organisations involved in selling and managing it may be more important than economic factors, such as the size and timing of the premium and potential payouts (Patt *et al*., 2009). However, private decisions often take place in the context of national policies and laws, which are not always

mutually-supportive (Stringer *et al.*, 2009), especially in the agropastoral sector where settlement is encouraged (Awuor *et al.*, 2011).

One major difference between public and private decision-making is that that latter is typically more responsive. An analysis of agricultural water schemes in South America, for example, found that private irrigation schemes increase in response to a warmer climate, whereas public ones do not, and that they are taken gradually (Seo, 2011b). Participatory stakeholder processes to inform public policy and law can take time. A case study of a resettlement programme in Mozambique showed that farmers and policymakers disagreed about the seriousness of the climate risks, and the potential negative consequences of proposed adaptive measures (Patt and Schroeter, 2008). In Bangladesh, the ambitious national Flood Action Plan (FAP) did not receive support from NGOs, who embarked upon an anti-FAP movement and attained what they perceived to be a more people-oriented national water policy (Mallick *et al.*, 2005).

There is increasing evidence that public decision-making for adaptation can be strengthened by understanding the decision-making of rural people in context (Bryan *et al.*, 2009). Local and indigenous knowledge for responding to weather events and a changing climate has been observed in, for example, the Peruvian Andes (see chapter 26), Samoa (Lefale, 2010 – see chapter 29), the Solomon Islands (Rasmussen et al, 2009 – see chapter 29), Canada (Ford et al, 2007) and the Indo-Gangetic Plains (Rivera-Ferre et al, 2013).

9.4.3. Practical Experiences of Adaptation in Rural Areas

There are wide-ranging and manifold examples of adaptation in rural areas, in both developed and developing countries. These practical experiences of adaptation are found in agriculture, water, forestry and biodiversity, and fisheries.

9.4.3.1. Agriculture

Agricultural societies have a history of responding to the impacts of change in exogenous factors, including (but not limited to) weather and climate (Mertz *et al.*, 2009). They undertake a range of adjustment measures relating to their farming practices – for example, planting, harvesting and watering/fertilizing existing crops; using different varieties, diversifying crops; implementing management practices such as shading and conservation agriculture (see Table 9-6).

[INSERT TABLE 9-6 HERE
Table 9-6: Examples of adaptations in the agricultural sector in different regions.]

Conservation agriculture shows promising results and can be used as an adaptation (Nyala *et al.*, 2011) and for sustainable intensification of production (Pretty *et al.*, 2011), with significant yield productions observed in South Asia and southern Africa (Erenstein *et al.*, 2012). In other cases, the potential effectiveness of adaptation under future climate scenarios has been modeled, for example in Cameroon (Tingem and Rivington, 2009), and for the African continent (Seo, 2011a). Water management for agriculture is also critical in rural areas under climate change, for example the use of rainwater harvesting (Biacin *et al.*, 2011; Kahinda *et al.*, 2010, Vohland and Barry, 2009; Rivera-Ferre *et al.*, 2013), and more efficient irrigation, particularly in rural drylands (Thomas, 2008).

Adaptations are also evident among small-scale livestock farmers (Rivera-Ferre and López-i-Gelats, 2012; (Kabubo-Mariara, 2009, 2008), who use many different strategies, including changing herd size and composition, grazing and feeding patterns, or diversifying their livelihoods, also they may use new varieties of fodder crops suited to the changing conditions (Salema *et al.*, 2010).

Diversified farms are more resilient than specialized ones (Seo, 2010); but rural societies also diversify their income sources beyond agriculture, which in many contexts allows them to reduce their risk exposure. Examples include the exploitation of gums and resins in Kenya (Gachathi and Eriksen, 2011).There may be some rural areas, however,

where limits to agricultural adaptation are reached, and thus the only option that remains is to migrate or diversify away from farming (Mertz *et al.*, 2011).

9.4.3.2. Water

As well as being an important input to agriculture, adaptation in water resources in general is critical in rural areas. Given projected reductions in water availability, improved management is required. The extent to which such adaptation measures have been implemented to date varies: in a study from Europe, Africa and Asia, the Elbe and Rhine basins had the highest level of water resource management measures in place, followed by the Orange and Guadiana, with lower levels in the Amu Darya and Nile Equatorial Lakes (Krysanova *et al.*, 2010). In the Middle East and North Africa, whilst supply-side measures are advanced, little attention has been paid to the demand-side measures that will be critical in a changing climate (Sowers *et al.*, 2010). In the cases of transboundary basins additional barriers exist to adaptive management measures, particularly in Africa (Goulden *et al.*, 2009a), although examination of potential institutional designs has been undertaken (Huntjens *et al.*, 2012). The need for effective water management for adaptation therefore exists not only at the basin level, but at a higher resolution, for example in human settlements and towns (Mukheibir, 2008).

Whilst the majority of focus on adaptation concerning water relates to its availability, it is also important to remember that many rural areas are subject to riverine or coastal flooding. In the low-lying Netherlands protection measures have been employed, including increasing river runoff, increasing storage for water (Delta Committee, 2008; Kabat *et al.*, 2009), and small scale containment of flood risks through increasing compartmentalisation (Klijn *et al.*, 2009). In the Mekong Delta in Vietnam, Columbia University's Center for International Earth Science Information Network has projected that a "one-meter sea-level rise could result in the displacement of more than seven million residents in the delta, and a two-meter rise would double to 14 million- or 50 percent of the delta residents." An increase in flood frequency and magnitude has threatened residents' lives and created instability in crop fields. As rapid industrialization has placed stresses on the environment and Vietnam's natural resources, many people in Mekong have adapted by moving east to cities with rapid economic growth. The government's "living with floods" program has encouraged rice farmers to shift to aquaculture, while the planned relocation of 20,000 "landless and poor households" has altered social networks and livelihoods (De Sherbinin *et al.*, 2011).

[INSERT TABLE 9-7 HERE
Table 9-7: Examples of adaptations in the water sector observed in different regions.]

9.4.3.3. Forestry and Biodiversity

Effective management is also essential for adaptation of forests and biodiversity to climate change. As with water resources, forests can adapt through management of forest fires, silvicultural practices, and the conservation of forest genetic resources. Ecological restoration, where required, is another effective adaptation measure – Benayas *et al.* (2009), in a meta-analysis of 89 studies, estimated this technique enhances the provision of biodiversity and environmental services by 44% and 25%, respectively. Moreover, ecological restoration increases the potential for carbon sequestration and promotes community organization, economic activities and livelihoods in rural areas (Chazdon, 2008), as seen in examples of the Brazilian Atlantic Forest (Calmon *et al.*, 2011; Rodrigues *et al.*, 2011). In other parts of Africa, the systematic analysis of current policies and practices in order to understand the nature and extent of intervention required is often lacking (Fobissie *et al.*, 2009).

Forest resources have been shown to play a role in enabling adaptation during extreme events in Zambia, Mali and Tanzania, although should take place within a managed context to ensure sustainability (Robledo *et al.*, 2011). As the climate changes, part of adaptive management may entail modification of existing biodiversity management practices. In addition to land and water management and law and policy, direct species management is important (Mawdsley *et al.*, 2009). In terms of managing protected areas, to maintain appropriate habitats a network approach may be effective (Hole *et al.*, 2011).

Community involvement in natural resources management and biodiversity conservation is highlighted as critical, with community-managed natural areas experiencing lower rates of deforestation than non-community-managed ones (Porter-Bolland et al, 2012). In Central and South America, protected areas of restricted use reduced fire substantially, but multi-use protected areas are even more effective; and that in indigenous reserves the incidence of forest fire was reduced by 16% as compared to non-protected areas (Nelson and Chomitz, 2011). Reflecting the growing evidence for community-based management and wise use, an emerging mechanism for ecosystem-based adaptation includes payment for ecosystem services (PES) (Montagnini and Finney, 2011), although there is virtually no peer-reviewed literature on PES specifically for emissions reduction (Campbell, 2009). Particularly developed in Central and South America (see table 27-5 for examples of PES schemes in Latin America), communities can be paid for collecting scientific data to contribute to research and monitoring protocols (Luzar *et al*., 2011), or for actively managing natural resources.

9.4.3.4. Fisheries

Adaptation in marine ecosystems is also of relevance to rural areas. Bleaching of coral reefs through rising temperatures causes habitat loss which, in turn, affects fisheries. Selective use of fishing gear is a recommended management measure, based on 15 global sites, to ensure sustainable harvesting of remaining fish stocks (Cinner *et al*., 2009). As with other ecosystems, the extent to which adaptation is required will depend on existing capacity. Of 5 countries in the southwestern Indian Ocean, the environmental sensitivity in Mauritius is offset by the higher adaptive capacity (based on a multi-faceted social adaptive capacity index they used in the study), although the more environmentally-sensitive parts of Madagascar will be priorities for intervention assistance (McClanahan *et al*., 2009). As with terrestrial natural resources, evidence from the marine resources sphere shows that fisheries co-management, involving local fishermen and allowing limited extraction of resources, favour a balance between resource conservation and livelihoods, e.g in Brazil (Francini-Filho and Moura, 2008), and the improvement of livelihoods, as well as the cultural survival of traditional populations (Hastings, 2011; Moura *et al*., 2009). Given the complexity of fisheries management and the particular open ecosystem in which this activity is carried out, the existing discussions about fisheries (adaptive) management are complex but also advanced in terms of introducing ecosystem, rights and participation principles into management (Andrew and Evans 2011; Charles 2011), which are essential to reduce vulnerability and adapt to climate change. Box 25-6 details vulnerability and adaptation in rural areas in Australia.

_____ START BOX 9-4 HERE _____

Box 9-4. Drought Adaptation in Rajasthan

Rajasthan in India is located in an arid ecological zone and experiences severe droughts, a condition that communities have learned to cope with through conservative use of natural resources. Ways in which communities have adapted to drought include ending production of crops such as wheat and cotton that require a large amount of water, storing fodder for times of drought and scarcity, using savings or borrowing “from cooperatives and banks” for drinking water well construction, bunding fields, digging and deepening ponds and wells to retain water, growing medicinal plants to contribute to revenue, making compost using earthworms for environmentally friendly fertilizer. With the help of a local NGO, women have also formed a self-help group (SHG) to collect money to lend to the needy during emergencies. Additionally, a government Food-for-Work Programme helps provide communities with wheat, cash, and subsidized fodder (Chatterjee *et al*., 2005).

Box 9-5. Adaptation to Extreme Events in Jamaica

Extreme weather events and severe droughts have badly affected Jamaica’s households, communities, and agriculture since the mid 1990’s. These changes will likely contribute to poverty and stunt Jamaica’s growth and

productivity. The adaptation methods that have already been used by farmers in St. Elizabeth, which is considered the breadbasket of Jamaica, include planting methods such as "quick crops and the scaling down of production during the dry season," when they will mature and be ready for the market during the tourist season. This also enables farmers to generate enough income to invest more during the rainy season to grow primary crops. Thus, farmers try to minimize risk because they are especially vulnerable to the dry season- their success during the rainy season is dependent on production during the dry season. Another adaptive strategy is to plant crops with multiple uses and crops that will be more tolerant to dry spells. In southern St. Elizabeth, a dry area, successful crop production depends on moisture retention, which is increase with practices such as "mulching, edging or perimeter planting, drip irrigation and managing the application of water to plants". During droughts, some farmers will "sacrifice a portion of the crops under cultivation," apply thicker mulching, borrow or share money for water, and using fertilizer on leaves. To recover from drought, farmers "scale down" so that their crops are more manageable and can grow successfully (Campbell *et al.*, 2011).

_____ START BOX 9-6 HERE _____

Box 9-6. Adaptation Initiatives in the Beverage Crop Sector

One of the leading initiatives to prepare small holder producers of beverage crops for adaptation to climate change is the AdapCC project which worked with coffee and tea producers in Latin America and East Africa (Schepp, 2010). This process used risk and opportunity analysis and participatory capacity building (CafeDirect/GTZ, 2010) to help farmers identify changes in management practices to both mitigate their contribution to climate change and adapt to the changes in climate they perceived to be occurring. In general the actions for adaptation were a reinforcement of principles of sustainable production, such as using tree shade.

The Coffee Under Pressure project of CIAT and Green Mountain Coffee has complemented the models of changes in coffee distribution with models of changes in distribution of 20 other potential crops that may have potential to replace coffee where it will cease to be viable in the future. This has been complemented with detailed studies of the vulnerability of producers in terms of exposition, sensitivity and capacity to adapt to climate change (Baca *et al.*, 2010). This indicates that there is a considerable variability in the overall vulnerability to climate change between different communities in the same region and even families within the same community. Facilitating processes of adaptation in this context will be a challenge, but supports the need for participatory community adaptation processes that would enable families to implement strategies appropriate to their own circumstances and capacity.

Policy recommendations to support adaptation in these sectors (Eakin *et al.*, 2011; Laderach *et al.*, 2011; Schepp, 2010; Schroth *et al.*, 2010) have prioritized the follows interventions to support adaptation:

- Community-based analysis of climate risks and opportunities as a basis for community adaptation strategies
- Improved recording and access to climate information including medium and long-term predictions
- Sustainable production techniques including soil and water conservation, shaded production systems, diversification of production systems
- Development of new varieties with broader adaptability to climate variation, higher temperatures and increased drought tolerance
- Financial support to invest in adaptation and reduce risks through climate insurance
- Organization of small producers to improve access to knowledge, financial support and coordinate implementation
- Environmental service payments and access to carbon markets to support sustainable practices
- Development of value chain strategies across all actors to support adaptation and increase resilience across the sectors.

There are possibilities for synergy between adaptation and mitigation. The sustainability standards Rainforest Alliance and Common Code for the Coffee Community are piloting climate-friendly standards for producers that aim to reduce the GHG emissions from agricultural practices, increase sequestration of carbon in soils and trees, but also prepare producers for adapting to climate change (SAN, 2011; Linne, 2010). The later consists of improved

understanding of climate impacts and promoting sustainable production practices to increase resilience in the production systems.

_____ END BOX 9-6 HERE _____

9.4.4. Limits and Constraints to Rural Adaptation

The Fourth Assessment Report stated with very high confidence that there are substantial limits and barriers to adaptation (Adger *et al*., 2007). Since that time additional evidence has shown that barriers do exist to adaptation – and that these barriers are both hard (physical) and soft (financial, social and cultural).

Lack of access to credit, water and land are major factors inhibiting adaptation for farmers in Africa and Asia. A multinomial logit analysis of climate adaptation responses suggested that access to water, credit, extension services and off-farm income and employment opportunities, tenure security, farmers' asset base and farming experience are key to enhancing farmers' adaptive capacity (Gbetibouo *et al*., 2010). A multinomial choice model fitted to data from a cross-sectional survey of over 8000 farms from 11 African countries showed that better access to markets, extension and credit services, technology and farm assets (labour, land and capital) are critical for helping African farmers adapt to climate change. Hence education, markets, credit and information about adaptation to climate change, including technological and institutional methods are important (Hassan and Nhemachena, 2008).

Rural households' lack of access to technologies and markets is also a major barrier to adaptation for certain production systems. According to a study of adoption of improved, high yield maize in Zambia, production and price risks could render input use unprofitable and prevent rural households from benefiting from technological change crucial for adaptation (Langyintuo and Mungoma, 2008). The severe 1997 drought in the Central Plateau of Burkina Faso highlighted that household with a larger resources base took the advantage of distress sales and high prices of agricultural commodities (Roncoli *et al*., 2001). A nationally representative rural household survey in Mozambique from 2005 shows that, overall, using an improved technology (improved maize seeds, improved granaries, tractor mechanization, and animal traction) did not have a statistically significant impact on household income. However when distinguishing between households using improved technologies, especially improved maize seeds and tractors, and those who do not, households who had better market access had significantly higher income (Cunguara and Darnhofer, forthcoming). Social characteristics of households heads and culture both affect access to adaptation options, based on modeled data from the Nile basin of Ethiopia (Deressa *et al*., 2009) and evidence from Burkina Faso (Nielsen and Reenberg, 2010), respectively.

Although access to credit, water, technologies and markets are barriers, more fundamental is access to information. Since adaptation strategies involve dealing with uncertainty, whether stakeholders have access to information for decision making and how they perceive and utilize this information affects their adaptation choices (Sheate *et al*., 2008; Patt and Schröter, 2008; Dockerty *et al*., 2006). Relevant information includes that on agricultural technologies that can be used in adaptation, but in developing countries agricultural research and extension systems are not integrated with climate planning to deliver this, as discussed by Moumouni and Idrissou (2013) for Benin. There is now an important literature on dissemination of short-term or seasonal weather forecasts to farmers in developing countries, as detailed in Box 9-7.

_____ START BOX 9-7 HERE _____

Box 9-7. Factors Influencing Uptake and Utility of Climate Forecasts

So far the uptake of information has been suboptimal (Vogel and O'Brien, 2006), but the potential for improved prediction and effective timely dissemination has been noted in South Africa (Archer et al, 2007; Klopper et al, 2006) and also in Ethiopia (Bryan et al, 2009). There have been attempts to assess factors influencing uptake and utility of climate forecasts. Agent-based social simulation models show that to be effective in reducing climate risk, trust in forecasts has to be high, and they have be right 60-70% of the time to benefit smallholder farmers (Ziervogel *et al*., 2005). As well as trust, the effects of user wealth, risk aversion, and presentational parameters, such as the

position of forecast parameter categories, and the size of probability categories, on perceived value of seasonal forecasts have been investigated (Millner and Washington, 2011). An assessment of the extent to which climate change scenarios are currently used in developing adaptation strategies within the agricultural development sector in Africa shows that annual climate information (such as seasonal climate forecasts) is used to a certain extent to inform and support some decisions, yet climate change scenarios are rarely used at present in agricultural development (Ziervogel and Zermoglio, 2009). Although, there is a large and growing literature on the role of seasonal forecasts, in particular on the needs of rural end-user groups, e.g. smallholder farmers in a mountainous village in southern Lesotho (Ziervogel, 2004), the optimal use of seasonal forecasts in risk management by smallholder farmers is largely limited by constraints related to legitimacy, salience, access, understanding, capacity to respond and data scarcity (Hansen *et al*., 2011).

The socio-cultural context of participatory processes in the dissemination and use of seasonal forecasts is important and affects who participates and what they gain (Peterson *et al*., 2010). Rural producers in three ecological zones of Burkina Faso who had taken part in appropriate participatory processes were statistically more likely to understand the probabilistic aspect of the forecasts and their limitations, to use the information in making management decisions and through a wider range of responses than those who had not taken part (Roncoli *et al*., 2009). Evidence from Malawi shows that forests can be important in reactive coping by providing food during shortages and a source of cash for coping with weather-related crop failure – but households most reliant on forests have low income per person, are located close to the forest, and are headed by individuals who are older, more risk averse, and less educated than their cohorts (Fisher *et al*., 2010). Gender differences have been observed in preferred dissemination channels (Box 9-2). Debates over forecast skill and farmer skill are also common to other parts of the world such as the USA, where interviews with farmers in Georgia showed that the social nature of information processing and risk management bears upon the ways farmers may integrate climate predictions into their agricultural management practices (Crane *et al*., 2010).

Stakeholder networks have been used to map forecast dissemination in Lesotho, and are useful for identifying obstacles (Ziervogel and Downing, 2004). There are promising signs for the integration of scientific-based seasonal forecasts with indigenous knowledge systems (Ziervogel *et al*., 2010). Ensuring improved validity and utility of seasonal forecasts will require collaboration of researchers, data providers, policy developers and extension workers (Coe and Stern, 2011), as well as with end users. Additional opportunities to benefit rural communities come from expanding the use of seasonal forecast information for coordinating input and credit supply, food crisis management, trade and agricultural insurance (Hansen *et al*., 2011). Attempts to use longer term crop forecasting options based on large-area seasonal crop yield forecasting and, genotypic adaptation based on long-term climate change projections have also been examined (Challinor, 2009). Climate forecasting has also been applied to ecosystem models for use in livestock farming (Boone *et al*., 2004). The IPCC SREX report identified the use of forecasts as a risk management measure (IPCC, 2012)

_____ END BOX 9-7 HERE _____

9.5. Key Conclusions and Research Gaps

9.5.1. Key Conclusions

There is a lack of clear definition of what constitutes rural areas, and definitions that do exist depend on definitions of the urban. Across the world, the importance of peri-urban areas and new forms of rural-urban interactions are increasing. Notwithstanding this, rural areas still account for almost half the world's population, about 75% of the developing world's poor people and 80% of the world's hungry. Rural areas therefore are important for assessing the impacts of climate change and the prospects of adaptation in these areas, constituting a dynamic, spatial category. A lack of focus on the rural sector in policy making increases its vulnerability to climate change. Over 90% of rural people worldwide live in developing countries.

Climate change in rural areas in developing countries will take place in the context of many important economic, social and land-use trends. In different regions, rural populations have peaked or will peak in the next few decades.

The proportion of the rural population depending on agriculture is extremely varied across regions, but declining everywhere. Poverty rates in rural areas are falling more sharply than overall poverty rates, and proportions of the total poor accounted for by rural people are also falling: in both cases with the exception of sub-Saharan Africa, where these rates are rising. Hunger and malnutrition are prevalent among rural children in South Asia and Sub-Saharan Africa, and recent hikes and volatility in priced of food exacerbated hunger and malnutrition among rural households, many of which are net food buyers. In developing countries,the levels and distribution of rural policies are affected in complex and interacting ways by processes of commercialisation and diversification, food policies, and policies on land tenure. Rural people are subject to multiple non-climate stressors, including under-investment in agriculture (though there are signs this is improving), problems with land policy, and processes of environmental degradation. Stronger rural-urban linkages through migration, transfer of public and private remittances, regional and international trade, inflow of investment and diffusion of knowledge (through new information and communication technologies) are more positive developments. In industrialized countries, there are important shifts towards multiple uses of rural areas, especially leisure uses, and new rural policies based on the collaboration of multiple stakeholders, the targeting of multiple sectors and a change from subsidy-based to investment-based policy.

Cases in the literature of observed impacts on rural areas often suffer from methodological problems of attribution, with regard to the difficulties of attributing extreme events to climate change, the status of local knowledge, and the action of non-climate shocks and trends. However, evidence for observed impacts, both of extreme events and other categories, is increasing. Impacts attributable to climate change include declining yields of major crops, some extreme events such as droughts and storms, and geographically-specific impacts such as glacier melt in the Andes.

Future impacts of climate change on the rural economic base and livelihoods, land-use and regional interconnections are at the latter stages of complex causal chains that flow through changing patterns of extreme events and/or effects of climate change on biophysical processes in agriculture, livestock, fisheries and less-managed ecosystems. This increases the uncertainty associated with any particular projected impact.

Major impacts of climate change in rural areas will be felt through impacts on water supply, food security and agricultural incomes. In certain countries shifts in agricultural production, of food and non-food crops, could take place. Price rises, which may be induced by climate shocks apart from other factors have a disproportionate impact on the welfare of the poor in rural areas, such as female headed households and those with limited access to modern agricultural inputs, infrastructure and education.

Climate change will lead to higher prices and increased volatility in agricultural markets, which might undermine global food supply security while affecting rural households, depending on whether they are net-buyers or net-sellers of food. The emerging literature suggests that deepening agricultural markets through trade reform and institutional efforts to improve the predictability and the reliability of the world trading system as well as by investing in additional supply capacity of small-scale farms in developing countries could help reduce market volatility and mitigate food supply shortages which might be caused by climate change

Migration patterns will be driven by multiple factors of which climate change is only one. Given these multiple drivers of migration and the complex interactions which mediate migratory decision-making by individual or households, the detection of the effects of climate change on intra-rural and rural-to-urban migration remains a major challenge.

Climate policies, such as encouraging cultivation of biofuels, and payments under REDD, will have significant secondary impacts on land-use, and resulting negative impact on livelihoods, in some rural areas. These secondary impacts, and trade-offs between mitigation and adaptation in rural areas, have implications for governance.

Valuation of climate impacts needs to draw upon both monetary and non-monetary indicators. Most studies on valuation highlight that climate change impacts will be significant especially for the developing regions, due to their economic dependence on agriculture and natural resources, low adaptive capacities, and geographical locations. The valuation of non-marketed ecosystem services and the limitations of economic valuation models which aggregate across multiple contexts pose challenges for valuing impacts in rural areas.

There are low levels of agreement on some of the key factors associated with vulnerability or resilience in rural areas, including rainfed as opposed to irrigated agriculture, small-scale and family-managed farms, and integration into world markets. There is greater agreement on the importance for resilience of access to land and natural resources, flexible local institutions, and knowledge and information, and the association of gender inequalities with vulnerability. Specific livelihood niches such as pastoralism and artisanal fisheries are vulnerable and at high risk of adverse impacts, partly due to neglect, misunderstanding or inappropriate policy towards them on the part of governments.

There is a growing body of literature on successful adaptation in rural areas and constraints upon it, including both documentation of practical experience, and discussion of preconditions. In developing countries adaptation can be linked to other development initiatives aiming for poverty reduction or improvement of rural areas, and "low regrets" measures to respond to current variability can shift the trajectory from disaster-focused to longer-term vulnerability reduction. Prevailing development constraints, such as low levels of educational attainment, environmental degradation, and gender inequalities create additional vulnerabilities which undermine rural societies' ability to cope with climate risks. The supply of information for decision-making, and the role of social capital in building resilience, are key issues.

9.5.2. Research Gaps

Research on climate change in rural areas, which truly takes in their nature as areas with shifting combinations of human activity, in which agriculture (food crops, non-food crops and livestock) is important but not necessarily predominant, and with changing patterns of interaction with towns, is only just beginning. Such research will need to be developed, and extended to rural areas and diverse categories of rural people throughout the world. One relevant area will be that of improving understanding of the respective roles of climate and other factors in rural-urban and rural-rural migration.

Research is required on the valuation and costing of climate change impacts which take note of the complexity and specificity of rural areas, with special emphasis on non-marketed ecosystem services and specific populations that have not as yet been studied. Research is also needed on the trade-offs and synergies between adaptation and mitigation in rural areas, and the appropriate governance structures to enhance synergy.

More research is needed on vulnerability, to identify the most vulnerable areas, populations and social categories, but it should include research on methodological questions such as conceptualizations of vulnerability, assessment tools, spatial scales for analysis, and the relations between short-term support for adaptation, policy contexts and development trajectories, and long-term resilience or vulnerability.

Research is needed on practical adaptation options, not only for agriculture but for non-agricultural livelihoods. Adaptation research must also look at adaptations to institutions, to better enable them to address lack of access to credit, markets, information, risk-sharing tools and property rights. Research into vulnerability, resilience and adaptation must all improve ways to manage knowledge, both local and scientific, for adaptation.

Frequently Asked Questions

FAQ 9.1: Why are rural areas important in the study of climate change impacts, assessments, and vulnerability?
No clear and unique definition of rural areas exist in literature, however it is clear that human settlements do not only include urban areas. Nearly half of the world's population, approximately 3.3 billion, lives in open country areas. This is particularly true in developing and least developed countries, where more than 50% and 75% of the population respectively lives in rural areas. These human settlements are strongly dependent on natural resources and agriculture which influences their socioeconomic structures, and therefore highly sensitive to climate variations – and even recent diversification is typically still natural resource-dependent (e.g. tourism, recreation). In addition, these regions are usually characterized by pre-existing vulnerabilities which can aggravate climate change impacts.

Isolation and marginality remain as factors that significantly affect adaptive capacity in rural areas and increase vulnerability.

There are important differences between rural areas in developing and developed countries. Rural areas in developing countries are characterized by higher prevalence of poverty, isolation and lower human development. In developed countries these features are also present, but they are usually associated and influenced by the proximity to towns, and their role as a place for recreational activities.

FAQ 9.2: What will be the major climate change impacts and adaptations in rural areas across the world?

Given the strong dependence on natural resources, impacts of climate change in rural areas will, be primarily observed as changes in the productivity of primary sectors, such as agriculture, forestry and fishing. Secondary (manufacturing) industries, and the livelihoods and incomes that are based on them, will in turn be substantially affected. Extreme events associated with climate change will also affect rural areas, mainly via heat stress, drought and flooding that impact on infrastructure (i.e. dams, roads, buildings, telecommunications and irrigation systems). Depending on the magnitude these extreme events can trigger economic and political turmoil, as well as migration. Existing isolation and marginalisation create current vulnerability which, in combination with exposure to climate change, increases the risks of adverse impacts.

Adaptation options are context-specific and will depend on the correct identification of relevant risks and the adaptive capacities of rural people with differing access to natural, financial, human and social capital. Examples of rural adaptations include modifying farming and fishing practices, introducing new species and varieties as well as recovering old ones, diversification, water management, modifying infrastructure and technology decisions, and both formal and informal risk sharing mechanisms. Adaptation will also include changes in institutional and governance structures.

Table 9-1: Major findings of the IPCC Fourth Assessment Report and the International Assessment of Agricultural Science and Technology for Development.

Importance of non-climate trends	Source
The significance of climate change needs to be considered in the multi-causal context of its interactions with other non-climate sources of change and stress (e.g. water scarcity, governance structures, institutional and jurisdictional fragmentation, limited revenue streams for public sector roles, or inflexible land use patterns)	W
Different development paths may increase or decrease vulnerabilities to climate-change impacts	W
Neglect by policy-makers and under-investment in infrastructure and services has negatively affected rural areas	I
Policy neglect specifically disfavours rural women	I
Assessment of climate change impacts on agriculture has to be undertaken against a background of demographic and economic trends in rural areas	E
Global numbers of people at risk from hunger will be affected by climate change, but more by socioeconomic trends as captured in the difference between the SRES scenarios	E
Specific characteristics of smallholder agriculture	
Subsistence and smallholder livelihood systems suffer from a number of non-climate stressors, but are also characterized for having certain resilience factors (efficiencies associated with the use of family labour, livelihood diversity to spread risks)	E
Traditional knowledge on agriculture and natural resources is an important resilience factor	I, E
The combination of stressors and resilience factors gives rise to complex and locally specific impacts, resistant to modelling	E, W
Impacts on agriculture and agricultural trade	
In low-latitude regions, temperature increases of 1-2°C are likely to have negative impacts on yields of major cereals. Further arming has increasingly negative impacts in all regions	E
Increases in global mean temperatures (GMTs) of 2-3 might lead to a small rise or decline (10-15%) in food (cereals) prices, while GMT increases in the range of 5.5°C or more might result in an increase in food prices of, on average, 30%	E
Forestry	
Loss of forest resources through climate change may affect 1.1 billion poor and forest-dependent people, including through impacts on Non-Timber Forest Products.	E
Valuation	
Robust valuations of climate change impact on human settlements are rare	W
Social and environmental costs are poorly captured by monetary metrics: non-monetary valuation methods should be explored	W, I
Adaptation	
Prospects for adaptation depend on the magnitude and rate of climate change	I
Adaptation actions can be effective in achieving their specific goals, but they may have other (positive or negative) effects, including resource competition	I
Diversification of agricultural and non-agricultural livelihood strategies is an important adaptation trend, but requires institutional support and access to resources	E
Links between adaptation and mitigation	
Mitigation and adaptation policies are in many cases, and certainly for agriculture, closely linked	K, E, W

Table 9-2: Major demographic, poverty-related, economic, governance, and environmental trends in rural areas of developed and developing countries.

	Developed countries	**Developing countries**
Demographic Trends	Rural population accounts for 22.3% of the total population (or about 276 million people) (UN-DESA Population Division, 2012). Rural areas account for 75% of land area in OECD countries (OECD 2006). Rural population has peaked (absolute numbers) in Europe and North America. Rural depopulation in some places, but also counter-urbanization with people moving from urban to rural areas elsewhere.	Rural population accounts for 50.3% of the total population (or about 2.5 billion people) in less developed countries (excluding LDCs), 71.5% (or about 608 million people) in the LDCs (UN-DESA Population Division, 2012) Rural population has already peaked in Latin America and Caribbean, East and South East Asia; expected to peak around 2025 in Middle East, North Africa, South and Central Asia; around 2045 in sub-Saharan Africa.
Dependence on agriculture	Agriculture accounts for only 13% of rural employment in the EU (2006), and less than 10% on average across developed countries; however, has a strong indirect influence on rural economies. Increased competition as a result of economic globalization has resulted in agriculture no longer being the main pillar of the rural economy in Europe. Economic policies are primary drivers. (Marsden, 1999, Lopez-i-Gelats, 2009)	Proportion of rural population engaged in agriculture declining in all regions(Figure 9-2).. Agriculture still provides jobs for 1.3 billion smallholders and landless workers (World Bank, 2008). Non-agricultural including labour-based and migration-based livelihoods increasingly existing alongside (and complementing) farm-based livelihoods. Agricultural initiatives and growth still important for adaptation and for small holders in Africa and Asia; (Osbahr *et al.,* 2008; Collier *et al.*, 2008; Kotir, 2010)
Poverty and Inequality	Per capita GDP in rural areas of OECD countries is only 83% of national average (but significant variation within and between countries): driven by out-migration, aging, lower educational attainment, lower productivity of labour, low levels of public services.	Rates of poverty (percentage of population living on less than US $ 2/day) and extreme poverty (percentage of population living on less than US $ 1.25/day) falling in rural areas in most parts of the world; but rural poverty and rural extreme poverty rising in sub-Saharan Africa. Recent price hikes and volatility exacerbated hunger and malnutrition among rural households many of which are net-food buyers (FAOSTATS, 2013). Hunger and malnutrition prevalent among rural children in South Asia and Sub-Saharan Africa (UN, 2010; IFAD, 2010; World Bank, 2007). Figure 9-2 and Table 9-3

Table 9-2 (continued)

Economic, Policy, Governance Trends	Shift from agricultural (production) to leisure (consumption) activities; focus on broader amenity values of rural landscapes for recreation, tourism, and forests, ecosystem services. (Bunce, 2008; OECD, 2006; Rounsevell *et. al.,* 2007) Agricultural subsidies under pressure from international trade negotiations and domestic budgetary constraints. As a result of recent price hikes, domestic price support has been lowered in OECD countries. New policy approach in OECD countries that focuses on investments and targets a range of rural economic sectors and environmental services.	Interconnectedness and economic openness in rural areas have encouraged shifts to commercial agriculture, livelihoods diversification and aid knowledge transfers (section 9.3.3). Interlinkages between land tenure, food security and biofuel policies impact rural poverty (see Chapter 7, section 7.1 and 7.3.2 for further details) Decentralization of governance and emergence of rural civil society. Movements towards land reform in some parts of Asia (Kumar, 2010). Emergence of economies in transition, characterised in places by co-existence of leading and lagging regions; political and democratic decentralization expanding leading to increasing complexity of policy (World Bank, 2007).
Environmental Degradation	Different socio-economic scenarios have varying impacts on land use and agricultural biodiversity (Reidsma *et al.,* 2006).	Resource degradation, environmentally fragile lands subject to overuse and population pressures, exacerbate social and environmental challenges. Multiple stressors increase risk, reduce resilience and exacerbate vulnerability among rural communities from extreme events and climate change impacts (Chapter 13, Section 13.2.6) .
Rural-Urban Linkages and Transformations	Changes in land-use and land-cover patterns at urban-rural fringe affected by new residential development, local government planning decisions, and environmental regulations (Brown *et al*., 2008).	Stronger rural-urban linkages through migration, commuting, transfer of public and private remittances, regional and international trade, inflow of investment and diffusion of knowledge (through new information and communication technologies) (IFAD, 2010). Continued out-migration to urban areas by the semi-skilled and low-skilled, reducing the size of rural workforce (IFAD, 2010). Trend for migration to small and medium-sized towns (Sall *et al*., 2010). Increased volumes of agricultural trade, growing by 5% on average (annually) between 2000-2008 (WTO, 2009). New initiatives of foreign direct investment (FDI) in agriculture in the form of large-scale land acquisitions in developing countries (Anseeuw *et al*., 2012; World Bank, 2010).

Table 9-3: Poverty indicators for rural areas of developing countries.

	Incidence of poverty (%)		Incidence of rural poverty (%)		Incidence of extreme poverty (%)		Incidence of extreme rural poverty (%)		Rural people as % of those in extreme poverty	
	1988	2008	1988	2008	1988	2008	1988	2008	1988	2008
Developing World	69.1	51.2	83.2	80.9	45.1	27.0	54.0	34.2	80.5	71.6

Source: adapted from IFAD, 2010

Table 9-4: Projected changes in areas suitable for production of tropical beverage crops by 2050.

Crop	Countries	Change in climate to 2050	Change in total area by 2050	Change in distribution by 2050
Coffee	Guatemala, Costa Rica, Nicaragua, El Salvador, Honduras, Mexico	2.0-2.5ºC increase in temperature 5-10% decline in total rainfall	Between 38 and 89% decline in area suitable for production	Minimum altitude suitable for production rises from 600 to 1000 m.a.s.l.
	Kenya	2.3ºC increase in temperature Rainfall increase from 1405mm to 1575 mm	Substantial decline in suitability of western highlands, some decline in area optimal for production in eastern highlands	Minimum altitude for production rise from 1000 to 1400 m.a.sl.
Tea	Kenya	2.3ºC increase in temperature Rainfall increase from 1655mm to 1732 mm	Majority of western highlands loose suitability, while looses are compensated by gains at higher altitude in eastern highlands	Optimum altitude for production change from 1500-2100 m.a.s.l. to 2000-2300 m.a.s.l.
	Uganda	2.3ºC increase in temperature Rainfall increase from 1334mm to 1394 mm	Considerable reduction in suitability for production across all areas	Optimal altitude change from 1450-1650 m.a.s.l. to 1550-1650 m.a.s.l.
Cocoa	Ghana, Ivory Coast	2.1ºC increase in temperature No change in total rainfall	Considerable reduction in area suitable for production; almost total elimination in Ivory Coast	Optimal altitude changes from 100-250 m.a.s.l. to 450-500 m.a.s.l.

Table 9-5: Illustrative sample of studies on economic value and changes in value from climate change.

Study : Author /s	**Country / Region**	**Findings and Estimates**
Vaghefi *et al*., 2011	Malaysia (2 degrees C rise in temperature)	Annual economic loss in rice production: $ 54.17 million
Zhai and Zhuang, 2009	South East Asian countries : Thailand, Vietnam, Philippines	GDP reduction from loss of agricultural productivity by 2080: 1.7-2.4%
Guiteras, 2007	India	GDP reduction from agricultural losses: 1-1.8% Consumption reduction for poor: 18%
ADB and IFPRI, 2009	Asia	Annually spending for coping with adverse agricultural impacts between 2010-2050: $4.2 - $ 5 billion
Mendelsohn *et al*., 2010	Mexico	Decline in farmland values for each degree of warming: 4-6000 pesos
Mendelsohn *et al*., 2007	U.S. A. (10% average increase in temperature)	Fall in crop land values for rural communities: 13%
Mendelsohn and Reinsborough, 2007	Canada (increasing precipitation) U.S.A. (increasing temperature)	Mixed effects with some improved profits Adverse impacts on farming
Wittrock *et al*., 2011	Canada (Canadian Global Model 2)	Crop losses under drought: CAN$ 7-171 per hectare
Franco *et al*., 2011	California (B1 – low emissions and A2 – medium emissions scenarios)	Annual Agricultural losses upto $3billion Flooding increases losses
World Bank, 2010a	Mozambique (Dynamic CGE model)	Damages to agriculture, hydropower and infrastructure (including coastal areas) by 2050: $7.6 billion
Mideksa, 2010	Ethiopia (Cline, CGCM2 and PCM)	Decline in GDP from agriculture and linked sectors: 10% from benchmark levels
Dinar *et al*., 2008	11 African countries (Ricardian analysis; various climate scenarios)	By 2100: Total losses of $48.2 billion to gains of $ 90 billion In 2020 for 1.6% warmer and 3.7% dryer climate: net farm revenues decline by upto 25%
Nelson *et al*., 2009	Africa (A2 scenario; CSIRO and NCAR models)	Food security impacts Decline in calore consumption per capita per day by: 500 calories
Schlenker and Roberts, 2010	Africa (A1B scenario; WCRP CMIP3)	Losses for crops except Cassava: likelihood of 95% that losses exceed 7% 5% probability that losses exceed 27%
ECLAC, 2010a, b	Guatemala, Belize, Costa Rica, Honduras (SRES A2 and B2; Regional climate models)	Losses in gross value of production upto 25% (Guatemala, followed by other countries)
Seo and Mendelsohn, 2008	South America (SRES A1; Canadian Climate Centre)	Loss in incomes of farmers by: 2020: 14% 2060: 20%
Sanghi and Mendelsohn, 2008	Brazil (Climate predictions from 14 GCMs)	Annual damages between: 1 – 39%
Fallon and Betts, 2010	Southern Europe (2 degrees C rise in temperature)	Increased costs of agricultural production
Olesena *et al*., 2011	Hungary, Serbia, Bulgaria, Romania	Negative impacts for crops in continental climatic zone

Table 9-6: Examples of adaptations in the agricultural sector in different regions.

Agricultural adaptations	**Where it has been observed and source**
Modifying planting, harvesting and fertilising practices for crops	Anchioreta in Brazil (Bonatti et al., 2012), semi-arid mountain regions of Bolivia (PNCC, 2007), Chile (Meza and Silva, 2009), maize and wheat crops in Argentina (Magrin et al., 2009; Travasso et al., 2009b), South Africa and Ethiopia (Bryan *et al*, 2009), composting and coraaling of livestock to collect waste in northern Burkino Faso (Barbier et al, 2009), Sahelian region of Mali (Adepetu and Berthe, 2007), in North West Province, Limpopo Province and KwaZulu Natal, South Africa (Thomas *et al*, 2007)
Changing amount or area of land under cultivation	Moving winter wheat northwards and expanding rice crops (Lin et al., 2005), South Africa (Bryan et al, 2009), expansion of fields in northern Burkino Faso (Barbier et al, 2009), increase in the size of plots in the Sahelian region of Mali (Adepetu and Berthe, 2007)
Using different varieties (e.g. early maturing, drought-resistant)	Early maturing cultivars in South Brazil (Walter et al, 2010), North America (Coles and Scott, 2009), drought-tolerant in Asia (Thomas, 2008; Zhao et al., 2010), South Africa and Ethiopia (Bryan *et al,* 2009), Ghana (Gyampoh et al, 2008), northern Burkino Faso (Barbier et al, 2009), Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), in North West Province, Limpopo Province and KwaZulu Natal, South Africa (Thomas *et al*, 2007)
Diversifying crops	Peruvian Andes (Lin, 2011), South America (Montenegro and Ragrab, 2010), northeastern Mexico (Eakin and Appendini, 2008; Eakin and Bojorquez-Tapia, 2008), Tasmania, Australia (Smart, 2010), in KwaZulu Natal, South Africa (Thomas et al, 2007)
Commercialisation of agriculture	Income generation from natural resources (e.g. fuelwood) in the Limpopo River Basin, Botswana (Dube and Sekhela, 2007), Ghana (Gyampoh *et al*, 2008), Limpopo Province, South Africa (Thomas et al, 2007)
Water control mechanisms (including irrigation and water allocation rights)	Improved rice harvests in monsoonal Asia (Hatcho et al., 2010); adaptation for quinoa (Bolivian Altiplano), tomatoes (central Brazil) and cotton (northern Argentina (Geerts and Raes, 2009); for rice in northeast China (Lin et al, 2005); small water harvesting pits (known as zai) in improved yields and incomes due to improved soil moisture in Ethiopia (Amede *et al*., 2011; Bryan *et al*, 2009) and Burkina Faso (Hertsgaard, 2011, Barbier *et al*, 2009), in South Africa (Bryan et al, 2009), amongst rural women farmers in the Eastern Cape, South Africa (Bryan *et al*, 2009), Ghana (Gyampoh et al, 2008), dry season vegetable production through irrigation in northern Burkino Faso to enable two crop cycles (Barbier et al, 2009), Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), in Limpopo Province, South Africa (Thomas et al, 2007)
Shading and wind breaks	For coffee in Brazil, Costa Rica and Colombia (Camargo, 2010), Ethiopia (Bryan *et al,* 2009)
Conservation agriculture (e.g. soil protection, agroforestry)	Honduras, Nicaragua and Guatemala (Holt-Gimenez, 2002), Burkina Faso (Hertsgaard, 2011, Barbier *et al*, 2009), Ethiopia (Bryan *et al*, 2009), Sahelian region of Mali (Adepetu and Berthe, 2007)
Modifying grazing patterns for herds	Arctic (Bartsch et al, 2010), East Africa (Eriksen and Lind, 2009) and southern Africa (O'Farrell *et al*., 2009), moving livestock to less densely populated pastures in northern Burkino Faso (Barbier et al, 2009) and the Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), in North West Province, Limpopo Province and KwaZulu Natal, South Africa (Thomas *et al*, 2007)
Providing supplemental feeding for herds/ storage of animal feed	Arctic (P. and M., 2008; Forbes and Kumpula, 2009), South Africa (Bryan *et al*, 2009), use of sorghum and hay residue for feeding livestock in northern Burkino Faso (Barbier et al, 2009), Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), cutting fodder for livestock in Limpopo Province, South Africa (Thomas *et al*, 2007)
Ensuring optimal herd size	Arctic (Forbes et al, 2009), culling of livestock in Northern Nigeria (Adepetu and Berthe, 2007), selling of livestock northern Burkino Faso (Barbier et al, 2009) and the Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007)
Developing new crop and livestock varieties (e.g. biotechnology and breeding)	Brazil and Argentina (Marshall, 2012; Urcola et al, 2010), Northern Nigeria (Adepetu and Berthe, 2007)

Table 9-7: Examples of adaptations in the water sector observed in different regions.

Type	Example	Where it has been observed and source
Supply-side mechanisms	Dams	Proposed in the Volta River in Ghana (van de Giesen *et al*., 2010).
	Reservoirs	Asia (Tyler and Fajber, 2009), particularly in areas where water stress is an issue of distribution rather than absolute shortage (Biemans et al, 2011; Rivera-Ferre et al 2013)
	Groundwater pumping	Arid and semi-arid South America (Burte et al., 2011; Döll, 2009; Kundzewicz and Döll, 2009; Zagonari, 2010)
	Groundwater recharge	Potential identified in India (Sukhija, 2008)
	Irrigation (often using water-saving technology)	Asia (Ngoundo et al., 2007; Tischbein etal., 2011)
	Fog interception practices	South America (Holder, 2006; Klemm et al., 2012)
	Water capture	Bolivia (PNCC, 2007)
Demand-side mechanisms	Improved management, e.g. through efficiency	Asia (Kranz et al, 2010), South America (Bell et al., 2011; Geerts et al., 2010; Montenegro and Ragab, 2010; Van Oel et al., 2010); Pampas Argentina (Quiroga and Gaggioli, 2011)
	Policies	Murray-Darling Basin Authority (MDBA) established to address over-allocation of water resources (Connell and Grafton, 2011; MDBA, 2011) See also box 26-3 on Australia's water policies;
	Reviewing allocation rights	Indogangetic Plains (Rivera-Ferre et al., 2013); Australia's MDBA reviewed the "exceptional circumstances" concept in drought policy (Productivity Commission, 2009);

Executive Summary

Climate change would reduce energy demand for heating and increase energy demand for cooling in the residential and commercial sectors (*high agreement, robust evidence*); the balance of the two depends on the geographic, socioeconomic and technological conditions. Increasing income will allow people to regulate indoor temperatures to a comfort level that leads to fast growing energy demand for air conditioning even in the absence of climate change in warm regions with low income levels at present. Energy demand will be influenced by changes in demographics (upwards by increasing population and decreasing average household size), lifestyles (upwards by larger floor area of dwellings), the design and heat insulation properties of the housing stock, the energy efficiency of heating/cooling devices and the abundance and energy efficiency of other electric household appliances. The relative importance of these drivers varies across regions and will change over time. [10.2]

Climate change would affect different energy sources and technologies differently, depending on the resources (water flow, wind, insolation), the technological processes (cooling) or the locations (coastal regions, floodplains) involved (*high agreement, robust evidence*). Gradual changes in various climate attributes (temperature, precipitation, windiness, cloudiness, etc.) and possible changes in the frequency and intensity of extreme weather events will progressively affect operation over time. Climate-induced changes in the availability and temperature of water for cooling are the main concern for thermal and nuclear power plants, but several options are available to cope with reduced water availability. Similarly, already available or newly developed technological solutions allow firms to reduce the vulnerability of new structures and enhance the climate suitability of existing energy installations. [10.2]

Climate change would influence the integrity and reliability of pipelines and electricity grids (*medium agreement, medium evidence*). Pipelines and electric transmission lines have been operated for over a century in diverse climatic conditions on land from hot deserts to permafrost areas and increasingly at sea. Climate change is *about as likely as not* to require the adoption of technological solutions for the construction and operation of pipelines and power transmission and distribution lines from other geographical and climatic conditions, adjustments in existing pipelines and improvements in the design and deployment of new ones in response to the changing climate and weather conditions. [10.2]

Climate change would have impacts, heterogeneous in both sign and size, on water resources and water use (*high agreement, robust evidence*), but the economic implications are not well understood. Economic impacts include flooding, scarcity and cross sectoral competition. Flooding can have major economic costs, both in term of impacts (capital destruction, disruption) and adaptation (construction, defensive investment). Water scarcity and competition for water, driven by institutional, economic or social factors, may mean that water assumed to be available for a sector is not. [10.3]

Climate change would negatively affect transport infrastructure (*high agreement, limited evidence*). Transport infrastructure malfunctions if the weather is outside the design range, which would happen more frequently should climate change. All infrastructure is vulnerable to freeze-thaw cycles and paved roads are particularly vulnerable to temperature extremes, unpaved roads to precipitation extremes. Transport infrastructure on ice or permafrost is especially vulnerable. [10.4]

Climate change would affect tourism resorts, particularly ski resorts, beach resorts, and nature resorts (high agreement, robust evidence) and tourists would be inclined to spend their holidays at higher altitudes and latitudes (*high agreement, medium evidence*). The economic implications of climate-change-induced changes in tourism demand and supply may be substantial, with gains for countries closer to the poles and higher up the mountains and losses for other countries. The demand for outdoor recreation is affected by weather and climate, and impacts will vary geographically and seasonally. [10.6]

Climate change strongly affects insurance systems (*high agreement, robust evidence*). More frequent and/or intensive weather disasters increase losses and loss variability in various regions and challenge insurance systems to offer affordable coverage while raising more risk-based capital, particularly in low- and middle-income countries. Economic-vulnerability reduction through insurance has proven effective. Large-scale public-private risk prevention

initiatives and government insurance of the non-diversifiable portion of risk offer example mechanisms for adaptation. Commercial reinsurance and risk-linked securitization markets also have a role in ensuring financially resilient insurance systems. [10.7]

Climate change would affect the health sector (*high agreement, medium evidence*) through increases in the frequency, intensity, and extent of extreme weather events adversely affecting infrastructure and increase the demands for services due to the human health impacts of climate change, placing additional burdens on public health, disease burden, and health care personnel and supplies; these have economic consequences. [10.8]

Markets provide an additional mechanism for adaptation and would thus reduce negative impacts and increase positive ones for any specific sector or country (*high agreement, medium evidence*). The impacts of climate on one sector of the economy of one country in turn affect other sectors and other countries though product and input markets. Markets increase overall welfare, but not necessarily welfare in every sector and country. [10.9]

The impacts of climate change would decrease productivity and economic growth, but the magnitude of this effect is not well understood (*high agreement, limited evidence*). Climate could be one of the causes why some countries are trapped in poverty, and climate change may make it harder to escape poverty traps. [10.9]

Not all key sectors have been subject to detailed research based on a comprehensive assessment across economic sectors. Few studies have evaluated the possible impacts of climate change on mining, manufacturing or services (apart from health, insurance and tourism).Further research, collection and access to more detailed economic data and the advancement of analytic methods and tools will be required to further assess the potential impacts of climate on key economic systems and sectors. [10.5, 10.8, 10.10]

10.1. Introduction and Context

This chapter discusses the implications of climate change on key economic sectors and services; e.g., economic activity. Other chapters discuss impacts from a physical, chemical, biological, or social perspective. Economic impacts cannot be isolated; and therefore, there are a large number of cross-references to other chapters in this report. In some cases, particularly agriculture, the discussion of the economic impacts is integrated with the other impacts.

Focusing on the potential impact of climate change on economic activity, this chapter addresses questions such as: how does climate change affect the demand for a particular good or service? What is the impact on its supply? How do supply and demand interact in the market? What are the effects on producers and consumers?

An inclusive approach was taken, discussing all sectors of the economy. Appendix A shows the list of sectors according to the International Standard Industrial Classification. This assessment reflects the breadth and depth of the state of knowledge across these sectors; many of which have not been evaluated in the literature. We extensively discuss five sectors: Energy (10.2), water (10.3), transport (10.4), tourism (10.6), and insurance (10.7). Other primary and secondary sectors are discussed in 10.5, and 10.8 is devoted to other service sectors. Food and agriculture is addressed in Chapter 7. Sections 10.2 through 10.8 discuss individual sectors in isolation. Markets are connected, however. Section 10.9 therefore assesses the implications of changes in any one sector on the rest of the economy. It also discusses the effect of the impacts of climate change on economic growth and development. Chapter 19 assesses the impact of climate change on economic welfare – that is, the sum of changes in consumer and producer surplus, including for goods and services not traded within the formal economy. This is not attempted here. The focus is on economic activity. Section 10.10 discusses whether there may be vulnerable sectors that have yet to be studied.

Previous assessment reports by the IPCC did not have a chapter on “key economic sectors and services”. Instead, the material assembled here was spread over a number of chapters. AR4 is referred to in the context of the sections below. In some cases, however, the literature is so new that previous IPCC reports did not discuss these impacts at any length.

10.2. Energy

Studies conducted since AR4 and assessed here confirm the main insights about the impacts of climate change on energy demand as reported in the SAR (Acosta Moreno *et al*., 1995) and reinforced by the TAR (Scott *et al.*, 2001) and AR4 (Wilbanks *et al.*, 2007): ceteris paribus, in a warming world, energy demand for heating will decline and energy demand for cooling will increase; the balance of the two depends on the geographic, socioeconomic and technological conditions. The relative importance of temperature changes among the drivers of energy demand varies across regions and will change over time. Earlier IPCC assessments did not write much about energy supply, but an increasing number of studies now explore its vulnerability, impacts and the adaptation options (Troccoli, 2010); (Ebinger and Vergara, 2011); (USGCRP, 2009). The energy sector will be transformed by climate policy (Bashmakov et al., forthcoming) but impacts of climate changes too will be important for secure and reliable energy supply.

10.2.1. Energy Demand

Most studies conducted since AR4 explore the impacts of climate change on residential energy demand, particularly electricity. Some studies encompass the commercial sector as well but very few deal with industry and agriculture. In addition to a few global studies based on global energy or integrated assessment models, the new studies tend to focus on specific countries or regions, rely on improved methods (more advanced statistical techniques) and data (both historical and regional climate projections), and many of them explicitly include non-climatic drivers of energy demand. A few studies consider changes in demand together with changes in climate-dependent energy sources, like hydropower.

Figure 10-1 sorts the assessed studies according to the present climate (represented by mean annual temperature) and current income (represented by GDP per capita). Neither indicator is ideal: country-level mean annual temperatures for large countries can hide large regional differences and average incomes may conceal large disparities, but they help cluster the national and regional studies in the search for general findings (Toth, 2013).

[INSERT FIGURE 10-1 HERE
Figure 10-1: GDP per capita (in 2009) and annual mean temperature (based on 1971-2000 climatology) in selected countries and US federal states. Source: Toth, 2013.]

The general patterns are (i) in countries and regions with already high incomes, climate-related changes in energy demand will be primarily driven by increasing temperatures, with associated heavier use of air-conditioning in warm climates, and (ii) lower demands for various energy forms (electricity, gas, coal, oil) in temperate and cold climates, while increasing incomes will play a marginal role. In contrast, changes in income will be the main driver of increasing demand for energy (mainly electricity for air conditioning and transportation fuels) in present-day low-income countries in warm climates.

At the global scale, energy demand for residential air conditioning in summer is projected to increase rapidly in the 21st century under the reference climate change scenario (medium population and economic growth globally, but faster economic growth in developing countries; no mitigation policies in addition to those in place in 2008) by the TIMER/IMAGE model (Isaac and Van Vuuren, 2009). The increase is from nearly 300 TWh in 2000, to about 4,000 TWh in 2050 and more than 10,000 TWh in 2100, about 75% of which is due to increasing income in emerging market countries and 25% is due to climate change. Energy demand for heating in winter increases too, but much less rapidly, since in most regions with the highest need for heating, incomes are already high enough for people to heat their homes to the desired comfort level (except in some poor households). In these regions, energy demand for heating will decrease.

These general patterns and especially the quantitative results of the projected shifts in energy and electricity demand can be modified by many other factors. In addition to changes in temperatures and incomes, the actual energy

demand will be influenced by changes in demographics (upwards by increasing population and decreasing average household size), lifestyles (upwards by larger floor area of dwellings), the design and insulation of the housing stock, the energy efficiency of heating/cooling devices, the abundance and energy efficiency of other selectric household appliances, the price of energy, etc.

10.2.2. Energy Supply

Changes in various climate attributes (temperature, precipitation, windiness, cloudiness, etc.) will affect different energy sources and technologies differently. Gradual climate change (CC) will progressively affect operation over time. Possible changes in the frequency and intensity of extreme weather events (EWEs) represent a different kind of hazard for energy installations and infrastructure. This section assesses the most important impacts and adaptation options in both categories. Table 10-1 provides an overview.

[INSERT TABLE 10-1 HERE
Table 10-1: Main projected impacts of CC and EWEs on energy supply.]

Currently, thermal power plants provide about 80% of global electricity and their share is projected to remain high in most mitigation scenarios (IEA, 2010aa). Thermal power plants are operated under diverse climatic conditions from the cold Arctic to the hot tropical regions and are well adapted to the prevailing conditions. However, they might face new challenges and will need to respond by hard (design or structural methods) or soft (operating procedures) measures as a result of climate change.

The most significant impact of CC on thermal power generation is the decreasing efficiency of thermal conversion as a result of rising temperature. This follows from Carnot's rule and cannot be offset per se. Yet there is much room to improve the efficiency of currently operating subcritical steam power plants (IEA, 2010b). As new materials allow higher operating temperatures in coal-fired power plants (Gibbons, 2012), supercritical and ultra-supercritical steam-cycle plants will reach even higher efficiency that can more than compensate the efficiency losses due to higher temperatures. Yet in the absence of CC, these efficiency gains from improved technology would reduce the costs of energy, so there is still a net economic loss due to CC. Another problem facing thermal power generation in many regions is the decreasing volume and increasing temperature of water for cooling, leading to reduced power generation, operation at reduced capacity and even temporary shutdown of power plants (Ott and Richter, 2008; Hoffmann *et al.*, 2010; IEA, 2012; Nee Schulz, 2012). Both problems will be exacerbated if CO_2 capture and handling equipment is added to fossil-fired power plants: energy efficiency declines by 8-14 % and water requirement per MWh electricity generated can double (IPCC, 2005).

Adaptation possibilities range from relatively simple and low-cost options like exploiting non-traditional water sources and re-using process water to measures like installing dry cooling towers, heat pipe exchangers and regenerative cooling (Ott and Richter, 2008; De Bruin *et al.*, 2009), all which increase costs. While it is easier to plan for changing climatic conditions and select the conforming cost-efficient cooling technology for new builds, response options are more limited for existing power plants, especially for those towards the end of their economic lifetime.

CC impacts on thermal efficiency and cooling water availability affect nuclear power plants similarly to their thermal counterparts (Williams and Toth, 2013). Whereas there is no escape from Carnot's rule affecting efficiency, a range of alternative cooling options are available to deal with water deficiency, ranging from re-using wastewater and recovering evaporated water (Feeley III *et al.*, 2008) to installing dry cooling (EPA , 2001).

The implications of EWEs for nuclear plants can be severe if not properly addressed. Reliable interconnection (onsite power and instrumentation connections) of intact key components (reactor vessel, cooling equipment, control instruments, back-up generators) is indispensable for the safe operation and/or shutdown of a nuclear reactor. For most of the existing global nuclear fleet, a reliable connection to the grid for power to run cooling systems and control instruments in emergency situations is another crucial item (IAEA (International Atomic Energy Agency), 2011). Several EWEs can damage the components or disrupt their interconnections. Preventive and protective

measures include technical and engineering solutions (circuit insulation, shielding, flood protection) and adjusting operation to extreme conditions (reduced capacity, shutdown) (Williams and Toth, 2013).

Hydropower is by far the largest of renewable energy sources in the current energy mix. It is projected to remain important in the future, irrespective of the climate change mitigation targets in many countries (IEA, 2010aa; IEA, 2010b). The resource base of hydropower is the hydrologic cycle driven by prevailing climate and topology. The former makes the resource base and hence hydropower generation highly dependent on future changes in climate and related changes in extreme weather events (Ebinger and Vergara, 2011; Mukheibir, 2013).

Assessing the impacts of climate change on hydropower generation is the most complex endeavour in the energy sector. A series of non-linear and region-specific changes in mean annual and seasonal precipitation and temperatures, the resulting evapotranspiration losses, shifts in the share of precipitation falling as snow and the timing of its release from high elevation make resource estimates difficult (see Chapters 2 and 3) while regional changes in water demand due to changes in population, economic activities (especially irrigation demand for agriculture) present competition for water resources that are hard to project (see Section 10.3). Further complications stem from the possibly increasing need to combine hydropower generation with changing flood control and ecological (minimum dependable flow) objectives induced by changing climate regime.

Focusing on the possible impacts of CC on hydroelectricity and the adaptation options in the sector in response to the changes in the amount, the seasonal and inter-annual variations of available water, and in other demands, the overall conclusion from the literature is that the impacts of CC and EWEs on hydropower generation is *likely* to increase in most regions and decrease in some, with diverging patterns across regions, watersheds within regions and even river basins within watersheds. Planning tools for long-term hydrogeneration may need to be enhanced to cope with slow but persistent shifts in water availability, and short-term management models may need to be enhanced to deal with the impacts of EWEs. A series of hard (raising dam walls, adding bypass channels) and soft (adjusting water release) measures are available to protect the related infrastructure (dams, channels, turbines, etc.) and optimize incomes by timing generation when electricity prices are high (Mukheibir, 2013).

Solar energy is expected to increase from its currently small share in the global energy balance across a wide range of mitigation scenarios (IEA, 2008; IEA, 2010aa; IEA, 2010ab; IEA, 2010ab; IEA, 2010b). The three main types of technologies for harnessing energy from insolation include thermal heating (TH) (by flat plate, evacuated tube and unglazed collectors), photovoltaic (PV) cells (crystalline silicon and thin film technologies) and concentrating solar power (CSP) (power tower and power trough producing heat to drive a steam turbine for generating electricity). The increasing body of literature exploring the vulnerability and adaptation options of solar technologies to CC and EWEs is reviewed by (Patt *et al.*, 2013).

All types of solar energy are sensitive to changes in climatic attributes that directly or indirectly influence the amount of insolation reaching them. If cloudiness increases under climate change (see Chapters 11 and 12 of the WGI report), the intensity of solar radiation and hence the output of heat or electricity would be reduced. Efficiency losses in cloudy conditions are less for technologies that can operate with diffuse light (evacuated tube collectors for TH, PV collectors with rough surface). Since diffuse light cannot be concentrated, CSP output would cease under cloudy conditions but the easy and relatively inexpensive possibility to store heat reduces this vulnerability if sufficient volume of heat storage is installed (Khosla, 2008; Richter *et al.*, 2009).

The exposure of sensitive material to harsh weather conditions is another source of vulnerability for all types of solar technologies. Windstorms can damage the mounting structures directly and the conversion units by flying debris, whereby technologies with smaller surface areas are less vulnerable. Hail can also cause material damage and thus reduced output and increased need for repair. Depending on regional conditions, strong wind can deposit sand and dust on the collectors' surface, reducing efficiency and increasing the need for cleaning.

CC and EWE hazards per se do not pose any particular constraints for the future deployment of solar technologies. Technological development continues in all three solar technologies towards new designs, models and materials. One of the objectives of these development efforts is to make new models less vulnerable to current climate and EWEs. Technological development also results in a diverse portfolio of models to choose from according to the

climatic and weather characteristics of the deployment site. These development efforts can be integrated in addressing the key challenge for solar technologies today: reducing the costs.

Harnessing wind energy for power generation is an important part of the climate change mitigation portfolio in many countries. Assessing the possible impacts of CC and EWEs on this technology and exploring possible adaptation options are complicated by the complex dynamics characterizing wind energy. Relevant attributes of climate are expected to change; the technology is evolving (blade design, other components); see (Kong *et al.*, 2005; Barlas and Van Kuik, 2010); there is an increasing deployment offshore and a transition to larger turbines (Garvey, 2010) and to larger sites (multi megawatt arrays) (Barthelmie *et al.*, 2008).

The key question concerning the impacts of a changing climate regime on wind power is related to the resource base: how climate change will rearrange the temporal (inter- and intra-annual variability) and spatial (geographical distribution) characteristics of the wind resource. (Pryor and Barthelmie, 2010) find that in the next few decades wind resources (measured in terms of multi-annual wind power densities) are estimated to remain within the ±50% of the values compared to the past 20 year mean values. The wide range of the estimates results from the circulation and flow regimes in different GCMs and regional climate models (RCMs) (Bengtsson *et al.*, 2006; Pryor and Barthelmie, 2010). A set of four GCM-RCM combinations for the period 2041-2062 indicates that average annual mean energy density will be within ±25% of the 1979-2000 values in all 50 km grid cells over the contiguous USA (Pryor *et al.*, 2011(a); Pryor and Barthelmie, 2013). Yet, little is known about changes in the inter-annual, seasonal or diurnal variability of wind resources.

Wind turbines already operate in diverse climatic and weather conditions. As shown in Table 10-1, siting, design and engineering solutions are available to cope with various impacts of gradual changes in relevant climate attributes over the coming decades. The requirements to withstand extreme loading conditions resulting from climate change are within the safety margins prescribed in the design standards, although load from combinations of extreme events may exceed the design thresholds (Pryor and Barthelmie, 2013). In summary, the wind energy sector does not face insurmountable challenges resulting from climate change.

In the coal fuel cycle, vulnerability in mining depends on the mining method. Open cast mining might be particularly affected by high precipitation extremes and related floods and erosion, and temperature extremes, especially extreme cold that might encumber extraction for some time, whereas impacts on coal cleaning and operation of underground mines will probably be less severe. Changes in drainage and run-off regulation for on-site coal storage as well as in coal handling might be required due to the increased moisture content of coal and more energy might be required for coal drying before transportation (CCSP, 2007). Using current carbon dioxide capture technologies would almost double water consumption per unit of electricity generated from coal-fired plants, exacerbating water supply problems in water-stressed regions and/or seasons. At the back end of the fuel cycle, the management of fly-ash, bottom ash and boiler slag may need to be modified in response to changes in some EWE patterns like wind, precipitation and floods.

Climate and weather related hazards in the oil and gas sector include tropical cyclones with potentially severe effects on off-shore platforms and on-shore infrastructure as well, leading to more frequent production interruptions and evacuation (Cruz and Krausmann, 2013). Gradual changes in air temperature and precipitation are projected to generate risk and opportunities for the oil and gas industry. For example, reduced sea ice thickness and coverage might open new shipping routes, thus reducing shipping costs, while ice scour and ice pack loading on marine structures would increase. However, most changes involve increased risks, such as thawing permafrost would increase construction costs on unstable ground relative to ice-based construction, while thaw subsidence would trigger increased maintenance costs. Sea level rise and coastal erosion would degrade coastal barriers, damage facilities and trigger relocation (Dell and Pasteris, 2010).

10.2.3. Transport and Transmission of Energy

Primary energy sources (coal, oil, gas, uranium), secondary energy forms (electricity, hydrogen, warm water) and waste products (CO_2, coal ash, radioactive waste) are transported in diverse ways to distances ranging from a few to

thousands of kilometres. The transport of energy-related materials by ships (ocean and inland waters), rail and road are exposed to the same impacts of climate change as the rest of the transport sector (see Section 10.4). This subsection deals only with transport modes that are unique to the energy sector (power grid) or predominantly used by it (pipelines). Table 10-2 provides an overview of the impacts of CC and EWEs on energy transmission, together with the options to reduce vulnerability.

[INSERT TABLE 10-2 HERE
Table 10-2: Main impacts of CC and EWEs on pipelines and the electricity grid.]

Pipelines play a central role in the energy sector by transporting oil and gas from the wells to processing and distributing centres to distances from a few hundred to thousands of kilometres. With the spread of CO_2 capture and storage (CCS) technology, another important function will be to deliver CO_2 from the capture site (typically fossil power plants) to the disposal site onshore or offshore. Pipelines have been operated for over a century in diverse climatic conditions on land from hot deserts to permafrost areas and increasingly at sea. This implies that technological solutions are available for the construction and operation of pipelines under diverse geographical and climatic conditions. Yet adjustments may be needed in existing pipelines and improvements in the design and deployment of new ones in response to the changing climate and weather conditions.

Pipelines will be mainly affected by secondary impacts of climate change: sea-level rise in coastal regions, melting permafrost in cold regions, and floods and landslides triggered by heavy rainfall. A proposed way to reduce vulnerability to these events is the amendment of land zoning codes, and the design and construction standards for new pipelines and structural upgrade for existing ones (Antonioni *et al.*, 2009; Cruz and Krausmann, 2013).

Due to the very function of the electricity grid to transmit power from generation units to consumers, the bulk of its components (overhead lines, substations, transformers) are located outdoors and exposed to EWE. The power industry has developed numerous technical solutions and related standards to protect those assets and provide reliable electricity supply under prevailing climate and weather conditions worldwide; however, much existing infrastructure is vulnerable to EWEs.

Higher average temperatures decrease transmission efficiency by about 0.4%/°C but this effect is relatively small compared to the physical and monetary damages that can be caused by EWEs (Ward, 2013). Historically, high wind conditions, including storms, hurricanes and tornados, have been the most frequent cause of grid disruptions (mainly due to damages to the distribution networks), and more than half of the damage was caused by trees (Reed, 2008). If the frequency and power of high wind conditions, as well as extreme precipitation events, will increase in the future, vegetation management along existing power lines and rerouting new transmission lines along roads or across open fields might help reduce related risks.

The economic importance of a reliable transmission and distribution network is highlighted by the fact that the damage to customers tend to be much higher than the price of electricity not delivered (lost production, electricity enabled commerce, service delivery, food spoilage, lost or restricted water availability). Designing and building climate-resilient infrastructure will depend on technical standards, market governance, and the type and degree of liberalization and deregulation of grid services.

10.2.4. Macroeconomic Impacts

Most economic research related to climate change impacts on the energy sector has focused on mitigation rather than the economic implications of climate change itself. Table 10-3 summarizes the recent studies on the economic implications of climate change and extreme weather impacts in the energy sector.

[INSERT TABLE 10-3 HERE
Table 10-3: Economy-wide implications of impacts of climate change and extreme weather on the energy sector.]

Assessing across a broad array of studies that focus on different regions and regional divisions, examine different climate change impacts, include a different mix of sectors, model different timeframes, make different assumptions about adaptation, and employ different types of models with different output metrics leads to the overall conclusion that the macroeconomic impact of climate change on energy demand is *likely* to be minimal in developed countries (Bosello *et al.*, 2007; Aaheim *et al.*, 2009; Bosello *et al.*, 2009; Jochem *et al.*, 2009; Jochem *et al.*, 2009; Eboli *et al.*, 2010a).

The current literature sheds less light on the implications for developing countries and on other climate impacts in the energy sector beyond those related to changes in energy demand. Europe is the focus of most of the literature so far. Asia, Africa, and Latin America are not well represented, appearing in only two global studies. The limited results indicate that developing countries *likely* face a greater negative GDP impact with respect to climate change implications for the energy sector than developed countries (Aaheim *et al.*, 2009; Boyd and Ibarraran, 2009; Eboli *et al.*, 2010a).

Despite the considerable number of potential climate change and extreme weather phenomena – higher mean temperatures, changes in rainfall patterns, changes in wind patterns, changes in cloud cover and average insolation, lightning, high winds, hail, sand storms and dust, extreme cold, extreme heat, floods, drought, and sea-level rise – and their potential impacts on electricity generation and transmission systems, fuel infrastructure and transport systems, and energy demand (Williams, 2013) – the range of impacts modeled in the literature (Table 10-3) is quite limited. Most studies consider changing energy demand (specifically, changes in electricity and fuel consumption for space heating/cooling) resulting from rising temperatures as the only or primary climate change impact. These studies draw upon recent literature refining the relationship between climate change and energy demand: the demand for natural gas and oil in residential and commercial sectors tends to decline with climate change because of less need for space heating, and demand for electricity tends to increase because of greater need for space cooling (Gabrielsen *et al.*, 2005; Gabrielsen *et al.*, 2005; Kirkinen *et al.*, 2005; Mansur *et al.*, 2005; Gunnar and Torben, 2010; Mideksa and Kallbekken, 2010; Rübbelke and Vögele, 2010).

Studies using a computable general equilibrium (CGE) model that consider only climate impacts in the energy sector find that the effect on GDP in 2050 is quite modest at -0.3% to 0.03% (Bosello et al. 2007) and -1.3% to -0.6% (Jochem *et al.*, 2009). These findings are largely consistent despite the fact that (Bosello *et al.*, 2007; Bosello *et al.*, 2009) are global studies that model only the change in demand due to rising temperatures, whereas (Jochem *et al.*, 2009) focus on the EU and model the change in demand plus six other climate impacts.

Studies using CGE models that examine the aggregate changes in GDP brought on by climate impacts in energy and several other sectors have also primarily found moderate shifts in GDP. (Aaheim *et al.*, 2009) conclude that in 2100 in cooler regions in the EU, GDP changes by -1% to -0.25% and in warmer regions changes by -3% to -0.5%. (Boyd and Ibarraran, 2009) project a -3% change in GDP in 2026 for Mexico, consistent with the warmer regions modeled by (Aaheim *et al.*, 2009). Roughly consistent with each other (Aaheim *et al.*, 2009; Eboli *et al.*, 2010a) find GDP impacts for the predominantly cooler regions of Japan, the EU, EEFSU, and Rest of Annex I as having a "significant positive impact", while the predominantly warmer regions of the USA, EEx (China/India, Middle East/Most of Africa/Mexico/parts of Latin America), and the Rest of the World have a "significantly negative impact." (Jorgenson *et al.*, 2004) find that overall GDP impacts are -0.6% to 0.7% in 2050 for the United States, which stands in contrast to (Eboli *et al.*, 2010a) with a "significantly negative impact" in the United States.

Several CGE studies attempt to evaluate how adaptation changes in the energy sector impact GDP but do not examine specific adaptation options since CGE models lack the necessary technological detail. They make general assumptions about the effectiveness of adaptation policy in reducing climate impacts. (Jorgenson *et al.*, 2004) find that pessimistic assumptions about adaptation imply a 0.6% reduction in GDP in 2050 but optimistic assumptions lead to a 0.7% gain in GDP. (Aaheim *et al.*, 2009) conclude that adaptation can mitigate the costs of climate change by 80% to 85%, and (Boyd and Ibarraran, 2009) find that adaptation can shift a 3% GDP loss in 2026 in Mexico to a gain in GDP of 0.33%.

Partial equilibrium models, by their nature, do not have a full macroeconomic representation and therefore rarely report changes in GDP. Instead, these models focus on details in the energy sector, such as price and quantity effects

for fuels and electricity (and the mix of generation). (Golombek *et al.*, 2011) report a 1% increase in the price of electricity for Western Europe in 2030 stemming from rising temperatures that affect demand and thermal efficiency of supply, as well as water inflow. (Gabrielsen *et al.*, 2005) conclude that for Nordic countries in 2040, as a result of rising temperatures that affect demand, changes in water inflow, and changes in wind speeds, the price of electricity will decline by 1%. Although the change in price differs in sign, the magnitude of change is small in both studies. In contrast, (Bye *et al.*, 2006) in looking at a hypothetical water shortage scenario in Nordic countries, conclude that the price of electricity can double over a 2 year period and then return to normal as water flow returns. (DOE, 2009) also finds that a drought scenario can lead to average monthly electricity prices that are 8.1% (November) to 24.1% (July) higher. In contrast to the significant price impacts found by (Bye *et al.*, 2006) and (DOE, 2009), (Koch *et al.*, 2012) conclude that thermal plant outages in Berlin resulting from heat wave-driven water temperatures that exceed regulatory limits can amount to a cumulative cost of 60 million EURO over the period 2010 through 2050 for 2850 MW of capacity. Assuming an 80% capacity factor, the premium for high water temperatures in Berlin is 0.075 EURO per MWh.

10.2.5. Summary

The balance of evidence emerging from the literature assessed in this section suggests that climate change per se will *likely* increase the demand for energy in most regions of the world. At the same time, increasing temperature will decrease the thermal efficiency of fossil, nuclear and solar power generation, the potential and dependability of hydropower, etc. However, temperature-induced impacts on energy supply will probably make a relatively small contribution to the overall increase in demand for energy and electricity. Similarly, CC impacts on energy supply will be part of an evolving picture dominated by technological development in the pursuit for safer, cheaper and more reliable energy sources and technologies as well as mitigation and adaptation response pathways.

Given the limitations in the literature, sweeping conclusions about results may be premature on macroeconomic implications. However, some narrow conclusions are possible. The change in GDP due to temperature-induced changes in energy demand – even if combined with other climate impacts – is relatively small in all of the studies. Ranging from -3% to 1.2%. (Jochem *et al.*, 2009) which is the most detailed and comprehensive study, report only a 1.3% drop in GDP in 2050 in Europe due to at least seven climate impacts in the energy sector. The GDP impact in warmer regions tends to be greater than in cooler regions, which benefit from less need for space cooling. Energy related economic impact for developing countries is anticipated to be negative, and positive in developed countries. Adaptation can lower the cost of climate change, but these results may be driven largely by assumption since specific policies have not been modeled. Results from some of the partial equilibrium models suggests that CGE modeling studies, which largely focus on changes in energy demand, may be neglecting some potentially costly impacts from extreme weather events like drought, which, if modeled, may lead to greater GDP impacts than reported thus far in the literature.

Much research is still needed to understand the implications of climate change and extreme weather on the energy sector and to identify cost-effective adaptation options. The best understood area is the implications of climate on energy demand. A comprehensive evaluation of a full range of supply-side climate change impacts and adaptation options for all aspects of energy infrastructure is needed. This information will help modelers make much better, empirically-based assumptions about the relationship of climate impacts and the economy, as well as about the effectiveness of adaptation options. Expanding research into developing countries is also much needed, as developing countries are more vulnerable to climate change impacts and probably face more significant economic implications.

10.3. Water

This section focuses on economic aspects of climate change in water related economic sectors. The biophysical water system, including infrastructure, is assessed in Chapter 3.

10.3.1. Water-Related Economic Losses

Between the 1950s and the 1990s, the annual economic losses from large extreme events, including floods and droughts, increased tenfold, with developing countries being hardest hit (Kabat *et al.*, 2003). Over the past few decades, flood damage constitutes about a third of the economic losses inflicted by natural hazards worldwide (Munich Re, 2005). The economic losses associated with floods worldwide have increased by a factor of five between the periods 1950-1980 and 1996-2005 (Kron and Berz, 2007). From 1990 to 1996 alone, there were six major floods throughout the world in which the number of fatalities exceeded 1,000, and 22 floods with losses exceeding US$1 billion each (Kabat et al., 2003). Although these increases are primarily due to several non-climatic drivers, climatic factors are also partly responsible (Kundzewicz *et al.*, 2007). SREX Chapter 4 {{1867 IPCC 2012}} provides a comprehensive look at the impacts of extreme events on water suppl(IPCC, 2012)y and flooding at wide range of spatial scales.

Most of the studies examining the economic impacts of climate change on the water sector have been carried out at the local, national, or river-basin scale; and, the global distribution of such studies is skewed towards developed countries (Schreider *et al.*, 2000; Chen *et al.*, 2001; Middelkoop *et al.*, 2001b; Choi and Fisher, 2003; Hall *et al.*, 2005). In other studies, the economic impacts of climate variability on floods and droughts in developing countries were reported as substantial. For example, the cost to Kenya of the floods associated with the 1997/8 El Niño and the drought associated with the 1998-2000 La Niña, show a cost to the country of 11% and 16% of GDP, respectively (Mogaka *et al.*, 2006). Floods and droughts are estimated to cost Kenya about 2.4% of GDP annually at mid-century, and water resources degradation a further 0.5% (Mogaka *et al.*, 2006). For Ethiopia, economy-wide models incorporating hydrological variability show a drop in projected GDP growth by up to 38% compared to when hydrological variability is not included (World Bank, 2006). However, it is not hydrological variability per se that causes the problem, but rather a lack of the necessary capacity, infrastructure, and institutions to mitigate the impacts (Grey and Sadoff, 2007). Similarly, future flood damages will depend not only on changes in the climate regime, but also on settlement patterns, land use decisions, flood forecasting quality, warning and response systems, and other adaptive measures (Pielke and Downton, 2000; Changnon, 2005; Ward *et al.*, 2008). In many developing countries, water related impacts are *likely* to be more pronounced with climate change (Chapter 3) and associated economic costs can be expected to be more substantial in the future, holding all other factors constant.

The Association of British Insurers (ABI) estimated the financial costs of climate change using insurance catastrophe models in the UK and across Europe. They found that climate change could increase the annual cost of flooding in the UK almost 15-fold by the 2080s under high emission scenarios. If climate change increased European flood losses by a similar magnitude, they estimate that costs could increase by up to $120-150 billion, for the same high emission scenarios (ABI, 2005). (Feyen *et al.*, 2012) project average annual damage in the EU to increase to Euro14-21.5 billion by 2100 depending on the scenario, compared to Euro6.4 billion today. Wobus et al., 2013, estimate an increase in continental US mean annual flood damages of $5 billion and $12 billion in 2050 and 2100, respectively.(Ntelekos *et al.*, 2010) estimate a range of $7-19 billion, depending on the economic growth rate and the emissions scenarios. Dasgupta et al report that by 2050 Bangladesh will face incremental cost to flood protection (against both sea and river floods) of $2.6 billion initial costs and $54 million annual recurring costs. (Ward *et al.*, 2008) found that the average annual costs to adapt to a 1in 50 year river flood to range from $3.5 to $6.0 billion per year for low- to upper-middle-income countries over the period 2010–50 for the A2 scenario.

10.3.2. Municipal and Industrial Water Supply

Beyond flood and other extreme event damages, municipal and industrial water supply economic systems are also impacted through anticipated changes in precipitation patterns and quantities. Economically, these impacts are evaluated as current costs of building in resiliency to the system to adapt to anticipated future changes. For example, the costs of adaptation to maintain supply and quality of water for municipal and industrial uses have been reported for the Assabet River near Boston (Kirshen *et al.*, 2006), Toronto (Dore and Burton, 2001) and Quito (Vergara *et al.*, 2007). Since much of this infrastructure has an economic and engineering life of less than 25 years, building flexibility into these systems is in most cases the best action now. (Nassopoulos *et al.*, 2012) suggest that neglecting to account for future climate change while designing water supply reservoirs can cost 0.2 to 2.8% of the net present

value, based on analysis for Greece. For sub-Saharan Africa, adapting urban water infrastructure (storage facilities, wastewater, and additional supply infrastructure) to a 30% reduction in runoff could be $2-5 billion per year (Muller, 2007). Climate change impacts on the Berg River in South Africa are estimated to account for 15% revenue loss for the water supply provider (Callaway et al 2012). For the OECD, the cost of adaption in the water supply sector is 1-2% of base costs and would save $6-12 billion per year (Hughes *et al.*, 2010). U.S. impacts are estimated to be less than 1% of municipal and industrial welfare (Hurd *et al.*, 2004) (Strzepek et al. 2013). In Colorado, a 30% decrease in annual runoff will result in a 12% treatment cost increase and a 22% rise in residential costs (Towler et al, 2011).

On a global scale, (Ward *et al.*, 2010) estimate the adaptation costs to provide enough raw water to meet future global industrial and municipal water demand, based on country-level demand projections to 2050. Increased demand is assumed to be met through a combination of increased reservoir yield and alternative backstop measures. The global adaptation costs are estimated to be US$12B/yr (on top of US$73B/yr to meet the needs of development), with 83-90% in developing countries; the highest costs are in Sub Saharan Africa, and may be as high has 16% of total global adaptation costs. The global cost estimates of climate-change related adaptation in the water resources sector amount to 0.04–0.06 percent of world GDP. Adding resilient adaptive measures to water infrastructure adds 10-20% to the total costs of developing countries meeting the water related millennium goals which is estimated to be only 0.33 percent of GDP, but may help avoid future economic losses. .

10.3.3. Wastewater and Urban Stormwater

More frequent heavy rainfall events may overload the capacity of sewer systems and water and wastewater treatment plants more often, and increased occurrences of low flows will lead to higher pollutant concentrations. While no studies have been conducted on the potential economic losses associated with these systems, estimates of the annual costs of adaptation have been reported. For example, for urban sewers, average over 17 climate models, is $3.0 billion per year in low- to upper-middle-income nations over the period 2010–50 for the A2 scenario (Hughes *et al.*, 2010). Similarly, the cost of building and maintaining additional storm water storage capacity in Canada necessary to manage a 100-year, 24-hour storm is $0.1-2 billion present value for 2010-2100 with a 3% discount rate (Price et al. 2010). Adaptation costs estimates (for a 10-year, 24-hour storm in 2100) for various locations in the USA are relatively low; e.g., $135 million for Los Angeles, $7 million for Boston and $40 million for Chicago (Neumann et al 2013). Bridges are also vulnerable to flood damage, and (Wright *et al.*, 2012) estimate adaptation costs of $140-250 billion in the USA through the 21st century.

10.3.4. Energy: Hydropower and Cooling Water

Using partial equilibrium river basin models, (Hurd *et al.*, 2004) (Strzepek et al. 2013) estimate USA welfare loses due thermal cooling water changes at $622 million per year up to 2100, a 6.5 % welfare loss in the energy sector. (Van Vliet *et al.*, 2012) find that the southeastern United States, Europe, eastern China, southern Africa and southern Australia could potentially be affected by reduced water available for thermoelectric power and drinking water, inducing changes to dry or hybrid cooling (with concomitant loss in electric output), or plant shut downs, with associated impacts on local and regional economic activity. For hydropower locations, adaption to climate change to maintain output has been reported; in Ethiopia, (Block and Strzepek, 2012) report that capital expenditures through 2050 may either decrease by ~3% under extreme wet scenarios, or increase by up to 4% under a severe dry scenario. In the Zambezi river basin, hydropower falls by 10% by 2030, and by 35% by 2050 under the driest scenario (Strzepek et al 2012). Lower generation is *likely* in the upstream powerstations of the Zambezi basin and increases are *likely* downstream (Fant *et al.*, 2012).

10.3.5. Inland Navigation

See 10.4.4.

10.3.6. Irrigation

Climate change impacts on the economics of irrigation reflect the anticipated change in temperature, precipitation, and agricultural demand and practices. These narrowly focused reports do not address the broader issues of food production (covered in Chapter 7), nor economy wide impacts (Chapter 19). For example, by 2080, the global annual costs of additional irrigation water withdrawals for currently existing irrigated land are estimated at $24-27 billion (Fischer et al 2007). The global cost of improved irrigation efficiency to maintain yields is $1.5-2.0 billion dollar per year in developing countries in 2050 for the A2 scenario. (Nelson *et al.*, 2009) find that adaptation for Ethiopia to maintain agricultural production in Ethiopia would be best achieved by soil water management from increased irrigated and drained areas, improved irrigation efficiency and research related to on-farm practices. Adaptation costs range from $68 million per year for the dry scenario dominated by irrigation, to $71 million per year under the wet scenario dominated by drainage (Strzepek et al. 2010).

10.3.7. Nature Conservation

Climate change is expected to worsen many forms of water pollution, including the load of sediments, nutrients, dissolved organic carbon, pathogens, pesticides, and salt, as well as thermal pollution, increased precipitation intensity, and low flow periods (Kundzewicz *et al.*, 2007). Future water demands for nature conservation will be different than today's (see Chapter 4). There is no published assessment of the economic implications.

10.3.8. Recreation and Tourism

Tourism and recreation use substantial amounts of water but the implications of climate-change-induced changes in tourism and recreation on water demand have yet to be quantified. See Section 10.6.

10.3.9. Water Management and Allocation

Changes in water availability, demand and quality due to climate change would impact water management and allocation decisions. Traditionally, water managers and users have relied on historical experience when planning water supplies and distribution(Adger *et al.*, 2007; UNFCCC, 2007). Water has been allocated based on societies' preferences. Under a changing climate, existing allocations may no longer be appropriate. Arndt et al 2012 examine the economy-wide implications of existing water allocations and alternative development paths and allocation to suggest climate-smart development strategies in Africa. Under stress situations, allocations of water for energy-generation and irrigation may have economy-wide welfare implications. Climate change impacts on undiscounted USA welfare over the 21st century range from plus $3 trillion for wet scenarios to minus $13 trillion under dry scenarios (Strzepek et al. 2013).

10.3.10. Summary

Economic impacts of climate change on water related economic sectors have been dominated by incurred economic losses, including flooding, scarcity and cross sectoral induced impacts. Flooding and drought can have major economic costs, in term of impacts (capital destruction, disruption) whereas estimates of adaptation costs (construction, defensive investment) remain relatively modest. Water scarcity and competition for water, driven by institutional, economic or social factors, may mean that water assumed to be available for a sector is not.

10.4. Transport

The impact of climate change on transport has received qualitative, but limited quantitative, focus in the published literature. The impact depends greatly on the climatic zone the infrastructure is in and how climate change will be manifest. There are three major zones:

Geographic Zone	Vulnerabilities to Changes in Climate
Freezing/Frost Zone	Permafrost, freeze-thaw cycles, precipitation intensity
Temperate Zone	Change in Precipitation intensity, maximum daily precipitation
Tropical Zone	Change in Precipitation intensity, maximum daily precipitation

As detailed below, several studies have actively explored the potential impacts of climate change on the transport sector, focusing on overall impacts such as impacts on transportation safety or disruptions of transportation service. Quantitative, economic analyses of the impact on physical infrastructure include (Larsen *et al.*, 2008; Chinowsky *et al.*, 2010; Hunt and Watkiss, 2010; Chinowsky *et al.*, 2011) and on wider economic implications (Arndt, 2012).

10.4.1. Roads

Studies on the direct effects of climate change on road networks are primarily focused on qualitative predictions and surveys concerning road impacts on road durability (TRB, 2008b; Koetse and Rietveld, 2009) (Eisenack et al 2012 ; Ryley and Chapman 2012) with some studies of the quantitative effects (MacArthur et al 2012; Nemry and Nemirel 2012). Chapter 8 addresses the indirect effects of climate change on roads in the areas of congestion and safety.

Paved road degradation is directly related to weather stressors that can lead to softening of the pavement as temperatures exceed design thresholds (Lavin, 2003) and an increase in the number of freeze-thaw cycles impacts both the base and pavement surface (FHWA, 2006). The melting of permafrost in northern climates as well as increased precipitation and flooding threaten the integrity of road base and sub-bases. Drainage presents a specific problem for urban areas that experience rainfall above their built capacity and will impact design standards and costs for urban transport (CCTF, 2008; Hunt and Watkiss, 2010; Lemmen and Warren, 2010). Increased fire danger from droughts could also pose a threat to roads.

Unpaved roads are vulnerable to a number of climate-based factors especially to increasingly intense precipitation, leading to wash out and disruption of service. In cold climates, temporary winter roads are susceptible to warming and associated lower connectivity of rural areas and reduced economic activity in Northern climates (Mills and Andrey, 2002). Warming could imply that ice roads can no longer be maintained.

10.4.2. Rail

Rail beds are susceptible to increases in precipitation, sea level rise, extreme events and incidence of freeze-thaw cycles (Nemry and Nemirel 2012). In Northern climates, the melting of permafrost (URS, 2010) may lead to ground settlement, undermining stability (Larsen *et al.*, 2008). Increased temperatures pose a threat to rail through thermal expansion. In urban areas, increased temperatures pose a threat to underground transport systems that will see a burden on increased need for cooling systems (Hunt and Watkiss, 2010). For example, £178 million has been allocated to finding a workable solution for increasing the capacity of London's underground cooling system (Arkell and Darch, 2006).

10.4.3. Pipeline

Increases in precipitation and temperature affect pipelines through scouring of base areas and unearthing of buried pipelines, compromised stability of bases built on permafrost, and increases in necessary maintenance (TRB, 2008a;

URS, 2010). Temperature increase can result in thermal expansion of the pipelines, causing cracking at material connection points. There has been no economic assessment of the impacts.

10.4.4. Shipping

Impacts of inland navigation vary widely due to projected rise or fall in water levels. Overall, the effects on inland navigation are projected to be negative, and are region-specific.

Increased frequency of flood periods will stop ship traffic on the Rhine more often. Longer periods of low flow will also increase the average annual number of days during which inland navigation is hampered or stagnates due to limited load carrying capacity of the river. Current projects on channel improvements can only partly alleviate these problems (Middelkoop *et al.*, 2001a). Economic impact could be substantial given the value of navigation on the Rhine (Krekt et al., 2011). See Chapter 23 for more detail.

(Millerd, 2010) analyzes the economic impacts of lower water levels in the Great Lakes, with consequent reductions in vessel cargo capacities and increases in shipping costs. The lower water levels predicted as a result of a doubling of the atmospheric carbon dioxide could increase annual transportation costs by 29%. More moderate climate change could result in a 13 percent increase in annual shipping costs. The impacts vary between commodities and routes.

Warming is *very likely* to lead to increased ice-free navigation and longer shipping season, but *is very likely* also lead to lower water levels from reduced runoff (Lemmen and Warren, 2010). In cold regions, increased days of ice-free navigation and a longer shipping season could positively impact shipping and reduce transportation costs (TRB, 2008b; Koetse and Rietveld, 2009; UNCTAD, 2009; UNECE and UNCTAD, 2010).

Ports will be affected by higher temperatures, sea level rise, increasingly severe storms, and increased precipitation (Becker *et al.*, 2011) (Nursey-Bray and Miller 2012; Nicholls, R. J. et al.,2008). Over $3 trillion in assets in 136 of the world's largest port cities are vulnerable to weather events (Potter *et al.*, 2008; UNCTAD, 2009; UNECE and UNCTAD, 2010).

Increased storminess in certain routes may raise cost of shipping through additional safety measures or longer routes that are less storm prone (UNCTAD, 2009; UNECE and UNCTAD, 2010). Transport costs would increase or new routes sought if storms disrupt supply chains by destroying port infrastructure connecting road or rail (Becker *et al.*, 2011). Increased storminess may also affect passage through lock systems (Potter *et al.*, 2008; UNCTAD, 2009). Increased storminess may increase maintenance costs for ships and ports and result in more frequent weather-related delays.

10.4.5. Air

Hotter air is less dense. In summer months, especially at airports located at high altitudes, this will result in limitations for freight capacity, safety, and weather-related delays, unless runways are lengthened (TRB, 2008a; Pejovic *et al.*, 2009). (Chapman, 2007) suggests that technological innovations will negate the challenges posed by extreme temperatures Increased storminess at airports, particularly those located in coastal regions, may increase the number of weather-related delays and cancellations (Pejovic *et al.*, 2009; Lemmen and Warren, 2010), with associated economic losses.

The impact of climate change on airport pavement is very similar to paved roads (DOT, 2002; Fortier *et al.*,). The effect of temperature on airports thus imposes a risk to the entire facility (Pejovic *et al.*, 2009) and related economic activity.

10.5. Other Primary and Secondary Economic Activities

This section assesses the impact of climate change on primary (agriculture, mining) and secondary economic activities (manufacturing, construction), unless they are discussed elsewhere in the chapter or the report.

10.5.1. Primary Economic Activities

Primary economic activities (e.g. agriculture, forestry, fishing, mining) are particularly sensitive to the consequences of climate change because of their immediate dependence on the natural environment. In some regions, these activities dominate the economy.

10.5.1.1. Crop and Animal Production

Chapter 7 assesses the impact of climate change on agriculture, including the effects on (international) markets for crops.

10.5.1.2. Forestry and Logging

Chapter 4 assesses the biophysical impact of climate change on forestry. Including adaptation in forest management, climate change would accelerate tree growth. This would reduce prices to the benefits of consumers all around the world. Low to mid latitude producers would benefit too as they switch to short-rotation plantations. Mid to high latitude producers would be hurt by lower prices while their productivity increases only modestly (Sohngen and Mendelsohn, 1997; Sohngen and Mendelsohn, 1998; Sohngen *et al.*, 2001); (Perez-Garcia *et al.*, 2002; Lee and Lyon, 2004; *Adaptation of Forests and People to Climate Change -- A Global Assessment Report.*2009). However, increased biomass prices may impact different forest based industries in different ways given their demand for renewable energy from the biomass sources (Moiseyev *et al.*, 2011).

10.5.1.3. Fisheries and Aquaculture

Chapter 4 assesses the impact of climate change on freshwater ecosystems, and Chapter 5, 6 and 30 on marine ecosystems. These assessments include the effects on commercially valuable fish stocks, but exclude the effects on markets. Adaptation and markets would substantially change the effect of climate change on fisheries (Link and Tol, 2009; Yazdi and Fashandi, 2010).

(Allison *et al.*, 2009), using an indicator based approach, analyzed the vulnerability of capture fishery of 132 economies. They find, incongruously, that the sign and size of climate-driven change for particular fish stocks and fisheries are uncertain but are *likely* to lead to either increased economic hardship or missed opportunities for development in countries that depend upon fisheries but lack the capacity to adapt. A major part of the gross turnover of nine key fish and cephalopod species in the Bay of Biscay remains potentially unaffected by climate change (Floc'h *et al.*, 2008). In contrast, Iberian-Atlantic sardine biomass and profitability declines due to climate change (Garza-Gil *et al.*, 2011). The economic impact of climate change on fisheries is dominated by the impact of management regime and market (Eide and Heen, 2002; McGoodwin, 2007; Eide, 2008; McIlgorm, 2010; Merino *et al.*, 2010).

Ocean acidification has a range of impacts on the biological systems (Doney *et al.*, 2009), but the studies on the economic impacts of ocean acidification are rare. (Brander *et al.*, 2012) estimate the economic impacts of ocean acidification on coral reefs under four IPCC marker scenarios using value transfer function approach and find that the annual economic impacts increase rapidly overtime, though it remains a small fraction of total income. Using a partial equilibrium model, (Narita *et al.*, 2012) estimate the economic impact of ocean acidification on shellfish, mollusks. By the turn of this century the cost of could be over $100 billion.

10.5.1.4. Mining and Quarrying

Climate change would affect exploration, extraction, production, and shipping in the mining and quarrying industry (Pearce *et al.*, 2011). An increase in climate-related hazards (such as forest fires, flooding, windstorm) affects the viability of mining operations and potentially increases operating, transportation, and decommissioning costs. Most infrastructure was built based on presumption of a stable climate, and is thus not adapted to climate change (Ford *et al.*, 2010; Ford *et al.*, 2011; Pearce *et al.*, 2011).

10.5.2. Secondary Economic Activities

10.5.2.1. Manufacturing

Climate change would impact manufacturing through three channels. First, climate change affects primary economic activities (see above), and this means that prices and qualities of inputs are different. Second, the production process is affected, or the quality of the product. The impact of climate change on energy demand is well understood (see 10.2). Using a biophysical model of the human body, (Kjellstrom *et al.*, 2009a) project labour productivity to fall, particularly of manual labour in humid climates. (Hübler *et al.*, 2008) uphold the finding with a German case study, and (Hsiang, 2010) corroborate it with a statistical analysis of weather data and labour productivity in the Caribbean for 1970-2006. Some manufacturing activity is location specific, perhaps because it is tied to an input or product market, and will thus have to cope with the current and future climate; other manufacturing has discretion over its location (and hence its climate). Third, climate change affects the demand for products. This is pronounced in manufactures that supply primary sectors (Kingwell and Farré, 2009) and construction material (see below). Unfortunately, there are only a few studies that quantify these effects (see Appendix A).

10.5.2.2. Construction and Housing

Climate and climate change affect construction in three ways. First, weather conditions are one of the key factors in construction delays and thus costs. Climate change would change the length of the building season. Additionally, precipitation affects the cost of construction through temporary flood protection (coffer) structures, slope stabilization management and dewatering of foundations. There are adaptation measures that may reduce some of the costs. (Apipattanavis *et al.*, 2010) show a reduction in the expected value of road construction delays and associated costs. Second, buildings and building materials are designed and selected to withstand a particular range of weather conditions. As climate changes, design standards will change too. Exterior building components including windows, roofing, and siding are all specified according to narrow environmental constraints. Climate change would introduce conditions that are outside the prescribed operating environment for many materials, resulting in increased failures of window seals, increased leaks in roofing materials, and reduced lifespan of timber or glass-based cladding materials. Similarly, the interior building systems that allow for proper airflow in a facility face significant issues with climate change. For example, the increases in temperature and precipitation will lead to increased humidity as well as indoor temperatures. This requires increased airflow in facilities such as hospitals, schools, and office buildings, that is, upgrades to air conditioning and fan units and perhaps further renovations that may be significant in scope and cost. Third, a change in the pattern of natural disasters would imply a change in the demand for rebuilding and repair. Unfortunately, these impacts have yet to be quantified.

10.6. Recreation and Tourism

Recreation and tourism is one of the largest sectors of the world economy. In 2011, it accounted for 9% of global expenditure, and employed 260 million people (WTTC, 2011). Supply of tourism services is the dominant activity in many regional economies.

Recreation and tourism encompass many activities, some of which are more sensitive to weather and climate than others: compare sunbathing to angling, gambling, business seminars, family visits, and pilgrimage. Climate change would affect the place, time and nature of these activities.

There is a large literature on the impact of climate change on tourism (Gössling *et al.*, 2012; Scott *et al.*, 2012a; Pang *et al.*, 2013). Some studies focus on the changes in the behavior of tourists, that is, the demand for recreation and tourism services (see 10.6.1). Other studies look at the implications for tourist operators and destinations, that is, the supply of recreation and tourism services (see 10.6.2). A few studies consider the interactions between changes in supply and demand (see 10.6.3).

10.6.1. Recreation and Tourism Demand

Conventionally, recreation does not involve an overnight stay whereas tourism does. That implies that recreation, unlike tourism, is done close to home (while leisure is done at home). Whereas tourists, to a degree, chose the climate of their holidays, recreationists do not (although climate is a consideration in the choice where to live). Tourists would adapt to climate change by changing the location, timing and activities of their holidays; recreationists would adapt only timing and activities (Smith, 1990).

10.6.1.1. Recreation

There has been no research on systematic differences of recreational behaviour due to differences in climate at large spatial scales. The impact of climate change on recreation is therefore largely unknown. The economic impact is probably limited, as people are more *likely* to change the composition rather than the level of their time and money spent on recreation. For instance, (Shaw and Loomis, 2008) argue that climate change would increase boating, golfing and beach recreation at the expense of skiing.

There are case studies of the impact of climate change on recreation. (Buckley and Foushee, 2012) find that a trend toward earlier visits to US national parks between 1979 and 2008. They argue this is due to climate change, but do not rigorously test this hypothesis nor control for other explanations. (Dempson *et al.*, 2001) note that the salmon fishery in Newfoundland is closed during hot weather and low water levels. (Ahn *et al.*, 2000) study the impact of climate change on recreational trout fishing in the Southern Appalachian Mountains, and (Whitehead *et al.*, 2009) the effect of sea level rise on sea shore fishing in North Carolina, finding a substantial decrease in the recreational value of these activities. (Daugherty *et al.*, 2011) conclude that climate change will make it more difficult to guarantee adequate water levels for boating and angling in artificial reservoirs. (Pouta *et al.*, 2009) project a reduction in cross-country skiing in Finland, particularly among women, the lower classes, and urban dwellers. (Shih *et al.*, 2009) find that weather affects the demand for ski lift trips. One could expect people to adopt other ways of enjoying themselves but such alternatives were excluded from these studies. There are positive effects too. (Richardson and Loomis, 2005) find that climate change would make trips to the Rocky Mountain National Park more enjoyable. (Scott and Jones, 2006; Scott and Jones, 2007) foresee an increase in golf in Canada due to climate change, (Kulshreshtha, 2011) sees positive impacts on Canadian recreation in general, and (Coombes *et al.*, 2009) predict an increase in beach tourism in East Anglia. (Graff Zivin and Neidell, 2010) find that people recreate indoors when the weather is inclement. (Scott *et al.*, 2007) estimate the relationship between visitors to Waterton Lakes National Park and *weather* variables for eight years of monthly observations; and use this to project an increase in visitor numbers due to *climate change*. A survey among current visitors indicates that a deterioration of the quality of nature would reduce visitor numbers.

10.6.1.2. Tourism

Climate (Becken and Hay, 2007; WTO and UNEP, 2008) and weather (Rosselló-Nadal *et al.*, 2010; Álvarez-Díaz and Rosselló-Nadal, 2010; Rossello, 2011; Førland *et al.*, 2012; Day *et al.*, 2013; Falk, 2013) are important factors in tourist destination choice, and the tourist sector is susceptible to extreme weather (Forster *et al.*, 2012; Forster *et*

al., 2012; Hamzah *et al.*, 2012; Tsai *et al.*, 2012). (Eijgelaar *et al.*, 2010), for instance, argues that so-called "last chance tourism" is a strong pull for tourists to visit Antarctica to admire the glaciers while they still can. (Farbotko, 2010; Prideaux and Mcnamara, 2012) use a similar mechanism to explain the rise in popularity of Tuvalu as a destination choice, but (Huebner, 2012) find no impact of future climate change on current travel choices. (Taylor and Ortiz, 2009) show that domestic tourists in the UK often respond to past weather. The hot summer of 2003 had a positive impact on revenues of the tourist sector. (Denstadli *et al.*,) find that tourists in the Arctic do not object to the weather in the Arctic. (Gössling *et al.*, 2006) reaches the same conclusion for tourists on Zanzibar, and (Moreno, 2010) for tourists in the Mediterranean.

(Maddison, 2001) estimates a statistical model of the holiday destinations of British tourists, (Lise and Tol, 2002) for Dutch tourists and (Bigano *et al.*, 2006) for international tourists from 45 countries; these models control for as other variables as possible. Tourists have a clear preference for the climate that is currently found in Southern France, Northern Italy and Northern Spain. People from hot climates care more about the climate in which they spend their holidays than people from cool climates. (Bujosa and Rosselló, 2012) study destination choice within Spain, and find the climate change would induce a northward shift.

However, whereas (Bigano *et al.*, 2006) find regularity in revealed preferences, (Scott *et al.*, 2008b) find pronounced differences in stated preferences between types of people. The impact of climate change on tourism demand may be more complicated than suggest by the econometric analyses reviewed above (Gössling and Hall, 2006).

(Hamilton *et al.*, 2005a; Hamilton *et al.*, 2005b; Bigano *et al.*, 2007) use the above econometric analyses to construct a simulation model of domestic and international tourism. (Hamilton and Tol, 2007) downscale the national results of these studies to the regions of selected countries. The advantage of such a model is that it considers the simultaneous change in the attractiveness of all potential holiday destinations (Dawson and Scott, 2013). The disadvantage is its stylized representation of the effect of climate on destination choice. Two main findings emerge. First, climate change would drive tourists to higher latitudes and altitudes. International tourist arrivals would fall, relative to the scenario without warming, in hotter countries, and rise in colder countries. Tourists from Northwestern Europe, the main origin worldwide of international travelers at present, would be more inclined to spend the holiday in their home country, so that the total number of international tourists falls. Second, the impact of climate change is dominated by the impact of population growth and, particularly, economic growth. In the worst affected countries, climate change slows down, but nowhere reverses, growth in the tourism sector.

10.6.2. Recreation and Tourism Supply

There are a number of biometeorological studies of the impact of climate change on tourism. (Yu *et al.*, 2009a) find that Alaska has become more attractive over the last 50 years, and Florida less attractive to tourists. (Yu *et al.*, 2009b) conclude that the climate for sightseeing has improved in Alaska, while the climate for skiing has deteriorated. (Scott *et al.*, 2004) show that climate change would make Mexico less attractive to tourists, and Canada more attractive. Florida and Arizona would lose market share in US tourism. (Perry, 2006) speculates that the hot summer of 2003 had a negative impact on tourism in the Mediterranean. (Matzarakis *et al.*, 2010) construct a composite index of temperature, humidity, wind speed and cloud cover, and use this to map tourism potential. (Lin and Matzarakis, 2008; Lin and Matzarakis, 2011) apply the index to Taiwan and Eastern China. (Endler and Matzarakis, 2010a; Endler and Matzarakis, 2010b; Endler and Matzarakis, 2011) use an index to study the Black Forest in Germany in detail, highlighting the differences between summer and winter tourism, and between high and low altitudes; the latter aspect is thoroughly investigated by (Endler *et al.*, 2010). (Zaninović and Matzarakis, 2009; Matzarakis and Endler, 2010) use this method to study Freiburg and Hvar. (Matzarakis *et al.*, 2007) project this potential into the future, finding that the Mediterranean will probably become less attractive to tourists. (Amelung and Viner, 2006; Hein *et al.*, 2009; Perch-Nielsen *et al.*, 2009; Giannakopoulos *et al.*, 2011; Amelung and Moreno, 2012; Amengual *et al.*, 2012) reach the same conclusion, but also point out that Mediterranean tourism may shift from summer to the other seasons. (Giannakopoulos *et al.*, 2011) notes that coastal areas in Greece may be affected more than inland areas because, although temperature would be lower, humidity would be higher. (Moreno and Amelung, 2009), on the other hand, conclude that climate change will not have a major impact (before 2050) on

beach tourism in the Mediterranean because sunbathers like it hot (Moreno, 2010; Rutty and Scott, 2010). (Amelung *et al.*, 2007) use a weather index for a global study of the impact of climate change on tourism, finding shifts from equator to pole, summer to spring and autumn, and low to high altitudes. (Perch-Nielsen, 2010) combines a meteorological indicator of exposure with indicators of sensitivity and adaptive capacity. She uses this to rank the vulnerability of beach tourism in 51 countries. India stands out as the most vulnerable, and Cyprus as the least vulnerable.

The main criticism of most biometeorological studies is that the predicted gradients and changes in tourism attractiveness have rarely been tested to observations of tourist behaviour. (De Freitas *et al.*, 2008) validate their proposed meteorological index to survey data. (Moreno *et al.*, 2008) and (Ibarra, 2011) use video of beach occupancy to test meteorological indices for beach tourism. (Gómez-Martín, 2006) tests meteorological indices against visitor numbers and occupancy rates. All four studies find that weather and climate affects tourists, but in a different matter than typically assumed by biometeorologists.

Studies on the supply side often focus on ski tourism. (Abegg and Elsasser, 1996) is one of the earliest papers. Warming of would raise the altitude of snow-reliable resorts, and fewer resorts would be snow-reliable (Hendrikx *et al.*, 2012; Steger *et al.*, 2012). (Elsasser and Bürki, 2002) argue that artificial snow-making cannot fully offset the loss in natural snowfall in the Swiss Alps. (Schmidt *et al.*, 2012) show that snow-making is less successful in lower areas, although that is the current strategy of operators in Austria (Wolfsegger *et al.*, 2008; Morrison and Pickering, 2012). (Hamilton *et al.*, 2007) highlight the importance of "backyard snow" to induce potential skiers to visit ski slopes. (Pickering *et al.*, 2010) find that skiers in Australia prefer natural snow over artificial snow. From a series of interviews, (Hill *et al.*, 2010) find that tourist operators in the Swiss Alps seek to maintain the status quo through adaptation, rather than search for viable alternatives to ski tourism; and argue that better coordination is needed for adaptation to be successful. (Scott and McBoyle, 2007) highlight that there are many options to adapt to a loss of snow for skiing. (Hoffmann *et al.*, 2009) use a survey of ski lift operators in the Swiss Alps. They find that the need for adaptation exceeds the ability to adapt and that adaptation is more prevalent on higher slopes (which are less vulnerable). (Scott *et al.*, 2006) study the impact of climate change on ski areas in eastern North America. Even with snowmaking, climate change could be an existential threat to 3 of the 6 ski areas by 2050; and climate change would lead to a contraction in each area in each scenario. (Dawson *et al.*, 2009) use past analogues to study the impact of future climate change on ski tourism in the Northeastern USA. They find that small and very large resorts will be hit hardest, and low-lying ones. (Scott *et al.*, 2008a) find that snowmobiling would have disappeared from the Northeastern USA by the end of the 21st century. (Mcboyle *et al.*, 2007) find the same for the Canadian lowlands. (Matzarakis *et al.*, 2012)Artificial snowmaking would halt the decline of ski resorts, but water scarcity and the costs of snowmaking would be increasingly large problems. (Scott *et al.*, 2003) reach the same conclusion for southern Ontario, (Scott *et al.*, 2007) for Quebec, (Hendrikx and Hreinsson, 2012) for New Zealand, (Steiger and Mayer, 2008) for Tyrol, and (Pons-Pons *et al.*, 2012) for Andorra. (Bicknell and Mcmanus, 2006) study adaptation for ski resorts in Southeastern Australia. They note that resorts may continue to be economically viable in the absence of snow by focusing on alternative activities. (Pickering and Buckley, 2010) note that artificial snow-making may be infeasible and uneconomic at the scale required to offset the loss of natural snow in Australia, and argue for a reorientation towards summer tourism and residential property development. (Moen and Fredman, 2007) find that alpine ski resorts in Sweden would become economically unviable, and that alternative livelihoods need to be developed. (Tervo, 2008) finds that the shortening of the Finnish ski season would be too limited to affect the economic viability of tourist operators, but (Landauer *et al.*, 2012) find that Finnish ski operators would find it difficult to convince their clients of the need to adapt. (Serquet and Rebetez, 2011) find that the Swiss Alps attract more tourists during hot summers, and argue that climate change would structurally improve the mountains as a summer tourism destination. (Matzarakis *et al.*, 2012) also argue that a proper assessment considers all seasons, using Austria as an example. (Bourdeau, 2009) argue along the same lines for the French Alps, stressing the importance of non-tourism alternatives as a source of economic development. (Steiger, 2010) finds that stakeholders in Tyrol think that gains in summer would not fully offset losses in winter. (Potocka and Zajadacz, 2009) argue that prudent management supplies tourism services suitable for all weather. (Steiger, 2012) finds that, in the first half of this century, demographic trends are more important to skiing in Austria than climate change. (Hopkins *et al.*, 2012) also argue that other factors dominate the impact of climate change.

Other studies consider beach tourism. (Scott *et al.*, 2012b) highlight the vulnerability of coastal tourism facilities to sea level rise. (Hamilton, 2007) finds that tourists are averse to artificial coastlines, so that hard protection measures against sea level rise would reduce the attractiveness of an area. (Raymond and Brown, 2011) survey tourists on the Southern Fleurieu Peninsula. They conclude that tourists who are there for relaxation worry about climate change, particularly sea level rise, while tourists who are there to enjoy nature (inland) do not share that concern. (Becken, 2005) finds that tourist operators have adapted to weather events, and argues that this helps them to adapt to climate change. (Belle and Bramwell, 2005) find that tourist operators on Barbados are averse to public adaptation policies. (Uyarra *et al.*, 2005) find that tourists on Barbados would consider holidaying elsewhere if there is severe beach erosion. (Buzinde *et al.*, 2010a; Buzinde *et al.*, 2010b) find that there is a discrepancy between the marketing of destinations as pristine and the observations of tourists, at least for Mexican beach resorts subject to erosion. They conclude that tourists have a mixed response to environmental change, contrary to the officials' view that tourists respond negatively. (Jopp *et al.*, 2013) find that an increase in tourism in the shoulder season may offset losses in the peak season in Victoria.

Some studies focus on nature tourism. (Wall, 1998) notes the impact of climate change on water-based tourism, on the coast through sea level rise and inland through drought. (Cavan *et al.*, 2006) find that climate change may have a negative effect on the visitor economy of the Scottish uplands as natural beauty deteriorates through increased wild fires. (Saarinen and Tervo, 2006) interviewed nature-based tourism operators in Finland, and found that about half of them do not believe that climate change is real, and that few have considered adaptation options. (Nyaupane and Chhetri, 2009) argue that climate change would increase weather hazards in the Himalayas and that this would endanger tourists. (Uyarra *et al.*, 2005) find that tourists on Bonaire would not return if coral was bleached. (Hall, 2006) finds that small tourist operators in New Zealand do not give high priority to climate change, unless they were personally affected by extreme weather in recent times. The interviewed operators generally think that adaptation is a sufficient response to climate change for the tourism sector. (Klint *et al.*, 2012) find that tourist operators in Vanuatu give low priority to adaptation to climate change and (Jiang *et al.*, 2012) find Fiji poorly prepared. (Saarinen *et al.*, 2012) find that tourist operators in Botswana think that climate change would not affect them. (Wang *et al.*, 2010) note that glacier tourism is particularly vulnerable to climate change, highlighting the Baishiu Glacier in China.

While the case studies reviewed above provide rich detail, it is hard to draw overarching conclusions. A few studies consider all aspects of the impact of climate change for particular countries or regions. (Ren Guoyu, 1996) shows that domestic tourism in China would shift northwards, that sea level rise would damage some tourist facilities, and that the overall impact of climate change on China's tourist sector would be negative. (Harrison *et al.*, 1999) conclude that climate change would make Scotland less attractive to tourists in winter but more attractive in summer. (Ceron and Dubois, 2005) assess the impact of climate change on tourism in France. They argue that the French Riviera may benefit because it is slightly cooler than the competing coastal resorts in Italy and Spain. The Atlantic Coast, although warming, would not become more attractive because of increased rainfall. It is not probable that the increase in summer tourism in the mountains would offset the decrease in winter tourism. (Jones *et al.*, 2006) study the impact of climate change on three festivals in Ottawa. They argue for heat wave preparedness for Canada Day, find that skating on natural ice may become impossible for Winterlude, and fret that the dates of the Tulip Festival may need to be shifted to reflect changing phenology. (Dawson and Scott, 2010) assess the impacts in the Great Lakes regions, finding reduced tourism potential in winter but increased opportunities in summer. (Turton *et al.*, 2010) conclude that tourist operators in Australia find the uncertainty about climate change too large for early investment in adaptation.

10.6.3. Market Impacts

There are only two papers that consider the economic impacts of rather stylized climate-change-induced changes in tourism supply and demand. Both studies use a computable general equilibrium model, assessing the effects on the tourism sector as well as all other markets. (Berrittella *et al.*, 2006a) consider the consumption pattern of tourists and their destination choice. They find that the economic impact is qualitatively the same as the impact on tourist flows (discussed above): Colder countries benefit from an expanded tourism sector, and warmer countries lose. They also find a drop in global welfare, because of the redistribution of tourism supply from warmer (and poorer) to colder

(and richer) countries. (Bigano *et al.*, 2008a) extend the analysis with the implications of sea level rise. The impact on tourism is limited because coastal facilities used by tourists typically are sufficiently valuable to be protected against sea level rise. The study finds that the economic impacts on the tourism sector are reinforced by the economic impacts on the coastal zone; and that the welfare losses due to the impact of climate change on tourism are larger than the welfare losses due to sea level rise.

10.7. Insurance

10.7.1. Main Results of AR4 and SREX

More intense or frequent weather-related disaster would affect property insurance, which is growing with the economy everywhere (WG II, 7.4.2.2.4). Insurability can be preserved through risk-reducing measures. Adaptation to climate change can be incentivized through risk-commensurate insurance premiums. Improved risk management would further financial resilience (WG II, 7.4.2.2.4., 7.6.3). Insurance is linked to disaster risk reduction and climate change adaptation, because it enables recovery, reduces vulnerability and provides knowledge and incentives for reducing risk ((IPCC, 2012)).

10.7.2. Societal Role of Insurance Covering Weather Hazards

Insurance internalizes catastrophe risk costs prior to catastrophic events, reducing the economic impact of weather-related and other disasters to individuals and enterprises, thus stabilizing income and consumption, and decreasing societal vulnerability. Insurance is based on the law of large numbers: the larger the pool of uncorrelated and relatively small risks, the more accurately the average loss per policy can be predicted and charged accordingly, allowing for a lower premium than with a smaller pool. Besides spreading risk over a diversified insured population, insurance spreads risk over time. However, weather-related disasters such as floods simultaneously affect many, and thus violate the principle of uncorrelated risks. Consequently, large losses are much more *likely*, the loss variance is greater, and the tail risk is higher ((Kousky and Cooke, 2012)). If insurance coverage is to be maintained, insurers would need more risk capital to indemnify catastrophic losses and remain financially solvent. This coverage is purchased in the reinsurance and capital markets. The capital costs account for a substantial portion of premiums and the affordability and viability of weather insurance are subjects of ongoing research given future climate change ((Charpentier, 2008); (Maynard and Ranger, 2012); (Clarke and Grenham, 2012)).

Increasing volatility and burden of losses in many regions are expected to fundamentally impact on the industry, leading insurers to adapt their business to the changing risk ((Herweijer *et al.*, 2009); (Phelan *et al.*, 2011); (Mills, 2012); (Paudel, 2012)).

10.7.3. Observed and Projected Insured Losses from Weather Hazards

Direct and insured losses from weather-related disasters have increased substantially in recent decades both globally and regionally ((IPCC, 2012); (Bouwer *et al.*, 2007); (Swiss Re, 2012); (Munich Re., 2012); (Crompton and McAneney, 2008); (Gall *et al.*, 2011); (Smith and Katz, 2013)). Substantially fluctuating global insured weather-related losses in the period 1980-2008 increased by US^{2008}1.4bn per year on average (Barthel and Neumayer, 2012). As a rule, insured loss figures are more accurate than direct economic loss estimates, because insurance procedures and payouts are regulated and monitored. Hence, estimates of direct overall losses are often derived from insurance losses ((Kron *et al.*, 2012); (Smith and Katz, 2013)). Economic growth, including greater concentrations of people and wealth in periled areas and rising insurance penetration, is the most important driver of the increase in losses.

Growth induced changes in past losses are removed by normalizing to current levels of destructible wealth. So far, there is only one study analyzing global normalized weather-related insured losses, but the period (1990-2008) is too short to infer any reliable trend (Barthel and Neumayer, 2012). A few studies focus on specific perils and regions, in

particular Australia, USA and Europe. Trends were detected for the USA and Germany, but not for Australia and Spain (Table 10-4). Trends in normalized insured losses can be influenced not only by changing hazards but also by changing damage sensitivities, adaptive measures, different normalization, and changes in insurance ((Barthel and Neumayer, 2012); (Crompton and McAneney, 2008); (Bouwer, 2011); (IPCC, 2012)). Prevention measures such as flood control structures, or improved building standards over time, would offset an increase in hazard ((Kunreuther *et al.*, 2009)). The 2011 Mississippi flood resulted in US$4.6bn direct losses, but losses exceeding US$200bn were avoided by flood controls, according to the U.S. Army Corps of Engineers ((Kron and Steuer, 2012); DeHaan *et al.*, 2012). Given such confounding factors, it is challenging to estimate to what degree developments in losses convey a climate signal ((Kron, 2012); (IPCC, 2012)). Studies analyzing changes in climate variables and losses in parallel are still rare. The number of days that a regional insurer in southwest Germany sustains hail losses displays an upward trend since 1986, while meteorological severe storm indicators also show upward trends ((Kunz *et al.*, 2009)). Variability and mean level of thunderstorm-related insured losses in the USA in the period 1970-2009 have substantially increased, while meteorological thunderstorm forcing potential has risen in parallel ((Sander *et al.*, 2013)). (Corti *et al.*, 2009) found an increase in modeled and partly observed insured subsidence losses in France over the period 1961-2002, consistent with an increase in dryness in central and southern Europe ((IPCC, 2012)). The observed rise in US normalized insured flood losses (Barthel and Neumayer, 2012) may partly correspond to *likely* increased heavy precipitation events in parts of the USA ((IPCC, 2012) , AR5WG1-2.6.2.1), while the evidence for climate driven changes in river floods is non-compelling ((IPCC, 2012)). The recent upswing in hurricane hazard and losses appears to be connected to multi-decadal climate variability ((Lonfat *et al.*, 2007); AR5WG1-Box14.2; AR5WG1-14.7.3). Loss trends have not been conclusively attributed to anthropogenic climate change, and sientific attribution methods have not been applied.

[INSERT TABLE 10-4 HERE
Table 10-4: Observed normalized insured losses from weather hazards.]

Many (AO)GCM-based projections agree that extreme winter storm wind speeds fall in the Mediterranean and increase in west, central, and northern Europe. Loss ratios, i.e. insured loss divided by insured value, follow the same pattern (e.g., (Schwierz *et al.*, 2010); (Donat *et al.*, 2011); (Pinto *et al.*, 2012); AR5WG1-Box14.3) (Table 10-5). Return periods per loss level are projected to shorten in large parts of Europe, indicating more frequent high losses (e.g., (Pinto *et al.*, 2012)) (Table 10-5). Projected overall losses and fatalities develop accordingly ((IPCC, 2012); (Narita *et al.*, 2010)). Across three modeling approaches calibrated to German insurance data, the 25-year loss is projected to change by –10% to +18% (2011-2040), +5% to +41% (2041-2070), and +45% to +58% (2071-2100) against 1971-2000, keeping exposures and damage sensitivities constant (A1B, (Held *et al.*, planned 2013)).

[INSERT TABLE 10-5 HERE
Table 10-5: Climate change projections of insured losses and/or insurance prices.]

Direct losses and fatalities from flooding will increase with climate change in many locations in the absence of adequate adaptation ((IPCC, 2012); AR5WG1-12.4.5.5; 11.3.2.5.2). Mean annual insured heavy rainfall and flood losses in the UK, the Netherlands, southern Norway and the Canadian province of Ontario were projected to rise with climate change; for Germany an increase of more than 90% in insured river inundation losses in the period 2041-2070 relative to the late 20th century was projected, keeping exposures and sensitivities constant ((Hattermann *et al.*, planned 2013)) (Table 10-5).

Direct losses and fatalities from tropical cyclones will increase with exposure and may increase with the frequency of very intense cyclones in some basins ((IPCC, 2012); AR5WG1-Box14.3; (Peduzzi *et al.*, 2012)). Studies for the North Atlantic project a climate-driven loss increase ((Pielke, 2007); (Emanuel, 2011)). (Ranger and Niehoerster, 2012), (Kunreuther *et al.*, 2012), and (Raible *et al.*, 2012) found insured losses change in opposite directions across a range of dynamical and statistical model projections. Insured typhoon-related property losses in China are projected to increase ((Dailey *et al.*, 2009)). Averaged across four GCMs, (Mendelsohn *et al.*, 2012) project rising climate driven direct losses for the coasts of Central America, the Caribbean, North America, and East Asia. (Narita *et al.*, 2009) report an increase in damages and fatalities in all parts of the world.

Hailstorm insurance losses in the Netherlands ((Botzen *et al.*, 2010b)) and Germany ((Gerstengarbe *et al.*, 2013)) are projected to increase. Paddy rice insurance payouts are projected to decrease ((Iizumi *et al.*, 2008)) (Table 10-5).

Rising insured wealth will increase both losses and premium income, not necessarily altering the ratio of both, indicating impact. Such automatic compensation is not effective for external drivers of loss, such as changing hazard properties. Hence, projection studies using ratios of losses to premiums or sums insured (while assuming constant insured property) can be justified as an approximation of the climate change impact (e.g., (Donat *et al.*, 2011)). Consequently, future economic growth is rarely projected ((Aerts and Botzen, 2011)).

10.7.4. Supply-Side Challenges and Sensitivities

10.7.4.1. High-Income Countries

The provision of weather hazard insurance is contingent on an insurer's ability to find a balance between affordability of the premiums and costs that have to be covered by the revenue. On the cost side, the expected level of losses, expenses for risk assessment, product development, marketing, operating, and claims processing are included. Moreover, the revenue must provide a return on shareholders' equity and allow for the purchase of external capital if large losses are incurred ((Charpentier, 2008); (Kunreuther *et al.*, 2009)).

The balance between affordability and profitability is sensitive to climate change. Increases in large weather-related losses may corrode an insurer's solvency if it fails to reflect the changes in its risk management, or is hampered in doing so by price regulation, as was the case with the upswing in Atlantic hurricane activity in the USA since the mid-1990s ((Grace and Klein, 2009)). Additionally, misguided incentives for development in hazard-prone areas, as with the US National Flood Insurance Program ((Kousky and Kunreuther, 2010); (Michel-Kerjan, 2010); (GAO, 2011)), can aggravate the situation (Table 10-6).

[INSERT TABLE 10-6 HERE
Table 10-6: Supply-side challenges and sensitivities.]

The additional uncertainty induced by climate change translates into a need for more risk capital ((Charpentier, 2008); (Kunreuther *et al.*, 2009); (Grace and Klein, 2009)). This raises insurance premiums and affects the economy (Table 10-6). Health and life insurance are also affected through the health impacts of climate change ((Hecht, 2008); (Leurig, 2011)). Liability insurance, too, may be susceptible to climate change. So far, no damages have been awarded for greenhouse gas emissions as such, but litigation where damages are sought is pending ((Mills, 2009); (Heintz *et al.*, 2009); (Patton, 2011)). A decision by the Supreme Court of Virginia in April 2012 denied defense costs under the specific liability insurance policy of an utility company (Supreme Court of Virginia, U.S.A., 2012)) (Table 10-6).

10.7.4.2. Middle- and Low-Income Countries

Middle- and low-income countries account for a small share of worldwide non-life insurance: 16% of premiums in 2011 ((Swiss Re, 2013b)). In high-income countries some 40% of direct natural disaster losses have been covered by insurance since 1980, about 4% in middle-income countries and less than 1% in low-income countries ((Wirtz *et al.*, planned 2013); (IPCC, 2012)). For instance, only about 1% of direct overall losses in the 2010 floods in Pakistan were insured ((Munich Re., 2011)).

The small share of insurance in risk financing is not deemed economically prudent, because other options, such as external credit or donor assistance, can be unreliable and late. This leaves a financial gap in the months immediately following the event, often exacerbated by overstretched public finances. Pre-disaster financing instruments such as insurance or trigger-based risk-transfer products are a better means of providing prompt liquidity for households, businesses, and governments ((Ghesquiere and Mahul, 2007); (Linnerooth-Bayer *et al.*, 2009); (IPCC, 2012)). These

may become more important if disaster incidence increases with climate change ((IPCC, 2012); (Collier *et al.*, 2009); (Hochrainer *et al.*, 2010)).

It is challenging to upscale catastrophe insurance because of low business volumes, high transaction costs, and high reinsurance premiums following large disasters. Small-scale insurance schemes in middle- and low-income countries may find it difficult to obtain sufficient risk capital ((Cummins and Mahul, 2009); (Mahul and Stutley, 2010)).

Microinsurance schemes, keeping transaction costs at the lowest operable level, mainly provide health and life cover to households and small enterprises in low-income markets. Supply of property insurance suffers from correlated weather risks, although weather-related agricultural damages are covered. Such weather coverage is growing, typically with government and NGO assistance or cross-subsidies from local insurers ((Linnerooth-Bayer and Mechler, 2011); (Qureshi and Reinhard, 2011)). These schemes may be particularly sensitive to a rise in disaster risk due to climate change ((Collier *et al.*, 2009); (Leblois and Quirion, 2011); (Clarke and Grenham, 2012)).

Adverse selection is another challenge: clients do not always disclose their high risk, e.g. a floodplain site, to the insurer so as to benefit from lower rates. Lower-risk participants are charged too high premiums and leave the scheme, thus increasing overall risk. In low-income countries, where data to establish homogenous risk groups are not available, this can cause disaster insurance markets to fail. Moral hazard is another issue, where the insured adopt more risky behavior than anticipated by the insurer, particularly in the absence of proper monitoring (e.g., (Barnett *et al.*, 2008); (Mahul and Stutley, 2010)).

10.7.5. Products and Systems Responding to Changes in Weather Risks

10.7.5.1. High-Income Countries

A rise in weather-related disaster risk may drive the need for more risk-based capital to cover the losses. There are several options that sustain insurability. Reducing vulnerability often makes sense even if expected climate change impacts will not materialize. Theoretically, risk-based premiums incentivize policyholders to reduce their vulnerability ((IPCC, 2012); (Hecht, 2008); (Kunreuther *et al.*, 2009)) (Table 10-7). Premium discounts for loss-prevention can further promote this ((Ward *et al.*, 2008); (Kunreuther *et al.*, 2009)) (Table 10-7). Moral hazard can be reduced by involving the policyholder to some extent in the payment of losses (deductibles, upper limits of insurance coverage: (Botzen and van den Bergh, 2009); (Botzen *et al.*, 2009)). Collaborative efforts of insurers and governments on damage prevention decrease risk ((Ward *et al.*, 2008); (Reinhold *et al.*, 2012)). For example, new building standards in Florida reduced mean damage per house by 42% in the period 1996-2004 relative to pre-1996 ((Kunreuther *et al.*, 2009)). Risk-based premiums are often hampered by price regulation, subsidies, competitive pressures, bundling of perils in one policy, and availability of data ((Maynard and Ranger, 2012)).

[INSERT TABLE 10-7 HERE
Table 10-7: Products and systems responding to changes in weather risks.]

Most commercial risk-assessment models only incipiently factor in changes in weather hazards, mainly to reflect higher hurricane frequencies ((Seo and Mahul, 2009)), assuming unchanging conditions for other weather hazards. Ignoring changing hazard conditions results in biased estimates of expected loss, loss variability and risk capital requirements ((Lonfat *et al.*, 2007); (Charpentier, 2008); (Watson and Johnson, 2008); (Herweijer *et al.*, 2009); 10.7.3). Other confounding factors, e.g. systemic economic impact, in recent large losses have been addressed (e.g., (Muir-Wood and Grossi, 2008)) (Table 10-7). Geospatial risk-assessment tools, e.g. flood-recurrence zoning with premium differentiation, counteract adverse selection ((Kunreuther *et al.*, 2009); (Mahul and Stutley, 2010)). Some insurers have offered weather alert systems and seasonal agricultural planning systems to clients (e.g., (Niesing, 2004); (*AgroClima. Informática Avanzada SA de CV.*2013)). Credit rating agencies and Solvency II insurance regulation in Europe contribute to enhanced disaster resilience ((Michel-Kerjan and Morlaye, 2008); (Kunreuther *et al.*, 2009); (Grace and Klein, 2009)). Insurers and researchers have projected climate change driven losses to allow

for adaptation of the industry (e.g., (Held *et al.*, planned 2013); (Kunreuther *et al.*, 2012); 10.7.3). Due to its short-term contracts the insurance sector is better adaptable than others ((Botzen *et al.*, 2010a)).

Reinsurers are key to the supply of disaster risk capital. They operate globally to diversify the regional risks of hurricanes and other disasters. Access to reinsurance enhances risk diversification of insurers. Periodic shortages in reinsurance capacity following major disasters have moderated over the last two decades because of easier new capital inflow ((Cummins and Mahul, 2009); (IPCC, 2012)).

Global diversification potential of large losses has fallen over recent decades because of increasing dependence between major insurance markets. For instance, the Thailand floods of 2011 disrupt industrial hubs and global supply chains ((Courbage *et al.*, 2012)).This process may continue with climate change ((Sherement and Lucas, 2009); (Kousky and Cooke, 2012)). However, global diversification potential can be increased by developing insurance markets in middle- and low income countries ((Cummins and Mahul, 2009)).

Very large loss events, say in excess of US$ 100bn, may make additional capacity desirable. These disasters can be diversified in the financial securitization market ((IPCC, 2012)). Natural catastrophe risks are not correlated with capital market risks and hence are attractive to institutional investors. For instance, a catastrophe bond assures the investor above-market returns as long as a parametric index (e.g., wind-based) does not exceed a threshold, but pays the insurer's loss otherwise. The catastrophe bond market reached critical mass after the hurricanes of 2004 and 2005, with some US$ 11bn of risk capital in effect by June 2011 ((Cummins, 2012); (Cummins and Weiss, 2009); (Michel-Kerjan and Morlaye, 2008); (Kunreuther and Michel-Kerjan, 2009)) (Table 10-7).

10.7.5.2. Middle- and Low-Income Countries

Index-based weather insurance is considered well-suited to the agricultural sector in developing countries (e.g., (Collier *et al.*, 2009); (IPCC, 2012)). Payouts depend on a physical trigger, e.g. cumulative rainfall at a nearby weather station, thus avoiding costly loss assessments. Moral hazard and adverse selection are removed ((Barnett *et al.*, 2008)). Risk-based premiums encourage adaptive responses ((Mahul and Stutley, 2010)) (Table 10-7). Basis risk, where losses occur but no payout is triggered, provokes distrust. Misunderstandings and scaling up of pilots pose further difficulties ((Patt *et al.*, 2010); (Leblois and Quirion, 2011); (Clarke and Grenham, 2012)). Suggested improvements include area-yield indices and coverage at aggregate level to reduce basis risk, and a cooperative architecture ((Clarke and Grenham, 2012); (Biener and Eling, 2012)) (Table 10-7). For both indemnity-based and index-based trigger concepts application prospects are identified, depending on the insured's characteristics and the market setting (Herbold, 2013; Swiss Re, 2013b).

Sovereign insurance is deemed appropriate in developing countries suffering from post-disaster financing gaps (see 10.7.4). Current schemes include government disaster reserve funds (FONDEN, Mexico) and pools of small states' sovereign risks (CCRIF, Caribbean) ((IPCC, 2012)). In both cases, peak risk is transferred to reinsurance and catastrophe bonds (Table 10-7).

10.7.6. Governance, Public-Private Partnerships, and Insurance Market Regulation

10.7.6.1. High-Income Countries

Theory favors an arrangement where individual risk is insured, but the non-diversifiable component of risk (that may rise with climate change) is public ((Borch, 1962); (Kunreuther *et al.*, 2009)). Accordingly, many high-income states have public-private arrangements involving government intervention on peak risk ((Aakre *et al.*, 2010); (Bruggeman *et al.*, 2010); (Schwarze *et al.*, 2011); (Paudel, 2012)) (Table 10-8). The pro-adaptive, risk-reducing features of insurance are more effective if the price reflects the risk and the pool of insured is larger, e.g. through bundled perils ((Bruggeman *et al.*, 2010); (Paudel, 2012)). People who cannot afford premiums can be covered by vouchers, leaving the price signal undistorted, or by subsidies ((Kunreuther *et al.*, 2009); (Aakre *et al.*, 2010)) (Table 10-8). Insurance regulation ensures availability, affordability, and solvency, but often adopts only short- to medium-

term views. Because of climate change, regulators have a new role in risk-adequate pricing, risk education, and risk-reduction in the long term ((Hecht, 2008); (Grace and Klein, 2009); (Mills, 2009); (Leurig, 2011)).

[INSERT TABLE 10-8 HERE
Table 10-8: Governance, public-private partnerships, and insurance market regulation.]

10.7.6.2. Middle- and Low-Income Countries

A key element of risk financing is the transfer of private risks to the insurance market. This reduces the governments' burden and uncertainty due to weather disasters ((Ghesquiere and Mahul, 2007)). Interest in public-private partnerships may evolve, e.g. between government, farmers, rural banks and insurers, in order to expedite agricultural development and resilience, e.g. by means of subsidies for start-up costs and the uppermost risk portion ((Collier *et al.*, 2009); (Mahul and Stutley, 2010)) (Table 10-8). As such systems have suffered from adverse selection and moral hazard ((Coble *et al.*, 1997); (Makki and Somwaru, 2001); (Glauber, 2004)), an improved design is needed. For instance, group policies foster mutual monitoring. Well-designed laws and regulations can encourage purchase of insurance. Insurance pools diversify weather risks across larger regions, reduce premiums and improve access to external risk capital ((Mendoza, 2009); (Hochrainer and Mechler, 2011); (Biener and Eling, 2012); (IPCC, 2012)).

In least developed countries, even incipient domestic insurance markets hardly exist. Climate change-related disaster risk management was proposed for inclusion in the adaptation regime of the UNFCCC. Insurance is a central element in these proposals, financed from an UNFCCC adaptation fund according to the principles of "common but differentiated responsibilities and respective capabilities" (UNFCCC Art.3.1) and "polluter pays" ((AOSIS, 2008); (Swiss Confederation, 2008); (MCII, 2008); (Warner and Spiegel, 2009); (Linnerooth-Bayer *et al.*, 2009); (MCII, 2012); (IPCC, 2012)) (Table 10-8).

Innovative insurance concepts, facilitating greater disaster risk capital, are available in middle- and low-income countries, at least at pilot stage. These can advance adaptation to climate change impacts. Everywhere, risk-based premiums foster risk awareness and risk reduction. Challenges include improved risk assessment, with sufficient detail and appropriate dynamics, and scaling-up of successful pilot schemes. Regulatory requirements for risk capital, and access to reinsurance and securitization market further contribute to a resilient insurance system. These are the provisions of sound risk management, even in the absence of climate change.

10.8. Services Other than Tourism and Insurance

Other service sectors of the economy include waste management, wholesale and retail trade, engineering, government, education, defense and health. Contributions to the economy vary substantially by country; however, overall worldwide economic activity related to government accounts for approximately 30% of global expenditures.

10.8.1 Sectors Other than Health

The literature on the impact of climate change on other sectors of the economy is sparse (see Appendix A). Few studies have evaluated the possible impacts of climate change, and particularly the economic impacts, on these sectors. (Tamiotti *et al.*,2009) conducted a qualitative assessment of climate and trade. (Travers and Payne, 1998) and (Subak *et al.*, 2000) find that weather significantly affects retail. (Sabbioni *et al.*, 2009) note that climate change may require a greater effort to protect cultural heritage. Chapter 12 discusses the impact of climate change on violent conflict, which has implications for military expenditures.

10.8.2. Health

Climate change-related alterations in weather patterns, particularly extreme weather and climate events, could affect the health sector through impacts on infrastructure and the delivery of health care services from changing demand. Health care facilities are priority infrastructure that can be damaged by storm surges, floods, wildfires, and other weather and climate events, compromising critical resources required for patient treatment; and physical damage and destruction of equipment and buildings (Carthey et al. 2009). Floods and wildfires can require evacuation of critical care patients, with attendant risks for the patients. Adverse impacts on transportation (such as flooded roads) can exacerbate the situation.

Increased demands for services put additional burdens on public health and health care personnel and supplies, with potential economic consequences. For example, more than 600,000 people required immediate assistance in hydrological events in 2002 through 2010 (EM-DAT 2011). Although the proportion seeking medical treatment are typically a small subset, the additional burden on health care facilities can be significant (Hess et al. 2009). Heatwaves and other extreme events can increase hospitalizations (Chapter 11) with attendant increased costs. Individuals looking for an air-conditioned location during high ambient temperatures also can increase hospital visits (Carthey et al. 2009). One trauma center in the U.S. found a 5.25% increase in hourly admissions for each approximately 5°C increase in temperature; and a 60-78% increase in admission for each 2.5 cm increase in precipitation in the previous three hours (Rising et al. 2006). Very large events that affect multiple health care facilities challenge the ability to properly care for the affected and those with ongoing health issues requiring medication or treatment. Areas projected to experience increases in the frequency and intensity of extreme events could consider additional “surge capacity” to increase the ability of health care facilities to manage such events without interruption of service (Banks et al. 2007; Hess et al. 2009).

Climate change is projected to increase the burden of major worldwide causes of childhood mortality: malnutrition, diarrheal diseases, and malaria (Chapter 11). Any increase in health burdens or risks would increase the demands for public health services (e.g. surveillance and control programs) and the demands for health care and relevant supplies (e.g. oral rehydration). Studies estimating the costs of additional cases of climate-sensitive health outcomes focus on the costs of treatment, not the costs of providing additional health services. Other omitted considerations include the costs of all the health risks of climate change, the costs of implementing new policies, and the costs of hedging health impacts under different scenarios (Hutton, 2011).

Health accounts for approximately 10% of global GDP by expenditure. Estimates of the costs of treating additional cases of climate sensitive health outcomes are in the range of billions of US$ annually (Ebi 2008; Pandey 2010). An estimate of the worldwide costs in 2030 of additional cases of malnutrition, diarrheal disease, and malaria due to climate change, assuming no population or economic growth, emissions reductions resulting in stabilization at 750 ppm CO2 equivalent in 2210, and current costs of treatment in developing countries, estimated treatment costs without adaptation could be $4-12 billion worldwide, depending on assumptions of the sensitivity of these health outcomes to climate change (Ebi 2008). The costs for additional infrastructure and health care workers were not estimated, nor were the costs of additional public health services, such as surveillance and monitoring. The costs were estimated to be unevenly distributed, with most of the costs borne by developing countries, particularly in South East Asia and Africa, to address the projected additional cases of diarrheal disease and malaria (Markandya and Chiabai 2009). The projected additional cases due to climate change were (in millions) 132 for diarrheal diseases; 4.7 for malnutrition; and 22 for malaria. This was against (in millions) 4,514 cases of diarrheal disease, 46 cases of stunting and wasting, and 408 cases of malaria in 2004 (WHO 2004). Development assistance for the health sector in the year 2002 from bilateral and multilateral agencies and foundations was US$ 9.3 billion (Hecht and Shah 2003).

A second global estimate assumed UN population projections, strong economic growth, updated projections of the current health burden of diarrheal diseases and malaria, two climate scenarios, and updated estimates of the costs of malaria treatment (Pandey 2010). In 2010, the average annual adaptation costs for treating diarrheal disease and malaria were estimated to be $3-5 billion, with the costs expected to decline over time with improvement in basic health services. Over the period 2010-2050, the average annual costs were estimated to be around $2 billion, with most of the costs related to treating diarrheal disease; the largest burden is expected to be in Sub-Saharan Africa.

The differences in costs from Ebi (2008) are primarily due to a reduction in the baseline burden of disease and lower costs for malaria treatment.

The malaria estimates from the global estimates of the costs of adaptation are comparable with estimates of the additional health care costs in 2025 in Southern Africa due to a climate change-related increase in the incidence of malaria (Van Rensburg and Blignaut 2002). Assuming low (high) cost scenarios, additional costs for the prevention and treatment of malaria in South Africa were estimated to be approximately $280 (3,764) million, or 0.23% of GDP, in 2025. Estimates for Botswana and Namibia are $ 9 (124) million and $ 13 (177) million, respectively. The high cost scenario for Namibia is about 4.6% of GDP.

(Bosello *et al.*, 2006) used a computable general equilibrium model to study the economic impacts of climate-change-induced changes in the mortality and morbidity due to cardiovascular and respiratory diseases, malaria, diarrhea, schistosomiasis, and dengue fever. They considered the effects on labor productivity and demand for health care, and found that health and welfare impacts have the same sign. The economy-wide health impacts were greater than simple aggregation of the costs of the individual health outcomes. Increased health problems were associated with an expansion of the public sector at the expense of the private sector.

Because any additional climate change-related cases are projected to occur primarily in low-income countries, where no or limited health care is provided by the government, the treatment costs will primarily be borne by families (WHO 2004). Time off from work to care for sick children would affect productivity.

The costs of cases of cholera in Tanzania due to climate change in 2030 were estimated to be in the range of 0.32 – 1.4 % of GDP (Trærup *et al.*, 2011), and the costs of treating additional cases of diarrhea and malaria in 2030 ranged from Rs. 3648–7787 lakhs, depending on the emission scenario (Ramakrishnan, 2011).

10.9. Impacts on Markets and Development

Prior sections of this chapter present the direct impacts of climate change on the economy sector by sector. There are, however, also indirect impacts. The effects that impacts in one sector may have on the rest of the economy are initially presented, followed by the impacts on economic growth and development.

10.9.1. General Equilibrium Effects

General equilibrium analysis describes how climate change impacts in one sector propagate to the rest of the economy, how impacts in one country influence other countries, and how macroeconomic conditions affect each impact (Ginsburgh and Keyzer, 1997). There are three channels through which impact diffuse. First, outputs of one sector are used as inputs to other sectors. For example, a change in crop yields would affect the food-processing industry. Second, products compete for the consumers' finite budget. If, for example, food becomes more expensive, less money would be spent on other goods and services. Third, sectors compete for the primary factors of production (labor, capital, land, water). If more labor is needed in agriculture to offset a drop in crop yields, less labor is available to produce other goods and services. Firms and households react to changes in relative prices, domestically and internationally. Ignoring these effects would lead to biased estimates of the impacts of climate change.

General equilibrium models can provide a comprehensive and internally consistent analysis of the medium-term impact of climate change on economic activity and welfare. However, these models necessarily make a number of simplifying assumptions, particularly with regard to the rationality of consumers and producers and the absence of market imperfections. Partial equilibrium models can be more detailed and more realistic.

Computable general equilibrium models have long been used to study the wider economic implications of changes in crop yields (Kane *et al.*, 1992). (Yates and Strzepek, 1998) show for instance that the impact of a reduced flow of the Nile on the economy of Egypt is much more severe without international trade than with, because trade would allow Egypt to focus on water-extensive production for export and import its food.

Older studies focused on the impact of climate change on patterns of specialization and trade, food prices, food security and welfare (Kane *et al.*, 1992; Reilly *et al.*, 1994; Winters *et al.*, 1998; Yates and Strzepek, 1998; Darwin and Kennedy, 2000; Darwin, 2004). This has been extended to land use (Lee, 2009; Ronneberger *et al.*, 2009), water use (Kane *et al.*, 1992; Calzadilla *et al.*, 2011), and multiple stresses (Reilly *et al.*, 2007). General equilibrium models have also been used to estimate the value of improved weather forecasts (Arndt and Bacou, 2000), a form of adaptation to climate change. Computable general equilibrium analysis has also been used to study selected impacts other than agriculture, notably sea level rise (Darwin and Tol, 2001; Bosello *et al.*, 2007), tourism (Berrittella *et al.*, 2006b; Bigano *et al.*, 2008b), human health (Bosello *et al.*, 2006) and energy (see 10.2).

(Bigano *et al.*, 2008b) study the joint impacts on tourism and coasts, finding that tourism dominates the welfare impacts. (Kemfert, 2002) and (Eboli *et al.*, 2010a) estimate the joint effect on the world economy of a range of climate change impacts, but conflate general equilibrium and growth effects. (Aaheim *et al.*, 2010) analyze the economic effects of impacts of climate change on agriculture, forestry, fishery, energy demand, hydropower production, and tourism on the Iberian peninsula. They find positive impacts on output in some sectors (agriculture, electricity) negative impacts in other sectors (forestry, transport) and negligible ones in others (manufacturing, services). (Ciscar *et al.*, 2011) study the combined impact on agriculture, coasts, river floods and tourism in the current European economy. They find an average welfare loss of 0.2-1.0% of welfare but there are large regional differences with losses in Southern Europe and gains in Northern Europe.

The following initial conclusions emerge. First, markets matter. Impacts are transmitted across locations—with local, regional and global impacts-- and across multiple sectors of the economy. For instance, landlocked countries are affected by sea level rise because their agricultural land increases in value as other countries face erosion and floods. Second, consumers and producers are often affected differently. The price increases induced by a reduction in production may leave producers better off while hurting consumers. Third, the distribution of the direct impacts can be very different than the distribution of the indirect effects. For instance, a loss of production may be advantageous to an individual company or country if the competition loses more. Fourth, a loss of productivity or productive assets in one sector leads to further losses in the rest of the economy. Fifth, markets offer options for adaptation, particularly possibilities for substitution. This changes the size, and sometimes the sign of the impact estimate.

10.9.2. Growth Effects

10.9.2.1. The Rate of Economic Growth

Climate change would also affect economic growth and development, but our understanding is limited. (Fankhauser and Tol, 2005) investigate four standard models of economic growth and three transmission mechanisms: economic production, capital depreciation, and the labor force. They find that, in three models, the fall in economic output is slightly larger than the direct impact on markets while the 4th model (which emphasizes human capital accumulation) points to indirect impacts that are 1.5 times as large as the direct impacts. The difference can be understood as follows. In the three models, the impacts of climate change crowd out consumption and investment in physical capital, while in the fourth model investment in human capital too is crowded out; lower investment implies slower growth. (Hallegatte, 2005) reaches a similar conclusion. (Hallegatte and Thery, 2007; Hallegatte and Ghil, 2008; Hallegatte and Dumas, 2009) highlight that the impact of climate change through natural hazards on economic growth can be amplified by market imperfections and the business cycle. (Eboli *et al.*, 2010a) use a multi-sector, multi-region growth model. The impact of climate change would lead to a 0.3% reduction of GDP in 2050. Regional impacts are more pronounced, ranging from -1.0% in developing countries to +0.4% in Australia and Canada. Sectoral results are varied too, with output changes ranging from output of +0.5% for power generation (to meet increased demand to air conditioning) to -0.7% for natural gas (as demand for space heating falls) and rice.

Using a biophysical model of the human body's ability to do work, (Kjellstrom *et al.*, 2009b) find that by the end of the century climate change may reduce labor productivity by 11-27% in the humid (sub)tropics. Assuming a output elasticity of labor of 0.8, this would reduce economic output in the affected sectors (involving heavy manual labor

without air conditioning) by 8-22%. Although structural change in the economy may well reduce the dependence on manual labor and air conditioning would be an effective adaptation, even the ameliorated impact would have a substantial, but as yet unquantified, impact on economic growth.

There are also statistical analyses of the relationship between climate and economic growth. (Barrios *et al.*, 2010) find that the decline in rainfall in the 20th century partly explains the economies of Sub-Saharan Africa have grown more slowly than those of other developing regions. (Brown *et al.*, 2011) corroborate this. (Dell *et al.*, 2012) find that, in the second half of the 20th century, anomalously hot weather slowed down economic growth in poor countries, in both the agricultural and the industrial sectors. (Dell *et al.*, 2009) find that one degree of warming would reduce income by 1.2% in the short run, and by 0.5% in the long run. The difference is due to adaptation. (Horowitz, 2009) finds a much larger effect: a 3.8% drop in income in the long run for one degree of warming.

10.9.2.2. Poverty Traps

Poverty is concentrated in the tropics and subtropics. This has led some analysts to the conclusion that a tropical climate is one of the causes of poverty. (Gallup *et al.*, 1999) emphasize the link between climate, disease, and poverty while (Masters and McMillan, 2001) focus on climate, agricultural pests, and poverty. Other studies (Acemoglu *et al.*, 2001; Acemoglu *et al.*, 2002; Easterly and Levine, 2003) argue that climatic influence on development disappears if differences in human institutions (the rule of law, education, etc) are accounted for. However, (Van der Vliert, 2008) demonstrates that climate affects human culture and thus institutions, but this has yet to be explored in the economic growth literature. (Brown *et al.*, 2011) find that weather affects economic growth in Sub-Saharan Africa – particularly, drought decelerates growth. (Jones and Olken, 2010) find that exports from poor countries fall during hot years. (Bloom *et al.*, 2003) find limited support for an impact of climate (rather than weather) on past growth in a single-equilibrium model, but strong support in a multiple-equilibrium model: Hot and wet conditions and large variability in rainfall reduce long-term growth in poor countries (but not in hot ones) and increase the probability of being poor.

(Galor and Weil, 1996) speculate about the existence of a climate-health-poverty trap. (Strulik, 2008; Bonds *et al.*, 2010; Bretschger and Valente, 2011; Ikefuji and Horii, 2012) posit theoretical models and offer limited empirical support, while (Tang *et al.*, 2009) offers more rigorous empirical evidence. This is further supported by yet-to-be-published analyses (Gollin and Zimmermann, 2008; Bretscher and Valente, 2010; Gollin and Zimmermann, 2010; Ikefuji *et al.*, 2010). Climate-related diseases such as malaria and diarrhea impair children's cognitive and physical development. This leads to poverty in their later life so that there are limited means to protect their own children against these diseases. Furthermore, high infant mortality may induce parents to have many children so that the investment in education is spread thin. An increase in infant and child mortality and morbidity due to climate change would thus trap more people in poverty.

(Zimmerman and Carter, 2003; Ikefuji and Horii, 2012) build a model in which the risk of natural disasters causes a poverty trap: At higher risk levels, households prefer assets with a safe but low return. (Carter *et al.*, 2007) find empirical support for this model at the household level, but (van den Berg, 2010) concludes the natural disaster itself has no discernible impact on investment choices. At the macro-economic level, natural disasters disproportionally affect the growth rate of poor countries (Noy, 2009).

(Devitt and Tol, 2012) construct a model with conflict-poverty trap, and show that climate change may exacerbate this. (Bougheas *et al.*, 1999; Bougheas *et al.*, 2000) show that more expensive infrastructure, for example because of frequent repairs after natural disasters, slows down economic growth and that there is a threshold infrastructure cost above which trade and specialization do not occur, suggesting another mechanism through which climate could cause a poverty trap. The implications of climate change have yet to be assessed.

10.9.2.3. Conclusion

In sum, the literature on the impact of climate and climate change on economic growth and development has yet to reach firm conclusions. There is agreement that climate change would slow economic growth, by a little according to some studies and by a lot according to other studies. There is disagreement whether climate change would affect the nature of economic development, with some studies suggesting that more people may be trapped in poverty and fewer people enjoying exponential growth.

10.10. Research Needs and Priorities

Evaluating the economic aspects of the impacts has emerged as an active research area. Initial work has developed in a few key economic sectors and through economy wide economic assessments. Data, tools and methods continue to evolve to address additional sectors and more complex interactions among the sectors in the economic systems and a changing climate.

Based on a comprehensive assessment across economic sectors, few key sectors have been subject to detailed research. Multiple aspects of energy impacts have been assessed, but others remain to be evaluated, particularly economic impact assessments of adaptation both on existing and future infrastructure, but also the costs and benefits for future systems under differing climatic conditions. Studies focused on the impacts of climate change on the energy sector indicate both potential benefits and detrimental impacts across developed and developing countries. In energy supply, the deployment of extraction, transport and processing infrastructure, power plants and other installations are expected to proceed rapidly in developing countries in the coming decades to satisfy fast growing demand for energy. Designing newly deployed facilities with a view to projected changes in climate attributes and extreme weather patterns would require targeted inquiries into the impacts of climate change on the energy related resource base, conversion and transport technologies.

The economics of climate change impacts on transportation systems and their role in overall economic activity have yet to be well understood. For water related sectors, improved estimation of flood damages to economic sectors, research on economic impacts of ecosystems, rivers, lakes and wetlands, ecosystems service, and tourism and recreation are needed. Economic assessments of adaptation strategies such as water savings technologies, particularly for semi-arid and arid developing countries, are also needed. Further, detailed studies are needed of the integrated impact of climate change on all water-dependent economic sectors, as existing studies do not examine competitiveness between water uses among sectors and economic productivity.

Although both tourism and recreation are sensitive to climate change, the literature on tourism is far more extensive. Current studies either have a rudimentary representation of the effect of weather and climate but a detailed representation of substitution between holiday destination and activities, or a detailed representation of the immediate impact of climate change but a rudimentary representation of alternatives to the affected destinations or activities.

Considerable research has been developed related to climate change and associated weather risk to insurance; however, limited research has been published on observed trends in normalized insured climate-related losses as compared to trends in direct economic climate-related losses, including insured property and agriculture losses as compared to direct economic losses. Additionally, no quantitative study could be found for projected impacts on health and life insurance, and only few on regional markets including scenarios on hazard, exposure, vulnerability and adaption status, regulation, risk capital availability. Furthermore, little is known regarding the temporal changes of vulnerability for insured risk such as how susceptibilities of structures to damage changed in the past and can be projected to change in the future.

Little literature exists on potential climate impacts on other economic sectors, such as mining, manufacturing, and services (apart from health, insurance and tourism); in particular assessments of whether these sectors are indeed sensitive to climate and climate change.

The spillover effects of the impacts of climate change in one sector on other markets are understood in principle, but the number of quantitative studies is too few to place much confidence in the numerical results. Similarly, the impact of climate and climate change on economic growth and development is not well understood, with some studies pointing to a small or negligible effect and other studies arguing for a large or dominant effect.

Frequently Asked Questions

FAQ 10.1: Why are key economic sectors vulnerable to climate change?

Many key economic sectors are impacted by changing climate conditions, related long term changes in temperature, precipitation, sea level rise, and extreme events. For example, in addition to many other purposes, energy is used to keep buildings warm in winter and cool in summer. A change in temperature would thus affect energy demand. Climate change affects energy supply, among others, through the cooling of thermal plant, though wind, solar and water resources, and through transport and transmission infrastructure. Water demand increases with temperature but falls with rising carbon dioxide concentrations. Water supply depends on precipitation patterns and temperature, and water infrastructure is vulnerable to extreme weather, while transport infrastructure is designed to withstand a particular range of weather conditions and climate change would expose this infrastructure to weather outside historical design criteria. Tourism is also affected by climate change, as most people prefer to spend part of their free time outdoors, be it hiking, skiing, or lazing on a beach in the sun. Climate change would lead people to enjoy themselves differently, at different times, and in different places. Health care systems are also impacted, as climate change affects a number of diseases and thus the demand for and supply of health care.

FAQ 10.2: How does climate change impact the financial services industry?

Insurance buys financial security against, among other perils, weather hazards. Climate change impacts, including increased weather variability, are anticipated to increase losses and loss variability in various regions through more frequent and/or intensive weather disasters. This will challenge insurance systems to offer coverage for premiums that are still affordable, while at the same time require more risk-based capital. Adequate insurance coverage will be challenging in low- and middle-income countries.

FAQ 10.3: Are other economic sectors vulnerable to climate change too?

Economic activities such as agriculture, forestry, fisheries and mining are exposed to the weather and thus vulnerable to climate change. Other economic activities, such as manufacturing and services, largely take place in controlled environments and are not really exposed to climate change. However, markets connect sectors so that the impacts of climate change spillover from one activity to all others. The impact of climate change on economic development and growth also affects all sectors.

Cross-Chapter Box

Box CC-WE. The Water-Energy-Food Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Ken Strzepek (UNU/USA), FerencToth (IAEA/Hungary), Blanca Elena Jimenez Cisneros (Mexico), Taikan Oki (Japan)]

Water, energy, and food are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure CC-WE-1. The depth and intensity of those linkages vary enormously between regions and production systems. Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Chapter 3.7.2, 7.3.2, 10.2,10.3.4, McMahon and Price, 2011, Macknick et al, 2012a, Cary and Weber 2008). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Kahn and Hajra 2009, Gertenet al. 2011). While food production and transport require large amounts of energy (Pelletier et al 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (7.3.2, Diffenbaugh et al 2012, Skaggs et al, 2012).

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change.]

Most energy production methods require significant amounts of water, either directly (e.g. crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Chapter 10.2.2 and 10.3.4, and Davies et al 2013, van Vliet et al 2012). Water is also required for mining, processing, and residue disposal of fossil fuels. Water for biofuels, for example, has been reported by Gerbens-Leenes et al. 2012 who computed a scenario of water use for biofuels for transport in 2030 based on the Alternative Policy Scenario of the IEA. Under this scenario, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water for energy currently ranges from a few percent to more than 50% of freshwater withdrawals, depending on the region and future water requirements will depend on electric demand growth, the portfolio of generation technologies and water management options employed (WEC 2010, Sattler et al., 2012). Future water availability for energy production will change due to climate change (Chapter 3.5.2.2).

Water may require significant amounts of energy for lifting, transport and distribution, treatment or desalination. Non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced or reclaimed wastewater vs. desalinated seawater (Plappally and Lienhard 2012, Macknick et al, 2012b). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user, Döll et al. 2012) is generally more energy intensive than surface water – in some countries, 40% of total energy use is for pumping groundwater. Pumping from greater depth (following falling groundwater tables) increases energy demand significantly– electricity use ($kWhr/m^3$) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard 2012). A lack of water security can lead to increasing energy demand and vice versa, e.g. over-irrigation in response to electricity or water supply gaps.

Other linkages through land use and management, e.g. afforestation, can affect water as well as other ecosystem services, climate and water cycles (4.4.4, Box 25-10). Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security (3.7.2, 4.4.4). Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water (McCornick *et al.*, 2008, Bazilian *et al.*, 2011, Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy demand, bioproductivity and other factors (see Figure WE-1 and Wise et al, 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this Assessment Report.

Appendix 10.A1. Industrial Classification and Chapter Outline

International Standard Industrial Classification (ISIC) of All Economic Activities, Rev.4, the outline of Chapter 10, and nil returns in a literature search on Scopus.

- A - Agriculture, forestry and fishing (10.5)
  - 01 - Crop and animal production, hunting and related service activities
  - 02 - Forestry and logging
  - 03 - Fishing and aquaculture
- B - Mining and quarrying (10.5)
  - 05 - Mining of coal and lignite
  - 06 - Extraction of crude petroleum and natural gas
  - 07 - Mining of metal ores
  - 08 - Other mining and quarrying
    - Climate change impact & quarrying: No results*
  - 09 - Mining support service activities
- C – Manufacturing (10.5, except C19)
  - 10 - Manufacture of food products
    - Climate change impact & food products: No results*
    - Climate change impact & food processing: No results*
  - 11 - Manufacture of beverages
    - Climate change impact & beverages: No results*
  - 12 - Manufacture of tobacco products
    - Climate change impact & tobacco: No results*
  - 13 - Manufacture of textiles
    - Climate change impact & textiles: No results*
  - 14 - Manufacture of wearing apparel
    - Climate change impact & apparel: No results*
  - 15 - Manufacture of leather and related products

        - Climate change impact & leather: No results*
    - 16 - Manufacture of wood and of products of wood and cork, except furniture; manufacture of articles of straw and plaiting materials
        - Climate change impact & wood: No results*
    - 17 - Manufacture of paper and paper products
        - Climate change impact & pulp paper: No results*
    - 18 - Printing and reproduction of recorded media
        - Climate change impact & printing: No results*
        - Climate change impact & recorded media: No results*
    - 19 - Manufacture of coke and refined petroleum products (10.2)
    - 20 - Manufacture of chemicals and chemical products
        - Climate change impact & chemical production: No results*
    - 21 - Manufacture of basic pharmaceutical products and pharmaceutical preparations
        - Climate change impact & pharmaceutical: No results*
    - 22 - Manufacture of rubber and plastics products
        - Climate change impact & rubber: No results*
        - Climate change impact & plastic: No results*
    - 23 - Manufacture of other non-metallic mineral products
        - Climate change impact & cement: No results*
        - Climate change impact & glass: No results*
    - 24 - Manufacture of basic metals
        - Climate change impact & steel: No results*
        - Climate change impact & iron: No results*
        - Climate change impact & alumina: No results*
        - Climate change impact & aluminum: No results*
    - 25 - Manufacture of fabricated metal products, except machinery and equipment
        - Climate change impact & metal: No results*
    - 26 - Manufacture of computer, electronic and optical products
        - Climate change impact & equipment: No results*
    - 27 - Manufacture of electrical equipment
        - Climate change impact & equipment: No results*
    - 28 - Manufacture of machinery and equipment n.e.c.
        - Climate change impact & equipment: No results*
        - Climate change impact & machinery: No results*
    - 29 - Manufacture of motor vehicles, trailers and semi-trailers
        - Climate change impact & vehicle: No results*
    - 30 - Manufacture of other transport equipment
        - Climate change impact & equipment: No results*
    - 31 - Manufacture of furniture
        - Climate change impact & furniture: No results*
    - 32 - Other manufacturing
    - 33 - Repair and installation of machinery and equipment
        - Climate change impact & equipment: No results*
        - Climate change impact & machinery: No results*
- D - Electricity, gas, steam and air conditioning supply (10.2)
    - 35 - Electricity, gas, steam and air conditioning supply
- E - Water supply; sewerage, waste management and remediation activities
    - 36 - Water collection, treatment and supply (10.3)
    - 37 – Sewerage (10.3)
    - 38 - Waste collection, treatment and disposal activities; materials recovery (10.8)
    - 39 - Remediation activities and other waste management services (10.8)
- F – Construction (10.5)
    - 41 - Construction of buildings
    - 42 - Civil engineering

- 43 - Specialized construction activities
- G - Wholesale and retail trade; repair of motor vehicles and motorcycles (10.8)
  - 45 - Wholesale and retail trade and repair of motor vehicles and motorcycles
  - 46 - Wholesale trade, except of motor vehicles and motorcycles
  - 47 - Retail trade, except of motor vehicles and motorcycles
- H - Transportation and storage (10.4)
  - 49 - Land transport and transport via pipelines
  - 50 - Water transport
  - 51 - Air transport
  - 52 - Warehousing and support activities for transportation
  - 53 - Postal and courier activities
- I - Accommodation and food service activities (10.6)
  - 55 - Accommodation
  - 56 - Food and beverage service activities
- J - Information and communication (10.8)
  - 58 - Publishing activities
  - 59 - Motion picture, video and television programme production, sound recording and music publishing activities
  - 60 - Programming and broadcasting activities
  - 61 - Telecommunications
  - 62 - Computer programming, consultancy and related activities
  - 63 - Information service activities
- K - Financial and insurance activities (10.7)
  - 64 - Financial service activities, except insurance and pension funding
  - 65 - Insurance, reinsurance and pension funding, except compulsory social security
  - 66 - Activities auxiliary to financial service and insurance activities
- L - Real estate activities (10.8)
  - 68 - Real estate activities
- M - Professional, scientific and technical activities (10.8)
  - 69 - Legal and accounting activities
  - 70 - Activities of head offices; management consultancy activities
  - 71 - Architectural and engineering activities; technical testing and analysis
  - 72 - Scientific research and development
  - 73 - Advertising and market research
  - 74 - Other professional, scientific and technical activities
  - 75 - Veterinary activities
- N - Administrative and support service activities (10.8 except N79)
  - 77 - Rental and leasing activities
  - 78 - Employment activities
  - 79 - Travel agency, tour operator, reservation service and related activities (10.6)
  - 80 - Security and investigation activities
  - 81 - Services to buildings and landscape activities
  - 82 - Office administrative, office support and other business support activities
- O - Public administration and defence; compulsory social security (10.8)
  - 84 - Public administration and defence; compulsory social security
- P – Education (10.8)
  - 85 - Education
- Q - Human health and social work activities (10.8)
  - 86 - Human health activities
  - 87 - Residential care activities
  - 88 - Social work activities without accommodation
- R - Arts, entertainment and recreation (10.6)
  - 90 - Creative, arts and entertainment activities
  - 91 - Libraries, archives, museums and other cultural activities

- 92 - Gambling and betting activities
- 93 - Sports activities and amusement and recreation activities

- S - Other service activities (10.8)
  - 94 - Activities of membership organizations
  - 95 - Repair of computers and personal and household goods
  - 96 - Other personal service activities
- T - Activities of households as employers; undifferentiated goods- and services-producing activities of households for own use (10.8)
  - 97 - Activities of households as employers of domestic personnel
  - 98 - Undifferentiated goods- and services-producing activities of private households for own use
- U - Activities of extraterritorial organizations and bodies (10.8)
  - 99 - Activities of extraterritorial organizations and bodies

*No results = no results for the impact of climate change on this particular economic activity. There may be results for the impact of climate change on a related activity, or for the impact of the activity on climate change.

Table 10-1: Main projected impacts of CC and EWEs on energy supply.

Tech	Changes in climatic or related attributes	Possible impacts	Adaptation options
Thermal and nuclear power plants	Increasing air temperature	Reduces efficiency of thermal conversion by 0.1-0.2% in the USA; by 0.1-0.5% in Europe where the capacity loss is estimated in the range of 1-2%/1°C temperature increase, accounting for decreasing cooling efficiency and reduced operation level/shutdown	Siting at locations with cooler local climates where possible
	Changing (lower) precipitation and increasing air temperature increases temperature and reduces the availability of water for cooling	Less power generation; annual average load reduction by 0.1-5.6% depending on scenario	Use of non-traditional water sources (e.g., water from oil and gas fields, coal mines and treatment, treated sewage); Re-use of process water from flue gases (can cover 25-37% of the power plants cooling needs), coal drying, condensers (dryer coal has higher heating value, cooler water enters cooling tower),, flue-gas desulphurization; Using ice to cool air before entering the gas turbine increases efficiency and output, melted ice used in cooling tower; Condenser mounted at the outlet of cooling tower to reduce evaporation losses (by up to 20%). Alternative cooling technologies: dry cooling towers, regenerative cooling, heat pipe exchangers; Costs of retrofitting cooling options depend on depend on features of existing systems, distance to water, required additional equipment, estimated at US$250,000-500,000/MW
	Increasing frequency of extreme hot temperatures	Exacerbating impacts of warmer conditions: reduced thermal and cooling efficiency; limited cooling water discharge; overheating buildings; self-ignition of coal stockpiles	Cooling of buildings (air conditioning) and of coal stockpiles (water spraying)
	Drought: reduced water availability	Exacerbating impacts of warmer conditions, reduced operation and output, shutdown	Same as reduced water availability under gradual CC
Hydropower	Increase/decrease in average water availability	Increased/reduced power output	Schedule release to optimize income
	Changes in seasonal and inter-annual variation in inflows (water availability)	Shifts in seasonal and annual power output; floods and lost output in the case of higher peak flows	Soft: adjust water management Hard: build additional storage capacity, improve turbine runner capacity
	Extreme precipitation causing floods	Direct and indirect (by debris carried from flooded areas) damage to dams and turbines, lost output due to releasing water through by-pass channels	Soft: adjust water management Debris removal Hard: increase storage capacity
Solar energy	Increasing mean temperature	Improving performance of TH (especially in colder regions), reducing efficiency of PV and CSP with water cooling; PV efficiency drops by ~0.5%/1°C temperature increase for crystalline Si and thin-film modules as well, but performance varies across types of modules, with thin film modules performing better; Long-term exposure to heat causes faster aging	

	Changing cloudiness	Increasing unfavourable (reduced output), decreasing beneficial (increased output) for all types, but evacuated tube collectors for TH can use diffuse insolation. CSP more vulnerable (cannot use diffuse light)	Apply rougher surface for PV panels that use diffuse light better; optimize fixed mounting angle for using diffuse light, apply tracking system to adjust angle for diffuse light conditions; Install/increase storage capacity
	Hot spells	Material damage for PV, reduced output for PV and CSP; CSP efficiency decreases by 3-9% as ambient temperature increases from 30 to 50°C and drops by 6% (tower) to 18% (trough) during the hottest 1% of time	Cooling PV panels passively by natural ail flows or actively by forced air or liquid coolants
	Hail	Material damage to TH: evacuated tube collectors are more vulnerable than flat plate collectors; Fracturing as glass plate cover, damage to photoactive material	Flat plate collectors: using reinforced glass to withstand hailstones of 35mm (all of 15 tested) or even 45 mm (10 of 15 tested); only 1 in 26 evacuated tube collectors withstood 45mm hailstones Increase protection to current standards or beyond them
Wind power	Windiness: total wind resource (multi-year annual mean wind power densities); *likely* to remain within ±50% of current values in Europe and North America; within ±25% of 1979-2000 historical values in contiguous USA	Change in wind power potential	Site selection
	Wind speed extremes: gust, direction change, shear	Structural integrity from high structural loads; fatigue, damage to turbine components; reduced output	Turbine design, lidar-based protection

Notes: TH: thermal heating; PV: photovoltaic; CSP: concentrating solar power.

Table 10-2: Main impacts of CC and EWEs on pipelines and the electricity grid.

Tech	Changes in climatic or related attribute	Impacts	Adaptation options
Pipelines	Melting permafrost	Destabilizing pillars, obstructing access for maintenance and repair	Adjust design code and planning criteria, install disaster mitigation plans
	Increasing high wind, storms, hurricanes	Damage to offshore and onshore pipelines and related equipment, spills; lift and blow heavy objects against pipelines, damage equipment	Enhance design criteria, update disaster preparedness
	Flooding caused by heavy rain, storm surge or sea-level rise	Damage to pipelines, spills	Siting (exclude flood plains), water proofing
Electricity grid	Increasing average temperature	Increased transmission line losses	Include increasing temperature in the design calculation for maximum temperature/rating
	Increasing high wind, storms, hurricanes	Direct mechanical damage to overhead lines, towers, poles, substations, flashover caused by live cables galloping and thus touching or getting too close to each other; indirect mechanical damage and short circuit by trees blown over or debris blown against overhead lines	Adjust wind loading standards, reroute lines alongside roads or across open fields, vegetation management, improved storm and hurricane forecasting
	Extreme high temperatures	Lines and transformers may overheat and trip off; flashover to trees underneath expanding cable	Increase system capacity, increase tension in the line to reduce sag, add external coolers to transformers
	Combination of low temperature, wind and rain, ice storm	Physical damage (including collapse) of overhead lines and towers caused by ice build-up on them	Enhance design standard to withstand larger ice and wind loading, reroute lines alongside roads or across open fields, improve forecasting of ice storms impacts on overhead lines and on transmission circuits

Table 10-6: Supply-side challenges and sensitivities.

Challenges that increase in the climate change context	Example / Explanation
Failure to reflect temporal changes in hazard condition in risk management	After the devastating 2004 and 2005 hurricane seasons, the losses of Florida's homeowners' insurance accumulated since 1985 exceeded the cumulative direct premiums earned by 31%. Consequence of the upswing and peak in hurricane activity: One insurer liquidated, two seized by regulation due to insolvency; reduced coverage availability in high-risk areas [9].
Misguided incentives additionally increasing risk	US National Flood Insurance Program (NFIP) allows for a vicious circle of built-up areas already existing within flood plains pressing authorities to construct or improve protecting levees which in turn lead to even more development attracted by NFIP premium discounts, although exposed to extreme flooding events [11;20] [(IPCC, 2012)]. Additionally, older properties situated within flood plains and accounting for 16% of losses in the period 1978-2008 pay premiums substantially below the risk-adequate level [1;6;7;11;13;14]. These features represent incentives to not reduce individual flood risk adequately. Policy holders residing in flood plains where flood cover was made precondition for mortgage drop the cover after only two to four years, accounting for missing insurance penetration and insufficient built-up of NFIP risk capital [11;13;14]. All these features, together with some others, account for the fact that NFIP has continuously been running a cumulative operating deficit, reaching more than US$ 20bn after the big hurricanes of 2006 [6;7;13;14].
Non-quantifiable uncertainties increasing risk	There is ambiguity as to what degree climate change may modify regional weather hazards – model projections are not unequivocal [2;3], and there is uncertainty about prospects of post-disaster regulatory/jurisdictional pressures, e.g. to extend claims payments beyond the original coverage [9]. Such uncertainties materialize in risk-based capital loadings [12].
Liability insurance impacted by new climate risk	Chances for success of litigation in the USA where damages from greenhouse gas emissions are sought seem small, due to legal obstacles [4;5;8;17], although fractional emissions allocation schemes and theories of continuous damage triggering are being discussed [16;19]. But defense costs can be high and may be covered by liability insurance [19]. As CO_2 emissions were declared pollution (US Supreme Court/EPA), regulation on limits for CO_2 emissions is ongoing and non-compliance could impose liability for CO_2 emissions in the near future, which will be covered by liability insurance. This pending risk has not yet been adequately taken into account, as was the case with escalating environmental liability claims in the late twentieth century [10;15]. The Supreme Court of Virginia ruled on 20 April 2012 that the intentional emissions of greenhouse gases by a specific energy company according to the plaintiffs contributed to global warming and damages such as that suffered by the Inupiat village of Kivalina. Hence, this damage could not be viewed as accident and would therefore not be covered by liability insurance [18].

Table 10-7: Products and systems responding to changes in weather risks.

Response option	Example/Explanation
Risk-adjusted premiums convey the risk to the insureds, encouraging them to adaptive measures	Insurance flood hazard zoning systems, e.g. HORA (Austria), SIGRA (Italy), and ZÜRS (Germany), hamper development in high-risk zones that lead to higher premiums [23]. Prior to Germany's disastrous River Elbe flood in 2002, 48.5% of insured households had obtained information on flood mitigation or were involved in emergency networks and 28.5% implemented one of several mitigation measures compared with 33.9% and 20.5%, respectively, of uninsured households [37].
Conditions of insurance policies incentivizing vulnerability reduction	Premium discounts for compliance with local building codes or other prevention options [24;39]; share of the insured in claims payment by deductibles or upper coverage limits, and exclusion of systematically affected property [1;6;7;8;9;12;18;37]; long-term natural-hazard insurance tied to the property and linked to mortgages and loans granted for prevention measures [24;25;33]. The latter is contested by modelled high risk capital requirements and ambiguity loadings, rendering multiyear policies relatively expensive and less flexible for the insurance market [31].
Amplifying factors in large disaster losses included in risk models	Evacuation and systemic economic catastrophe impacts, adversely affecting regional workforce and repair capacity, or knock-on catastrophes following initial catastrophes, e.g. long-term flooding following hurricane landfall [35].
Diversifying large disaster risk across securitization markets	Following the hurricane disasters of 2004 and 2005, securitisation instruments, e.g. catastrophe bonds, industry loss warranties and sidecars, acquired greater prominence, and have been recovering again from the market break in 2008 [13;15;17]. Investors in insurance linked securities are attracted by the lack of correlation to typical financial market risks (e.g., currency risks), and the well defined loss-per-index structure. The higher transparency relative to other asset-backed securities, such as mortgage-backed securities, contributed to the better performance of catastrophe bonds following the financial crisis of 2007/2008 [13;15]. As bonds typically cover large losses, the basis risk, i.e. suffering damage without parametric triggering, is not substantial [38]; further reduction may be feasible by optimizing index measurements [13]. Weather derivatives are further instruments used to transfer risks to the capital markets [14;27;34]. Also multiple-trigger "hybrid" products are available, combining a parametric trigger-based catastrophe bond with a trigger-based protection against a simultaneous drop in stock market prices, thereby hedging against a double hit from direct disaster loss and losses incurred by the asset management side [4;15;28].
Index-based weather crop insurance products	Agricultural insurances predominantly cover crop, but also livestock, forestry, aquaculture, and greenhouses. Main products are indemnity-based crop insurance (covers for single perils and multiple peril events), and index-based crop insurance [36]. The latter is available in 40% of middle-income countries, with enlarged systems beyond pilot implementation in India and Mexico [20;30]. Risk-based price signals may better foster adaptation if schemes are coupled with access to advanced technology, e.g. drought-resistant seed [3;12;20;30]. Various index definitions (cumulative rainfall, area-yield, etc.) and applications exist or have been proposed [3;26;27;29]. Adjusting to uncertain regional changes in temporal hazard condition is a basic challenge with climate change [11;21;26].
Improvements in index-based weather insurance	Basis risk can be reduced if the index scheme is applied to an area-yield trigger in a region with homogeneous production potential (e.g., based on a sample) and/or to the uppermost disaster risk layer only [11;12;19]. It can be better absorbed if index insurance works at aggregate level, e.g. to cover crop-credit portfolios or cooperatives, and if satellite-based remote-sensing technology can once be used to establish plot identification, yield estimation and loss assessment [19]. Pooling local schemes across climate regions under one cooperative parent organization, thus realizing central management, economics of scale and risk diversification, can reduce capital requirements and advance performance [5;10;32]. The disaster risk layer and high start-up costs (weather-data collection, risk modelling, education) necessitate subsidies from the state or donors [12;30].
Sovereign insurance schemes	Economic theory about the public sector's risk neutrality argues (i) that risks borne publicly render the social cost of risk-bearing insignificant and (ii) that disaster loss is seen small in comparison with a government's portfolio of diversified assets [2]. This theory proved inadequate if applied to relatively vulnerable small-sized middle to low-income countries [16], thereby rehabilitating sovereign insurance. For the Caribbean scheme CCRIF, that pools states, the reduction in premium cost per country is expected to be 45–50% [29]. Pooling natural catastrophe risks across an array of megacities has also been proposed, but not yet implemented [22].

Table 10-8: Governance, public-private partnerships, and insurance market regulation.

Structural element	Example/Explanation
Public-private arrangements involving government intervention on the non-diversifiable disaster risk portion	Systems with government intervention range from ex ante risk financing design, such as public monopoly natural hazard insurance (e.g. Switzerland, with inter-cantonal pool) or compulsory forms of coverage to maximize the pool of insureds (e.g. Spain, France, with unlimited state guarantee on top), to ex post financing design, such as taxation-based governmental relief funds (e.g. Austria, Netherlands). In between these boundaries rank predominantly private insurance markets, in several countries combined with governmental post-disaster ad hoc relief (e.g. Germany, Italy, UK, Poland, USA) [16]; see also [1;4;5;13;14;15;18].
Care for people who cannot afford insurance (any more)	Either by funds outside the insurance system, e.g. insurance vouchers [8], or by premium subsidies (particularly for the catastrophic risk portion) [1;8;18;20].
Public-private partnership to expedite agricultural development	Insurance improve the farmers' creditworthiness that in turn strengthens their adaptive capacity. For instance, by means of loans farmers can step from low-yield to higher-yield cropping systems [3;9;10].
Proposals for adaptation-oriented climate change risk management frameworks to UNFCCC	Risk prevention and risk reduction is the starting point (AOSIS, Switzerland and MCII) that can absorb many of the smaller weather risks, and various forms of insurance are meant to cover all of the remaining risks [2;9;11;12;17;19]. The global framework, where the wealthy agree to pool risks with the most vulnerable, equals social insurance that is different from a risk-based share in insurance funds [6].

Executive Summary

The health of human populations is sensitive to shifts in weather patterns and other aspects of climate change (*very high confidence*). These effects occur directly, due to changing incidence in temperature and humidity extremes and occurrence of floods, storms, droughts, and fires. Indirectly, health may be damaged by ecological disruptions brought on by climate change (crop failures, shifting patterns of disease vectors), or social responses to climate change (such as displacement of populations following prolonged drought). Variability is a risk factor in its own right – it is more difficult to protect human health in a highly variable climate than one that is more stable. There is emerging evidence of non-linearities in response (such as greater-than-expected mortality due to heat waves) as climates become more extreme. [11.3, 11.5]

The most important effect of climate change is that it will exacerbate current risks to health. *[very high confidence]* Although new infections and other conditions may emerge under climate change *[low confidence],* the largest risks by far will apply in populations already most affected by climate-related diseases. Thus, for example, the risks of under-nutrition from climate change will fall mainly on populations already experiencing under-nutrition. [11.3]

The most effective adaptation measures for health in the immediate term, therefore, are programs that extend basic public health measures and essential health services, increase capacity for disaster preparedness and response, and alleviate poverty. [11.6] *[very high confidence*]

In recent decades, climate change has contributed to levels of ill-health (*likely*) though the present world-wide burden of ill-health from climate change is relatively small compared with other stressors on health and is not well quantified. Changes in temperature, rainfall and sea-level have altered distribution of some disease vectors, increased heat wave casualties, and reduced food production for vulnerable populations. *[moderate confidence]* [11.4]

If climate change continues as projected in scenarios in the next few decades, the major increases of ill-health compared to no climate change will occur through:

- Greater incidence of injury, disease, and death due to more intense heat waves, storms, floods, and fires. [11.4] *[very high confidence]*
- Increased risk of under-nutrition resulting from diminished food production in poor regions. [11.6] *[high confidence]*
- Loss of work capacity and reduced labor productivity in vulnerable populations [11.6] *[high confidence]*
- Increased risks of food- and water-borne diseases and vector-borne infections. [11.5] *[high confidence]*
- Modest improvements in some areas due to lower impacts of cold, shifts in food production, and reduction of disease-carrying vectors. These positive effects will be out-weighed, world-wide, by the magnitude and severity of the negative effects of climate change. [11.5] *[high confidence]*
- Impacts on health will be reduced, but not eliminated, in populations that benefit from rapid social and economic development *[high confidence],* particularly among the poorest and least healthy groups *[very high confidence]* [11.7]

In addition to their implications for climate change, essentially all the important Climate Altering Pollutants (CAPs) other than CO_2 have near-term health implications *[very high confidence*]. In 2010, more than 7% of the global burden of disease was due to inhalation of these air pollutants [*high confidence*], accounting potentially for an economic impact of 1-2 trillion USD , depending on the economic valuation method used *[low confidence*]. [Box 11-4]

In the highest IPCC Representative Concentration Pathway, RCP8.5, by 2100 most of the world land area will be experiencing 4-7 degree higher temperatures than the recent past due to anthropogenic climate change. This means that important tipping points for health impacts may have been exceeded in many areas of the world during this century. These include sea level rise, storms, loss of agricultural productivity, and daily temperature/humidity conditions that exceed coping mechanisms, making potentially large areas seasonally uninhabitable for normal human activities, including growing food or working outdoors. [11.8] *[high confidence]*

There are opportunities to both reduce emissions of CAPs and at the same time improve local health in the communities that take action – in addition to the health protection for populations worldwide from climate change abatement. Among others, mitigation-related actions that will return health co-benefits as well include:

- Reducing local emissions of health-damaging and climate-altering air pollutants from energy production and use in households and communities, through better combustion, energy efficiency, and a shift to cleaner renewable energy sources. [11.9] *[very high confidence]*
- Providing access to reproductive health services and thus improving child and maternal health through increased birth spacing, while reducing population growth and consequent CAP emissions over time. [11.9] *[high confidence]*

11.1. Introduction

This chapter examines what is known about the effects of climate change on human health and, briefly, the more direct impacts of Climate-Altering Pollutants (CAPs) on health. We review diseases and other aspects of poor health that are sensitive to weather and climate. We examine the factors that cause populations and individuals to be particularly susceptible to ill-health due to variations in weather and climate, and describe steps that may be taken to reduce the impacts of climate change on human health. The chapter also includes a section on health "co-benefits." Co-benefits are positive effects on human health that arise from interventions to reduce emissions of CAPs.

Per IPCC guidelines, this is not a comprehensive, systematic review, but a scientific assessment based on the judgment of the authors. Literature was identified using a published protocol (Hosking and Campbell-Lendrum, 2012) and other approaches, including extensive consultation with technical experts in the field, through the multi-stage review process**.**

We begin with an outline of measures of human health, the major driving forces that act on health world-wide, recent trends in health status, and health projections for the remainder of this century.

11.1.1. Present State of Global Health

The Fourth Assessment Report pointed to dramatic improvement in life expectancy in most parts of the world in the 20th century, and this trend has continued through the first decade of the 21st century (Wang, 2012). Rapid progress in a few countries (especially China) has dominated global averages, but most countries have benefited from substantial reductions in mortality. There remain sizable and avoidable inequalities in life expectancy within- and between-nations according to education, income and ethnicity (Beaglehole and Bonita, 2008) and in some countries, official statistics are so patchy in quality and coverage that it is difficult to draw firm conclusions about health trends (Byass, 2010). At a regional level, inequalities in mortality have diminished, and convergence has been particularly marked amongst adults (Clark, 2011). Amongst children, mortality rates continue to fall, twice as quickly in the first decade of this century as in the 1990s (World Health Organization, 2011). The greatest decreases have occurred in urban areas and in wealthy parts of the world, and progress is uneven: more than 20 countries, mostly in sub-Saharan Africa, showed no reduction in child mortality between 1990 and 2006 (United Nations, 2010) (see Box 11-1).

_____ START BOX 11-1 HERE _____

Box 11-1. Climate Change and the Millennium Development Goals

The Millennium Development Goals (MDGs) were established in 2000, as a way of focusing attention on some of the most pressing international development goals. Progress toward many of the goals, which are to be accomplished by 2015--and any subsequent related development efforts--will be affected by climate change. For example, Goal 4 states that the world community should "reduce by two thirds, between 1990 and 2015, the under-five mortality rate."[1] Figure 11-1 shows the current trends in reduction in child mortality worldwide by cause and indicates how far they are expected to fall above the MDG reduction goal by 2015. Each color represents a different child-mortality "disease wedge" with different risk factors and interventions. It also indicates overall how much faster they together must decline if the MDG is even to be reached ten years late, i.e., by 2025. According to the scenarios reported by WG1, the greatest impacts of climate change will occur after this date (ie mid-century). There are three ways climate change interacts with these wedges:

1) Two of the major causes of child mortality, diarrhoeal diseases and malaria, are directly influenced by the changes in temperature and rainfall to be expected with climate change (11.5.2; 11.5.1), probably making their reduction more difficult as climate change proceeds.
2) Malnutrition/under-nutrition is a major contributor to all the child-mortality wedges represented here, and will be more difficult to control as climate change proceeds (11.6.1)
3) On a more positive note, improving combustion of solid-fuel in poor households will both help reduce one of the major wedges, acute respiratory illnesses, and mitigate climate change through reduction in CAPs, a co-benefit (11.9.1).

[INSERT FIGURE 11-1 HERE
Figure 11-1: Climate change acts against human development: to reach the Millennium Development Goal for child mortality, the reduction in climate-sensitive causes of death at an early age must accelerate. Projected child mortality, 2008-2030, including climate-sensitive causes. Sources: Mortality projections by cause from WHO. Population projections from UN DESA. Child mortality rates from IGME. (World Health Organization, 2008a; Interagency Group for Child Mortality Estimation, 2011; United Nations, Department of Economic and Social Affairs, Population Division, 2011).]

_____ END BOX 11-1 HERE _____

Health Adjusted Life Expectancy (HALE), a measure that incorporates premature mortality and years of healthy life lost due to disease and injury, has also improved substantially, world-wide, but with big differences between countries. For instance, in 2010 male HALE was 27.9 years in Haiti and 68.8 years in Japan (Salomon *et al.*, 2012). (World Health Organization, 2009a; World Health Organization, 2010; World Health Organization, 2011a)Not all indicators are positive. For instance, child under-nutrition, implicated in about a third of all deaths under 5 years, increased in some countries between 2005 and 2008, and about 180 million children world-wide are stunted (short for their age) as a consequence (World Health Organization, 2010).

For specific causes of death, the patterns differ widely by region. The dramatic decline in cardiovascular disease in high-income countries is not seen in parts of the world that are developing rapidly, such as India and China. In those countries, the numbers of deaths from heart disease and stroke are increasing for two reasons; ageing populations and prevalent risk factors such as high blood pressure and cigarette smoking (Samb *et al.*, 2010). Cancer, diabetes, overweight, obesity, and mental disorders such as depression are also reported more commonly than previously in many low and middle income countries (Finucane *et al.*, 2011).

Most researchers anticipate mortality rates will continue to fall world-wide, and WHO estimates the total burden of disease (measured in DisabilityAdjusted Life Years per capita) will be cut by as much as 30% in 2030, compared with 2004 (World Health Organization, 2008b; World Health Organization, 2008c). These projections assume that economic and social development continue without interruption, particularly among poor populations, and as

already noted, the global figures are dominated by trends in a few large countries (China and India in particular) (Mathers and Loncar, 2006). The underlying causes of poor health are expected to change substantially, with much greater prominence of chronic diseases and injury, largely due to changes in population structure. On its "baseline development" scenario, WHO projects the top three causes of burden of disease in 2030, world-wide, to be depression, ischemic heart disease and road traffic accidents (World Health Organization, 2008c).

11.1.2. Developments since AR4

The relevant literature has grown considerably since publication of AR4. For instance, the annual number of MEDLINE citations on climate change and health doubled between 2007 and 2009 (Hosking and Campbell-Lendrum, 2012). We ran the same search protocol once more in January 2013 and found the number of citations per annum continued to grow after 2009, but at a slower rate. In addition, there are many reviews, reports and international assessments that do not appear in listings such as MEDLINE but include important information nevertheless, for instance, the World Development Report 2010 (The World Bank, 2010), the Climate Vulnerability 2010 report (DARA, 2010), and the 2011 UN Habitat report on cities and climate change (United Nations Human Settlements Programme, 2011). Many of these publications were reviews and commentaries, and a smaller number of quantitative studies linking climate change and health. One review of the scientific literature from 2008 to 2011 identified 40 studies of this latter kind, most focused on high-income countries (Hosking and Campbell-Lendrum, 2012).

Since the AR4, there have been improvements in the methods applied to investigate climate change and health. They include more sophisticated modeling of possible future impacts (for example, work linking climate change, food security, and health outcomes) (Nelson *et al*., 2010) and new methods to model the effects of heat on work capacity and labor productivity (Kjellstrom *et al*., 2009b). Other developments include coupling of high-quality, longitudinal mortality data sets with down-scaled meteorological data, in low-income settings (for instance, through the INDEPTH Network) (see Box 11-2).

_____ START BOX 11-2 HERE _____

Box 11-2. Weather, Climate and Health – a Long-Term Observational Study in African and Asian Populations

Given the dearth of scientific evidence of the relationship between weather/climate and health in low- and middle-income countries, we report on a collaborative study from sub-Saharan Africa and Asia. The INDEPTH Network currently has 43 members in 20 countries in Africa, Asia and Oceania. Using standardized health and demographic surveillance systems members have collected information on births, migration and deaths by cause over an average of 20 years.[2] Currently, there are about 3.4 million people under surveillance.

To study long-term relationships between weather and health, the authors collected information on all deaths occurring in 11 INDEPTH populations between 1 January 2000 and 31 December 2009 contributing about 10 million person-years of observation over 10 years (Diboulo *et al*., 2012). Time dependent methods were used to relate meteorological data to health outcomes. Seasonality in mortality varies between age groups, and there are differences in susceptibility to weather related factors by gender. In the elderly population deaths related to dust storms and heat have been more pronounced compared with other ages. For example, in Nounain Burkina Faso, the relative risk of dying for the elderly above 60 years is associated with the temperature on the day preceding the death, as shown in Figure 11-2.

[INSERT FIGURE 11-2 HERE
Figure 11-2: Relationship between the risk of dying and average temperature on the preceding day, persons aged over 60 years, Nouna, Burkina Faso. Y-axis: log(RR), X-axis: Temp in °C, lagged by one day. Dotted lines show 95% confidence limits. Source: Diboulo et al, 2012.]

[FOOTNOTE 2: http://www.indepth-network.org]

_____ END BOX 11-2 HERE _____

Since AR4, studies of the ways in which responses to climate change may affect health, so-called "co-benefits," have multiplied (Haines *et al*., 2009). There has been growing interest also in effects of greenhouse emissions other than climate change. A prime example is ocean acidification (Doney *et al*., 2008).

Much has been written on links between climate, socioeconomic conditions and health, for example related to occupational heat exposure (Kjellstrom *et al*., 2009b) and malaria (e.g. (Gething *et al*., 2010; Béguin *et al*., 2011)) There is also growing appreciation of the social upheaval and damage to population health that may arise from the interaction of large-scale food insecurity, population dislocation, and conflict (Princeton Study, 2013).

11.1.3. Non-Climate Health Effects of Climate-Altering Pollutants (CAPs)

CAPs affect health in other ways than through climate change, just as CO_2 creates non-climate effects such as ocean acidification. The effects of rising CO_2 levels on calcifying marine species are well documented and the risks for coral reefs are now more closely defined than they were at the time of the AR4. There are potentially implications for human health such as malnutrition in coastal populations that depend on local fish stocks, but, so far, links between health and ocean acidification have not been closely studied (Kite-Powell *et al*., 2008). CAPs such as black carbon and tropospheric ozone are also constituents of air pollution, and have major effects on human health. See section 11.5.3 and Box 11-4.

11.2. How Climate Affects Health

There are three basic pathways by which climate change affects health as illustrated in Figure 11-3. These provide the organization for the chapter.

- **Direct impacts**, which relate primarily to heat, weather extremes, and floods that directly impact human health and safety. [11.4]
- **Effects mediated through natural systems,** for example, disease vectors, water-borne diseases, and air pollution. [11.5]
- **Effects heavily mediated by human systems**, for example, occupational impacts, malnutrition, refugees, and mental stress. [11.6]

[INSERT FIGURE 11-3 HERE
Figure 11-3: Ways in which climate, climate variability and climate change may influence human health.
Source: E. Garcia (2011).]

To a considerable extent, the health impacts in each of these categories could be greatly ameliorated by efforts to improve infrastructure, public health services, disaster management, and poverty alleviation, although at considerable cost and effort. There is another category of impacts, however, that would be much more difficult to deal with:

- **Lower probability extreme climate regimes** beyond 2050 for which there seems no reasonable adaptation options. [11.8]

Before exploring what is known in each of these areas, however, we summarize what is known about vulnerability that affects all these types of impact.

11.3. Vulnerability to Disease and Injury due to Climate Variability and Climate Change

In the IPCC assessments, vulnerability is defined as the propensity or predisposition to be adversely affected (Chapter 19). In this section, we consider causes of vulnerability to ill-health associated with climate change and climate variability, including internal characteristics of the individuals affected, properties of the population in which these individuals live, and factors in the physical environment.

The background climate-related disease rate of a population is the best single indicator of the vulnerability to climate change - doubling of risk of disease in a low disease population has much less absolute impact than doubling of the disease when the background rate is high.

We have divided the causes of vulnerability into sections for convenience. In practice, these factors combine, often in complex and place-specific manner. There are some factors (such as education, income, health status and responsiveness of government) that act as generic causes of vulnerability. Low levels of parental education, for example, are consistently associated with higher child mortality in times of stress, whether it is military conflict, famine, or other natural disasters. The quality of governance – how decisions are made and put into practice – affects a community's response to threats of all kinds (Bowen et al, 2012). But the precise causes of vulnerability, and therefore the most relevant coping capacities, vary greatly from one setting to another. Vulnerability to heat, for example, varies spatially: the factors that are important in rural areas differ from those that put people at risk in cities (Reid *et al*., 2009). In a similar vein, severe drought in Australia has been linked to psychological distress and to food insecurity – but only for those residing in rural and remote areas. (Berry et al, 2010). The link between high ambient temperatures and increased incidence of salmonella food poisoning has been demonstrated in many places (e.g. (Zhang *et al*., 2010)), but the lag varies from one country to another, suggesting that the mechanisms differ (deficiencies in food storage may be the critical link in some places, food handling problems may be most important elsewhere) (Kovats *et al*., 2004).

The 2010 World Development Report concluded that all developing regions are vulnerable to economic and social damage resulting from climate change – but for different reasons (The World Bank, 2010). The critical factors for Sub-Saharan Africa, for example, are the current climate stresses (in particular, droughts and floods) that are projected to worsen with climate change, sparse infrastructure and high dependence on natural resources. Asia and the Pacific, on the other hand, are distinguished by the very large number of people living in low-lying areas prone to flooding (this includes roughly half the population of Vietnam, and nearly all of Bangladesh).

11.3.1. Geographic Causes of Vulnerability

Location has an important influence on the potential for losses caused by climate change (Samson *et al*., 2011). Those living in inland cities at mid- and low latitudes, where present-day temperatures are frequently close to tolerable maxima, will be more severely affected by further warming than people living at high latitudes (Kjellstrom *et al*., 2013). The inhabitants of low-lying coral atolls are exquisitely sensitive to flooding, contamination of fresh water reservoirs due to sea level rise, and salination of soil, all of which may have important effects on health (Nunn, 2009). Rural populations that rely on subsistence farming in low rainfall areas are at high risk of under-nutrition and water-related diseases in future drought, although this vulnerability may be modified strongly by local factors, such as access to markets and irrigation facilities (Acosta-Michlik *et al*., 2008). In high-income countries, location remains an important measure of susceptibility to the adverse effects of climate change. For example, living within 100- and 500-year flood zones, or within 5 km of coasts subject to sea level rise have been proposed, in the United States, as indicators of vulnerability to flooding (Acosta-Michlik *et al*., 2008; English *et al*., 2009). Living in rural and remote areas confers increased health risk because of poor access to services and generally higher levels of social and economic disadvantage. (Smith, 2008) Populations that are close to the present limits of transmission of vector-borne diseases are most vulnerable to changes in the range of transmission due to rising temperatures and altered patterns of rainfall (Zhou *et al*., 2008).

11.3.2. Current Health Status

Climate extremes may promote the transmission of certain infectious diseases and the vulnerability of populations to these diseases will depend on the baseline levels of pathogen and vector. In the United States, as one example, arboviral diseases such as dengue and the encephalitides are rarely seen after flooding, compared with the experience in other parts of the Americas. The explanation lies in the scarcity of dengue and other viruses circulating in the population, pre-flooding (Keim, 2008). Schistosomiasis was present in parts of Portugal in the 1950s. However, disease control efforts have eliminated the microbe from local snail populations so that although there is a competent vector and climate projections indicate that both parasite survival and vector survival will be favoured by rising temperatures, the risk of schistosomiasis returning to Portugal is low (Casimiro *et al.*, 2006). On the other hand, the high prevalence of HIV infection in many populations in Sub-Saharan Africa multiplies the health risks of prolonged drought, which may lead to migration, family disruption, deepening poverty, and increased exposure to unsafe sex.

11.3.3. Age and Gender

Children, young people, and the elderly are at increased risk of climate-related injury and illness (Perera, 2008). For example, illness due to malaria, diarrhea, and malnutrition is presently concentrated amongst children, for reasons of physiological susceptibility. In principle, children are expected to be more vulnerable to heat-related illnesses, due to their small body mass to surface area ratio, but evidence of excess heat-related mortality in this age group is mixed. In California, a study of summer mortality records for 1999-2003 reported a stronger association of heat and mortality among infants (aged less than 1 year) and those aged 65 years and over than other age groups (Basu and Ostro, 2008). Other studies have sought, but not detected, such an association (Kovats and Hajat, 2008). Malaria parasites in the blood are more plentiful and mortality from malaria is more common in childhood (from about 6 months to 3 years) due to less well-developed immune responses to infection with the plasmodium (Michon *et al.*, 2007). Children dehydrate more rapidly than adults when affected by diarrhoeal diseases, and case-fatality rates are correspondingly higher. In some circumstances, children may be protected from climate-related diseases. For instance, maternal antibodies lower the risk of dengue fever in children in the first year of life. Children are generally at greater risk when food supplies are restricted. Households with children tend to have lower than average incomes, and childhood is a particularly sensitive period for health and development (Cook and Frank, 2008). Young people are at risk of mental health-related climate change impacts because, unlike for physical illness, mental illness peaks in youth.

Older people are at greater risk from storms, floods, heat-waves and other extreme events, in part because they tend to be less mobile than younger adults and so find it more difficult to avoid hazardous situations and also because they are more likely to live alone, in some cultures. Older people are also more likely to suffer from health conditions that limit the body's ability to respond to stressful events. Chronic diseases such as diabetes and ischemic heart disease, for example, magnify the risk of death or severe illness associated with high ambient temperatures (Basu and Ostro, 2008; Sokolnicki *et al.*, 2009). People over 65 years are also more strongly affected by air pollution due to ozone and other photochemical oxidants (Medina-Ramon *et al.*, 2006).

Vulnerability is associated with gender but the relationship is complex (World Health Organization, 2011b). In the United States, it is reported that males are at greater risk of death following flooding, perhaps because in this setting they are more commonly exposed to risk (e.g. many of the flood drownings in the US are motor-vehicle related, and on average, in this country, males drive more than females do) (Jonkman and Kelman, 2005). A study of the health effects of flooding in Hunan province, China, also found an excess of flood deaths among males, often related to rural farming (Abuaku *et al.*, 2009). In Canada's Inuit population males are exposed to dangers associated with insecure sea ice, while females may be more vulnerable to the effects of diminished food supplies (Pearce *et al.*, 2011). In the Paris 2003 heatwave, females were more affected than males in every age group except those aged 25-64. In this instance, the male dominance in the working age group may be related to differential exposures to heat in occupational settings. In Bangladesh, females are more affected than males by a range of climate hazards, at least in part because a greater proportion suffers from poverty and poor nutrition, and women are more frequently exposed to water-logged environments (Neelormi *et al.*, 2009). There may also be physiological differences in resilience.

After controlling for differences in age and co-morbidities, it appears that females are more strongly affected than males by high temperatures (Yu *et al.*, 2010) and ozone air pollution (Medina-Ramon and Schwartz, 2008). There are signs also that the effect of food insecurity on growth and development in childhood may be more damaging for girls than boys (Cook and Frank, 2008).

Pregnancy is a period of increased vulnerability to a wide range of environmental hazards, including extreme heat (Strand *et al.*, 2012) and infectious diseases such as malaria, foodborne infections and influenza (Jamieson *et al.*, 2006)(van Kerhove et al, 2011).

11.3.4. Socioeconomic Status

Socioeconomic status typically is measured by educational attainment, occupational prestige and personal income. At a national level, the poorest countries are most susceptible to damage caused by climate change, including health effects. Likewise, individuals and households most vulnerable to climate hazards are those with relatively low socioeconomic status. A review of global trends in tropical cyclones found that mortality risk depended on storm intensity, effective governance, and levels of poverty (Peduzzi *et al.*, 2012). A study of the impacts of flooding in Bangladesh found that household risk reduced with increases in both average income and number of income sources. Poorer households were not only more severely affected by flooding, but they took preventive action less often, and received assistance after flooding less frequently than did more affluent households. This was explained partly by financial obstacles to relocation and other coping strategies, but there were differences also in knowledge of hazards and in beliefs about the preventability of flooding (Brouwer *et al.*, 2007).

Occupation is also directly related to vulnerability to climate variability and extremes. For instance, outdoor occupations, which tend to have low socio-economic status, have been linked with disease and injury caused by flooding in China (Abuaku *et al.*, 2009) and heat-waves in the United States (Centers for Disease Control and Prevention, 2008). Tawatsupa et al (2010) report differences in Thailand in the impacts of heat in the workplace in relation to socio-economic status. High socioeconomic status is not always protective: Singapore is one of the wealthiest countries in Asia, but in the 2000s experienced a resurgence of dengue fever, despite a considerable investment in vector control (Egger et al, 2008). In Brisbane, Australia, heat-wave mortality was related to age and gender, but not to small area measures of social disadvantage (Yu *et al.*, 2010). This null finding, contrary to what has been observed elsewhere with individual-level measures of SES, (Medina-Ramon *et al.*, 2006) may be due to the much greater variability in housing quality in Australia within neighborhoods than exists between neighborhoods, or the relatively flat social gradient in access to protective factors such as air conditioning and private transport.

In many countries, race and ethnicity are powerful markers of health status and social disadvantage. Black Americans have been reported to be more vulnerable to heat-related deaths than other racial groups in the United States (Basu and Ostro, 2008). This may be due to a higher prevalence of chronic conditions such as over-weight and diabetes, (Lutsey *et al.*, 2010) to financial circumstances (for instance, lower incomes may restrict access to air conditioning during heat-waves), (Ostro *et al.*, 2010) or to community-level characteristics (such as higher local crime rates or disrupted social networks). Indigenous peoples who depend heavily on local resources, and live in parts of the world where climates are changing quickly, are generally at greater risk of economic losses and poor health. Studies of the Inuit people, for example, show that rapid warming of the Canadian Arctic is jeopardizing hunting and many other day-to-day activities, with implications for livelihoods and well-being (Ford, 2009). Climate change in the North-West of Alaska led to increased vulnerability to accidents, diseases, mental stress, and food insecurity. Increase in temperature in the traditional ice cellars used for storage of fish and meat of sea mammals increases risks of food-borne and gastrointestinal diseases (Brubaker, M., Berner, J., Chavan, R., Warren,J., 2011). In Australia, indigenous peoples experience higher rates of diarrheal diseases and other climate-sensitive conditions than the remainder of the national population and their general health status is poorer, which places them at additional risk of climate stressors such as heat-waves (Petheram *et al.*, 2010). They also experience greatly elevated rates of mental illness, suicide (Hunter, 2009) and related health behaviours, and these create substantial underlying vulnerability to climate change (Berry *et al.*, 2010a)(Berry, 2009).

11.3.5. Public Health and Other Infrastructure

The physical environments around where people live and work can influence the health risks due to climate variability and climate change. In Cuba, a country with a well-developed public health system, dengue fever has been a persistent problem in the larger cities, due in part to the lack of a constant supply of drinking water in many neighbourhoods (leading to people storing water in containers that are suitable breeding sites for the disease vector, *A. aegypti*) (Bulto *et al.*, 2006). A study of the city of Phoenix, in the US, found the number of heat distress calls during heat waves was higher in areas affected by the urban heat island effect (which was measured by the proportion of impervious surfaces and minimum night time temperatures) (Uejio *et al.*, 2011).

11.3.6. Projections for Vulnerability

Population growth may be one of the strongest influences on vulnerability to the health effects of climate change. Increasing numbers of people, in locations that are already resource-poor and are affected by climate risks, will magnify harmful impacts. Most of the projected growth in populations will occur in large, low latitude hot countries in which a high proportion of the workforce is deployed outdoors with little protection from heat. About 150 million people currently live in cities affected by chronic water shortages (< 100 L per person per day of sustainable freshwater flows) and in 50 years, unless there are rapid improvements in urban environments, demographic growth will push the number affected by chronic water shortages to around a billion (McDonald *et al.*, 2011). Under a "business as usual" scenario, the OECD projects that about 1.4 billion people will be without access to basic sanitation in 2050 (OECD, 2012). The age structure of the population also has implications for vulnerability. The proportion aged over 60, world-wide, is projected to increase from about 10% presently to about 32% by the end of the century (Lutz *et al.*, 2008). Overweight and obesity, associated with relatively poor heat tolerance, are becoming more common in most countries, and this trend is expected to continue (Finucane *et al.*, 2011).

Future trends in social and economic development are critically important to vulnerability. For instance, countries with a higher Human Development Index (HDI) (a composite of life expectancy, education and literacy and GDP per capita) are less affected by the floods, droughts and cyclones that take place (Patt *et al.*, 2010). Therefore policies that boost health, education and economic development should reduce future vulnerability. Overall, there have been substantial improvements in the HDI, but this has been accompanied by increasing inequalities between and within countries, and has come at the cost of high consumption of environmental resources (UNDP, 2011). The relation between national wealth and health is roughly log linear, suggesting that an extra dollar buys more health gain in low-income countries than in medium and high income settings. It is notable also that the protective effects of national wealth are related to the severity of climate extremes. Peduzzi (2012) found "that poverty levels are less significant when facing very intense tropical cyclones, whereas at the lower intensities only the poorest suffer heavy losses."

11.4. Direct Impacts of Climate Meteorological Changes on Health

11.4.1. Heat and Cold Extremes

Although there is strong evidence for the effects of variation in weather and season on a range of health outcomes, assessment of health impacts of observed climate change in the last few decades is challenging. Over the multi-decadal time scales that are necessary to measure climate change, the constellation of factors that influence disease rates is strongly affected by many other social and environmental factors. This means that robust studies require not only long time series of data on climate and disease rates, but also information on all other established or potential causative factors, coupled with statistical analysis to apportion changes in health states to the various contributing factors. To complicate matters further, wherever risks are identified, health agencies are mandated to intervene immediately, confounding long-term analyses. Finally, there is no clear consensus on appropriate methods and standards for studies correlating long-term time trends in environmental variables and health outcomes. Such studies are therefore relatively rare, and seldom conclusive.

Since AR4, there is stronger evidence both for increases in some meteorological exposures that are hazardous to human health, and of attribution of these changes to anthropogenic influences. The IPCC Special Report on Extreme Events SREX [to be updated with data from AR5 WG1] concludes that it is very likely that there has been an overall decrease in the number of cold days and nights, and an overall increase in the number of warm days and nights, at the global scale.

In some cases, the connection between meteorological hazards and health impacts is sufficiently direct to draw strong inferences about cause and effect (Sauerborn and Ebi, 2012). Most notably, the association between unusually hot days (defined as departures from average daily maximum temperatures for a specified location and date over 20 or 30 year baseline period) and increases in mortality is very robust (see studies reviewed in section 11.2.2 above). The observed *very likely* increase in daily maximum temperatures is therefore *likely* to have caused an increase in the number of heat-related deaths in mid-latitude populations. The decrease in minimum temperatures may have contributed to a decline in deaths associated with cold spells in the same populations, but there is no strong evidence in the literature so far. Moreover, the influence of seasonal factors other than temperature on winter mortality suggests that heat impacts on health may outweigh the benefits of fewer cold days (Kinney *et al.*, 2012; Ebi and Mills, 2013). Quantification globally, remains highly uncertain, as there are few studies of the large developing country populations in the tropics, and those which do exist point to effects of heat, but not cold, on mortality (Hajat *et al.*, 2010). There is also significant uncertainty over the degree of physiological, social or technological adaptation to increasing heat over long time periods. For other extreme events and weather disasters (such as floods or drought), there is no good evidence of a climate change signal (IPCC, 2012).

11.4.1.1.Mechanisms

It is physiologically plausible that circulatory diseases are more common at high temperatures; for instance, displacement of blood to the skin surface may lead to circulatory collapse. In this regard, indoor thermal conditions are important, including ventilation, humidity, radiation from walls or ceiling and the presence or absence of air-conditioning, but these variables are seldom well-measured in epidemiological studies (Anderson *et al.*, 2012). Biological mechanisms are less evident for other causes of death that have been related to weather. For instance, there is an association of ambient temperature with suicide (Page *et al.*, 2007; Likhvar *et al.*, 2011; Kim *et al.*, 2011).

Some investigators have reported that mortality increases more during heat waves than would be anticipated solely on the basis of physiologic tolerance to temperature (D'Ippoliti *et al.*, 2010; Anderson and Bell, 2011), although the added effect is relatively small in some series, and most evident with prolonged heat waves. (Gasparrini and Armstrong, 2011) Some studies have shown larger effects of heat and heat waves earlier in the hot season (Anderson and Bell, 2011; Rocklov *et al.*, 2011). This may be testament to the importance of acclimatisation and adaptive measures, or may result from a large group in the population that is genuinely susceptible to heat early in the season (Rocklov *et al.*, 2009; Rocklov *et al.*, 2011).

The extreme heat wave in Europe in 2003 led to numerous epidemiological studies. The reports from France (Fouillet *et al.*, 2008)concluded that a very large proportion of the extra deaths occurred in elderly people (80% above age 75). However, heat wave-related mortality in younger ages was also substantial (approximately 3,000 deaths). Questions were raised at the time as to why this event had such a devastating effect (Kosatsky, 2005). It is still not clear, but one contributing factor may have been the relatively mild influenza season the year before. Recent studies have found that when the previous year's winter mortality is low, the effect of summer heat is increased (Ha *et al.*, 2011). This relationship between risk factors in winter and summer time may complicate the attribution of heat and cold effects (e.g. with climate change), given their inter-dependence; milder winters may leave a higher proportion of vulnerable people, and predispose to a stronger subsequent summer heat effect (Stafoggia *et al.*, 2009).

Most studies of heat have been in high-income countries, but there has been work recently in low- and middle-income countries, suggesting heterogeneity in vulnerability by age groups and socio-economic factors similar to that seen in higher-income settings (McMichael *et al.*, 2008; Bell *et al.*, 2008b; Pudpong and Hajat, 2011).

Studies of temperature-related morbidity, most commonly based on hospital admission or emergency presentations, find increases particularly in cardio-vascular, respiratory and kidney diseases. (Hansen *et al*., 2008; Lin and Chan, 2009; Knowlton *et al*., 2009). Rapid changes in temperature may upset the balance between humans and parasites. It has been proposed that the speed with which organisms adapt to changes in temperatures is broadly speaking a function of mass, and in support of this proposition, laboratory studies have shown that microbes respond more quickly to a highly variable climate than do their multi-cellular hosts (Raffel *et al*., 2012).

Health risks during heat extremes are greater in people carrying out physical activity. The intra-body surplus heat created by physical activity causes particular vulnerability to heat effects in these population groups. This has importance for recreational physical activity outdoors and it is of special relevance to analysis of the impacts of climate change on occupational health (see separate section below) (Ebi and Mills, 2013). Since the association between unusually hot days and increases in mortality is so well documented, it is possible to conclude that an observed increase in daily maximum temperatures is *likely* to have caused an increase in the number of heat-related deaths. The decrease in minimum temperatures may have contributed to a decline in deaths associated with cold spells in the same populations. There are very few studies of the large developing country populations in the tropics, and those which do exist point to effects of heat, but not cold, on mortality (Hajat *et al*., 2010). There is also significant uncertainty over the degree of physiological, social or technological adaptation to increasing heat over long time periods.

11.4.1.2.Near-Future Impacts

Under predicted climate change scenarios, it is likely heat waves will increase in frequency and intensity and worsen heat-related exposures, although acclimatization and improvements in energy efficiency may mitigate some of these effects (Wilkinson *et al*., 2007a; Wilkinson *et al*., 2007b; Bi and Parton, 2008; Hanna *et al*., 2011; Maloney and Forbes, 2011). In Australia, the number of "dangerously hot" days, when core body temperatures may increase by ≥ 2ºC and outdoor activity is hazardous, is forecast to rise from the current 4 to 6 days per year to 33-45 days per year by 2070 for non-acclimatized people. Among acclimatized people, an increase from 1-5 days per year to 5-14 days per year is expected (Hanna *et al*., 2011).

For reasons given above, it is not clear whether winter mortality will decrease in a warmer, but more variable climate (Kinney *et al*., 2012; Ebi and Mills, 2013). Overall, the increase in heat-related mortality is projected to outweigh gains due to fewer cold periods, especially in tropical developing countries with limited adaptive capacities and large exposed populations (Wilkinson *et al*., 2007b). A study of three Quebec cities projected an increase in summer mortality that clearly outweighed a small reduction in autumn deaths, and only slight variations in winter and spring (Doyon *et al*., 2008). Another study, using years of life lost as the outcome, and located in Brisbane, Australia, found the gains associated with fewer cold days were outweighed by the effects of more hot days when warming exceeded 2ºC. (Huang *et al*., 2012). The same trend is reported for New York City: by the 2050s, premature mortality due to heat is projected to increase by 70% (Knowlton *et al*., 2007). It is not certain how rapidly populations may adjust to increased heat. In New York, it was estimated that acclimatisation may reduce the impact of added summer heat by roughly a quarter (Knowlton *et al*., 2007).

11.4.2. Floods

In the IPCC Fourth Assessment Report, floods were reported to be the most frequent natural weather disaster. This is still true; in 2010, the ten most important disasters, judged by the number of people affected, included six floods and these floods accounted for more than 90% of the total number of victims, i.e., 175 million people (Guha-Sapir *et al*., 2011). Most of the losses occurred in mid- to low-income countries such as China, Pakistan (Dar *et al*., 2011), Thailand, Cambodia, India, and Colombia. For instance, in 2007 flooding along the southern coast of Mozambique affected 285,000 people, caused 140,000 to be displaced from their homes, and led to 29 deaths (World Bank, 2011). However, as exemplified by severe, damaging floods in Australia in 2010 and in the north-east of the United States in 2012, developed countries are not immune. (Guha-Sapir *et al*., 2011; Powell, 2012).

Mechanisms

The direct impacts of storms and floods include drowning, injuries, hypothermia and infectious diseases, whereas indirect health effects result from damage to infrastructure and water supplies, displacement of people, and disruption to people's lives (Jonkman and Kelman, 2005). Over the last 10 years, floods in Europe have killed more than 1,000 people and affected over 3.4 million. Worldwide, it is estimated that two thirds of flood deaths are due to drowning, and 70% of flood-related deaths are male (Jonkman and Kelman, 2005).

The attribution of deaths to flood events has been found to be complex with immediate traumatic deaths being most easily recorded (WHO/HPA, 2012). There is some uncertainty as to whether flood events are associated with a longer-term effect on mortality in the flooded population (Milojevic *et al*., 2011). A study in rural Bangladesh found no effect on flooding on subsequent diarrhoeal disease, but a small increase (RR 1.25) in acute respiratory infections (Milojevic *et al*., 2012). Another report on Bangladesh found no evidence of increased risk of mortality or diarrhea during 3 years after flooding (Milojevic *et al*., 2012).

Flood-related injuries have been caused when people are evacuating from flood waters, attempting to save family or valuables, or during the clean-up process (Schnitzler *et al*., 2007; Jakubicka *et al*., 2010). Drinking water can become contaminated by bacteria, sewage, agricultural waste or chemicals (CDC, 2011). Infectious diseases and vector mosquitos for malaria or dengue fever may also be affected by floods (Kouadio *et al*., 2012). In many countries, heavy rainfall and flooding have led to outbreaks of leptospirosis (caused by contact with bacteria of the genus *Leptospira*, an organism which circulates in a wide variety of animal hosts, including rats) (Lau *et al*., 2010). Flooding and storms may have profound effects on peoples' mental health (Neria, 2012). A study of the aftermath of the 2007 England and Wales floods found that the prevalence of mental health symptoms (including psychological distress, anxiety and depression) was two to five times higher among individuals who reported flood water in the home compared to individuals who did not (Paranjothy *et al*., 2011). In Taiwan, a survey conducted 3 months after Typhoon Markot found the prevalence of Post Traumatic Stress Disorder was 25.8% among 271 evacuated school children (Yen *et al*., 2011).

We found no studies of near-future impacts of storms and flooding published since AR4.

11.4.3. Ultraviolet Radiation

Ambient UV levels and maximum summertime day temperatures are related to the prevalence of non-melanoma skin cancers. In one study in the United States, the number of cases of squamous cell carcinoma was 5.5% higher for every 1°C increment in average temperatures, and basal cell carcinoma was 2.9% more common with every 1° C increase. These values correspond to an increase in the effective UV dose by 2% for each 1°C (van der Leun *et al*., 2008). Higher temperatures in the northern countries and countries with temperate climates may result in an increase in the time which people spend outdoors and, thus in additional UV-induced-adverse effects. Notably, however, skin cancer rates are rising already in many countries, for other reasons, such as changes in travel and recreation.

11.5. Ecosystem-Mediated Impacts of Climate Change on Health Outcomes

11.5.1. Vector-Borne and Other Infectious Diseases

Vector-borne diseases (VBDs) refer most commonly to infections transmitted by the bite of infected insects such as mosquitoes or ticks. These are perhaps the most well-studied of the diseases associated with climate change, due to their widespread occurrence and sensitivity to climatic factors (Bangs *et al*., 2006; Bi *et al*., 2007; Halide and Ridd, 2008; Wu *et al*., 2009). Table 11-1 summarizes what is known.

[INSERT TABLE 11-1 HERE
Table 11-1: Vector-borne diseases.]

11.5.1.1. Malaria

Malaria is mainly caused by four distinct species of plasmodium parasite (Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae, Plasmodium ovale), transmitted between individuals by Anopheline mosquitoes. In 2010 there were an estimated 216 million episodes of malaria world-wide, causing 655,000 deaths, mostly of children under 5 years in the African Region (WHO, 2011). World-wide, there have been significant advances made in malaria control in the last 20 years (Feachem, 2011), but the disease persists and is a challenge, particularly, in Africa. For example, large outbreaks have occurred in highland regions in East Africa, and these may have been promoted, at least in part, by rising temperatures locally (Chaves and Koenraadt, 2010).

The influence of temperature on malaria development appears to be non-linear, and is vector-specific (Alonso *et al.*, 2011). Daily minimum temperature fluctuation acts to speed up parasite development, whereas variations around the maximum temperature tend to slow processes down (Paaijmans *et al.*, 2010). Analysis of environmental factors associated with the malaria vectors *Anopheles gambiae* and *Anopheles funestus* in Kenya found that abundance, distribution and disease transmission are affected in different ways by precipitation and temperature (Kelly-Hope *et al.*, 2009). There are lag-times according to the life cycle of the vector and the parasite: a study in one county of central eastern China reported that malaria incidence was related to maximum temperature and average humidity one month prior to identification of the case (Zhang *et al.*, 2012).

More work has been done since AR4 to elucidate the role of local warming on malaria transmission in the East African highlands, but this is hampered by the lack of time series data on factors such as levels of drug resistance and intensity of vector control programmes. Earlier research had failed to pick out a clear increase in temperatures accompanying increases in malaria transmission, but new studies with aggregated meteorological data over longer time periods have confirmed increasing temperatures since the 1950s (Omumbo *et al.*, 2011; Stern *et al.*, 2011). The strongly non-linear response to temperature means that even modest warming may drive large increases in transmission of malaria, if conditions are otherwise suitable (Pascual *et al.*, 2006; Alonso *et al.*, 2011). A detailed review (Chaves and Koenraadt, 2010) concluded that decadal temperature changes have played a role in changing malaria incidence in East Africa. But malaria is very sensitive also to socioeconomic factors and health interventions, and the generally more conducive climate conditions have been offset by more effective disease control activities. The incidence of malaria has reduced over much of East Africa (Stern *et al.*, 2011) although increased variability in disease rates has been observed in some high altitude areas (Chaves et al, 2012).

At the global level, economic development and control interventions have dominated changes in the extent and endemicity of malaria over the last 100 years (Gething *et al.*, 2010). Although modest warming is likely to have facilitated malaria transmission, the proportion of the world's population affected by the disease has been reduced, largely due to control of *P. vivax* malaria in moderate climates with low transmission intensity.

11.5.1.2. Dengue Fever

Dengue is the most rapidly spreading mosquito-borne viral disease, showing a 30-fold increase in global incidence over the past 50 years. Estimates for the population at risk range from 30% to 54.7% of the world's population (2.05–3.74 billion). Three quarters of the people exposed to dengue are in the Asia-Pacific region. The disease is associated with climate on spatial (Beebe *et al.*, 2009; Russell *et al.*, 2009; Li *et al.*, 2011), temporal (Hii *et al.*, 2009; Hsieh and Chen, 2009; Herrera-Martinez and Rodriguez-Morales, 2010; Earnest *et al.*, 2011; Gharbi *et al.*, 2011; Pham *et al.*, 2011; Descloux *et al.*, 2012) and spatiotemporal (Chowell *et al.*, 2008; Chowell *et al.*, 2011; Lai, 2011) scales.

The principal vectors for dengue, *Aedes aegypti* and *Aedes albopictus* are climate-sensitive. Over the last two decades, climate conditions have become more suitable for *albopictus* in some areas (eg over central northwestern

Europe) but less suitable elsewhere (eg over southern Spain) (Caminade *et al*., 2012) Distribution of *Aedes albopictus* in northwestern China is highly correlated with annual temperature and precipitation (Wu *et al*., 2011). Temperature, humidity and rainfall are positively associated with dengue incidence in Guangzhou, China, and wind velocity is inversely associated with rates of the disease. (Lu and Lin, 2009; Li *et al*., 2011)**.** A study in Dhaka, urban Bangladesh reported increased rates of admissions to hospital due to dengue with both high and low river levels (Hashizume and Dewan, 2012). In some circumstances, it is apparent that heavy precipitation favors the spread of dengue fever, but drought can also be a cause if households store water in containers that provide suitable mosquito breeding sites (Beebe *et al*., 2009; Padmanabha *et al*., 2010).

_____ START BOX 11-3 HERE _____

Box 11-3. Case Study: Dengue Fever

Dengue Fever (DF) and its haemorrhagic manifestations are caused by four antigenically distinct serotypes (1 to 4) belonging to the Flaviviridae family. Each year within the "dengue belt" (between 35ºN and 35ºS latitude) there occur about 50-100 million cases of Dengue Fever and 500,000 cases of Dengue Haemorrhagic Fever (DHF) and Dengue Shock Syndrome (DSS) (Chadee *et al*., 2007). Prior to 2006, no consistent patterns had been reported in the seasonal distribution of DF and *Ae. aegypti* adult populations within the Americas. However, seasonality in dengue transmission is well known in South East Asia, with transmission occurring mostly during the wettest months of the year (Gubler and Kuno, 1997; Chadee *et al*., 2007).

Figure 11-4 shows most DF cases in Trinidad (80%) were recorded during the wet season when the *Aedes aegypti* mosquito population density was four to nine times higher than the dengue transmission threshold (Macdonald, 1956). This led to a control programme that concentrated on reducing the mosquito population before the onset of the rains, by application of insecticides (temephos) into the water drums that serve as primary breeding sites of *Ae. aegypti* in the Caribbean. The one-off treatment effectively controlled the mosquito populations for almost 12 weeks after which the numbers reverted to levels observed in the untreated control areas.

[INSERT FIGURE 11-4 HERE
Figure 11-4: Rainfall, temperature, Breteau index (number of water containers with *A. aegypti* larvae per 100 houses), and dengue cases, Trinidad (2002-2004). Source: Chadee *et al*. (2007).]

Recent climate change scenarios for the period 2071-2100 project altered dynamic circulation patterns in both dry and wet seasons, therefore changing the intensity and frequency of rainfall events (Campbell *et al*., 2011). In addition, projections include greater variability in rainfall patterns during November to January, with the northern Caribbean region receiving more rainfall than in the southern Caribbean (Campbell *et al*., 2011). There may be water shortages during drought periods, and flooding after episodes of heavy rainfall, both of which affect the breeding habitats of *Ae. aegypti* and *Ae. albopictus*. Vector control strategies will need to be planned and managed astutely to systematically reduce mosquito populations.

_____ END BOX 11-3 HERE _____

11.5.1.3.Tick-Borne Diseases

These include tick-borne encephalitis (TBE) and *Lyme borreliosis* (LB). TBE, is caused by tick-borne encephalitis virus, and is endemic in temperate regions of Europe and Asia. Western Siberia has the highest incidence of the disease in the world. Asian countries affected by TBE include China, Japan, Mongolia, and South Korea. Lyme disease is an acute infectious disease caused by the spirochaete bacteria *Borrelia burgdorferi* and is reported in Europe, the USA and Canada. *Borrelia* is transmitted to humans by the bite of infected ticks belonging to a few species of the genus *Ixodes* ("hard ticks"). Many studies have found that climate may have an influence on the distribution of tick-borne diseases (Okuthe and Buyu, 2006; Lukan *et al*., 2010; Tokarevich *et al*., 2011; Estrada-Peña *et al*., 2012; Andreassen *et al*., 2012)**.**

In North America, there is good evidence of northward expansion of the distribution of the tick vector (*Ixodes scapularis*) in the period 1996 to 2004 based on an analysis of active and passive surveillance data (Ogden *et al*., 2010). However, there is no evidence so far of any associated changes in the *distribution* in North America of human cases of tick-borne diseases.

Studies since AR4 have confirmed a marked rise in TBE cases since the 1970s in central and Eastern Europe. Spring-time daily maximum temperatures rose in the late 1980s, sufficient to encourage transmission of the TBE virus. Variations in illness rates across the region demonstrate that climate change alone cannot explain the increase, and socioeconomic changes (including changes in agriculture and recreational activities), have strongly affected patterns of disease (Sumilo *et al*., 2008; Randolph, 2010). In the Czech Republic, between 1970 and 2008, there are signs of lengthening transmission season and higher altitudinal range in association with warming (Kriz *et al*., 2012). However, the complex ecology and epidemiology of tick-borne diseases such as *Lyme borreliosis* and TBE make it difficult to attribute particular changes in disease frequency and distribution to specific environmental factors such as climate (Gray *et al*., 2009).

11.5.1.4. Other Vector-Borne Diseases

Hemorrhagic fever with renal syndrome (HFRS) is a zoonosis caused by the Hanta virus, and leads to approximately 200,000 hospitalized cases each year. The incidence of this disease has been associated with temperature, precipitation, and relative humidity (Fang *et al*., 2010; Liu *et al*., 2011). Plague, one of the oldest diseases known to man, remains endemic in many natural epidemic foci around the world. Outbreaks have been linked to seasonal and inter-annual variability in climate (Stenseth *et al*., 2006; Nakazawa *et al*., 2007; Holt *et al*., 2009; Xu *et al*., 2011). Chikungunya fever is another climate-sensitive mosquito-transmitted viral disease, (Anyamba *et al*., 2012) first identified in Africa, now present also in Asia, and recently emerging in parts of Europe (Angelini *et al*., 2008).

11.5.1.5. Near-Future Impacts

Using the A1B climate change scenario, Béguin et al. (2011) projected differences in the population at risk of malaria to 2030 and 2050. If there was no change in GDP per capita, the model projected 5.2 billion people at risk in 2050, out of a predicted global population of 8.5 billion. The additional malaria transmission areas are shown in red in Figure 11-5. Keeping climate constant, and assuming strong and equitable economic growth, would lead to 1.74 billion people at risk (approximately half the present number at risk). Factoring in climate change would increase the "best case" estimate of the number of people at risk of malaria in 2050 to 1.95 billion, which is 200 million more than if disease control efforts were not opposed by higher temperatures and shifts in rainfall patterns.

[INSERT FIGURE 11-5 HERE
Figure 11-5: Contraction of the area of malaria transmission if economic development progresses as forecast (top panel, in blue); expansion in areas of transmission through higher temperatures (bottom panel, in red). Based on IPCC scenario A1B, projections to 2050. Source: Béguin *et al*. (2011).]

There are no studies that project the return of established malaria to Northern America or Europe, where it was once prevalent. Although suitable vectors for *P. vivax* malaria abound in these parts of the world, the risk of re-introduction is thought to be very low, barring civil strife or a breakdown of health services.

We could identify only one study published since 2006 that models future risk of dengue under climate change. Åström (2012) estimated the population at risk out to the year 2050. The study was based on routine disease reports, surveys, population projections, estimates of GDP growth and the A1B scenario for climate change. Three global circulation models were run to 2050, at which time, 4.86 billion people were projected to live in areas at risk of dengue - 6.1% or 280 million more than would have been expected otherwise. Under scenarios of high GDP growth, the number exposed to dengue in 2050 falls to 4.46 billion, ie the adverse effects of climate change are balanced by the beneficial outcomes of development. This study considered only the margins of the geographic distribution of

dengue (where economic development has its strongest effect) and did not examine changes in intensity of transmission in areas where the disease is already established.

Kearny (2009) used biophysical models to examine the potential extension of vector range in Australia. He predicted that climate change would increase habitat suitability throughout much of Australia. Changes in water storage as a response to a drier climate may be an indirect pathway, through which climate change affects mosquito breeding (Beebe *et al.*, 2009).

11.5.2. Food and Water-Borne Infections

Human exposure to climate-sensitive pathogens occurs by ingestion of contaminated water or food, incidental ingestion during swimming or by direct contact with eyes, ears or open wounds. Pathogens in water may be concentrated by bivalve shellfish (e.g., oysters) or deposited on irrigated food crops. Pathogens of concern for waterborne exposure may be enteric and transmitted by the fecal oral route (enteric viruses, bacteria and protozoa) or may occur naturally in aquatic systems (bacteria and protozoa). Climate may act directly by influencing growth, survival, persistence, transmission or virulence of pathogens; indirect influences include climate-related perturbations in local eco-systems and/or the habitat of species that act as zoonotic reservoirs.

11.5.2.1. Vibrio

Vibrio is a genus of native marine bacteria that includes a number of human pathogens, most notably *V. cholerae* which causes cholera. Although cholera is unique in that it can be transmitted both by drinking water and by environmental exposure in seawater and seafood, other Vibrio species are solely linked to seawater and shellfish. These primarily include *V. parahaemolyticus* and *V. vulnificus*, with *V. alginolyticus* emerging in importance (Weis, 2011). Risk of infection is influenced by temperature, precipitation and accompanying changes in salinity due to freshwater run off, addition of organic carbon or other nutrients or changes in pH. These factors all affect the spatial and temporal range of the organism and also influence exposure routes (eg direct contact or via seafood).In countries with endemic cholera, there appears to be a robust relationship between temperature and the disease (e.g., (Paz, 2009; Islam, 2009; Reyburn *et al.*, 2011)). In Bangladesh, precipitation has been shown to be predictive of cholera cases, and higher risk is associated with both high rainfall (and stream level) events as well as below threshold rainfall levels (and lower stream levels) (Hashizume, 2008). This bi-modal pattern is hypothesized to be due to increased water-washed contamination during heavy rains and decreased sanitation (and increased direct contamination) during drier events (Hashizume, 2008).

11.5.2.2. Enteric Bacteria and Viruses

Rates of diarrhea have been associated with high temperatures (Kolstad and Johansson, 2011); however, with a few exceptions we do not know the specific cause of the diarrheal illness nor the mechanism for the association with temperature. Exceptions include *Salmonella* and *Campylobacter*, which are among the most common zoonotic food and waterborne bacterial pathogens worldwide and both show distinct seasonality in infection and higher disease rates at warmer temperatures, especially when outbreaks are excluded. The association between climate (especially temperature) and non-outbreak ('sporadic') cases of salmonellosis may, in part, explain seasonal and latitudinal trends in diarrhea (Lake, 2009).

Among the enteric viruses, there are distinct seasonal patterns in infection that can be related indirectly to temperature. Enterovirus infections in the U.S. peak in summer and fall months (Khetsuriani *et al.*, 2006). After controlling for seasonality and interannual variations, hand, foot and mouth disease (caused by coxsackievirus A16 and enterovirus 71), shows a linear relationship with temperature in Singapore with a rapid rise in incidence when the temperature exceeds 32°C (Hii *et al.*, 2011). However, it is not clear what the underlying driver is and if temperature is confounded by other seasonal factors. Other studies have shown that when released into the environment, enterovirus persistence is negatively correlated with temperature (e.g., (Wetz *et al.*, 2004)).

Temperature is directly linked with enteric disease risk in Arctic communities, where rising temperatures and loss of permafrost may result in transport of sewage (which is often captured in shallow lagoons) into groundwater, drinking water sources or other surface waters (Martin, D., B. Belanger, P Gosselin, J Brazeau,C.Furgal and S.Dery, 2007). Additionally, thawing may damage drinking water intake systems (for those communities with such infrastructure) (Hess, 2008). Harper et al. (2011) showed that in coastal Arctic communities in Canada, higher temperatures precede reports of infectious gastroenteritis with high temperatures corresponding with a 3.9-fold increase in clinic visits within 3 weeks; however this trend was not statistically significant.

Rainfall has also been associated with enteric infections. Pathogens are more likely to be taken up by produce crops (eg lettuce) under conditions of both flooding and drought (Ge *et al.*, 2012) and this is reflected also in patterns of illness (Bandyopadhyay *et al.*, 2012). Higher concentrations of enteric viruses have been noted in drinking water (surface and ground) and recreational water following heavy rainfall (e.g., (Futch, 2010; Jofre *et al.*, 2010)). Likewise, cases of hand, foot and mouth disease (echovirus 71 or coxsackievirus A16) in Singapore increase linearly with cumulative rainfall of up to 75 mm per week (Hii *et al.*, 2011). In the Arctic (Canada), rainfall and increased snowmelt were associated with both deterioration in water quality in reservoirs (evidenced by fecal indicator bacteria) and increased clinic visits for infectious gastroenteritis (Harper *et al.*, 2011).

Illness caused by infection with the rotavirus caused about 450,000 deaths in children under 5 years old in 2008 (Tate *et al.*, 2012). There are seasonal peaks in the number of cases in temperate and subtropical regions but less distinct patterns are seen within 10º latitude of the equator (Cook *et al.*, 1990). Variations in the timing of peak outbreaks between countries or regions (Turcios *et al.*, 2006; Atchison *et al.*, 2010) and variations with time in the same country (Dey *et al.*, 2010) have been attributed to fluctuations in the number and seasonality of births (Pitzer *et al.*, 2009; Pitzer *et al.*, 2011). While vaccination against rotavirus is expected to reduce the total burden of disease, it may also increase seasonal variation (Tate *et al.*, 2009; Pitzer *et al.*, 2011).

11.5.2.3.Near-Term Future

Kolstand and Johansson (2011) project an increase of 8-11% in the risk of diarrhea in the tropics and subtropics due to climate change, up to 2039. In 2040-69 and 2070-99, Kolstad and Johansson projected risk increases of 15-20% and 22-29% respectively using the A1B scenario and 19 coupled atmosphere-ocean climate models from the World Climate Research Programme Coupled Model Intercomparison Project (CMIP3). This study did not projections for economic growth and social development.

Zhou *et al.* (2008) estimated the transmission of schistosomiasis due to *S. japonicum* in China based on rising temperatures in 2030 and 2050. They concluded that an additional 784 thousand km^2 would become suitable for schistosomiasis transmission in China by 2050 (Figure 11-6).

[INSERT FIGURE 11-6 HERE
Figure 11-6: Projected risk map of schistosomiasis*(S. japonicum)* transmission in China in 2050. For comparison the current risk map in 2000. Green area denotes the range of schistosomiasis in 2000. The blue area shows the geographic expansion. Adapted from (Zhou *et al.*, 2008).]

Mangal et al. (2008) constructed a mechanistic model of the transmission cycle of another species, *S. mansoni* and reported a peak in the worm burden in humans at an ambient temperature of 30°C, falling sharply as temperature rises to 35°C. The authors attribute this to the increasing mortality of both the snails and the water-borne intermediate forms of the parasite, and noted that worm burden is not directly linked to the prevalence of schistosomiasis.

11.5.3. Air Quality

Nearly all the non-CO_2 climate-altering pollutants (CAPs – see Ch x of WGI) are health damaging, either directly or by contributing to secondary pollutants in the atmosphere. Thus, like the ocean acidification and ecosystem/ agriculture fertilization impacts of CO_2, the other CAPs have non-climate-mediated impacts, particularly on health. Although not reviewed in detail in this assessment, the health impacts of non-CO_2 CAPs are substantial globally. See Box 11-4.

_____ START BOX 11-4 HERE _____

Box 11-4. Health and Economic Impacts of Climate-Altering Pollutants (CAPs) Other than CO_2

Although other estimates of the global health impacts of human exposures to particle and ozone pollution have been done in recent years (e.g.(UNEP, 2011)), the most comprehensive was the Comparative Risk Assessment carried out as part of the Global Burden of Disease Project (Lim *et al*., 2012). It found that the combined health impact of the household exposures to particle air pollution from poor combustion of solid cooking fuels plus general ambient pollution was about 6.8 million premature deaths annually, with about half a million overlapping, i.e., coming from the contribution to general ambient pollution of household fuels. It also found that about 150 thousand premature deaths could be attributed to ambient ozone pollution. Put into DALY terms, particle air pollution was responsible for about 190 million lost DALYs in 2010, or about 7.6% of all DALYs lost. This burden puts particle air pollution among the largest risk factors globally, far higher than any other environmental risk and rivaling or exceeding all of the five dozen risk factors examined, including malnutrition, smoking, high blood pressure, and alcohol.

The economic impact of this burden is difficult to assess as evaluation methods vary dramatically in the literature. Most in the health field prefer to consider some version of a lost healthy life year as the best metric although the economics literature often uses willingness to pay for avoiding a lost life (Jamison *et al*., 2006). Another difficulty is that any valuation technique that weights the economic loss according to local incomes per capita will value health effects in rich countries more than in poor countries, which would seem to violate some of the premises of a global assessment; see WGIII, ch 3 for more discussion. Here, however, we will use the mean global income per capita (~ USD 10,000 in 2010) to scope out the scale of the impact globally without attempting to be specific by country or region.

The WHO CHOICE approach for evaluating what should be spent on health interventions indicates that one annual per capita income per DALY is a reasonable lower bound (World Health Organization, 2009b). This would imply that the total lost economic value from global climate-altering pollutants in the form of particles is roughly USD 1.9 trillion, in the sense that the world ought to be willing to pay this much to reduce it. This is about 2.7% of the global economy (approximately USD 70 trillion in 2010).

On the one hand, this shows that global atmospheric pollution already has a major impact on the health and economic well-being of humanity today, due mainly to the direct effects rather than those mediated through climate. If CO_2 is not controlled and climate change continues to intensify while air pollutant controls become more stringent, the climate impacts will become more prominent. The quite different time scales for the two types of impacts make comparisons difficult, however.

Unfortunately, the twin goals of protecting health and climate do not always lead to congruent actions. All particles are dangerous for health, but some are cooling, such as sulfates, and some warming, such as black carbon (Smith *et al*., 2009). Indeed, as indicated in WGI (Ch x), elimination of all anthropogenic particles in the atmosphere, a major success for health, would have only a minor net impact on climate. As discussed in the co-benefits section below (11.9), there are nevertheless specific actions that will work toward both goals.

_____ END BOX 11-4 HERE _____

Although there is a large literature on the health effects of particle air pollution (see Box 11-4), WGI indicates that there is little evidence that climate change, per se, will affect long-term particle levels in a consistent way. Thus, we

focus here on chronic ozone exposures, which are found in WGI (Ch x) to be enhanced in some scenarios of future climate change.

11.5.3.1. Long-Term Outdoor Ozone Exposures

Tropospheric ozone is formed through photochemical reactions that involve nitrogen oxides (NO_x), carbon monoxide (CO), methane (CH_4), and volatile organic compounds (VOCs) in the presence of sunlight and elevated temperatures (US EPA, 2007). Therefore, if temperatures rise, many air pollution models (Ebi and McGregor, 2008; Tsai *et al.*, 2008; Chang *et al.*, 2010; Polvani *et al.*, 2011) project increased ozone production especially within and surrounding urban areas (Hesterberg *et al.*, 2009). Even small increases in atmospheric concentrations of ground-level ozone may affect health (Bell *et al.*, 2006; Ebi and McGregor, 2008; Jerrett *et al.*, 2009). For instance, Bell et al. (2006) found that even levels that meet the US EPA 8-hour regulation (0.08 ppm over 8 hours) were associated with increased risk of premature mortality. There is a lack of association between ozone and premature mortality only at very low concentrations (from 0 to ~10 ppb) but the association becomes positive and approximately linear at higher concentrations (Bell *et al.*, 2006; Ebi and McGregor, 2008; Jerrett *et al.*, 2009). In an analysis of 66 United States cities with 18 years of follow-up (1982-2000), ozone was found to be significantly associated with cardiopulmonary mortality (Smith *et al.*, 2009). See also the global review by WHO, which includes data from developing countries (WHO 2006).

11.5.3.2. Acute Air Pollution Episodes

Wildfires, which may increase under climate change, release large amounts of particulate matter and other toxic substances that may affect larger numbers of people (Handmer *et al.*, 2012; Finlay *et al.*, 2012)**.** During a fire near Denver (USA) in June 2009, 1-hour concentrations of PM_{10} and $PM_{2.5}$ reached 370 $\mu g/m^3$ and 200 $\mu g/m^3$, and 24-hour average concentrations reached 91 $\mu g/m^3$ and 44 $\mu g/m^3$, compared to the 24-hour WHO air quality guidelines for these pollutants of 50 $\mu g/m^3$ and 25 $\mu g/m^3$, respectively (Vedal and Dutton, 2006).

One study of world-wide premature mortality attributable to air pollution from forest fires estimated there were 339,000 deaths per year (range 260,000 to 600,000) (Johnston *et al.*, 2012). The regions most affected are Sub-Saharan Africa and Southeast Asia (Johnston *et al.*, 2012).

Extremely high levels of PM_{10} were observed in Moscow due to forest fires caused by a heat wave in 2010. Daily mean temperatures in Moscow exceeded the respective long-term averages by 5°C or more for 45 days and 10 new temperature records were established in July and 9 in August, based on measurements since 1885, and an anti-cyclone in the Moscow region prevented dispersion of air pollutants. The highest 24-h pollution levels recorded in Moscow during these conditions were between 430 and 900 $\mu g/m^3$ PM10 most days, but occasionally reached 1500 $\mu g/m^3$. The highest 24-h CO concentration was 30 mg/m^3 compared to the WHO AQG of 7 $\mu g/m^3$, and the levels of formaldehyde, ethyl benzene, benzene, toluene and styrene were also increased (State Environmental Institution "Mosecomonitoring", 2010).

There is an interaction of ozone and heat waves as well. Dear et al. (2005) modeled the daily mortality on heat and ozone during the European summer heatwave of 2003 and found that possibly 50% of the deaths could have been associated with ozone exposure rather than the heat itself.

11.5.3.3. Aeroallergens

Allergic diseases are common and are climate-sensitive. Warmer conditions generally favour the production and release of air-borne allergens (such as fungi and lower plant spores and pollen) and, consequently, there may be an effect on asthma and other allergic respiratory diseases, such as asthma, allergic rhinitis, conjunctivitis and dermatitis (Beggs et al, 2010). Children are particularly susceptible to most allergic diseases (Schmier and Ebi, 2009). Increased release of allergens may be amplified if higher CO_2 levels stimulate plant growth. Visual

monitoring and experiments have shown that increases in air temperature cause earlier flowering of prairie tallgrass (Sherry *et al*., 2007). Droughts and high winds may produce windborne dust and other atmospheric materials, which contains pollen and spores, and transport these allergens to new regions.

Studies have shown that increasing concentrations of grass pollen lead to more frequent ambulance calls due to asthma symptoms, with a time lag of 3-5 days (Heguy *et al*., 2008). Pollen levels have also been linked to hospital visits with rhinitis symptoms (Breton *et al*., 2006). A cross-sectional study in the three climatic regions of Spain documented a positive correlation between the rate of child eczema and humidity, and negative correlation between child eczema and air temperature or the number of sunshine hours (Suarez-Varela *et al*., 2008).

11.5.3.4.Near-Term Future

It is projected by WGI that climate change could affect future air quality, including levels of photochemical oxidants and, with much less certainty, fine particles ($PM_{2.5}$). If this occurs there will be consequences for human health. (Bell *et al*., 2007; Dong *et al*., 2011; Chang *et al*., 2012; Lepeule *et al*., 2012; Meister *et al*., 2012). High temperatures may also magnify the effects of ozone (Ren *et al*., 2008; Jackson *et al*., 2010). Increasing urbanization, use of solid biomass fuels and industrial development in the absence of emission controls could also lead to increases in ozone chemical precursors (Selin *et al*., 2009; Wilkinson *et al*., 2009).

Most post-2006 studies on the projected impacts of future climate change on air pollution-related morbidity and mortality have focused on ozone (see Table 11-2; Bell *et al*., 2007; Selin *et al*., 2009; Tagaris *et al*., 2009). Most studies focus on Europe, the U.S. and Canada. Projections are rare for other areas of the world, notably the developing countries where air pollution is presently a serious problem and is expected to get worse.

[INSERT TABLE 11-2 HERE
Table 11-2: Projected future health impacts of climate change through air pollution.]

Higher temperatures may magnify the effects of air pollutants like ozone, although estimates of the size of this effect vary (Ren *et al*., 2008; Jackson *et al*., 2010). In general, all-cause mortality related to ozone is expected to increase in the US and Canada (Bell *et al*., 2007; Tagaris *et al*., 2009; Jackson *et al*., 2010; Cheng *et al*., 2011). Under a scenario in which present air quality legislation is rolled out everywhere, premature deaths due to ozone would be wound back in Africa, South Asia and East Asia. Under a maximum feasible CO_2 reduction scenario related to A2, it is projected that 460,000 premature ozone-related deaths could be avoided in 2030, mostly in South Asia (West *et al*., 2007).

A study that investigated regional air quality in the United States in 2050, using down-scaled climate model (Goddard Institute for Space Studies, Global Climate Model), concluded there would be about 4000 additional annual premature deaths due to increased exposures to $PM_{2.5}$ (Tagaris *et al*., 2009). Air pollutant-related mortality increases are also projected for Canada but in this case they are largely driven by the effects of ozone (Cheng *et al*., 2011)On the basis of the relation of asthma to air quality in the last decade (1999-2010), Thompson et al. (2012) anticipate that the prevalence of asthma in South Africa will increase substantially by 2050. Sheffield et al. (2011), applying the SRES A2 scenario, projected a median 7.3% increase in summer O_3-related asthma emergency department visits for children (0-17 years) across New York City by the 2020s compared to the 1990s.

11.6. Health Impacts Heavily Mediated through Human Institutions

11.6.1. Nutrition

At its most simple, nutrition can be considered as resulting from the interaction of three main elements: agricultural production (net of post-harvest wastes and storage losses), governance and human disease, especially those which affect appetite, nutrient absorption and catabolism (Black *et al*., 2008; Lloyd *et al*., 2011). Many of these factors are

influenced by climate. Malnutrition, referring to insufficient nutrient intake, is also related very closely to a temporary or long-term ability to pay for sufficient food, i.e., poverty.

11.6.1.1.Mechanisms

See Chapter 7 for a discussion of the impact of climate change on agricultural production.

The magnitude of detected decline in land-based agricultural production due to increasing temperatures and changes in rainfall is small compared to the increase in harvests due to improved farming knowledge and technology (Lobell *et al.*, 2011). It is also minor in comparison to the amount of food fed to livestock, used for biofuels, consumed beyond baseline needs by the overnourished and wasted in other ways (Foley *et al.*, 2011). Against this background, the global food price fluctuates, though with a recently rising trend. While the main driver is higher energy costs, amplified by speculation, (Piesse and Thirtle, 2009) there is growing speculation (Auffhammer, 2011) that extreme weather events, especially floods, droughts (Williams and Funk, 2011) and heatwaves have contributed to higher prices, which, all else being equal, will increase the number of malnourished people.

The modeling of past and future agro-climatic effects, even without considering their health impact, is a formidable challenge, and some argue the existing agro-climate models are excessively simple and biased toward the optimistic (Butler, 2010; Gornall *et al.*, 2010). Moreover, the strength of the carbon fertilization effect (CFE) may have been overstated (Long *et al.*, 2006; Leakey *et al.*, 2008). Higher concentrations of CO_2 may also enhance the growth of pests (Ziska *et al.*, 2009; Nelson *et al.*, 2009; Nelson *et al.*, 2010) and damage some crops, including cassava, a staple for about 750 million mostly poor people (Gleadow *et al.*, 2009). These effects to date are generally not incorporated into models.

11.6.1.2.Near-Term Future

Since AR4 four studies have been published which project the effect of climate change on food availability (undernourishment) and malnutrition (acute and chronic).[3] It is important to distinguish between undernourishment (hunger), caused by lack of food, and malnutrition which is due not only to food intake but to other factors (eg chronic infections).

[FOOTNOTE 3: In technical terms, these are called “wasting” (acute) and “stunting” chronic. The former is measured as deviations from the weight for height, the latter from weight for age.]

Ebi (2008) projected the climate-attributable numbers of malnourished children to 2030 and reported a 10% (4,673,000 cases) increase against the counterfactual of no climate change. Nelson et al. (2009; 2010) built a global agricultural supply and demand projection model (IMPACT 2009) and a crop simulation model (DSSAT) to estimate crop production, with and without CO_2 enrichment. The authors projected per capita calorie under climate models from NCAR and CSIRO (the world projected in the former is wetter and dryer). The authors estimate that there would be about 25 million additional malnourished children in 2050 with climate change (Nelson *et al.*, 2009), focusing on the effect of investment in agricultural productivity (see Table 11-3). In those parts of the world most affected by under- and mal-nutrition (Sub-Saharan Africa and the Middle East and North Africa), comprehensive investments in agriculture would reduce the anticipated impact of climate change, but not entirely.

[INSERT TABLE 11-3 HERE
Table 11-3: Number of malnourished children less than 5 years of age (in millions) in 2000 and under the NCAR climate model (using A2 scenario from AR4) till 2050. Assumptions for investment in agricultural productivity: + only in developing countries; ++ both in developing and developed countries. Results assume no CO_2 fertilization effects. Adapted from Nelson *et al.* (2009).]

Lloyd et al. (2011) built a model for estimating future undernourishment (too little food) and child malnutrition (stunting), under two climate change scenarios and a reference scenario without climate change. While the estimates

of undernourished children were based on food availability projections from Nelson et al. (2009), stunting was modeled using "food" and "non-food" causes. The increase in severe stunting attributable to climate change in 2050 ranged from 31% in central Sub-Saharan Africa to 62% in South Asia. The comparison was a world without climate change, in which the numbers of undernourished and stunted children fell. The authors concluded that climate change will hold back efforts to reduce child malnutrition in the most severely affected parts of the world, even with allowances for economic growth.

In a subsequent paper, Lloyd et al. (2011) estimated the number of malnutrition-attributable childhood deaths. The relationship between severity of stunting and mortality was drawn from Black et al. (2008). For 2030, their model projected 108,028 malnutrition-related childhood deaths from climate change (8.0% out of a total of 1,256,440 malnutrition-related deaths). For 2050, they estimated this number to be 96,460 out of 614,361 (15.7%). Hence, while the absolute number of children dying from malnutrition would fall by half between 2030 and 2050 due to social and economic development, the proportion attributable to climate change would double.

Grace et al (2012) modeled the relationship between climate variables (temperature and precipitation), food production and availability as well as child stunting in Kenya. The authors conclude that climate change will increase the proportion of small-for-age children in countries such as Kenya that are dependent on rain-fed agriculture, unless there are substantial investments in education and infrastructure.

In summary, we have high confidence that climate change will have a substantial negative impact on (i) per capita calorie availability, (ii) childhood malnutrition, particularly stunting and (iii) on malnutrition–related child deaths and DALYs lost (high agreement with medium evidence).

11.6.2. Occupational Health

Since the AR4 much has been written on the effects of heat on working people (Kjellstrom *et al*., 2009a; Dunne *et al*., 2013) and on other climate-related occupational health risks (Bennett and McMichael, 2010).

11.6.2.1. Heat Strain and Heat Stroke

The basic processes of human thermoregulation are well-understood (Parsons, 2003). If the body temperature goes beyond 38°C, performance may be impaired. Temperature above 39°C risks symptoms of "heat stroke": organ damage, loss of consciousness, and death. Pre-existing disease or malnutrition increases vulnerability. Experimental and field studies have documented the risks of excessive heat exposure (Ramsey and Bernard, 2000; Parsons, 2003) and detailed exposure response relationships were described long ago (Wyndham, 1969). Heat remains an occupational health issue even in a high-income country like the USA (Luginbuhl *et al*., 2008). Moreover, at higher temperatures there is potential conflict between health protection and economic productivity (Kjellstrom *et al*., 2011): as workers take longer rests to prevent heat stroke, hourly productivity goes down.

11.6.2.2. Heat Exhaustion and Work Capacity Loss

There are international standards of maximum recommended workplace heat exposure and hourly rest time (e.g. (ISO, 1989; Parsons, 2003)) for both acclimatized and non-acclimatized people. In hot countries during the hot season, large proportions of the workforce are affected by heat, and the economic impacts of reduced work capacity may be sufficient to jeopardize livelihoods (Lecocq and Shalizi, 2007; Kjellstrom *et al*., 2009a; Kjellstrom *et al*., 2011; Kjellstrom and Crowe, 2011). Kjellstrom et al. (Kjellstrom *et al*., 2009a; Kjellstrom and Crowe, 2011; Kjellstrom *et al*., 2011) and Dunne et al. (Dunne *et al*., 2013) estimate that loss of work productivity during the hottest and wettest seasons has already occurred, at least in Asia and Africa.

11.6.2.3. Other Occupational Health Concerns

Exposure to heat affects psychological performance (Hancock *et al.*, 2007) and increased risk of injuries (Ramsey, 1995). In areas where vector-borne diseases, such as malaria and dengue fever, are common, people working in fields without effective protection may experience a higher incidence of these diseases when climatic conditions favour mosquito breeding and biting (Bennett and McMichael, 2010). Increasing heat exposure in farm fields during the middle of the day may lead to more work during dawn and dusk when some of the vectors are biting humans more actively.

Another risk factor is increased chemical poisoning where solvents are used, because higher temperatures make the solvents evaporate faster and may lead to higher occupational exposures (Bennett and McMichael, 2010). In the Arctic, the part of the world that is now experiencing the fastest increase of temperatures, traditional hunting and fishing activities are affected by reduction in sea ice and there is a greater risk of drowning (Ford *et al.*, 2008).

11.6.2.4. Near-Term Future

Projections have been made of the future effects of heat on work capacity (Kjellstrom *et al.*, 2009b; Dunne *et al.*, 2013). Temperature and humidity were both included, and the modeling took into account the changes in the workforce distribution relating to the need for physical activity. In South East Asia in 2050 the model indicates that more than half the afternoon work hours will be lost due to the need for rest breaks (Kjellstrom *et al.*, 2013). By 2100, under RCP4.5 Dunne et al. (2013) project up to 20% loss of productivity globally. There is an unfortunate trade-off between health impact and productivity loss, which creates risks for poor and disenfranchised laborers working under difficult working conditions and inflexible rules (Kjellstrom *et al.*, 2009a; Kjellstrom *et al.*, 2011).

11.6.3. Mental Health

Mental illness, a major contributor to the global burden of disease, (Mathers and Loncar, 2006) leads to functional impairment and disordered behaviour in domains as diverse as crime, housing, employment, relationships, violence, education, physical health, substance use and health behaviours. Poor mental health is associated in general with lower levels of resilience, coping and adaptive capacity. Overwhelmed by repeated disasters, an increasing numbers of people may lose hope, as appears to happen with farmers facing severe drought (Berry *et al.*, 2011).

Manifestations of disaster-related psychiatric trauma include severe anxiety reactions (such as post-traumatic stress) and longer-term impacts such as generalised anxiety, depression, aggression and complex psychopathology (Ahern *et al.*, 2005). For slow-developing events such as prolonged droughts, impacts include chronic psychological distress and increased incidence of suicide (Hanigan *et al.*, 2012; O'Brien *et al.*, Under review)(Alston, 2008).

Harsher weather conditions increase the stress on those who are already mentally ill, worsening their condition and prognosis; and may create sufficient stress for some who are not yet ill to become so (Berry *et al.*, 2010b). Functional impairment means diminished population-level resilience, adaptive capacity and coping. There may be impacts on agricultural productivity, fishing, forestry, tourism, mining, subsistence farming and other economic endeavours reliant on the land. As more than half the world's population now lives in cities, disasters such as cyclones, heatwaves and major floods can easily stress or destroy infrastructure and take lives *en masse*, by affecting whole zones of cities. Here again, the vulnerable are most at risk: cities have zones of concentrated disadvantage (where mental disorders are disproportionately prevalent) (Berry, 2007) and these typically lie on the least advantageous land, land that is most prone to disaster (such as flood plains). Impacts on infrastructure and immediate loss of life, in turn, compromise local industries, businesses and households; and when these face extreme pressure, livelihoods, families and eventually whole communities can struggle to cope. Of particular importance, to the extent that deteriorating community functioning involves loss of social capital, mental health will be at risk because the presence of social capital is strongly protective for health, especially for mental health. (Berry *et al.*, 2010b).

The impacts of extreme weather events on mental health are broad-ranging: Major Depressive Disorder is the most common disorder, followed by Post-Traumatic Stress Disorder, other anxiety disorders and, mental distress. (Crabtree, 2012). A cyclone and flooding disaster in Queensland, in 2010-11 cost that Australian state US$7 billion in infrastructure repairs alone with consequences for livelihoods and health. Disadvantaged communities received the most damage to homes, businesses and incomes *and* reported higher rates of trauma-related impact per traumatic exposure than did less disadvantaged respondents (Clemens *et al.*, in preparation). That is, there was a linear dose-response effect for all victims but the response was significantly larger for disadvantaged communities. Two years later, another flood event affected that state before these same communities had recovered from the first.

In addition to indirect effects on mental health via the risk/disadvantage cycle, extreme weather events may adversely affect mental health *directly*, through immediate psychiatric trauma, heat impacts on certain classes of psychiatric medication), and a distressing sense of loss, known as 'solastalgia', that people experience when 'their' land is damaged (Albrecht *et al.*, 2007) and they lose amenity and opportunity.

11.6.4. Violence and Population Displacement

A study in Milwaukee, Wisconsin reported temperatures above 27.2°C were associated with increased accidents and self-harm (Li, T., Horton, R., Kinney,P., 2011). In Adelaide, South Australia, assault-related injuries among 15–64 year-olds increased significantly during heat waves (Nitschke *et al.*, 2007), and others have reported a relationship between high temperatures and increased risk of suicide. (Page *et al.*, 2007). Changes in behavior in times of extreme temperatures, however, may reduce the risks of some forms of injury. For example, in South Australia a significant decrease in automobile accidents was found during heat waves in the 75+ age group (Nitschke *et al.*, 2007).

Soil degradation, freshwater scarcity, population pressures and other forces that are related to climate are all potential causes of conflict. A study of internal conflict in African countries from 1981-2002 found a positive correlation between country-level temperature increases and probability of armed conflict and suggested that the effects of temperature change on agriculture might be a significant factor (Burke *et al.*, 2010). The relationships are not straightforward, however, as many factors influence conflict and violence. A study drawing on data from 1960-99, including more than 160 countries, found that poverty, low economic growth and high dependence on primary commodity exports were strongly associated with civil war, while ethnic and religious diversity as well as democracy were not (Collier and Hoeffler, 2004). The resultant ambiguity has recently led to more highly specified models that take account of variables such as social networks, indigenous knowledge and family cohesion that reduce vulnerability to climate disasters (Adger *et al.*, 2003). In Sub-Saharan Africa it has been reported climates that are more suitable for agriculture are associated with a lower risk of conflict (Hendrix and Glaser, 2007). Another study argues that environmentally induced migration can increase the risk of conflict, particularly in less-developed countries, and the risk is compounded by rapid population growth and limited migration opportunities (Reuveny, 2007).

Impacts of drought on human health also occur largely through indirect pathways; such as impacts on agriculture and population displacement (MacDonald, 2010; Kolmannskog, 2012).

Although the relationship between climate and armed conflict should not be overstated, in view of other social, cultural, political and economic factors that play a part, there is ample evidence that the depletion and altered distribution of natural resources may heighten the risk of violent conflict (Brauch, 2002; Oberthür *et al.*, 2002). Using data from 1950 to 2004 from the tropics, Solomon et al. (2010) found that the probability of new civil conflicts arising doubles during El Niño years relative to La Niña years. A study of a thousand years of violent conflict in Europe and various reconstructions of temperature and precipitation, found that conflict was exacerbated during cold periods that were associated with crop failures and food shortages (Tol and Wagner, 2010). Similar findings have been reported in China (Zhang *et al.*, 2006), and indeed the links between rapid climate change, starvation and civil disorder and collapse are apparent as far back as the first agricultural settlements roughly 10,000 years before the present (McMichael *et al.*, 2012).

11.7. Adaptation to Protect Health

Life expectancies and years of healthy life have increased considerably over the past century due to improvements in public health and health care strategies, policies, and measures, due to greater understanding of the complex factors driving adverse health conditions, as well as actions in other sectors, such as providing access to safe water and improved sanitation. In some situations, climate variability and change threatens continuing advances in reducing the burden of climate-sensitive health outcomes. The degree to which programs and measures will need modification to address any additional pressures from climate change will depend on factors such as the current burden of climate-sensitive health outcomes, the effectiveness of current interventions, projections of where, when, and how the health burden could change with climate change, the feasibility of implementing additional programs, other stressors that could increase or decrease resilience, and the social, economic, and political context for intervention (Ebi *et al*., 2006). The process of adaptation will be on-going adjustments to the degree and rate of climate change and other factors driving the incidence and geographic range of climate-sensitive health outcomes.

The scientific literature on adaptation to climate change has expanded since AR4, but investment in specific health protection activities is growing less rapidly. A review by the World Health Organization in 2012 estimated that commitments to health adaptation internationally amount to less than 1% of the annual health costs attributable to climate change in 2030 (World Health Organization, 2012).

The value of adaptation is demonstrated by the population health impacts of recent disasters associated with extreme weather and climate events. For example, more than 500,000 people died when cyclone Bhola (category 3 in severity) hit East Pakistan (present day Bangladesh) in 1970. In 1991, a cyclone of similar severity caused about 140,000 deaths. In November 2007, cyclone Sidr (category 4) resulted in 5-10,000 deaths even though the population had grown by more than 30 million in the intervening period (Mallick *et al*., 2005). Bangladesh achieved this remarkable reduction in mortality through effective collaborations between governmental and non-governmental organizations and local communities (Khan, 2008). Alongside improving general disaster education (greatly assisted by rising literacy rates, especially among women), the country deployed early warning systems and built a network of cyclone shelters. Early warning systems included both high technology information systems and relatively simple measures such as training volunteers who could distribute warning messages by bicycle.

Efforts to adapt to the health impacts of climate change can be categorized as incremental, transitional, and transformational actions (O'Brien *et al*., 2012). Incremental adaptation occurs when information on the risks of climate change is integrated into policies and measures, without changing underlying assumptions. This includes improving public health and health care services for climate-sensitive health outcomes, without necessarily considering the possible impacts of climate change. Transitional adaptation occurs with changes in underlying assumptions, including shifts in attitudes and perceptions. This includes vulnerability mapping, early warning systems, and other measures. Transformation occurs with changes in social and other structures that mediate the construction of risk.

11.7.1. Improving Basic Public Health and Health Care Services

Because the baseline health status of a population may be the single most important predictor of the future health impacts of climate change and the costs of adaptation (Pandey, 2010), reducing background rates of disease and injury is an important step to improving population resilience and minimizing poor health outcomes from climate change.

Most health adaptation is focusing on improvements in basic public health functions to reduce the current adaptation deficit, such as enhancing disease surveillance, monitoring risky exposures, and facilitating coordination between health and other sectors to address shifts in the incidence and geographic range of diseases (Woodward *et al*., 2011). An example is Lusaka, Zambia, where the incidence of cholera rises sharply following heavy rainfall, with lower risk in parts of the city with effective drainage networks (Sasaki *et al*., 2009).

Health care interventions may reduce harm caused by climate and other environmental stressors. As one example, following the introduction of vaccination programs in the United States, seasonal outbreaks of rotavirus, a common climate-sensitive pathogen, were delayed and diminished in magnitude (Tate *et al*., 2009). Post-disaster initiatives also are important. For example, an assessment of actions to improve the resilience of vulnerable populations to heatwaves recommended staff planning over the summer period, cooling of health care facilities, training of staff to recognize and treat heat strain, and monitoring of those in the highest risk population groups (World Health Organization Regional Office for Europe, 2009). Similarly, diabetes care was compromised following Hurricane Katrina in the United States by a lack of blood glucose testing kits, and insulin and other diabetes medications (Cefalu *et al*., 2006). Ensuring essential medical supplies for care of individuals with chronic conditions, including effective post-disaster distribution, would increase the ability of communities to manage large-scale floods and storms. Another example is in Benin, where one measure proposed as part of the national response to sea level rise and flooding is expanded health insurance arrangements, so that diseases such as malaria and enteric infections can be treated promptly and effectively (Dossou and Glehouenou-Dossou, 2007).

11.7.2. Health Adaptation Policies and Measures

Transitional adaptation moves beyond focusing on reducing the current adaptation deficit to designing into programs and measures considerations of how a changing climate could alter health burdens and the effectiveness of intervention actions. Ten "essential public health services" underpin coping with the health risks of climate change (Frumkin *et al*., 2008). For example, maintaining and improving food safety in the face of rising temperatures and rainfall extremes depends on effective interactions between human health and veterinary authorities, integrated monitoring of food-borne and animal diseases, and improved methods to detect pathogens and contaminants in food (Tirado *et al*., 2010). Indicators of community functioning and connectedness are relevant as well, because communities with high levels of social capital tend to be more successful in disseminating health and related messages, ensuring compliance with behavioural norms and providing support to those in need (Frumkin *et al*., 2008).

Vulnerability Mapping

Remote sensing technologies are now sufficiently fine-grained for mapping local vulnerability factors and can be used to guide interventions to reduce exposures and/or impacts. For example, these technologies can be used to map surface temperatures and urban heat island effects at the neighborhood scale, indicating where city greening and other urban cooling measures could be most effective, and alerting public health authorities to populations that may be at greatest risk of heatwaves (Luber and McGeehin, 2008). Mapping at regional and larger scales may be useful to guide adaptation actions. In Portugal, modeling of Lyme disease indicates that future conditions will be less favorable for disease transmission in the south, but more favorable in the center and northern parts of the country (Casimiro *et al*., 2006). This information can be used to modify surveillance programs before disease outbreaks occur. To capture a more complete picture of vulnerability, mapping exercises also should consideration of climate sensitivity and adaptation capacity, such as was done in an assessment of climate change and risk of poverty in Africa (Thornton *et al*., 2008).

11.7.3. Early Warning Systems

Early warning systems have been developed in many areas as a means of alerting public health authorities to climate-related health risks. Effective early warning systems take into consideration the wide range of factors that can drive risk.

Heatwave and health warning systems (HHWS) are designed to prevent negative health impacts. Components of an effective HHWS include forecasting weather conditions associated with increased morbidity or mortality, predicting possible health outcomes, identifying triggers of effective and timely response plans that target vulnerable populations, communicating heatwave and prevention responses, and evaluating and revising the system to increase

effectiveness in a changing climate (Lowe *et al.*, 2011). Of seven studies of the effectiveness of heatwave early warning systems to reduce heat-related mortality, six reported fewer deaths during heatwaves after implementation of the system (Palecki *et al.*, 2001; Weisskopf *et al.*, 2002; Ebi *et al.*, 2004; Tan *et al.*, 2007; Fouillet *et al.*, 2008; Chau *et al.*, 2009); only Morabito et al. (2012) was inconclusive. For example, in the summer of 2006, France experienced high temperatures similar to those experienced during the 2003 heatwave, with about 2000 excess deaths. This was more than 4000 less than was anticipated on the basis of the experience in 2003. A national assessment attributed the lower than expected death toll to greater public awareness of the health risks of heat, improved health care facilities, and the introduction in 2004 of a heatwave early warning system (Fouillet *et al.*, 2008). A review of the heatwave early warning systems in the twelve European countries with such plans concluded that evaluations of the effectiveness of these systems is urgently needed to inform good practices, particularly understanding which action increase resilience (Lowe *et al.*, 2011).

Early warning systems also have been developed using predictive models for vector-borne and food-borne infections. In Botswana, an early warning system forecasts malaria incidence up to 4 months in advance based on observed rainfall; inter-annual and seasonal variations in climate are associated with outbreaks of malaria in this part of Africa. Model outputs include probability distributions of disease risk and measures of the uncertainty associated with the forecasts (Thomson *et al.*, 2006). The incidence of several bacterial enteric infections varies with ambient temperature (Fleury *et al.*, 2006); this information has been used to develop health alerts based on projected temperatures. A study of campylobacteriosis in the United States developed models of monthly disease risk with a very good fit in validation data sets (R^2 up to 80%) (Weisent *et al.*, 2010).

11.7.4. Role of Other Sectors in Health Adaptation

Other sectors play an important part in protecting against disease and injury resulting from climate change. EuroHEAT, a European review of public health responses to extreme heat, identified transport policies building design, and urban land use as important elements of national and municipal heatwave and health action plans (World Health Organization Regional Office for Europe, 2009). A study examining well-established interventions to reduce the urban heat island effect (replacing bitumen and concrete with more heat-reflective surfaces, and introducing more green spaces to the city) estimated these would reduce heat-related emergency calls for medical assistance by almost 50% (Silva *et al.*, 2010). Urban green spaces lower ambient temperatures, improve air quality, provide shade, and may be good for mental health (van den Berg *et al.*, 2010). However, the extent to which changes in these factors reduce heatwave-related morbidity and mortality depend on location. A study in London, UK, found that built form and other dwelling characteristics more strongly influenced indoor temperatures during heatwaves than the urban health island effect (Oikonomou and Wilkinson, 2012).

A review of food aid programs indicates that a rapid response to the risk of child under-nutrition, targeted to those in greatest need, with flexible financing and the capacity to rapidly scale-up depending on need, may reduce damaging health consequences (Alderman, 2010).

Community programs designed for other purposes can facilitate adaptation. In the Philippines, for example, interventions in low-income urban settings include savings schemes, small-scale loans, hygiene education, local control and maintenance of water supplies, and neighborhood level solid waste management strategies (Dodman *et al.*, 2010). All these have the potential to reduce the harmful effects of climate extremes on health.

Migration

Migration is a common coping strategy in the face of adverse changes in climate, and may itself have significant effects on health, positive and negative (McMichael *et al.*, 2012)(McMichael et al., 2010). Within the Pacific, there has been migration from outer islands to urban centers, partially due to environmental pressures, improving economic and educational opportunities for some. But there is a cost in infectious diseases and other health problems caused by crowding associated with a lack of adequate water supplies, waste disposal, and housing (Locke, 2009). Large numbers of Pacific islanders have also moved to countries around the Pacific rim and

comparisons of the health of migrants and peers in the islands show mixed effects (higher levels of risk factors such as raised blood pressure and cigarette smoking among migrants, but also lower mortality rates overall and higher life expectancies). Climate-related migration includes the movements of population between countries, and within country shifts, such as flows to cities from drought and heat-affected rural areas (Acosta-Michlik *et al*., 2008). Where people choose to live reflects a complex balance of risks and benefits. Where large numbers of people are forced to migrate at the same time, there may be considerable social, cultural, economic and health implications for receiving communities, particularly where these peoples may be traumatised (McMichael *et al*., 2012). A study in Indore in India found that low-income households were willing to live in flood-prone areas because of other advantages provided by these sites, including access to health care and low-cost housing (United Nations Human Settlements Programme, 2011).

11.8. Limits to Adaptation: Low-Probability Extreme Climates

Most attempts to quantify health burdens associated with future climate change consider relatively short time horizons (e.g. 2030 or 2050) and modest increases in global average temperature, typically less than 2 degrees Celsius during the time frame considered. Because of the longevity of some greenhouse gases in the atmosphere and inertia of the climate system, emissions today will, however, contribute to warming far beyond 2050. Moreover, research published since AR4 raises doubt over whether it will be possible to limit global warming to 2°C above pre-industrial temperatures (Rogelj *et al*., 2009; Anderson and Bows, 2011; PriceWaterhouseCoopers, 2012). Therefore it is important to examine the likely consequences of warming beyond 2 degrees, what we have called high-end warming scenarios (New *et al*. 2011).

It can be assumed that the increase in many important climate-related health impacts at increasingly higher levels of warming will be greater than simple linear increments; that is, that the health consequences of a 4°C temperature increase will be more than twice those of a +2°C world (see Figure 11-7). Nonlinear and threshold effects have been observed in the mortality response to extreme heat (Anderson and Bell, 2011; McMichael, In Press), agricultural crop yields, as key determinants of childhood nutrition and development (Schlenker and Roberts, 2009; Lobell *et al*., 2011), and infectious diseases (Altizer *et al*., 2006), for example. These are briefly elaborated here.

[INSERT FIGURE 11-7 HERE
Figure 11-7: Extreme warming by 2100 from RCP8.5. Mean temperatures above levels around 2000. Note higher effects over land. Source: WGI AR5 _____.]

11.8.1. Exceeding Adaptation Limits in High-End Warming Scenarios

The prospect of rapid and extreme levels of warming raises questions about the biological limitations to human adaptability. As discussed above, when the surrounding environment exceeds body temperature at high humidity, the body has limited capacity to lose excess heat, and over time the core temperature will rise with, eventually, fatal consequence.

Sherwood and Huber (2010) argue that humans cannot tolerate sustained periods of wet-bulb temperatures above 35°C. They conclude that a global mean warming of roughly 7°C above current temperatures would create small land areas where metabolic heat dissipation would become impossible. An increase of 11-12°C would enlarge these zones to encompass most of today's human population. While transformative adaptation measures such as underground settlements or "bubble cities" might make such conditions habitable for humans, present ways of life would become impossible.

Working conditions are hazardous at lower thresholds. The U.S. military, for example, suspends all physical training and strenuous exercise when the wet bulb globe temperature (WBGT) exceeds 32°C (Willett and Sherwood, 2012) while international labor standards suggest the time acclimatized individuals spend doing low intensity labor such as office work be halved under such conditions (Kjellstrom *et al*., 2009a). (WBGT is a heat index closely related to the wet-bulb temperature that also incorporates measures of radiant heat from the sun and evaporative cooling due to

wind.) Assuming no adaptation and a transition in the labor force from agricultural to more service and industrial occupations, Kjellstrom *et al*. (2009b) estimate that global mean warming of 3.4°C above preindustrial temperatures will lead to losses in labor productivity of 11-27% in Andean and Central America, Southeast Asia and the Caribbean. Dunne *et al*. (2013) estimate losses to global labor productivity under a similar degree of warming in an analysis that fixes the population distribution to that of 2010 and does not consider changes in the labor force. They estimate that, under the RCP 8.5 scenario in which carbon dioxide concentrations continue to rise through 2200, global labor productivity will be reduced during the hottest months to 60% in 2100 and less than 40% in 2200.

Maloney and Forbes (Maloney and Forbes, 2011) use two heat balance models to examine the potential constraints heat will place on human activity in Perth, Australia in 2070. The authors consider a business-as-usual emissions scenario in which mean *regional* temperature increases by 6°C and assume temperature variability, relative humidity and wind speed mirror current conditions. They estimate that the number of days when heat balance will not be possible while undertaking moderate activity is estimated to increase from less than one to 11-23 days per year for acclimatized individuals, and from 13-14 to 56-60 days per year for unacclimatized individuals (ranges reflect the estimates derived from the two models). Heat stroke, an uncontrolled rise in core body temperature, would ensue in less than two hours for those performing physical labor on 15-26 days out of the year for acclimatized and 67-68 days out of the year for unacclimatized individuals, relative to 1-2 and 17-18 days out of the year at present.

Willett and Sherwood (2012) estimate future changes in summertime WBGT across 15 geographic regions. With regional warming of 5°C and assuming constant relative humidity, extreme prolonged heat events during which the 5-day average maximum WBGT is 35°C or higher are predicted to occur for over 90% of the summer in India, Northern Australia, Southeastern USA and the Caribbean, compared to current rates between 20-35%. It is projected that tropical and mid-latitude regions will be particularly badly affected, even though they will be warming less than the global average, due to greater increases in absolute humidity. Although the authors do not attempt to model the health impacts of such prolonged extreme heat, unprotected outdoor labor during the daytime in these conditions would be perilous for most of the summer.

11.8.2. Agricultural Limitations and Human Nutrition

Agricultural crops similarly have physiological limitations in terms of thermal and water stress. Analysis of six decades of late-spring barley yields in the Czech Republic show a strong and symmetrical inverted U-shaped relationship to rainfall and to temperature (Brázdil *et al*., 2009). Beyond the climate tolerance range, yields decline rapidly with too much or too little heat or soil moisture. However, current models to estimate the human health consequences of climate-impaired food yields at higher global temperatures are essentially linear (Lloyd *et al*., 2011; Lake *et al*., 2012), reflecting uncertainties about non-linear parameter values, future extreme events and climatic thresholds for other influences such as infestations and plant diseases.

Experimental field studies by the International Rice Research Institute have estimated that rice yields decline by about 10% for each 1°C rise in overnight temperature during flowering (Peng *et al*., 2004). Rice seed set is impaired at air temperatures above about 35°C (Yoshida *et al*., 1981), although there is the potential to breed more heat tolerant cultivars (Matsui *et al*., 2001; Jagadish *et al*., 2010). Corn fails to germinate at about 40°C (Blacklow, 1972; Birch *et al*., 1998). The lethal temperature for wheat appears to be about 47.5°C, while key phenological stages such as sowing to emergence and grain-filling have lower maximum temperature thresholds of 32.7°C and 35.4°C, respectively (Porter and Gawith, 1999; Porter and Semenov, 2005). For more information see Chapter 7, and recent reviews such as Texeira et al. (Teixeira *et al*., 2011). Water insufficiency is likely to constrain agriculture under extreme warming in some regions. For example, failures of rain-fed crops due to lack of available water are predicted to occur once every two years in much of southern Africa with a 5°C global average temperature increase (Thornton *et al*., 2011).

11.8.3. Infectious Disease Patterns under Extreme Warming

Substantial warming (above the global average) in higher-latitude regions will open up new terrain for some infectious diseases that are limited at present by low temperature boundaries. The northwards extensions in Canada and Scandinavia of tick populations, the vectors for Lyme disease and tick-borne encephalitis respectively, provide a foretaste of how this can happen (Lindgren and Gustafson, 2001; Ogden *et al*., 2006).

On the other hand, the emergence of new temperature regimes that exceed optimal conditions for vector and host species will reduce the potential for infectious disease transmission and, with high enough temperature rise, may eventually eliminate some infectious diseases that exist at present close to their upper tolerable temperature limits. For example, adults of two malaria-transmitting mosquito species are unable to survive temperatures much above 40°C in laboratory experiments (Lyons *et al*., 2012), although in the external world they may seek out tolerable microclimates. Reproduction of the malaria parasite within the mosquito is impaired at lesser raised temperatures (Paaijmans *et al*., 2009). Larval development of *Aedes albopictus,* an Asian mosquito vector of dengue and chikungunya, also does not occur at or above 40°C (Delatte *et al*., 2009).

11.8.4. Health Consequences of Displacement, Migration, and Social Conflict

More human migration can be expected under extreme levels of warming as adaptive capacity becomes overwhelmed by the impacts of climate change in more regions. Gemenne (2011) argues that the most significant difference between the nature of human migration in response to 4°C of warming relative to 2°C would be to remove many people's ability to choose whether to stay or leave when confronted with environmental changes. Health studies of refugees, migrants, and people in resettlement schemes suggests that forced displacement, in turn, is likely to lead to more adverse health impacts than voluntary migration or planned resettlement (McMichael *et al*., 2012).

Water scarcity is predicted to increase as a result of climate change in large portions of Africa, South Asia and the Americas (Fung *et al*., 2011). Modeling by Fung *et al*. (2011) suggests that while population growth will be the primary determinant of water scarcity in a +2°C world, in a +4°C scenario climate change will become the more important driver. It is prudent to assume such climate-induced water scarcity will lead to social and geopolitical tensions that may result in conflict, violence and displacement.

11.8.5. Reliance on Infrastructure

Under severe climate regimes, societies may be able to protect themselves with an increases prevalence of enclosed living and working environments, first for their most vulnerable members: the young, old, ill, and manual laborers. Reliance on the needed infrastructure, however, also entails increased vulnerability to unreliability of electricity and water supplies. What once was an inconvenience can become a serious health hazard if many people rely on such protection (Anderson and Bell, 2012).

11.9. Co-Benefits

Essentially every human activity affects (and is affected by) climate and health status in some way, but not all are strongly linked to either and even fewer strongly to both. Here we focus on the latter, i.e., measures to mitigate the atmospheric concentration of warming CAPs (climate altering pollutants) that also hold the potential to significantly benefit human health (Haines *et al*., 2007; Apsimon *et al*., 2009; Smith and Balakrishnan, 2009; UNEP, 2011; Shindell *et al*., 2012).The literature on health co-benefits associated with climate change mitigation strategies falls into five categories (Smith *et al*., 2009; Smith and Balakrishnan, 2009): Those that also (1) Reduce emissions of health-damaging pollutants, either primary or precursors to other pollutants; (2) Increase access to reproductive health services; (3) Decrease ruminant meat consumption; (4) Increase active transport from modifications to the built environment; (5) Increase in urban green-space. In addition, there are side effects of mitigation measures, such

as geoengineering, for example, that are potentially deleterious for human health, and these are addressed in WGIII, chapter x. In Table 11-4, we summarize what is known about the five categories, and below provide some additional detail for the first two.

[INSERT TABLE 11-4 HERE
Table 11-4: Summary of recent research on co-benefits of climate change mitigation. See text for details on the first two categories.]

11.9.1. Reduction of Co-Pollutants

Most of the publications related to CAPs and health-damaging pollutants refer to fuel combustion and fall into two major categories: 1) improvement in energy efficiency will reduce emissions of CO_2 and health-damaging pollutants if the energy is derived from combustion of fossil fuels or non-renewable biomass fuels, either directly or through the electric power system; in addition, 2) increases of combustion efficiency (decreasing emission of incomplete combustion products) will have both climate and health benefits, even if there is no change in energy efficiency and/or fuel itself is renewable, i.e. carbon neutral. This is because a number of the products of incomplete combustion are climate altering and nearly all are damaging to health (Smith and Balakrishnan, 2009).

Studies of the health co-benefits of reduction in air pollutants include sources that produce outdoor air pollution (Bell *et al*., 2008a) and household sources (Po *et al*., 2011). In many parts of the world, household fuel (poorly combusted biomass and coal) is responsible for a substantial percent of primary outdoor fine particle pollution as well, perhaps a sixth to a quarter in China and India, for example (Chafe *et al*., (Submitted)) indicating that reductions in emissions from household sources could yield co-benefits through the outdoor pollution pathway as well.

Another category of air pollution co-benefits comes from controls for methane emissions that both reduce radiative forcing and potentially reduces human exposures to ambient ozone, for which methane is a precursor.

11.9.1.1. Outdoor Sources

Primary co-pollutants, such as particulate matter (PM) and carbon monoxide (CO) are those released at the point of combustion, while secondary co-pollutants, such as tropospheric ozone and sulphate particles, are formed downwind from the combustion source via atmospheric chemical interactions (Jerrett *et al*., 2009). As noted in Section 11.2, outdoors, the production and distribution of some secondary co-pollutants is exacerbated by temperature-associated attributes of climate change itself, thus posing a positive feedback effect.

The burden of disease from outdoor exposures in a country may often be greater in populations with low socioeconomic status, both because of living in areas with higher exposures and because these populations often have worse health and are subjected to multiple additional negative environmental and social exposures (Morello-Frosch *et al*., 2011).

11.9.1.2. Household Sources

Globally, the largest exposures from the pollutants from poor fuel combustion occur in the poorest populations. This is because household use of biomass for cooking is distributed nearly inversely with income. Essentially, no poor family can afford gas or electricity for cooking and very few families who can afford to do so, do not. Thus, the approximate 41% of all world households using solid fuels for cooking are all among the poor in developing countries (Bonjour *et al*., forthcoming in 2013).

11.9.1.3. Primary Co-Pollutants

Outdoor exposure to PM, especially to particles with diameters less than 2.5 μm ($PM_{2.5}$), contributes significantly to ill-health including cardio- and cerebrovascular disease, chronic and acute respiratory illnesses, lung cancer, and possibly other diseases. The Comparative Risk Assessment (CRA) for outdoor air pollution done as part of the Global Burden of Disease (GBD) 2010 Project found approximately 3.2 million premature deaths globally from ambient particle pollution or about 3% of the global burden of disease (Lim *et al.*, 2012). Importantly, reductions in ambient PM concentrations have also been shown to decrease morbidity and premature mortality (Boldo *et al.*, 2010). A significant portion of ambient particle pollution derives from fuel combustion, perhaps 80% globally (GEA, 2012).

Because of higher exposures, an additional set of diseases has been associated with combustion products in households burning biomass and/or coal for cooking and heating. Thus, in addition to the diseases noted above, cataracts, low birth weight, and stillbirth have been associated strongly with exposures to incomplete combustion products, such as PM and CO. CO has impacts on unborn children in utero through exposures to their pregnant mothers (World Health Organization Regional Office for Europe, 2010). There is also growing evidence of exacerbation of tuberculosis (Pokhrel *et al.*, 2010) in adults and cognitive effects in children (Dix-Cooper *et al.*, 2012). The CRA of the GBD-2010 found 3.5 million premature deaths annually from household air pollution derived from cooking fuels or 4.4% of the global burden of disease (Lim *et al.*, 2012). Importantly, there are also studies showing health benefits of household interventions, including child pneumonia (Smith *et al.*, 2011), blood pressure (McCracken *et al.*, 2007; Baumgartner *et al.*, 2011), lung cancer (Lan *et al.*, 2002), and chronic obstructive pulmonary disease (Chapman *et al.*, 2005). Another half a million premature deaths are attributed to household cookfuel's contribution to outdoor air pollution, making a total of about 4 million in 2010 or 4.9% of the global burden of disease (Lim *et al.*, 2012).

Black carbon (BC), a primary product of incomplete combustion, is both a strong CAP and health-damaging (IPCC, 2007; Ramanathan and Carmichael, 2008; Bond *et al.*, 2013). A systematic review, meta-analysis, and the largest cohort study to date of the health effects of BC found that there were probably stronger effects on mortality from exposure to BC than for undifferentiated fine particles ($PM_{2.5}$) (Smith *et al.*, 2009). The conclusion is that BC abatement represents an opportunity to achieve both climate mitigation and health benefits, a conclusion shared by other recent reviews as well (UNEP, 2011).

Other co-pollutants with CO_2 from fuel use are carbon monoxide, non-methane hydrocarbons, and sulfur and nitrogen oxides. Each of these poses risks as well as being climate altering in different ways. See WGI for their climate potential and WHO reviews of health impacts (World Health Organization Regional Office for Europe, 2010)(WHO, 2006).

11.9.1.4. Secondary Co-Pollutants

In addition to being a strong CAP, methane (CH_4) is also a significant precursor to regional anthropogenic tropospheric ozone production, which itself is a CAP. Thus, reductions in CH_4 could lead to reductions in ambient tropospheric ozone concentrations, which in turn could result in reductions in population morbidity and premature mortality and climate forcing.

One study found that a reduction of global anthropogenic CH_4 emissions by 20% beginning in 2010 could decrease the average daily maximum 8-h surface ozone by 1 ppb by volume, globally; sufficient to prevent 30,000 premature all-cause mortalities globally in 2030, and 370,000 between 2010 and 2030. (West *et al.*, 2006) CH_4 emissions are generally accepted as the primary anthropogenic source of tropospheric ozone concentrations above other human-caused emissions of ozone precursors (West *et al.*, 2007) and thus, the indirect health co-benefits of CH_4 reductions are epidemiologically significant. On the other hand, the CRA of the GBD-2010 estimated 150,000 premature deaths from all ozone exposures globally in 2010, indicating a more conservative interpretation of the evidence for mortality from ozone (Lim *et al.*, 2012).

In an analysis of ozone trends from 1998-2008 in the United States, Lefohn et al. (Lefohn *et al.*, 2010) found that 1-hour and 8-hour ambient ozone averages have either decreased or failed to increase due to successful regulations of ozone precursors, predominantly NO_x and CH_4 (Lefohn *et al.*, 2010). This is consistent with the US EPA (US EPA, 2010) conclusion that in the US, for the period 1980-2008, emissions of nitrogen oxides and volatile organic compounds fell by 40% and 47%, respectively (US EPA, 2010; Lefohn *et al.*, 2010). These results point to the effectiveness of reducing ambient ozone concentrations through regulatory tools that reduce the emissions of ozone precursors, some of which, like CH_4, are GHGs.

Not every CAP emitted from fuel combustion is warming. The most prominent example is sulfur dioxide emitted from fossil fuel combustion, which changes to particle sulfate in the atmosphere. Although health damaging, sulfate particle have a cooling effect on global radiative forcing. Thus, reduction of sulfur emissions, which is important for health protection, does not qualify as a co-benefit activity since it actually acts to unmask more of the warming effect of other CAP emissions (Smith *et al.*, 2009). See also WGI, Ch. x.

11.9.1.5. Case Studies of Co-Benefits of Air Pollution Reductions

A recent UNEP- and WMO-led study of black carbon and tropospheric ozone found that, if all of 400 proposed BC and CH_4 mitigation measures were implemented on a global scale, the estimated benefits to health would come predominately from reducing $PM_{2.5}$ (0.7 – 4.6 million avoided premature deaths; 5.3 – 37.4 million avoided years of life lost) compared to tropospheric ozone (0.04 – 0.52 million avoided premature deaths; 0.35 – 4.7 million avoided years of life lost) based on 2030 population figures (UNEP, 2011). About 98% of the avoided deaths would come from reducing $PM_{2.5}$, with 80% of the estimated health benefits occurring in Asia (Anenberg *et al.*, 2012).

A study of the benefits of a hypothetical 10-year program to introduce advanced combustion cookstoves in India found that in addition to reducing premature mortality by about 2 million and DALYs by 55 million over that period, there would be reduction of 0.5-1.0 billion tons CO_2-eq (Wilkinson *et al.*, 2009).

In their estimation of effects of hypothetical physical and behavioral modifications in UK housing, Wilkinson and colleagues (Wilkinson *et al.*, 2009) found that the magnitude and direction of implications for health depended heavily on the details of the intervention. However, the interventions were found to be generally positive for health. In a strategy of housing modification that included combined fabric, ventilation, and fuel switching, along with behavioral changes, it was estimated that 850 fewer DALYs, and a savings of 0.6 megatonnes of CO_2 per million population in one year could be achieved. These calculations were made by comparing the health of the 2010 population with and without the specified physical and behavioral modifications (Wilkinson *et al.*, 2009).

Markandya *et al.* (2009) assessed the changes in emissions of $PM_{2.5}$ and subsequent effects on population health that could result from climate change mitigation measures aimed to reduce GHG emissions by 50% by 2050 (compared with 1990 emissions) from the electricity generation sector in the EU, China, and India (Markandya *et al.*, 2009). In all three regions, changes in modes of production of electricity to reduce CO_2 emissions were found to reduce $PM_{2.5}$ and associated mortality. The greatest effect was found in India and the smallest in the EU. The analysis also found that health benefits greatly offset the cost of GHG emission reductions, especially in the Indian context where emissions are high but costs of implementing the measures are low (Markandya *et al.*, 2009).

11.9.2. Access to Reproductive Health Services

Population growth is another factor involved in the consumption of resources and emissions of CAPs. Although population growth rates and total population size do not alone determine emissions (WG1), population size is an important factor. One study showed that CO_2 emissions could be lower by 30% by 2100 if access to contraception was provided to those women expressing a need for it (O'Neill *et al.*, 2010). Providing the unmet need for these services in aresa such as the Sahel region of Africa with both high fertility and high vulnerabity to climate change can potentially significantly reduce human suffering as climate change proceeds (Potts and Henderson, 2012). This is important not only in poor countries, however, but also rich ones like the US, where there is unmet need for

services as well as high CO_2 emissions per capita. Slowing population growth through lowering fertility, as might be achieved by increasing access to family planning has been associated with improved maternal and child health in two main ways: increased birth spacing and reducing births by very young and old mothers.

11.9.2.1. Birth and Pregnancy Intervals

Current evidence supports, with medium confidence, that short birth intervals (defined as birth intervals between <19 and <25 months and inter-pregnancy intervals <6 months) are associated with increased risks of uterine rupture and bleeding (placental abruption and placenta previa) (Bujold *et al*., 2002; Conde-Agudelo *et al*., 2007). There is also a correlation between short birth interval and elevated risk of low-birth-weight: Zhu et al. (Zhu, 2005) found, in a review of three studies performed in the United States that a J-shaped relationship existed between inter-pregnancy spacing in that the lowest risk of adverse birth outcomes (i.e., low birth weight, existed between 18-23 months and risk increased as it departed, in either direction (Zhu, 2005).

Although an ecological analysis, a review across 17 countries shows a strikingly coherent picture of the relationship between birth spacing (as preceding birth intervals), malnutrition, and reductions in child, infant and neonatal mortality (Figure 11-8) with risk of child malnutrition and mortality both increasing with shorter birth intervals (Rutstein, 2005). One study estimated that shifting birth spacing from current patterns in the world to a minimum of 24 months would reduce by 20% (~2 million) the current excess child mortality in the world (Rutstein, 2005; Gribble *et al*., 2009).

[INSERT FIGURE 11-8 HERE
Figure 11-8: Reduction in child (under 5 years) mortality due to increasing spacing of birth (Previous Birth Interval) based on studies in 17 countries. Source: Rutstein (2005).]

11.9.2.2. Maternal Age at Birth

Risk of death during delivery is highest in very young and very old mothers, which are also the age groups most wishing to control their fertility (Engelman, 2010). Women who begin child bearing under the age of 20 years are at an increased risk of developing pregnancy complications such as cephalopelvic disproportion, obstructed labor, preterm delivery, toxemia, bleeding, and maternal death (Tsui *et al*., 2007). Additionally, children born to women under the age of 20 are at increased risk of fetal growth retardation and low birth weight, which can both lead to long term physical and mental developmental problems (Tsui *et al*., 2007). Childbearing at later ages (>35 years) is associated with increased risks for the child of miscarriage, perinatal mortality, preterm birth, low birth weight, congenital and chromosomal abnormalities, and increased risks for the mother of placental previa, gestational diabetes, cesarean delivery and maternal death (Cleary-Goldman *et al*., 2005; Ujah *et al*., 2005).

Thus, providing access to family planning saves women's lives by reducing the total number of births and, in particular, through the reduction of births in high-risk groups (Prata, 2009). Studies have found that when women have access to family planning, it is the highest risk age groups (youngest and oldest women) who reduce their fertility most, in other words, family planning has a differential impact on maternal mortality reduction through reducing births in the highest risk groups (Diamond-Smith and Potts, 2011).

11.10. Conclusions

11.10.1. It is certain that a range of human diseases are sensitive to climate conditions, but the health impacts of these diseases are also affected by many other changing factors, making it currently difficult to quantify precisely the influence of climate change itself on present-day patterns of disease globally.

11.10.2. Much reduction of health impacts from climate change can be avoided through provision of basic health improvements to world's poor populations.

11.10.3. Much additional reduction can come from targeted adaptation efforts, such as early warning systems and good disaster management.

11.10.4. The world is not progressing rapidly with these advances, however, leading to a likely increasing net health impact from climate change in next decades.

11.10.5. There are residual health impacts that cannot be handled through adaptation in any reasonable way particularly if climate change proceeds to extreme conditions.

11.10.6. Well-chosen adaptation and mitigation measures may achieve substantial health gains (co-benefits), in the short- to medium-term.

11.11. Key Uncertainties and Research Recommendations

The key uncertainty for estimating health impacts from climate change over the next few decades is the extent that society will provide basic public health services, disaster warning and response systems, and poverty alleviation throughout the world. With a strong response, climate change health effects will be relatively small, but otherwise climate-attributable cases of disease and injury will steadily increase. Research is needed into exactly how interventions should be implemented to optimally improve health in the short-term, and lower the health threat of climate change. Another question that warrants attention is the best ways to motivate local, national, and international actions to greatly reduce servere poverty, and improve health services and disaster warning/response systems. More work needs to be done as well to evaluate the effects and costs of health adaptation policies and interventions.

There is a lack of robust analytical methods to untangle complex climate–health relationships such as the effect of more extreme weather on water and sanitation provision and diarrhoea rates (WHO/DFID, 2010). Risk assessment frameworks are needed that not only make the best use of traditional epidemiologic methods but also take into account the specific characteristics of climate change. These include the long-term and uncertain nature of the exposure and the effects on multiple physical and biotic systems that have the potential for diverse and widespread effects, including high-impact events.

In the longer term, there are plausible scenarios for rather extreme climate regimes by the end of the century or before, on pathways that are committed to even more extreme climates in the following century. It is difficult to do research directly on the effect of conditions that do not exist yet at any scale. Nevertheless, trying to understand the health impacts of these lower probability but severe future climates that could potentially affect the lives of nearly every baby born from today onwards given global life expectancies should have high priority. This understanding can help society understand how valuable actions today are to both mitigate and be ready for such conditions.

Frequently Asked Questions

FAQ 11.1: How is climate change thought to affect human health?
There are three major routes by which climate change is thought to affect health 1) by direct impacts, such as heat stress and floods; 2) by indirect impacts mediated through the natural environment, such as shifts in patterns of disease-carrying mosquitoes and waterborne diseases; and 3) indirect impacts mediated through societal systems, such as damage to health care systems by extreme weather events, malnutrition and mental illness from altered agricultural production, and stress and malnutrition from population displacement due to sea-level rise.

FAQ 11.2: Will climate change have benefits for health?
Yes, some populations in temperate areas may be at less risk from extreme cold and some populations may benefit from greater agricultural productivity and lower levels of vector-borne disease, but the overall impact for nearly all populations and for the world as a whole is expected to be much more negative than beneficial.

FAQ 11.3: Who is most affected by climate change?

As climate change mainly acts to exacerbate existing disease patterns and for the next decades will not probably not create significant new ones, those populations already under stress from disease will be most affected. Thus, most assessments indicate that it is poor and disenfranchised groups everywhere that will bear the most risk and, globally, the greatest burden will fall on poor countries, particularly on poor children, who are most affected today by such climate-related diseases as malaria, malnutrition, and diarrhea.

FAQ 11.4: What is the most important adaptation strategy to reduce the health impacts of climate change?

Accelerating current public health and medical interventions directed toward reducing existing disease in the world, particularly for climate-related diseases in poor countries, is the single most important step that can be taken to reduce the health impacts of climate change. Reducing poverty is the next most important for health globally.

FAQ 11.5: What are health "co-benefits" of climate change mitigation measures?

A number of mitigation measures to reduce emissions of climate-altering pollutants (CAPs) seem to have important direct health benefits in addition to reducing the risk of climate change, a relationship called "co-benefits." For example, increasing energy efficiency reduces health-damaging air pollution from fuel combustion; reducing ruminant meat consumption in many populations reduces both CAPs and the risk of chronic disease such as cancer; increasing the opportunities and attractiveness of active transport (walking and cycling) in place of travel by motor vehicle reduces air pollution and improves health directly; and providing access to reproductive health services slows population and energy demand growth and reduces risks of child and maternal mortality.

[1] All diseases included show some seasonality of occurrence
S – no specific climate drivers reported
[2]Effects are *Anopheles* spp
[3] Location specific
[4] Seasonal peaks changed following vaccination

Table 11-2: Projected future health impacts of climate change through air pollution.

Location	Health impact	Models used		Climate scenario	Key assumptions	Outcome	Reference
United States	Ozone-related morbidity and mortality	Multipollutant, multiscale air quality from Community Multiscale Air Quality (CMAQ) Modeling System	GISS-GCM driven by A1B SRES emissions scenario for the period 1950-2055 and downscaled to a 36-km resolution using Mesoscale Meteorological model version 5 (MM5)	Global temperature increase of 1.59°C in 2050, compared to 1990s	Population held constant at 2000 levels	Climate change-driven air quality-related health effects will adversely affect greater than 2/3 of the continental U.S	Potential Impact of Climate Change on Air Pollution-Related Human Health Effects (Tagaris et al. 2009)
	$PM_{2.5}$-related morbidity and mortality	Meteorological data from Goddard Institute for Space Studies (GISS) Global Climate Model (GCM)			Mortality rates held constant at 2000 levels	Approximately 4000 additional annual premature deaths due to climate change impacts on $PM_{2.5}$ compared to 300 due to climate change-induced ozone changes	
		Penn State/NCAR Meso scale Model (MM5 model) used to downscale GISS-GCM outputs to a regional scale			Disease incidence rates held constant at 2000 levels	$PM_{2.5}$ and ozone-related health impacts vary spatially	
		Health effect analysis conducted using U.S. EPA's Environmental Benefits Mapping and Analysis Program (BenMAP)				Increased premature mortality due to elevated ozone concentrations will be offset by lower mortality from reductions in $PM_{2.5}$ in 11 states	
South-central Canada (Montreal, Ottawa, Toronto, Windsor)	air pollution mortality	GCM	GCM downscaled using regression-based statistical method for the periods 2040-2059 and 2070-2089	Air temperature from SRES A2 and B2 scenarios	Population and age structure not directly taken into account	Air pollution-related mortality could increase about 20–30% by the 2050s and 30–45% by the 2080s, projected with climate change	Differential and combined impacts of extreme temperatures and air pollution on human mortality in south-central Canada. Part II: future estimates (Cheng et al. 2008)
						Increase in air pollution-related mortality would be largely driven by increases in ozone effects	
Africa, Middle East, South Asia, Southeast Asia, East Asia, Japan and Australia, Former Soviet Union, Europe, North America, Latin America	Premature ozone-related mortality	GCM	GCM and LMDz-INCA models driven by SRES A2 emissions scenario for 2030	Baseline simulation from 2000	World population of 9.17 billion by 2030	Under current legislation (CLE) scenario, estimated reduction in premature ozone-related human mortalities by 190,000 globally in 2030, mostly in Africa	Human mortality effects of future concentrations of tropospheric ozone (West et al. 2007)
		Laboratoire de Météorologie Dynamique (LMDz)-Interaction Chimie - Aérosols (INCA) chemistry-climate model			Spatial distribution by region based on 2003 population from Landscan database	Under maximum feasible reduction (MFR) scenario, estimated reduction in premature ozone-related human mortalities by 460,000 in 2030, with the greatest reductions in South Asia	
					Constant baseline mortality rates through 2030		

Table 11-3: Number of malnourished children less than 5 years of age (in millions) in 2000 and under the NCAR climate model (using A2 scenario from AR4) till 2050. Assumptions for investment in agricultural productivity: + only in developing countries; ++ both in developing and developed countries. Results assume no CO_2 fertilization effects. Adapted from (Nelson *et al.*, 2009).

Scenario	South Asia	East Asia/ Pacific	Eu + Centr. Asia	LA & Carrib.	Middle East/ N.Africa	Sub2-Sah. Africa	Devel. Countr.
2000	75.6	23.8	4.1	7.7	3,5	32.7	147.9
2050							
No climate change	52.3	10.1	2.7	5.0	1.1	41.7	113.3
NCAR	59.1	14.5	3.7	6.4	2.1	52.2	138.5
NCAR + adaptation	54.2	10.1	3.0	4.9	1.4	44.1	118.9
NCAR ++adaptat'n	53.7	10.5	3.0	4.8	1.3	43.5	117.2

Table 11-4: Summary of recent research on co-benefits of climate change mitigation. See text for details on the first two categories.

Co-benefit category	**Benefits for health**	**Benefits for climate**	**Select publications since 2006**
Reduction of co-pollutants from outdoor and household sources	See text	See text	(Bell *et al*., 2008a)
			(Markandya, Armstrong et al. 2009)
			(Smith and Balakrishnan, 2009)
			(Smith, Jerrett et al. 2009)
			(Wilkinson *et al*., 2009)
			(Lefohn, Shadwick et al. 2010)
			(World Health Organization Regional Office for Europe 2010)
			(Po *et al*., 2011)
			(Anenberg *et al*., 2012)
			(Lim, Vos et al. 2012)
Greater access to reproductive health services	See text	See text	(Conde-Agudelo *et al*., 2007)
			(Tsui, Creanga et al. 2007)
			(Gribble, Murray et al. 2009)
			(Prata 2009)
			(O'Neill, Jackman et al. 2010)
			(Diamond-Smith, Potts 2011)
			(Potts and Henderson, 2012)
Increases in urban green space	Reduced temperatures and heat island effects; reduced noise; enhanced safety; psychological benefits; better self-perceived health status	Reduce air pollution; more carbon sequestration (through forests and soil)	(McMichael, Powles et al. 2007)
			(Mitchell and Popham, 2007)
			(Babey *et al*., 2008)
			(Friel, Dangour et al. 2009)
			(Maas *et al*., 2009)
			(van den Berg *et al*., 2010)
			(van Dillen *et al*., 2011)
Less ruminant (red) meat consumption	May reduce (ischaemic) heart disease, stroke, colorectal cancer, breast cancer and prevalence of overweight/obese individuals	Fewer CH_4 emissions	(Sinha, Cross et al. 2009)
			(Smith and Balakrishnan, 2009)
			(Jakszyn *et al*., 2011)
			(Pan, Sun et al. 2012)
			(Xu *et al*., 2012)
Increases in active transport from modifications to the built environment, including smart growth	Increased physical activity; reduced obesity; reduced chronic disease; improved mental health; reduced exposure to air pollution; increased local access to essential services, including food stores; enhanced safety	Reduce CAP emissions associated with vehicle transport; possible mitigation of emissions through sequestration	(Babey *et al*., 2007)
			(Reed and Ainsworth, 2007)
			(Kaczynski and Henderson, 2008)
			(Casagrande *et al*., 2009)
			(Rundle *et al*., 2009)
			(Woodcock *et al*., 2009)
			(Grabow *et al*., 2011)
			(Durand *et al*., 2011)
			(McCormack and Shiell, 2011)

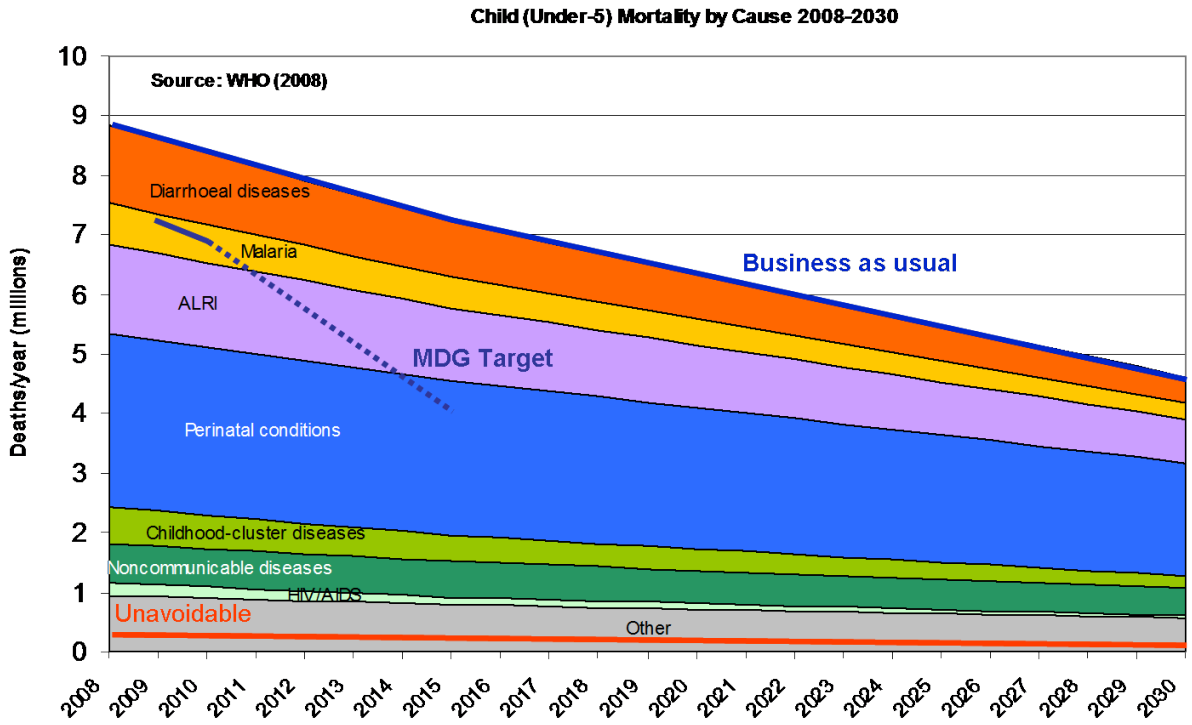

Figure 11-1: Climate change acts against human development: to reach the Millennium Development Goal for child mortality, the reduction in climate-sensitive causes of death at an early age must accelerate. Projected Child Mortality, 2008-2030, Including Climate-Sensitive Causes. ALRI is Acute Lower Respiratory Infections. Sources: Mortality projections by cause from WHO. Population projections from UN DESA. Child mortality rates from IGME. (Interagency Group for Child Mortality Estimation, 2011; United Nations, Department of Economic and Social Affairs, Population Division., 2011; World Health Organization, 2008).

Executive Summary

Climate change threatens human security, because it a) undermines livelihoods, b) compromises culture and identity, c) increases migration that people would rather have avoided, and d) undermines the ability of states to provide the conditions necessary for human security (high agreement, robust evidence). Human security breakdowns almost never have single causes, but instead emerge from the interaction of multiple factors. For populations that are already socially marginalized, resource dependent, and have limited capital assets, human security will be progressively undermined as the climate changes [12.1.2; 12.2]. Increases in the rate and magnitude of climate change increase the risk to human security by exacerbating negative feedbacks between cultural processes, migration and violent conflict [12.7].

Climate change affects cultures and the cultural expressions important for maintaining identity and traditional and local forms of knowledge (medium evidence, high agreement) Climate change impacts will lead to significant changes in environmental and societal conditions throughout the natural world, and in human settlements. These changes will compromise dimensions of the cultural core and assets that are highly valued by societies [12.3]. The magnitude of the perceived loss depends on the robustness of cultural identity and the mechanisms for maintaining and transferring knowledge. Culture and local and traditional forms of knowledge are highly dynamic and context dependent, reflecting and reasserting values, and shaping both adaptive and maladaptive responses.

Traditional and indigenous forms of knowledge are a major resource for adapting to climate change except when the changes exceed the knowledge repertoire (high agreement, robust evidence). Indigenous peoples have adapted to highly variable and changing social and ecological conditions [12.3]. The current rate and magnitude of change will increasingly constrain the efficacy of indigenous and traditional knowledge in adaptive responses [12.3]. Currently many indigenous peoples are politically and economically marginalized and live in regions or depend on natural resources that are highly sensitive to climatic changes. Local and traditional knowledge are often neglected in policy and research, and mutual recognition and integration of local and traditional knowledge with scientific knowledge will increase the effectiveness of adaptation responses [12.3].

Climate change will have significant impacts on forms of migration that compromise human security (medium agreement, medium evidence). Some migration flows are sensitive to changes in resource availability and ecosystem services. Major extreme weather events have in the past led to significant population displacement, and changes in the incidence of extreme events will amplify the challenges and risks of such displacement. There is evidence that many vulnerable groups do not have the resources to be able to migrate to avoid the impacts of floods, storms and droughts. There is evidence from models, scenarios and observations that coastal inundation and loss of permafrost can lead to migration and resettlement [12.3.2, 12.4.2]. Migrants themselves may be vulnerable to climate change impacts in destination areas, particularly in urban centres in developing countries [12.4.2].

Mobility is a widely used and often effective strategy to maintain livelihoods in response to social and environmental changes (high agreement, medium evidence). There is robust evidence that migration and mobility are adaptation strategies in all regions of the world that experience climate variability. People that lack the ability to move will face higher exposure to weather-related extremes in both rural and urban areas in the developing world [12.4.3]. There is some evidence to suggest that expanding opportunities for mobility reduce vulnerability and

enhance human security. Observations of implementation of planned resettlement show that legitimate and inclusive planning processes help alleviate the conflict and insecurity that individuals and communities may experience.

Some of the factors that increase the risk of violent conflict including civil wars are sensitive to climate change (medium agreement, medium evidence). The evidence on the direct effect of climate change and variability on violence is contested. Though there is little agreement about causality, there is robust evidence that shows that low per capita incomes, economic contraction, and inconsistent state institutions are associated with the incidence of civil wars. These factors are sensitive to climate change. Climate change policy responses, particularly those associated with changing property rights to land, water and resources, can increase the risk of violent conflict. A range of policies and institutions at multiple scales has been demonstrated to reduce the effects of environmental change on the risk of violent conflict. Economic growth, high per capita incomes, strong democratic institutions, social protection during economic and climate shocks, and robust institutional structures that protect property rights and manage conflict all reduce the risk that climate variability and extremes will lead to violence.

People living in places affected by violent conflict are particularly vulnerable to climate change (high agreement, modest evidence). Evidence shows that large-scale violent conflict harms infrastructure, institutions, natural capital, social capital, and livelihood opportunities. Since these assets facilitate adaptation to climate change, there are strong grounds to infer that conflict drives vulnerability to climate change impacts [12.5.2].

Climate change will lead to new challenges to states and will shape both conditions of security and national security policies (medium agreement, medium evidence). Physical aspects of climate change, such as sea level rise, extreme events, and hydrologic disruptions, pose major challenges to vital transportation, water, and energy infrastructure [12.6]. Some states are experiencing major challenges to their territorial integrity, including Arctic countries, small island states, and other states highly vulnerable to sea level rise [12.5.4]. Some impacts of climate change, such as changes in sea ice, transboundary and shared water resources, and the migration of pelagic fish stocks, have the potential to increase rivalry among states. There is evidence that the presence of robust institutions can manage many of these rivalries such that human security is not severely eroded [12.6]. These threats to national security will affect the capacity of states and communities to provide human security.

12.1. Concepts and Evidence

12.1.1. Human Security in the IPCC Assessment Reports

This chapter assesses the risks climate change poses to individuals and communities, including threats to livelihoods, culture, and political stability. These issues were raised by Working Group II (WGIIAR4) in the Fourth Assessment Report (AR4). That report identified the risk climate change poses to livelihoods (chapters 5, 7, 9 10, 16, and 17), cultures and indigenous peoples globally, but this Chapter is the first systematic assessment across the dimensions of human security.

Both WGIIAR4 and the Special Report on Extremes (SREX) noted the risks climate change poses to: water, soil, food, health and individual well-being. Chapter 7 of WGIIAR4 referred to security as a fundamental social goal, and Chapter 11 noted that the risks climate change poses to national security were poorly understood. It was also noted that migration, crises and violent conflicts increase vulnerability to climate change (Chapter 19). Chapters 7, 16 and 17 of WGIIAR4 noted that migration has the potential to enhance the adaptive capacity.

New research since AR4 has addressed the linkages between climate change and human security (Matthew et al., 2010; O'Brien et al., 2010; Oswald Spring, 2011; Scheffran et al., 2012a; Gleditsch, 2012). Specific dimensions of human security, such as food security; public health and well-being; livelihoods; and regional perspectives are examined systematically in Chapters 11, 13 and 19, and in chapters 22-29 of this report and this Chapter cross-refers to those assessments.

12.1.2. Definition and Scope of Human Security in this Assessment

There are many definitions of human security, which vary according to discipline, emphasis on risk factors, and values. This Chapter defines human security as a condition that exists when the vital core of human lives is protected, and where people have the freedom and capacity to live with dignity. In this assessment, in the context of climate change, the vital core of human lives includes the universal and culturally specific, material and non-material elements necessary for people to act on behalf of their interests. Many processes influence human security, notably: the operation of markets, the state, and civil society. Poverty, discrimination of many kinds, and extreme natural and technological disasters undermine human security.

The concept of human security has been informed by many disciplines and multiple lines of evidence and studies that use diverse methods (Paris 2001, Alkire, 2003; Owen 2004, Gasper 2005, Hoogensen and Stuvøy 2006, Mahoney and Pinedo 2007, Brauch et al., 2009, Inglehart and Norris 2012). The concept was developed in parallel by UN institutions (UNDP 1994; Commission on Human Security, 2003); and by scholars and advocates in every regional of the world (Najam 2003, Kaldor 2007, Poku and Sandkjaer 2009, Rojas 2009, Chourou, 2009, Sabur 2009, Othman 2009, Wun Gaeo 2009, Black and Swatuk 2009). In the past decade the linkages between elements of human security, global environmental change and climate change specifically has been examined through international research programmes (for example Matthew et al., 2010; Afifi and Jaeger, 2010; Foresight, 2011; Scheffran et al. 2012a). The assessment in the Chapter is based on systematic reviews. These were carried out firstly using searches of scientific databases of relevant studies published from 2000 till 2013, with searches targeted at the core dimensions of culture; indigenous peoples; traditional knowledge; migration; conflict; and transboundary rivalry. These searches were supplemented by open searches to capture book and non-journal literature.

_____ START BOX 12-1 HERE _____

Box 12-1. Relationship between Human Rights and Human Security in the Context of Climate Change

Human security is inclusive of political, sociocultural and economic human rights (CHS 2003), which are both an important element of human security, and instrumental to its achievement. Climate change puts human security and human rights at risk (Slade, 2007; Humphreys, 2010; Caney, 2010). Research on climate change risks to human rights examines legal issues in policy, litigation and compensation (Posner, 2007). Several cases have tested these rights, especially of women, children, indigenous peoples, and other minorities in practice (Oswald Spring, 2008). Others argue that rights may not be useful in climate policy (Depledge and Carlane, 2007; Adelman, 2010).

The victims of human rights violations are also vulnerable to climate change impacts. In places with extreme human rights violations, their protection is an important adaption strategy dealing with specific climate impacts (Barnett, 2009).

_____ END BOX 12-1 HERE _____

This Chapter assesses research on how climate change may exacerbate these and other threats to human security, and how these factors restrict the ability to adapt to climate change. Research on human security focuses on threats to the vital core of lives, including discrimination, economic crises, epidemics, extreme events, and violence (CHS, 2003; Oswald Spring, 2011, 2012). That body of knowledge has shown that underlying processes such as low health status, illiteracy, poverty, and restricted access to economic and social resources, reduce the freedom and capacity of individuals and groups to adapt to climate change, including (CHS, 2003; Betancourt et al., 2010; Goldsworthy, 2010). The systematic review in this Chapter reflects the dominant findings from the scientific literature that the impacts on livelihoods, cultural impacts, migration or conflict are overwhelmingly negative. But the literature on human security also reflects evidence that some elements of human security are not sensitive to climate change impacts, particularly those dimensions that are mainly driven by economics and other social change.

Research on the specific interaction of human security and climate change focuses on how cultural, demographic, economic, and political forces interact with impacts and risks, affecting individuals and communities (Krause and Jütersonke, 2005; Hoogensen and Stuvøy 2006; O'Brien, 2006; Betancourt et al., 2010). The analysis concerns

drivers of vulnerability across multiple scales and sectors, including, gender relations, culture, political institutions and markets. Each of these areas has its distinct disciplinary focus, methods and levels of evidence as discussed in Box 12-2.

_____ START BOX 12-2 HERE _____

Box 12-2. The Nature of Evidence about Climate Change and Human Security

Understanding the effects of climate change on human security requires evidence about social and environmental processes across multiple scales and sectors. This process-based evidence is not coherent and contiguous; it comes in different forms, and is collected through a wide array of methods used in different academic disciplines. For example, this Chapter assesses anthropological research where culture influences responses to climate change or may be shaped by climate change; alongside political and economic studies which use data sets to test for correlations between climatic factors and violent conflicts; and historical observations using documentary and archaeological methods. These diverse sources strengthen the robustness of the conclusions for this assessment (Van de Noort, 2011; Nielsen and Reenberg, 2012)

Research on human security and climate change relies on theories, models and evidence on how climate variability, anthropogenic climate change and environmental risks affect human security. There is some evidence on causal links in empirical studies.

This Chapter reviews empirical studies from the social sciences using both quantitative and qualitative data, including case studies. Some studies examine the interactions between environmental changes and social outcomes. Few explicitly address climate change and human security links, but some provide evidence of climate change impacts on human security (Ford et al., 2010). Individual case studies often explain causality in given contexts, but their results may not be generalized. Where evidence from multiple comparative case studies agree, generalization is sometimes possible.

This Chapter also assesses quantitative studies about large social units with correlations among different factors. Correlations alone do not explain causality, although they may test theories of causality. The absence of a correlation does not necessarily disprove a causal theory.

Given the complexity of the links between climate change and human security; uncertainties in the research on the biophysical dimensions of climate change; and the nature of the social science, highly confident statements about the effects of climate change on human security are not meaningful (Scheffran et al., 2012a). Yet there is robust evidence about many of the links between climate change and human security: in this Chapter the standardized IPCC language of uncertainty is applied to those areas where appropriate.

_____ END BOX 12-2 HERE _____

Human security and insecurity are universal issues. In every country there are individuals and groups who are insecure (Mahoney and Pinedo, 2007; Pietsch and McAllister, 2010). Much research suggests that while the impacts of climate change on human security will be experienced most in developing countries, human security is at risk for vulnerable populations everywhere (Naess et al., 2006; Leichenko and O'Brien, 2008; Berrang-Ford et al., 2011;).

The Chapter also evaluates research on the interaction between the state and human security, suggesting that increased human insecurity may rise with an inability to adapt to climate change, thus creating risks to national security through migration and violent conflicts. The analysis extends to assess how states protect the human security of their citizens. In other words, this chapter examines the security of the state insofar as it affects human security by affecting the ability of states to protect their citizens.

The framing of climate change as a security issue has been controversial. Some authors suggest that discourses on climate change and national security tend to downplay human security dimensions, and skew mitigation and adaptation responses towards state interests rather than the most vulnerable (Barnett 2007 and 2009; Brauch, 2009;

Dalby 2009; Floyd 2008; Trombetta 2009; Verhoeven 2009; Oels, 2013). Nevertheless, some countries associate climate change risks with conventional security risks and many countries are concerned about the risks climate change poses to relations between states (see sections 5 and 6). This Chapter therefore adopts a broad approach to human security, which is widely supported in the literature (Barnett, 2001; Brauch et al., 2008, 2009 and 2011; Matthew et al., 2010; O'Brien et al. 2010).

12.2. Economic and Livelihood Dimensions of Human Security at Risk from Climate Change

12.2.1. Climate Change Impacts on Material Aspects of Livelihood Security

Extensive evidence shows that climate change impacts on human security by altering the ensemble of assets, capabilities, entitlements, and activities required for securing a means of living (Battisti and Naylor, 2009; Hertel et al., 2010; Schlenker and Lobell, 2010; Chapter 13). Livelihoods are associated with people's access to five capital assets: social, natural, financial, human and physical. The systematic review on livelihoods and climate change is elaborated in Chapters 8, 9, 13, 18, and 22. Local and indigenous ecological knowledge (Box 18-4), diversification of activities to reduce risks, access to infrastructure and other resources interact together with changes in climate to impact livelihoods (Section 9.2).

To summarise the evidence in cognate Chapters, there are two ways by which climate change impacts upon the material aspects of livelihood security. First, it affects livelihood vulnerability through increasing exposure to shocks and stressors. Climate-related shocks brought about by storms and floods can directly destroy assets and impact on livelihoods (Deligiannis, 2012). Households that are land-less or reliant on climate sensitive capital are particularly vulnerable to such shocks (Chapter 9; Chapter 8; Chapter 22; Chapter 13, Fig. 13.2). Second, climate change can prompt mitigation and adaptation strategies that can advance or undermine human insecurity (Deligiannis, 2012) (Section 12.2.3). Because the most vulnerable and marginalized have low adaptive capacity, they will suffer the greatest impacts from climate change (e.g. Tanner and Mitchell, 2008). Those at greater risk include individuals and households below the poverty line, whose vulnerability is exacerbated by limited access to resources, entitlements, information, and decision-making processes. Much evidence shows that poorer households in both rural and urban areas have higher vulnerability to weather-related risks, with the mechanisms driving this vulnerability discussed in Table 12-1.

_____ START BOX 12-3 HERE _____

Box 12-3. Gender Dimensions of Human Insecurity

A growing body of evidence indicates that human insecurity associated with climate variability and change is differentiated by gender as well as other social factors (Antwi-Agyei et al., 2012; Arora-Jonsson, 2011; Buechler, 2009; Terry, 2009; Ahmed and Fajber, 2009). In many regions of the world, women have less access to financial resources, land, education, health and other basic rights, and are excluded from decision making processes, making them less able to cope with and adapt to climate change impacts (Djoudi and Brockhaus, 2011; Demetriades and Esplen, 2008; Paavola, 2008). Evidence shows how poor women in developing countries are struggling to protect their lives, homes, assets and livelihoods from weather related hazards . Socially ascribed gender responsibilities for so-called reproductive work, such as childcare, healthcare and domestic work, including the collection of water and firewood, is directly affected by impacts of climate change on nutrition, disease burden and water availability (Denton, 2002).

_____ END BOX 12-3 HERE _____

Table 12-1 summarizes studies on how climate variability and change affects the material aspect of human security. Evidence is categorized under two main dimensions: 1) deprivation of immediate basic needs; and 2) erosion of livelihood assets and human capabilities (Table 12-1). Evidence on the impacts of climate change on basic needs relates to agriculture and food security, water stress and scarcity as well as destruction of homes and properties (Carter et al., 2007; Leary et al., 2008; Peras et al., 2008; Paavola, 2008; Tang et al., 2009). Growing evidence

indicates that climate variability and change disrupts production and income, reduces spending, or alters other common practices of resource-dependent households (Chapter 13). Adverse impacts of climate change on the health and education of children can eventually lead to the erosion of human capability (Costello et al., 2009; UNDP, 2007). Similarly, evidence based on projections using various socio-economic and climate change scenarios indicates an increase in economic and health risks, including loss of lives in both less developed and developed countries (Hall et al., 2003; Tang et al, 2009; Kainuma et al., 2004).

[INSERT TABLE 12-1 HERE
Table 12-1: Observed and projected impacts of climate variability and change on basic needs and livelihoods, and their role in undermining human security.]

12.2.2. Impacts of Adaptation Actions on Livelihood Dimensions of Human Security

Established research methods and evaluations of development interventions provide robust evidence on how livelihoods can be secured in the context of external shocks and how opportunities can be enhanced through adaptation. Much of this research comes from development economics and related disciplines (Elllis, 2000; Dercon, 2004), and is increasingly applied to climate change adaptation studies. Livelihoods can provide people with opportunity (Chapter 13.2.1) and adaptation options that can be transformed into capabilities and assets (Chapter 13.2.1). Adaptation interventions and strategies that have been documented to reduce risks to human security include: 1) diversification of income-generating activities in agricultural and fishing systems (Paavola, 2008; Galvin, 2009; Tolossa, 2008; Badjeck et al., 2010; Coulthard, 2008; West and Hovelsrud, 2010); 2) migration for risk-spreading among pastoralists (Galvin, 2009) and fishers (Badjeck et al., 2009; Perry and Sumaila, 2007); 3) the development of insurance systems (Badjeck et al., 2010); and 4) education of women (Boyle et al., 2006, Rammohan and Johar, 2009).

There is emerging evidence, however, that some adaptation interventions in specific circumstances can decrease human security. For instance, agricultural intensification can initially minimize decline in yield, but may extend household production to marginal and steep lands that can in turn increase soil erosion, nutrient loss or landslides (Deligiannis, 2012).

12.3. Cultural Dimensions of Human Security

12.3.1. How Culture Interacts with Climate Impacts

Culture is analysed in this Chapter as dynamic and encompassing knowledge, worldviews, beliefs, norms, values, social relationships, perceptions of risk, power relations and responses to the world (Crate, 2008; 2011; Heyd, 2008; Roncoli *et al.*, 2009; Strauss, 2009; O'Brien and Wolf, 2010; Tingley *et al.*, 2010; Rudiak-Gould, 2012; Sudmeier-Rieux, 2012). In this definition culture shapes resilience, and drives both adaptive and maladaptive responses (Siurua and Swift, 2002; Pearce *et al.*, 2009; Nielsen and Reenberg, 2010; Petheram *et al.*, 2010; Buikstra *et al.*, 2010; Paul and Routray, 2011). This assessment focuses on the dimensions of culture that maintain identity and a sense of belonging, and that carry potential for creating unequal power relations and conflict.

Climate change is driven by, embedded in, and acts upon culture in myriad ways: consumption and energy use that drives anthropogenic emissions of greenhouse gases, are culturally embedded. And the phenomenon of climate change is perceived through scientific as well as other cultural expressions (Norgaard, 2011). Similarly, there are widely different cultural expressions of weather, risk and the need for adaptation to such hazards (Hulme, 2008; Adger et al., 2013). Since climate change has consequences for people there is high confidence that it also has significant cultural implications (Crate, 2011; Strauss 2012), with knock-on effects for human security.

For many indigenous and rural communities in particular, culture is constructed around livelihood activities such as pastoralism, herding, farming, fishing, and hunting and gathering. Research has documented how livelihoods and cultural practices have been affected by observed changes in diverse direct and indirect climate impacts: seasonal

weather patterns, extreme events, extreme drought and flood cycles, sea level rise, erosion, subsidence, coral bleaching, salinization, species abundance and composition, relocation and increasingly dangerous travel conditions (Oswald Spring et al., 2013). Many of these anthropological studies suggest that further significant changes in the natural resource base upon which many cultures depend, would directly affect the cultural core, worldviews, cosmologies and mythological symbols of indigenous cultures (Crate, 2008; Gregory and Trousdale, 2009; Jacka, 2009). Conversely many cultures have adapted to significant societal and environmental changes throughout history and colonial encounters (Nuttall, 2009; Cameron, 2012; Strauss, 2012). Much research in this area concludes that analysis of cultural understanding of environment, risk and social practices increases the explanatory power of models of risk (Ifejika Speranza *et al.*, 2008; Jacka, 2009; Adger al., 2011).

A further set of research examines cultural, local and individual perceptions and narratives of risk, resilience and adaptive capacity. It finds mixed results: that culturally embedded perceptions in some cases increase human security and in some cases are negative to human security outcomes by way of facilitating or hindering adaptation (Rudiak-Gould, 2012; Gómez-Baggethun *et al*., 2012; Burningham *et al.*, 2008; West and Hovelsrud, 2010; Zamani *et al.*, 2006; Nursey-Bray *et al*., 2012). In scientific studies of how resource-dependent communities articulate climate change, anthropological studies have shown that perception of climate change is often based on how English language terms are translated and understood in the local language (Rudiak-Gould, 2012), and the perception is interpreted through personal lifestories and culture (Kuruppu and Liverman, 2011). Anthropological studies have analysed how the concept of climate change is translated in various cultures and have observed both denial, particularly in situations where religions or cognitive frames do not perceive changing climate (Rudiak-Gould, 2012; Kuruppu and Liverman, 2011; Sánchez-Cortés and Chavero, 2011; Lipset, 2011). This denial of climate change is observed across all societies, and explained by sociological analysis as resulting from paralysis in the face of externally-imposed change (O'Brien and Wolf, 2010; Norgaard, 2011).

Scientific information on weather variability and change is framed through cultural practices: climate forecast or downscaling results are presented but not necessarily understood and assimilated well by, for example, local farmers (Roncoli, 2006). Local perceptions of what kind of knowledge is trustworthy may in fact question both scientific findings (Burns *et al.*, 2010; Ingram *et al.*, 2002) and how to deal with uncertain climate information (Roncoli *et al.*, 2011). Human security is further weakened if (climate) policy does not consider the cosmologies and epistemologies embedded in culture (Jacka, 2009; Stadel, 2008). Table 12-2 illustrates the different dimensions in which climate change is interpreted and against which human security is affected.

[INSERT TABLE 12-2 HERE
Table 12-2: Cultural dimensions of human security in the context of climate change.]

12.3.2. Community and Culture at Risk

Cultural dimensions of climate change are manifest in collective action and community. Community is a contested term in various disciplines (Gibson and Cameron, 2011). Community, as used here, refers to place-based groups that exhibit some form of unity and obligation among the members.

There is a significant body of research that analyses community and collective action for adaptation. Its principal finding is that community-led action is effective for reducing risks and building capacity for adaptation (Davidson *et al.*, 2003; Catto and Parewick, 2008; Harries and Penning-Rowsell, 2011; Gero *et al.*, 2011; Fazey *et al.*, 2010; Furgal and Seguin, 2006; Sudmeier-Riuex *et al.*, 2012; Anik and Khan, 2011; Adler, *et al*., 2012). Specifically this literature finds that community participation in risk and vulnerability assessments produces more sustainable solutions (Ardalan *et al.*, 2010; Gero *et al.*, 2011) and that so-called co-management and learning, increases adaptive capacity (Fazey *et al.*, 2010; Armitage *et al.*, 2011; Dumaru, 2010; Ford *et al*., 2007). Caveats to such analysis highlight structural barriers to community-led action and shows that participation in collective action is limited by hierarchical power relations (Singleton, 2000; Herbert, 2005; Davidson *et al.*, 2003; King, 2008; Ensor and Berger, 2009; Nielsen and Reenberg, 2010; Onta and Resurrection, 2011).

Table 12-2 reports on evidence across issues of culturally-determined perceptions of climate risks and responses. It highlights major findings that flexibility and livelihood diversification are two key factors in successful adaptation to variability in resource abundance (de Sherbinin *et al.*, 2008; Desta and Coppock, 2004; Ford *et al.*, 2006; Kalikoski *et al.*, 2010; Hovelsrud *et al.*, 2010a,b; Rybråten and Hovelsrud, 2010; McNeeley, 2011; Marshall 2011; Eakin *et al*., 2012; Ford and Goldhar, 2012; Berkes and Armitage, 2010). Further evidence suggests that changing socio-economic and environmental conditions may constrain existing coping community mechanisms (Rattenbury *et al.*, 2009; West and Hovelsrud, 2010; Quinn *et al.*, 2011). Local community responses are also shaped by political and economic globalization, in terms of a decoupling of production- and political networks from the local level (Keskitalo, 2009), and by colonial history (Marino, 2012).

12.3.3. Indigenous Peoples

There are about up to 500 million indigenous people worldwide (see Glossary for an inclusive definition), living under a wide range of social, economic and political conditions and locations (Nakashima *et* al., 2012). Indigenous peoples represent the world's largest reserve of cultural diversity and the majority of languages, and assessments of the cultural implications of climate change for human security illustrate similarities across geographical regions and climatic conditions. For many indigenous communities, there are significant linkages between historical colonization and current climatic changes (Cameron 2012; Howitt et al 2012; Salick and Ross 2009; Marino, 2012). It is argued in some literature that research on climate change in regions with significant indigenous populations often has assumptions concerning indigenous peoples being more connected to place than others (Cameron 2012) while scientists and indigenous peoples are increasingly using hybrid knowledge across scientific and traditional domains (Huntington 2011).

To a great extent the livelihood and culture of indigenous peoples are closely connected to natural resources, and in many parts of the world they are economically and socially marginalized (Crate and Nuttall, 2009). There is a *general agreement* that historically indigenous peoples have a high adaptive capacity to highly variable environmental conditions, but less so with respect to rapidly changing socio-economic conditions and globalization (Tyler *et al.*, 2007; Crate and Nuttall 2009). Conversely, the lack of adaptation to colonization and globalization may reflect resilience and the determination of indigenous peoples to maintain cultures and identities - and so does not necessarily indicate low adaptive capacity. The challenge of maintaining cultures and livelihoods will be exacerbated by climate change (Crate and Nuttall 2009; Rybråten and Hovelsrud, 2010). Such risks are exacerbated when: traditional practices – including those related to mobility - no longer prove effective in responding to climate variability (Green *et al.*, 2010); governments relocate communities (Hitchcock, 2009; McNeeley, 2011); policy and disaster relief creates dependencies (Wenzel, 2009; Fernandez-Gimenez et al. *et al.*, 2012); there are inadequate entitlements to resources (Shah and Sajitha, 2009); income inequality within and between communities increases (Green *et al.*, 2010); there are constraints to the transmission of language and knowledge between generations (Forbes, 2007).

Climate change poses challenges for indigenous peoples, including to their knowledge systems, cultural practices, adaptive strategies, and post-colonial power relations. The extensive literature on the Arctic shows that for indigenous peoples the changing ice conditions pose risks in terms of access to food, and dangerous travel conditions (Ford *et al.*, 2008; Ford *et al.*, 2009; Hovelsrud *et al*., 2011a). Additionally there are uneven societal consequences related to sea ice use, local physiological setting and community socio-cultural dynamics (Ford *et al.*, 2008), illustrating the heterogeneity within indigenous groups found elsewhere (Barrett, 2001).

Some studies show that current indigenous adaptation strategies may not be sufficient to meet the projected changes (Wittrock *et al.*, 2011. Indigenous peoples are often portrayed as victims of climate change (Salick and Ross 2009), and as vulnerable to the consequences (ACIA 2005), with implications for their human security. Indigenous peoples have a right to maintain their livelihoods and their connections to homeland and place (Howitt *et al.*, 2011), and it is suggested that the consequences of climate change are challenging this right (Box 12-1; Crate and Nuttall 2009). Some raise the question whether the western judicial system can uphold indigenous rights in the face of climate change (Williams 2012).

Much research with indigenous peoples concludes that lack of involvement in resource management decreases resilience and thereby human security, and that it is necessary to focus on indigenous perceptions of risk and traditional knowledge of change, hazards and coping strategies and collective responses (Ellemor, 2005; Finucane, 2009; Turner and Clifton 2009; Sánchez-Cortés and Chavero, 2011; Brown, 2009). Tourism development and industrial activities are particular risks for indigenous peoples when they are not involved in decision-making (Petheram *et al.*, 2010). Lack of formal participation in international policy and management negotiations may pose risks for indigenous peoples because their perspectives may not be heard (Schroeder, 2010), and there are examples of successful indigenous lobbying and advocacy in the case managing persistent organic pollutants and heavy metals in the Arctic (Selin and Selin, 2008).

12.3.4. Local and Traditional Forms of Knowledge

There is *agreement* among researchers that involvement of local people and their local, traditional or indigenous forms of knowledge is critical for ensuring human security (Ellemor, 2005; Kesavan and Swaminathan, 2006; Burningham *et al.*, 2008; Mercer *et al.*, 2009; Pearce *et al.*, 2009; Anik and Khan, 2012). We define such forms of knowledge (also traditional ecological knowledge, farmers' knowledge, indigenous science, ethnoscience) (Nakashima and Roué, 2002) as 'a cumulative body of knowledge, practice and belief, evolving by adaptive processes and handed down through generations' (Berkes 2012: 7). In addition to reasserting culture, identity and traditional values, such forms of knowledge are experiential, dynamic, and highly context dependent, developed through interactions with other forms of knowledges, including scientific, and viewpoints (Ford *et al.*, 2006; Orlove *et al.*, 2010; Sánchez-Cortés and Chavero, 2011; Eira *et al.*, 2013).

Although some studies warn that the emphasis on the value of local/traditional knowledge may be overrated, such knowledge is increasingly seen as a critical source for understanding change, for identifying socio-economic aspects, for developing adaptation strategies and policies, as critical input to climate scientists. For example, such knowledge serve as a basis for forecasting local weather, and provide the necessary insights about the local climate elements needed for relevant meteorological forecasting (Nyong *et al.*, 2007; Tyler *et al.*, 2007; Gearheard *et al.*, 2010; Hovelsrud and Smit, 2010; Orlove *et al.*, 2000). Local and traditional knowledge are often not included in adaptation planning (King *et al.*, 2007; Ifejika Speranza *et al.*, 2008; Tàbara *et al.*, 2003), or not valued or pursued properly in scientific studies (Huntington: 2011).

Local andtraditional knowledge about historical changes and events, and adaptation strategies to changing conditions are valuable for evaluating responses to change and policy (Angassa and Oba, 2008; Desta and Coppock, 2004; Eira *et al.*, 2013; Ford *et al.*, 2008; Lefale, 2010; Osbahr *et al.*, 2010; Orlove *et* al., 2000; Fernández-Giménez, *et al.*, 2012). It is an important contribution for mitigating natural disasters (Rautela, 2005), maintaining domestic biodiversity (Emperaire and Peroni, 2007), and developing sustainable adaptation and mitigation strategies (Nyong *et al.*, 2007). Among the Borana in Africa indigenous pastoralists' technical and organizational practices have been ignored in development, which has contributed to progressive land degradation, erosion of social structures, and poverty (Homann *et al.*, 2008). Evidence from mountain regions exposed to floods illustrates that incorporation of local knowledge into policy and decision-making reduces risk (Alcántara-Ayala et al., 2004).

Local and traditional knowledge are living resources (Nakashima and Roué 2002; Berkes 2012;) and can be retained through intergenerational transmission, its integration with other forms of knowledge (King and Goff, 2010; Kalanda-Joshua *et al.*, 2011), and its utilization in monitoring and assessments (Klintenberg *et al.*, 2007; Kalabokidis *et al.*, 2008) and in disaster risk management (Becker *et al.*, 2008; Mercer *et al.*, 2009; Pareek and Trivedi, 2011; Bilbao *et al.*, 2010; Kalabokidis *et al.*, 2008). There is *strong evidence* that mutual integration and co-production of local and traditional and scientific knowledge will enhance resilience, increase adaptive capacity and reduce vulnerability (Kofinas, 2002; Oberthür *et al.*, 2004; Tyler *et al.*, 2007; Anderson *et al.*, 2007; Vogel *et al.*, 2007; West *et al.*, 2008; Armitage *et al.*, 2010; Frazier *et al.*, 2010; Marfai *et al.*, 2008; Flint *et al.*, 2011; Ravera *et al.*, 2011; Nakashima *et al.*, 2012; Eira *et al.*, 2013).

Although local stakeholders and scientists may identify competing opportunities and constraints when attempting to reconcile for example local development with resilience to natural hazards (Frazier *et al.*, 2010), the interface

between scientific and local, traditional or indigenous knowledge can be seen as a source of inventiveness rather than where validity of knowledge is contested (King and Goff, 2010). Conversely, projects integrating climate projections and local observations reveal different results or discontinuities, often attributed to different perspectives and cultures (Marin, 2010; Mark *et al.*, 2010). This creates barriers for integration (Kwiatkowski, 2011; Ravera *et al.*, 2011), illustrating the need for incorporating local and indigenous knowledge and observations into climatology, and for creating locally relevant and trustworthy climate projections (Ingram *et al.*, 2002; Ifejika Speranza *et al.*, 2008; Smit et al 2010).

There are many challenges in managing, utilizing, acknowledging and incorporating these forms of knowledge (Huntington 2011), and the participatory approach may not be sufficient because of the cultural and social dynamics of power and interpretation (Roncoli *et al.*, 2011). Some studies suggest that local/traditional knowledge may not be sufficient to provide the proper response to surprising or infrequent risks, hazards or events (Nunn, 2000; Burningham *et al.*, 2008; Kuhlicke, 2010). Additionally if local/traditional knowledge is perceived to be less reliable because of changing environmental conditions (Ingram *et al.*, 2002; Ford *et al.*, 2006), or because of extreme or new events that are beyond the current local knowledge and cultural repertoire (Valdivia *et al.*, 2010; Hovelsrud *et al.*, 2010a), then community vulnerability, and the vulnerability of local/traditional knowledge itself, may increase (Kalanda-Joshua *et al.*, 2011). In the case of coastal communities in India, the societal and environmental conditions have changed to the point at which local knowledge is no longer as applicable as it was in the past (Kesavan and Swaminathan, 2006). In the Himalayas erosion of local/traditional knowledge occurs through government regulations of traditional building materials and practices. The social cohesion embedded in such practices is weakened because of a move towards concrete construction which changes the reliance on and usefulness of traditional knowledge about wood as building material (Rautela, 2005). New conditions may require new knowledge to facilitate and maintain flexibility and improving livelihoods (see also Homann *et al.*, 2008).

12.4. Migration and Mobility Dimensions of Human Security

12.4.1. Impacts of Climate Change on Displacement, Migration, and Mobility

12.4.1.1. Nature of Evidence on Climate Change and Migration

Migration is prevalent in every part of the world, driven by economic and other imperatives. Existing migration systems may be significantly disrupted by impacts of climate change in a number of important dimensions. Migration, defined in terms of temporal and spatial characteristics, is generally classed as a permanent or semi-permanent move by a person of at least one year that involves crossing an administrative but not necessarily a national border. As a result, migrants alter their baseline population of reference and their local networks (Brown and Bean, 2005).

The most significant contemporary trend in migration by volume of movement continues to be major movements of people from rural to urban settlements. The proportion of the global population that is urban has risen from 10 percent in 1900 to over 50 percent in 2009 and is projected to reach 59 percent by 2030 (UNDP 2009; Grimm et al., 2008). Around 80 percent of all migration is presently within countries. Existing global migration trends mapped onto ecological zones by de Sherbinin et al. (2012) show that the past four decades have seen out-migration from mountain regions and from drylands. Net migration to coastal zones was over 70 million people in the 1990-2000 census period, even though cities and coastal zones themselves are at risk from the impacts of climate change.

As with other elements of human security, the dynamics of interaction with climate change are multi-faceted and direct causation is difficult to establish. There is a growing literature on the demographic, economic and social processes of climate migration interactions (Afifi and Jäger 2010; Piguet et al., 2011; Serrano Oswald et al., 2013). The major emphases are on disentangling causation and multiple drivers of migration; displacement of populations from extreme events; governance challenges and the rights of international migrants and displaced peoples; and on the challenges of migration for urban sustainability and climate impacts (Foresight 2011; Black et al., 2011a,c; White, 2011a; Parnell and Walawege, 2011; Seto, 2011 Geddes et al., 2012;).

The most common methods used to examine the actual processes of migration and climate change risks include statistical inference to explain observed migration patterns with climate or related impacts as independent variables; sample surveys of actual migrants to explain their individual drivers of the decision to migrate; and other modeling techniques and indepth qualitative studies designed to explain the social processes and context by which migration decisions are made, often using historical analogies (McLeman and Hunter, 2010; Piguet, 2010). Some modeling studies project impacts of climate change on the viability of continued habitation and examine the impact of rainfall decline or land inundation as a risk factor for the displacement of people. These studies have, for risks such as sea level rise, quantified potential displacement (Nicholls et al., 2011). As with all the major elements of human security in this Chapter, the issue of causality between environment or risk and the human security outcomes of migration are not established.

12.4.1.2. Do Climate Change Impacts Increase Displacement or Restrict Mobility?

It is widely established that extreme weather events displace populations because of their loss of place of residence or economic disruption. This Section reviews evidence on how displacement is highly differentiated socially and has significant economic and social costs (Hallegatte, 2012). Much of the literature, such as reviewed in IPCC SREX report, concludes that with an increasing incidence and changing intensity of extreme weather events due to climate change, there may be increased levels of displacement.

Much evidence shows a distinct temporal dimension to displacement ranging from localised and short-term movement of people, through intra-regional migration to international displacement as a result of large-scale events. The Pakistan floods of 2010 caused primarily localised displacement for large numbers of people across a wide area (Gaurav et al., 2011). The evidence on displacement as a result of climate-related extremes suggests that most displaced people attempt to return to their original residence and rebuild as soon as practical.

In general, structural causes of vulnerability, such as income inequality, race, class, and discrimination, deeply affect the livelihood drivers of displacement and the consequences of return. The migration associated with Hurricane Katrina, for example, shows that in New Orleans economically disadvantaged populations were displaced in the immediate aftermath and have not returned (Myers et al., 2008). Fussell et al. (2010) found that 14 months later black residents returned more slowly, because they had suffered greater housing damage. Adams et al. (2009) identified factors that have led to a ‘chronic disaster syndrome’ where some populations are unlikely to return, and Hori and Shaefer (2010) suggest that displacement affected human security through housing, economic and health outcomes. There is also evidence of gender differentials in displacement from extreme events, especially when they lose their social networks or their social capital, and are often affected by adverse mental health outcomes in situations of displacement (Tunstall et al., 2006; Oswald Spring, 2008; Hunter and David, 2011).

Structural vulnerabilities affect the ability to cope with climate change and extreme events without migrating. Hurricane Mitch in 1990 affected different Central American countries and displaced up to two million people either temporarily or permanently. The impact was highly differentiated by country, with much lower displacement rates in Belize compared to Nicaragua, Honduras and El Salvador, with large scale displacement and an increase in international migration of 300 percent from Honduras (Glantz and Jamieson, 2000; McLeman and Hunter, 2010). But the impacts of such events are highly uneven. While the poorest households in Honduras were hardest hit by the hurricane (McSweeney and Coomes, 2011), they were less vulnerable to storms a decade later due to changes in land tenure and better early warning systems (Villagrán, 2009).

Not all populations are displaced by extreme weather events. A further strand of evidence on migration shows social differentiation in access to the resources necessary to migrate (Renaud et al., 2011; Black et al., 2012). A review by Black et al. (2012) proposed that populations that are trapped through lack of mobility. Figure 12-1 illustrates these dynamics, showing how vulnerability is inversely correlated with mobility, leading to those being most exposed and vulnerable to the impacts of climate change having the least capability to migrate. Therefore, climate change risks may be most significant when they reduce and constrain opportunities.

[INSERT FIGURE 12-1 HERE
Figure 12-1: Relationship between vulnerability to environmental change and mobility. Lack of mobility and high vulnerability are positively correlated. Adapted from Black et al. (2013).]

One consistent theme of the hazards literature is that while migration responses are common, movement is costly and disruptive and hence may only be used as an 'adaptation of last resort' (McLeman, 2009). Paul (2005) found that there was little displacement in Bangladesh as a result of flooding in affected villages and that residents perceived an influx of migrants due to the reconstruction. Hurlimann and Dolnicar (2011) showed for eight Australian settlements that relocation and migration was perceived to be the least desirable adaptation. Haug (2002) showed that pastoralists displaced due to drought in Sudan in the 1990s attempted to return to their previous settlements after the drought, notwithstanding conflict and other factors. McLeman and Hunter (2010) reviewed historical cases of displacement migration and concluded that non-migration or rapid return migration significantly outweighs permanent migration following hurricane impacts in the Caribbean, Dust Bowl migration in the 1930s USA, or dry season migration in the West African Sahel.

Table 12-3 summarises studies on weather extremes and long-term environmental change with migration outcomes showing that some events and trends lead to increased displacement of populations (column 1); while others lead to reduce mobility and significant trapped populations (column 2). Table 12-3 also demonstrates that in many circumstances (column 3) sections of populations are differentially affected, on the basis of ethnicity, wealth or gender (Elliot and Pais, 2006; Gray and Muller, 2012; Upton, 2012). Table 12-3 therefore demonstrates that the key impacts of climate change include increased displacement; reduced mobility and trapped populations; and migrant populations moving towards destinations likely to be more hazardous due to the impacts of climate change (Black et al., 2011a).

[INSERT TABLE 12-3 HERE
Table 12-3: Empirical evidence on observed or projected mobility outcomes (migration, immobility, or displacement) associated with weather-related extremes or impacts of longer-term climate change.]

Studies highlight that long distance migration is reduced by drought in pastoral systems and hence is experienced as reduced mobility (Findley, 1994; van der Geest, 2011; Sánchez et al., 2012). All pioneer migration to urban centres requires significant human and financial capital and hence is restricted to wealthier populations. Henry et al. (2004) confirmed in a multi-year study of Burkina Faso that the movement to other rural areas increased in dry years, but long distance or international migration was limited to years of high agricultural productivity. Kniveton et al. (2011) model migration movements from the 1980s in Burkina Faso and project that future scenarios of decreased rainfall would significantly increase rates of out-migration from rural areas.

Displacement migration as an adaptation to environmental change has a potential interaction with conflict: increased demands on local resources and services can create competition with resident populations, or where there is ethnic tension and distrust between migrants and residents (Reuveny, 2007; Warner et al., 2010; Hendrix and Salehyan, 2012). Evidence in this area is mixed. There is no established consensus on relationships between resource scarcity (whether the initial state or resulting from immigration) and conflict (Section 12.5; Hendrix and Salehyan, 2012). An analysis of multiple cases of large scale population displacement in Africa (from causes such as civil war and conflict) report that significant conflict emerged in receiving areas in around 50 percent of cases, and is less likely when migrants and residents are of the same ethnicity and religion (Reuveny, 2007). Conversely, conflict, particularly large-scale violent conflict, can lead to displacement. This is most common where much of the population is dependent on the environment for livelihoods, as conflict impacts the ability of communities to access resources and respond to environmental variation, increasing the propensity for migration out of the area (Raleigh, 2011). That such displacement may initiate new conflict in receiving areas indicates the complex nature of conflict, and that migration will simply be one contributing factor.

There is some evidence that new migrants are more at risk in cities for two reasons. First, low income migrants are vulnerable to labour market discrimination, access to services such as health care and to crime and violence (McMichael et al., 2012; Fox and Beall, 2012). Second, low-income migrants cluster in high-density areas with exposure to flooding and landslides, with these risks increasing with climate change (Chatterjee, 2010; McMichael

et al., 2012). Migrants in Buenos Aires, Lagos, Mumbai and Dakar (Chatterjee, 2010; World Bank, 2010; Mehrotra et al., 2011) are more likely to be exposed to weather-related hazards than long-term residents. In Dakar (1998-2008), 40 percent of new migrants resided in areas with high flood risk. Wang et al. (2012) found that migrants had less knowledge about typhoon risks in Shanghai. Tompkins et al. (2009) showed that new migrants in the Cayman Islands are most vulnerable to tropical cyclones as they are least likely to prepare for cyclones, live in locations with high exposure to cyclone impacts, and interact mostly with expatriates without previous cyclone experience. There is no established evidence that rapid urbanization itself is a source of conflict: Buhaug and Urdal (2013) test hypotheses on social disorder and population growth in 55 cities in Africa and find that rapid growth of city populations does not drive urban unrest.

12.4.1.3. Migration Trends and Long-Term Climate Change

Long-term environmental change, sea-level rise, coastal erosion, and loss of agricultural productivity (Table 12-3) will have a significant impact on displacement. Barbieri et al. (2010) estimated emigration rates in Brazil from affected rural areas and found that de-population occurs with relatively modest rates of warming. In their scenarios the biggest increase in migration comes from productive agricultural areas that support a large labour force. Medelsohn et al. (2007) concluded that in dryland Brazil urban migration is highly likely due to agricultural income loss.

Longer term environmental change caused by climate change also amplifies existing trends such as rural to urban migration, though results diverge on the importance of climate change and resource scarcity. Modelling studies with future projections on Mexico-US migration rates (Feng et al., 2009), and on Brazilian internal migration (Barbieri et al., 2011) show that projections of drying increase emigration in established migration routes and de-population of rural areas (Kniveton et al., 2011). Barrios et al. (2006) used statistical modelling of changes in rainfall to explain migration rates to African cities. They observed rainfall decreases during the past fifty years and showed statistically they only partially explained differences in urbanization rates, with shortages in rainfall increasing urbanization in sub-Saharan Africa, but often propelled by simultaneous liberalization and policy change.

Nicholls et al. (2011) estimate displacements based on potential sea-level changes till 2100. A 0.5m sea-level change implies a likely land loss of 0.877 million km^2 by 2100, displacing 72 million people, with no adaptation investment and with 2.0 metres, 1.789 million km^2 would be lost, displacing 187 million people, or 2.4 percent of global population, mostly in Asia. If all coasts were protected with dikes and beach nourishment, these estimates fall to 0.041-0.305 million people displaced by 0.5-2.0 m of sea level rise. Hallegatte et al. (2011) assume that such protection measures are very likely as the cost of not investing in protecting urban land and infrastructure is so great. Existing migration trends are also likely to exacerbate impacts of climate change and vulnerability themselves. There is a well-documented drift of population into coastal and regional settlements. Curtis and Schneider (2011) project 12 million people to be affected by sea-level rise by 2030 in four major coastal areas in the US.

Even in areas under threat from long-term climate change, individual migration decisions and aggregate flows are embedded in economic and cultural imperatives. Mortreux and Barnett (2009) found that migration from Tuvalu was not driven by perceptions of climate change and that despite forecasts that the island could become uninhabitable, residents have remained for reasons of culture and identity. Shen and Gemenne (2011) concur that both Tuvalu residents and migrants from Tuvalu in New Zealand did not cite climate change as a reason for movement. Both studies also argue that environmental risks directly affect perceptions of potential well-being and economic opportunities: hence the impacts of climate change may be a more significant driver of future international migration. Observational studies of international migration show that past migration flows are the greatest predictors of future flows because of identity and cultural linkages in both source and destination regions (Serrano Oswald, 2013).

12.4.2. Migration as an Adaptation to Climate Change Impacts

From a human security perspective, migration is a widely used adaptation strategy that reduces risks in highly vulnerable places. Studies have outlined the social processes by which migration reduces vulnerability, and often conclude that a greater emphasis on mobility within adaptation policies would be effective (Barnett and Webber, 2010; Bardsley and Hugo, 2010; Warner, 2010; Gemenne, 2011). This emerging literature focuses on four areas of government intervention: a) social protection mechanisms such as cash transfers to reduce the likelihood of temporary displacement from weather-related extremes (Johnson and Krishnamurthy, 2010); b) adaptation in destination regions, by reducing the vulnerability of migrants in growing urban areas; c) protection and assistance of migrants as they move with rights to citizenship and ability to make economic linkages back to source regions and countries (Fox and Beall, 2012; Martin, 2012); and d) dealing with the prospect of relocation of settlements.

With observed climate changes, such as melting permafrost, and projected changes in resource productivity and risks, various governments are engaged in planning to move settlements as part of adaptation strategies (de Sherbinin et al., 2011). Scientific literature on these policies most often portrays resettlement as a failure of adaptation and a policy of last resort (Barnett and Webber, 2010; Fernando et al., 2010; Hugo, 2011; de Sherbinin et al., 2011). Most of the evidence to date, learning from other resettlement programmes, demonstrates negative social outcomes for those resettled, often analysed as breaches in individual human rights (Johnson, 2012; Bronen, 2011). There is some documented examples of settlements that are already planning for their own relocation, such as five indigenous communities in Alaska that are threatened with increased erosion, loss of ice cover and flooding over the past decades (Bronen, 2010). These settlements have undertaken planning for relocation and have received government funding for these processes. In line with all major analyses in this area, Bronen (2010) concludes that while the relocations are feasible, cultural and psychological elements at individual and community level are difficult to assess. There is significant resistance to relocation, even where such options are well planned and have robust justifications, as demonstrated by (Marino, 2012) for relocation in Alaska.

_____ START BOX 12-4 HERE _____

Box 12-4. Evidence on the Existence of Environmental Migrants and International Policy to Protect Them

Legal and political research has shown that the term climate refugee is not meaningful. First, the quantified global estimates of 'environmental refugees' proposed by Myers (2002) and others, for example, and repeated in policy documents, have been widely criticised (Black et al., 2011a; Taccoli, 2009; Piguet, 2010; Gemenne, 2011; Jakobeit and Methmann 2012; Bettini, 2013). Most present research focuses on the multiple drivers and on migration processes and shows that models of displacement fail to include other adaptation strategies and that quantifying displacement as the prime migration issue fails to account for the reality of migration systems and existing flows.

Second, there is widespread agreement in the scientific and legal literature that the use of refugee in this context is 'erroneous as a matter of law, and conceptually inaccurate' (McAdam, 2011, p. 102). The arguments put forward for a specific legal instrument to deal with migrants who have been displaced as a direct result of climate change impacts include issues of rights given that such migration is imposed and involuntary (Bell, 2004); the scale of the potential issue with the potential for large populous areas to be inundated in the future due to sea level rise in particular (Bates, 2002); and the particular status of small island nations where displacement could affect sovereignty (Biermann and Boas, 2009; Williams, 2008; Owens, 2008).

For international displacement and migration, there is a growing literature on the nature of displacement; whether there are governance mechanisms facilitating migration at present; and the optimal design of such mechanisms in future (e.g. Biermann and Boas 2009, Williams, 2008; Bryavan and Rajan, 2006; Docherty and Giannini, 2009; Martin, 2009; McAdam, 2011). This literature focuses on strategies for adaptation, mitigation and resilience building, and concludes that significant adaptation may be required to protect and to empower internal or international migrants triggered by climate change. Several legal proposals have been analysed by socio-legal studies suggesting new multilateral conventions, or compensation mechanisms to countries where the population is forced to migrate (Bierman and Boas, 2012).

New international governance mechanisms for international displacement address the difficulties to develop such an instrument in international law. Most migration and climate studies point to the environment as triggers and not causes for migration decisions. Some studies focus on the geo-political implications of changing the Geneva Convention on refugees to include environmental migrants as well as the lack of global instruments to handle internal displaced peoples or international migrants (Martin, 2009; Cournil, 2011). Others discuss the implications of climate migrant status in international migration, where full citizenship and economic status in destination countries are often not realised (McAdam, 2011; Hartmann, 2010). Many small island countries are reluctant themselves to have their international migrants designated as being victims of climate change (McNamara and Gibson, 2009; Farbotko, 2010; Fabrtoko and Lazrus, 2012; Barnett and O'Neill, 2011).

_____ END BOX 12-4 HERE _____

12.5. Dimensions of Conflict and Vulnerability to Climate Change

12.5.1. Climate Change as a Cause of Violent Conflict

In the past decade there has been a significant increase in research investigating the interactions between climate change and violent conflict, reflecting policy discourses that climate change impacts and resource scarcity could escalate conflict risks. Changes in climate will bring groups of people into conflict over property rights, markets, and public goods. Offsetting those risks, there is evidence that in specific circumstances resource scarcity drives adaptation and innovation (Butzer 2012, Gausset and Whyte 2005, Mehta 2010). And resource scarcity rarely escalate to violence, and violent conflict itself has generally become less common and less intense since 1991 (Goldstein 2011, Themnér and Wallensteen 2012). Risks between climate change and conflict are defined as emerging in Chapter 19 (19.4) as this is a new area of research. This Chapter concludes that there are multiple interactions between conflict and climate change impacts, and that some well established contributing factors to conflict are sensitive to climate variability and change.

There is a modest amount of research that explores the relationship between large-scale disruptions in climate and the collapse of past empires (using statistical analysis and data derived from archaeological and other historical records). For example, the timing of the collapse of the Khmer empire in the Mekong basin in the early 15th century corresponds to an unusually severe prolonged drought (Buckley et al 2010). DeMenocal (2001) summarizes evidence that suggests that major changes in weather patterns coincided with the collapse of several previously powerful civilizations, including the Anasazi, the Akkadian, Classic Maya, Mochica, and Tiwanaku empires. The precise causal pathways that linked these changes in climate to changes in civilizations are not well understood due to data limitations. This evidence from historical antecedents cannot be taken to mean future changes in climate will lead to large-scale political collapse due to diverse changes and globalization in the contemporary world (Butzer 2012).

A modest body of research shows that the Little Ice Age was associated with more cases of political upheaval and warfare than in any other period (Parker 2008, Zhang et al 2011), including in Europe (Tol and Wagner 2010), China (Brook 2010), and the Ottoman empire (White 2011b). These studies all show that climate change can exacerbate major political changes given certain social conditions, including a predominance of subsistence producers, conflict over territory, and autocratic systems of government with limited power in peripheral regions.

There is very little research that explores the risks that climate change poses to violent conflict between states in the past half century. Most recent studies agree that systemic trends towards peace between countries are unlikely to be affected by the impacts of climate change, even with respect to expected changes in transboundary rivers (Bernauer and Siegfried 2012, Brochmann and Hensel 2009, Dinar et al 2011, Feitelson et al 2012, Gartzke 2012, Goulden et al., 2010, Tir and Stinnett 2012, Wolf 2007). All studies show that there are robust institutions that mediate information and create commitments to shared solutions to manage the transboundary impacts of climate variability. The growth and improved capacity of these institutions is major reason why war between states is increasingly rare (Goldstein 2011).

There is a modest amount of research that finds an association between increases in temperature and violent crime (Anderson 1987, Anderson 2001, Breetzke and Cohn 2012, Butke and Sheridan 2010, Field 1992, Gamble and Hess 2012, Rotton and Cohn 2001). Theories that explain that pathways between higher temperatures and violent crime are contested (Breetzke and Cohn 2012, Gamble and Hess), and there is also debate about the effect of very high temperatures on violent crime, with some evidence showing that violent crime falls in conditions of extreme heat (Gamble and Hess 2012, Rotton and Cohn 2001). These debates highlight uncertainties that limit conclusions about the effects of climate change on violent crime. Evidence for this relationship between temperature and violent crime is mostly from cities within the United States, and from crime data in recent decades, whereas historically, and globally, rates of violent crime generally fall as per capita wealth increases (Cole and Gramajo 2009, Neumayer 2003). Studies that seek to discover the major causes of violent crime do not identify temperature and other climate variables are significant, with factors relating to culture, income, and policy explaining most of the variation between countries and over time (Cole and Gramajo 2009, Fajnzylber et al 2002, Karstedt 2001, Kawachi et al 1999, Neumayer 2003).

Most of the research on the connections between climate change and violent conflict focuses on the connections between climate change and civil war. For the most part this research examines rainfall or temperature variability as proxies for the kinds of longer-term chances that might occur due to climate change (see also Chapter 19). One study examines the relationship between temperature and violent conflict (Burke et al. 2009), although this has been challenged (Buhaug 2010). The vast majority of studies seek evidence from Africa, and using satellite-enhanced rainfall data collected since 1980. A global study by Hsiang et al (2011), finds that since 1950 and in countries that are teleconnected to ENSO the risk of war within countries rises during an ENSO period. This study is supported by some studies that find associations between deviations in rainfall and civil war (Miguel et al. 2004, Hendrix and Glaser 2007), but contradicted by others that find no significant association between droughts and floods and civil war (Buhaug 2010, Buhaug and Theisen 2012, Theisen et al., 2012, Slettebak 2012). Examination of individual conflict shows that there is no prospect of identifying specific civil wars as being primarily driven by climate. Box 12-5 demonstrates multiple resource and political dimensions of the Darfur conflict with no studies concluding that the conflict was climate-driven.

_____ START BOX 12-5 HERE _____

Box 12-5. Climate and the Multiple Causes of Conflict in Darfur

Climate variability is popularly reported to be a significant cause of the mass killing in the Darfur region that began in 2003 (see Mazo 2009): long term drought and vulnerability of the population to drought has been identified as the trigger and cause. Five detailed studies of the conflict conclude that climate variability and related environmental changes are proximate but not primary causes of the violence.

The detailed studies find that the violence in Darfur has multiple causes, notably:

- The legacy of past violence, which established groups that had a history of violent action, and a supply of weapons
- Manipulation of ethnic divisions by elites in Khartoum
- Weakening of traditional conflict resolution mechanisms through government policies, and as a consequence of famines
- Systematic exclusion of local groups from political processes, including of the Fur, Masalit, and Zaghawa ethnic groups
- Limited economic development and inadequate provision of public services and social protection, stemming from governance and policy failures, political instability, and misuse of official development assistance
- Desertification, declining productivity of arable land, and increased aridity.

(Brown 2010; Hagen and Kaiser 2011, Kevane and Gray 2008, Sunga 2011, Verhoeven 2011)

All analyses agree that it is not possible to isolate any of these specific causes as being most influential (Hagen and Kaiser 2011, Kevane and Gray 2008, Sunga 2011, Verhoeven 2011). Most authors identify government practices as being far more influential drivers than climate variability, noting also that similar changes in climate did not

stimulate conflicts of the same magnitude in neighboring regions, and that in the past people in Darfur were able to cope with climate variability in ways that avoided large scale violence.

These studies therefore dispute the identification of the Darfur conflict as being caused by climate change, arguing that attributing this conflict to climate change masks the culpability of actors and the major drivers of insecurity.

_____ END BOX 12-5 HERE _____

There remains significant disagreement about the nature of the evidence and the strength of the conclusions that can be drawn from it. There is agreement that climate is only one factor in the risk of civil war, and that where other risk factors are extremely low (such as where per capita incomes are high, and states are strong democracies), the impact of changes in climate on civil war is negligible (Bernauer et al 2012, Koubi et al 2012, Scheffran et al. 2012a).

A growing body of research examines the connections between climate variability and smaller scale violent conflicts (communal violence). There is some agreement that both increased rainfall and decreased rainfall in resource-dependent societies enhances the risk of localized violent conflict, particularly in pastoral societies in Africa (Adano et al 2012, Butler and Gates 2012, Hendrix and Salehyan 2012, Raleigh and Kniveton, 2012, Theisen 2012). In all such cases, the presence of institutional structures that protect property rights and manage conflict are highlighted as the critical factors in mediating such risks (Adano et al. 2012, Benjaminsen et al., 2012, Butler and Gates 2012, Hidalgo et al. 2010, O'Loughlin et al 2012, Gausset 2005, Theisen 2012).

In response to the challenges of finding direct associations between changes in climate and violence, some research has examined the effects of changes in climate on factors that are known to increase the risk of civil war (Berholt and Lujala 2012, Koubi et al. 2012). Civil war has been studied extensively using quantitative and qualitative techniques, and there is strong agreement about factors that increase the risk of civil war, namely: a recent history of civil violence, low levels of per capita income, low rates of economic growth, economic shocks, inconsistent political institutions, and the existence of conflict in neighboring countries (Blattman and Miguel 2010, Brückner and Ciccone 2010, Dixon 2009, Hegre and Sambanis 2006, Miguel et al. 2004, Weede 2004). Nevertheless, almost all studies note that there are few convincing theories that explain the ways these factors cause violence.

Many of the factors that increase the risk of civil war are sensitive to climate change. For example, there is robust evidence that climate change will slow rates of economic growth and impede efforts to grow per capita incomes, particularly in Africa where the risk of conflict is highest (chapter 10) (Eboli et al 2010, Mendelsohn et al. 2000, Mendelsohn et al. 2006, Stern 2007). Extreme events, which may become more intense due to climate change, can also produce economic shocks (Bergholt and Lujala, 2012; Hallegatte 2012; Adam, 2013), although the direct association between disasters and violent conflict is contested (Bergholt and Lujala 2012, Pelling and Dill 2010, Slettebak 2012). There is some evidence that under certain circumstances disasters can provide critical opportunities to build peace in conflict settings, and to improve governance institutions (Bruckner and Ciccone 2011, Kingsbury 2007, Olson and Gawronski 2010). There are theoretical reasons, but limited evidence, to suggest that climate change can lead to more inconsistent political institutions (Barnett and Adger 2007, Scheffran et al. 2012b).

In summary, there is justifiable common concern that climate change may increase the risk of violent conflict in certain circumstances (Bernauer et al. 2012; Gleditsch, 2012; Sceffran et al., 2012), even if the strength of the effect is uncertain. This concern is justified given robust knowledge of the factors that increase the risk of civil wars, and evidence that some of these factors are sensitive to climate change, There is also general agreement in the literature that there is a need for theories and data that explain the processes that lead from changes in climate to violence, including on the institutions that help avoid violent outcomes (Barnett and Adger, 2007; Sheffran and Battaglini, 2011; Buhaug and Theisen 2012, Gleditsch, 2012; Murtinho and Hayes, 2012;). However, confident statements about the effects of future changes in climate on violence of any kind are not possible given the absence of generally supported theories and evidence about causality (see Box 12-5).

12.5.2. Conflict and Insecurity Associated with Climate Policy Responses

Research is beginning to show that climate change mitigation and adaptation actions can increase the risk of violent conflict, as well as compound vulnerabilities in certain populations (Bumpus and Liverman 2008; Adger and Barnett 2009; Dabelko, 2009; Webersik 2010; Fairhead et al. 2012, Marino and Ribot, 2012,). There is evidence that violent political struggles occur over the distribution of benefits from natural resources (Peluso & Watts, 2001). On this basis, in circumstances where property rights and conflict management institutions are ineffective, efforts to mitigate or adapt to climate change that change the distribution of access to resources have the potential to create and aggravate violent conflict.

Actions taken in response to climate change can aggravate significant inequalities or grievances (Marino and Ribot, 2012), limit access to land and other resources required to maintain livelihoods, or otherwise undermine critical aspects of human security (Bumpus and Liverman 2008, Fairhead et al. 2012). Instances of maladaptation or greenhouse gas mitigation efforts at odds with local priorities and property rights increase the risk to populations and may increase the risk of conflict, particularly where institutions governing access to property are weak, or favour one group over another (Barnett and O'Neill, 2010; Butler and Gates 2012, McEvoy and Wilder, 2012).

Research on the rapid increase in biofuels finds evidence connecting "land grabbing," land dispossession, and social conflict (Molony and Smith 2010; Borras Jr. et al. 2010; Dauverge and Neville 2010; Vermeulen and Cotula 2010). Some research has identified links between increased biofuels production, food price spikes, and social instability such as riots (Johnstone and Mazo 2011).

The provision of financial resources in payment for ecosystem services projects such as are associated with Reduced Emissions from Deforestation and Forest Degradation (REDD) have the potential to stimulate violent conflicts (Melick 2010). For example, efforts to ensure 'REDD readiness' in Tanzania (Beymer-Farris and Bassett, 2012) and the Congo basin (Brown et al., 2011) have placed communities opposed to marginalization and displacement in conflict with conservationists and governments. Eriksen and Lind (2009) likewise find that climate change adaptation in Kenya has the capacity to aggravate surrounding conflicts.

Climate change mitigation will increase demand for deployment of less carbon-intensive forms of energy, including hydropower, some of which have historically resulted in social conflict and human insecurity (for example forced resettlement), and this is a basis for concerns about increased violence and insecurity in the future (Conca 2005; McDonald-Wilmsen et al., 2010; Sherbinin et al. 2011). Other research points to an increased use of nuclear power increasing the threat of nuclear proliferation or incidents of nuclear terrorism (Socolow and Glaser 2009).

12.5.3. Violent Conflict and Vulnerability to Climate Change

Many of the capacities required to adapt to climate change are threatened by the presence of ongoing or recent conflict (Barnett 2006, Brklacich et al., 2010). There is a strong body of evidence from development studies and political science that violent conflict undermines human security and the capacity of individuals, communities, and states to cope with changes (Stewart and Fitzgerald 2001; Blattman and Miguel 2010,). This evidence base suggests, with *high confidence*, that where violent conflict emerges and persists, capacity to adapt to climate change is likely to be low (as illustrated in Figure 12-2) (Barnett, 2006; Lind and Eriksen, 2006; Eriksen and Lind, 2009; Adger, 2010).

[INSERT FIGURE 12-2 HERE
Figure 12-2: Conflict and post-conflict societies exhibit low levels of governance and human development. Source: Adger (2010).]

There is some evidence that violent conflict degrades the quantity and quality of natural resources, and often leads to these resources being exploited inefficiently. Chronic political instability in Zimbabwe, is, for example implicated in high levels of illegal bush meat hunting (Lindsey et al., 2011). Conflict, and the displacement of large populations,

can also alter the abundance and distribution of biodiversity and can result in significant deforestation (Chase and Griffin, 2011; Lindsell et al., 2011; Stevens et al, 2011).

Violent conflict interrupts the ability of resource dependent individuals and communities to access natural resources (Pike, 2004; Detraz, 2009; Kolmannskog 2010; Raleigh, 2011), and in so doing limits their capacity to adapt to climate change. The denial of strategic space as a tactic in violent conflicts (through for example, deliberate destruction of crops and spreading of landmines in conflict affected regions) can reduce the capacity of individuals and communities to access natural capital (Berhe, 2007; Unruh, 2011).

Conflict disrupts markets and destroys infrastructure, limits education and the development of human capital, causes death and injury among a state's workforce, and decreases the ability of individuals, communities and the state to secure credit (Blattman and Miguel 2010, Goodhand, 2003; Stewart et al., 2001). Conflict thus creates poverty and constrains livelihoods which in turn increases vulnerability to the impacts of climate change (Nigel, 2009; Deng 2010a, Hilson and van Bockstael, 2011). Thus violent conflict is a major cause of hunger and famines (de Waal 1993, Messer and Cohen 2011, Rowhani et al., 2011).

The capacity for collective action is a critical determinant of the capacity to adapt to climate impacts, and this too can be undermined by violent conflict, depending on the nature of violence and the strategies households adapt in response (Deng, 2008 and 2010b). When conflict exacerbates existing horizontal inequalities between ethnic or religious groups, foments distrust in local or government institutions, or isolates individuals and households, capacities that are critical to coping with climate impacts are also degraded (Bogale & Korf, 2007). In situations where there is violent conflict, efforts to address climate change that provide financial or resource flows, or political levers that can be captured by local elites or illegitimate institutions, may compound divisions where such efforts (Brown et al., 2011; Verhoeven, 2011).

Conflict related displacement also creates and exacerbates social isolation and accompanying sources of vulnerability. Isolation from social networks can make it difficult to achieve pillars that underlie traditional livelihoods, such as marriage, access to land, or access to communal social safety nets in times of vulnerability (Raleigh, 2011; Kolmannskog 2010).

Violent conflict can decrease the capacity of local and state level institutions to function effectively (Feitelson et al., 2012; Tignino, 2011). For example, chronic political conflict has reduced the ability of governance institutions at many scales to manage water resources in the Gaza Strip effectively (Shomar, 2011), parts of the Balkans (Skoulikidis, 2009), and the Middle East (Zeitoun et al., 2012). Instability has affected planning process around urban land use in Palestine (Raddad et al., 2010) and traditional institutions for governing fishery rights in the Lake Chad Basin have been challenged by the presence of armed groups and illegal taxation systems sustained by non-legitimated government agents (Bene et al., 2003). Political instability has also been shown to contribute to poor urban governance in some regions of Iraq (Hassan, 2010).

Violent conflict may also undermine the ability of states to prevent and respond to natural disasters and humanitarian crisis (Keen, 2008). A lack of trust in government commitment or capacity to respond, the presence of police or military forces that lack legitimacy, or recent conflict between government and local forces, hampers the ability of these institutions to provide effective relief (Wisner, 2001).

12.5.4. Peace-Building Activities in Promoting Adaptation

It is widely established that resource management has significant potential to contribute to conflict management by channeling competing interests over resources into non-violent resolutions (Conca and Dabelko, 2002; Conca and Wallace 2009; Hammill and Matthew 2012). This research on environmental peacebuilding and peacemaking considers that natural resource management, and by extension climate change adaptation, can build peace to avoid conflicts, and broker peace in conflict situations.

Research on bilateral and multilateral interactions between two or more states from 1948 to 2008 shows evidence of significant formal cooperation among river basin riparian states, and no cases of water causing two states to engage in war (Wolf et al, 2003; De Stefano et al. 2010). Transboundary water cooperation, particularly joint management, flood control, and technical cooperation, can form a basis for longer-term cooperation on a range of contentious issues. Efforts at basin wide institutional development to lower conflict potential focuses on moving from the common assertion of rights to water to addressing the multiple values of water, and to sharing benefits across national boundaries (Sadoff and Grey 2002).

Beyond water, there is less evidence about the effectiveness of efforts to enhance cooperation and lower conflict around natural resources. Some transboundary conservation areas, referred to as 'peace parks', are designed to reduce conflict and enhance cooperation across borders. The evidence of the effectiveness of peace parks is limited and ambiguous, with some studies showing some evidence of political, economic and conservation cooperation (Ali and Marton-LaFevre, 2007), but also conflict generation between local communities, elites and states (Duffy 2002).

12.6. National Security Dimensions of Climate Change

Climate change will affect state security through mechanisms such as impacts on critical infrastructure, threats to territorial integrity, changing access to resources, or responses to climate change. State militaries are active in assessing and responding to these challenges (Dabelko, 2009). These infrastructure and geopolitical impacts directly affect state capacities to provide a range of ecological, economic, social, and political services that fundamentally contribute to human security (Barnett, 2003; Barnett et al., 2010; Webersik, 2010).

12.6.1. Critical Infrastructure and State Capacity

Climate change is expected to damage a range of critical infrastructure, with water and sanitation, energy, and transportation infrastructure posing especially severe vulnerabilities (Chapter 8; Rozenzweig et al., 2011; UN Habitat, 2011). Climate change is expected to exacerbate water supply problems in sensitive urban areas, to limit the ability to cool power plants, to increase energy demand beyond capacity in areas of high temperature increase, to disrupt power supply and telecommunications in areas of increased snow and ice storms, and to damage vital transportation infrastructure in areas subject to flooding and storm surge (see Chapter 8). Areas that are vulnerable to flooding and landslides will have greater risk of such infrastructure damage (Adelekan, 2010; Awuor et al., 2008; Revi 2005).

Climate change impacts on critical infrastructure will reduce the ability of some states to provide social and public services (see Chapter 8). For example, power outages stemming from water shortages or storms can in turn lead to reductions in service delivery on the part of hospitals, police forces and emergency response forces. Damage to roads, rails, airports, bridges and related transport infrastructure can similarly reduce the ability of governments to provide for citizen needs. Hughes et al. (2010) estimate a modest 1-2 percent additional investment costs to adapt water supply infrastructure to climate change, but with wide variation between countries. Thawing permafrost, for example, will affect water infrastructure but affect the whole viability of settlements and infrastructure in high latitude areas (Chapter 28; Larsen et al., 2008; Marino, 2012). In poorer countries or where economies depend heavily on climate-sensitive activities such as agriculture, climate impacts are expected to lead to significant declines in income and in turn government revenues. Mideksa (2010) estimates losses of nearly ten percent in Ethiopia GDP.

12.6.2. Geopolitical Issues

Analysis of the actions of states and security institutions show that many states view current and anticipated climate changes as contributing to geopolitical concerns (Dabelko 2009; Smith 2011). The ability of states to share resources and provide human security is challenged by climate change impacts. Climate change can create contested terrestrial

and marine territorial claims and in extreme cases can threaten the territorial integrity or viability of states (Barnett and Campbell, 2010; Houghton et al., 2010; Yamamoto and Esteban, 2010).

For small island states and countries with significant areas of soft low-lying coasts (Hanson et al., 2011) such as Bangladesh, Tanzania (Kebede and Nicholls, 2012), and Singapore (Ng and Mendelsohn, 2005) sea-level rise and extreme events threaten to erode and subsume significant land areas and associated infrastructure and settlements without significant adaptation investment (Chapter 5; Nicholls et al., 2011). For countries comprised entirely of low-lying atolls, sea-level rise, ocean acidification, and increases in episodes of extreme sea-surface temperatures, compromise human security for existing or larger numbers of people (Barnett and Campbell 2010, Fisher 2011). With projected high levels of sea-level rise beyond the end of this century, the physical integrity of low lying islands is under threat (Chapter 29, Houghton et al., 2010). The opening of resources, such as the social, economic and political dimensions of loss of sea ice in the Arctic (Chapter 28), represents an example of climate change impacts being geopolitically significant to states, even in the absence of direct conflict (Box 12-6).

Productive ocean fisheries are already directly affected by climate change, with loss of yields in the tropics, changing range of important commercial species in temperate regions, and greater variability in productivity and species composition in virtually all oceans (MacNeil et al., 2010). Fishing, as an economic activity often involves changing practices and locations, but the increased globalization of fisheries operations (Berkes et al., 2006) has been suggested to increase transboundary rivalry and threaten the sustainability of some fisheries (MacNeil et al., 2010).

_____ START BOX 12-6 HERE _____

Box 12-6. Evidence on Security and Geopolitical Dimensions of Climate Change Impacts in the Arctic

Impacts of climate change on the Arctic region exemplify the multiple interactions of human security with geopolitical risks. System wide changes in the Arctic region affect multiple countries and a global commons resource given Arctic roles in regulating the global climate and ocean systems (Carmack et al., 2012; Duarte et al., 2012). Anticipated changes will contribute to greater geopolitical considerations and human insecurity in the Arctic region. They include: food insecurity affecting specific cultures and knowledge systems (outlined in Section 3); energy security implications through opening of sub-sea oil and gas reserves; increased shipping; and increased presence of militaries in the region.

Summer Arctic ice has had five of the lowest recorded minima in the period 2007-11 (Duarte et al., 2012), and projections of future loss suggest an ice-free Arctic ocean in summer by mid-century or before, with implications for land based infrastructure, shipping, coastal communities and transport (Holland et al., 2006; Stephenson et al., 2011; Larsen et al., 2008; See Chapter 28). There is only limited evidence on changes either creating or reviving terrestrial and maritime boundary disputes among Arctic countries (Borgerson, 2008; Lusthaus, 2010). Further, there is little evidence that the changing Arctic will become a site for violent conflict (Berkman, 2010; Brosnan et al., 2011; Young 2009; Young, 2012), given political institutions such as the Arctic Council are providing a forum for resolving resource sharing, new transportation practices, and boundary disputes. Research on livelihoods and cultural change dimensions of human security, however, also concludes that climate and ecological shifts will contribute significant challenges for adaptation (Nuttall, 2012; Hovelsrud et al., 2011b).

_____ END BOX 12-6 HERE _____

The impacts of climate-induced water variability on transboundary water basins constitute a cluster of geopolitical concerns. The high levels of international interdependence on transboundary rivers such as the Nile, Limpopo, Amu Darya, Syr Darya, Mekong, Ganges, Brahmaputra, and Indus connect the conditions of the rivers with national development trajectories. Climate change is anticipated to affect the timing and rate of flow of these rivers, contributing to concern over negative outcomes from additional stresses stemming from increased consumption and increased populations.

Research on transboundary conflict and cooperation prioritizes rate of change rather than absolute scarcity in connection with the risk of conflict over water, particularly between states (De Stefano et al. 2012). This focus stems from higher perceived risk of conflict when institutions at local, state, and regional levels have less time to adapt to scarcity or variability by dealing with disputes through diplomatic and other non-violent mechanisms (Wolf et al. 2003; De Stefano et al. 2010; De Stefano et al. 2012). Sudden changes in flow that heighten risk and challenge institutional responses include declines in seasonal snow or glacial melt. Transboundary basin institutions and international legal mechanisms have demonstrated the ability to lessen the likelihood of violent conflict (McCaffrey, 2000; Sadoff and Grey, 2002; Dellapenna and Gupta 2009; Tir and Stinnett, 2012;). Other research emphasize these transboundary water institutions receive limited financial and political investment, do not always include all riparians, and are present in only a limited number of transboundary basins (Conca et al., 2002).

Research on bilateral and multilateral interactions between two or more states from 1948 to 2008 shows significant formal cooperation among river basin riparian states while most interactions are low levels of cooperation and low levels of conflict (Wolf et al., 2003; De Stefano et al., 2010). Some find that the presence of a shared river basin is correlated with increased risk of state-to-state or dyadic conflict (Gleditsch et al., 2006), but the evidence suggests only a limited number of overtly violent conflicts between states and no cases of water causing two states to engage in formal war. Zeitoun and Warner (2006) and Zeitoun and Mirumachi (2008) distinguish between equitable and inequitable cooperation among transboundary riparians cooperating through joint water management institutions. Relative power differentials between countries, territories, or groups stemming from upstream or downstream position, economic power, or military power can undercut the wider conflict reduction impacts of formal institutional cooperation.

Geoengineering - intentional large-scale interventions in the earth system - either to reduce the sun's radiation that reaches the surface of the earth or to increase the uptake of carbon dioxide from the atmosphere (See Chapter 20), is increasingly considered a strategy to address climate change. The uncertainty and high likelihood of differential impacts of geoengineering (such as reduced precipitation in Asia (Ricke et al. 2011) with negative food production implications), are anticipated sources of tension or conflict between states (Robock 2008; Preston, 2013). The ability of states to unilaterally deploy geoengineering under limited international legal mechanisms creates the potential for conflict. A history of security institutions deploying geoengineering and weather modification presents the prospect of military involvement in climate change responses or reactions to them (Fleming, 2010). The degree of securitization of climate change is debated (Brzoska, 2012, add cites), but in the case of geoengineering, concern stems from possible dual use that potentially would violate the 1977 UN Convention on the Prohibition of Military or Any Other Hostile Use of Environmental Modification Techniques (Keith, 2000; Robock, 2008Corner and Pidgeon, 2010).

12.7. Synthesis

The evidence reviewed in this Chapter shows that climate change poses risks to various dimensions of human security, which arise through diverse causal processes, and which will be manifest at different scales. There is high agreement in the literature for this conclusion that comes from multiple lines of evidence. There are, however, multiple and competing perspectives on the nature and causes of insecurity arising from climate change (Barnett 2010). For example, farmers in the Sahel are concerned about the risks climate change poses to their livelihoods (Mertz et al. 2009), whereas people in Tuvalu report that the cultural impacts of migration are a primary concern (Mortreux and Barnett 2009). Organisations whose mandates include various aspects of human security also tend to focus on some risks of climate change over others. For example the International Council on Human Rights Policy is concerned with the risks climate change poses to human rights, the International Organization for Migration is concerned with the implications of climate change for migration, and the United States National Intelligence Council is focused on the risk climate change will increase political instability. In this respect the framing of climate change as an issue of human security facilitates conversations across the boundaries of diverse policy communities (Gasper 2010).

The risks that climate change poses to human security arise through multiple and interacting processes: those processes also operate across diverse spatial and temporal scales. High levels of complexity means that no

conceptual model or theory captures the full extent of the interactions between all of climate change, livelihoods, culture, migration and violent conflict. However, as this Chapter has shown, there are feedbacks between the key elements of livelihoods, culture, migration, and violent conflict. Figure 12-3 depicts interactions between the primary elements discussed in this Chapter. Deterioration in livelihoods, for example, is a human security issue in its own right, and also gives rise to migration, which may be adaptive, or unavoidable and undesirable: such movements in turn imply changes in important cultural expressions and practices, and, in the absence of institutions to peacefully manage the settlement of migrants in destination areas, can increase the risk of violent conflict. This conflict can in turn undermine livelihoods, impel migration, and weaken valued cultural expressions and practices. The evidence in the Sections above shows that some interventions and policies enhance human security, while others inadvertently can exacerbate insecurity (depicted in red and blue arrows in Figure 12-3).

[INSERT FIGURE 12-3 HERE
Figure 12-3: Synthesis of evidence on the impacts of climate change on elements of human security and the interactions between elements. Examples of positive and negative changes in security associated with interventions indicated by arrows.]

A key finding of this Chapter is that institutions are integral to the risks climate change poses to all dimensions of human security. Again there is high agreement on this finding, with multiple lines of evidence from food security, to migration, to conflict resolution. The risks climate change poses to human security sometimes arise directly through interaction of material effects of changes in climate, through physical, biological and ultimately impacts in society. But evidence in this Chapter suggest that often the risks to human security also arise through ways in which institutions anticipate and react to these perceived or actual changes (Barnett et al. 2010; Ribot 2011; Artur and Hilhorst 2012). These institutional responses can significantly dampen or amplify the way changes in climate give rise to human insecurity (see Figure 12-3). For example, although declining productivity in crops and fisheries impacts on the food available to semi-subsistence farming and fishing households, anticipated or actual increasing scarcity on food markets also causes higher food prices, which can further undermine food security in those households (Chapter 7, and Badjeck et al., 2010; Downing 2002; Oluoko-Odingo 2011).

Adaptation and mitigation strategies can also dampen or increase human insecurity. With respect to both adaptation and mitigation strategies, there is an emerging consensus that those that are imposed on communities are more likely to impact negatively on human security than those that facilitate communities to respond in ways that are consistent with their capabilities and values (medium agreement, limited evidence) (Ensor and Berger, 2009; Barnett and O'Neill 2011, Marino 2012, Mercer et al. 2012). Adaptation strategies that seek to reduce exposure to climate change, through the development of large infrastructure or the resettlement of communities against their will, carry risks of disrupted livelihoods, displaced populations, deterioration of valued cultural expressions and practices, and in some cases violent conflict. Conversely, strategies such as the provision of microfinance, assistance to overcome barriers to mobility, and improving access to education and health care, enhance the ability of vulnerable populations to make and implement decisions that are consistent with their own capabilities and values. Hence such interventions are increasingly being shown to offset the adverse effects of climate change on livelihoods, unwanted migration, culture, and violent conflict. Similarly, mitigation policies that entail changes in property regimes that are not consistent with resource ownership and use can impact negatively on human security (Bumpus and Liverman 2008; Beymer-Farris and Bassett, 2012). There is as yet more limited evidence to demonstrate that mitigation activities that align with local interests and institutions can have co-benefits for human security, mitigation, and adaptation (Klein et al., 2005; Ayers and Huq, 2009; Laukkonen et al., 2009; Moser 2012).

Thus, climate change is not yet the primary risk to human security: it is one of many drivers of human security that vary in priority depending on location and circumstance. For regions where human insecurity is prevalent, these additional factors include poverty, discrimination, and inadequate provision of public services and public health, and opportunities for education. Investments in institutional responses to facilitate adaptation can dampen many of the potential adverse effects of climate change on human security (see Figure 12-3). Conversely, inappropriate climate policy responses may accelerate and amplify human insecurity.

There remains much uncertainty about the future impacts of climate change on human security. On the basis of current evidence about the observed impacts of climate change on environmental conditions, climate change will be

an increasingly important driver of human insecurity in the future (see Figure 12-3). At very high rates of projected warming, all of the aspects of human security discussed in this chapter will be adversely affected (for example in high latitude regions Box 12-6). At high rates of warming the rate of changes in environmental conditions in most places will be without any precedent in human history (New et al. 2011). Hence the evidence about the effects of past and present changes in climate on human security that informs much of the current literature on human security and climate change will be increasingly of diminishing value in analysing the human security implications of rapid or severe climate change.

Frequently Asked Questions

FAQ 12.1: How does lay knowledge of risks help adaptation to climate change?

Lay and traditional knowledge about the environment and climate are deeply rooted in history, and encompass important aspects of human life. Such knowledge is instrumental in shaping responses to climate change in all parts of the world. For many indigenous and local communities, for example, culture is constructed around livelihood activities, such as herding, hunting, fishing or farming. These cultural expressions include critical knowledge on dealing with highly variable environmental and societal conditions. Cultural perceptions of resilience to climate change, however, can either facilitate or hinder adaptation. Traditional knowledge is instrumental in developing community adaptation strategies and is increasingly seen a critical source for both scientific understanding of the consequences of climate change and for developing successful adaptation policies [12.3].

FAQ 12.2: How does migration contribute to adaptation to climate change impacts in vulnerable regions?

Patterns of migration are well established and primarily driven by economic factors: the dominant movement in the world is still from rural to urban areas within countries. Some migration flows are sensitive to changes in resource availability and ecosystem services and hence some rural to urban migration flows may be amplified by climate change impacts in developing and urbanizing countries. Migrants themselves may be vulnerable to climate change impacts, particularly in hazardous urban destinations. Given multiple motivations for all migration decisions, it is difficult to categorise any individual as a climate migrant [12.4].

FAQ 12.3: Will climate change cause war between countries?

Climate change has the potential to increase rivalry between countries over shared resources. For example, there is concern about rivalry over changing access to the resources in the Arctic and the future of transboundary rivers. Climate changes represent a challenge to the effectiveness of the diverse institutions that manage relations over these resources. However, there is high scientific agreement that this increased rivalry is unlikely to lead directly to warfare between states based on the evidence to date. That evidence shows that the nature of resources such as transboundary water and a range of conflict resolution institutions have able to divert rivalries in ways that avoid violent conflict [12.5 and 12.6].

Table 12-1: Observed and projected impacts of climate variability and change on basic needs and livelihoods, and their role in undermining human security.

Dimensions of impacts		**Evidence from observations**	**Projections**
Deprivation of immediate basic needs	**Livelihood assets**	• Agricultural households faced with droughts have been observed to engage in environmentally destructive activities, such as reducing fallows, and increasing charcoal and timber production in Tanzania (Paavola 2008) • Household assets such as livestock may be disposed in times of crop failures: for example in the 1999/2000 drought in Ethiopia and the 1999-2004 drought in Afghanistan (Carter et al. 2007; de Weijer 2007). • Riverbank erosion associated with changed hydrological regimes causes loss of agricultural land (Paul and Routray, 2010). • Flooding is another source of crop failure	• Climate volatility is expected to increase with associated impacts on staple grains and an increase in poverty (Ahmed et al, 2009). • Changes in the viability of crops used to feed livestock will have an impact on the poor. In some locations maize yields are projected to decline substantially (Jones and Thornton, 2003). • Riverbanks may be further destabilized by environmental change and human interventions (Le et al, 2007) •
	Water stress and scarcity	• Glaciers and ice caps melts continue to affect water catchments downstream, leading to water stress and scarcity. • Example: glacial retreat of Mount Kilimanjaro is expected to bring acute problem of water scarcity particularly in the arid and semi-Arid regions of Africa (Kumssa and Jones 2011). • Glacier recession in the Cordillera Blanca in Peru is altering the hydrological regime with implications for local livelihoods and water availability in the arid coastal zone (Mark et al, 2010;	• Insecurity of water supply associated with climate change threatens the achievement of Millennium Development Goals to reduce the number people without sustainable access to safe drinking water (Hadipuro 2007). • The reduction in glacier extent and the associated loss of hydrological buffer is expected to increase (Vuille, 2008)
	Destruction of homes and properties	• Floods and related climate shocks destroy shelter and properties and curtail people's ability to meet basic needs. • Examples: A flood in Fiji (2009) brought economic losses of F$24 million affecting at least 25% of farm households (Lal 2010). • Sea level rise and increased frequency of extreme events rise the risk of loss of lives, homes, and properties and damages infrastructure and transport systems (Adrianto and Matsuda, 2002; Suarez et al. 2005; Philips and Jones 2006; Ashton et al. 2008; Von Storch et al. 2008).	• In the Netherlands, the total amount of urban area that can potentially be flooded has increased six-fold during the 20th century and may double again during the 21st century (de Moel et al., 2011). • In England and Wales, projected changes in flood risk mean economic damages may increase up to 20 times by the 2080s (Hall et al. 2003).

Erosion of livelihood and human capabilities	**Agriculture and food security**	• Interaction of climate change with poverty and other political, social, institutional and environmental factors adversely affects agriculture production and exacerbates the problem of food insecurity (Downing 2002; Trotman et al. 2009; Saldana-Zorrilla 2008; Kumssa and Jones 2011). • Examples: most of the studies focus in Africa, due to its dependence on rain-fed agriculture (Kumssa and Jones 2011; in Kenya, Oluoko-Odingo 2011; in Southern Africa, Drimie and Gillespie 2010; in Zimbabwe and Zambia (Mubaya et al. 2012).	• Studies of African agriculture using various climate scenarios indicate that increasing temperature and rainfall variation have serious impacts on crops and livestock production that are likely to lead to increased poverty, vulnerability and loss of livelihoods. • Examples: Ethiopia (Deressa and Hassan 2009); Kenya (Kabubo-Mariara 2009); Burkina Faso, Egypt, Kenya and South Africa (Molua et al. 2010); and sub-Saharan Africa (Jones and Thornton 2009). • Livelihood insecurity among small-scale rain-fed maize farmers in Mexico is predicted due to potential loss of traditional seed sources (Bellona et al. 2011).
	Human capital	Health: • Food shortage, absence of safe and reliable access to clean water and good sanitary conditions, and destruction of shelters and displacements, all have negative bearing on human health (Costello et al. 2009) • Poor nutrition combined with mental health conditions after a disaster can lead in the long run to erosion of human capability (Costello et al. 2009)	Health: • A comparative analysis of African and non-African countries using an 'income-climate trap model' that explains the multi-directional interaction between income, climate and life expectancy, reveals that climate is important in determining both life expectancy and income. • Climate change is likely to worsen localized conditions that could see many less developed countries, particularly from Africa, sinking deeper into an income-climate trap of underdevelopment in health (Tang et al. 2009). • Analysis of the economic and climatic impacts of three emission scenarios and three tax scenarios, estimates the impacts on food productivity and malaria infection to be very severe in some Asian countries (Kainuma et al. 2004).
		Education: • Droughts and floods can intensify the pressure to transfer children to the labour market (Ethiopia and Malawi, UNDP 2007). • - Indian women born during a drought or flood in the 1970s were 19 percent less likely to ever attend primary school, when compared with women of the same age who were not affected by natural disasters (UNDP 2007).	Loss of lives: • Studies of the impacts of future floods using a combination of socio-economic and climate change scenarios for developed countries predict an increase in fatalities. • Example: In the Netherlands, sea level rise combined with other factors potentially increases the number of fatalities four times (Maaskant et al. 2009)

Table 12-2: Cultural dimensions of human security in the context of climate change.

Core climate change dimensions	**Cultural dimensions**	**Role in shaping HS (facilitating - hindering adaptation, action, response)**	**References**
Climate science and policy	Framing of climate change in a dominant language (English) Global climate change policy developments	How concepts and uncertainties are translated, imported and incorporated facilitate or hinder adaptation; Available explanatory tools facilitates adaptation; Successful translation of climate change impacts facilitates adaptation; Lack of trust in science and in policy hinder adaptation; Policy and decision-making that is inclusive of cultural perspectives increases security; Policy not recognizing the connection between nature and culture hinders adaptation; Awareness of culture facilitates adaptation	Ifejika Speranza *et al.*, 2008; Stadel, 2008; Jacka, 2009; Bogale and Korf, 2009; Green, *et* al., 2010; Burch, 2010; Schroeder, 2010; Osbahr *et al.*, 2010; McNeely, 2011; Gero *et al.*, 2011; Sánchez-Cortés and Chavero, 2011; Roncoli, et al, 2011; Kuruppu and Liverman, 2011; Rudiak-Gould 2012
Impacts of environmental conditions and extreme events and changing natural resource base	Elements of cosmology such as: World views Coupling of nature-culture Power relations Heterogeneity within groups and communities	New technologies may facilitate adaptation; Livelihood diversification and flexibility facilitate adaptation; Limitations of local knowledge hinder adaptation; Narratives and history about past changes and current conditions may drive adaptation; Erosion of cultural core may decrease human security; Institutional responses and resource management will impact human security; Co-management of resources increases adaptive capacity; Lack of awareness and understanding of culture constrains action and hinders adaptation; Knowledge and cultural repertoire limited for responding to new challenges will hinder adaptation; Perceptions of resilience may hinder or facilitate adaptation;	Nunn, 2000; Seixas and Berkes, 2003; Davidson *et al.*, 2003; Desta and Coppock, 2004; Herbert, 2005; Zamani *et al*., 2006; Ford *et al.*, 2006, 2008; Crona, 2006; Aguilar *et al.*, 2009; Kuruppu and Liverman 2011, Rudiak-Gould, 2012; Roncoli *et al*., 2011; Gearheard *et al*., 2010; Hovelsrud and Smit, 2010; Nyong *et al.*, 2007; Tyler *et al.*, 2007; Angassa and Oba, 2008; Osbahr *et al.*, 2010; Lefale, 2010 Crate, 2008; Gregory and Trousdale, 2009; Harries and Penning-Rowsell, 2011; Gero *et al.*, 2011; Fazey *et al.*, 2010; Furgal and Seguin, 2006; Sudmeier-Riuex *et al.*, 2012; Anik and Khan, 2012; Kuhlicke, 2010; Valdivia *et al.*, 2010; Kesavan and Swaminathan, 2006; Jacka, 2009; Pearce *et al.*, 2010; Adler, *et al*., 2012; Gómez-Baggethun *et al*., 2012; Burningham *et al.*, 2008; West and Hovelsrud, 2010; Nursey-Bray *et al*., 2012; Armitage *et al.*, 2011; Dumaru, 2010; King, 2008; Nielsen and Reenberg, 2010; Onta and Resurrection, 2011; de Sherbinin *et al.*, 2008; Kalikoski *et al.*, 2010; Hovelsrud *et al.*, 2010a,b; Rybråten and Hovelsrud, 2010; McNeeley, 2011; Marshall 2011; Berkes and Armitage, 2010; Ford and Goldhar, 2012; Eakin *et al*., 2012;
Scientific observations monitoring, models, projections, scenarios	Local, traditional and indigenous knowledge through observations and experience	Mutual integration of traditional, local and scientific knowledge may facilitate adaptation and strengthen human security; Climate projections with local relevance will facilitate adaptation; Knowledge included in climate policy and decision making decreases risks and increases human security: Intergenerational knowledge transfers facilitate adaptation; Knowledge not included in adaptation planning decreases human security	Orlove *et al.*, 2000, 2010; Ingram *et al.*, 2002; Tàbara *et al.*, 2003; Alcántara-Ayala et al., 2004; Gearheard *et al*., 2010; Roncoli, 2006; Forbes, 2007; Anderson *et al.*, 2007; Vogel *et al.*, 2007; Nyong *et al.*, 2007; Tyler *et al.*, 2007; Catto and Parewick, 2008; Frazier *et al.*, 2010; Marfai *et al.*, 2008; Mercer *et al.*, 2009; Pearce *et al.*, 2009; Marin, 2010; Mark *et al.*, 2010; Smit et al 2010; Burns *et al.*, 2010; Hovelsrud and Smit, 2010; Kalanda-Joshua et al., 2011; Flint *et al*., 2011; Ravera *et al.*, 2011; Sánchez-Cortés and Chavero, 2011; Huntington, 2011; Eira *et al.*, 2013.

Table 12-3: Empirical evidence on observed or projected mobility outcomes (migration, immobility, or displacement) associated with weather-related extremes or impacts of longer-term climate change.

	Drought and land degradation
Evidence for increasing migration, mobility or increased displacement.	↑ Ethiopia: Outmigration of household heads due to drought related famine, although different coping strategies lead to variations in the timing of migration (Meze-Hausken, 2000). ↑ Mexico: Increased propensity to migrate to the United States related to years with negative crop productivity (Feng et al., 2010) ↑ Western Sahara: Droughts play a crucial role in patterns of international migration from refugee camps (Gila et al., 2011). ↑ Kenya: Households farming high quality soil are less likely to migrate, especially temporary labour migration (Gray, 2011). ↑ India: Temporary migration identified as 'the most important' coping strategy in times of drought in rural villages (Jülich, 2011). ↑ Burkina Faso: Simulations of dry climate scenario produces increased migration fluxes compared to wet scenarios. Highest international migrant flows are shown with the dry climate scenarios (Kniveton et al., 2011). ↑ Canada: Higher population loss associated with settlements containing areas of poorer quality agricultural soils during droughts of 1930s (McLeman and Ploeger 2011). ↑ Guatemala: Outmigration was commonly attributed to soil degradation, resulting in migration to the expanding agricultural frontiers by open forests (López-Carr, 2012). ↑ Sahel: In three case regions, the pressure to migrate significantly increased since the 1970s possibly as a response to the onset of the persistent droughts. (Scheffran et al., 2012b; 2012c).
Evidence for decreased migration, mobility or significantly trapped populations.	↓ Mali: Reduced international migration during 1980s drought and an increase in cyclical migration (Findley, 1994). ↓ Nepal: Deforestation, population pressure and agricultural decline leads to local mobility, especially among women, but no increases in internal or international migration (Massey et al., 2010; Bohra-Mishra and Massey, 2011) ↓ Uganda: High soil quality marginally increases migration, especially permanent non-labor migration. (Gray, 2011).
Evidence for socially-differentiated mobility outcomes.	⇅ Burkina Faso: Land degradation is associated with less first time migration, but more migration for previous migrants. Land degradation greater influence on migration than rainfall variability (Henry et al., 2004). ⇅ Burkina Faso: Drier region populations more likely to migrate than people from regions with more rainfall. Rainfall deficits have different impacts depending on the duration and distance of the migration (Henry et al., 2004). ⇅ United States: Dustbowl migrants from Oklahoma to California in the 1930s had different social and economic capital endowments to those who stayed within state (McLeman and Smit, 2006). ⇅ Ecuador: Influence of natural capital on migration differed between men and women. Access to land facilitates migration in men; women are less likely to migrate from environmentally degraded areas (Gray, 2010). ⇅ Ethiopia: Male migration increases with drought. However, marriage related moves by women decrease with drought. (Gray and Mueller, 2012). ⇅ Burkina Faso: Labour migration became a key off-farm livelihood strategy after droughts in the 1970s for those groups dependent on rain-fed agriculture. However, those with large cattle herds relied on livestock sales as a coping strategy with negative implications for future resilience (Nielsen and Reenberg, 2010). ⇅ Mongolia: Diversity in herders' mobility strategies to mobility in response to climate change. For a minority, responses entailed greater overall annual mobility. Other herding households experienced significant reductions in mobility (Upton, 2012). ⇅ Tanzania: Agent based models concluded the normalised rate of need-driven migration was greatest under extreme drying, whereas aspirational migration was less sensitive to changes in rainfall (Smith et al., 2013).

	Flooding	
Evidence for increasing migration, mobility or increased displacement.	↑	USA: counties and parishes in Louisiana of the 77 impacted counties experienced 82% of the total population increase in the year following Hurricane Katrina (Frey and Singer, 2006).
	↑	Vietnam: Cumulative impacts of seasonal flooding increases outmigration rates in the Mekong Delta (Dun, 2011).
	↑	Bangladesh: 22% of households affected by tidal-surge floods, and 16% affected by riverbank erosion, moved to urban areas. (Penning-Rowsell et al., 2013).
Evidence for decreased migration, mobility or significantly trapped populations.	↓	Bangladesh: No out-migration detected after 2004 tornado in Bangladesh as a result of the effective distribution of disaster aid (Paul, 2005).
	↓	Senegal: Over 40 percent of new migrant populations located in high risk flood zones in Dakar (Quoted in Black et al., 2011b).
Evidence for socially-differentiated mobility outcomes.	⇅	USA: Emergency evacuation responses and return migration after the event highly differentiated income, race, class and ethnicity (Elliott and Pais, 2006; Falk et al., 2006; Landry et al., 2007).
	⇅	Bangladesh: Wide variation among groups in attitudes and capabilities for migration as an adaptation to the impact of cyclone Aila (Kartiki, 2011)

	Sea level rise	
Evidence for increasing migration, mobility or increased displacement.	↑	United States: Underlying driver of sea level rise caused initial depopulation. Final abandonment was a result of the population falling below levels to support local community services. (Arenstam Gibbons and Nicholls, 2006).
	↑	Vanuatu: Whole village displacement associated with inundation, both from sea level rise and tectonic movement on Torres Islands (Ballu et al., 2011).
	↑	United States: The impact of future sea-level rise will extend beyond the inundated counties through migration networks that link inland and coastal areas and their populations (Curtis and Schneider, 2011).
	↑	Papua New Guinea: Population considering resettlement on Bougainville to the main island due to coastal erosion, land loss, saltwater inundation and food insecurity (Oliver-Smith, 2011).
	↑	United States: Coastal villages in Alaska affected by sea-level rise and coastal erosion. The population as Shishmaref have decided to relocate (Oliver-Smith, 2011; Marino, 2012).
Evidence for decreased migration, mobility or significantly trapped populations.	↓	Tuvalu: On the island of Funafuti, climate change is not a cause for concern nor cited as a reason for migration (Mortreux and Barnett, 2009).

Executive Summary

This chapter discusses how livelihoods, poverty and the lives of the poor, and inequality interact with climate change, climate variability, and extreme events in multifaceted and cross-scalar ways. It examines how current impacts of climate change, projected impacts up until 2100, and climate change responses affect livelihoods and poverty. The Fourth Assessment Report stated that the socially and economically disadvantaged and marginalized are disproportionally affected by climate change. Yet, climate change is rarely the only factor that affects livelihood trajectories and poverty dynamics; it interacts with a multitude of non-climatic factors, which makes detection and attribution challenging.

Climate change constitutes an additional burden to the rural and urban poor. It acts as a threat multiplier, often with negative outcomes for livelihoods (*very high confidence, based on robust evidence, high agreement*).

- Weather events and climate, ranging from subtle shifts in trends to extreme events, affect poor people's lives directly through impacts on livelihood assets, such as losses in crop yields, destroyed homes, food insecurity, and loss of sense of place, and indirectly through increased food prices and climate policies. [13.2.1, 13.3]
- Changing climate trends provoke shifts in rural livelihoods such as from crop-based to mixed livestock- and forest-based livelihoods or to wage-based labor in agricultural and urban employment. [13.2.1.2]
- Urban and rural transient poor who face multiple deprivations slide into chronic poverty as a result of weather events or extreme events, or a series of events, when they are unable to rebuild their eroded assets (*limited evidence, high agreement*) [13.2.1.3]
- Many weather events that affect poor people remain unrecognized, such as short periods of extreme temperature or minor changes in the distribution of rainfall, due to short time series and geographically sparse, aggregated, or partial data, inhibiting detection and attribution in many low-income countries. [13.2.1]

Climate change worsens existing poverty, exacerbates inequalities, and triggers new vulnerabilities and some opportunities. Poor people are poor for different reasons and thus are not all equally affected, and not all vulnerable people are poor. Climate change interacts with non-climatic stressors and entrenched structural inequalities to shape vulnerabilities (*very high confidence, based on robust evidence, high agreement*).

- Socially and geographically marginalized people exposed to persistent inequalities at the intersection of gender, age, race, class, caste, indigeneity, and (dis)ability are particularly negatively affected by weather events and climate. Context-specific conditions of marginalization shape differential vulnerability. [13.1.2.5]
- Preexisting gender inequalities are increased or highlighted by weather events and climate. Gendered impacts depend on customary and new roles in society, often entailing higher workloads, occupational hazards indoors and outdoors, psychological and emotional distress, and mortality in climate-induced disasters. [13.2.1.5]

- Very scarce evidence exists that demonstrates positive impacts of climate change on the poor, including flood preparedness, collective action, institutional change, and social asset accumulation. Often, the more affluent can better take advantage of shocks and crises, given their flexible assets and power status. [13.1.3, 13.2.1.4]

Climate change will create new poor, in low-income countries and middle- to high-income countries and jeopardize sustainable development. Most severe impacts are projected for urban areas and some regions in sub-Saharan Africa and Southeast Asia (*medium confidence, based on medium evidence, medium agreement*).

- Future impacts of weather events and climate will slow down economic growth and poverty reduction, further erode food security, and trigger new poverty traps, the latter particularly in urban areas. [13.2.2.4, 13.4]
- Climate change will exacerbate multidimensional poverty in low and lower middle-income countries, including high mountain states and countries with indigenous people threatened by sea level rise and relocation, and create new poverty pockets in upper middle- to high-income countries. [13.2.2]
- Urban and wage-labor dependent poor households, as well as regions with high food insecurity, above all in Africa, and high inequality, will be particularly affected due to food price increases. [13.2.2.3, 13.2.2.4]

Policy responses for climate change mitigation or adaptation will result in mixed and potentially detrimental outcomes for poor and marginalized people (*medium confidence, based on low evidence, high agreement*).

- Mitigation efforts such CDM and REDD+, as well as land acquisition for food and biofuel production, show preliminary negative impacts on the poor, particularly indigenous people and (women) smallholders. [13.3.1]
- Insurance schemes, social protection programs, and disaster risk reduction may enhance long-term livelihood resilience among poor and marginalized people, if policies address multidimensional poverty. [13.3.2.2, 13.4.1]
- Climate-resilient development pathways will have only marginal effects on poverty reduction, unless structural inequalities are removed and needs for equity among the poor and non-poor met. [13.3.1, 13.4.2]

13.1. Scope, Delineations, and Definitions: Livelihoods, Poverty, and Inequality

Understanding the impacts of climate change on livelihoods and poverty requires examining the complexities of poverty and the lives of the poor and non-poor as well as the multifaceted and cross-scalar intersections of poverty and livelihoods with climate change. This chapter examines these complexities. First, it presents the concepts of livelihoods, poverty, and inequality, and their relationships to each other and to climate change. Second, it describes observed impacts of weather events and climate on livelihoods and poverty and impacts for 2015-2100 for the urban and rural poor. Third, it discusses impacts of climate change mitigation and adaptation responses on livelihoods and poverty. Finally, it outlines implications for poverty alleviation efforts and climate-resilient development pathways.

Livelihoods and Poverty is a new chapter in the AR5. Although the AR4 WGII contributions mentioned poverty, as one of several non-climatic factors contributing to vulnerability, as a serious obstacle to effective adaptation, and in the context of endemic poverty in Africa (Technical Summary, Chapters 7, 8, 18, 20), no systematic assessment was undertaken. Livelihoods were more frequently addressed in the AR4, predominantly with reference to livelihood strategies and opportunities, diversification, resource-dependent communities, and sustainability, yet a coherent livelihood lens for assessing impacts was lacking. This chapter addresses these gaps and how climate change intersects with other stressors to shape livelihood choices and trajectories, affect the spatial and temporal dimensions of poverty dynamics, and reduce or exacerbate inequalities given differential vulnerabilities.

13.1.1. Livelihoods

Livelihoods (see also Glossary) are understood as the ensemble or opportunity set of capabilities, assets, and activities that are required to make a living (Chambers and Conway, 1992; Ellis *et al.*, 2003). They depend on access to natural, human, physical, financial, social, and cultural capital (assets); the social relations people draw upon to combine, transform, and expand their assets; and the ways people deploy and enhance their capabilities to be, act, and make lives meaningful (Scoones and IDS, 1998; Bebbington, 1999). Livelihoods are dynamic and people adapt to and change with internal and external stressors. Ultimately, successful livelihoods transform assets into income, dignity, and agency, to improve living conditions, a prerequisite for poverty alleviation (Sen, 1981).

Livelihoods are universal. The poor and the rich both pursue livelihoods to make a living. However, the adverse impacts of weather events and climate increasingly threaten and erode basic needs, capabilities, and rights, particularly among poor and disenfranchised people, in turn shaping their livelihoods (UNDP, 2007; Leary *et al*., 2008; Adger, 2010; Quinn *et al*., 2011). Some livelihoods are directly climate-sensitive, such as smallholder agriculture, seasonal employment in agriculture (e.g. tea, coffee, sugar), fishing, pastoralism, and tourism. Climate change also impacts households dependent on informal livelihoods or wage labor in poor urban settlements, directly through unsafe settlement structures or indirectly through rises in food prices.

13.1.1.1. Dynamic Livelihoods and Trajectories

A livelihood lens allows for a multidimensional and grounded analysis of people's complex lives by recognizing the flexibility and constraints with which they construct and adapt their livelihoods, and their dynamic decision making under climatic and other stressors. Livelihood analyses focus on the wider institutional, cultural, and policy contexts as well as shocks, seasonality, and trends, including processes that force poor and vulnerable people onto undesirable trajectories or toward enhanced wellbeing. Better infrastructure and technology as well as diversification of asset and activity portfolios and social support capabilities can boost livelihoods, spreading risks and broadening opportunities (Batterbury, 2001; Ellis *et al*., 2003; Clot and Carter, 2009; Carr, 2013). The sustainable livelihoods framework (Chambers and Conway, 1992) is the most widely-used approach for identifying how specific strategies may lead to cycles of livelihood improvements or impoverishment and critical thresholds beyond which certain livelihoods are radically transformed (Sabates-Wheeler *et al*., 2008). Yet, it has been criticized for not sufficiently explaining the wider structural processes that constrain livelihoods and wellbeing (Scoones, 2009).

13.1.1.2. Multiple Stressors

Livelihoods rarely face only one stressor or shock at a time. The literature emphasizes the synergistic relationship between weather events and climate and a variety of other environmental, social, and political stressors; jointly, they impinge on livelihoods and reinforce each other in the process, often negatively (Reid and Vogel, 2006; Schipper and Pelling, 2006; Tschakert, 2007; IPCC, 2007; Morton, 2007; Easterling *et al*., 2007; O'Brien *et al*., 2008; Eakin and Wehbe, 2009; Eriksen and Silva, 2009; Ziervogel *et al*., 2010). "Double losers" may emerge from simultaneous exposure to climatic change and other stressors such as economic globalization, rapid urbanization, and the spread of infectious diseases, further marginalizing vulnerable groups (O'Brien and Leichenko, 2000; Eriksen and Silva, 2009). Climatic and other stressors affect livelihoods at different scales: the level of spatial (e.g., village, nation) or temporal (e.g., annual, multi-annual) analysis affects detection and attribution of impacts. Impacts, both direct and indirect, are often amplified or weakened at different levels. Global or regional processes interact with local and national processes, often mediated by institutions, to generate locally experienced stressors and shocks (Reid and Vogel, 2006; Thomas *et al*., 2007; Paavola, 2008; Pouliotte *et al*., 2009) (see Figure 13-5 within FAQ 13.2).

Multiple stressors, simultaneous and in sequence, differentially shape livelihood dynamics and trajectories based on inequalities and differential vulnerabilities. More affluent households may be able to capitalize on shocks and crises while poorer households with less flexible opportunity sets are forced to erode their asset bases. Some coping strategies and limited ability to adapt may result in adverse consequences. Such maladaptive actions (see Glossary, Chapters 14, 16) undermine the long-term sustainability of livelihoods and results in downward trajectories, further impoverishment, and poverty traps (Ziervogel *et al*., 2006; Tanner and Mitchell, 2008; Barnett and O'Neill, 2010).

13.1.2. Dimensions of Poverty

Poverty is a complex concept with conflicting definitions and considerable disagreement in terms of framings, methodologies, and measurements. Despite differences in approaches emphasizing distinct aspects of poverty at the individual or collective level, such as income, capabilities, and quality of life (Laderchi *et al*., 2003), poverty is now recognized as multidimensional (UNDP, 1990). Poverty is influenced by social, economic, institutional, political,

and cultural drivers; reversing it requires efforts in multiple domains by promoting opportunities and empowerment, and enhancing security (World Bank, 2001). In addition to material deprivation, poverty considers agency and identity, and a sense of belonging and socio-cultural heritage (O'Brien and Leichenko, 2003). The AR4 identified poverty as "the most serious obstacle to effective adaptation" (Confalonieri *et al*., 2007, p.417).

13.1.2.1. Framing and Measuring Multidimensional Poverty

Over the last six decades, conceptualizations of poverty have become increasingly broader, poverty measurements more multifaceted, and spatial and temporal analyses more nuanced. Attention to multidimensional deprivations – hunger, illiteracy, unclean drinking water, lack of access to health services and electricity, and social isolation (WHO, 2006) – has shifted the analytical lens to the dynamics of poverty and its institutionalization within social and political norms. However, given these shifting conceptualizations over time, reliable measurement remains challenging. This, in turn, complicates attribution of climate change impacts and responses on the world's poor.

In climate change literature, poverty and poverty reduction have been predominantly defined through an economic lens, reflecting various growth and development discourses (Hirschman, 1988; Sachs, 2006; Collier, 2007). Less attention has been paid to relational poverty, produced through material social relations and in relation to privilege and wealth (Sen, 1976; Mosse, 2010; Alkire and Foster, 2011; UNDP, 2011a; Chen and Ravallion, 2012). Yet, such framing allows for addressing the social and political contexts that generate poverty and vulnerability to climate change (McCright and Dunlap, 2000; Bandiera *et al*., 2005; Leichenko and O'Brien, 2008). Many climate policies to date favor market-based responses using sector-specific and economic growth models to counter trends that may slow down the achievements of the 2000 Millennium Development Goals (MDGs). For instance, the World Bank encourages "mitigation, adaptation, and the deployment of technologies" that "allow[s] developing countries to continue their growth and reduce poverty" (World Bank, 2010, p.257). A relational approach highlights the integral role of the poor in all social relations (Pogge, 2009; O'Brien *et al*., 2010; Gasper, 2010; UNRISD, 2010; St.Clair and Lawson, 2013), challenging earlier constructions of the poor as an underclass, undeserving, and with inadequate moral values (O'Connor, 2002; Mosse, 2010). It also emphasizes equity, human security, and dignity (UNRISD, 2010; Deacon and Cohen, 2011; Haarstad and St Clair, 2011). Akin to the capabilities approach (Sen, 1985; Sen, 1999; Nussbaum, 2001; Alkire, 2005; Nussbaum, 2011), the relational approach stresses the needs, skills, agency, and aspirations of poor people while tackling structural causes of poverty, inequalities, and uneven power relations.

The IPCC AR4 (Yohe *et al*., 2007) highlighted that – with *very high confidence* – climate change will impede nations' ability to alleviate poverty and achieve sustainable development, as measured by progress towards the MDGs. Empirical assessments of the impact of climate change on MDG attainment are limited (Fankhauser and Schmidt-Traub, 2011), and the failure to reach these goals by 2015 has significant non-climatic causes (e.g. Hellmuth and IRI, 2007; UNDP, 2007). To date, global indicators for seven out of the eight MDGs, including income poverty, have improved since 1990. However, at a country level, only half of all countries are on track for income poverty reduction. The 2010 UNDP Multidimensional Poverty Index, measuring intensity of poverty based on patterns of simultaneous deprivations in basic services (education, health, and standard of living) and core human functionings, states that 1.7 billion people are multidimensionally poor, a far higher number than the 1.29 billion (World Bank, 2012a) indicated by the income-centered International Poverty Line (IPL) set at $1.25/day.

[INSERT FIGURE 13-1 HERE
Figure 13-1: Multidimensional poverty and income poverty, with linear regression relationship (dotted line) and shaded 95% confidence interval based on 96 countries (HDR, 2011). The map inset shows the Poverty Gap Index score in Viet Nam, aggregated at district level, expressed as ratio of poverty line of yearly expenditure per capita).]

13.1.2.2. Geographic Distribution and Trends of the World's Poor

Geographic patterns of poverty are uneven and shifting. In 1990, most of the world's $1.25 poor (93%) lived in low-income countries (LICs). By 2008, the majority of the poor (>70%) resided in lower and upper middle-income countries (LMICs and UMICs), in part because some LICs such as India, Nigeria, and Pakistan evolved to MIC

status. To date, one billion people live under $1.25/day in MICs and a second billion between $1.25 and $2, with an additional 320m and 170m in the LICs, respectively. Of the approximately 2.4 billion living under $2/day, half live in India and China. By 2020, 60-80% of world poverty at $1.25and 40-55% at $2 will be concentrated in sub-Saharan Africa with the rest in South Asia (Sumner, 2010; Sumner *et al*., 2012). Using the $1.25/day poverty line suggests that at least 70% of the poor live in rural areas in developing countries (IFAD, 2011), despite worldwide urbanization. Yet, this poverty line considerably understates urban poverty since it overlooks the high costs of food and non-food needs in many urban contexts (Mitlin and Satterthwaite, 2013). Estimates of poverty by use of national accounts means (see Chapter 19) suggest low poverty levels by 2025 as these estimates project $2 poverty to be eliminated in large MICs such as India and Indonesia, whereas surveys means (e.g. Chen and Ravallion, 2012; Sumner *et al*., 2012; Sumner, 2012a) project a $2 poverty split between current LICs and MICs at least until 2030.

This shift in distribution of global poverty toward MICs challenges the orthodox view that most of the world's extreme poor live in the poorest countries, and suggests that substantial pockets of poverty can persist in areas with higher levels of average per capita income. Understanding the shift in the geography of poverty is vital for attributing climate change impacts on poverty. For example, both climate finance and research focusing on climate impacts and vulnerabilities are largely directed towards LICs. Less attention is paid to the poor in MICs and HICs, where poverty and income inequality are rising (OECD, 2011; Gower *et al*., 2012).

13.1.2.3. Spatial and Temporal Scales of Poverty

Poverty is also socially distributed, across spatial and temporal scales. Not everybody is poor in the same way. Spatially, factors such as access to and control over resources and institutional linkages from individuals to the international level affect poverty distribution (Anderson and Broch-Due, 2000; Murray, 2002; O'Laughlin, 2002; Rodima-Taylor, 2011). Even at the household level, poverty differs between men and women and age groups, yet data constraints impede systematic intra-household analysis (Alkire and Santos, 2010). The distribution of poverty also varies temporally, typically between chronic and transient poverty (Sen, 1981; Sen, 1999). Chronic poverty describes an individual deprivation, per capita income, or consumption levels below the poverty line over many years (Gaiha and Deolalikar, 1993; Jalan and Ravallion, 2000; Hulme and Shepherd, 2003). Transient poverty denotes a temporary state of deprivation, and is frequently seasonal and triggered by an individual's or household's inability to maintain income or consumption levels in times of shocks or crises (Jalan and Ravallion, 1998).

Individuals and households can fluctuate between different degrees of poverty and shift in and out of deprivation, vulnerability, and wellbeing (Leach *et al*., 1999; Little *et al*., 2008; Sallu *et al*., 2010). Poor people often find themselves in poverty traps – situations in which escaping poverty becomes impossible without external assistance due to unproductive or inflexible asset portfolios (Barrett and McPeak, 2006). A poverty trap can also be seen as a "critical minimum asset threshold, below which families are unable to successfully educate their children, build up their productive assets, and move ahead economically over time" (Carter *et al*., 2007 p.837). As of 2008, a total of 320 to 443 million of people were trapped in chronic poverty (Chronic Poverty Research Centre, 2008), leading Sachs (2006) to label <$1.25/day poverty as a trap in itself. Poverty traps at the national level are often related to poor governance, reduced foreign investment, and conflict (see Chapter 10).

13.1.3. Inequality and Marginalization

Specific livelihoods and poverty alone do not necessarily make people vulnerable to weather events and climate. The socially and economically disadvantaged and the marginalized are disproportionately affected by the impacts of climate change and extreme events (*robust evidence*) (Kates, 2000; Paavola and Adger, 2006; Adger *et al*., 2007; Cordona *et al*., 2012). These include the poor and indigenous people in North America (Field *et al*., 2007) and Africa (Boko *et al*., 2007). Inequality is a useful lens for examining why multidimensional poverty continues to exist, and in some cases has increased, despite poverty reduction efforts. Vulnerability, or the propensity or predisposition to be adversely affected (Field *et al*., 2012a) by climatic risks and other stressors, emerges from the intersection of different inequalities, and uneven power structures, and hence is socially-differentiated (Sen, 1999; Banik, 2009; Field *et al*., 2012a). Vulnerability is often high among indigenous people, women, children, the

elderly, and disabled people due to multiple deprivations that inhibit the poor and marginalized from managing daily risks and shocks (Eriksen and O'Brien, 2007; Ayers and Huq, 2009; Boyd and Juhola, 2009; Barnett and O'Neill, 2010; O'Brien *et al*., 2010; Petheram *et al*., 2010; OECD, 2011), and may present significant barriers to adaptation.

Global inequality is persistent. In 2007, the top quintile of the world's population received 83% of total the income whereas the bottom quintile took in 1% (Ortiz and Cummins, 2011). Within most countries, income inequality has increased as economic activity and sector-specific growth constrains the productive capacity of the poor who disproportionately bear the externalities of economic growth such as environmental degradation (UNRISD, 2010; UNDP, 2011b). An inequality lens also highlights growing poverty in MICs and HICs (Gower *et al*., 2012; Gough, 2012; Taylor and Xiaoyun, 2012; Sumner, 2012b). Recognizing how inequality and marginalization perpetuate multidimensional poverty is an essential prerequisite for climate-resilient development pathways (see 13.4).

13.1.4. Interactions between Livelihoods, Poverty, Inequality, and Climate Change

This chapter opens its analytical lens from a conventional focus on poor developing countries as the prime victims of climate change to a broader understanding of livelihood and poverty dynamics and inequalities across spatial and temporal scales, revealing the highly unequal impacts of climate change. It highlights the bidirectional relationship between climate change and poverty. Addressing structural inequalities that create and sustain poverty and vulnerability (Huq *et al*., 2005; Schipper, 2007; Lemos *et al*., 2007; Boyd and Juhola, 2009; Williams, 2010; Perch, 2011) is "a prerequisite for sustainability in the context of climate change" (Field *et al*., 2012a, p.20). Uneven social relations that disproportionally burden the poorest with the brunt of climate change's negative impacts, if ignored, contribute to maladaptation (Barnett and O'Neill, 2010).

Poverty and persistent inequality are the "most salient of the conditions that shape climate-related vulnerability" (Ribot, 2010, p.50), affect livelihood options and trajectories, and create conditions in which people have few assets to liquidate in times of hardship or crisis (Mearns and Norton, 2010). The poor and marginalized usually have the least buffer to face even modest climate hazards and suffer most from successive events with little time for recovery. They are the first to experience asset erosion, poverty traps, and barriers and limits to adaptation. As shown in sections 13.2 and 13.3, climate change is an additional burden to the poor (*very high confidence*), and it will force some poor from transient into chronic poverty and create new poor (*high confidence*).

The complex interactions among weather events and climate, dynamic livelihoods, multidimensional poverty and deprivation, and persistent inequalities create an ever-shifting context of risk. Climate change, climate variability, and extreme events synergistically add on to and often reinforce other environmental, social, and political calamities (Field *et al*., 2012a). Despite the recognition of these complex interactions, the literature shows no single conceptual framework that captures them concurrently, and few studies exist that overlay gradual climatic shifts or rapid-onset events onto livelihood risk spaces. Hence, explicit attention to how livelihood dynamics interact with climatic and non-climatic stressors is useful for identifying processes that force poor and vulnerable people onto undesirable trajectories and trap them in destitution, constitute critical thresholds beyond which a certain livelihood is no longer feasible, or offer escape routes toward enhanced wellbeing. Figure 13-2 illustrates these dynamics.

[INSERT FIGURE 13-2 HERE
Figure 13-2: Livelihood dynamics under simultaneous climatic, environmental, and socioeconomic stressors and shocks leading to differential risk spaces and livelihood trajectories over a lifetime.]

13.2. Assessment of Climate Change Impacts on Livelihoods and Poverty

This section reviews the evidence and agreement about the relationships among climate change, livelihoods, poverty, and inequality. It first describes observed impacts to date (13.2.1) and then projected impacts (13.2.2). The focus on climate change effects on livelihood decision making and trajectories, spatial distributions of poverty and shifts from transient to chronic poverty, and differential vulnerability and poverty traps due to intersecting inequalities demonstrates the multifaceted interactions between weather events and climate and non-climatic

stressors. Building on deductive reasoning and theorized linkages among climate change, livelihoods, and poverty, this section draws on a wide range of empirical studies and simulations to provide evidence across multiple scales, contexts, and social and environmental processes to assess climate change impacts. Cases of observed impacts often rely on qualitative data, and sometimes lack methodological clarity and rigorous detection and attribution.

13.2.1. Evidence of Observed Climate Change Impacts on Livelihoods and Poverty

Weather events and climate impact the lives and livelihoods of millions of poor people (Field *et al.*, 2012b). Even minor changes in precipitation amount or temporal distribution, short periods of extreme temperatures, or localized weather events can have serious impacts on livelihoods (Douglas *et al.*, 2008; Ostfeld, 2009; Midgley and Thuiller, 2011). Many such events remain unrecognized given that standard climate observations typically report precipitation or temperature by month, season, or year, thus obscuring changes that directly impact decision making, for instance, in agriculture (Tennant and Hewitson, 2002; Barron *et al.*, 2003; Usman and Reason, 2004; Douglas *et al.*, 2008; Salack *et al.*, 2012; Lacombe *et al.*, 2012). This difficulty in detection and attribution is compounded by a lack of long-term continuous and dense networks of climate data in many LICs (UNECA, 2011) and, as shown for the Sumbanese in Eastern Indonesia, by phenomenological experiences of events such as drought (Orr *et al.*, 2012).

13.2.1.1. Impacts on Livelihood Assets and Human Capabilities

Climate change, climate variability and extreme events interact with numerous aspects of people's livelihoods. This section presents empirical evidence of impacts on natural, physical, financial, human, and social and cultural assets.

Weather events and climate impact *natural assets* on which certain livelihoods depend, such as rivers, lakes, and fish stocks (*robust evidence*) (Thomas *et al.*, 2007; Nelson and Stathers, 2009; Osbahr *et al.*, 2010; Bunce *et al.*, 2010a; Bunce *et al.*, 2010b; D'Agostino and Sovacool, 2011) (see Chapters 3, 4, 5, 6, and 30). During the 20th century, water temperatures increased in Lake Tanganyika and winds decreased (Verburg and Hecky, 2009; Adrian *et al.*, 2009; Tierney *et al.*, 2010). Thus, studies since the late 1970s have observed a 20% drop in primary production and a 30% decline in fish, a key protein source in the area; these drops may exceed effects of overfishing and other human impacts (O'Reilly *et al.*, 2003). The Middle East and North Africa (MENA) face dwindling water resources due to less precipitation and rising temperatures combined with mounting water demand due to population and economic growth (Tekken and Kropp, 2012), resulting in rapidly decreasing water availability, expected to be 30-70% less per person in 2025 (Sowers *et al.*, 2011). In MENA (Sowers *et al.*, 2011), the Andes and Himalayas (Orlove, 2009), the Caribbean (Cashman *et al.*, 2010), Australia (Alston, 2011), and in cities (Satterthwaite, 2011), policy allocation often favors more affluent consumers, at the expense of less powerful rural and/or poor users.

Weather events and climate also erode farming livelihoods (see Chapters 7, 9), via declining crop yields (Hassan and Nhemachena, 2008; Apata *et al.*, 2009; Sissoko *et al.*, 2011; Sietz *et al.*, 2012), at times compounded by increased pathogens, insect attacks, and parasitic weeds (Stringer *et al.*, 2007; Byg and Salick, 2009), and reduced availability of and access to non-timber forest products (Hertel and Rosch, 2010; Nkem *et al.*, 2012), and biodiversity and medicinal plants (Van Noordwijk, 2010). For agropastoral and mixed crop-livestock livelihoods, extreme high temperatures threaten cattle (Hahn, 1997; Thornton *et al.*, 2007; Mader, 2012; Nesamvuni *et al.*, 2012) ; in Kenya, for instance, people may shift from dairy to beef cattle and from sheep to goats (Kabubo-Mariara, 2008).

The most extreme form of erosion of natural assets is the complete disappearance of people's land on islands and in coastal regions (McGranahan *et al.*, 2007; Solomon *et al.*, 2009; Perch and Roy, 2010) (see Chapter 5). Densely populated coastal cities with high poverty counts such as Alexandria and Port Said in Egypt (El-Raey *et al.*, 1999), Cotonou in Benin (Dossou and Glehouenou-Dossou, 2007), and Lagos and Port Harcourt in Nigeria (Abam *et al.*, 2000; Fashae and Onafeso, 2011) have already been affected by floods and are at risk of submersion, while resettlements are planned for the Mekong River Delta and the Limpopo River (de Sherbinin *et al.*, 2011).

Damage to *physical assets* due to weather events and climate is well documented for poor urban settlements, often built in risk-prone floodplains and hillsides susceptible to erosion and landslides. Impacts include homes destroyed

by flooding water and disrupted water and sanitation services. Flooding has adversely affected large African cities (e.g., Accra, Nairobi, Kampala, and Lagos), mainly due to inadequate drainage and increasing precipitation in dense settlements (Douglas *et al*., 2008), and informal settlements in Latin American cities (Hardoy and Pandiella, 2009; Hardoy *et al*., 2011). Loss of physical assets in poor areas after disasters is often followed by looting (Hardoy and Pandiella, 2009) and displacement due to loss of property (Douglas *et al*., 2008). Increasing flash floods attributed to climate change (Sudmeier-Rieux *et al*., 2012) have severely damaged physical assets in the Himalayas, such as terraces, orchards, stream embankments, and roads (Hewitt and Mehta, 2012; Azhar-Hewitt and Hewitt, 2012).

Erosion of *financial assets* during periods of increased climate stress result from loss of farm income and jobs (Hassan and Nhemachena, 2008; Iwasaki *et al*., 2009; Alderman, 2010; Jabeen *et al*., 2010; Alston, 2011) and increased costs of living (Gabrielsson *et al*., 2012). Urban flooding in Lagos slums undermines job opportunities (Adelekan, 2010). Income losses due to weather events are compounded by expenses for agricultural inputs (seeds, equipment), school tuition, uniforms, and books, and health expenses throughout the year (Thomas *et al*., 2007).

Equally important, albeit frequently overlooked, is the damage to *human assets* as a result of weather events and climate, such as increased food insecurity, undernourishment, and chronic hunger due to failed crops (*medium evidence*) (Misselhorn, 2005; Patz *et al*., 2005; Funk *et al*., 2008; Gentle and Maraseni, 2012) or spikes in food prices most severely felt among poor urban populations (Ahmed *et al*., 2009; Hertel and Rosch, 2010). During the Ethiopian drought (1998-2000) and Hurricane Mitch in Nicaragua (1998), poorer households tended to engage in asset smoothing, reducing their consumption to very low levels to protect their assets, whereas wealthier households sold assets and smoothed consumption (Carter *et al*., 2007). In such cases, the poor further erode nutritional levels and human health while desperately holding on to their limited assets. Dehydration, heat stroke, and heat exhaustion, from exposure to heat waves undermine people's ability to carry out physical work outdoors and indoors (Semenza *et al*., 1999; Kakota *et al*., 2011) (see Chapter 11). Psychological effects from extreme events include sleeplessness, anxiety and depression (Byg and Salick, 2009; Keshavarz *et al*., 2013), loss of sense of place and belonging (Tschakert *et al*., 2011; Willox *et al*., 2012), and suicide (Caldwell *et al*., 2004; Alston, 2011) (*medium evidence*).

Finally, weather events and climate also erode *social and cultural assets*. A series of climatic and non-climatic stressors and changing trends disrupt informal social networks of the poorest, elderly, women, and women-headed households, preventing mobilization of labor and reciprocal gifts (Osbahr *et al*., 2008; Buechler, 2009), as well as formal social networks, including social assistance programs (Douglas *et al*., 2008). Indigenous people (see Chapter 12) witness their cultural points of reference disappearing (Ford, 2009; Green *et al*., 2010; Bell *et al*., 2010).

13.2.1.2. Impacts on Livelihood Dynamics and Trajectories

Weather events and climate also affect livelihood trajectories and dynamics in livelihood decision making, often in conjunction with cross-scalar socio-economic, institutional, or political stressors. Shifting in and out of hardship, vulnerability, and wellbeing on a seasonal basis is not uncommon. To a large extent, these shifts from coping and hardship to recovery are driven by annual and inter-annual climate variability. Figure 13-3 illustrates an annual "wheel of hardship" for the Lake Victoria Basin in East Africa (Gabrielsson *et al*., 2012).

[INSERT FIGURE 13-3 HERE
Figure 13-3: 'Wheel of hardship' – a generalized seasonal calendar depicting livelihood conditions and stress based on experiences of smallholder farmers in the Lake Victoria Basin in Kenya and Tanzania (Gabrielsson *et al*., 2012).]

Shifts in livelihoods often occur due to changing climate trends, linked to a series of environmental, climatic, and political stressors (*robust evidence*). Farmers may change their crop choices instead of abandoning farming (Kurukulasuriya and Mendelsohn, 2007) or take on more lucrative income-generating activities (see Figure 13-2). Around Mali's drying Lake Faguibine, livelihoods shifted from water-based to agro-sylvo-pastoral systems, as a direct impact of lower rainfall and more frequent and more severe droughts (Brockhaus and Djoudi, 2008). Diverse indigenous groups in Russia have changed their livelihoods as result of Soviet legacy and climate change; for example, many Viliui Sakha have abandoned cow-keeping due to youth out-migration, growing access to consumer goods, and seasonal changes in temperature, rainfall, and snow (Crate, 2013). Under certain converging shocks and

stressors, people adopt entirely new livelihoods. After Hurricane Stan (2005), land-poor coffee farmers in Chiapas, Mexico, turned from specializing in coffee to being day laborers and subsistence farmers (Eakin *et al.*, 2012). In South Africa, higher precipitation uncertainty raised reliance on livestock and poultry rather than crops alone in 80% of households interviewed (Thomas *et al.*, 2007). In South India and southern Africa people migrated to the coasts, switching from climate-sensitive farming to marine livelihoods (Coulthard, 2008; Bunce *et al.*, 2010a; Bunce *et al.*, 2010b). In West Africa, shifting seasonality of rains hamper crop and water management of small-scale farmers (Yengoh *et al.*, 2010a; Yengoh *et al.*, 2010b; Armah *et al.*, 2011; Karambiri *et al.*, 2011; Lacombe *et al.*, 2012).

13.2.1.3. Impacts on Poverty Dynamics: Transient and Chronic Poverty

Limited evidence documents the extent to which climate change intersects with poverty dynamics, yet, there is *high agreement* that shifts from transient to chronic poverty due to weather and climate are occurring, especially after a series of weather or extreme events (Scott-Joseph, 2010). Households in transient poverty may become chronically poor due to a lack of effective response options to weather events and climate, compared with more affluent households (see Figure 13-2). Often, multiple deprivations drive these shifts, with socially and economically marginalized groups particularly prone to slipping into chronic poverty. Limited and maladaptive responses such as sending younger children to work may contribute (Tanner and Mitchell, 2008). Women-headed households, people in informal settlements, children, and indigenous communities are particularly at risk, due to compounding stressors such as lack of governmental support, urban infrastructure, and formal land tenure (see 13.2.1.5 and Chapter 12).

Urban poor in Africa, Asia, and Latin America may slip from transient to chronic poverty given the combination of population growth and flooding threats in low-elevation cities and growth and water stress in drylands (Balk *et al.*, 2009), along with other multiple deprivations (Mitlin and Satterthwaite, 2013). Poverty shifts also occur in response to food price increases, though the strength of the relationship between weather events and climate and food prices is still debated (see Chapter 7 and 13.3.1.4). Urban poor are particularly at risk since they are almost exclusively net buyers of food (Cranfield *et al.*, 2007; Cudjoe *et al.*, 2010; Ruel *et al.*, 2010). In rural areas, those dependent on natural resources may also slip from transient to chronic poverty, for instance when access to forests is restricted, e.g., under conservation efforts or conflicts, and alternative income-generating resources such as non-timber forest products become unavailable, particularly for women-headed households (Shackleton *et al.*, 2007; Fisher *et al.*, 2010). In southern Africa, Misselhorn (2005) showed in a meta-study of 49 cases of food insecurity that climatic drivers and poverty were the two dominant and interacting causal factors. Poor pastoralists have collapsed into chronic poverty when livestock assets have been lost (Thornton *et al.*, 2007). Many of these shifts remain undetected, incompletely captured in poverty data and adaptation monitoring. The bulk of attention is oriented toward extreme events, rapid-onset disasters, and subsequent impacts on livelihoods and the poor. Subtle changes are rarely tracked, making quantification of long-term trends and attribution difficult.

13.2.1.4. Poverty Traps and Critical Thresholds

Poverty traps arise when climate change, variability, and extreme events make the poor even poorer. Yet, attribution remains a challenge. Among the urban poor, poverty traps have been reported especially for wage laborers who erode their financial capital due to increases in food prices (Ahmed *et al.*, 2009; Hertel and Rosch, 2010) and for those in informal settlements exposed to floods and landslides, with nowhere else to go and no governmental support (Hardoy and Pandiella, 2009). In rural areas, poverty traps are reported when poverty impacts of climate change persist over decades, mainly due to recurring stress on ecological systems and environmental degradation, such as in the Sahel (Kates, 2000; Hertel and Rosch, 2010; Sissoko *et al.*, 2011; UNCCD, 2011), and when people are unable to rebuild assets after a series of stresses (Eriksen and O'Brien, 2007; Sabates-Wheeler *et al.*, 2008; Sallu *et al.*, 2010). Poverty traps and destitution are also described in pastoralist systems, triggered through droughts, restricted mobility due to conflict and insecurity, adverse terms of trade, and the conversion of grazing areas to agricultural land, such as for biofuel production (Eriksen and Lind, 2009; Homewood, 2009; Eriksen and Marin, 2011). Other poverty traps result from heavy debt loads due to the inability to repay loans and distress sales (Renton, 2009; Ahmed *et al.*, 2012) and persistent discrimination through legal structures and formal institutions, especially for women and other marginalized groups (Campbell *et al.*, 2009; McDowell and Hess, 2012). Culturally-induced

poverty traps also exist, such as forced kin solidarity in farming systems in Ethiopia, due to which more affluent farmers avoid investing in soil fertility, which would protect against climate shocks (Di Falco and Bulte, 2012).

Despite *limited evidence*, there is *high agreement* that critical thresholds, or irreversible damage (Heltberg *et al*., 2009), result from the convergence of various factors, many of which are not directly related to climate change. For instance, the poor often rely on social networks, including reciprocal gifts and exchanges, to protect themselves from shocks and crises such as droughts (Little *et al*., 2006). Yet, given limited assets and ability to mobilize labor and food, particularly for smaller and women-headed households and the elderly, the exhaustion of these reciprocal ties can indicate an imminent slipping into poverty traps or chronic poverty (Pradhan *et al*., 2007; Osbahr *et al*., 2008). Injuries, disabilities, disease, psychological distress, for instance from accidents following flood events, critically lower poor people's main asset, labor (Douglas *et al*., 2008), and may plunge poor individuals and households deeper into deprivation, forcing some over critical thresholds into chronic poverty.

Few studies illustrate positive livelihood trajectories as a result of climate change or climate-induced shocks, and they tend to refer to more affluent and powerful constituencies while very scarce evidence exists of poor people escaping poverty traps (see Box 13-1). In Honduras, for example, Hurricane Mitch (1998) helped the poor to bring about institutional changes, more equitable land distribution, and better flood preparedness (McSweeney and Coomes, 2011). In Lake Victoria Basin, collective actions have emerged as a result of HIV/AIDS and climate change, enhancing social asset accumulation (Gabrielsson and Ramasar, 2012).

13.2.1.5. Implications for Inequality

Climate variability and change as well as climate-related disasters contribute to and exacerbate inequality, both in urban and in rural areas, in LICs, MICs, and HICs. Mounting inequality is not just a side effect of weather and climate but of the interaction of related impacts with multiple deprivations at the context-specific intersections of gender, race, class, caste, indigeneity, age, and (dis)ability, embedded in uneven power structures, also known as intersectionality (Shields, 2008; Nightingale, 2011). In many cities in Latin America, upper middle- and high-income people living in flood-prone areas or high-risk slopes can afford insurance and lobby for protective policies, in contrast to poor residents (Hardoy and Pandiella, 2009). In northern welfare states, in the aftermath of the financial crisis, modified social policies and fiscal regimes amplify unevenly distributed climate impacts (Gough, 2012). This section illustrates how climate impacts intersect with inequality, primarily along the lines of gender, age, and indigeneity, cross-referencing other dimensions of inequality covered in other chapters.

_____ START BOX 13-1 HERE _____

Box 13-1. Climate and Gender Inequality: Complex and Intersecting Power Relations

Preexisting ***gender inequality*** is increased or highlighted as a result of weather events and climate-related disasters intertwined with socioeconomic, institutional, cultural, and political drivers that perpetuate differential vulnerabilities (*robust evidence*) (Lambrou and Paina, 2006; Brouwer *et al*., 2007; Shackleton *et al*., 2007; Adger *et al*., 2007; Carr, 2008; Demetriades and Esplen, 2008; Galaz *et al*., 2008; Osbahr *et al*., 2008; Buechler, 2009; Hardoy and Pandiella, 2009; Nightingale, 2009; Renton, 2009; Terry, 2009; Dankelman, 2010; MacGregor, 2010; Alston, 2011; Arora-Jonsson, 2011; Resurreccion, 2011; Zotti *et al*., 2012). While earlier studies have tended to highlight women's quasi-universal vulnerability in the context of climate change (e.g. Denton, 2002), this general thrust can mask the complex and intersecting power relations and other deep structural and place-based causes of inequality (Nightingale, 2009; UNFPA, 2009; Arora-Jonsson, 2011). Moreover, the construction of economically poor women as vulnerable victims is a one-dimensional narrative that denies women's agency and emphasizes their vulnerability as their intrinsic problem (MacGregor, 2010; Manzo, 2010; Arora-Jonsson, 2011).

Gendered livelihood impacts: Men and women are affected by climate variability and change, albeit differentially. Campbell *et al*. (2009) and Resurreccion (2011), in case studies from Vietnam, found increased workloads for both partners linked to weather events and climate, contingent on socially accepted gender roles: men tend to work longer hours during extreme events and women take on extra responsibilities during disaster preparation and recovery (e.g.,

storing food and water and taking care of the children, the elderly, and the sick) and when their husbands migrate. In Cambodia, Khmer men and women accepted culturally-taboo income-generating activities under duress, when rice cropping patterns shifted due to increased temperatures and more irregular rainfall (Resurreccion, 2011). The ten-year drought in Australia's Murray-Darling Basin differentially affected men and women, due to their distinct roles within agriculture (e.g. Eriksen *et al*., 2010). Alston (2011) noted social disruption and depression, most profound in areas with almost total reliance on agriculture, no substitute employment, and limited service infrastructure (Table 13-1). Climate variability amplifies food shortages in which women consume less food and suffer from water-borne diseases and reproductive tract infections following floods (Neelormi *et al*., 2008; Campbell *et al*., 2009). In Nepal, shifts in the monsoon season, longer dry periods, and decreased snowfall force Dalit girls and women ('untouchable' caste) to grow drought-resistant buckwheat and provide more day labor to the high caste Lama landlords while Dalit men seek culturally-taboo patronage protection to engage in cross-border trade (Onta and Resurreccion, 2011).

Feminization of responsibilities: Increased workloads due to weather events and climate are often unevenly distributed, adding to already long lists of women's labor and caring duties (Nelson and Stathers, 2009; MacGregor, 2010; Petrie, 2010; Arora-Jonsson, 2011; Kakota *et al*., 2011; Resurreccion, 2011). The additional work for women, as shown in South Africa, takes a psychological and physical toll (Babugura, 2010). In Ghana, some husbands prevent their wives from engaging in additional agricultural production as a response to gradually shifting rainfall seasonality, thereby undermining both women's agency as well as overall household wellbeing (Carr, 2008).

Occupational hazards: Increasing cases of heat death are reported among male workers on sugarcane plantations in El Salvador due to kidney failure (Peraza *et al*., 2012) and heat-related indoor work emergencies in Spain among young (<50) able-bodied urban men (García-Pina *et al*., 2008) while anecdotal evidence suggests that women tea pickers in Malawi, Kenya, India, and Sri Lanka suffer and die from heat stress as payment by quantity undermines rest breaks (Renton, 2009) (see Chapter 11). In cases of male outmigration due to unsustainable rural livelihoods, women in Bangladesh face unsafe working conditions, exploitation, and loss of respect (Pouliotte *et al*., 2009).

Emotional and psychological distress: Climate-related disasters or gradual environmental deterioration can affect women's mental health disproportionally due to their multiple social roles (UN ECLAC, 2005; Demetriades and Esplen, 2008; Babugura, 2010; Hargreaves, 2013). Increased gender-based violence within households is reported as a social consequence of weather events and climate, including incremental climate change, not just disasters, due to greater stress, family conflict, and disrupted safety nets, in Australia (Alston, 2011; Parkinson *et al*., 2011; Whittenbury, 2013), the U.S. (Jenkins and Phillips, 2008; Anastario *et al*., 2009), and LICs such as Vietnam (Campbell *et al*., 2009) and Bangladesh (Pouliotte *et al*., 2009). In Nepal, human trafficking of girls and women may have increased by 20-30% during political conflict and floods and droughts (Nellemann *et al*., 2011).

Mortality: During floods, social conditioning often constrains poor women's mobility as many are not allowed to learn how to swim (Demetriades and Esplen, 2008); yet, in Nicaragua, it forced middle-class women to stay in risk-prone houses (Bradshaw, 2010). More women die in hurricanes and floods when they are socio-economically disadvantaged and the disasters exacerbate existing patterns of discrimination (Neumayer and Plümper, 2007; Ray-Bennett, 2009). Evidence from Hurricane Mitch and other disasters shows a higher mortality rate among men in the case of culturally-imposed roles as heroic life-savers (Röhr, 2006; Campbell *et al*., 2009; Resurreccion, 2011).

[INSERT FIGURE 13-4 HERE
Figure 13-4: Intersecting dimensions of inequality.]

[INSERT TABLE 13-1 HERE
Table 13-1: Gendered impacts of Australia's ten-year drought.]

_____ END BOX 13-1 HERE _____

Medium evidence highlights impacts of climate stresses and extreme events on *children* (Cutter *et al*., 2012; O'Brien *et al*., 2012). Children in urban slums suffer from inadequate water supplies and malnutrition, which exacerbates impacts from heat stress, while excessive rain heightens water-borne diseases (Bartlett, 2008). Flood-related mortality in Nepal was twice as high for girls as for women (1.33% versus 0.6%) and also higher for boys than for

men, and for young children in general six times higher than before the flood (Pradhan *et al.*, 2007). Lower caloric intake due to two back-to-back droughts and price shocks in Zimbabwe in the 1980s has resulted in physical stunting among children and reduced lifetime earnings (Alderman, 2010). In Mali, the incidence of child food poverty increased from 41% to 52% since the 2006 food price increases (Bibi *et al.*, 2010).

Health impacts of weather events and climate differentially affect *the elderly* and *socially isolated* (Frumkin *et al.*, 2008). In Vietnam the elderly, widows, and disabled people, in addition to single mothers and women-headed households with small children, were least resilient to floods and storms and slow-onset events such as recurrent drought (Campbell *et al.*, 2009). In Australia, older citizens have shown feelings of distress as a result of familiar landscapes altered by drought, loss of home gardens, social isolation, and physical harm related to heat stress and wild fires (Pereira and Pereira, 2008; Horton *et al.*, 2010; Polain *et al.*, 2011). Elderly citizens in the U.K. may experience higher vulnerability to heat waves due to misinformation propagated through bonding networks (Wolf *et al.*, 2010). Studies in Europe, U.S., U.K., Japan, Korea, and New Zealand report higher heat-related mortality among the elderly, children, and persons of lower socio-economic status (Baccini *et al.*, 2008). Much evidence, though anecdotal, suggests differential damages of Hurricane Sandy in New York (2012).

Inequality and disproportionate effects of climate-related impacts also occur along the axes of *indigeneity* and *race*. Examples include low-income African-American residents of New Orleans after Hurricane Katrina (Elliott and Pais, 2006), Afro-Latinos and displaced indigenous groups in urban Latin America (Hardoy and Pandiella, 2009), and the indigenous in the Russian North (Crate, 2013) and Bolivia's highlands (Andersen and Verner, 2009; Valdivia *et al.*, 2010; McDowell and Hess, 2012). See Chapter 12 for diverse impacts on indigenous cultures and lifestyles.

13.2.2. Understanding Future Impacts of Climate Change on Livelihoods and Poverty

Future climate change, as projected through modeling, will continue to affect poor people in rural and urban areas, both in the global North and South, alter their livelihoods, and make efforts to reduce poverty more difficult (*high confidence*). Studies reveal a broad range of future impacts, depending on the climatic, agro-economic, and demographic models employed, their key variables, time frame, ranging from 2016-2100, and spatial scale, varying from a country's agro-ecological zones to the global. Only some projections include adaptation.

Projections emphasize the complexity and heterogeneity of future climate impacts, including winners and losers in close geographic proximity. Anticipated impacts are expected to interact with multiple stressors, most notably social vulnerability (Iglesias *et al.*, 2011), low adaptive capacity and subsistence constraints under extreme poverty (Liu *et al.*, 2008), natural resource dependence (Adano *et al.*, 2012), population increases (Müller *et al.*, 2011), weak institutional support (Menon, 2009; Xu *et al.*, 2009; Skoufias *et al.*, 2011a; Skoufias *et al.*, 2011b), ethnic conflict and political instability (Challinor *et al.*, 2007; Adano *et al.*, 2012), large-scale land conversions (Assuncao and Cheres, 2008; Thornton *et al.*, 2008), and inequitable trade relations (Challinor *et al.*, 2007; Jacoby *et al.*, 2011).

13.2.2.1. Projected Impacts by Geographic Region

Climate change will exacerbate vulnerability and in turn further entrench poverty (*very high confidence*). Wheeler (2011) employs an extensive dataset to analyze climate risk and coping ability by country. The 20 countries most at risk of extreme weather in 2015 will include those with considerable poverty, although not all poor people will be at risk. Of these top 20, seven are LICs (Bangladesh, Ethiopia, Kenya, Madagascar, Mozambique, Somalia, and Zimbabwe), eight are lower MICs (Bolivia, Djibouti, Honduras, India, Philippines, Sri Lanka, Vietnam, and Zambia), four are upper MICs (China, Colombia, Cuba, and Thailand), and one is a HIC (Hong Kong). For the top five (China, Djibouti, India, Kenya, and Somalia), climate contributes between 46.4% and 87.5% to a 2008-2015 increase in national vulnerability, in contrast to income, urbanization, and regulation. Highest vulnerability to sea level rise by 2050, based on low-elevation coastal zones, areas of storm surge zones, and population density, is expected for India, China, Indonesia, and the Philippines (all MICs) and Bangladesh (LIC), while Qatar, Bahamas, and Bahrain (all HICs) show the highest percentage of vulnerable population (>30%). India and Indonesia are projected to experience a 80% and 60% increase, respectively, in the sizes of their populations vulnerable to sea

level rise, housing a combined total of over 58 million of the most vulnerable people by 2050; an increase of six million people vulnerable to sea level rise in China will bring its total to 22 million, and Bangladesh's vulnerable population is predicted to grow to 27 million people – more than double its 2008 size (Wheeler, 2011).

Geographically, highly vulnerable regions are those exposed to sea-level rise and extreme events overlaid with high concentrations of multidimensional poverty, including pockets of poor people in MICs: mega-deltas in Bangladesh, Thailand, Myanmar, and Vietnam (Eastham *et al.*, 2008; Wassmann *et al.*, 2009), watersheds in the Himalayas (Xu *et al.*, 2009), ecologically-fragile areas in China (Taylor and Xiaoyun, 2012), drylands (Anderson *et al.*, 2009; Piao *et al.*, 2010), mountain areas (Beniston, 2003; Valdivia *et al.*, 2010; Gerlitz *et al.*, 2012; McDowell and Hess, 2012; Gentle and Maraseni, 2012), river deltas subject to resource extraction (Syvitski *et al.*, 2009), and coastal areas with severe ecosystem deterioration in eastern and southern Africa (Bunce *et al.*, 2010a; Bunce *et al.*, 2010b).

13.2.2.2. Anticipated Impacts on Economic Growth and Agricultural Productivity

The majority of projected impact studies focus on the anticipated consequences of climatic changes and shocks on agricultural productivity, mainly in Africa, Asia, and Latin America and primarily focus on impacts on economic growth, changes in food prices and food security, and, subsequently, extrapolated changes in poverty head counts.

For future poverty head counts impacted by climate change, the literature shows disagreement. Tubiello et al. (2008) project that, by 2080, the number of undernourished people could increase by up to 170 million, using the A2 SRES scenarios, and up to a total of 1,300 million people assuming no CO_2 fertilization. In contrast, Skoufias et al. (2011b), using 2055 predictions based on the Nordhaus (2010) ICE model, state that under business as usual and optimal abatement, poverty (measured at $2/day) could be reduced by 800 million people, due to annual, global, and real per capita growth rate of 2.2% up to 2055. However, lower probability extreme events would reverse this trend, and mitigation under optimal abatement typically excludes the poor (Skoufias *et al.*, 2011b). One study of Zambia illustrates the range of potential shifts in poverty headcounts based on climate change and responses. Thurlow et al. (2009) estimate that by 2016, Zambia's poverty headcount would increase by 300,000 people under average climate variability, and by 650,000 under a worst ten-year rainfall sequence.

Projections of future climate change impacts on GDP use non-disaggregated poverty data. For instance, Mendelsohn et al. (2006) use dynamic coupled ocean–atmosphere models and market response functions to simulate the distribution of climate impacts for 2100. Independent of the climate scenarios, poor countries, mainly in Africa and Southeast Asia, will face the largest losses (0.2-1.2% reduction in GDP) and, under experimental models, up to 23.8% drop in GDP; in contrast, the richest quartile will encounter both positive and negative effects, ranging -0.1% to +0.2% GDP, and up to a 0.9% GDP increase under experimental models. Changes in GDP reflect climate-sensitive economic sectors, especially water and energy, with poor nations in low latitudes already facing high temperatures and thus more vulnerable to decreased agricultural productivity with increased warming.

A growing body of literature estimates future changes in agricultural production and food prices due to climate change, variability, and extreme events, primarily in the global South (Slater *et al.*, 2007; Thomas *et al.*, 2007; Assuncao and Cheres, 2008; Burke *et al.*, 2011). Mixed trends are projected for major staples for all continents until the mid of the 21st century (see Chapter 7). By mid-century the production of coarse grains in Africa may be reduced by 17-22 % due to climate change; the well-fertilized modern seed varieties seem more susceptible to heat stress than traditional ones (Schlenker and Lobell, 2010). By 2080, a significant decrease in land productivity is expected for sub-Saharan Africa (-14% to -27%) and Southeast Asia (-18% to -32%), coupled with increase in water demand, while lowest risks are projected for North America, Europe, East Asia, Russia, and Australia (Iglesias *et al.*, 2011).

13.2.2.3. Implications for Livelihood Assets, Trajectories, and Poverty Dynamics

Projections of future climate change impacts on livelihood assets highlight the erosion of financial capital as a result of increased food prices (Thurlow *et al.*, 2009; Seo *et al.*, 2009; Ahmed *et al.*, 2009; Hertel *et al.*, 2010; Jacoby *et al.*, 2011; Skoufias *et al.*, 2011b), human assets due to decline in nutritional status (Liu *et al.*, 2008), and natural

assets due to lower agricultural productivity (Thurlow *et al*., 2009; Jones and Thornton, 2009; Skoufias *et al*., 2011b). They also show a substantial increase in future heat-related mortality (Basu and Samet, 2002; McGregor *et al*., 2006; Sherwood and Huber, 2010; Huang *et al*., 2011), increasing infectious disease transmission rates (Green *et al*., 2010), and other health impacts (see Chapter 11). Impacts on social and cultural assets have received little attention. Exceptions address losses of social identity and cultural connections with land and sea among indigenous populations threatened by sea level rise and potential relocation (Green *et al*., 2010) and conflicts between ethnic and/or religious groups (Adano *et al*., 2012) (see Chapter 12). Poor households with limited social networks will be worst off, including in places such as Nepal (Menon, 2009) and Indonesia (Skoufias *et al*., 2011a).

Climate change is also projected to cause shifts in livelihood trajectories. Simulated probabilities of failed seasons, using current daily rainfall data and 2050 projections in the length of growing period, show transitions from cropping to livestock in marginal cropping areas in Africa (Thomas *et al*., 2007; Jones and Thornton, 2009). By 2050, expanding vector populations, especially tsetse, and a >20% reduction in the length of the growing period, as simulated under HadCM3 and A1F1, are expected for livestock-dependent livelihoods and mixed crop-livestock livelihoods in semi-arid to arid Africa and Asia, combined with increasing water scarcity and loss in stovers due to maize substitution (Thornton *et al*., 2007), which will stress livelihoods of poor farmers and pastoralists.

Future climate change impacts on disaggregated poverty are mainly addressed through projected changes in food prices and price-induced earnings associated with impacts on agricultural production (Schmidhuber and Tubiello, 2007). Changes in price-induced earnings lower the welfare of low-income households, particularly urban and wage-labor dependent households that use a large income share to purchase staple crops. For instance, a one-time maximum extreme dry event, simulated for 1971-2000 and 2071-2100 using the IPCC-SRES A2 scenario for a sample of 16 developing countries, shows a 95-110% increase in poverty for urban wage populations in Malawi, Zambia, and Mexico, while self-employed farming households consolidate assets and face the smallest increase in vulnerability (Ahmed *et al*., 2009). Similarly, under low productivity scenarios assuming rapid temperature increase by 2030, poverty among the agricultural self-employed in 15 LICs and MICs may drop due to benefits from selling surplus production at higher prices, by as much as 40% in Chile and the Philippines; however, higher food prices may lead to a drop in national welfare, as steep as 55% in South Africa (Hertel *et al*., 2010). In most developing countries the poverty headcount is expected to decline in some occupational strata and increase in others; only in most African countries are yield impacts expected to be too severe to allow any benefits (Hertel and Rosch, 2010).

13.2.2.4. Impacts on Transient and Chronic Poverty, Poverty Traps, and Thresholds

Existing projections do not provide robust evidence to estimate whether shifts from transient to chronic poverty are expected to occur as a result of climate change, and to what extent. However, a predicted increase in the number of urban poor, especially wage laborers, suggests that a large number may shift from transient to chronic poverty due to high exposure to food price increases, or find themselves in a poverty trap, especially under scenarios with long-duration climatic shifts and prolonged droughts (Ahmed *et al*., 2009; Hertel *et al*., 2010). In Zambia, for example, almost half of the 650,000 new poor under the worst historic 10-year period projected until 2016 are expected to be in urban areas (Thurlow *et al*., 2009). In Tanzania, Ahmed et al. (2011), based on a high precipitation volatility GCM, predict up to 1.17 million new poor into the 21st century. Shifts in and out of poverty may occur by 2050 for small-scale coffee farmers in Central America, because of suitable coffee growing areas moving to higher altitudes, especially when constrained by unequal access to agro-technical and climatic information (Laderach *et al*., 2011).

Poor countries will experience greater poverty as a result of climate change and extreme events (*high confidence*), due to location and low-latitude high temperatures (Mendelsohn *et al*., 2006), anticipated further decline in adaptive capacity combined with reductions in agricultural productivity (Iglesias et al., 2011), greater inequality and deep-rooted poverty (Jones and Thornton, 2009), and lower levels of education and large numbers of young dependents (Skoufias *et al*., 2011c). Although robust projections on poverty traps are lacking, they may be associated with emerging hotspots of hunger, such as those projected for Tanzania, Mozambique, and the Democratic Republic of Congo (DRC) by 2030 (Liu *et al*., 2008). Based on SRES scenarios, Devitt and Tol (2012) simulate coupled climate change- and conflict-induced poverty traps up until 2100 for the DRC and several other sub-Saharan countries.

Some climate change projections (see WG1 Chapters 11, 12 and 14) indicate the possibility of large impacts from climate change that may exceed thresholds beyond which detrimental shocks to livelihoods and poverty may occur, unless strong adaptation and/or mitigation responses are implemented in a timely manner. In parts of Africa, particularly the Sahel, and the Indian sub-continent, the risk of heat stress may become acute toward the end of the century, preventing people from practicing agriculture (Patricola and Cook, 2010; Dunne *et al.*, 2013). Since women do most of the agricultural work, they will suffer disproportionally from heat stress; for instance, in Africa, women carry out 90% of hoeing and weeding and 60% of harvesting work (Blackden and Wodon, 2006 p. 18). In the glacier-dependent Himalayan region, excessive runoff and flooding will threaten livelihoods (Xu *et al.*, 2009). Relocation would represent a critical threshold for indigenous groups, due to sea level rise for the Torres Strait Islanders between Australia and Papua New Guinea (Green *et al.*, 2010) and permafrost degradation and increased and seasonally erratic precipitation for the Viliui Sakha in the Russian North (Crate, 2013).

13.3. Assessment of Impacts of Climate Change Responses on Livelihoods and Poverty

Climate change responses interact with social and political processes to affect sustainable development and climate resilient pathways (Chapter 20), and in turn, livelihoods and poverty. Climate mitigation and adaptation responses include formal policies by governments, NGOs, bilateral and multilateral organizations as well as actions by individuals and communities. This section reviews evidence of impacts of mitigation responses (13.3.1) and of adaptation responses (13.3.2) in the context of livelihood and poverty dynamics and inequalities. This section draws upon empirical evidence, some of which is preliminary as several policies are still in their infancy.

13.3.1. Impacts of Mitigation Responses

This section assesses the observed and potential impacts of four climate change responses on livelihoods and poverty: the two mitigation responses most significant for poverty alleviation under the UNFCCC, the CDM and REDD+, and two mitigation responses outside of the UNFCCC, voluntary carbon offsets and biofuel production. Many synergies between climate change mitigation policies and poverty alleviation have been identified in the literature (Klein *et al.*, 2005; Ürge-Vorsatz and Tirado Herrero, 2012), but evidence of positive outcomes is limited. Policies aimed at mitigating climate change are often detrimental to poor people and their livelihoods (*high confidence*) (Collier *et al.*, 2008; Böhm, 2009; Hertel and Rosch, 2010).

13.3.1.1. The Clean Development Mechanism (CDM)

The CDM (see 21.6.1.4) aims to promote social, economic, and environmental dimensions of sustainable development through progress along 15 indicators including poverty alleviation. CDM projects as diverse as low-cost energy services in India, micro-hydro projects in Bhutan and Peru, efficient firewood use in Nigeria, and biogas digesters in China, are expected to generate livelihood benefits and employment, and reduce poverty among beneficiaries, according to the UNFCCC secretariat (UNFCCC, 2011; UNFCCC, 2013). However, most of the statistical information in official reports on CDM is based either on project documents or on surveys of projects.

The assessment of the CDM in the peer-reviewed literature is more cautious and pessimistic than UNFCCC, and two reviews (Olsen, 2007; Michaelowa and Michaelowa, 2011) contend that the current CDM design is neither pro-poor nor contributes to sustainable development. Shortcomings include obstacles and ethical dilemmas in carbon trading (Liverman, 2009; Newell and Bumpus, 2012), difficulties with implementation (Borges da Cunha *et al.*, 2007; Minang *et al.*, 2007; Gong, 2010), and procedural limitations (Lund, 2010). Case studies suggest that CDM may favor carbon offset goals over poverty reduction goals (Wittman and Caron, 2009), undermine local and non-governmental voices (Shin, 2010; Corbera and Jover, 2012), compete with the informal sector (Newell and Bumpus, 2012), and accentuate uneven development by threatening local livelihood security (Boyd and Goodman, 2011). Only a few CDM programs have shown positive impacts for poor communities, such as one in Peru that enhanced health and employment (Boyd and Juhola, 2009) and some in India supporting community-designed plans to strengthen participation of marginalized groups (Subbarao and Lloyd, 2011; Boyd and Goodman, 2011).

13.3.1.2. Reduction of Emissions from Deforestation and Forest Degradation (REDD+)

Reducing emissions through carbon forestry as part of UN REDD+ may adversely affect the livelihoods of poor people. Experience with forest carbon projects to date is inadequate to permit broad generalizations about the effects of REDD+ on livelihoods and poverty (Cotula *et al*., 2009; Hayes and Persha, 2010; Springate-Baginski *et al*., 2010). In a study of 20 forest carbon projects in Latin America, Africa and Asia, only five had conducted some form of assessment of the outcomes or impacts, demonstrating a lack of rigor in project evaluation (Caplow *et al*., 2011).

Some studies show favorable results in terms of poverty alleviation (Ferraro *et al*., 2011) and are optimistic about REDD+ (Kanowski *et al*., 2011; Rahlao *et al*., 2012) but raise concerns about its future developments (Hodgdon *et al*., 2012; Rana *et al*., 2012). Others have voiced concerns about negative impacts on the poor (Phelps *et al*., 2010; Larson, 2011; Van Dam, 2011; McDermott *et al*., 2011; Börner *et al*., 2011; Rahlao *et al*., 2012; Neupane and Shrestha, 2012; Mahanty *et al*., 2012) and on indigenous peoples (Shankland and Hasenclever, 2011). Latent negative impacts include exclusion of local populations from forest use, and the undermining of local ownership in the processes of documenting the state of their forests due to external monitoring and verification mechanisms (Gupta *et al*., 2012). Benefit flows may be unevenly distributed with regards to ethnicity (Krause and Loft, 2013), gender (UN-REDD, 2011; Peach Brown, 2011) or simply not target the poor (Hett *et al*., 2012). Also, the absence of a global REDD+ mechanism means that progress on REDD+ may occur as much through voluntary bilateral and public-private processes as through multilateral, regulatory requirements (Agrawal *et al*., 2011). Without a global agreement and mandated emissions reductions, the price of carbon will remain uncertain and vary greatly across different carbon forestry projects (Bailey *et al*., 2011), to the advantage of carbon credit buyers rather than the poor.

The 2010 Cancun Agreements highlight safeguards for governments to observe in REDD+ implementation, such as respect for the interests, knowledge, rights, and sustainable livelihoods of local communities and indigenous people. The extent to which these safeguards will be observed in practice is unclear due to the early implementation state of REDD+ in most countries as well as the uncertainty of the future of the global carbon market (Lohmann, 2010).

13.3.1.3. Voluntary Carbon Offsets

The voluntary carbon offset (VCO) market is significant from a livelihoods and poverty perspective because it typically targets smaller projects and may be better at reaching poor communities, though it is modest in size compared to the regulated market (~ 1%). Also, those involved in the VCO market, namely individuals, companies, organizations, and countries that have not ratified the Kyoto Protocol, are often more willing to pay for carbon offsets with co-benefits such as poverty alleviation (MacKerron *et al*., 2009).

Activities under VCO are dominated by renewable energy, primarily wind power (30%), forestation projects, including REDD (19%), and methane destruction in landfills (7%) (Peters-Stanley and Hamilton, 2012). It is too early to tell whether these VCO projects are successful in terms of poverty alleviation and other social goals, and results to date are highly mixed (Jindal *et al*., 2008; Swallow and Meinzen-Dick, 2009; Jindal, 2010; Estrada and Corbera, 2012; Stringer *et al*., 2012). Reported benefits include livelihood diversification, increased disposable income, biodiversity conservation, and strengthening local organizations, while exacerbated inequalities and loss of access to local resources are known negative impacts (Estrada and Corbera, 2012). A study in Kenya, Senegal, and Peru shows reduced losses of soil fertility in three soil carbon sequestration projects, but also the inability of the poorest farmers to participate and only marginal impacts on poverty reduction (Antle and Stoorvogel, 2009). Out of 78 projects in 23 countries in sub-Saharan Africa, only one promoted local social, economic, and environmental benefits while the rest focused mainly on efficiency of emission reductions (Karavai and Hinostroza, 2013).

13.3.1.4. Biofuel Production and Large-Scale Land Acquisitions

Biofuel production, often linked to large-scale transnational land acquisitions (LSLA), constitutes a mitigation response that raises two major livelihoods and poverty concerns: food price increases and dispossession of land (see Chapters 4, 9). LSLA have soared since 2008 (Von Braun *et al*., 2009; Deininger *et al*., 2011; Borras Jr *et al*., 2011), partly linked to climate change responses (*high agreement*). Production of biofuels is considered the primary driver, but there may be links to climate change through increasing food prices (Daniel, 2011), food insecurity (Robertson and Pinstrup-Andersen, 2010; Rosset, 2011; Sulser *et al*., 2011), and the potential that carbon markets, e.g. REDD+, may increase land prices (Cotula *et al*., 2009; Zoomers, 2010; Anseeuw *et al*., 2012). According to Anseeuw (2012), LSLA goals globally are primarily biofuels (40%), food (25%) and forestry (3%), with significant regional variation. The recent IPCC special report on renewable energy highlighted the uncertainties around the role of biofuels in food price increases and risks of deteriorating food security with future deployment of bioenergy (Edenhofer *et al*., 2011).

Increasing demand for biofuels shifts land from food to fuel production, which may increase food prices (Collier *et al*., 2008), disproportionally affecting the poor (Von Braun and Ahmed, 2008; Ruel *et al*., 2010; Bibi *et al*., 2010). Despite high agreement that biofuel production plays a role in food prices, little consensus exists on the size of this influence. Statistical analyses of the influence of biofuels on the 2007/08 food price increase range from 30% (Von Braun and Ahmed, 2008) to 70% (Mitchell, 2008), while economic modeling suggests a smaller direct role (<30%) (Aksoy and Isik-Dikmelik, 2008; Elobeid and Hart, 2008; Baffes and Haniotis, 2010; Ajanovic, 2011). Several studies link the 2007/08 price spike to speculation in agricultural futures markets (Runge and Senauer, 2007; Gilbert and McLeman, 2010; Ghosh, 2010) driven partly by potential future profits from biofuels (Trostle *et al*., 2011).

LSLA have also triggered a land rush in LICs, which affects livelihood choices and outcomes. New competition for land dispossesses smallholders, displaces food production, degrades the environment, and pushes the poor onto more marginal lands less adaptable to climatic stressors (Cotula *et al*., 2009; Borras Jr *et al*., 2011; Rulli *et al*., 2013; Weinzettel *et al*., 2013). The expansion of bioenergy, and biofuels in particular, increases the corporate power of international actors over governments and local actors with harmful effects on national food and agricultural policies (Dauvergne and Neville, 2009; Glenna and Cahoy, 2009; Hollander, 2010; Mol, 2010; Fortin, 2011; Jarosz, 2012), further marginalizing smallholders (Ariza-Montobbio *et al*., 2010; De Schutter, 2011; Neville and Dauvergne, 2012). There is growing apprehension that increased competition for scarce land undermines women's access to land and their ability to benefit economically from biofuel investment (Molony, 2011; Arndt *et al*., 2011; Chu, 2011; Julia and White, 2012; Behrman *et al*., 2012; Perch *et al*., 2012). Concerns differ to some extent among regions, with the greatest risk for negative outcomes for smallholders in Africa (Borras *et al*., 2011).

Mainstream economic modeling suggests optimism that biofuels may boost investment, employment, and economic growth, in LICs such as Mozambique (Arndt *et al*., 2009) and MICs such as India (Gopinathan and Sudhakaran, 2011) and Thailand (Silalertruksa *et al*., 2012), yet limited evidence exists on potential benefits being realized. A major government initiative to promote jatropha cultivation in India has failed (Kumar *et al*., 2011) and in some cases has left rural people worse off (Bastos Lima, 2012) whereas in Malawi it offered supplemental livelihood opportunities (Dyer *et al*., 2012) . Even though income and employment in Brazil may have increased due to ethanol production (Ferreira and Passador, 2011), structural inequalities in the sector remain (Peskett, 2007; Hall *et al*., 2009; Bastos Lima, 2012). Biofuel production in itself will not transform living conditions in rural areas without being integrated into development policies (Hanff *et al*., 2011; Jarosz, 2012; Dyer *et al*., 2012).

13.3.2. Impacts of Adaptation Responses on Poverty and Livelihoods

Even well-intentioned adaptation projects (see Chapters 14-16) and efforts may have unintended and sometimes detrimental impacts on livelihoods and poverty, and may exacerbate existing inequalities. This section assesses the effects of autonomous and planned adaptation and formal insurance schemes on the livelihoods of poor populations.

13.3.2.1. Impacts of Autonomous and Planned Adaptation Strategies on Livelihoods and Poverty

Autonomous adaptation strategies, such as diversification of livelihoods (Smith *et al*., 2000; Mertz *et al*., 2009), migration (McLeman and Smit, 2006; Tacoli, 2009) (see Chapter 12), storage of food (Smit and Skinner, 2002; Howden *et al*., 2007), communal pooling (Linnerooth-Bayer and Mechler, 2006), market mechanisms (Halstead and O'Shea, 2004), saving, credit societies, and systems of mutual support (Andersson and Gabrielsson, 2012) have been found to have positive effects on poverty reduction in certain contexts, or at least prevent further deterioration as a result of a weather events and climate, especially when supported by policy measures (Adger *et al*., 2003; Urwin and Jordan, 2008; Stringer *et al*., 2009). Yet, some autonomous strategies such as diversification and storage are often unavailable to the poorest, who lack the required resources or surplus (Smithers and Blay-Palmer, 2001; Osbahr *et al*., 2008; Seo, 2010). In some cases, risk reduction strategies involve a trade-off with higher-income options (Hazell and Hess, 2010; Alpizar *et al*., 2011; Benson *et al*., 2012). Moreover, autonomous adaptation strategies can increase vulnerability for others or be subject to local elite capture (McLaughlin and Dietz, 2008; Bhattamishra and Barrett, 2010). For example, richer farmers in Mozambique with access to irrigation benefited from higher producer prices and ready availability of casual labor from poorer farmers during the 2002/03 drought (Eriksen and Silva, 2009). There is no evidence regarding the effect of autonomous responses of the poor in MICs and HICs.

Few rigorous assessments of the effects of pilot adaptation projects exist outside of organizations' own assessments (Mapfumo *et al*., 2010; Nkem *et al*., 2011) or evaluations of the extent to which planned adaptation activities have been implemented or integrated into development (Gagnon-Lebrun and Agrawala, 2006; Gigli and Agrawala, 2007). An assessment of the only completed GEF/WB-funded adaptation project, in the Caribbean, Colombia, and Kiribati, did not directly appraise the effects on poverty and livelihoods. Other projects, though, such as in India's Karnataka Watershed, increased agricultural productivity, income, and employment, benefiting the poorest and landless and improving equity (IEG, 2012). New insights emerge from ecosystem-based adaptation (see Chapters 15, 16).

13.3.2.2. Insurance Mechanisms for Adaptation

Insurance mechanisms (see Glossary) reflect the tendency that some formal adaptation measures reach the wealthier more easily while prohibitive costs may prevent poor people from accessing such mechanisms. Nonetheless, public and private insurance systems have been proposed by the World Bank and UNFCCC as an adaptation strategy to reduce, share, and spread climate change-induced risk and smooth consumption, especially among poor households (Mechler *et al*., 2006; Hertel and Rosch, 2010; Akter *et al*., 2011; Benson *et al*., 2012). Formal insurance schemes can potentially provide a way out of poverty traps (Barnett *et al*., 2008) caused by the years-long process for a household to rebuild assets after climate shocks (Dercon, 2006; Hertel and Rosch, 2010).

Poor people tend not to be insured via formal institutions, though strategies such as risk spreading, social networks, local credit, asset markets, and dividing herds between kin act as informal risk management mechanisms (Barnett *et al*., 2008; Pierro and Desai, 2008; Giné *et al*., 2008; Hertel and Rosch, 2010). Unable to access insurance, poor people are often forced to invest in low-risk, low-return livelihood activities, which makes accumulating assets to escape chronic poverty very difficult (Elbers *et al*., 2007; Barnett *et al*., 2008). As a response, new insurance mechanisms such as micro-insurance directed at low-income people, and weather index insurance for crops and livestock, have emerged, but have shown mixed results (Barnett *et al*., 2008; Mahul *et al*., 2009; Akter *et al*., 2011; Matsaert *et al*., 2011; Biener and Eling, 2012). Experiences from South Asia and several African countries illustrate positive effects of micro-insurance although affordability may limit the potential for the poorest (Yamauchi *et al*., 2009; Hochrainer-Stigler *et al*., 2012). Another reason for the slow uptake is that farmers may not fully understand the merits and function of the new insurance schemes (Giné and Yang, 2009; Patt *et al*., 2010).

13.4. Implications of Climate Change for Poverty Alleviation Efforts

This section considers the implications climate change has for poverty alleviation efforts and what they may mean for current and future pathways for sustainable development. Evidence from observed and projected interactions between climate, poverty reduction, and development highlights how addressing climate change and poverty may

result in diminished success or productive synergies with respect to eradicating poverty, managing risk, pursuing sustainable development, and designing climate-resilient pathways, which are "evolutionary processes for managing change within complex systems to reduce disruptions and enhance opportunities" (see Glossary). This section builds on the findings from 13.1 to 13.3 and stresses the need to attend to the complexity of livelihood dynamics, multi-dimensional poverty, and intersecting inequalities to successfully navigate climate-resilient development pathways.

Observed impacts of weather events and climate on livelihoods and poverty and impacts projected from the sub-national to the global level suggest that livelihood resilience, poverty alleviation, and development are already undermined and will continue to be eroded into the future (*high confidence*). Climate change will slow down the pace of poverty reduction, jeopardize sustainable development, and further erode food security (*high confidence*) (Stern, 2009; Hope, 2009; Thurlow *et al.*, 2009; Iglesias *et al.*, 2011; Skoufias *et al.*, 2011b). Currently poor and food-insecure regions will continue to be disproportionately affected into the future (*high agreement*) (Challinor *et al.*, 2007; Lobell *et al.*, 2008; Assuncao and Cheres, 2008; Liu *et al.*, 2008; Thornton *et al.*, 2008; Menon, 2009; Jones and Thornton, 2009; Nordhaus, 2010; Jacoby *et al.*, 2011; Burke *et al.*, 2011; Skoufias *et al.*, 2011a; Adano *et al.*, 2012). Poorer countries will experience continued decline in adaptive capacity, which will hamper development (*high confidence*). Iglesias *et al.* (2011), for instance, project increasing inequality among continents in the case of progressively severe climate change scenarios. Posey (2009) highlights lower adaptive capacities in communities with greater concentrations of racial minorities and low-income households than in more affluent communities, due to multidimensional inequality and marginalization. Although there is *high agreement* about the heterogeneity of future impacts on poverty, few studies consider more diverse climate change scenarios (Skoufias *et al.*, 2011b) or the potential of four degrees and beyond (New *et al.*, 2011). The World Bank (2012b, p.65) states that "climate change in a four degree world could seriously undermine poverty alleviation in many regions."

13.4.1. Lessons from Climate-Development Efforts

Two key models have attempted to integrate climate and poverty concerns into development efforts: mainstreaming adaptation into development priorities and pro-poor adaptation (see also Chapters 14-16). Lessons from "adaptation as development," in which development is seen as the basis for adaptation, and "adaptation plus development," in which development interventions address future climate threats (Ayers and Dodman, 2010), typify the disagreement in policy spheres about what sustainability constitutes (Le Blanc *et al.*, 2012) and the practical gulf between climate change policy and development spheres (Ayers and Dodman, 2010). To date, observed and projected climate change impacts are not systematically integrated into poverty reduction programs, although such integration could result in substantial resilience to covariate and idiosyncratic shocks and stresses (Béné *et al.*, 2012). At the same time, science and policy emphasis on rapid-onset events, sectoral impacts, and poverty statistics has diverted attention from threats to sustainability and resilient pathways. Even where legal reforms to secure the rights of the poor exist, as in Mexico's Climate Law, inequalities persist (MacLennan and Perch, 2012). Without addressing the climatic, social, and environmental stressors that shape livelihood trajectories, including poverty traps (see Figure 13-2), and the underlying causes of poverty, persistent inequalities, and uneven resource access and institutional support, adaption efforts and policies will be nothing more than temporary fixes. At the same time, poverty alleviation alone will not necessarily lead to more equality (Pogge, 2009; Milanovic, 2012). Box 13-2 provides insight into three examples.

_____ START BOX 13-2 HERE _____

Box 13-2. Lessons from Social Protection, Disaster Risk Reduction, and Energy Access

Social protection (SP): Considerable challenges emerge at the intersection of climate change adaptation, disaster risk reduction, and social protection. SP programs include public and private initiatives that transfer income or assets to the poor, protect against livelihood risks, and raise the social status and rights of the marginalized (see Glossary). Cash transfer programs are among the principal instruments used by governments for poverty alleviation (Barrientos and Hulme 2008; Niño-Zarazúa 2010). There is *medium agreement* among scholars and practitioners that SP helps the chronically poor reduce risk and protect assets during crises (Devereux *et al.*, 2010; Barrientos, 2011; Dercon, 2011; Devereux *et al.*, 2011). However, at the regional and municipal level, SP does not address local government

capacity to ensure risk reduction by providing water, sanitation, drainage, health care, and emergency services. Also, SP does not strengthen local collective capacity to proactively address climate change risks and take action.

SP that supports pro-poor climate change adaptation and disaster risk reduction by strengthening the resilience of vulnerable populations to shocks is labeled "adaptive social protection" (ASP) (Davies *et al*., 2009). ASPs have almost exclusively focused on LICs and some MICs rather than on poor people in HICs. Few studies exist on the effectiveness of ASP for addressing incremental climatic changes and rapid-onset events, and the changing nature of climate risks, embedded in an understanding of dynamic livelihood trajectories (Heltberg *et al*., 2009; Arnall *et al*., 2010; Bee *et al*., 2013). For instance, the Productive Safety Net Program in Ethiopia, one of the more successful SPs, had positive effects on household food consumption and asset protection (Devereux *et al*., 2006; Slater *et al*., 2006). Yet, this and programs such as Brazil's *Bolsa Familia* and *Bolsa Verde* offer few concrete pathways to tackling systemic vulnerabilities and inequalities that inhibit effective responses to severe shocks, though they stress the role of local governments in addressing livelihood security and resilience in the long term rather than focusing on short-term disaster relief (Gilligan *et al*., 2009; Conway and Schipper, 2011; Béné *et al*., 2012; UNDP, 2012).

Disaster risk reduction (DRR): The development and application of DRR (see Glossary) has been among the most important routes for generating attention from local governments and civil society about the risks of extreme weather, and came to the fore as the concentration of disaster deaths from extreme weather in LICs and MICs became evident (United Nations 2009, 2011). Now, DRR is increasingly employed as an adaptation measure, for example through community-based climate risk reduction (Tompkins *et al*., 2008; Meenawat and Sovacool, 2011; McSweeney and Coomes, 2011; Field *et al*., 2012b) and has helped identify DRR roles for local governments (IFRC 2010). Yet, sometimes disaster management-oriented adaptation can favor property and investments of the relatively richer and divert attention and funding from measures that address the poor, as suggested in a case study of Vietnam (Buch Hansen, 2013). The effectiveness of DRR in supporting pro-poor climate change adaptation will depend on governance structures to address changing risk contexts in policies and investments while responding to the needs and priorities of their low-income population. Experiences from Hurricane Katrina and the Tōhoku earthquake and tsunami exhibit the additional and multiplier effect of a disaster on top of underlying structural inequalities. Their persistence years later, as shown with Katrina (Schwartz, 2007; Zottarelli, 2008; Fussell *et al*., 2010), further stresses the need for expanded analyses beyond the events themselves and the recognition of the many factors that perpetuate the vicious cycle of poverty, multidimensional deprivation, and inequality.

Energy access: Energy is critical for rural development (Barnes *et al*., 2010; Kaygusuz, 2011; Kaygusuz, 2012) and for alleviation of urban poverty (Parikh *et al*., 2012). One proposed climate-resilient pathway is to increase renewable energy use, which has the potential to boost energy access for billions of people who currently have no access to safe and efficient energy, while cutting GHG emissions from rising non-renewable energy consumption (Casillas and Kammen, 2010; Edenhofer *et al*., 2011). Benefits include better health (see Chapter 11), employment, and cost savings relative to fossil fuels (Edenhofer *et al*., 2011; Jerneck and Olsson, 2012). Yet, *limited evidence* exists that renewable energy creates more jobs than conventional energy (Karakezi *et al*., 2006; Akella *et al*., 2009).

_____ END BOX 13-2 HERE _____

13.4.2. Toward Climate-Resilient Development Pathways

Given the multiple challenges at the climate-poverty-development nexus, debates increasingly focus on transforming the development pathways themselves toward greater social and environmental sustainability, equity, resilience, and justice, calling for a fundamental shift toward climate-resilient development pathways (see Chapter 20). This perspective acknowledges the major shortcomings in dominant global development pathways, above all rising levels of consumption and emissions, privatization of resources, and limited capacities of local governments and civil society to counter these trends (Pelling, 2010; Eriksen *et al*., 2011; O'Brien, 2012; UN, 2012a).

At Rio+20 in 2012, an Open Working Group was created by the UN General Assembly to develop Sustainable Development Goals (SDGs) building on the Millennium Development Goals (MDGs), which are criticized for not explicitly addressing the root causes of poverty, inequality, or climate change (Melamed, 2012; UN, 2012b) and the

anticipated failure to reach MDG 1 (eradicate extreme poverty and hunger by 2015), with or without climate change (Tubiello *et al*., 2008). Early SDG debates reveal a stronger focus on eradicating extreme poverty and environmental problems facing the poor (UN, 2012a). This framing of development acknowledges shared global futures that require collective action from the richest, not merely promoting welfare for the poorest, to address both climate change and poverty (Ayers and Dodman, 2010; UN, 2012a; UN, 2012b). Little information exists to date to project how these SDGs will support climate-resilient development pathways. Formulating goals, however, will not suffice unless the global institutional framework for sustainable development is radically reformed (Biermann *et al*., 2012).

Paying attention to dynamic livelihoods and multidimensional poverty and the multifaceted impacts of climate change and climate change responses is central to achieving climate-resilient development pathways (see Chapter 20). Evidence from sections 13.2 and 13.3 suggests that increasing global inequality, new poverty in MICs and HICs, and more people shifting from transient to chronic poverty overlaid with business-as-usual development and climate policies, will bring the poor and the marginalized precariously close to the two most undesirable future scenarios as conceptualized in the shared socio-economic pathways (SSPs) (see Figure 20-2): social fragmentation (fragmented world) and inequality (unequal world). At the community level, inadequate governance structures and elite capture often propel less affluent households into deeper poverty. There is *high agreement* among scholars of global governance that fragmentation also exists at the level of the global climate regime (Biermann, 2010; Roberts, 2011; Mol, 2012), rooted in deep and entrenched inequalities (Parks and Roberts, 2010). The extent to which fragmentation promotes positive or negative outcomes of climate and development goals is contested, ranging from polycentric governance modes (Ostrom, 2010) to conflictive fragmentation (Biermann *et al*., 2009; Mittelman, 2013). Evidence from this chapter demonstrates that, in order to move toward the SSP1 (sustainability), a fundamental rethinking of poverty and development is needed that emphasizes equity among the poor and non-poor to collectively address GHG emissions and vulnerabilities while striving toward a joint, just, and desirable future.

13.5. Synthesis and Research Gaps

Previous IPCC reports have stated that climate change would cause disproportionally adverse effects for the world's poor. However, they presented a rather generalized view that all poor people were vulnerable, in contrast to earlier scientific studies highlighting vulnerability as contextual with variation over time and space. This chapter is entirely devoted to exploring poverty in relation to climate change. It uses a livelihoods lens to assess the interactions between climate change and the multiple dimensions of poverty, not just income poverty. This lens also reveals how inequalities perpetuate poverty to shape differential vulnerabilities and in turn the differentiated impacts of climate change on individuals and societies. This chapter illustrates that climate change adds an additional burden to the multiple facets of poor people's lives and livelihoods. Moreover, it emphasizes that climate change may create new groups of poor people, not only in low-income countries but also in middle- and high-income countries. Neither alleviating poverty nor decreasing vulnerabilities to climate change can be achieved unless entrenched inequalities are reduced. This chapter concludes that climate change policy responses often do not benefit the world's poor, and highlights lessons for climate-resilient development pathways.

Eight major research gaps are identified with respect to the observed and projected impacts of climate change and climate change responses:

- Poverty dynamics are not sufficiently accounted for in current climate change research. Most research as well as poverty measurements remain focused on only one or two dimensions of poverty. Insufficient work assesses the distribution of poverty at the level of households, spatial and temporal shifts, critical thresholds that plunge some transient poor into chronic poverty, and poverty traps, in the context of climatic and non-climatic stressors. Many of these dynamics remain hidden, incompletely captured in poverty statistics and disaster and development discourses. Key assumptions in economic models (e.g., constant within-country distribution of per-capita income over time, linear relationship between economic growth and poverty headcounts) are ill-suited to capture local and sub-national poverty dynamics, confounding projections of future poverty levels.
- Though an abundance of studies exists that explore climate change impacts on livelihoods, the large majority does not focus on trajectories but only offers snapshots. In contrast to static representations, an

explicit exploration of livelihood dynamics reveals how people respond to a series of climatic stressors and shocks over time.

- Few studies examine how the structural inequalities, power imbalances, and intersecting axes of privilege and marginalization shape differential vulnerabilities to climate change. Although there is a growing body of literature on climate change and gender as well as on indigeneity, other axes such as age, class, race, caste, and (dis)ability, have been underexplored. Understanding how simultaneous and intersecting inequalities determine climate change impacts reveals which particular drivers of vulnerability are at play in one context, while absent in another.
- Very limited research examines climate change impacts on poor people and livelihoods in middle- to high-income countries. Despite mounting evidence of observed impacts of climatic events on the poor in MICs and HICs, as documented for the European heat wave, Hurricane Katrina in the U.S., and the ten-year drought in Australia, the majority of research on the poverty-climate nexus remains focused on the poorest countries.
- There remains a lack of rigorous data collection and analysis with respect to 'small' disasters in poor people's lives. This gap leads to significant underestimation of lived experiences with climate change, in which particular loss and harm remain largely undetected. There is a need for more climatology research informed by the needs of vulnerable livelihoods, for instance on the effects of changing winds as a combined result of climate change and land cover change, and their effects on increasing evaporation and water availability.
- Not enough consideration is given to the "long tails" in terms of extreme stressors and shock events, such as the potential of four degrees and beyond, underestimating the range of possible impacts on the poor and marginalized.
- There is a lack of in-depth research on the direct and indirect effects of mitigation and adaptation climate-related policies such as CDM, REDD+, biofuels, and insurance, on livelihoods, poverty, and inequality. More in-depth research has the potential to improve the capacity of these policies to become pro-poor.
- Limited understanding exists of how poverty alleviation and more equality between the poor and the non-poor are best built into climate-resilient development pathways in order to strive toward a just and desirable future for all.

Frequently Asked Questions

FAQ 13.1: How important are climate change-driven impacts on poverty compared to other drivers of poverty?

Poverty is a complex social and political problem, intertwined in numerous ways with processes of socioeconomic, cultural, institutional, and political marginalization, inequality, and deprivation, in low-, medium-, and high-income countries. Climate change intersects with the multidimensional facets of poverty to drive not only income poverty but also undermine wellbeing, agency, and a sense of belonging. This complexity makes measuring impacts and attribution to climate change exceedingly challenging. Even modest changes in seasonality of rainfall, temperature, and wind patterns, as observed for instance among climate-sensitive livelihoods in high mountain environments, drylands, and the Arctic, and in informal settlements and urban slums, can push transient poor and marginalized people over a critical threshold into chronic poverty as they lack access to effective response options. Impacts of extreme events, such as floods, droughts, and heat waves, especially when occurring in a series, can significantly erode poor people's assets and further undermine their protection in terms of labor, housing, infrastructure, and social networks. Indirect impacts, such as increases in food prices due to climate-related disasters and/or policies, can also harm the poor, including the urban poor who are net buyers of food.

FAQ 13.2: How do multiple stressors interact with dynamic livelihoods and structural inequalities?

Multiple stressors, or factors such as shifts in seasons and market volatility, interact and reinforce each other to affect livelihood opportunities and decision making. A variety of stressors and opportunities emerge from macro-level forces such as climate change, globalization, and technological change, as well as from conditions such as politics and infrastructure at the regional, national, and local levels. Institutions, policies, and decision making mediate which stressors result in shocks for particular livelihoods and households. Moreover, structural inequalities amplify and compound the effects of these stressors, especially for livelihoods and households with limited asset flexibility and/or those who experience inequalities and marginalization along the axes of gender, age, class, race,

indigeneity, and (dis)ability. The dynamic interplay between weather events and climate, institutions, and livelihoods is socially differentiated, allowing virtuous cycles and positive trajectories for some and vicious cycles and downward trajectories for others, at particular points in time. For instance, a women-headed household from the lowest caste in Nepal may struggle to satisfy additional labor demands to produce drought-resistant subsistence crops and fulfill sharecropping contracts to the high caste landlord while more affluent men-headed households from this high caste may benefit from shifting seasonal precipitation patterns and new local market opportunities.

[INSERT FIGURE 13-5 HERE

Figure 13-5: Multiple stressors related to climate change, globalizations, and technological change interact with national and regional institutions to create shocks to place-based livelihoods. Inspired by transition theory (Geels, 2011).]

FAQ 13.3: Are there unintended negative consequences of climate change policies for people who are poor?

Policies related to climate change mitigation and adaptation may have unintended and potentially detrimental effects for poor people and their livelihoods. Climate-related policies have compound consequences. For example, the recent rapid increase in large-scale land acquisitions emerged, at least partially, as a result of climate change mitigation policies to promote biofuels, as well as a growing concern about food security in high- and middle-income countries. Conversion of presumably marginal or idle land in countries in Africa, Latin America, and Southeast Asia has contributed to food price increases and also has displaces smallholders' croplands. Poor urban residents are particularly vulnerable to food price increases as they use a large income share to purchase food while some agricultural self-employed groups may actually benefit from increased food prices. Besides stress on food security, other adverse consequences of biofuels have been reported for poor and marginalized people, including declining biodiversity, competition for water, and unfavorable shifts in access to and control over resources, often to the detriment of women farmers and other disadvantaged groups. However, in some cases, men and women who find employment in the biofuel industry acknowledge opportunities to participate in the cash economy.

Table 13-1: Gendered impacts of Australia's ten-year drought.

Impacts	*For men*	*For women*
Increased workload	Heartbreaking and physically demanding tasks include feeding livestock, carting water, destroying frail animals	Increased work includes assisting with farm tasks and working off the farm for additional income
Community effects	Locked into farms, loss of political power	Increased interactions and caregiving work, taking care of others' health at the expense of their own
Psychological toll	Feel demonized (farmers responsible for crisis), increased stress, social isolation, depression, and high suicide levels	Working lives appear indefinite, and increased stress

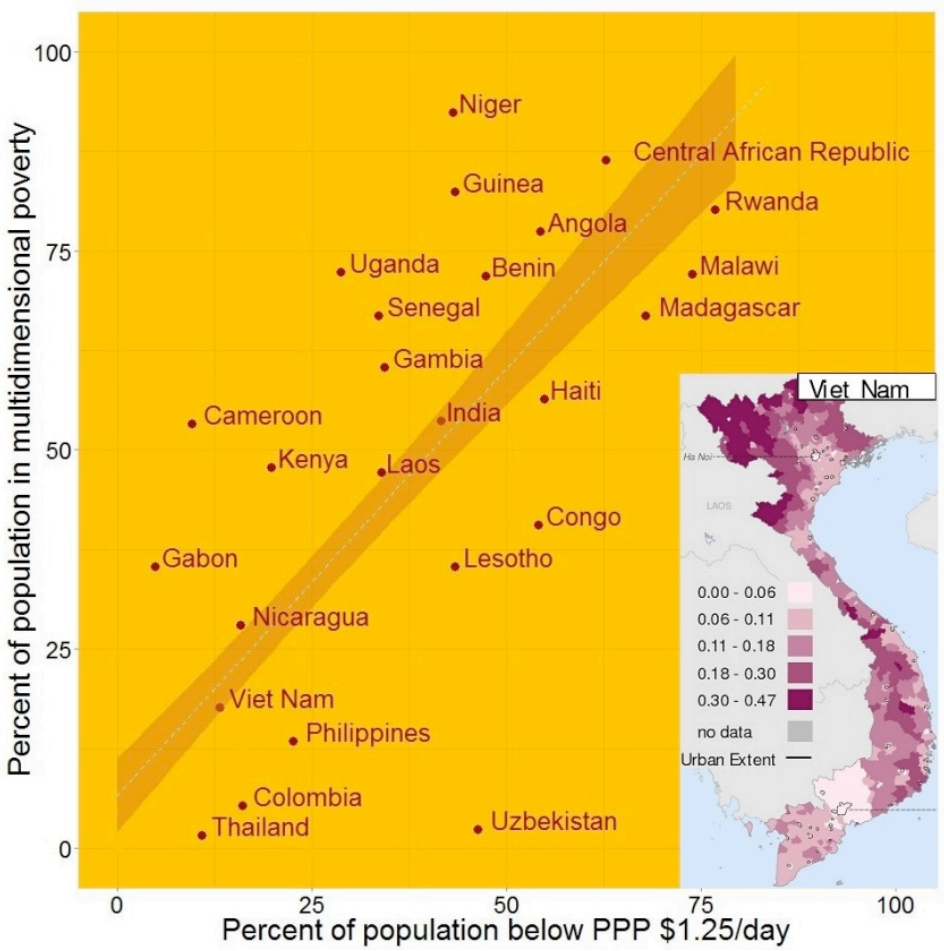

Figure 13-1: Multidimensional poverty and income poverty, with linear regression relationship (dotted line) and shaded 95% confidence interval based on 96 countries (HDR, 2011). The map inset shows the Poverty Gap Index score in Viet Nam, aggregated at district level, expressed as ratio of poverty line of yearly expenditure per capita).

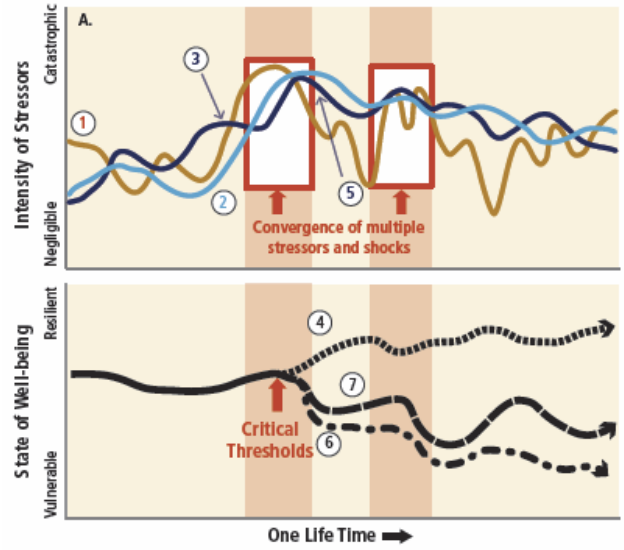
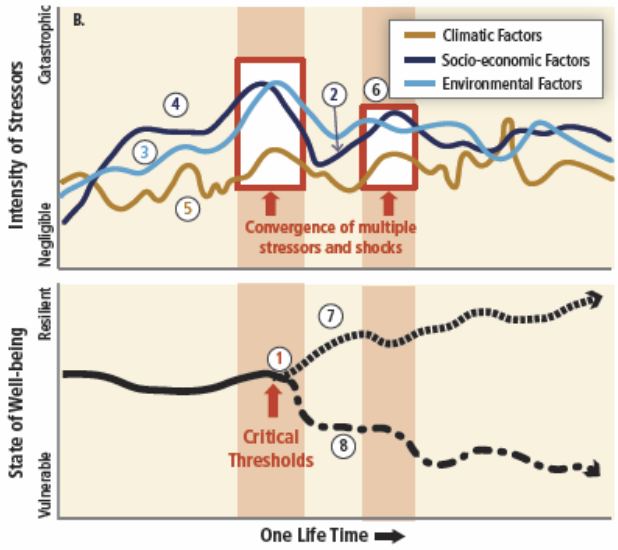
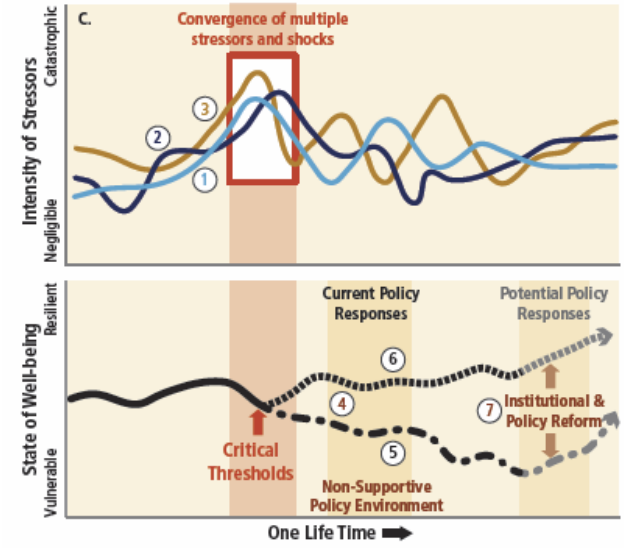


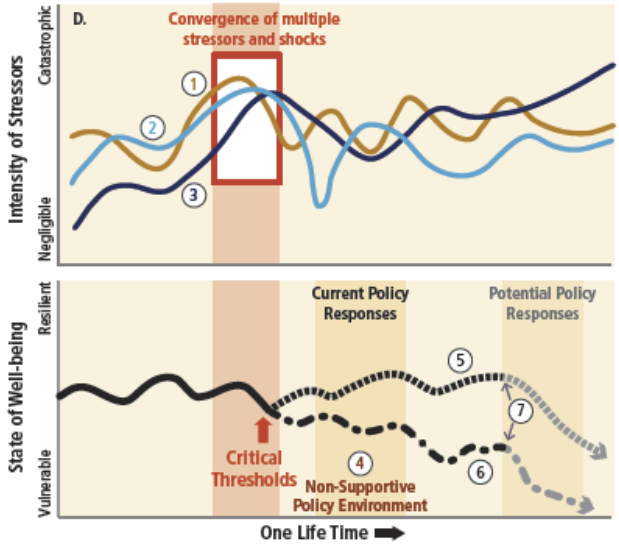
A. Botswana's drylands (Sallu et al., 2010). Over the past 30 years, rural households have faced 1) droughts, late onset and increased unpredictability of rainfall, and frost, 2) drying of Lake Xau, and land degradation. Households responded differently to these stressors, given their financial and physical assets, diversification of and within livelihood activities, family relations, and institutional and governmental support. Despite 3) weakening of social networks and declining livestock due to lack of water, distinct livelihood trajectories emerged. 4) "Accumulators" were often able to benefit from crises, for instance through access to salaried employment or 5) new hunting quotas, while 6) "dependent" households showed a degenerative trajectory, losing more and more livelihood assets, becoming reliant on governmental support after another period of convergent stressors. 7) "Diversifiers" had trajectories fluctuating between vulnerable and resilient states.



B. Coastal Bangladesh (Pouliotte et al., 2010) 1) Households in Surbarnabad have faced a critical threshold and shifted from rice and vegetable cultivation to saltwater shrimp farming, 2) which has grown due to a strong export market and international donor and national government support. This shift is a result of a combination of environmental and socio-economic factors, out of which climatic stressors appear to only play a minor role: 3) saltwater intrusion due to 4) the construction and poor management of the Bangladeshi Coastal Embankment Project, the construction of a dam in India, local water diversions, 5) and sea level rise and storm surges. The conversion to shrimp farming 6) has caused rising disease levels and 7) concentrated wealth and power for the more affluent families while 8) further diminishing the livelihood options for the poor who lack the resources to grow crops in salinated water and lose grazing areas and dung from formerly accessible rice fields.



C. Mountain environments (McDowell & Hess, 2012). Indigenous Aymara farmers in highland Bolivia face land scarcity, pervasive poverty, climate change, and lack of infrastructure due in part to racism and institutional marginalization. 1) The retreat of the Mururata glacier causes water shortages, compounded by 2) the increased water requirements of cash crops on smaller and smaller "minifundios" and market uncertainties. 3) High temperatures amplify evaporation, and flash floods coupled with delayed rainfall cause irrigation canals to collapse. 4) The current policy environment makes it difficult to access loans and obtain land titles, 5) pushing many farmers onto down-ward livelihood trajectories while 6) those who can afford it invest in fruit and vegetable trees at higher altitudes. 7) Sustained access to land, technical assistance, and irrigation infrastructure would be vital policy responses to enhance wellbeing.



D. Urban flooding in Lagos (Adelekan, 2010). Flooding threatens the livelihoods of people in Lagos, Nigeria, where >70 percent live in slums. 1) Increased severity in rainstorms, sea level rise, and storm surges, coupled with 2) the destruction of mangroves and wetlands, disturb people's jobs as traders, wharf workers, and artisans, while destroying physical and human assets. 3) Poor urban management, lacking infrastructure for water supply, and inadequate stormwater drainage have not kept up with urban growth. 4) Inadequate policy responses, including uncontrolled land reclamation, make these communities highly vulnerable to flooding. 5) Only some residents can afford sand and broken sandcrete blocks. 6) Livelihood conditions in these slums are expected to further erode for most households. 7) Given policy priorities for the construction of high-income residential areas, current residents fear eviction.

Figure 13-2: Livelihood dynamics under simultaneous climatic, environmental, and socioeconomic stressors and shocks leading to differential risk spaces and livelihood trajectories over a lifetime.

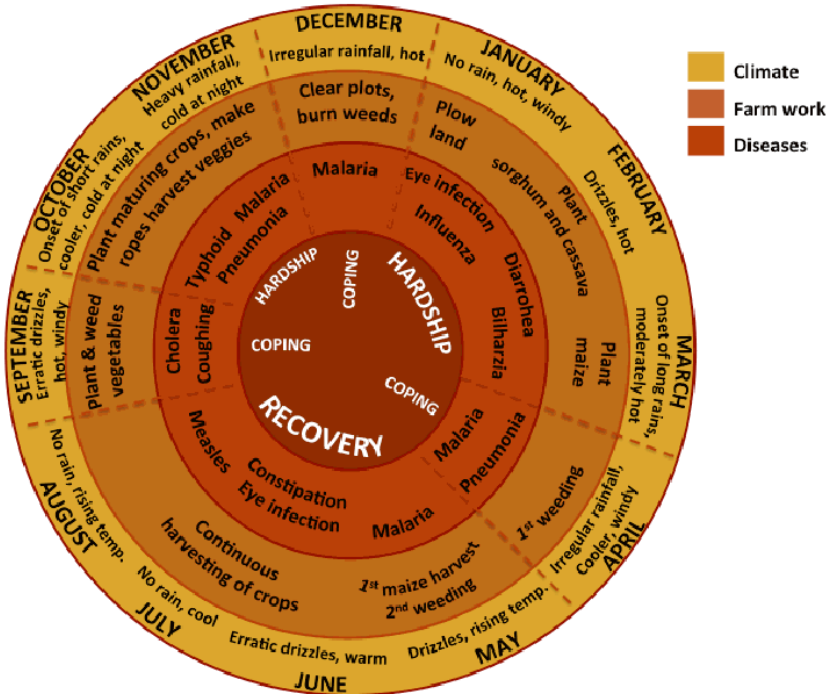


Figure 13-3: 'Wheel of hardship' – a generalized seasonal calendar depicting livelihood conditions and stress based on experiences of smallholder farmers in the Lake Victoria Basin in Kenya and Tanzania (Gabrielsson *et al.*, 2012).

Executive Summary

Since AR4 the framing of adaptation has moved further from a focus on biophysical vulnerability to the wider social and economic drivers of vulnerability (*high agreement, robust evidence*). These include the gender, age, health, social status and ethnicity of individuals and groups and the political system in place within a region and country. [14.1, 14.2]

An emphasis continues to be placed on engineered and technological adaptation options, but there is growing awareness of the need for ecosystem-based, institutional, and social measures, including the provision of climate-linked safety nets for those who are most vulnerable (*high agreement, robust evidence*). Adaptation measures are increasing and becoming more integrated within wider policy frameworks. Integration streamlines the adaptation planning and decision making process and embeds climate sensitive thinking in existing and new institutions and organizations. This helps avoid mismatches with development planning, facilitates the blending of multiple funding streams and reduces the possibility of maladaptive actions. [14.3]

Approaches to selecting adaptation options continue to emphasize minimizing costs, achieving co-benefits, and incremental change, but there is increasing recognition that transformative changes may be necessary in order to prepare for climate impacts (*medium agreement, medium evidence*). While no-regret, low-regret and win-win strategies have attracted most attention in the past, there is increasing recognition that an adequate adaptive response will mean acting in the face of continuing uncertainty about the extent of climate change and the nature of its impacts. While attention to flexibility and safety margins is becoming more common in selecting adaptation options, many see the need for more transformative changes in our perception and paradigms about the nature of climate change, adaptation and their relationship to other natural and human systems. [14.1, 14.3.4]

Among the many actors and roles associated with adaptation two are increasingly recognized as critical to progress; namely those associated with local governance and those with the private sector (*high agreement, medium evidence*). These two groups will bear the main responsibility for translating the top-down flow of risk information and financing, and in scaling up the bottom-up efforts of communities and households in planning and implementing their selected adaptation actions. Local institutions, including local governments, NGOs and civil society organisations, are among the key actors in adaptation but are often limited by lack of resources and capacity. [14.4.2, 14.4.3] Private entities, from individual farmers and SMEs (small to medium enterprises) to large

corporations, will seek to protect their production systems, supply lines and markets, by pursuing adaptation related opportunities. These goals will help expand adaptation activities but they may not align with government or community priorities without coordination and incentives. [14.4.8]

Adaptation assessments continue to evolve leading to a general awareness among decision makers and stakeholders of climate risks and adaptation needs and options, however, this is often not translated into the implementation of even simple adaptation measures within ongoing activities or risk management planning (the 'adaptation bottleneck') (*high agreement, medium evidence*). Most of the assessments of adaptation done so far have been restricted to impacts, vulnerability and adaptation planning, with very few assessing the processes of implementation and evaluation of actual adaptation actions [14.5.1]. Assessments that include include both top-down assessments of biophysical climate change risks and bottom-up assessments of what makes people vulnerable to those risks will help to deliver local solutions to globally derived hazards (the 'adaptation paradox'). Also, assessments that are linked more directly to particular decisions and that provide information tailored to facilitate the decision making process and best suited to delivering effective adaptation measures and overcoming the 'adaptation bottleneck' [14.5.3

Evaluation of adaptation effectiveness is still in its infancy (*high agreement, medium evidence*). Experience in selecting metrics to identify adaptation needs and to measure effectiveness is increasing. [14.6.2, 14.6.3] But the search for metrics for adaptation will remain contentious with multiple alternatives competing for attention as governments, institutions, communities and individuals value needs and outcomes differently and many of those values cannot be captured in a comparable way by metrics. [14.6.4] The demand for metrics to measure adaptation needs and effectiveness is increasing as more resources are directed to adaptation. These indicators need to track not just process and implementation, but also the extent to which targeted changes are occurring. [14.6.2.3]

Maladaptation is a cause of increasing concern to adaptation planners, where intervention in one location or sector could increase the vulnerability of another location or sector, or increase the vulnerability of the target group to future climate change (*high agreement, medium evidence*). [14.7.3] The definition of maladaptation used in AR5 has changed subtly to recognize that maladaptation arises not only from inadvertent badly planned adaptation actions, but also from deliberate decisions where wider considerations place greater emphasis on short-term outcomes ahead of longer-term threats, or that discount, or fail to consider, the full range of interactions arising from the planned actions. [14.7.1]

14.1. Introduction

The rapid pace of climate change and its associated impacts means that we must adapt. In AR5, adaptation is defined in the following way, "In human systems, the process of adjustment to actual or expected climate and its effects, which seeks to moderate harm or exploit beneficial opportunities. In natural systems, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate." The distinction between human and natural systems directs our attention to differences in planned and unplanned adaptation. Natural systems have the potential to adapt through evolutionary processes, although humans may intervene to promote particular adjustments. In contrast, adaptation in human systems requires intentionality and therefore, is the result of planned efforts to address needs and advance options. Coping behavior remains common, such as in instances where immediate actions are taken to prepare for and respond to natural hazards and other extreme events. However, as individuals, communities, and governments account for and take initiatives to address actual and expected climate impacts, they are engaging in planned modes of adaptation.

A further classification that is becoming increasingly important in negotiations and implementation, and integral to AR5, is between incremental and transformational adaptation. The former refers to actions where the central aim is to maintain the essence and integrity of incumbent socio-economic systems and institutions, such as incremental adjustments to cropping systems through new varieties and more efficient irrigation. Alternatively, transformational adaptation seeks to change the fundamental attributes of systems in response to actual or expected climate and its effects. It includes not just changes in activities, such as changing from cropping to livestock or migrating to take up cropping elsewhere, but also changes in our perception and paradigms about the nature of climate change,

adaptation and their relationship to other natural and human systems (Kates *et al.,* 2012; IPCC SREX, 2012, Section 8.6.2.3). Differentiation between these two perspectives is essential since it affects how we approach adaptation, how we integrate it into planning and policy, and how we allocate adaptation funding in both developed and developing countries.

This chapter establishes a foundation for understanding adaptation by reviewing core concepts related to adaptation, with a focus on mapping out broad categories of needs and options. Adaptation needs refer to circumstances requiring action to ensure safety of populations and security of assets in response to climate impacts while adaptation options are the array of strategies and measures available and appropriate to address needs. Since identifying needs and selecting and implementing options requires the engagement of individuals, organizations, and governments at all levels, this chapter also considers the range of actors involved in these processes and summarizes the balance needed between adaptation and potential maladaptation. An ongoing theme throughout the chapter is the concept of mainstreaming or the integration of adaptation to climate change with other areas of government action and responsibility. This chapter also highlights some important tools in implementing adaptation, namely approaches to assessing needs at national, subnational and sectoral levels, and the challenges of applying metrics to determine adaptation needs and the effectiveness of adaptation actions. In the course of these discussions, this chapter establishes a foundation for the three adaptation chapters that follow. The existence of adaptation options does not necessarily mean that these options can be implemented when the need arises. Therefore, Chapter 15 examines adaptation planning and implementation, including the challenges faced and how these can be addressed. Chapter 16 focuses on adaptation opportunities and constraints while Chapter 17 assesses the economic costs and benefits of adaptation.

Summary of Key Findings from AR4

The Fourth Assessment Report (AR4) refined the basic terminology of adaptation and concluded that adaptation to climate change was already taking place, but on a limited basis. Societies have a long record of adapting to the impacts of weather and climate through a range of practices that include crop diversification, irrigation, water management, disaster risk management, and insurance, but climate change poses novel risks often outside the range of experience.

AR4 found that deliberate adaptation measures in response to anticipated climate change were being implemented by a range of public and private actors, on a limited basis, in both developed and developing countries. These measures are undertaken through policies, investments in infrastructure and technologies, and behavioral change, but they are seldom undertaken in response to climate change alone. Many actions that facilitate adaptation to climate change are undertaken to deal with current extreme events such as heat waves and cyclones and often embedded within broader sectoral initiatives such as water resource planning, coastal defense and disaster management planning.

AR4 concluded that there are individuals and groups within all societies that have insufficient capacity to adapt to climate change. The capacity to adapt is dynamic and influenced by economic and natural resources, social networks, entitlements, institutions and governance, human resources, and technology. But, high adaptive capacity does not necessarily translate into actions that reduce vulnerability. New planning processes were being implemented to attempt to overcome these barriers at local, regional and national levels in both developing and developed countries. AR4 noted the establishment of the National Adaptation Programmes of Action (NAPAs) and that some developed countries had established national adaptation policy frameworks. Other conclusions from the AR4 relating the implementation of adaptation policies and measures, barriers to adaptation and the economic costs of adaptation are summarized in Chapters 15, 16 and 17.

14.2. Adaptation Needs

Adaptation involves reducing risk and vulnerability, while building the capacity of nations, regions, cities, communities and individuals to cope with climate impacts as well as mobilizing that capacity by implementing

decisions and actions (Tompkins *et al.,* 2010). Vulnerability is the degree to which a system is "susceptible to, and unable to cope with, adverse effects of change" and is traditionally viewed as being comprised of three elements: exposure, sensitivity, and adaptive capacity (IPCC, 2007a, IPCC SREX, 2012). In other words, vulnerability is the stress faced by a system or individual, the extent to which the system will be affected, and the degree to which the system is able to cope with or respond to these stresses (Cutter, 1996; Cutter *et al*., 2003; O'Brien *et al*., 2004; Adger, 2006).

Adaptation requires that there is adequate information on risks and vulnerabilities to identify needs and appropriate adaptation options to mitigate risks and build capacity. This process of identifying needs is often rooted in a formal risk or vulnerability assessments. The risk-hazard framework, drawn primarily from risk and disaster management, focuses on the adverse effects that natural hazards and other climate impacts can have on a given location (Füssel and Klein, 2006). The emphasis in this approach is on the physical and biological aspects of impacts and adaptation (Burton *et al*., 2002). An alternative approach, which is rooted in a political economy perspective, examines the ways in which individuals, groups and communities are vulnerable to climate impacts. Here, the focus is on social vulnerability, with an emphasis on how structural factors such as institutions shape socioeconomic conditions that place human populations at risk (Blaikie *et al*., 1994; Adger and Kelly, 1999). Approaches to identifying needs and options are discussed further in the section 14.4 on assessments.

Assessments typically provide insight into the risks and vulnerabilities that will result from climate change in communities, cities, and nations and, in turn, offer a means to identify the presence of adaptation needs. Although needs are specific to particular groups and places, they tend to fit into a set of more general categories as summarized in 14-1. For instance, vulnerability at the national and sub-national levels is affected by geographic location, biophysical conditions, institutional and governance arrangements, and resource availability, including access to technology and economic stability.

[INSERT TABLE 14-1 HERE
Table 14-1: Categories and examples of adaptation needs.]

14.2.1. Institutional Needs

Institutions consist of formal and informal rules and norms the provide the enabling environment for implementing adaptation actions (Bryan et al., 2009; Chuku, 2009; Aakre and Rübbelke, 2010; Compston, 2010; Moser and Ekstrom, 2011b). These institutions provide the guides, incentives, or constraints that shape the distribution of climate risks, establish incentive structures that can promote adaptation, foster the development of adaptive capacity, and establish protocols for both making and acting on decisions (See 14.2.3.2 and Agrawal, 2010). At the international level, institutions and institutional actors enable and facilitate the distribution of adaptation resources and capacity support to developing countries. In many instances, international and national-level policies and programs can facilitate localized strategies through the creation of legal frameworks and the allocation of resources (Adger, 2001; Corfee-Morlot *et al*., 2009; Bulkeley and Betsill, 2005). Similarly, institutions, including political systems, policies, and politics at the national or sub-national levels can influence the vulnerability of certain sectors or can facilitate the success of adaptation actions within their jurisdictions (Chuku, 2009; Compston, 2010). For instance, drawing on case studies of water systems in the Middle East and North Africa, Sowers *et al*. (2011) maintain that the largely centralized systems of planning, taxation, and revenue distribution render governments more vulnerable since they are limited in their ability to adapt to climate change.

Local governments have the potential to directly enhance the adaptive capacity of vulnerable areas and populations by developing regulations including those related zoning, storm water management and building codes and attending to the needs of vulnerable populations through measures such as basic service provision and the promotion of equitable policies and plans (Adger *et al*., 2003; Nelson *et al*., 2007; Brooks *et al*., 2005). In the course of specific actions, local governments influence vulnerability and capacity by shaping access to resources and structuring individual and collective responses to climate impacts (Agrawal, 2010). There also are a number of ongoing political issues that shape the relationships local governments have to managing climate risks (Corfee-Morlot et al. 2011). For instance, short-term election cycles, when dealing with long-term issues can limit incentives to make

investments. Similarly, the proximity that authorities have to interest groups can sway their decisions toward other issues, while the drive to engage the public in planning and other activities can orient priorities in ways that do not support adaptation (Corfee-Morlot et al. 2011).

There are four critical institutional design issues that can be evaluated in order to understand institutional needs (Gupta *et al*., 2010; Agrawal**,** 2010). The first is the extent to which institutions are flexible. The uncertainty associated with climate change, presence of rapidly changing information and conditions, and emerging ideas on how best to foster adaptation requires continual evaluation, learning, and refinement (Gupta *et al*., 2010; Agrawal**,** 2010). Second is the extent to which adaptation is or has the potential to be integrated into short and long term policymaking, planning, and program development (Conway and Shipper, 2011). Third, is the potential for effective coordination, communication, and cooperation within and across levels of government and sectors (Schipper, 2009; Conway and Shipper, 2011; Agrawal, 2010). Finally, in order to promote adaptive capacity, it is important to identify the extent to which institutions are robust enough to attend to the needs of diverse stakeholders and foster their engagement in adaptation decisions and actions (Urwin and Jordan, 2008; Gupta *et al.,* 2010).

14.2.2. Social Needs

From a social perspective, vulnerability varies as a consequence of the capacity of groups and individuals to cope with the impacts of climate change. Among the key factors associated with vulnerability are gender, age, health, social status, ethnicity, and class (Adger et al., 2009; Smit et al., 2001). Climate change is expected to have a significant impact on the poor as a consequence of their lack of financial resources, poor quality of shelter, exposure to the elements, and limited provision of basic services, (Patz et al., 2008; Moser and Satterthwaite, 2010; Huq et al., 2007; Shikanga et al., 2009; Kovats and Akhtar, 2008; Revi, 2008; Tol et al., 2004; Gething et al., 2010; Rosenzweig et al., 2010). Due to limited financial resources and often compromised health and nutritional status, along with the sick and elderly, the poor are at increased risk from illness and death from climate-impacts such as increased pollution, higher indoor temperatures, exposure to toxins and pathogens from floods, and the emergence of new disease vectors (Kasperson and Kasperson, 2001;Haines et al., 2006; Costello et al., 2009; O'Neill and Ebi, 2009; Tonnang et al., 2010; Costello et al., 2011; Ebi, 2011; Harlan and Ruddell, 2011; Huang et al., 2011; McMichael and Lindgren, 2011; Semenza et al., 2012).

At the individual level, women, the elderly, those with health challenges and disabilities, low social, minority, and class status are among the least able to cope with threats from climate impacts (Adger *et al*., 2009; Smit *et al*., 2001). These individual factors also are often associated with and compounded by community-level conditions. Many poor and ethnic minorities live in substandard housing, lack access to basic services, have compromised health, and are at threat due to excessive densities, poor access roads, and inadequate drainage (Moser and Satterthwaite, 2010; Huq *et al*., 2007; Shikanga *et al*., 2009; Kovats and Akhtar, 2008; Revi, 2009; Baker, 2011). In rural areas, adaptation needs also are linked to the viability of agricultural activity (Bosello *et al*., 2009).

The causes and solutions of vulnerability take place at different social, geographic, and political scales (Ribot, 2010). Therefore, in order to identify critical needs of populations, and the underlying conditions giving rise to these needs, social assessments are best conducted across institutional domains and by spanning from the local to the national. Local assessments provide a means to identify existing vulnerabilities as well as policies, plans, and natural hazards contributing to these vulnerabilities. More specifically, at this level, social needs can be evaluated in terms of availability of natural, physical, human, political, and financial assets, stability of livelihood, and livelihood strategies (Moser, 2006; Heltberg *et al*., 2008). Alternatively, regional and national assessments can provide a basis for ascertaining institutional conditions associated with long-standing inequities and development paths that may need to be addressed in order to generate robust options.

14.2.3. Biophysical and Environmental Needs

Climate change is altering ecological systems, biodiversity conservation, and resources associated with ecosystem services (Convention on Biological Diversity, 2009; Mooney *et al.,* 2009; Hoegh-Guldberg, 2011). For instance,

González et al. (2010) used observed and modeled changes of global patterns of biome shifts under climate change and concluded that up to half of the terrestrial ecosystems were vulnerable often due to changes in stressors such as wildfire. They suggested that significant changes in management plans of natural resource management organisations. In addition to the responses of ecosystems to climatic change, a number of studies have identified impacts on ecosystem services, particularly the effects of climate change on agricultural productivity (Coles and Scott 2009), downstream industries and enterprises (Preston and Stafford Smith 2009), and freshwater ecosystems (Ormerod et al 2010).

Natural systems are important not only for their own sake, but also because they contribute to human welfare and prosperity in the face of a changing climate. For instance, coastal wetlands and coral reefs can help to protect against storm surges and rising sea levels (Hoegh-Guldberg, 2011) while the maintenance of wetlands and green spaces can control run-off and flooding associated with increases in precipitation (Jentsch and Beierkuhnlein, 2008; Mooney *et al*., 2009). Consequently, there is a need to protect these systems and resources within the changing climate, but many practices to improve and maintain ecosystem services are based on untested assumptions and limited information (Carpenter *et al.,* 2009). Tallis *et al*. (2008) found that only 16% of projects designed to deliver "win-win" goals of alleviating poverty and protecting biodiversity actually delivered both goals. Goldman et al. (2008) found that research projects that focused on delivering ecosystem services, rather than on biodiversity goals, attracted a wider set of funders and better-encompassed landscapes and the people within them.

14.2.4. Resource Needs

Successful implementation of adaptation actions depends on the availability of appropriate human capacity, information, access to technology and funding (Yohe and Tol, 2001; Adger, 2006; Eakin and Lemos, 2006; Smit and Wandel, 2006, World Bank, 2010). In some cases a supposed lack of information has been used as a rationale for inaction (Moser and Ekstrom, 2011a). To address this concern, the Nairobi Work Program, established at COP12 in 2006 with a goal of helping developing countries make better informed decisions based on sound scientific, technical and socio-economic data, has made repeated calls for better observation systems, information sharing, and modeling capacity (UNFCCC/SBSTA/2008/3). Developed and developing countries have acted upon this priority by establishing institutions to provide information services at national, regional, and global scales (UKCIP, 2011; NCCARF, 2012; CCCCC, 2011; WMO, 2011), and there is an ongoing need to promote information acquisition and dissemination (OECD, 2009).

Financial resources for adaptation have been slower to become available for adaptation than for mitigation in both developed and developing countries. Within developing countries only modest funding has been available for adaptation actions and much of this funding has been directed towards capacity building, standalone projects, or pilot programs. This not only has left financial needs, but has meant that there is less expertise in adaptation assessment and implementation, which is further confounded by the lack of clarity about the distinction between adaptation and more common sustainable development and/or poverty reduction planning (Cruce, 2008; McGray *et al*., 2007). Overall, at both international and national levels there is a need to develop financial instruments that are equitable in both their delivery of resources and in sharing the burden of supporting the instruments (Levina, 2007; World Development Report, 2010; Chapters 1,6 and 17). Also, financial mechanisms for disaster risk management are also inextricably linked with those for adaptation (Mechler *et al.,* 2010) and mechanisms for adaptation will have to balance immediate needs for essential development and disaster recovery with longer term goals directed to climate resiliency.

Financial transfers required in the future for climate change will likely approach those on current development expenditure (Peskett *et al*., 2009). Therefore, there is a related need to design delivery channels so that funding reaches the poor as they often are most vulnerable to the impacts of climate change. For example, for adaptation financing, working at the sub-national level will be important and mechanisms like microfinance merit a closer look (Agrawala and Carraro, 2010). Another important concern is that with new money being made available for climate change research, policy development, and practice, people may place too much emphasis on addressing climate change as an isolated priority to the detriment of other equally pressing social, economic, and environmental issues (Ziervogel and Taylor, 2008).

14.3. Adaptation Options

Identifying needs stemming from climate risks and vulnerabilities provides a foundation for selecting adaptation options. Over the years, a number of categories of options have been identified. These options include a wide range of actions that, as summarized in Table 14-2, can be organized into three general categories: structural/ concrete, institutional, and social (Carmin, et al, forthcoming 2013).

[INSERT TABLE 14-2 HERE
Table 14-2: Categories and examples of adaptation options.]

14.3.1. Structural / Concrete Options

This category highlight adaptation options that are discrete, with clear outcomes and outputs that are well defined in scope, space and time. They include structural and engineering options, the application of discrete technologies, the use of ecosystems and their services to serve adaptation needs, and the delivery of specific services at the national, regional and local levels. The notion of 'concrete' reflects the orientation of the Adaptation Fund, where the focus is on "discrete activities with a collective objective(s) and concrete outcomes and outputs that are more narrowly defined in scope, space, and time." (Adaptation Fund Board, undated).

Engineering is often at the forefront of delivering adaptation technologies and strategies (Dawson, 2007). Most engineering options are expert driven, capital-intensive, large-scale, and highly complex (McEvoy et al., 2006; Morecroft and Cowan, 2010; Sovacool, 2011). The most commonly cited engineered options include building seawalls, beach nourishment, upgrading existing infrastructures, and retrofitting buildings (Blanco et al., 2009; Koetse and Rietveld, 2012; Ranger and Garbett-Shiels, 2012).

Engineered adaptation options typically have two general limitations. First, they often must cope with uncertainties associated with projecting climate impacts arising from assumptions about future weather, population growth, and human behavior (Dawson, 2007; Furlow et al., 2011). Second, the longevity and cost of engineered infrastructure affect the feasibility at the outset (Koetse and Rietveld, 2012). They also are subject to consequences that were not anticipated. For example, after coastal Eastern England was devastated by the North Sea storm surge in 1953, hard engineered sea walls were put in place to protect the coast from erosion and inundation. However, the engineered alterations resulted in a new array of coastal instabilities, including disturbances in sediment supply and damages to coastal ecosystems (Adger et al., 2009; Turner et al., 2010). As a result, many have promoted a "phased capacity expansion" strategy, which allows engineered projects to undertake design modification as conditions or knowledge change and facilitate incremental project construction to ease the burden of upfront financing (Colombo and Byer, 2012).

In addition to engineering, structural adaptation measures in various sectors are being developed based on recent advances in technology and information processing. In food and agriculture sector, a suite of adaptation options have been developed and applied to reduce the adverse impacts of climate change on production (FAO, 2007; Stokes and Howden, 2010; Chapters 7 and 9). Technologies range from improved irrigation methods, plant breeding for greater drought tolerance, adjusting planting based on simulated yields (Semenov, 2006; Semenov, 2008; Bannayan and Hoogenboom, 2008), to transfers of traditional technologies such as floating gardens (Irfanullah *et al.,*2008).

With the rapid diffusion of Information and Communication Technologies (ICT), such as mobile phones and the internet, the unprecedented speed at which information is produced and shared is posing a new set of possibilities for communication. ICT provides opportunities for both top-down dissemination of relevant information such as weather forecasts, hazard warnings, market information, and advisory services. It can also generate essential information through bottom-up processes such as 'crowd sourcing' of useful information such as local flood levels, disease outbreaks, and the management of disaster responses. MacLean (2008) identifies three kinds of effects of the

rapid advances in ICT on adaptation and development in general: direct use for monitoring and measuring climate change as described above; as a medium for raising awareness; and as an enabler for a 'networked governance' based on networked open organisations.

Ecosystem-based adaptation (EBA), which is the use of biodiversity and ecosystem services as part of an overall adaptation strategy to help people to adapt to the adverse effects of climate change (Convention on Biological Diversity, 2009), is becoming an integral approach to adaptation. Often, when faced with climate related threats, first consideration is given to technological and engineered approaches to adaptation. However, working with nature's capacity and pursing ecological options, such as coastal and wetland maintenance and restoration, to absorb or control the impact of climate change in urban and rural areas can be efficient and effective means of adapting (Huntjens *et al.*, 2010, Jones *et al.*, 2012). The use of mangroves and salt-marshes as a buffer against damage to coastal communities and infrastructure has been well researched and found to be effective both physically and financially in appropriate locations (Morris, 2007, Day *et al.*, 2007). They can also provide biodiversity co-benefits, support fish hatcheries and have mitigation value (Adger et al., 2005, Convention on Biological Diversity, 2009, Reid and Huq, 2005). Other EBA activities include integrative adaptive forest management (Bolte *et al.*, 2009; Guariguata, 2009; Reyer *et al.*, 2009), and the use of agro-ecosystems in farming systems (Tengö and Belfrage, 2004,), land and water protection and management, and direct species management (Mawdsley *et al.*, 2009).

Ecosystem-based approaches have a number of limitations. For instance, efforts at managing some ecosystems to provide particular services may be at the expense of other services. For example, to provide an effective wetland buffer for coastal protection may require emphasis on silt accumulation possibly at the expense of wildlife values and recreation (Convention on Biological Diversity, 2009, Dudley *et al.*, 2010). Similarly Goldstein et al (2012) found that in land-use decision making in Hawaii tradeoffs existed between carbon storage and water quality, and between environmental improvement and financial returns. A further consideration is that ecosystem-based approaches are often more difficult to implement and assess as they usually require cooperation across institutions, sectors and communities, and their benefits are also spread across a similarly wide set of stakeholders (Jones *et al.*, 2012). As yet it is difficult to demonstrate the effectiveness of this approach compared with others because, as with adaptation as a whole, there have been few formal assessments of the outcomes of ecosystem-based projects (Carpenter et al. 2009, Munroe et al. 2012).

Service provision consists of a diverse range of concrete measures. For instance, one measure to support to the most vulnerable populations is social safety nets. Efforts to address long-term and child malnutrition, which often result from loss of livelihood due to extreme weather events, particularly floods and droughts, (Hoddinott, *et al.*, 2008; Alderman, et al, 2009) offer an example of how safety nets can serve as a climate adaptation measure. While some studies have shown that food programs can be counterproductive to promoting livelihood or may not prevent malnutrition in non-emergency situations (e.g., Bhutta, *et al.*, 2008), programs designed to provide support via food programs, micro-finance or insurance at times of extreme events can provide an important bridge for vulnerable populations (Alderman *et al.*, 2010; Hoeppe and Gurenko, 2006; Hochrainer *et al.*, 2007; Meze-Hausken *et al.*, 2009).

Public health services also are important for tackling projected increases of disease incidences spurred on by climate change (Ebi and Burton, 2008; Garg et al., 2009; Edwards et al., 2011; Huang et al., 2011). For example, in countries where malaria is endemic, frequent adaptation options for addressing possible outbreaks include increasing use of mosquito nets, insecticides sprays, and controlling mosquito breeding by reclaiming land and filling drains(Garg et al., 2009). Governments at all levels are often also responsible for maintaining adequate access to services that are projected to be further stressed due to climate change (Laukkonen et al., 2009; Ernstson et al., 2010). Frequently cited options in this domain include, among others, clearing drainage systems to prevent floods, diversifying water supple services to account for changing water supplies (Kiparsky et al., 2012), and maintaining open public spaces dedicated for disaster recovery and other emergency purposes (Hamin and Gurran, 2009).

At the local level, infrastructure associated with the provision of basic services, such as water, sanitation, solid waste disposal, power, storm water and roadway management, and public transportation are integral to increasing adaptive capacity (Paavola, 2008; Hardoy and Pandiella, 2009; Bambrick et al., 2011; Barron et al., 2012). Housing services are particularly critical because new patterns in temperature and precipitation will alter the habitability and stability

of residences while increased frequency and intensity of natural disasters will place settlements and homes on both stable and unstable land at greater risk (Dodman and Satterthwaite, 2008). Although one option is to relocate people inhabiting vulnerable areas, some argue that in situ upgrading may be more cost effective, especially for addressing informal settlements in developing countries (Revi, 2008).

There are repeated calls for technology transfer to and sharing between developing countries in adaptation to match the programs associated with mitigation (UNFCCC, 2006). However, the circumstances are different. Unlike mitigation, where low-carbon technologies are often new and protected by patents held in developed countries, in adaptation the technologies are often familiar and applied elsewhere. For example, agricultural practices that are well known in a region some distance away may now be applicable but unfamiliar within a region of interest. There are some technologies that may become more important in adapting to climate change. Improved water transport and application through irrigation, or through water use efficiencies in industry all have particular technologies that need to be more widely available, as will desalination technologies. Revised building codes are another important opportunity to increase resilience to climate impacts, but again institutional issues such as enforcement are just as important.

14.3.2. Institutional Options

Numerous institutional measures can be used to foster adaptation. These range from financial instruments such as taxes, subsidies, and insurance arrangements to social policies and regulations (Hallegatte, 2009; Heltberg *et al.,* 2009; de Bruin *et al*., 2009). For instance, in the U.S., post-disaster funds for loss reduction are added to funds provided for disaster recovery and can be used to buy out properties that have experienced repetitive flood losses and to relocate residents to safer locations, to elevate structures, to assist communities with purchasing property and altering land-use patterns in flood-prone areas and undertaking other activities designed to lessen the impacts of future disasters (FEMA, 2010). Planning measures such as building codes and rezoning are institutional measures that can improve the safety of hazard-prone communities (Biderman et al., 2008; Bartlett et al., 2009). While zoning can be used to procure sites for low-income populations (Dodman and Satterthwaite, 2008; Biderman et al., 2008; Bartlett et al., 2009), if it increases property and housing values it also has the potential to exclude the poor from these areas.

A number of funding and financial issues are linked to institutions. At the international level, agreements and donors have a critical role to play in promoting and supporting the allocation and flow of financial resources (OECD, 2011). For instance, the Adaptation Fund, which is set up under the Kyoto Protocol and funded through a levy on most CDM projects, is of particular importance to developing countries as it is pioneering the direct access mechanism which allows countries to access funds without having to work through a multi-lateral development agency. The direct access mechanism highlights the role of institutions in building and maintaining capacity, not just in the technical aspects of adaptation assessment and project design, but also in financial management and due diligence (Brown *et al*., 2010).

Effective governance is important for the efficient operations of institutions. In general, governance rests on the promotion of democratic and participatory principles as well as on ensuring access to information, knowledge, and networks. The basic premise is that robust governance measures can promote adaptation by building adaptive capacity (Adger *et al*., 2009). This argument is reflected in assessment of river-basin planning in Brazil, where Engle and Lemos (2010) found that improving governance mechanisms appears to enhance adaptive capacity. However, they also note that this is not a simple relationship as tradeoffs exist between different aspects of governance that can make some approaches more or less appropriate for given contexts.

14.3.3. Social Options

The complexity of climate adaptation means that adaptation options are heavily influenced by forms of learning and knowledge sharing (Collins and Ison, 2009). Many have noted that education is a key indicator for how people select adaptation options (Chinowsky et al., 2011; Sovacool et al., 2012), while a lack of education is a constraint

that contributes to vulnerability (Paavola, 2008). For example, in a study of how farmers in the Nile Basin of Ethiopia select adaptation options, the researchers found a positive relationship between the education level of the household head and the adoption of improved technologies and adaptation to climate change (Deressa et al., 2009).

Awareness raising, extension, outreach, and other educational programs are important for disseminating knowledge about adaptation options (Aakre and Rübbelke, 2010; Birkmann and Teichman, 2010) as well as for helping to build social capital that is critical for social resilience (Adger, 2003; Krasny et al., 2010; Wolf et al., 2010). In this regard, education can be seen as a public good that promotes dialogue and networks (Boyd and Osbahr, 2010), and, therefore, allows the development of resilience at both the level of the individual learner and at the level of socio-ecological systems (Krasny et al., 2010).

Informational strategies are integral to adaptation. Early warning systems are critical to ensuring awareness of natural hazards and to promoting timely response, including evacuation. A number of approaches being employed around the world, including tone alert radio, emergency alert system, presentations and briefings, and reverse 911 (Pulwarty 2007; Van Aalst et al. 2008, Ferrara de Giner *et al*., 2011). Awareness raising through scenario development, computer modeling and role playing is effective in preparing both responsible authorities and the public (Box 14-1). As previously noted, ICT is facilitating rapid dissemination of information. However, low-tech measures such as brochures, public service announcements, and direct contact with local residents also are important to fostering awareness and response (National Research Council 2007).

_____ START BOX 14-1 HERE _____

Box 14-1. Scenarios and Public Education

Recently the U.S. Geological Survey's Multi-hazard Demonstration Project developed a hypothetical but realistic scenario for large winter storms called ARkStorm (the "AR" refers to atmospheric rivers) in California that was partially based on storms that struck California in 1861 and 1862, but that used state-of-the art modeling approaches. The scenario, which was developed by more than 100 scientists, engineers, and policy and insurance experts, included data on the meteorological aspects of the storms and on impacts such as flooding, landsides, damage to the built environment, and direct and indirect economic losses, as well as activities and expenditures required for recovery (see Porter et al. 2011 for details). ARkStorm was preceded by an earthquake scenario for Southern California, which was connected to a public education campaign and large-scale earthquake exercise known as the Great Southern California Shakeout. The same team is now developing a tsunami scenario for the ports of Los Angeles and Long Beach. All scenarios are accompanied by outreach to constituencies such as government officials and owners and managers of critical infrastructure systems, and include media collaborations, public service announcements, billboards, and other materials aimed at informing the public about hazards and their potential impacts.

_____ END BOX 14-1 HERE _____

Behavioral measures are among the suite of options that are integral to advancing climate adaptation. Government incentives can spark behavioral change. For example, to slow runoff into storm sewers and reduce flooding, a number of cities in the U.S. run "Disconnect your Downspout" programs. These programs will provide information to households and some offer rebates on supplies. Many poor and vulnerable communities have taken steps to adapt to changes in climate, particularly those in flood prone areas. For instance, some local communities in Manila are increasing the number of floors in homes and building makeshift bridges (Porio, 2011).

14.3.4. Selecting Adaptation Options

Selecting specific adaptation options can be challenging partly due to the rate, uncertainty, and cumulative impacts of climate change. However, such signals need to be interpreted and weighed against other cultural, economic, political or social signals that may encourage change. Indirect signals from regulators or customers may be a stronger signal to the agents responsible for adapting than the observed climate itself (Berkhout *et al*., 2006). Also,

rarely will adaptation options be designed to address climate risks or opportunities alone (IPCC, 2007b), instead actions will often be undertaken with other goals (such as profit or poverty reduction) in mind, while also achieving climate-related co-benefits. Gains in reduced vulnerability, enhanced resilience or greater welfare will often be co-benefits generated as a result of changes and innovations driven by other factors. Thus, rather than focusing on adaptation options addressing specific dimensions of climate change, more attention is being paid to mainstreaming climate change into wider government policy and private sector activities (Sietz *et al*., 2011).

A variety of systematic techniques have been developed for selecting options (e.g., DeBruin, 2009; Ogden and Innes 2007, 2009; Füssel 2009). Quantification and other systematic approaches to selecting options have many virtues. However, they also have limitations. For instance, most of these methodologies do not account for a range of critical factors such as leadership, institutions, resources, and barriers (Smith, et al., 2009). As an alternative, a variety of strategies have been recommended for selecting options. Strategies dominating the early adaptation literature emphasized maintaining the current system and minimizing costs while achieving some form of benefit. For instance, no-regrets, low-regrets strategies draw on measures that minimize costs and support existing or complementary goals. Win-win approaches are measures that both reduce climate risk and provide other social, economic or environmental benefits (Hallegatte, 2009). Adaptive management also is a strategy that is highlighted in the early adaptation literature. This approach, which draws on natural systems perspectives, places an emphasis on taking incremental action and then using the lessons learned to inform future actions. The intent is that by monitoring changes that take place and learning from the process, it will be possible to make better-informed decisions in the face of uncertainty (Holling 1978).

As ideas about adaptation have evolved, there has been a shift in orientation from traditional approaches that emphasize maintaining the status quo to more transformative strategies. This is best characterized by the integration of sustainable development into general conceptualizations of adaptation and from an emphasis on natural evolution to recognition of the centrality of human and policy intervention (IPCC SREX, 2012) and from engineering solutions to a balance of structural, institutional and social measures. Emerging trends in adaptation place an emphasis on the need for transformation, which has a distinct logic that differs from traditional strategies. Transformation refers to changes "in the fundamental attributes of a system, often based on altered paradigms, goals, or values. Transformations can occur in technological or biological systems, financial structures, and regulatory, legislative, or administrative regimes" (Glossary, AR5).

Whether the focus is on traditional or transformational strategies, a number of recommendations have been advanced for guiding the selection and sequencing of adaptation options. Given uncertainty, most approaches emphasize the need for basing decisions on multiple scenarios and for taking a long-term perspective. In terms of selecting specific options, the trend has remained consistent in noting the importance of accounting for resource availability and capacity limitations, and ensuring that overall approaches are (Table 14-3): flexible so they can be altered as conditions change, include safety margins so that more rapid rates of climate change are taken into account, can be implemented incrementally over time so that the financial burden is distributed, and find complementarities in structural/ concrete, institutional, and social measures (Hallegatte, 2009; Carmin and Dodman, forthcoming). In addition, the selection of measures must take into account both expert and local knowledge, equity, and stakeholder perceptions (Martens et al, 2009). Further, as discussed in detail in Chapter 16, an emphasis has been placed on identifying options that can be mainstreamed into sector initiatives and, in particular, with efforts in areas of climate mitigation, disaster risk reduction, and sustainable and economic development (Agrawala, 2005; Stern, 2006; Nelson et al., 2007; Agrawala and van Aalst, 2008; Ayers and Dodman, 2010; Willbanks and Kates, 2010; Willbanks et al. , 2003; Dowlatabadi, 2007; Klein, et al. , 2007; Swart and Raes, 2007; Larsen and Gunnarsson-Ostling, 2009).

[INSERT Table 14-3 HERE
Table 14-3: Considerations when selecting adaptation options.]

14.4. Actors and Roles in Adaptation

Climate adaptation requires the engagement of governmental, nongovernmental, private sector and community actors across levels and sectors. The identification of diverse needs, generation of appropriate options, and successful implementation of adaptation measures is predicated on diverse actors contributing their views, ideas, and expertise. This section outlines the roles of some of the main groups of actors and the challenges facing those groups in responding to climate change.

14.4.1. National and State Governments

Governments at all levels play important roles in advancing adaptation and in enhancing the adaptive capacity and resilience of diverse stakeholder groups. National governments are integral to advancing an adaptation agenda as they decide many of the funding priorities and tradeoffs, develop regulations, promote institutional structures, and provide policy direction to district, state, and local governments. In developing countries national governments are usually the contact point and initial recipient of international adaptation financing. State governments may have similar powers, the extent depending on the federal arrangements applicable to the country. In some countries, both developed and developing, state governments lead the national government in promoting and implementing adaptation (Mertz *et al*., 2009).

Drawing on an analysis of published articles, Berrang-Ford *et al*. (2011) found that upper levels of government, particularly national governments, tended to be more anticipatory, used institutional mechanisms such as laws and policies to foster adaptation. In some instances financial support was made available, particularly where adaptation was taking place at the national level. In addition, the engagement of national government actors can help mobilize political will, support the creation and maintenance of climate research institutions, establish horizontal networks that promote information sharing (Westerhoff *et al*., 2011) and, in some cases, facilitate the coordination of budgets and financing mechanisms (Alam *et al*., 2011; Kalame *et al*., 2011). Although there are general trends in the impact that national actors have on adaptation efforts, there also are differences between developed and developing countries. Among the key differences noted are that higher income countries more often include governmental engagement in planning and implementation, focus on non-resource-based sectors, pursue long-term planning processes that include activities such as building partnerships and research, and rely on institutional, governmental, and guideline-based protocols. Low and Middle-income countries tend to be engaged more in reactive adaptations based on community level mobilization often with weak engagement by governments (Berrang-Ford *et al*., 2011).

14.4.2. Local Governments

Local governments are integral and critical actors in advancing, or impeding, adaptation and in shaping the options identified and selected. As institutional actors, they influence the distribution of climate risks, mediate between levels of government as well as between social and political processes, and they establish incentive structures that affect both individual and collective action at all levels (Agrawal and Perrin, 2008). They are in a pivotal position to promote widespread support for adaptation initiatives, foster intergovernmental coordination, and facilitate implementation, both directly and through mainstreaming into ongoing planning and work activities (Carmin *et al*., 2012; Anguelovski and Carmin, 2011).

Despite the critical role they play, local governments, particularly those in developing countries, are faced with numerous challenges that limit their ability to identify needs and pursue adaptation options. Often, these governments must attend to backlogs of basic and critical services such as housing and water supply or focus their attention on addressing outmoded and outdated infrastructure. They also may lack institutional capacity or have difficulty gaining coordination among departments as conflicts emerge to obtain scarce resources (Dodman *et al*., 2009; Hardoy and Romero Lankao, 2011). Also, they may encounter roadblocks both from within their communities as well as from other levels of government in setting priorities, obtaining and allocating resources, and engaging in coordinated action if their attention is focused on adaptation rather than more commonly accepted priorities.

Tompkins et al (2010) found from a survey of 300 adaptive[1] projects in the UK, that more than half were driven by concerns not directly related to climate change. Nevertheless, there are a number of indicators that demonstrate whether local government has institutionalized and mainstreamed adaptation. These include the presence of an identifiable champion from within government, climate change being an explicit issue in municipal plans, resources are dedicated to adaptation, and adaptation is incorporated into local political and administrative decision making (Roberts, 2008, 2010).

[FOOTNOTE 1: The definition of adaptation was extended to include any actions that affected the ability to cope with or adapt to climate change whether or not motivated by climate change.]

14.4.3. Local Civil Society and Nongovernmental Organizations

Civil society actors, including NGOs and community-based organizations (CBO), contribute to adaptation, both through dedicated initiatives as well as in the course of their ongoing work. They play a particular role in community-based adaptation (Menard, 2013). NGOs also have the potential to support government action, or highlight inaction, as well as to take independent action that facilitates adaptation across and beyond government programs. Cameroon, for example, has low adaptive capacity with limited ties within and across levels of government. While many government departments had limited awareness and were taking little to no action on climate change, Brown *et al*. (2010), found that NGOs and other civil society organizations contributed to government capacity. While many NGOs working at the local level focus on sustainable development rather than climate change, organizational representatives took advantage of the synergies in these two areas and were helping local residents prepare for climate impacts.

Governments initiate some programs, while others originate from NGOs and CBOs. In Quito, local NGOs receive funding from the government to train indigenous farmers to improve water resource management, particularly in the context of urban agriculture, diversify crops and privilege those that are native, and replant native tree species in hillside areas. The NGOs also work with indigenous communities, teaching them to monitor variations in rainfall and flows from local rivers and then sharing that data with municipal staff so that tracking of water levels is up-to-date (Carmin *et al*., 2012; Anguelovski and Carmin, 2011).

Civil society actors can play a role in hindering adaptation actions as well as alerting governments and the public to critical issues. These range from those who call into question the validity or urgency of climate change (Boykoff, 2008, McCright and Dunlap, 2013) to questioning the risks of particular approaches to adaptation, such as the use of gene technologies for developing new crop varieties (Hällström, 2008).

14.4.4. International Organizations and Institutions

International organizations and institutions include intergovernmental organizations, multilateral and bilateral agencies, multinational corporations, and nongovernmental organizations. These actors engage in a variety of activities that affect adaptation at the international, national, and local levels. Among the roles played by intergovernmental organizations is the formation of treaties and agreements and creation of international funding mechanisms. For instance, the Adaptation Fund and the Nairobi Work Programme, among others, are international institutions designed to facilitate adaptation at the national and regional levels (Ayers, 2009; Ayers and Huq, 2009; Flam and Skjaerseth, 2009; Hardee and Mutunga, 2009; Kalame *et al*., 2011; Lu, 2011). Multilateral and bilateral agencies typically focus on the provision of development assistance and the creation and implementation of capacity building programs. Through these efforts, agencies allocate funds, transmit information, and disseminate technology.

International NGOs, particularly international development, aid, and humanitarian organizations, have long histories of working on adaptation-related activities. Organizations such as CARE and Red Cross/Red Crescent work directly with communities to plan for water and sanitation as well as offer educational programs designed to provide information about climate risks (Suarez *et al*., 2008). Numerous development organizations work on issues related

to livelihood. Development initiatives not only have the potential to address poverty alleviation, but can reduce vulnerability by promoting adaptive capacity (Burton *et al*., 2002; Huq *et al*., 2003). As a number of studies show, while these activities may be oriented to promoting rural livelihoods in the context of environmental and development projects, they have co-benefits of building local capacity and promoting adaptive responses that enable communities to be better prepared to cope with climate impacts (Rojas Blanco, 2006; Pouliotte, 2009).

14.4.5. Local Communities

Many communities pursuing adaptation are engaging community-based, civil society, and nongovernmental organizations (NGOs) in planning and implementation. One approach that relies extensively on communities and community organizations is community-based adaptation (CBA). CBA is characterized by the engagement of local residents to identify measures that can reduce vulnerability while building local adaptation capacity. CBA can both engage as well as empower residents to plan for and take action to address the impacts of climate change (Reid *et al*., 2010; Ebi, 2008). It relies on participatory processes and not only considers hazard prone areas, issues in service delivery, and gaps in infrastructure, but often attends to local social and cultural norms as a means to take a holistic approach to reducing vulnerability (Ayers and Forsyth, 2009). The outputs of these processes have included numerous recommendations and plans of action, including the design and implementation of early warning systems, infrastructure development, and improvements in service delivery (Ensor and Berger, 2009; Douglas *et al*., 2008).

Communities have a long history of participating in vulnerability assessments and risk-mapping in the context of disaster risk reduction (Yamin *et al*., 2005; Larsen and Gunnarsson-Östling, 2009). Many of these ideas and methods have carried over into adaptation initiatives as a means to identify climate-related hazards and risks (Van Aalst *et al*., 2008). For instance, CBA has been adopted in the Philippines and Bangladesh to plan for flood reduction and disaster management (Ensor and Berger, 2009) as well as in cities such as Durban where local communities are engaged in climate risk assessments and adaptation planning (Carmin *et al*., 2012). These activities are designed to foster the transition from assessment to planning to implementation and, in the process, to sensitize communities to climate-related issues while promoting wide-spread adaptation action.

Community members also can contribute to local knowledge in support of government initiatives. For instance, in efforts to address climate adaptation and sustainable resource management needs, local residents from the southwest Yukon in Canada supported forest management plans by providing input on strategic benchmarks and design of appropriate harvest activities (Ogden and Innes, 2009). Governments have also used community engagement to ensure that local needs are met. For example, the Government of Fiji introduced a provision to delegate responsibility for surveying and assessing damage to the affected communities. The information that was collected was then used to inform the design of disaster response and recovery programs (Meheux *et al*., 2010).

14.4.6. Households

As adaptation is local in nature, households are the front line both in making decision about when and how to adapt and suffering the consequences increasing climate risks (Lansigan *et al*., 2007). The ability to respond to climate impacts is strongly related to household income, with wealthier households often being less exposed and having greater resources to draw upon, both to adapt and to recover from climate shocks (Masozera et al. 2007). Nevertheless, even they remain vulnerable weather shocks and the flow-on consequences, such as loss of power and/or water and livelihood disruption. Similarly cultural, social circumstances, gender and age affect the roles, empowerment and expectations of individual household members in both adaptation actions and in responses to climate impacts (Demetriades and Esplen, 2008). Poor rural households face some of the greatest difficulties from climate change. Climate related shocks threaten to overwhelm their current methods of income and consumption smoothing (Baez *et al*. 2013). For example many households protect consumption by sharing with and borrowing from relatives and friends, but such systems can fail as the frequency of damaging events increase (Deressa *et al*., 2009). There is also some evidence that poor farmers will seek to protect income by relying on low risk crops rather than higher value production systems (Azariadis and Stachurski, 2005). Frequent shocks can lead to a depletion of assets, both financial and human and eventually to a poverty trap. Evidence shows that school attendance suffers,

especially for girls, and early childhood malnutrition can impede development and capacity for the rest of life (Carter *et al*., 2007; World Bank 2010: Chpt 1). Stresses from climate events often adds to other pressures leading to rural to urban migration, which can increase the stresses in both locations. In many Arab countries men and boys migrate leading to further crowding and competition for jobs in the cities, while women are left to manage the farms often without rights of access to markets, rights to water *etc*. that were vested in the men (Verner, 2012: Chpts 1 and 7). This emphasizes the importance to households of social safety nets to avoid poverty traps (Morduch and Sharma, 2002; De Janvry *et al*. 2006; Hess *et al*., 2006).

14.4.7. Indigenous Peoples

Indigenous actors are in a particular position in relation to climate change. Many live in locations that are particularly exposed to climate change with resource-based livelihoods, and often with limited external resources and support to respond to a changing climate. As such they are often politically and economically marginalized and face substantial risks to livelihoods and culture from climate change (12.3). They are also the owners of knowledge systems that have served them through generations of climate variability, that provide local relevance, and that are attuned to their culture values and attitudes. (Nakashima, 2012). This knowledge is threatened through loss of context, concern about its continuing relevance and neglect (12.3.3). The respectful blending of this knowledge with that from scientific knowledge systems, which could inform both science and Indigenous Peoples, is still far from complete (Alexander *et al*., 2011, Thornton & Scheer, 2012). But progress is being made, including sharing of climate information and knowledge (Ziervogel et al. 2010) and in local information collection and monitoring (King et al., 2008; Anguelovski and Carmin, 2011). For instance, agro-pastoralists in Makueni District, Kenya are involved in monitoring, assessing, and adapting to the effects of drought through observing local weather and wildlife behavior signs (Speranza *et al*., 2010). Most progress is made in these exchanges if they are seen as a source of new insights for all those engaged rather than "contesting validities" (King and Goff, 2010).

14.4.8. Private Sector

The role of the private sector is fundamental in delivering adaptive changes. Most often, the focus falls on the role of the private financial sector in providing risk management options including insurance and finance for large projects (see Chapter 15). However, the delivery of adaptation actions ranges more widely and spans different types of private enterprise, from small farmers, to SMEs (Small to Medium Enterprises) to multinational companies. KPMG (2008) used published reports and interviews to identify the sectors where businesses face the greatest risks. In order of perceived importance the core risks were regulatory, physical, reputational and litigation risks. The sectors identified as most at risk included an expected cluster around oil & gas and aviation, and also a group less commonly perceived to be at risk, including health care, the financial sector, tourism and transport.

As shown in Figure 14-1, **t**here are three general ways in which the private sector can become involved in adaptation (Khattri, *et al.,* 2010). The first, internal risk management is critical to firms and enterprises protecting their own interests and ensuring continuity of supply and markets. The second form of involvement recognizes that business is a stakeholder and therefore needs to participate in public sector and civil society initiatives, such as, The New York City Panel on Climate Change, which consists of diverse stakeholders, including representatives from the private sector (Rosenzweig *et al*., 2011). Third, climate adaptation also provides a wide range of new opportunities to the business community. Even in developing countries Khattri *et al*., (2010) identified opportunities for working in the healthcare, waste and water management, sanitation, housing, energy, and information sectors through fostering cooperation across government departments and NGO and promoting public-private partnerships.

[INSERT FIGURE 14-1 HERE
Figure 14-1: A typology of private sector engagement in adaptation (Khattri *et al*., 2010).]

Despite broad-scale recognition of the need to adapt, such as the World Economic Forum's (2012) ranking of the failure to adapt as one of the highest global risks and on a par with terrorism, and despite some examples of private sector engagement in adaptation, most assessments conclude that action in each of the potential arenas has been

slow to emerge (Khattri *et al*., 2010, Agrawala *et al*., 2011). KPMG (2008) concluded that while companies are well used to managing business risk they are yet to integrate the long-term risks of climate change into these systems. Nor are they preparing to grasp the competitive advantages that will accrue to those taking early action. Most of the private sector appears to be unaware of the scale of the threat and opportunities for their businesses or are awaiting further guidance and action by governments. They have trouble in accessing and applying information on the extent of the threats and impacts from climate change and have yet to engage in the detailed cost benefit analysis of adaptive actions. Also, there are still questions of whether and how adaptation finance should be made available to the private sector in developing countries (Persson *et al*., 2009; IFC, 2010, Agrawala *et al*., 2011) although this is being piloted through the Pilot Program for Climate Resilience (World Bank, 2008; IFC and Asian Tiger Capital Partners, 2010). Private sector engagement and investment in adaptation is expected to make a substantial contribution to reducing climate risk, but the distribution of its investments will be selective and will be unlikely to match government and civil priorities (Atteridge, 2011).

14.5. Adaptation Assessments

14.5.1. Purpose of Assessments

Identifying adaptation needs requires an assessment of the factors that determine the nature of, and vulnerability to, climate risks (climate impacts and vulnerability assessments) and an assessment of adaptation options to mitigate risks (adaptation assessment).

Assessments help decision makers understand the impacts, vulnerability and adaptation options in a region, country, community or sector. They are often characterized into 'top-down' and 'bottom-up' assessments. Top-down assessments are used to measure the potential impacts of climate change using a scenario and modeling driven approach. Bottom-up assessments begin at the local scale, address socio-economic responses to climate, and tend to be location-specific (Dessai and Hulme, 2004). They are often used to determine the vulnerability of different groups to current and/or future climate change and their adaptation options, using stakeholder intervention and analyzing socio-economic conditions and livelihoods (UNFCCC, 2010). There are also policy-based assessments, which assess current policy and plans for their effectiveness under climate change within a risk-management framework (UNDP APF; UNDP, 2005). In practice assessments have become increasingly complex, often combining elements of top-down and bottom-up approaches (e.g., Dessai et al., 2005). Decision-makers use both in the policy process (Kates and Wilbanks, 2003; McKenzie Hedger et al., 2006).

14.5.2. Trends in Assessments

A variety of frameworks have been developed for the assessment of climate impacts, vulnerability and adaptation. 'Impacts-based' approaches focus primarily on the biophysical climate change impacts to which people and systems need to adapt. 'Adaptation-based' approaches examine the adaptive capacity and adaptation measures required to improve the resilience or robustness of a system exposed to climate change (Smit and Wandel, 2006). 'Vulnerability-based' approaches focus on the risks themselves by concentrating on the propensity to be harmed, then seeking to maximize potential benefits and minimize or reverse potential losses (Adger, 2006; IPCC, 2007). In practice these approaches are interrelated, especially with regard to adaptive capacity (O'Brien et al., 2006),

The 'standard approach' to assessment has been the climate scenario-driven impacts-based approach, which developed from the seven-step assessment framework of the IPCC (Carter et al., 1994; Parry and Carter, 1998):

1) Define problem (including study area and sectors to be examined)
2) Select method of problem assessment
3) Test methods/conduct sensitivity analyses
4) Select and apply climate change scenarios
5) Assess biophysical and socio-economic impacts
6) Assess autonomous adjustments
7) Evaluate adaptation strategies.

This approach dominated the assessment sections of the first three IPCC reports, and aims to evaluate the likely impacts of climate change under a given scenario and to assess the need for adaptation and/or mitigation to reduce any resulting vulnerability to climate risks (IPCC 2007). These frameworks are described as 'first generation' or 'type 1' assessment studies (Burton et al., 2002). The standard impact approach is often described as top-down because it combines scenarios downscaled from global climate models to the local scale with a sequence of analytical steps that begin with the climate system and move through biophysical impacts towards socio-economic assessment (IPCC, 2007).

The 'second generation' assessments (Burton et al., 2002) are characterized by vulnerability and adaptation assessments, which pay greater attention to information around vulnerability to inform decisions on adaptation. They focus on the participation of vulnerable groups in decision-making around adaptation options (LEG 2002).

Adaptation assessments continue to evolve, but most synthesis now include 'top-down' and 'bottom-up' approaches, and include the assessment of both biophysical climate change risks and the factors that make people vulnerable to those risks. There is a shift towards integrating community-based planning into national adaptation plans. The Government of Nepal proposes 'LAPA assessments' (Local Adaptation Plans of Action) that seek to integrate top-down and bottom-up models (Government of Nepal, 2011). There is also increasing attention to institutional capacity assessments and policy environments as key factors that can both drive vulnerability, and also determine the type and success of different adaptation options. The generic elements of adaptation and vulnerability assessment are reflected in the UKCIP guidelines presented in Figure 14-2.

[INSERT FIGURE 14-2 HERE
Figure 14-2: A generic framework for vulnerability and adaptation assessments (UKCIP, 2011).]

14.5.3. Issues and Tensions in the Use of Assessments

Adaptation and risk assessments give rise to various tensions, three of which are discussed in this section. The first is the 'adaptation paradox' which recognizes that climate change is a global problem, whilst vulnerability is locally experienced (Ayers, 2011). Top-down assessments of climate scenarios are deemed necessary in order to understand the climate change scenarios that render climate risk. However, the factors that make people vulnerable to climate risks are locally generated, so require locally driven bottom-up analysis. Bottom-up analysis tends to prioritise groups based on factors related to poverty and development that drive vulnerability. Top-down assessments tend to prioritise those most exposed to climate risks. Analysis in Nepal that assessed both under-development and climate change impacts showed that, at the household scale, there was a strong correlation between local measures of poverty and vulnerability to climate change (Ghimire et al. 2010). However, when indicators were aggregated at district scale, the correlation was weaker - even when the vulnerability index used included poverty as a proxy for adaptive capacity alongside climate hazard risk and exposure (Ghimire et al. 2010).

There are also tensions around ownership and participation. Assessments managed under global climate change governance structure of the UNFCCC are developed under an 'impacts-based' paradigm (Burton et al 2002). This impacts-based approach requires external scientific and technological expertise for defining climate change problems, and formulating technological adaptation solutions, based on specific knowledge of future climate conditions. Such assessments are necessarily 'top-down' because this expertise exists at the global and national level. At the local level, the capacity to adapt is based on the underlying securities that determine vulnerability to these impacts in the first place (Adger et al., 2003). Accessing this information requires 'bottom-up' and participatory assessments that engage local vulnerable people. These vulnerable groups and institutions do not have access to the climate impacts science necessary to fulfill the requirements of top-down impacts-based assessments. So there is a tension between enabling local participation under assessments driven by a global climate impacts remit.

The numerous assessments that have been carried out have led to a general awareness among decision makers and stakeholders of climate risks and adaptation needs and options. But this awareness is often not translated into the

implementation of even simple adaptation measures within ongoing activities or within risk management planning. To overcome this 'adaptation bottleneck' assessments may need to be linked more directly to particular decisions and the information tailored to facilitate the decision making process (Preston and Stafford Smith, 2009; Brown *et al.*, 2011). Specific techniques such as decision scaling, which seeks to understand which climate conditions would result in hazardous conditions of concern for particular stakeholder groups are a step in this direction (Moody and Brown, 2012; Brown *et al.*, 2012).

14.5.4. National Assessments

Under the Convention, all Parties are encouraged (Annex 1 countries are required) to report on their activities in relation to 'vulnerability assessment, climate change impacts and adaptation measures" (FCCC/CP/1999/7). Parties are encouraged to use the IPCC Technical Guidelines for Assessing Climate Change Impacts and Adaptations (Carter et al., 1994) and the UNEP Handbook on Methods for Climate Change Impacts Assessment and Adaptation Strategies (described above). Annex 1 countries are due to submit their 6th Communications by 2014 and most non-Annex I countries are due to have submitted at least one Communication and some their second. As such, National Communications have formed the first avenue for assessing and reporting on climate risk and vulnerability assessments at the national level.

National Adaptation Programmes of Action are designed as a vehicle for Least Developed Countries (LDCs) to communicate their most "urgent and immediate adaptation needs" to the UNFCCC for funding from the LDC Fund. "Urgent and immediate needs" are defined as those for which further delay in implementation would increase vulnerability or increase adaptation costs at a later stage (LEG, 2002:1). The approach adopted to vulnerability assessment under NAPAs vary. Although the guidelines allow for more participatory and 'bottom-up' mechanisms to be adopted, time and funding limitations has meant that often the NAPA process remains largely top-down, focused on impacts and only consulting the communities to verify this information (Ayers, 2001; Huq and Khan, 2006).

Under the Cancun Adaptation Framework (CAF), a process was established to enable least developed country Parties (LDCs) to formulate and implement National Adaptation Plans (NAPs). NAPs are intended to build on NAPAs but shift the focus towards identifying medium- and long-term adaptation needs and developing and implementing strategies and programmes to address those needs. Other developing country Parties are also invited to employ the modalities formulated to support the national adaptation plans in the elaboration of their planning efforts. Early guidelines (LDC Expert Group, 2002) propose a country-specific approach is adopted tailored to national circumstances, mixing top-down policy-first assessments with bottom-up approaches.

14.6. Measuring Adaptation

Adaptation has tended to lag behind mitigation efforts in both in research and in the climate negotiations. In part this because adaptation and development specialists, governments, NGOs and international agencies have found it difficult to clearly define and identify precisely what constitutes adaptation, how to track its implementation and effectiveness, and how to distinguish it from effective development (Burton *et al.*, 2002; Arnell, 2009; Doria, *et al.* 2009). A contributing reason is that adaptation has no common reference metrics in the same way that tonnes of greenhouse gases or radiative forcing values are for mitigation. This section seeks to explore the feasibility of finding metrics for measuring adaptation effectiveness.

The search for metrics[2] for adaptation will remain contentious with many alternatives competing for attention. This is inevitable as there are multiple purposes and viewpoints in approaching the measurement of adaptation (Hulme, 2009). Brooks et al (2011) asked 'what constitutes successful adaptation' and suggested that the criteria by which success might be assessed include, feasibility, efficacy/effectiveness, efficiency, acceptability/legitimacy, and equity (derived from Yohe and Tol, 2002; Adger, 2005; Stern, 2006), to which they added sustainability (see also Fankhauser and Burton, 2011). Also institutions, communities and individuals value things differently and many of those values cannot be captured in a comparable way by metrics (Adger and Barnett, 2009).

[FOOTNOTE 2: Here a 'metric' is defined as any type of measurement used to gauge some quantifiable component of performance; it is largely synonymous with the term 'indicator'. 'Metric' is used here to reduce confusion with the wider uses of the terms 'measure' and 'indicate'.]

At least three uses of measurements are relevant to adaptation each requiring different characteristics of its metrics. The first use seeks metrics to help determine the need for adaptation. These metrics usually focus on measuring vulnerability, but that term is not well defined as is discussed below. Further, even within this application often the goal is not to produce a score or rating for application but to elucidate information on the nature of vulnerability and to better identify adaptation options (Smit and Wandel, 2006). Hinkel (2010) identifies six uses that vulnerability indicators are sometimes expected to serve and concludes that they can truly serve only their core purpose; i.e. to identify vulnerable people, communities and regions. The second use of metrics relates to measuring and tracking the process of implementing adaptive actions, such as spending on coastal protection, the number of early warning plans implemented as part of a program, or the number of agricultural specialists with appropriate training in climate risks. Here the selection of appropriate metrics is usually less contentious but although there is disagreement as to how much they represent adaptation versus normal development. The third use relates to measuring the effectiveness of adaptation. This set is essential to help measure progress and provide feedback on the effectiveness of actions, but are among the most difficult to identify as adaption outcomes take time to become identifiable.

14.6.1. What Needs to be Measured?

The measurement of vulnerability is central to many adaptation metrics and initially it was approached from an impacts point of view. Here vulnerability is usually defined as a function of (i) exposure to specific hazards or stressors, (ii) sensitivity to their impacts and (iii) the target population's capacity to adapt (IPCC 2001, Chapter 17). This approach continues to be used as the basis of many assessments and adaptation prioritization efforts. Recently the emphasis has moved from better defining exposure and potential impacts to a better understanding of the factors that affect societies' sensitivity to those impacts and their capacity to adapt. This reflects the increasing recognition of the importance of considering social vulnerability alongside biophysical vulnerability. Various terms have been used to describe these different emphases including biophysical versus social vulnerability, outcome versus contextual vulnerability (Sections 14.2.1.1.1 and 14.2.1.1.2; Eakin and Luers, 2006; Füssel and Klein, 2006; Eriksen and Kelly, 2007; Füssel, 2007; Füssel, 2010) and scientific framing versus a human-security framing of vulnerability (O'Brien, 2006). O'Brien *et al.* (2007) argue that scientific and human-security frameworks affect the way we approach adaptation, with the scientific framework leading to building local and sectoral capacity to make changes rather than address the fundamental causes of vulnerability, or climate change itself, within their broader geopolitical and economic contexts.

Other questions also arise even within a given conceptual framework for considering vulnerability. A system of measurement is usually developed to allow comparisons between different places, social groups or sectors of activity, although experience repeatedly cautions us to be cautious in doing so (Schröter *et al.*, 2005). Also, a system's vulnerability is not static but can respond rapidly to changes in economic, social, political and institutional conditions over time (Smit and Wandel 2006; Smit and Pilifosova, 2003).

It has also been suggested that a framework based on the concept of resilience is more appropriate than a vulnerability framework in many contexts. For example, in a development context resilience "evokes positive and broad development goals (e.g., education, livelihood improvements, food security), includes multiple scales (temporal and spatial) and objectives, better captures the complex interactions between human societies and their environments, and emphasizes learning and feedbacks" (Moss *et al.*, to appear). A resilience approach also leads to more focus on interactions between social and biophysical systems (Nelson *et al.*, 2007). However, the concept of resilience has proven very difficult to apply in practice and is particularly resistant to attempts to establish commonly accepted sets of indicators. Some (e.g. Klein *et al.*, 2003) have suggested that resilience has become an umbrella concept that has not been able to support effectively planning or management.

Recently Brooks et al. (2011) have outlined a framework tracking adaptation that combines the establishment of upstream metrics to assess how well risks are being managed by institutions, and downstream metrics to track whether the interventions are reducing the vulnerability of affected groups. The upstream metrics would focus on assessments of institutional capacity, managerial performance, integration of climate risk management into planning processes and tracking and feedback processes. The downstream metrics would focus on measures to track development performance and changes in vulnerability. Attribution of these changes to particular interventions would be desirable, but not essential to track progress.

But understanding vulnerability does not necessarily translate to effective adaptation. Smit *et al*. (2001), Osman-Elasha *et al*. (2009) and others have suggested that the focus should be on increasing adaptive capacity within the context of the full range of biophysical and socio-economic stressors. However, as the scope of the metrics is widened to include aspects of development and sustainability they often become less suitable for other purposes such as helping to identify "the full and additional costs of adaptation" (McGray *et al*., 2007).

In deriving indices of vulnerability there are again two broadly different approaches. One is to deductively identify indicators that theoretically should be strongly related to vulnerability, while the other is inductive and uses observed data to seek correlations between indicators and observed consequences of vulnerability, such as the number of people killed or affected by climate related events in recent history. There is some commonality in identifying the desirable criteria for selecting indicators, which have been concisely summarized by Perch-Nielsen (2010) in Table 14-4.

[INSERT TABLE 14-4 HERE
Table 14-4: Set of criteria for selection of indicators.]

14.6.2. Established Metrics

14.6.2.1. Vulnerability Metrics

Numerous metrics continue to be prepared for a variety of purposes and at scales ranging from estimating the vulnerability of communities to comparing countries. Several reviews, including Moss (2001, to appear) Srinivarsan and Prabhakar (2008), and Prabhakar and Srinivarsan (2011), discuss both the design and effectiveness of many of the existing proposals for adaptation metrics.

Eriksen and Kelly (2007) found strong divergence among five 'indices' for comparing national vulnerability published over the period 1995 to 2003. (Namely the Dimensions of vulnerability of Downing *et al*., 1995; the Index of Human Insecurity (IHI) of Lonergan *et al*. 1999; the Vulnerability-resilience indicators of Moss *et al*., 2001; the Environmental Sustainability Index of the World Economic Forum, 2002; and the Country-level risk measures, Brooks and Adger 2003.) Between them, 29 indicators were used with only five indicators appearing in more than one study. They were able to compare the 20 countries ranked as most vulnerable from three of the studies and found little overlap with only five countries ranked in the top 20 in more than one study. However, it must be noted that the indices were developed at different times and for different purposes. They concluded that the indices focused on measuring a snapshot of aggregate conditions rather than on delivering guidance on societal processes that can be targeted to reduce vulnerability.

There are a series of disaster related indices designed to assess relative risks across countries and regions, and to provide benchmarks on which to assess progress (UNDP Disaster Risk Index, 2004; Hotspots Index of Dilley *et al*., 2005; the Americas Index of Cardona, 2005; and an index for South Asia of Moench *et al*., 2009). Again there has been little effort to further analyse, validate or compare these indices.

14.6.2.2. Metrics and Resource Allocation

Vulnerability indices have usually been designed to better understand the drivers of vulnerability or to compare countries, regions, communities etc. in terms of the risks they face from climate change and their capacity to deal with them. This is not necessarily the same as designing an allocation index or rule to be used to allocate limited resources equitably and efficiently among entities (countries, regions or other administrative groups, or different proponents of adaptation). For allocation we might expect that vulnerability and coping/adaptive capacity would remain a core consideration, but so also should the ability of the recipients to absorb the funding and implement policies and projects to actually achieve the projected benefits (UNFCCC, 2007; Wheeler, 2011).

One of the longest running and prominent use of metrics in funding is the World Bank's process of allocating IDA concessional funds to developing countries which faces many issues analogous to the same process for adaptation. The World Bank uses the Country Policy and Institutional Assessment (CPIA) based on 16 criteria to estimate the extent to which a country's policy and institutional framework supports sustainable growth and poverty reduction, and consequently the effective use of development assistance. These criteria are the main components used to calculate a Country Performance Rating, which in turn is a major component, along with population and recent performance measures, in calculating allocations to the poorest developing countries with long-term, no interest (IDA) loans. The CPIA and the ultimate IDA allocation formulae are controversial, much debated (Alexander 2010), often fine-tuned (IEG, 2009) but still commonly used as a reference point for this type of procedure (GTZ, 2008).

An explicit example of the use, and non-use, of adaptation metrics was in establishment of the Pilot Program for Climate Resilience (PPCR). The governing body made up of contributors, recipients and other stakeholders set up an independent expert group to make recommendations as to which countries might be included as pilots within the c. USD1billion program (Climate Investment Funds, 2009). The expert group refrained from using a simple index, but instead country selection was done across 9 regions and each based on a suite of indices appropriate for the region and on expert judgment. It is interesting to note that on moving to the next step of deciding on allocation of financial resources to the selected pilot countries the governing body of the PPCR chose not to use an approach based on indicators, but to provide guidance to the countries of the possible range of funding and to base allocations on the quality of the proposals bought forward (Climate Investment Funds, 2009). Similarly, none of the other governing bodies of international adaptation funding mechanisms (e.g. the GEF, the Adaptation Fund) has chosen to use a defined set of metrics within their decision-making.

Wheeler (2011) has developed an index of vulnerability based on weather related disasters, sea-level rise and agricultural productivity. The index can be adjusted according to user preferences to develop allocation formulas based only on biophysical vulnerability, further adjusted for economic development and governance, and finally for project costs and probability of success. Klein and Möhner (2011) have discussed the options for the Green Climate Fund based on experience to date and conclude that science cannot be relied upon for a single objective ranking of vulnerability.

14.6.2.3. Metrics for Monitoring and Evaluation

The IPCC's *Fourth Assessment Report* provided little discussion of the role of evaluation and monitoring of adaptation responses as a component of building adaptive capacity (Adger *et al*., 2007). Preston *et al*. (2011) identify three specific roles of evaluation: a) ensuring reduction in societal and ecological vulnerability; b) facilitating learning and adaptive management; and c) providing accountability for adaptation investments (see also GIZ 2011). A central challenge in developing robust monitoring and evaluation frameworks for adaptation is the existence of multiple, valid points-of-view that can be used to evaluate adaptation (Gagnon-Lebrun and Agrawala, 2006; Perkins *et al*., 2007; Füssel, 2008; Smith *et al*., 2009; Ford *et al*., 2011; Preston *et al*., 2011). This challenges the selection of appropriate metrics for the monitoring and evaluation of adaptation and its contribution to vulnerability reduction (Burton and May, 2004; Gagnon-Lebrun and Agrawala, 2007; Hedger *et al*., 2008; IGES, 2008; Ford *et al*., 2011).

One of the central unresolved tensions in progressing evaluation is the relative merit of targeting adaptation processes versus outcomes. Preston *et al*. (2011) suggest the evaluation of adaptation processes may be a more robust approach to evaluation, due to the difficulties in attributing future outcomes to adaptation strategies and the long-time lags that may be needed to assess the performance of a particular strategy (Berkhout, 2005; Dovers and Hezri, 2010; Ford *et al*., 2011). The OECD analyzed the monitoring and evaluation processes across 106 adaptation projects across six development agencies and found that Results Based Management and Logical Framework approaches dominated as they do in normal development projects (Lamhauge *et al*., 2011). They also drew attention to the need for appropriate baselines and complimentary sets of indicators that track not just process and implementation, but also the extent to which targeted changes are occurring. Monitoring programs themselves will need careful design to ensure that they remain in place over the long timeframes needed for the outcomes to be identified; that they contain incentives for beneficiaries to comply with conditions and that compliance itself does not impose undue burdens.

A number of national and international organizations have guides to monitoring and evaluating adaptation activities (McKenzie Hedger *et al*., 2008; UNDP, 2008; WRI, 2009; World Bank, 2010; GIZ, 2011). These guides tend to focus on the wider framework of identifying and managing adaptation-related activities and within that the criteria for the selection of metrics for monitoring and evaluating those activities. These issues are dealt with in Chapters 15 and 16.

14.6.3. Validation of Metrics

The practice of developing and applying metrics in adaptation has been subject much scrutiny. Eakin and Luers (2006) express serious concerns about national-scale vulnerability assessments ranging from the quality of the available data, the selection and creation of indicators, the assumptions used in weighting of variables and the mathematics of aggregation. Downing (to appear) has made a similar critique. Nevertheless indices will continue to be used and the challenge is to identify and maintain basic standards of best practice.

One of the most comprehensive attempts to validate a system for measuring important components of adaptation is that of Brooks, *et al*., 2004. They used the probability of national climate related mortality from the CRED data-base as a proxy for risk and selected a set of 46 social, governance, economic and biophysical measures as indicators of social vulnerability. They found that 11 were effective indicators of mortality rates and these were confirmed as useful by a small focus group of seven adaptation experts. These experts also ranked the variables in terms of their perception of their usefulness leading to a total of 12 different rankings to which was added an equal ranked set to give 13 measures of vulnerability. Countries were then scored against these 13 rankings and the number of times a country appeared in the top quintile of countries in a particular ranking was used as an indicator of its overall vulnerability.

Perch-Nielsen (2010) developed an index to estimate the vulnerability of beach tourism using a systematic approach by establishing a framework to identify the types of measures needed and a systematic approach to identify measures that covered the range of countries and time scales. The derivation of the index from the separate measures was also subjected to robustness (sensitivity) testing to determine the most appropriate methods of scaling and combining the measures.

14.6.4. Assessment of Existing and Proposed Metrics for Adaptation

Srinivarsan and Prabhakar (2008) conducted a wide-ranging stakeholder survey to assess the attitudes to, and requirements for, indicators of adaptation. Stakeholders agreed that no single metric can capture the multiple dimensions of adaptation and that refinements of methodologies (e.g. rationale for index selection, aggregation methods, and data checking) are badly needed. Preston *et al*. (2009) has suggest that, rather than seeking particular metrics, researchers should focus on developing rigorous processes for selecting metrics that can be applied in a range of contexts.

But metrics for adaptation remain a necessity. Their derivation challenges the adaptation community to clarify its goals, conceptual models, definitions and applications. But as both theory and practice has shown indicators alone are not sufficient to guide decisions on which adaptation actions to take, on how to modify sustainable development activities, or on resource allocation. Downing (2003) noted that the climate change community was far from adopting common standards, paradigms or analytic language. This still appears to be true, making the search for commonly accepted metrics, even within well-specified contexts, a challenging task.

14.7. Addressing Maladaptation

The adaptation literature is replete with advice to avoid maladaptation, but it is less clear precisely what is included as "maladaptation". In a general sense it refers to cases where actions to improve the welfare of target groups may result in adverse climate-related outcomes or increased vulnerability to climate change to either the target community at a later date, or more immediately to other communities. For example, the construction of well engineering of roads to withstand current and future climate extremes may foster new settlement into areas highly exposed to the impacts of future climates; or increased water harvesting upstream to cope with erratic rainfall may harm and reduce the opportunities for communities downstream to manage their own risks. The AR5 defines maladaptive actions as "those that may lead to increased risk of adverse climate-related outcomes or increased vulnerability to climate change now or in the future". Actions that are potentially maladaptive need not be inadvertent as in the IPCC AR3 and AR4 definition, nor "taken ostensibly to avoid or reduce vulnerability to climate change" (Barnett and O'Neill 2010) as the actions may be assessed as appropriate given the full range of climate and non-climate considerations and pressures that apply. There should be clarity as to what is maladaptive action, or lack of action, lest the avoidance of maladaptation becomes a barrier to effective implementation of adaptation. In the road example above, the immediate and multiple benefits to the community of a reliable road system (including as evacuation route in floods etc.) might be judged as outweighing the longer-term risk of inappropriate settlement patterns. The true maladaptation in this case would be the failure to implement appropriate incentives or regulations to avoid settlement in the highly exposed areas.

The complexity of the concept and terminology is further demonstrated by the recent introduction by Thomsen et al. (2012) of the term "manipulation" that has some similarities to the concept of maladaptation. They see adaptation as "behaviors that are respectful of the intrinsic integrity of social-ecological systems and change is directed toward internal or self-regulating modification", whereas manipulation consists of behaviors that disregard this integrity and seek to override self-regulation. Their example is the management of Noosa beach in northern Australia. This coastline is characterized by cycles of erosion and depletion of beach sands, but rather than enhance the self-regulatory processes and adapting by managed retreat and expansion according to the cycle, management has sought to maintain a static beach profile through hard constructions and beach nourishment. This may seem synonymous with maladaptation, but they differ because with manipulation there is a decision not to adapt. Niemeyer et al. (2005) also describe the state of individual beliefs about climate change that might lead to adaptive, maladaptive or non-adaptive behaviors, while Eriksen et al. (2011) and Brown (2011) discuss avoiding outcomes that are essentially maladaptive under a title of 'sustainable adaptation'.

14.7.1. Causes of Maladaptation

Maladaptation arises in many forms but several broad causes can be identified. One is development policies and measures that deliver short-term benefits or economic gains but lead to greater vulnerability in the medium to long-term, such as the construction of 'hard' infrastructure that may reduce flexibility and the range of future adaptation options (Adger *et al*., 2003; Eriksen and Kelly, 2007, OECD**,** 2009), or the failure to encompass the full range of risks, such as the effects of increasing storm surge in the design of a coastal defense system (UNFCC, 2007d). Adaptation efforts aimed at armoring the coastline may result in coastal erosion elsewhere while building levees along a flood-prone area might encourage unwanted development within that area often accentuated by a false sense of safety (Grothmann and Patt, 2005; Repetto, 2009; National Research Council, 2007) and the levees may increase damage when they fail as in Bangladesh in 1999 and New Orleans in 2003 (IDS, 2006). Similarly, agricultural policies that promote the growing of a high yielding crop varieties through subsidies with the objective of boosting

production and increasing revenues may reduce agro-biodiversity and increase exposure and vulnerability of mono-crops to climate change and finally undermine the adaptive capacity of farmers (World Bank, 2010).

Another cause is the failure to account for multiple interactions and feedbacks between systems and sectors leading to inadequate or inaccurate information for developing adaptive responses and strategies that are maladaptive (Scheraga *et al*. 2003, Satterthwaite *et al*, 2009, Pittock, 2011). An assessment of the downstream impacts of upstream rainwater harvesting in a semi-arid basin in Southern India showed that, once the full range of externalities were accounted for, the net benefits were insufficient to pay back investment costs (Bouma *et al*., 2011). Similarly, the conversion of coastal mangroves into shrimp farms that may increase economic productivity, but also lead to increased vulnerability to flooding and storm surges (Klein, 2010).

14.7.2. Screening for Maladaptation

Five dimensions of maladaptation were identified by Barnett and O'Neill (2010) including actions that, relative to alternatives: (i) increase emissions of greenhouse gases; (ii) disproportionately burden the most vulnerable; (iii) have high opportunity costs; (iv) reduce incentives and capacity to adapt; and (v) set paths that limit future choices. These dimensions are useful pointers to the potential for maladaptation but their application tends to be subjective. The first assumes a fungibility between mitigation and vulnerability; the second turns on the interpretation of "disproportionately", and the third on "high" and on how opportunity costs are compared with current benefits. The dimensions were used by Barnett & O'Neill (2010) to describe maladaptive potential of the Wonthaggi desalinization plant to improve water supply to Melbourne, Australia. They conclude the plant will (i) increase GHG emissions (unless the promised wind power energy source is completed), (ii) lead to higher water costs that will disproportionally affect the poorer households; (iii) divert money and attention from more cost effective recycling and rainwater harvesting, (iv) reduce incentives to adapt through water conservation approaches, and (v) as a large sunk cost has locked out other options. The plant also affected significant cultural sites of the Bunurong Aboriginal community (Lee and Chung, 2007).

14.7.3. Experiences with Maladaptation

Maladaptation is a cause of increasing concern to adaptation planners, where intervention in one sector could increase vulnerability of another sector or increase the vulnerability of a group to future climate change. An example is the situation experienced by subsistence and smallholder agriculturalists in Palca, Bolivia who, in the face of stressors relating to land access, small holdings etc., moved away from their long established practices of diversification of crop varieties and planting locations to more intensive farming practices and cash cropping. They are now seeing evidence of climate change and the new practices make them more vulnerable to these changes leading to a risk of insufficient adaptation and maladaptation (McDowell and Hess, 2012). But there can also be tensions between development goals and climate change goals, where people may be aware of a climate related risk but are willing to take that risk (or they may have limited choice) given their current circumstances (IPCC SREX 2012, section 4.2.2).

Some studies warn against the simplistic use of maladaptation to communicate the state of high exposure to risks resulting from certain type of livelihoods. For example, the periodic movement of the nomadic pastoralists following the grass and water is a traditional and effective way of dealing with climate variability (Agrawal and Perrin, 2008), but is increasingly being described by some as maladaptive. More focused studies such as Young et al. (2009) put the breakdown of traditional pastoralism in the Sudan into the wider social and political context that led to restrictions on movement, asset stripping and escalating violence and undermined by policies not conducive to mobility.

14.7.4. Relationship between the Adaptation Deficit and Maladaptation

Adaptation deficit is a related but different concept from maladaptation and is defined as the gap between the current state of a system and a state that minimizes adverse impacts from existing climate conditions and variability. It can also be described as the inadequate adaptation to the current climate conditions (Burton *et al*., 2002; Burton, 2004; Parry, 2009; Chapter 17.xxx). The deficit may arise from past inaction, the mismanagement and depletion of natural resources, or maladaptive decisions in the past. The adaptation deficit may also result from a low level of development and the consequential reduced capacity to cope with climate variability. Thus, the adaptation deficit may be considered part of a larger 'development deficit' (World Bank, 2010). In the process of building future adaptive capacity it is important to reduce the current adaptation deficit along with designing effective risk management and climate change adaptation measures (Hallegatte *et al*., 2011).

14.8. Research Gaps and Data Gaps

[To be developed along with other chapters in next draft – a single section in a chosen chapter]

Frequently Asked Questions

FAQ 14.1: Are there different definitions of adaptation, and if so why, and are they important?

The most commonly used definitions of adaptation remain based on the IPCC AR3 (2001) definition ("adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities"), but with some important elaborations being introduced. The IPCC SREX (2012) and AR5 have modified the definition to deal separately with human and natural systems and included an element of purposefulness in human adaptation actions (i.e. "which seeks to moderate harm ...")[3]. Earlier IPCC Reports also defined the terms 'anticipatory', 'autonomous' and 'planned' adaptation, but the use of these terms in the IPCC and the literature has been inconsistent. The focus now is more on identifying terms in use in the UNFCCC negotiations such as 'concrete adaptation' measures [14.3.1] and incremental versus transformative adaptation [14.3.4].

Similarly, questions arise as to whether adaptation to climate change can, or should, be distinguished from normal development actions [15.x]. Adaptation and development are inextricably linked. Development that brings improvements in livelihoods, greater access to resources and more resilience to the wide variety of volatilities faced by household and communities, will usually also achieve adaptive outcomes. However, pursuing development priorities without looking ahead to a world with a changed climate could undermine development efforts either by failing to adjust to the possibility of changed climate [14.2; 15.x] or through actions that cut off options to deal with changed climates, i.e. maladaptation [14.6]. Increasing focus on the costs of adaptation and on evaluating adaptation practices has led to more attention to what constitutes *successful* adaptation. Some definitions of success emphasize reducing risks to a predetermined level while other focus on achieving predetermined levels of social and or economic well being [17.x].

[FOOTNOTE 3: IPCC AR5 definition of adaptation is "In human systems, the process of adjustment to actual or expected climate and its effects, which seeks to moderate harm or exploit beneficial opportunities. In natural systems, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate."]

Table 14-1: Categories and examples of adaptation needs.

Categories	Examples of needs
Institutional	Inadequate laws, policies, incentives, plans, and procedures, as well as a lack of informal norms, to promote and support adaptation.
Social	Public and private needs arising from social conditions, such as poverty, health status, ethnicity, and age that increase vulnerability and risks.
Biophysical and Environmental	Need for actors and actions to maintain or improve ecosystem health, ecological productivity, and agricultural productivity while also addressing increasing the vulnerabilities of peoples who depend on these ecosystem services.
Resource	Insufficient financial, human, technological, informational, and social resources required for planning and implementing adaptation.

Table 14-2: Categories and examples of adaptation options.

Category	Examples of Options
Structural/Concrete	
Engineered	Sea wall; Water storage; Improved drainage; Beach nourishment; Flood shelters
Technological	New crop & animal varieties; Efficient irrigation and water use; Hazard mapping and monitoring; Early warning systems; Home insulation
Ecosystem-based	Wetland re-establishment; Re-establish floodplains; Bushfire fuel-reduction actions
Services	Social safety nets; Food banks; Vaccination programs, Municipal services
Institutional	
Economic	Financial incentives; Insurance & other risk spreading
Laws and Regulations	Land zoning laws; Building standards; Easements
Government Policies and Programs	National & local adaptation plans; Urban upgrading programs; Municipal water conservation programs; Disaster planning and preparedness
Social	
Educational	Awareness raising; Extension services
Informational	Hazard mapping and monitoring; Early warning; Community support groups
Behavioral	Household preparation; Evacuation planning; Retreat and migration; Water conservation; Storm drain clearance.

Based on: Carmin et al, 2013.

Table 14-3: Considerations when selecting adaptation options.

- Minimizing cost
- Maximizing benefit
- Mainstreaming with goals, programs, activities
- Flexibility
- Safety margins
- Resource availability
- Potential for incremental implementation
- Equity
- Stakeholder input

Table14-4: Set of criteria for selection of indicators.

	Criterion	Explanation
Validity	Well-founded	Based on a tested theoretical framework
	Accurate	Really measuring what it should
	Non-ambiguous	Agreement on the direction of influence between the indicator and vulnerability
Use	Comprehensible	Relatively easy for users to understand
Type	Relevant	Applicable to many geographic and economic conditions
	Responsive to changes	Can be influenced by action
	High information content	No yes/no indicators, and preferably actual performance data instead of model-based data
Data	Available	Data that is publicly and easily available
	Homogenous and periodical data	Data that is collected homogeneously, making it suitable for international comparisons

Executive Summary

Adaptation planning is transitioning from a phase of awareness and promotion to the construction of concrete responses in societies (high agreement, robust evidence). [15.2] The combined efforts of a broad range of international organizations, scientific reports, and media coverage have raised the importance of adaptation to climate change. National-level plans and adaptation strategies for developed countries are dominated in the literature than for developing countries; whereas, more implementation cases are documented at the local level in developing countries. Attention to climate change impacts and disaster risk management, which are key elements of adaptation planning, appear to have a more prominent role in developed countries. In contrast, there is a trend to link adaptation planning to development needs and stresses in developing countries. This has had implications in terms of the resources and institutional needs to support adaptation planning and its implementation in developed and developing countries. Although the transition in adaptation planning represents a positive trend compared to the previous IPCC reports, it is not clear yet whether the observed adjustments and changes to perceived climate risks represent evidence of a societal shift towards a well-adapting society.

The social dimensions of adaptation have attracted more attention, including the relationship between adaptation, and development and disaster risk management (high agreement, robust evidence). [15.2.1] Climate change adaptation (CCA) takes place as a response to multiple stimuli, which highlights the need of connecting CCA with the development and disaster risk management (DRM). The importance of CCA is influenced by how the issue is framed, and to the extent that it is viewed as a public safety issue or a development issue, it may have greater resonance within national and local policies. Therefore, the linkages between adaptation, development

and DRM need to be more explicit targeting co-benefits among them. As knowledge of impacts and vulnerabilities solely is not sufficient to lead to the most effective and efficient adaptation policy decisions, due to the context specificity of adaptation, it is needed to build operational approaches of adaptation planning by recognizing the structural socio-economic conditions and agency of individuals and communities in low and middle-income countries.

The national level plays a key role in adaptation planning and implementation, while adaptation responses have diverse processes and outcomes at national, subnational and local levels (high agreement, high evidence). [15.2.2] National governments assume a coordinating role of adaptation actions in subnational and local levels of government, including the provision of information and policy frameworks, creating legal frameworks, actions to protect vulnerable groups, and financial support to other levels of government. Despite the embryonic state of the adaptation process, an assessment of the characteristics and effectiveness of the coordinating role of national adaptation strategies and plans is an urgent pending task. The number of adaptation responses has increased at the local level in developed and developing countries. However, there is a common trend that local governments are hindered by the absence of applicable guides to adaptation decision-making. Local councils and planners are often confronted by the complexity of adaptation, and even when information is available, they are left with a portfolio of options to prepare for future climatic changes and the potential unanticipated consequences of their decisions. Therefore, linkages with national and subnational levels of government, as well as the collaboration and participation of a broad range of stakeholders are important.

Adaptation efforts in some developing countries provide a 'win-win' adaptation strategy that strengthens resilience to climate change while improving economic stability and environmental quality. (high agreement, medium evidence). [15.3.1] Climate change adaptation efforts also improve ecosystem resilience by implementing sustainable forestry quotas, expanding floodplain setbacks, implementing coastal afforestation, coral reef propagation, restoring degraded lands, maintaining healthy vegetation on slopes, incentivizing development away from coastal areas and bluffs, and removing barriers to the migration of plants and animals. These linked approaches highlight the need for greater emphasis on nature-based protection strategies or buffers. Low cost behavioral actions can provide benefits within a short time.

There are many strategies and approaches to climate change adaptation, which include decreasing vulnerability, increasing resilience, increasing adaptive capacity, and/or decreasing the risk of impacts (high agreement, high evidence). [15.2.3] Decreasing risk, especially for developed countries, has been planned by a top-down approach including engineered infrastructure-based solutions such as dikes to prevent flooding and coastal inundation and dams to improve water supplies. Strategies adopted in developing countries, e.g., those in NAPAs, are almost identical with standard development projects. Bottom-up approaches are particularly useful in efforts seeking to reduce social vulnerability and addressing adaptation to climate change as a process. However, adaptation to climate change also requires complementary top-down strategies through different levels of governments to realize mainstreaming adaptation. Adaptation planning also highlights the importance of intergovernmental and multidisciplinary approaches integrating science and planning.

A no-regrets co-benefits approach of improving resilience through an emphasis on disaster risk reduction has become increasingly common. (high agreement, medium evidence). [15.2.3.2,] Disaster risk reduction (DRR) includes managing hazards from extreme weather events and helps communities to deal with the uncertainty of climate change. Climate change adaptation and disaster risk reduction are within separate agencies, although they share similar objectives and challenges, and there must be an effort towards better coordination. On the other hand, disaster risk management strategies by themselves often fail to account for a wide spectrum of threats and scales needed for climate change adaptation. The root causes of climate change vulnerability cannot be addressed through risk management alone. Due to the uncertainty, dynamic complexity, and short to long timeframes associated with climate change, robust adaptation efforts require iterative risk management strategies.

A variety of tools are being employed in adaptation planning and implementation depending on social and management context (high agreement, robust evidence). [15.2.4] Uncertainties in climate change coupled with the complexities of social-ecological systems requires adaptation planning and implementation are dynamic. Information and knowledge on climate change risks from various stakeholders and organizations are essential

resources for making adaptation planning. Multidisciplinary efforts have been engaged to develop, assess and communicate climate information and risk assessments across timescales. These efforts use a mixed portfolio of products from simple agroclimate calendars to computerized decision-support tools. Although a wide range of adaptations are possible with current technologies and management practices, development and diffusion of technologies can expand the range of adaptation possibilities by expanding opportunities or reducing costs. The status quo generally requires no new capital costs and may be more profitable in the short term than developing more climate-resilient technologies. Monitoring and early warning systems play an important role in helping to adjust adaptation implementation, especially on the local scale.

Adaptation planning and implementation is considered as a social learning process to formulate efficient plans, which allows periodical adjustments in order to reduce the uncertainty of the impacts of climate change and societal needs to cope with them (high agreement, medium evidence). [15.3.3] Social learning is a relevant but under-investigated feature of planning and a critical part in the innovations for adaptation. Understanding of why and how learning takes place is needed to improve the impact and efficiency of the plan, improve the transferability of best practices, increase public support, and translate the learning into new plans. Monitoring and evaluation are two important learning tools in promoting this process. Although the importance of evaluation in adaptation is recognized, this topic is under-researched and requires significant work.

Adaptation governance plays a key role to promote the transition from planning to implementation of adaptation. (high agreement, medium evidence). [15.4] The role of governance is highlighted in building adaptive capacity to climate change, providing the connections between individuals, communities, organizations, agencies, and institutions at multiple levels and in articulating top-down or bottom-up perspectives. As a multidimensional issue involving many state and non-state actors functioning on varying scales of global, national and local levels, a coordination of roles and responsibilities enhances institutional networking for effective implementation of climate change adaptation. Multilevel governance offers the chance to identify options for switching from reactive to proactive adaptation processes which are essential in safeguarding investments and infrastructures especially in urban adaptation. The creation of larger governance networks through coordination is reported to expand the adaptive capacity of local actors, as well as enhancing learning opportunities for policy formulations.

15.1. Introduction

As impacts of climate change have become apparent around the world, adaptation has attracted increasing attention. The impacts are expected to be particularly severe in the developing world and among marginalized communities because their adaptive capacity is limited. Until the mid-1990s, research on climate change focused almost exclusively on understanding of climate system dynamics and modeling of future climate. More recently, several programmes have been developed that give more prominence to studies of vulnerability and adaptive capacity and associated adaptation options, measures and strategies, including local, regional, and sectoral studies.

Chapter 17 of the IPCC Fourth Assessment Report (AR4) (Adger et al., 2007) presented the following major findings on adaptation practice:

- Adaptation to climate change is already taking place, but on a limited basis.
- Adaptation measures are seldom undertaken in response to climate change alone.
- Many adaptations can be implemented at low cost, but comprehensive estimates of adaptation costs and benefits are currently lacking.
- Adaptive capacity is uneven across and within societies.
- There are substantial limits and barriers to adaptation

There are many definitions and characteristics of adaptation strategies and varieties of implementation (Carter et al., 1994; Burton et al., 2005, Biesbroek et al., 2010). For the purpose of this chapter, adaptation strategies in general are defined as a general plan of action for addressing the impacts of climate change, including climate variability and extremes. It will include a mix of policies and measures with the overarching objective of reducing the country's vulnerability. This chapter will review the literature on climate change adaptation to assess the progress and limitations of adaptation planning and implementation. As the Fifth Assessment Report of the IPCC Working Group

II has four inter-related chapters for adaptation, this chapter focuses on the assessment of cases at different levels, from international to local in various sectors to assess:

- The resent status of climate change adaptation planning and implementation across the globe. The practices of adaptation planning and implementation have extended from international and national to local levels, and different sectors (e.g., disaster risk reduction, water resource planning, agriculture, urban planning) treat adaptation within their traditional context of planning to various degrees.
- Characteristics of adaptation in different settings. Adaptation planning characterizes decision-making under the uncertainty of climate change projections, other climatic factors, as well as societal changes in the long term. Countries take different strategies and approaches such as low-regret policy, climate proofing approach, science-driven and community-based approaches. Flexible and adaptive approaches are also emphasized. To understand the characteristics of the strategies and approaches to adaptation is also a challenge of this chapter.
- Barriers and opportunities for adaptation. It has been indicated that there are substantial limits and barriers to perform adaptation planning and implementation whereas the opportunities are also recognized. This chapter tries to identify the barriers to and opportunities for adaptation in developing and developed countries.
- Capacities for adaptation and how are they built? Capacities for adaptation planning and implementation are wide including institutional and financial abilities, capacities to access and use scientific information, technologies, decision-making measures, human resources and social awareness.
- Governance of adaptation. As adaptation has a wide range of stakeholders, its success or failure depends on governance, which is quite complicated because of many reasons. How climate change adaptation is being coordinated across different levels of governance is a key question regarding this subject.

Following national and region-specific syntheses (Biesbroek et al., 2010; Bierbaum et al., 2013), the Chapter highlights factors motivating and facilitating the development of adaptation strategies; the scientific and technical information, support and collaborative mechanisms being used for the development and implementation; promotion of climate change awareness and strategies through communication; present and evolving forms of multi-level governance and responsibilities to implement the proposed actions, mechanisms and arrangements for incorporating adaptation into integrated management and sectoral actions; and how the strategies and their implementation are being evaluated.

Figure 15-1 shows a general cycle of adaptation and the environment it occurs. It has major components of adaptation planning and implementation and this chapter will discuss them in the following sections.

[INSERT FIGURE 15-1 HERE
Figure 15-1: Four main phases of adaptation planning and implementation: needs, planning, implementation, and evaluation. This is a cyclic, iterative process. Building capacity to respond to change, whether expected or unexpected, creates resilience in societies to cope in the face of uncertainties in climate change projections. Efforts in adaptation need to be linked with development or disaster risk management. This is particularly true and important in developing countries. Adaptation governance underlies the capacity and governance takes place at multiple scales: international, national, sub-national, and local.]

15.2. Status of Adaptation Planning and Implementation

The combined efforts of a broad range of international organizations, scientific reports, and media coverage have raised the importance of adaptation to climate change. These efforts have fostered a growing number of adaptation responses in developed and developing countries. The assessment of literature indicates adaptation planning is transitioning from a phase of awareness and promotion to the development and construction of adaptation responses. This transition represents a positive trend compared to earlier IPCC reports, it is not clear yet how effective these responses currently are and will be in the future. Despite the current dynamics of adaptation planning, there are still limited evidence of its implementation that is readily identifiable from development and disaster risk reduction plans.

The review of the international literature identifies a high heterogeneity of adaptation planning. The heterogeneity is related to the context specific nature of adaptation, but also to the differences in resources, values, needs, and perceptions among and within societies. The diversity of adaptation strategies, plans and actions at the national, subnational, and local level indicates differences in approaches between developed and developing countries. Although attention to climate change impacts and disaster risk management are key elements of adaptation planning, they appear to have a more prominent role in developed countries. In contrast, the literature reflects a trend to link adaptation planning to development needs and stresses in developing countries. This has had implications in terms of the resources and institutional needs to support adaptation planning and its implementation in developed and developing countries.

Although more attention is being paid to the institutional dimension of adaptation, it remains an underdeveloped area. Embryonic discussions of the transformations needed in the structure and operational culture of institutions to address adaptation to climate change are occurring in both developed and developing countries. Researchers have been reporting on the limitations of current institutional arrangements to support the implementation process of adaptation, critically so at the local level. Other unintended consequences include the difficulty to mainstream adaptation planning and delays in its implementation as a result of the mismatch of organizations and responsibilities.

Central to this discussion and one of the critical aspects identified in the review of the international literature is the trend to consider adaptation planning as a problem-free process capable of delivering positive outcomes. There is the risk of underestimating the complexity of adaptation planning as a social process. This can lead to creating unrealistic expectations in societies, and overestimating the capacity of planning to deliver the intended outcome of preparing societies to adapt to the negative impacts of climate change. This highlights the importance of monitoring, evaluating and reviewing adaptation planning and implementation.

15.2.1. Responding to Present and Future Climate Impacts

The international literature reports the dynamic creation of plans, strategies, legislation and projects at national, subnational, and local levels (Bulkeley, 2006; Biesbroek, 2009; Romero-Lankao and Dodman, 2011). The number of adaptation plans and strategies has grown at the national and subnational level in high-income countries, but at a lower pace in low and middle-income countries. Berrang-Ford et al. (2011) document a sharp increase in the peer-reviewed literature addressing adaptation to climate change (1741 articles published between 2006 and 2009). Preston et al. (2009) identify at least 62 different adaptation plans publicly released in the United States, Canada, United Kingdom and Australia, and they expected that number would double by the end of 2009. Tompkins et al. (2010) document over 300 adaptation actions in the UK in 2005. The non-peer reviewed literature reports a dynamic growth of adaptation plans and strategies at the national, subnational, and local level. A significant number of those publications are descriptive and provide limited information on the progress made so far in adaptation planning and its implementation.

The international literature has begun to pay attention to the need for improving the understanding of adaptation processes. Berrang-Ford et al. (2011) highlights the limited understanding of these processes and how adaptation planning is actually taking place. The majority of studies on adaptation to climate change report on the assessment of potential vulnerability of the social and natural systems to the negative impacts of climate change. They note that most publications describe an intention to act rather than concrete adaptation actions. In a review of adaptation articles in the journal Climatic Change Arnell (2010) as well concludes that very few published examples of case studies of how adaptation to climate change is actually being delivered, or on the barriers that will influence how adaptation takes place. Tompkins et al. (2010) question whether the observed adjustments and changes to perceived climate risks represent evidence of a societal shift towards a well-adapting society, or are merely unconnected actions of individuals motivated by different stimuli. Other studies report little research has been carried out on climate change adaptation actions to date as distinguished from determinants of adaptation capacity (National Research Council, 2011).

Some literature has focused on the social dimension of adaptation and adaptation planning. Orlove (2009), Ribot (2010), Boyd and Juhola, (2009) and others observe that adaptation analysis and many recommended measures tend to focus on the physical hazards rather on than on the underlying stressors creating them thus neglecting the drivers of vulnerability, and thus, limiting the effectiveness for interventions. Hardee and Mutunga (2010), Lemos et al. (2007), and Sietza et al. (2011) indicate that the disproportionate focus on the impacts of climate change could obscure opportunities for connecting development pressures, poverty, social inequality and climate change, particularly for the reduction of social vulnerability. Hulme et al. (2009), Barnett and Campbell (2009) suggest knowledge of impacts and vulnerabilities does not necessarily lead to the most cost-effective and efficient adaptation policy decisions, partly due to the context specificity of adaptation. Thus Sanchez-Rodriguez (2012) highlights the need to build operational approaches of adaptation planning by recognizing the structural socio-economic conditions and agency of individuals and communities in low and middle-income countries. These studies follow on decades of research and practice in the disaster risk reduction field (Blaikie et al., 1997; IPCC, 2012) and shows positive examples of the adaptation research community beginning to learn from other long-standing disciplines.

Attention to the social dimensions of adaptation, including rates of change in social conditions, in part of the international literature coincides with the interest of international organization and scholars in the relationship between adaptation and development. The literature supports the long-standing contention that adaptation takes place as a response to multiple stimuli - not just climate (IPCC, 2007; Tompkins et al., 2010). The importance of climate adaptation is also influenced by how the issue is framed. For example, to the extent that it is viewed as a public safety issue or a development issue, it may have greater resonance within local government (Measham et al., 2010). Other authors consider integrating local knowledge and experience, including households, into multidimensional and multi-scale approaches to guide the construction of adaptation responses to climate change, and integrate them with development strategies (Ewing et al., 2008; Moser and Satterthwaite, 2008; Hodson and Marvin, 2009). Stringer et al. (2009) consider that the linkages between adaptation and development should be made more explicit. Dovers (2009) stresses the need of connecting climate adaptation more closely to existing policy and existing agendas, knowledge, risks, and issues communities already face.

Important steps for mainstreaming adaptation have been identified but the challenges remain in their operationalization within the current structures or operational cultures of national, subnational and local agencies. Multilateral Development Agencies encourage efforts in this direction through a number of guidelines, publication and development assistance (UNDP, 2005; USAID, 2007; OECD, 2009; UNEP, 2010; World Bank, 2010; UN-HABITAT, 2011). Central to these efforts is the role of planning that connects adaptation and development needs and challenges (Blanco and Alberti, 2009; Dovers, 2009; Juhola and Westerhoff, 2011). Urban, regional, and development planning have struggled to create interdisciplinary perspectives to address the multidimensional reality they seek to modify. This issue will be addressed in more detail in section 15.3.1.2 within the context of institutional arrangements.

15.2.2. International, National, and Local Assessment

15.2.2.1. International Mechanisms for Supporting Adaptation Planning

There has been a large growth of adaptation planning initiatives at the international, national, subnational, and local level since the last IPCC report (UK, Germany, Australia, Canada, the Caribbean among others). The assessment of the literature illustrates a diversity of approaches that have evolved in adaptation planning across and within countries, the challenges to create multilevel governance to support dynamic adaptation planning and implementation, the central role of climate change impacts and risk management in adaptation strategies and plans, and different perceptions, resources, and approaches in these strategies and plans between developed and developing countries. Many of these adaptation initiatives are at an embryonic state and it is difficult to extract conclusions of their effectiveness, efficiency, and equity at this point. The dynamic pace of the creation of adaptation strategies and plans stresses the importance of monitoring and evaluation. While the Adaptation Fund and Pilot Program in Climate Resilience have outlined monitoring and evaluation criteria, little is found in the literature to support effective and sustained implementation of these two dimensions (Adger et al., 2009b; Preston et al., 2009; Tompkins et al., 2010; Wolf et al., 2010).

15.2.2.1. International Mechanisms for Supporting Adaptation Planning

International mechanisms for supporting regional adaptation planning are an important resource for the creation of adaptation responses. The directives and initiatives of the European Commission (EC) have fostered the creation of a significant number of National Adaptation Strategies and Plans in EU member countries since the last IPCC report. Adaptation planning responses at the local level have also multiplied in these countries in response to these directives. Other relevant regional initiatives are the South Pacific Regional Environmental Programme (SPREP) supported by a number of international agencies, and in the Caribbean through the Caribbean Catastrophic Risk Insurance Facility (Pulwarty et al., 2010).

The international literature reports a growing number of mechanisms developed by Multilateral Development Organizations, development cooperation agencies from Developed countries (UK, USA, Canada, Sweden, Denmark, Norway, Japan, Spain, the Netherlands among others), United Nations programs (UNDP, UNEP, UN-HABITAT, WMO, FAO and other agencies), and International Non-Governmental Organizations (OXFAM, CARE, IFRC, ICLEI and others). These organizations focus on their particular geographic and thematic areas of interest. An example in the case of development agencies is the collaboration between the UK and Canada (IDFG and IDRC) to create the Climate Change Adaptation in Africa (CCAA). This initiative supported 46 projects mostly in rural areas of several countries. The initiative focused on three areas: participatory action research, communication and networking, and networking education and training. Development agencies have also supported adaptation planning in a number of developing countries in Africa, Asia, and Latin America, the South Pacific, and the Caribbean.

Multilateral Development Agencies (MDA) have developed mechanisms to mainstream climate change in their project planning. They have created guidelines and provided support for adaptation planning in developing countries. Some MDA focus on guidelines for the creation of adaptation projects (USAID, 2007), other highlights the importance of integrating adaptation planning with development co-operation (OECD, 2009). The World Bank has led the systematic examination or 'portfolio screening', of its set of policies, programs or projects, with the aim of identifying how concerns about climate change can be combined with an agency's development priorities, such as poverty reduction, institutional development and capacity building (Klein et al., 2007; World Bank, 2010).

The United Nations Development Programme (UNDP) has a broad range of mechanisms supporting adaptation planning, including guidelines (UNDP, 2005), information resources, support to national adaptation planning, and as an implementation organization in some of the early projects approved by the Adaptation Fund. Together with the United Nations of Environmental Programme (UNEP) provide support to Sub-Sahara countries in Africa through the Climate Change Development Initiative (CCDARE). Other UN agencies have created information mechanisms supporting adaptation planning. Particularly relevant are the activities United Nations Framework Convention on Climate Change for least developing countries through the National Adaptation Programmes of Action (NAPAs) and for less developed countries through the National Adaptation Plans (NAPs) discussed in the next section.

Relevant funding mechanisms are associated with the Global Environmental Facility (GEF) adaptation funds (LDCF and SCCF), support for the Pilot Program for Climate Resilience (PPCR), and special purpose adaptation funds for UN Agencies. The Adaptation Fund (AF) set up under the Kyoto Protocol is of particular importance to developing countries as it is pioneering the direct access mechanisms, which allows countries to access funds without having to work through a multi-lateral development agency. The AF indicators suggest a focus on addressing the adaptation deficit and climate -proofing development for incremental changes in existing risks while the PPCR framework has a stronger focus on the mechanisms through which adaptation is integrated into development planning and practice.

International non-governmental organizations has growing presence fostering adaptation planning in developing countries. Large organizations have created diverse mechanisms to support adaptation at the local level. For example, Oxfam America has developed a risk management framework with enable poor farmers in Ethiopia to strengthen their food and income security through a combination of improved resource management (risk reduction), microcredit ("smart" risk taking), risk transfer (insurance), and risk reserves (savings). Oxfam has also published guidelines to support local adaptation planning (Crane, 2013). The International Federation of Red Cross (IFRC)

have extensive mechanisms focusing on disaster risk management and vulnerability reduction and its integration with climate change adaptation (IFRC, 2009; Braman et al., 2010). CARE has also extensive mechanisms addressing climate change adaptation and community resilience (Action Aid, CARE, WWF, 2012). It is worth mentioning a number of other International NGOs have created mechanisms to support adaptation planning at the local level in developed countries (ICLEI, 2008; Pew Center, 2009).

Information centers have also arisen with guidelines, information, case studies, and other support tools to facilitate adaptation planning by MDA, UN agencies, and international NGOs. Some of these center are: IFRC's Climate Center, CARE's Climate Change information Center, World Bank Adapt, UNDP Adaptation Learning Mechanism, and weAdapt of the Stockholm Environmental Institute.

The fast growth of international mechanisms for supporting adaptation planning has assisted the creation of adaptation strategies, plans, and actions at the national, subnational and local level. The international literature documents a growing number of projects sponsored through these mechanisms. Their monitoring and evaluation can help sponsoring organizations, stakeholders, and government agencies to extract learning lessons to increase and improve the efficiency of adaptation planning and implementation. It is worth noting that so far little attention has been provided to critical reflections during the adaptation process.

15.2.2.2. National Adaptation Plans

The IPCC Fourth Assessment Report documented the international recognition of the importance of adaptation to climate change. This is reflected in the growing number of national governments creating national adaptation strategies, policies, and plans. The international literature illustrates the diversity of approaches used in these national initiatives, from National Adaptation Programmes for Action (NAPAs) in least developed countries targeting key sectors (Ciplet at el., *in press*), to the efforts to create national holistic plans in response to regional directives in some European countries (Biesbroek et al., 2009, 2010). The NAPA focus on existing coping strategies and actions at the grassroots level in Least Developed Countries (LDCs) , and build upon that to identify priority activities, recognizing that local communities are the main stakeholders. At the same time, the movement to introduce climate change adaptation policies into national policies has accelerated in the developed countries as well. National adaptation initiatives and their heterogeneity reflect the idiosyncrasies of the domestic political structures, socio-economic conditions, values and perceptions, and development stresses and opportunities.

The analysis of the international literature identifies national governments assume a coordinating role of adaptation actions in subnational and local levels of government. Early evidences suggest that some of the coordination roles of national governments include: the provision of information of potential impacts risks to strengthen actions of state and local governments, providing policy frameworks to guide decisions at subnational level, driving and coordinating the creation of legal frameworks, direct action in case of sectors and resources key for national development (agriculture, fisheries, health, ecosystem protection, among others), actions to protect vulnerable groups, and financial support to other levels of government. In some cases, national governments are key actors securing international funding for subnational and local levels of government. Despite the embryonic state of the adaptation process, an assessment of the characteristics and effectiveness of the coordinating role of national adaptation strategies and plans is an urgent pending task.

National adaptation is an evolving process. Thirteen European countries have created National Adaptation Strategies—Austria, Belgium, Denmark, Finland, France, Germany, Hungary, the Netherlands, Norway, Portugal, Sweden, Spain, United Kingdom (only two of them were created before the last IPCC report, Finland and Spain) (Prutsch et al., 2010). Some of these strategies have evolved to a National Adaptation Plan (France, Germany, UK). While these may represent a new political commitment to adaptation at national political levels (Biesbroek et al., 2010) , many institutional challenges and barriers to future policy implementation remain. Many projects do not have defined an implementation agency (Swart et al., 2003). Australia's federal government has invested in research through CSIRO Climate Adaptation National Research Flagship and the National Adaptation Research Facility and supports local government's climate change adaptation role (Local Adaptation Pathways Program). However, a governance system integrating adaptation planning across all levels of government is still pending (Doran, 2011).

Some countries recognize the learning process of adaptation and have programmed the evaluation of their national adaptation strategies and plans (UK, Germany, Australia among others). The federal government in Mexico has taken steps to update its National Adaptation Strategy from 2007 (Gobierno Federal, 2012). Although these steps update and upgrades adaptation planning, there remain obstacles for their implementation. Within the U.S., as in other areas, although substantial adaptation planning is occurring in various sectors, levels of government, and the private sector, few measures have as yet to be implemented and fewer have been evaluated (Bierbaum et al., 2013).

The experience resonates with the perspective that most strategies can be regarded as just the start of a policy process rather than its culmination emphasizes the importance of considering evaluation planning and its implementation a learning process (Hulme et al., 2009; Biesbroek et al., 2011; Pulwarty et al., 2012).

Institutional obstacles affect differently the coordinating roles of national adaptation strategies and plans. Particularly affected are the creation of policy frameworks to guide decisions at subnational and local level and the integration of adaptation in sectorial policies. Evidence of this problem begins to be addressed in some studies. The ADAM project in Europe considers most barriers to actual adaptation to be related to policy co-ordination and implementation (Hulme et al., 2009). Particularly challenging is multi-level coordination within with other levels of government and between the government and other sectors in society. Multi-level governance is a challenge in developed and developing countries (Storbjork, 2007; Unwin and Jordan, 2008; Gupta et al., 2010; Gero et al., 2012; Rodima-Taylor et al., 2012). Early identification of these barriers and actions to address them are part of the pending task in national adaptation strategies and plans. Governance structures have seldom efficient multi-level practices despite decades of development planning. This remains a major obstacle to achieve efficient adaptation planning and implementation. Sections 15.3.1.1 and 15.3.1.2 address this issue further.

National Adaptation Programmes of Action (NAPAs)

National adaptation responses have a particular condition in the case of the Least Developed Countries through the experience of UNFCCC's NAPAs (National Adaptation Programmes of Action). Established in 2001, NAPA is an organized planning process for adaptation sponsored by the United Nations Framework Convention for Climate Change (UNFCCC) (Ciplet *et al*., in press). As of November 2010, the UNFCCC Secretariat received forty-seven NAPAs.

The international literature stresses the reliance on this program (Agrawal, 2008; Agrawal and Perrin, 2008; Stringer et al., 2009). The NAPAs have emphasized the connecting local level adaptation and development. More than 50% of the projects under this program are concentrated in three key sectors for development and livelihoods: food security, terrestrial ecosystems and water resources. One study of NAPAs in four African countries illustrates that they are attracting the support of a greater range of actors but linkages between development and adaptation need to be made more explicit (Stringer et al., 2009).. They find the enthusiasm for broader participation in the rhetoric of international politics does not yet match the realities of its enactment on the ground. Another study identified only 20% of projects described in the NAPA documents that incorporate local institutions as the focus of adaptation projects and identified even fewer that incorporate local institutions as agents or partners in facilitating adaptation. The researchers, Agrawal and Perrin (2008) suggest that projects tend to build the capacity of national governments and agencies rather than local actors and local institutions still seems to be valid. Other authors document financial difficulties in NAPA projects leading to cumulative delays and the outdatedness of many of the needs first assessed (Ciplet at el., *in press*). Sustained monitoring , evaluation and feedback to learning of the NAPAs process are needed to help these countries transcend from a project by project basis to an adaptation process within the context of domestic and local development efforts.

15.2.2.3. Sub-National Adaptation Plans

The international literature has paid less attention to adaptation planning and implementation at the subnational level. There are major differences on the role subnational governments play in the governance structure of countries, from those with strong concentration of political and economic power to a very minor role in governance and decision-

making. The role of subnational governments in adaptation planning reflects the governance structure of each country.

The review of the international literature identifies subnational governments have often a complementary role to national governments in adaptation planning according to the governance structure in each country (Moser, 2005; West and Gawith, 2005; Lemmen et al., 2008; Pew Centre, 2009; USGCRP, 2009). Although the development of adaptation governance has not created guiding frameworks for subnational governments in most countries, the literature reflects an active participation of states and provinces in some countries. For instance, Gero et al. (2012) report all states and territories in Australia have begun creating or amending laws, policies, and action plans to account for climate change adaptation. The provincial governments in Canada have also an active role in the creation of adaptation planning. 24 out of 32 states in Mexico have created Climate Action Plans in the last 6 years with technical support from the federal government of Mexico and some financial support from international sources (Gobierno Federal, 2012). A growing number of states have created also climate actions plans that include adaptation actions in the United States.

In addition to state by state efforts, supra-state organizations are also recognizing, supporting, and fostering attention on adaptation, though concrete action to date is limited (Pew Centre, 2009). In some instances, states are collaborating on sector specific issues that concern them regionally (Bierbaum et al., 2013). For example, in the American West, water managers are collaborating and sharing information regionally (Brekke et al., 2009; Barsugli et al., 2012). Similarly, in the Great Lakes region, Midwestern states and Canadian provinces have expressed concern over the impact of climate change on their joint water basin (though concrete adaptive management actions have not yet been specified) (Dinse et al., 2009). Canada's Regional Adaptation Collaborative Program is also an example of regional collaboration of subnational governments. Further examples have appeared also across borders (for example, the Western Climate Initiative that includes 7 states in the U.S. and 4 provinces in Canada). Regional adaptation plans have also been created in European countries such as the Climate Change Adaptation Plan in East England (Staples, 2011). The embryonic state of these regional collaborations does not allow drawing conclusion of their operation and outcomes for this report. However, it is a process worth monitoring during the coming years.

15.2.2.4. Local Adaptation Plans

The international literature shows a significant increase in the number of planned adaptation responses at the local level in rural and urban communities of developed and developing countries since the last IPCC report. Climate adaptation is context dependent and it is uniquely linked to location, making it predominantly a local government and community level of action. However, limited economic, human, technical resources at the local level highlight the importance of national and subnational levels of government, as well as the collaboration and participation of a broad range of stakeholders. Despite the obligation to act, local governments are hindered by the absence of applicable guides to adaptation decision-making, especially adaptation to extreme events (Corfee-Morlot et al., 2009; Glaas et al., 2010; Gero et al., 2012). Local councils and planners are often confronted by the complexity of adaptation without adequate access to guiding information, data on local vulnerability and the potential impacts of climate change. Even when information is available, they are left with a portfolio of options to prepare for future climatic changes but without effective guidance on decision-making and the potential unanticipated consequences of those decisions (Mathew et al., 2012).

The central role of local governments addressing the challenges of adaptation planning and implementation is reflected in the literature (Blanco and Alberti, 2009; Sanchez-Rodriguez, 2009; Rosenzweig and Solecki, 2010; Simon, 2010; Matthews, 2012;), but scholars stress also the importance of partnerships between public, civic, and private in the adaptation process (Agrawal, 2010; Tompkins and Ealkin, 2012). The complexity and uniqueness of each locality is often not recognized by policy planners because of the lack of understanding and consultation with the local community (Geiser and Rist, 2009; Ribot, 2010). Inclusive and participatory approaches in adaptation planning are encouraged by international organizations (UNDP, 2005, 2010; World Bank, 2010; UN-HABITAT, 2011) and scholars (Moser, 2008; Moser and Satterthwaite, 2008).

15.2.2.4.1. Rural and community adaptation planning

Community-based adaptation, an example of local level planning and implementation, is a course of action that allows local stakeholders to bring skills and knowledge into the planning process. Because climate change impacts occur locally, the scale of community engagement and the approaches used have been critical to the success or failure of adaptation programs where they occur (Picketts et al., 2012).

Ford et al. (2011) examined adaptation plans that were implemented in developed nations from 2006 to 2009, and found that stakeholder participation was commonly mentioned as part of the planning process. Patt and Schröter (2008) document barriers to implementing climate change adaptation strategies in Mozambique that resulted from differing perceptions of climate risk between farmers and policy makers, and the perceived potential for negative consequences of the proposed adaptation plans. These studies suggest that without broader stakeholder agreement at the local level, successful implementation of adaptation is not possible. However, in other case studies of community-based participatory adaptation projects, local farmers such as those in Sri Lanka needed no additional incentives to participate in adaptation programs that they recognized as an opportunity to improve their harvests and income. The creation of community organizations can provide an avenue for local participation, and provides a mechanism that helps to sustain adaptation efforts. Community-based adaptation in Bangladesh has included participatory action plan development, an approach that combines consensus-building and participatory rural appraisal. The needs, skills and assets of the communities were assessed by conducting household surveys and consultation meetings (Ensor and Berger, 2009).

Indigenous and rural peoples, however, are not only potential victims of climate change. Attentiveness to environmental variability, shifts and trends is an integral part of their ways of life. Community-based and local knowledge continue to offer valuable insights into environmental change due to climate change, and complement broader-scale scientific research with local precision and nuance. Indigenous societies have elaborated coping strategies to deal with unstable environments, and in some cases, are already actively adapting to early climate change impacts (Nakashima et al., 2012). Indigenous Arctic communities are providing systematic observations of climate change impacts, which complement scientific data and frame local efforts to adapt.

Other authors have studied the role of the business community in adaptation planning. Howe (2011) notes the adaptive capacity of businesses vary with the types of business, location, and socio-cognitive characteristics of business owners. Other perspectives (Berkholt et al., 2006; Tompkins et al., 2010) suggest that market forces are unlikely by themselves to lead to efficient adaptation requiring public ploicy interventions. Other studies suggest business responses can be motivated by other forces. For example, the study of climate adaptation in the UK mentioned above found that responses to regulation, industry standards such as ISO14001, and corporate social responsibility obligations have at least as great an influence on adaptive behavior in the business community as direct climate-related risks and can produce public benefits (Tompkins et al., 2010)

15.2.2.4.2. Urban areas

A growing number of urban areas have created disaster management plans at the local level, often in response to climate-related disasters (OECD, 2010; Dodman, 2012; EEA, 2012). Few of these plans have incorporated climate change adaptation so far. The peer and non-peer reviewed literature reports a growing number of adaptation plans at the local level. Urban areas are the locus of a number of those planning initiatives (Roberts, 2008; Blanco and Alberti, 2009; Hamin and Gurran, 2009; Lowe et al., 2009; Parzen, 2009; Sanchez-Rodriguez, 2009; Corfee et al., 2010; Rosenzweig and Solecki, 2010; Rosenzweig et al., 2011; Matthews, 2012; New York, 2012; ; Rotterdam, 2012). This includes special issues in some academic journals (for example, papers included in the special issue Habitat International vol. 33, 2009 and Current Opinion in Environmental Sustainability vol. 2, 2010 and vol. 3, 2011). The non-peer reviewed literature also documents a growing number of adaptation plans to climate change in large cities (New York (2012), Chicago (2012), London (2010), Toronto (2008), Mexico City (2008), Sao Paulo, Rotterdam (2012)), but increasingly in medium-size cities (King County in Washington State, Santa Cruz in the US, Cartagena in Colombia (2005), Durban (2012) and Cape Town in South Africa (2006)) (note that this list of urban

areas is intended for illustrative purposes). The experiences in these cities provide early lessons potentially useful to other cities.

Chapter 8 discuses in detail the impacts, vulnerability and adaptation of climate change in urban areas. A review of the literature allow identification of the difference in the adaptive plans of urban areas (Romero-Lankao and Dodman, 2011; Rosenzweig et al., 2011; Carmin et al., 2012). These differences are particularly evident between urban areas in developed and in developing countries and they reflect diverse conditions, resources, perceptions, and governance structures among cities (Agrawala and van Aalst, 2008; Ayers, 2008; Bartlett, 2008; Caney, 2008; Moser and Satterthwaite, 2008; Revi, 2008; Roberts, 2008; Simon, 2010; Stren, 2008; Tanner et al., 2008; Hardoy and Pandiella, 2009; O'Demsey, 2009; Hardoy and Romero-Lankao, 2011;). The literature suggests that responding to current climate extremes and potential future impacts of climate change are primary determinants in the creation of adaptation plans (Rosenzweig and Solecki, 2010; Rosenzweig et al., 2011; Carmin et al., 2012). For instance, adaptation plans in London, Toronto, New York City, Chicago, Rotterdam focus on responses to the impacts of climate change and sea level rise with a strong emphasis on protective infrastructure.

As yet the extent to which adaptation plans in cities of developing countries will follow a similar approach or if they will consider the guidelines suggested by MDA and other international organizations to mainstreaming adaptation into municipal and development planning remains unclear (UNDP, 2005, 2010; USAID, 2007; World Bank, 2010). The difference in approaches to adaptation planning has implications for adaptation governance, institutional arrangements, resources, and stakeholders involvement in the adaptation planning process and its implementation. This is an issue that merits further analysis in the near future. Related to this discussion is the gap between disaster risk management and climate change adaptation in urban areas. Enforcing parallel agendas for disaster risk management and climate change adaptation runs the risk of duplicating efforts and resources, creating competing actions and potential conflicts with unintended negative consequences, including maladaptation. Anguelovski and Carmin (2011) suggest that few urban areas have the resources and know-how to institutionalize adaptation planning in developing countries. Section 15.3.1.1 addresses this issue further.

15.2.3. Strategies and Approaches

15.2.3.1. An Overview

Strategies include decreasing vulnerability, increasing resilience, increasing adaptive capacity, and/or decreasing the risk of impacts (Few et al., 2007; IPCC, 2012). Decreasing risk, especially for high-income nations, has furthered through with engineered infrastructure-based solutions such as dikes to prevent coastal inundation from sea-level rise, new dams to improve water supplies, and other designs to reduce flooding. These approaches have been implemented in European countries such as the UK, Germany, especially the Baltic Sea region, and in U.S. coastal cities such as San Francisco and New York (Hofstede, 2008; Garrelts and Lange, 2011; Rumbach and Kudva, 2011; Rosenzweig et al., 2011). In some case, such as flood risk planning, government policies have made implementing a diverse set of adaptation planning options more difficult because of the institutional preference for construction of large-scale protection designs (Harries and Penning-Rowsell, 2011). However, adaptation finance channelled through national governments is not likely to reach the lowest income and most vulnerable people, and infrastructure-based approaches to climate change adaptation often fail to include local residents in the adaptation planning process (Sabates-Wheeler et al., 2008; Rumbach and Kudva, 2011). In addition to the need to secure funding for infrastructure-related plans, implementation of top-down approaches can require numerous legislative and executive actions (Wheeler, 2008, 2011; Harries and Penning-Rowsell, 2011; Marino, 2011). In a review of adaptation planning for cities of the United States, planning for the effects of excessive heat in urban areas primarily consisted of future infrastructure changes, such as cool paving materials; but in actual heat-related emergencies, public health campaigns and community mobilization were necessary (Ebi and Schmier, 2005; O'Neill et al., 2010). During a 1999 heat wave in Milwaukee Wisconsin, USA, the coordination of 20 different agencies was involved, demonstrating the need for additional adaptation strategies in addition to infrastructure planning (O'Neill et al., 2010).

In contrast to top-down strategies to fortify infrastructure, there are local organizational and community-based approaches (Ensor and Berger, 2009; Pelling, 2011). Community participation in adaptation planning appears to be more common in developing countries where community level planning is more common (Ford et al., 2011). Public awareness campaigns have aided the adaptation process. In the case of farming households in the Nile basin of Ethiopia, Di Falco and Veronesi (2011) demonstrated that farmers that were better informed were more proactive, and more likely to adopt new technologies useful in reducing drought-related crop failure.

15.2.3.2. Disaster Risk Management and Adaptation

A no-regrets co-benefits approach of improving resilience through an emphasis on disaster risk reduction has become increasingly common. Disaster risk reduction (DRR) includes managing hazards from extreme weather events and helps communities to deal with the uncertainty of climate change (Mitchell et al., 2010; IPCC, 2012) Proponents of merging DRR with climate change adaptation also note that currently, climate change adaptation and disaster risk reduction are within separate agencies, although they share similar objectives and challenges. Current regional and international institutions that have merged DRR and climate change adaptation include CARICOM (Caribbean Community Comprehensive Disaster Strategy) and CHARM (Comprehensive Hazard and Risk Management) in the South Pacific (Mitchell et al., 2010). In Bolivia, the Intercooperation project, utilizes traditional knowledge to improve agricultural production and to provide better decision making in risk-management (Mitchell et al. 2010). On the other hand, disaster risk management strategies by themselves often fail to account for the differing spectrum of threats and scales needed for climate change adaptation. A critique of climate change and disaster risk efforts in Canada by Etkin et al. (2012) showed that the root causes of climate change vulnerability cannot be addressed through risk management alone.

The need for better coordination between risk management agencies and climate change adaptation efforts is exemplified by the current dilemma faced by the Inupiat village of Shishmaref, Alaska. Village inhabitants are descendants of indigenous nomadic people that established a post-colonial sedentary community in response to government modernization, infrastructure development, and the need to send their children to school. Currently, the village and island where it is situated are experiencing increased flooding and high rates of coastal erosion (United States General Accounting Office (USGAO), 2009). The village has failed to find the funding needed to relocate, even though the community has rights to land off the island in a safer location. Planners, researchers and advocates have worked unsuccessfully with multiple government agencies in order to plan and organize relocation (Marino, 2011), because recovery funds are tied to rebuilding infrastructure in the same location without upgrades.

A recent Foresight project report on migration and environmental change (2011) examined the drivers of migration in 30 countries, and although the reasons for migration were multi-faceted, the primary driver of migration was economic adversity (Foresight Government Office for Science, 2011). Although economic changes can be produced by climate change impacts, the two are not always coupled. Tidal flooding in Semarang, Indonesia has not resulted in migration, even though communities affected by flooding are middle-income, and assumed to have the financial capacity to move. Some families, who own their land, are not abandoning their homes even when flooding becomes an everyday occurrence (Harwitasari and van Ast, 2011).

15.2.3.3. Adaptation, Development, and Ecosystems

International organizations are increasingly emphasizing the important relation between adaptation to climate change and development (UNDP, 2005; OECD, 2009; UNEP, 2010; World Bank, 2010; UN-HABITAT, 2011). IPCC (2012), Boyd and Juhola (2009) and others illustrate that the debate of climate change is dominated at present by impacts-led approaches that focus on climate risks rather than on human vulnerability. Knowledge of impacts and vulnerabilities does not necessarily lead to the most cost-effective and efficient adaptation policy decisions, partly due to the context specificity of adaptation which makes detailed planning at the national level challenging (Hulme et al., 2009). Dovers (2009) highlights the importance of connecting climate adaptation more closely to existing policy and management in communities, professions, and agencies, and to their existing agendas, knowledge, risks, and issues they already face.

Adaptation to climate change can be viewed as a continuous learning process (not a single outcome) likely to require regular revisiting of development policies, plans and projects as climate and socioeconomic conditions change (Hinkel et al., 2009; Hofmann et al., 2011). Most strategies can be regarded as just the start of a policy process rather than its culmination (Hulme et al., 2009). Projects in Asia implemented by the Global Environment-Least Developed Country Fund have linked adaptation efforts with development, and allowed for a holistic approach that builds institutional resilience, flexible technologies, and enhanced community capacity (Sovacool et al., 2012).

Research has long shown that coupling adaptive improvements in infrastructure with governance and community welfare, improved community resilience by enhancing local ownership, and created organizations increases adaptive capacity (IPCC, 2012). Climate change adaptation efforts also improve ecosystem resilience by implementing sustainable forestry quotas, expanding floodplain setbacks, implementing coastal afforestation, coral reef propagation, restoring degraded lands, maintaining healthy vegetation on slopes, incentivizing development away from coastal areas and bluffs, and removing barriers to the migration of plants and animals, (Sovacool et al., 2012). Increasingly, the good practices of planning and implementing integrated coastal and watershed management measures have been shown to apply equally to climate change adaptation (Tobey et al., 2010). These linked approaches highlight the need for greater emphasis on nature-based protection strategies or buffers. Adaptation efforts in Bangladesh, Cambodia, Bhutan, and the Maldives that are embedded in the development context are providing a 'win-win' adaptation strategy that improves resilience to climate change while improving economic stability and environmental quality. Even though the funds invested in adaptation linked to development is relatively small ($40 million in 2007), the Asian Development Bank estimates that every dollar invested could yield as much as $40 in economic benefits in twenty years (Sovacool et al., 2012).

Examples of such measures include: developing early warning information systems, health/heat action plans, vaccination, health system planning, flood risk planning, drought and water scarcity risk management, water demand management, coastal and flood defenses, economic diversification, natural hazard monitoring, reinforcing the built and green infrastructure environments (e.g. roads, bridges, electric wires, wetlands, land-use (IPCC, 2012).

In spite of the many positive attributes of community-based and development-based adaptation efforts, there are concerns that a disproportionate focus on the impacts of climate change could obscure opportunities for connecting development pressures, poverty, social inequality and climate change, particularly for the reduction of social vulnerability (Lemos et al., 2007; Hardee and Mutunga, 2010; Sietza et al., 2011). Other authors consider it critical to wholly integrate knowledge and experience into multidimensional and multi-scale approaches in order to guide the formation of adaptation responses, and effectively combine them with development strategies (Ewing et al., 2008; Hodson and Marvin, 2009). Moser and Satterthwaite (2008) propose considering the roles of not only different levels of government but also individuals, households, and civil society organizations. They suggest a framework of pro-poor asset adaptation for climate change as a conceptual and operational framework. Moser (2008) proposes a second-generation asset-based policy as an effort to sustain current poverty reduction policies focusing on the provision of housing, urban services and infrastructure, health, education and microfinance.

15.2.3.4. Stakeholder Participatory Approaches

Both procedural and distributional equity in adaptation requires considering the spread of adaptation benefits, costs, and residual climate impacts across regions, sectors, and population groups and peoples access and capability to take advantage of those benefits. Thomas and Twyman (2005) highlight the fact that climate change does not occur independently of other social processes. Despite the fact that social change is a central element of development, there is inadequate not attention paid to livelihoods in development studies to connect adaptation, vulnerability, and development (Paavola, 2008b; Sanchez-Rodriguez, 2009).

To address vulnerabilities to climate change, stakeholder participation is essential so that local impacts can be addressed and coping mechanisms including social and cultural capabilities are recognized and employed. Lyytimäki (2011) examined the role of national-level media coverage in Finland in relation to disseminating climate policies. Their work showed that the majority of news that mentioned climate change actually focused on additional

issues of culture, economy, and lifestyle issues. Marshall et al. (2010) examined the reasons behind sub-optimal adoption of seasonal forecasts by livestock owners in Queensland, Australia, and found that environmental awareness as well as social factors significantly influenced their willingness to adopt new grazing practices.

Stakeholder participation takes many forms, including integration of climate change impact scenarios in local decision making processes (Romanenko et al., 2007; Schmidt-Thomé and Kaulbarsz, 2008; Gawith et al., 2009). One example, in the Baltic Sea Region, includes two projects referred to as Sea level change affecting the spatial development of the Baltic Sea Region (SEAREG), and Developing policies and adaptation strategies for climate change in the Baltic Sea Region(ASTRA) that focused on integration of potential climate change impacts in local decision making. The resulting communication process produced a set of tools referred to as Decision Support Frame (DSF). The DSF addresses uncertainty in climate change model results, but also includes a vulnerability assessment and a discussion platform to help identify stakeholders, and to clarify climate change impacts and downscaled model uncertainty (Schmidt-Thomé and Kaulbarsz, 2008). Challenges addressed in the project included the explanation of the creation, application and uncertainty of complex climate models, as well as the inclusion of social scientists into applicable communication and application frameworks for climate change adaptation strategies. The ASTRA project followed the winter storm of January 2005, and was tasked with identifying what stakeholders perceive as the biggest potential impacts from climate change. The task of ASTRA is the sustained result of SEAREG by continuing awareness-raising efforts, and the development of adaptation strategies based on SEAREG scenarios (Schmidt-Thomé and Kaulbarsz, 2008).

15.2.4. Adaptation Tools and Decision Support Processes

15.2.4.1. An Overview

Uncertainties in climate change coupled with the complexities of social-ecological systems require adaptation planning and implementation are dynamic. Information and knowledge on climate change risks from various stakeholders and organizations are essential resources for making adaptation planning. Several multidisciplinary efforts, some of which are discussed below, have been engaged to develop, assess and communicate climate information and risk assessments across timescales. These efforts use a mixed portfolio of products from simple agroclimate calendars to computerized decision-support tools.

15.2.4.2. Science Supporting Adaptation Planning and Implementation

Adaptation planning and implementation takes place in a dynamic form on local, regional or global scales with complex management and governance processes, need to be implemented (Moser, 2009). The degree and type of feedback of a social-ecological system to climate change for planned adaptation measures are the major indicators of concern. (e.g. Berkhout et al., 2006). It has also long been recognized that adaptation is embedded within a process of social learning (IPCC, 2007, Ch 17) requiring the integration of science and policy in a fundamental and structured way.

Some of the earliest evidence of U.S. states beginning to address and plan for the impacts of anthropogenic climate change comes from states which had received federal financial and/or technical assistance to assess impacts and vulnerabilities and from existing concerns with climate variability or in response to experiencing severe climate-related disasters such as from ENSO (Miles et al., 2000; Moser, 2005; Pulwarty et al., 2009). In the U.S. the Regional Integrated Sciences and Assessment for academically led, Federal funded mechanisms to The Regional Integrated Sciences and Assessments (RISAs) have developed as decentralized scientific applications and policy experiments (Brunner, 1996) centered at Universities basis for a collaborative framework between monitoring, research, and management networked at regional and local levels (Pulwarty et al., 2009; Bierbaum et al., 2013). RISAs are somewhat different from other such knowledge management and applications efforts having been initiated out of a need to provide information on climate extremes and variability before moving out to climate change. Evolutionary or learning-based approaches to “assessment” such as designed and developed by RISA-type programs have proven effective at entering into national, regional and local plans of action for responding to

complex environmental problems than traditional, discrete integrated knowledge assessments (Pulwarty et al., 2009).

In UK, a national program was developed to access climate impacts across the country and to incentivize adaptive behavior since 2005 (Pringle, 2011). In Australia an interdisciplinary program was developed by the federal government to carry out adaptation activities through the NCCARF – National Climate Change Adaptation Research Facility. Government of Canada Regional Adaptation Collaboratives program, which supported science research for creation of adaptation plans (http://www.nrcan.gc.ca/earth-sciences/climate-change/community-adaptation/regional-collaborative/48). This program was instrumental in catalyzing further advancement and generated some comprehensive adaptation plans for regions across Canada. In Canada the OURANOS Consortium produces projections of regional climate trends and offer expertise in climatology and climate simulation.

The Caribbean Community and Common Market (CARICOM) with collaboration from the Organization of American States established the Caribbean Community Climate Change Centre (5Cs) in 2005 to guide the development of regional adaptation planning and implementation in the Caribbean. The 5Cs coordinates funding and provides guidance to regional impacts assessment and adaptation efforts. These include supporting critical capacity in regional climate modeling and sea-level monitoring, embedding climate risk information into environmental impacts statements, conducting and mainstreaming vulnerability and capacity assessments into national and local planning, facilitating within-country networks and to a Masters Degree program with a specialization in climate policy and impacts assessment. Climate adaptation has also been top issues in Mountainous areas and a series of relevant activities have been carried out (http://www.icimod.org/ and http://mri.scnatweb.ch/).

Local communities and NGOs are demanding an increasingly active role of public institutions in the delivery of technological options to cope with emerging climate challenges (Prowse and Scott, 2008; Rodima-Taylor et al., 2012). Aside from their traditional roles, some NGOs serve important information clearinghouse roles regarding adaptation (e.g., the Pew Center for Global Climate Change or the virtual Adaptation Network [http://adaptationnetwork.org]). Others have emerged as active partners in adaptation, such as the Center for Clean Air Policy (CCAP), CAKE and ICLEI Local Governments for Sustainability. CCAP is working with nine U.S. cities (and one Canadian city, Toronto) in its Urban Leaders Adaptation Initiative to help operationalize key steps in the local adaptation process (Lowe et al., 2009). ICLEI, a non-profit network of local government members, provides web-based information in support of local sustainability efforts using customized tools and case studies on assessing climate resilience and climate change adaptation. With a collaboration with King County, WA, ICLEI developed a procedural guidebook for local, regional, and state governments on how to begin preparing for the impacts of climate change (Center for Science in the Earth System and King County, 2007).

Most of these adaptation plans initially focus on few high risk areas and are then conducted in collaboration with locally based university researchers and consulting teams. Researchers have helped identify some of the physical and social characteristics that allow for the adoption of effective partnerships and implementation practices during events (Birkland, 1997; Pulwarty et al., 2009; IPCC, 2012; Mimura, 2012; Rodima-Taylor et al., 2012). These include the occurrence of previous strong focusing events (such as catastrophic extreme events) that generate significant public interest and the personal attention of key leaders, a social basis for cooperation including close intersectoral partnerships, and the existence of a supported collaborative framework between research and management such as RISAs, OURANOS, UKCIP, 5Cs. The successful boundary organizations:

- Perform basic and applied research on local climate dynamics impacts, and information prototypes relevant to stakeholder interests
- Support the integrated research base for operational informational and transition of new climate applications products
- Develop and maintain multi-way risk communication among research teams, member agencies, and stakeholders for developing information relevant for planning and decision making

While often initiated by interest in climate variability, these are advancing into climate change and adaptation planning support integrating the multiple timescales of climate risks (across extremes variability and trends). As has been noted, these efforts – while valuable and expanding – are as yet at too small level to meet the rapidly growing demand (USGCRP, 2009; Bierbaum et al., 2013). One recurring theme and lesson is the value of investments in

knowledge and information, including monitoring systems and early warning information systems that include clearer understanding of resources, health and livelihood impacts (Pulwarty et al., 2012).

Support for vulnerability and adaptation research, establishing adequate decision support institutions, as well as the building of the necessary capacity in science, the consulting world, and in government agencies, is still lags behind a rapidly growing need. With this in mind the development of climate extension services is leading to the development of the UN Global Framework on Climate Services.

15.2.4.3. Monitoring, Modeling, and Spatially Integrated Tools

The use of a decision support system (DSS) is a very effective means for a policy analyst or planner to compare different possible interventions. Through creating information products (reports, maps, diagrams, figures, visualizations, etc.), decision support systems provide knowledge of better choices about how socio-ecological coupled systems can achieve efficient, effective and equitable adaptation to global climate change. The complex, multi-scale, interdisciplinary nature of climate change impact on socio-ecological coupled systems has made the computer-based modeling approach a robust tool for understanding the evolving processes and the future conditions of the systems (Alter, 2004; Pyke et al., 2007). Typically with the widespread application of cellular automata and the multi-agent techniques since the 1980s, modeling of the behavior of physical, socio-economic or coupled systems has gained a new dynamic pace, and the role of the modeling approach in decision support tools has been enhanced (e.g., Epstein and Axtell, 1996; Wolfram, 2002).

Recent years have seen integration of monitoring systems and/or modeling systems with the techniques of geographical information systems, remote sensing and global positioning systems and “discussion support” or a dynamic dialogue between researchers and practitioners. As a result, much more powerful, process-visual and spatially implicit decision support systems have been developed. One example of this kind is the development of the Invasive Species Forecasting System (ISFS) (Stohlgren et al., 2005), which, through combining USGS science and NASA Earth observations with software engineering and high-performance computing expertise, is capable of providing regional-scale assessments of invasive species patterns and vulnerable habitats. In the Yellow River, the second largest drainage basin of China, the drying up of the channel near the mouth of the river in low-flow seasons forced governments to develop a basin-scale decision support system (Li and Li, 2009). Numerous such applications have also been made in the management of water quality, air quality, land use, crop production, and more (e.g., Jamiesona and Fedra, 1996a,b; Huang et al., 1998; Gimblett, 2002; Qin et al., 2008).

15.2.4.4. Decision Making Tools

Adaptation decision making can be kept informed by various tools, which are developed generally in ‘top-down’ and ‘bottom-up’ forms. The *top-down* tools normally downscale simulated climate scenarios to a regional level and then adopt expert opinions, apply multi-criteria optimization methods, or perform cost-effectiveness or cost-benefit analyses to assess impacts so as to identify most feasible adaptation measures (Carter et al., 1994; IPCC-TGICA, 2007; Adger et al., 2009a,b).

In the *bottom-up* approach, affected actors make their own impacts transparent and decisions at different levels on adaptive options, and the society consisting of all the stakeholders itself organizes social and institutional activities in the light of actions and interactions among all the stakeholders. Advances in stakeholder participatory methods, cellular automata and multi-agent modeling techniques have significantly enhanced the development of this type of decision making tool in recent years (Epstein and Axtell, 1996; Wolfram, 2002; Kaner et al., 2007).

The central difference between the top-down and bottom-up based tools lies in the fact that the former focuses largely on the behavior of a system as an entity, while the latter concerns mainly the roles of actors in the system. As a result, top-down based tools may yield adaptation options that may or cannot be accepted by most individuals, while bottom-up based tools may select adaptation options acceptable to most individuals but not-effective for significantly minimizing the impacts to the whole system. There is no single tool that suits all circumstances of

adaptation decision making, although information development tools such as CRiSTAL help to coordinate diver information on vulnerability and risk, and the specification of the problem and the available 'inputs' to the decision process may provide a choice of a suitable tool (Gimblett, 2002). IPCC (2012) notes the distinct differences in problem orientation and solution space depending on whether an adaptation plan commences with a climate modeling outputs-based versus that of a risk and vulnerability-based framework.

15.2.4.5. Communication Tools

Communication is a major component of social learning process and effectively exchanging and sharing information about climate change related risks and effects of adaptation measures is crucial to the identification of a right adaptation pathway out of multiple possibilities. A wide range of communication tools are being employed to carry out multi-way participatory dialogues among information developers (e.g. scientists, trainers, project implementers, government agencies, etc.) and the receivers who in turn also influence the nature of information being produced. (e.g. community members, household heads, school children, groups at risks, government regulators, etc.). They include brochures, bulletins, posters, magazines, policy briefs, desktop presentations, articles, drama, role-playing, music, group discussions, training of trainers, videos, TV and radio broadcasts, internet, and many more. While all these tools are effective in communicating risks, some of them are more cost-effective and complex than others, and some reach a wider audience than others. At the local level, interactive communication strategies such as theater, role-playing, music, and group discussions where community members are involved in debating climate risks and possible solutions to cope with climate change exert a positive effect on communities' behavior and practices, while reports, concept notes, brochures, magazines, presentations and workshops are more effective with policy makers at local and national levels. At country/regional level, nevertheless, broad dissemination channels such as TV, radio and internet broadcast, high-level summits, etc. have been effective in catering a wider range of stakeholders and creating widespread awareness as demonstrated in Advancing Capacity for Climate Change Adaptation (ACCCA) project (http://www.acccaproject.org/), UK Climate Impacts Program (UKCIP) (Pringle, 2011) and the special report of IPCC, 2012.

In addition to these commonly applied tools, innovative ways of communicating which can effectively inform the process of climate change adaptation planning and implementation are being employed. These include learning-by-doing, hands-on exercises, and training of trainers that use practical and creative cases. This is reflected particularly by the IPCC Fourth Assessment Report (IPCC, 2007), ACCCA project (http://www.acccaproject.org/), UKCIP (Pringle, 2011), the first U.S. National Assessment of the Potential Consequences of Climate Variability and Change, and the U.S. Climate Change Science Program Synthesis and 2013 National Climate Assessment products.

To assist the syntheses, a variety of rule- or matrix-based methods has been applied for screening adaptation options. For example, the Adaptation Decision Matrix uses subjective scoring to compare the relative cost-effectiveness of alternative adaptation measures (Benioff and Warren, 1996), while the RamCo (Rapid Assessment Module for Coastal Zones) system uses a series of structured questions for a decision matrix to illustrate adaptive opportunities for coastal zone management (Research Institute for Knowledge Systems, 2012). For generating visualizations and customized reports, greater emphasis on user interaction, sensitivity analysis and capabilities has been placed in recent years (Sarewitz et al., 2000; Sarewitz, 2004). Furthermore, multi-criterion and multi-actor participatory approaches that allow users to consider alternative adaptation strategies and evaluate tradeoffs have also been deployed, typically in the development of tools for environmental assessment and management (TEAM) (Julius and Scheraga, 2000).

15.2.4.6. Insurance and Social Safety

Insurance allows people and households to recover quickly and encourages adoption of new techniques so as to increase assets in a short period. These market-based arrangements have immense potential by allowing households and individuals to take advantage of the financial products offered by insurance companies and banks. Throughout the world, crop insurance and risk-pooling have allowed national economies, communities and individuals to develop the full potential of their agricultural sector by transferring weather-related risks away from the farmer.

Informal arrangements have existed for a long time, and still constitute the main source of risk management for the majority of the world's population. In the absence of (or with incomplete) market institutions and public support, individual households respond to risk by protecting themselves through informal and personal arrangements. Access to savings instruments and credit can also be facilitated. When these types of microfinance are properly provided, such as part of a well-managed and targeted intervention, it allows these households to increase their assets, improve their ability to alleviate risk and reduce their reliance on money lenders (Chu and Gupta, 1998; Holzmann and Jorgensen, 2000; Townsend, 2006).

Crop insurance will likely play a greater role in the developing world in absorbing shocks as climate-change related disasters become increasingly problematic for agricultural production. A project in Ethiopia provides a promising model. Oxfam America (http://www.oxfamamerica.org/)has developed a risk management framework to enable poor farmers in Ethiopia to strengthen their food and income security through a combination of improved resource management (risk reduction), microcredit ("smart" risk taking), risk transfer (insurance), and risk reserves (savings). This project—The Horn of Africa Risk Transfer for Adaptation (HARITA)—was initiated in 2007 and brings together Ethiopian farmers, local insurers and international re-insurers, relief societies, credit and savings institutions, local government agencies, and a local agricultural research organization. The project enables Ethiopia's poorest farmers to pay for insurance with their own labor. Meanwhile, the governments of Malawi and India have initiated pilot projects with national smallholder farmers associations that have pioneered rainfall insurance schemes to ensure payouts when rain falls below a crop-specific rainfall index. Such risk-pooling efforts, where premiums are low since they are collected only to insure immediate livelihood recovery rather than full asset losses, are also being tested at the regional-scale in the Caribbean. Index insurance has been recently introduced to overcome obstacles to traditional agricultural and disaster insurance markets. If the rainfall amount is below the threshold, then the insurance pays out. Of particular note is the Caribbean Catastrophe Risk Insurance Facility (CCRIF), the world's first index-based parametric insurance mechanism. It is a new partnership among 16 Caribbean countries and the World Bank with support from several countries, and will be tested over the coming years (CCRIF, 2012). Despite these advances, the expansion of weather-indexed crop insurance faces key challenges especially in targeting those engaged in non-commercial marginal agriculture.

15.2.5. Bridging Planning to Implementation

For adaptation planning and implementation, a variety of tools are employed depending on the social and management context. Development and diffusion of new technologies and management practices ia another important area for adaptation efforts. Although a wide range of adaptations are possible with current technologies and management practices, development and diffusion of technologies can expand the range of adaptation possibilities by expanding opportunities or reducing costs. While effective communication is important, the research experience shows that broad societal processes that create dynamic pressures and unsafe conditions are not easy to change, yet are fundamental to human vulnerability. More challenging is an understanding the socialization of lessons learned by particular individuals and organizations through their own, direct trial and error experiences. The mismatch between the current structure and operational culture of municipal planning institutions and the need for multidimensional collaboration in adaptation is reported as a planning and implementation barriers in both developing and developed countries.

Several studies have identified the characteristics of pre-decisional practices in implementation that lead to effective practice over the long-term (Fischhoff, 2009, IPCC, 2012). These include: 1) understanding of the goals, objectives, and constraints of communities in the target system; 2) mapping practical pathways to different outcomes carried out as joint problem definition and fact-finding strategies among research, extension and farmer communities; 3) bringing the delivery persons (e.g. extension personnel, research community etc.) to an understanding of what has to be done to translate current information into usable information; 4) interacting with actual and potential users to better understand informational needs, desired formats of information, and timeliness of delivery; 5) assessing impediments and opportunities to the flow of information including issues of credibility, legitimacy, compatibility (appropriate scale, content, match with existing practice) and acceptability; and 6) relying on existing stakeholders' networks and organizations to disseminate and assess climate information and forecasts.

15.3. Capabilities for Adaptation Planning and Implementation

15.3.1. Institutional Arrangements: Public- and Private-Sector Stakeholders and Priorities

While there is growing recognition that adaptation planning is essential (Ayers and Huq, 2009; Wilbanks and Kates, 2010; Ford et al., 2011), attempts at implementation have increased appreciation of the magnitude of the institutional challenges of linking adaptation planning and implementation including the problems of multi-scale coordination and support among national, state (provincial), and municipal governments to foster adaptation planning at the local level. Several studies, including municipalities in Denmark (Vammen Larsen et al., 2012), local adaptation in Florida (Mozumder et al., 2011), local governments in Australia (Doran, 2011; Gero et al., 2012; Municipal Association of Victoria (MAV), 2011), and in Sweden (Glaas et al., 2010; Storbjörk, 2007) illustrate the difficulties in creating efficient interdisciplinary integrated approaches in adaptation planning and implementation. One of the most significant challenges lies in introduce changes to the national and subnational institutional landscape in order to foster adaptation planning. Institutions are comprised of formal rules and informal codes of behavior that shape expectations and guide interactions (Ostrom, 1990). Adaptation planning follows formal institutions associated with regulations, policies, and standards created and enforced by government actors but also requires the participation of informal institutions through interactions among stakeholders according to cultural, social, and political conditions in societies (Moser and Satterthwaite, 2008; Carmin et al., 2012). Chapter 14 describes the importance of these institutional frameworks for adaptation. This section assesses the extent to which the international literature has addressed the issue of institutional arrangements fostering adaptation planning, what role different organizations (public, private, and social) and stakeholders in those arrangements have played, and what lessons can be learned from these experiences.

15.3.1.1. Institutional Capacity of National and Local Governments

The review of the broad international literature suggests the development of institutional arrangements for adaptation planning is at an early stage both at the national and at the subnational level (Carmin et al., 2012; Gero, 2012; Glaas et al., 2010; Gupta et al., 2010; Rodima-Taylor et al., 2012; Tompkins et al., 2010). Huntjens et al. (2012) compare adaptation to climate change in the Netherlands, Australia, and South Africa in an effort to identify strategies that move from individual impacts to more holistic approaches increasing the adaptive capacity of the system. Tompkins et al. (2010) and other studies of climate change adaptation in the United Kingdom consider a broad range of adaptation actions, from small adjustments to creating deeper systematic change in public and private organizations. These authors argue that the transition to deeper systematic changes could eventually result from a set of simultaneous changes (changes in technology, user practices, regulation, industrial networks, infrastructure, symbolic meanings, and culture). Some of these elements are part of the institutional adjustments discussed above. As with other studies, in the context of adaptation planning, find there is no evidence to show that adaptation planners are deliberately working towards transitions and with little real evidence of climate change adaptation initiatives trickling down to local government level.

Climate adaptation is uniquely linked to location, and it is often a responsibility of local governments, stakeholders, and communities (Mattews et al., 2012). The importance of multilevel institutional arrangements is increasingly cited (Corfee-Morlot et al., 2009; Gero et al., 2012; Storbjork, 2007; Vammen Larsen et al., 2012; Wilson 2006). Carmin et al. (2012) describe the importance of developing regulations, policies, and codes to support the institutionalization of local climate actions. Roberts (2010) describes the difficulties of operationalizing development in Durban, where some departments were able to mainstream adaptation activities into their ongoing work while others did not have that capacity. Vammen Larsen et al.'s (2012) study in Denmark reports the rapid incorporation of climate change in the Strategic Environmental Assessments (SEA) of the new municipal plans prepared by local governments in that country in 2009. The study showed that the current structure of the municipal organization is made of different professional silos with their own internal norms, cultures and procedures that may hinder horizontal coordination across professional sectors and departments. The study showed also there are few national requirements or guidelines to help local governments integrate climate change into spatial planning. The lack of national guidelines is also reported in Norway (Amundsen et al., 2010) in Sweden (Glaas et al., 2011;

Storbjork, 2007) and in Australia (Gero et al., 2012; Municipal Association of Victoria (MAV), 2011). Vammen Larsen et al. (2012) stress that climate change does not posses clear institutional characteristics as a municipal professional area. Rather, it is viewed as a void with no clear rules and norms according to which politics is to be conducted and policy measures agreed upon. While the institutionalization of climate change integration has begun, it is unknown whether the municipalities will be successful in developing the governing capacity needed.

15.3.1.2. Role of Spatial Planning

The review of the literature above suggests that planning has been widely considered in adaptation, but perhaps not enough attention has been given to study the capacity of current planning institutions. This is required in order to move toward a balance of top-down and bottom-up strategies in adaptation. Planning is considered a societal tool to create order among activities and interests driving growth in societies, to reduce conflicts among them, and to seek the well-being of their inhabitants (Blair, 1973). Some of the literature is beginning to focus on the capacity of planning to address adaptation to climate change. Juhola and Westerhoff (2011) stress the transition of adaptation from being first considered a matter of relevance only to the environmental sector, to a development challenge that will require the participation and cooperation of a multitude of sectors to avoid potential conflicts. Sanchez-Sanchez-Rodriguez (2012) highlights the role and limitations of planning in the construction of operational approaches to adaptation, particularly in urban areas of low-income and middle-income countries. He questions if planning institutions have the vision, capacity, and flexibility to update themselves, and to guide future urban growth in order to meet the challenges facing to their future. This is an important question given the expectations that planning will be able to create order and balance in adaptation to climate change, and in light of the reticence of planning institutions to change their operations and structures.

Mozumder et al. (2011) study on the role of experts and decision-makers building adaptation to climate change in the Florida Keys reveals they are currently operating with limited information, and lack a formal institutional framework necessary to shape and execute adaptation measures. Other studies suggest there have been few changes in forecasts, plans, design criteria, investment decisions, budgets or staffing patterns in response to climate risks (Repetto, 2008; Berrang-Ford et al., 2011).

Biesbroek et al. (2009) considers that climate change could also lead to changes in the traditional administrative structures to which spatial planners are accustomed. Other literature emphasizes the role of spatial planning as a switchboard for adaptation and sustainable development change (Füssel, 2007; Hallegatte, 2009; Preston et al., 2011). Biesbroek et al. (2009) stress spatial planning coordinates the different relevant socio-economic objectives and desires, and shaping spatial developments in a long-term perspective. However, they recognize it is becoming more and more a pragmatic challenge for spatial planners to include climate change as an important consideration in the planning process, especially in the context of sustainable development. Bulkeley (2006) concludes that given the complexity, uncertainties and scale of the climate change issue, spatial planning might play a key role in facilitating the development of both adaptation and mitigation strategies with a spatial component. However, not enough attention has been provided yet to the institutional arrangements needed to enable adaptation through spatial planning.

The review of the international literature discussed above identifies two major trends: First there is the assumption that current of planning structures and operational cultures will be able to meet the needs of adaptation on different scales (regional, national, and subnational); and second, there are studies that document the shortcomings, challenges and opportunities of planning as a societal process that is needed to create and implement adaptation, bringing more attention to the institutional changes required to build efficient responses to climate change.

Some literature on adaptation has suggested the importance of considering adaptation planning as a learning process (Glaas et al., 2010; Hinkel et al., 2009; Hofmann et al., 2011) likely to require regular revisiting of development policies, plans and projects as climate and socioeconomic conditions change and adaptation plans need revision. Holden (2008) suggests that social learning is a relevant but under-investigated feature of planning and a critical part in the adaptation of innovations but there are few analytical tools to assess how and when learning is taking place, and amongst different professional and public communities. Considering adaptation planning a social learning

process would allow for periodical adjustments in order to reduce the uncertainty of the impacts of climate change and societal needs to cope with them. This is relevant in light of the need to develop new tools to cope and adapt with the impacts of climate change (Frommer, 2009). But it will require major efforts in multilevel and cross-sectoral collaboration, as well as a broader attention by scholars and practitioners to develop a better understanding of this process.

Important learning tools in adaptation planning are monitoring, evaluation and feedback. Although some recognize the importance of evaluation in adaptation, this topic is under-researched and requires significant work to go beyond the simple evaluation criteria that have been developed to date (Doria et al., 2009). Preston et al. (2009) suggest the institutional arrangements for the evaluation of adaptation processes are still in their developmental infancy. Monitoring and evaluation are often advocated within adaptation decision making frameworks, but methods for undertaking such work are rarely articulated, and adaptation plans frequently fail to acknowledge the importance of core design principles for adaptation policies and measures such as efficacy, efficiency and equity. Reidsma et al. (2010) and IPCC SREX (2012) argue that in order to assess the effectiveness of adaptation strategies, frameworks should not start from the modeling perspective, but from the stakeholders' perspective.

Adger and Barnett (2009) argue that metrics used to determine the goals of adaptation, the measures of its success and the trade-offs involved, can be understood only in terms of the social context in which adaptation takes place. Communities value things differently, and this must be taken into account if adaptation is to be effective, efficient, legitimate, and equitable (Barnett and Campbell, 2009). Arnell (2010) highlights the importance of context in the analysis and evaluation of adaptation. His review shows that local circumstances significantly affect what adaptation options are considered feasible, what information is likely to be used, what assessment techniques are adopted, and, crucially, how adaptation decisions are actually made. This work indicates that it could be difficult to make generalized assessments about the contribution of adaptation to managing the risks posed by climate change, and to construct generalized models of the adaptation process.

By the same token, Engle (2011) calls attention to the limited effort to evaluate adaptive capacity across vulnerability and resilience frameworks, and to improve the understanding of adaptive capacity dynamics. For him, it is important to identify what builds adaptive capacity and what functions as limits and barriers to adaptation. Hinkel (2010) questions the use of vulnerability as a concept to increasing awareness of the importance of adaptation, to guide the allocation of adaptation funds, monitoring of adaptation policy, and conducting scientific research. He finds it misleading to speak of measuring vulnerability as it raises false expectations.

Providing spatial planning a bigger role in institutionalizing adaptation planning at the local level requires the participation and cooperation of a multitude of sectors to avoid potential conflicts (Juhola and Westerhoff, 2011). Anguelovski and Carmin (2011) highlights the ways in which public, private, and civil society actors and institutions articulate climate goals, exercise influence and authority, and manage urban climate planning and implementation processes. They document that urban areas tend to formalize and institutionalize their work through the establishment of dedicated climate units, either within a relevant department or as a separate and cross-cutting office. However, they recognize few local governments have had the resources and know-how to institutionalize adaptation to climate change.

Koch et al. (2007) stress the gap in understanding and evaluating how institutional networks operate. Their research results in South Africa show that few institutions fully understand the implications of adaptation, and their roles and responsibilities have not yet been properly defined. They suggest constraints relating to capacity, lack of awareness and poor information flow need to be addressed. Adaptation challenges the hierarchical manner in which government works, and a more collaborative approach to climate change adaptation is needed. These and other recent contributions in the literature (Adger et al., 2009b; Preston et al., 2009; Tompkins et al., 2010; Wolf et al., 2010) move the discussion of adaptation planning to climate change to a better understanding of the elements needed to operationalize this concept, building responses to present and future climate impacts.

15.3.1.3. Institutional Arrangements and Disaster Risk Management

The divide between the Disaster Risk Management (DRM) and the Climate Change Adaptation (CCA) communities at the national, subnational, and local level is evident in a large number of countries (Birkmann and Teichman, 2010; Falaleeva et al., 2011; Schipper and Pelling, 2006; World Bank, 2010). International pressure to draft separate disaster and adaptation strategies and policies has now become enshrined in divergent laws, creating further obstacles to institutional integration of DRM and CCA. The convergence of adaptation planning and disaster risk management offers opportunities to more efficent use of resources and effective and coherent short and long-term responses to hidrometeorological events and climate change (IPCC, 2012). It can enhance attention to climate change adaptation and awarness of the need of short, medium, and long-term strategies to build resilient and sustainable communities. This convergence helps decision-makers build a better understanding of present and future risks and their consequences for development. One of the problems they face is the short-term horizons of local plans compared with the long-term implications of vulnerability and climate change.

The convergence of DRM and CCA need building capabilities in institutions to recognize and better understand vulnerabilities to hydrometeorological and climate change simultaneously (Agrawal and Perrin, 2008; Agrawal 2010). Some early examples in this direction are ecouraging. In a study of current and future city-wide flood risks to Ho Chi Minh City in Vietnam, Storch and Downes (2011) connects spatial planning scenarios linking urban growth and climate change (sea-level rise scenarios) in order to explore the main driving forces for future risks. There is a growing interest connecting initiatives for disaster risk management and climate change adaptation planning (Bierkman, 2010; Rosenzweig and Solecki, 2010; Carmin et al., 2012). The World Bank prepared guidelines to connect disaster risk management, poverty reduction and climate change adaptation and emphasize the role of planning and participatory approaches (World Bank, 2010). Mathew et al. (2012) describes the benefits of defining adaptation options in consultation with local authorities in a study on climatic hazards in Kochi, India. Frazier et al. (2010) explore stakeholder participation in the context of coastal hazards concluding that adaptation planning tends to be more difficult in areas that lack recent disaster experience.

Some countries expand the divide between DRM and CCA. For instance, Mexico published a new National Climate Change Law in 2012, but instead of integrating DRM as one of its key components, it published simustaneously a new Disaster Risk Management Law. In general little progress has been made integrating DRM and CCA at the national, subnational, and local level. The Birkmann and Teichman (2010) study on the U.K. Germany, and Fiji found that little action has been taken at the national level to establish working relationships between adaptation planning and DRM. The convergence of DRM and CCA require new institutional arrangements, particularly in terms of legislation, operational and management structures, working agendas, and time horizons (Birkmann and Teichman, 2010; Falaleeva et al., 2011; Schipper and Pelling, 2006).

15.3.1.4. Enhancing Institutional Capacity

Two key issues emerge in the literature as essential for enhacing the institutional capacity of adaptation: multilevel governance and cross-sectoral frameworks. Although these two issues interact dynamically in adaptation planning and implementation, they have different connotations and require specific actions to enhance and strengthen their practices.

15.3.2. Knowledge Development and Sharing

Scientists and managers across agencies and management systems would benefit from greater sharing of data, models, and experiences in climate change adaptation (West et al., 2009). Indigenous observations and interpretations of meteorological phenomena have guided seasonal and inter-annual activities of local communities for millennia. However the number of documents published about knowledge development and sharing is still limited. The available documents deal mainly with general principles rather than practical applications. The current section outlines the main relevant issues surrounding knowledge development and sharing in adaptation to climate change.

15.3.2.1. Science and Technologies for Observation, Monitoring, and Prediction

Development and diffusion of new technologies and management practices will be critical to many adaptation efforts. The role of technology is not so much to make adaptation possible-a wide range of adaptations are possible with current technologies and management practices-but to expand the range of adaptation possibilities by expanding opportunities or reducing costs (Smith et al., 2009). The status quo generally requires no new capital costs and may be more profitable in the short term than developing more climate-resilient technologies (Yang et al., 2007). Several researches indicated the autonomous adaptation to climate change of many animals and plants (Mastrandrea et al., 2010; Tingley et al., 2009).

15.3.2.2. Early Warning Information Systems

Monitoring and early warning systems (EWS) have long-played important roles in helping in adjustment, and adaptation especially on the local scale. The disaster research community has shown that successful warnings of impending events are those that are complemented by information on the risks actually posed by the hazards as well as the potential strategies and pathways to mitigate the damage in the particular context in which they arise (Drabek, 1999; UNISDR, 2006). While current science and technology do not resolve the uncertainties in modeling, and in the response of ecosystems to climate change and management interventions at levels needed for probabilistic early warning, the need for precise climate information is often overstated (Smith et al, 2009). Local level early warnings based on traditional knowledge (e.g. water turning a different color, winds shifting) are frequently used. The use of radios, megaphones, and cell phones are also used at the local level to warn. Countries that have not developed such systems, even in part, to develop and inform strategic response options often illustrate a broader lack of institutional flexibility and preparedness and thus higher vulnerability. Given the links between near term and long-term climate variability and change, the early warning construct is, of necessity, being applied to more extended timescales.

The impacts of climate change will be most strongly felt by resource insecure populations, who are more vulnerable to changes in the distribution and magnitude of extreme weather events, as these affect crops, disease outbreaks and soil and water quality. The use of climate data analyses and projections in early warning and information systems is an important and established mechanism to mitigate the effects of natural disasters (Pulwarty and Verdin, 2013). An early warning information system involves much more than developing and disseminating a forecast.

The long-standing experience with climate extremes and variability offers many usable lessons. The U.S. National Integrated Drought Information System offers an end to end system in which monitoring and forecasting, risk assessment and communication are integrated, but as importantly interagency cross-coordination is a goal and is are increasingly embedded with states and local communities (Pulwarty and Verdin, 2013; Bierbaum et al., 2013) The USAID's Famine Early Warning System Network (FEWSNet), for instance, integrates seasonal climate forecasts into 3- and 6-month food security outlooks, and it has developed 10-20 year climate projections for food insecure regions of Africa. FEWSNet has also created livelihood zone maps, profiles, and baselines for some of the most food insecure countries of Sub-Saharan Africa, Central Asia, Central America, and the Caribbean. These maps and profiles describe areas in terms of food production, income generation, and market opportunities, and they make distinctions between different wealth groups and their respective coping capacities for dealing with shocks, including drought. These are valuable tools that could help countries develop adaptation strategies to cope with the predicted increases in drought frequency and severity.

The EWSs are often utilized for disaster management by traditional media (radio, TV). However, to ensure the collection and dissemination of information and delivery of early warnings, the EWSs need new Information and Communication Technologies (ICT) for analysing and processing information, and providing automated alerts to vulnerable populations (Karanasios, 2011). Local coping strategies are an important element of planning for adaptation, and ICTs can be used in a number of productive ways, particularly by leveraging existing ICT successes in developing countries such as telecentres and mobile phones, as well as by introducing emergent ICTs in

conjunction with existing sectoral policies, planning and budgeting (UNFCCC, 2007).Insurance and and the basis for finacial services mechanisms are discussed in detail in Chaptet 10.

15.3.2.3. Science and Technologies for Vulnerability Assessment, and Adaptation Planning and Implementation

Effective collaboration and linkages between managers and scientists offer a variety of opportunities for adaptation implementation. First, resource scientists have monitoring data and research results that are often under-used. Second, monitoring efforts could be conducted with specific objectives in mind to increase usefulness for managers. Finally, scientists can support management by targeting their research. All of these are opportunities for interactions between scientists and managers that provide information relevant to major management challenges (Füssel, 2007).

Adaptation action, such as changes in crops and crop varieties, improved water management and irrigation systems, and changes in planting schedules and tillage practices, can limit negative effects and take advantage of beneficial changes in climate (Yang et al., 2007). The adaptation part of this is based on a science-policy collaborative exchange that has operated in various forms for about a decade, and has successfully co-produced scientific assessments (Corfee-Morlot et al., 2011).

ICTs can help strengthen the physical preparedness of livelihood systems for climate change-related events. These can contribute to design of defences and determination of their optimal location, and make the livelihood system more robust. As an example geographic information system (GIS) technology was applied to foster the ability of the community to deal with climate change hazards and trends in the Philippines (IAPAD, 2010) and form modelling processes of climate change adaptation which which supports regional stakeholders to develop better protection of key spaces in the landscape (Bardsley and Sweeney, 2010). Visualization of sea level rise and climate change damage in Delta, British Columbia, and subsequent illustrations of options for adaptation, has led to increased awareness of long-term risks and response challenges between practitioners in this community, as well as by local government and the public (Shaw et al. 2009).

By sharing observations and reflections through ICT tools, users foster new ways of assimilating or translating information, which can be shared through wider networks, and then influence action, enabling new experiments/practices to take place. This generation of new and broader learning cycles will in turn strengthen systematic resilience (Ospina and Heeks, 2010). Karanasios (2011) outlines the range of new and emergent ICTs (e.g. wireless broadband, sensor networks, GIS and Web-based tools) being applied to climate change issues, and investigates their use in developing countries.

15.3.2.4. Science and Technologies for Individual Sectors

The adoption of advanced technologies greatly facilitated agricultural development. New varieties and new fertilizers, pesticides, and agricultural techniques have been actively adopted (Yang et al., 2007). In the sector of logistics, on a global scale, most sea ports are in the beginning stages of considering adaptation to climate change. There is an opportunity for the scientific community to engage with this sector to create the knowledge base needed to understand and improve resilience and efficiency in the coming century (Becker et al., 2011). The European Spatial Planning Adapting to Climate Events Project (ESPACE) asserts that while adaptation presents a variety of new issues for urban planning, it can be an opportunity for good planning to thrive. It is further argued that good planning can positively contribute to adaptive efforts if it works within its means, and correctly uses the tools available to it such as adaptation through infrastructure and design (porous surfacing, green roofs, etc.) (ESPACE, 2008). The linkage between disaster risk reduction (DRR) and adaptation can help communities to build resilience and live with change.

15.3.2.5. Technology Development, Transfer, and Diffusion

Technology is essential for adaptation to climate change, and access to technologies is an important component of a society's adaptive capacity. In some settings, adaptation could be made more effective and efficient by technologies such as new crop varieties tolerant of changed conditions and more efficient water treatment. However, successful deployment of technology is dependent on local social and institutional contexts. Technologies will therefore be more effective when used within multiple adaptation measures that integrate different sectors and social, institutional, and infrastructural dimensions (Rawlani and Sovacool, 2011).

Technologies related to information collection and diffusion are particularly important for adaptation, including technologies for data collection and information dissemination during extreme events and emergencies. Despite remaining uncertainties, technologies to project climate changes, and identify potential impacts and vulnerabilities are frequently seen as precursors to successful adaptation planning. Developing countries require enhanced access to improved climate models, but also adaptation planning tools that focus on robustness in the face of uncertainty (Dessai et al., 2009).

Technology choices can both reduce and exacerbate risk (Jonkman et al., 2010). For example, technologies can strengthen physical infrastructure, such as bridges and buildings, so that they can withstand more extreme hazards. However, relatively centralized high-technology systems can increase efficiency under normal conditions but risk cascading malfunctions in the event of emergencies. In some circumstances, technologies to reduce short-term risk and vulnerability can contribute to increased future vulnerability to larger extreme events (Etkin, 1999; Moser, 2010). This was seen in the impacts of Hurricane Katrina on New Orleans, where a flood defense system enabling construction in a floodplain was subject to catastrophic failure in the face of a particularly large extreme event (Freudenburg et al., 2008; Link, 2010).

Planning for physical infrastructure intended to last decades should account for potential changes in associated social conditions, such as land use, transport, and water and sanitation requirements, in order to avoid maladaptation. Technology development and transfer should promote flexible solutions, for example multiple, smaller dams that can resolve local as well as more distant needs. This has been expressed in Thailand's Sufficiency Economy approach, where local development is judged against contributions to local, national and international wealth generation (UNDP, 2007).

International efforts for technology transfer have been concentrated in the UNFCCC framework's five themes: technology needs and needs assessments, technology information, enabling environments, capacity building, and mechanisms for technology transfer. A key project is developing a technology transfer clearinghouse called TT:CLEAR, and establishing a Technology Centre and Network (UNFCCC, 2012). However, successful technology transfer requires not only exchange of technological solutions, but also strengthening policy and regulatory environments, and capacities to absorb, employ and improve appropriate technologies. In both developed and developing countries, multilateral institutions can support collaboration which engages private interests in regulatory planning and possibly activities, particularly if ongoing funding is expected (Tessa and Kurukulasuriya, 2010).

15.3.2.6. Education and Training

Developing general guidance on potential climate change impacts, vulnerability, and adaptation helps the promotion of flexible approaches to adaptation planning and implementation. It means investing in climate science extension personnel including translators, who could work in partnership with managers and planners to translate the projections of climate models, understand potential impacts, and help design adaptation responses. These individuals would also function as outreach staff who could explain to the public what climate change might mean to long-standing opportunities or management goals (West et al., 2009).

The farmers in Northeast China learn to adapt to climate change through experience and self-judgment, but also, and importantly, from neighbors' practices and scientific demonstrations. Scientists played a supporting role by discerning long-term climate trends, predicting future scenarios, and recommending development blueprints and

technologies (Yang et al., 2007). In the built environment sector of Australia, (Lyth et al., 2007) recommend that education about and for climate change adaptation in accredited courses be addressed in an integrated way with education about and for climate change mitigation in Australia. Programs for Master and Ph.D degreees with specific applications for climate change impacts, vulnerability, adaptation, and capacity assessment have been established in many universities such as United Nations Univerwsity and The University of the West Indies.

15.3.2.7. Local and Traditional Knowledge

Local and traditional knowledge is gained by longtime recognition and adjustment to adverse events. The value of local knowledge was given primacy, be it to complement scientific climate data, to provide insights about and for climate change adaptation, or as a source of community-based environmental monitoring (Newsham and Thomas, 2011; Nakashima et al, 2012).

Rural populations have an considerable capacity to adapt to a range of climatic and non-climatic risks. However, this capacity does have limits that can be exceeded, especially when climate-related stresses are superimposed on other forces that give rise to vulnerability. Whether that threshold is exceeded is strongly influenced by the role that higher-level actors such as governments choose to play in providing adaptation assistance and capacity-building (McLeman et al., 2008). Local agro-ecological knowledge in North Central Namibia has provided farmers with resilience in the face of a highly variable, and hence uncertain, climate for perhaps hundreds of years (Newsham and Thomas, 2011). Most of the farmers in the Mekong river delta had applied them personally during major flood events in the past such as lifting the ground floor level, moving important items to upper floors, sending the children to day care centers, and selling livestock in case of very large floods (Birkmann, 2011). A summary of the integration of indigenous peoples' knowledge and observations of environmental processes in developing collective responses to climate change in Africa, Australia, small islands in the Asia-Pacific region, and the Arctic Ocean concludes that knowledge co-development helps to realize the purpose of developing climate change mitigation, adaptation strategies and actions (Green and Raygorodetsky, 2010).

Adaptation plans in developing countries tend to be stakeholder-driven, and implemented at the local level, where there is ample opportunity to include capacity-building as part of the adaptation plan (Berrang-Ford et al., 2011; Ford et al., 2011). Some recent climate community-scale adaptation plans as well as local adaptation methods have increased adaptive capacity by re-introducing indigenous varieties of crops that are selected by local farmers to be more resilient to changing conditions, and by initiating subsistence farming of a broad variety of vegetables in regions where local economies are dependent on the success of a few to sometimes one cereal crop (Deressa et al., 2009; Ensor and Berger, 2009).

15.3.3. Learning and Capacity-Building

15.3.3.1. Perception of Climate Change and Adaptation

In regions where there is awareness of climate change, people tend to have greater adaptive capacity and are more proactive in adaptation responses (Di Falco and Veronesi, 2011). However, there are still cases where there are gaps in knowledge between projected and perceived risks, as well as the degree of uncertainty. Individuals in flood-prone areas, in educated, affluent regions as well as developing countries, commonly miscalculate the degree of flood risk (Lata and Nunn, 2012; Ludy and Kondolf, 2012; Bell and Tobin, 2007). In some cases, people are aware of the dangers from flooding, riverbank erosion, etc., but do not necessarily attribute these risks to possible manifestations of climate change or the need to adapt to changing hazard frequency (Lata and Nunn, 2012). Additionally, there have been very few documented changes in forecasts, plans, design criteria, investment decisions, budgets or staffing patterns in response to climate risks (Berrang-Ford et al., 2011; Repetto, 2008). Because there is uncertainty about the future climate, new decision making tools need to be developed to cope with the impacts (Frommer, 2009). Adaptation in addition to mitigation is growing in mainstream policy efforts in response to climate change (Preston et al., 2009). However, there is a significant gap between adaptation recommendations and planning, and actual implementation efforts (Berrang-Ford et al., 2011; Repetto, 2008).

Building capacity to respond to change, whether expected or unexpected, creates resilience in communities to cope in the face of uncertainties in climate change projections. Because in both developed and developing countries, climate change adaptation is not viewed as a high priority because of more immediate needs that are based on short-term economic welfare (Coles and Scott, 2009). In developing countries there are also additional challenges in obtaining basic human requirements and to address human health. People in developing countries are particularly vulnerable to climate change and more directly impacted by climatic hazards, in part because their economies tend to be more natural resource-dependent (Nath and Behera, 2010; Reid et al, 2010; Handmer, 2009). Greater exposure is often accompanied by a deficit of adaptive capacity, because poorer, less educated populations tend to have less access to information about climate risks, and fewer economic and technical resources available (Sissoko et al., 2011; Reid et al., 2010).

15.3.3.2. Balancing Mitigation and Adaptation Responses to Climate Change

Three major themes where adaptation and mitigation issues are expected to coincide are agriculture, built environment and carbon sequestration through re-vegetation. In north central Victoria, Australia, Jones et al. (2007) describe adaptation and mitigation efforts that are jointly managed by a greenhouse consortium and a catchment management authority. They conclude that when managing climate change risks, adaptation and mitigation can be integrated at the operational level. However, significant gaps in understanding the benefits of adaptation and mitigation on the local and global scales remain. Links between adaptation and mitigation can be strengthened by reduction of emissions from deforestation and forest degradation, as they contribute to conserving and restoring ecosystem service (Van Aalst et al., 2008). The Klima-Werkstatt project (Germany) has invested in climate change mitigation and adaptation by communicating the added value of climate-friendly products and services. It provides demand-oriented knowledge transfer, and develops opportunities for stakeholder participation. A long-term goal is to develop a stakeholder network that is a self-supporting structure (Frommer, 2009).

15.3.3.3. Opportunities to Improve the Communication between Science and Practice in the Creation of Decisionmaking Support Information and Tools

Decision analysis tools have been valuable as a means of informing decision-makers. Whether it is multicriteria analysis, benefit-cost analysis, or any number of other tools, part of the analytical process will always be difficult and challenging primarily because of underlying uncertainties and differing local conditions (Smith et al., 2009). Decision support systems for climate adaptation have been set up for various sectors such as water (Stakhiv and Stewart, 2010), ecosystem (Munang et al, 2010), and tourism (Scott and Lemieux, 2010). Several efforts at defining frameworks to guide decision-makers dealing explicitly with climate adaptation are a valuable start, but more practice-oriented evaluation of such tools is merited (Smith et al., 2009). Networks are useful tools to develop individual adaptation options on the local and regional scales, e.g., the KLARA-Net builds on four fields of action, as follows: ‘spatial planning + building industry + water resources management’, ‘agriculture, viniculture + forestry’, ‘tourism’, and ‘health’. Each of these fields of action is operationalized by a working group (Frommer, 2009).

15.3.3.4. Developing Localized Information for Adaptation Planning and Implementation

Community-based climate change adaptation plans have included strategies for disseminating information on climate change and raising awareness using novel and creative methods, including art and essay writing contests, public information posters, and signs on rickshaws. Community engagement offers additional opportunities to discuss climate change impacts in plans by including baseline surveys of community members, public discussions at existing village level social platforms, demonstration projects, and festivals (Mekong River Commission, 2010; Ensor and Berger, 2009). It also allows incorporation of local or traditional knowledge into climate change adaptation plans.

Conservation management of important and threatened resources can be strengthened by using local knowledge. In Kenya, local ecological knowledge about the harvesting of papyrus and the recovery time between harvests has been critical to developing sound conservation strategies (Terer et al., 2012). The local plant knowledge shared among tribal elders of the Standing Rock Lakota tribe has served as an adaptive asset that may be important for the survival of cultural practices under changing climatic conditions (Ruelle and Kassam, 2011). Additionally, indigenous knowledge has been used to predict weather and climate for generations in Malawi. Local farmers in this Sub-Saharan region of Africa rely on indigenous knowledge, and have not found conventional scientific weather predictions as useful at the local level (Kalanda-Joshua et al., 2011)

15.3.4. Preparing for Surprises: Role of Buffers

Disaster risk reduction is an important but often unrecognised and undervalued service provided by healthy ecosystems (UNISDR, 2011). The above cases suggest that under transitional climate change, due to climate variability and extreme events appear thresholds may be breached more frequently. In the face of mounting evidence of the biological and ecological consequences of climate change, and of the possibility that changes to ecosystems may in fact be rapid, large, and sometimes irreversible (i.e. there may be thresholds that, once crossed, will exacerbate coping challenges to humans), policy makers and resource managers are confronted with the need to develop ways to proceed with decision-making in the realms of both mitigation and adaptation, despite the many uncertainties associated with thresholds (Scheffer, 2009).

For instance, forest protected areas help conserve ecosystems that provide habitat, shelter, food, raw materials, genetic materials, a barrier against disasters, a stable source of resources and many other ecosystem goods and services – and thus can have an important role in helping species, people and countries adapt to climate change. Such systems continue to serve as a natural storehouse of goods and services into the future (Dudley, 2008). As part of its Climate Change Framework Strategy (World Bank, 2008), the World Bank is advocating that ecosystem-based adaptation to maintain ecosystem services and sustainable income-generating activities in the face of climate change. The Reduced Emissions from Deforestation and forest Degradation (REDD) is a major effort to produce co-benefits of reducing GHGs and ensuring livelihoods (Ezzine-de-Blas et al, 2011). Protected areas have been recognized for several decades as an essential tool for conserving biodiversity.

Guatemala's Mayan Biosphere Reserve provides employment for over 7 000 people and generates an annual income of approximately US$47 million (Poverty and Conservation Learning Group (PCLG), 2002). In Madagascar, a study of 41 reserves found that the economic rate of return of the protected area system was 54 percent, essentially from watershed protection and to a lesser extent from ecotourism (Naughton-Treveset al., 2005). Thus, protected areas provide a safety net which can be valuable in times of stress, such as extreme climate events.

In Kimbe Bay, Papua New Guinea, a network of marine protected areas were developed based on coral reef protection to help the Bay's ecosystems withstand the impacts of a warming ocean and continue to provide food and other resources to local communities (Green et al., 2009). In Samoa, mangroves are being planted as part of a larger restoration project to enhance food security and protect local communities from storm surges anticipated to increase as a result of climate change. In Myanmar, communities are replanting mangroves in the Irawaddy Delta following the destructive impact of Cyclone Nargis, which devastated life and property in the absence of mangrove forests, cleared over time for paddy cultivation (Tripartite Core Group, 2008). Mangrove restoration in Vietnam has been shown to attenuate wave height and thus reduce wave damage and erosion (Mazda et al., 1997). Sri Lanka's Muthurajawela marsh, a coastal peat bog covering some 3,100 hectares, is an important part of local flood control. Low cost behavioral actions can provide benefits within a short time. One such example, the Humbo Project, assists communities affected by ecosystem degradation including loss of biodiversity, erosion, and flooding with an opportunity to benefit from carbon markets. Farmer-managed natural regeneration has been involved in the regeneration of 2728 ha of degraded native forests in Humbo, Ethiopia (Brown et al., 2010). Benefits have included fodder and firewood in the first year, and fruit and non-timber products within three years. Indigenous communities have been using such low cost actions for generations. Highly rated adaptation options that are being implemented add climate change to already existing activities for managing climate-related and other risks. These include

integrated ecosystem and water management, integrated coastal zone management, risk-based allocation policy, risk management as basic strategy, and new institutional alliances (Füssel, 2007).

The impacts of climate change now give these approaches a renewed role as adaptation tools for a changing climate. Their importance in this respect is threefold (see Box CC-EA):

1) In supporting species to adapt to changing climate patterns and sudden climate events by providing refuges and migration corridors
2) In protecting people from sudden climatic events and reducing vulnerability to floods, droughts and other weather-induced problems
3) Indirectly, in supporting economies to adapt to climate change by reducing the costs of climate-related negative impacts.

15.4. Governing Adaptation

An assessment of the literature draws attention to the point that adaptation to climate change poses governance challenges such that arrangements inconsistent with governance principles. The role of governance is highlighted in building adaptive capacity to climate change (Engle and Lemos, 2010) and providing the connections between individuals, communities, organisations, agencies, and institutions at multiple organizational levels (Folke et al., 2005) and in articulating top-down or bottom-up perspectives which are both critical in policy formulation (Unwin and Jordan, 2008). Such organisations often draws from various knowledge systems and experiences in developing a common understanding and policies on an issue critical for cross-institutional coordination and multi-stakeholders actions. For example, mechanisms to facilitate learning processes are considered to support the management of complexity especially in cross-boundary and large scale resource systems. (Huntjens et al., 2012).

15.4.1. Factors for Adaptation Governance - Institutional, Financial, Incentives, Information Management

An assessment of the literature points out that adaptation is influenced by social factors which require having learning, cooperation and communication as part of the planning especially at the local level where the action takes place (Resilient Cities, 2011). Accountability is considered a factor which highlights a participatory process (Akompab et al., 2012). Similarly, knowledge is important for adaptation governance following the opportunity it offers for learning especially in supporting a feedback mechanism for improvement (Nilsson et al., 2012) and providing the context for adaptive governance (Bruner, 2010) in contribution to overall adaptive capacity to climate change (Preston et al., 2011). Incentives for economic growth and profitability in coping with climate change are also considered as an important factor of governance (Manuel-Navarrete et al., 2009).

Institutional dynamics is a factor of adaptation governance especially in fostering transboundary collaboration (Wilder et al., 2010). This is important in overcoming some of the adaptation barriers posed by hierarchical government structure by shifting towards a more collaborative approach following the multi-dimension and numerous state and non-state actors involved in adaptation (Koch et. al., 2007). Decentralised decision-making, open information sources, and plurality of user interests are important factors of governance emphasized in the literature for promoting multilevel institutions that are robust and able to learn (Bisaro et al., 2010; Rao, 2012). Case studies of fishing communities in northern Norway and north-west Russia showed that the adaptive capacity of local actors to respond to climate change is influenced politically beyond their immediate locality, within broader governance system (Keskitalo and Kulyasova, 2009). An instructive lesson on cost-effectiveness, sustainability, citizenship and social cohesion is taken from the UNISDR (2011) Global Assessment Report on Disaster Rick Reduction. The report notes that the central government level responsibility for disaster risk management needs to be located in a ministry or department, preferably with planning oversight and some fiscal responsibility that can provide political authority and policy coherence across sectors. Emergency management organizations can rarely play that role. The decentralization of responsibilities to local governments needs to be accompanied by a decentralization of capacities and resources – otherwise it may become an obstacle to effective DRM. Decentralization should be incremental and approaches such as twinning may facilitate capacity development, and will only be effective when it is carried out in real partnership with disaster prone households and communities and

their organizations. There are a growing number of positive examples of such partnerships. In many countries this however implies a change in the culture of public administration and the critical role of key individuals or policy entrepreneurs at every level cannot be underestimated.

15.4.2. Cross-Sector Coordination

Norman (2009) highlights the importance of intergovernmental and multidisciplinary approaches integrating science and spatial planning as an efficient approach to address those conflicts between adaptation and mitigation as discussed in 15.2.2.2. Bottom-up approaches can be particularly useful in efforts seeking to reduce social and urban vulnerability, and addressing adaptation to climate change as a process. However, adaptation to climate change requires also complementary top-down strategies through urban and state institutions (Raschky, 2008).

Linking climate change risks to systems and sectors, and the corresponding response planning and implementation actions occurring at different spatial and temporal scales, requires cross-coordination. Jurisdictional scales and mandates across sectors, and local, national and sub-national policies, constrict the potential benefits of close dependencies between institutions, institutional systems and organizational units in planning and implementation of adaptation (Dovers and Hezri, 2010). The lack of coordination in the scale of governance together with unclear division of tasks and responsibilities of actors, especially under conflicting timescales of interventions, are significant barriers to adaptation (Biesbroek et al., 2011) and future coordination of implementation in the same framework with other policy domains (Biesbroek et al., 2010). As a multidimensional issue involving many state and non-state actors functioning on varying scales of global, national and local levels, a coordination of roles and responsibilities enhances institutional networking for effective implementation of climate change adaptation (Koch et al., 2007; Amundsen et al., 2010). The creation of larger governance networks through coordination is reported to expand the adaptive capacity of local actors (Keskitalo and Kulyasova, 2009), as well as enhancing learning opportunities for policy formulations (Owen, 2010).

As systems evolve to handle problems that surpass contemporary political/administrative systems and boundaries, governance serves as an adaptive tool in generating thrust and empowering communities in a collective vision to effectively and coherently respond to emerging issues of climate change in mitigation and adaptation (Meadowcroft, 2009), using justifiable manners in the attribution of benefits and responsibilities under differentiated capabilities (Paavola and Adger, 2006). The quality of governance of adaptation is increasingly relevant under different strategies of responding to climate change and reducing greenhouse gas emissions in ways that foster complementarity rather than counteraction, building synergies, and reducing trade-offs (Laukkonen et al., 2009). With a centralized national planning that has dominated climate change adaptation strategies such as NAPAs, NAPs etc., governance plays a central role in setting priorities among competing interests, managing inclusion or exclusion, and mediating power relations between various actors that often influences fairness or skewedness in the distribution of benefits. Capturing various perspectives of multiple stakeholders and actors holding different views, power and influence, is pivotal in mutually achieving short-term coping needs and long-term adaptation to climate change (O'Brien et al., 2008).

Governance of adaptation thus creates the space and conditions for achieving specific goals or collective outputs by aligning principles and norms for regulations, decision making procedures and organizations in providing an overarching system to comprehensively address a challenge (Biermann et al., 2009). As a dynamic process, changes in resource regimes under human-environment interactions exposed to climate impacts must be matched with timely institutional reforms in exploiting the windows of opportunities for planned interventions (Young, 2010; DeWulf et al., 2011). Against uncertainties of system response to climate impacts, coordination in resource extraction such as fishery, forestry, watersheds, etc., in deciding on flexibility in management regimes, capacity adjustment schemes and the regulations implemented are important adaptation measures (Mcllgorm et al., 2010). This thus draws on either a centralized guidance of collective action or using subunits in a decentralized system which are both effective based on the circumstances of application (OECD, 2004; Underdal, 2010).

The perturbations triggered by the changing climate to both human and natural systems equally affect current institutions prompting institutional changes in adapting to the changes (Dovers and Hezri, 2010). Except for

prioritizing interventions in national plans and strategies in favor of most vulnerable communities or sectors, there is no evidence of a risk-sharing framework underlying any adaptation planning process. This remains a contentious issue as inter-generational and intra-generational equity and ethical responsibility take hold on the governance process of climate change (Beckman 2008; Page 2008), which undermines the legitimacy and effectiveness of some of the decisions and measures put in place (Paavola, 2008a).

15.4.3. Sustaining Adaptation Implementation

Public-private partnerships are considered to favor sustainable outcomes of the implemented actions for adaptation but are not without their challenges. There are also opportunities such as injecting competitive networks capable of spurring innovative and dynamic governance of sustainability (Smith and Fischlein, 2010). The sustainability of private-public partnership is built on the effectiveness of the governance scheme driving the partnership as is the case of a tropical forest, whereby actions at local levels could have direct implications at the global level, and vice versa, e.g., in REDD+, following the nuances of the uniqueness of time and place (Van Laerhoven, 2010). Characterized by multiple users and uses of tropical forest goods and services under different access rights and ownership patterns, governance could minimize trade-offs under asymmetric power configurations and sustaining implemented adaptation actions (Agrawal et al., 2008). In avoiding a disproportionate risk burden in shared natural resource systems by poorly dependent communities such as in water basins, the devolution of management rights to local communities is considered as a measure for sustainably internalizing risks, enhancing the resilience and adaptive capacity of local communities (Engle and Lemos, 2010), and providing equity and justice (Thomas and Twyman, 2005) especially when captured in planning adaptation.

15.4.4. Feedback and Adjustment Mechanism

Effective governance thus provides safeguards to social-ecological thresholds surrounded by uncertainties, surprises and complex causalities capable of tipping the system. Migration, for example, carries the flip sides of a tested adaptive response (Barnett and Webber, 2010), as well as a risk source of vulnerability to natural resource system thresholds some of which are characterized by slow-onsets (Warner, 2010) which could be addressed with policy and institutional governance (Paavola, 2008b). There is historical evidence of mobility and population distribution as adaptive responses to environmental challenges especially among African herdsmen (Tacoli, 2009; Nakashima et al., 2012). However, the effectiveness of such a technique for adaptation is viewed as generating new risks and security concerns (Brown et al., 2007). Characterized by uncertainties and surprise events, the approaches for adaptation in adjustment to future climate change are considered in the literature to have inescapable feedback trade-offs, such as efficiency over equity or equity over cost and legitimacy, etc. (Adger et al., 2009a).

Joint planning, co-management or co-implementation are considered as cost-effective measures in addressing common risks, especially common pooled resource risks, using collective action such as transboundary water river basins (Wiering et al., 2010). This has resulted in regional initiatives such as in Europe through the EU for example, and other bilateral cross-border co-operation drawing on interdependencies and transnational actors sometimes operating in a political sphere, and steering a process outside of national jurisdictions but contributing to national interests (Andonova et al., 2009).

15.5. Research Needs for Maximizing Opportunities

This chapter reviewed the literature on climate change adaptation (CCA) to assess the progress and limitations of adaptation planning and implementation being undertaken at present. The focus of this chapter is on assessing cases at different levels, from international to local in various sectors from different aspects such as present status and characteristics of CCA planning and implementation, barriers and opportunities to adaptation, capacity for adaptation and capacity-building, and governance of adaptation. Research has identified major issues in moving from planning to implementation which concern reconciling short-term and long-term goals for vulnerability

reduction, overcoming the disconnect between local risk management practices and national institutional and legal frameworks, including mandates policy and planning.

The literature is clear that adaptation planning is transitioning from a phase of awareness and promotion to the construction of concrete responses in societies. The combined efforts of a broad range of international organizations, scientific reports, and media coverage and the very important, occurrence of ongoing extremes event impacts such as Hurricane Sandy and the Drought of 2012 in the US, have raised the importance of adaptation to climate change. In agreement with Biesbroek et al. (2010) and this Chapter, several strategies cite the possible economic damage of unavoidable climate change as a major motivating factor for action, however, few, if any, strategies actually analyze the costs of adaptation. New non-traditional areas of international concern are emerging in the area of national security and economy and trade and receiving increasing attention but are not yet amenable to assessment.

In the literature, more national-level plans and adaptation strategies for developed countries are mentioned than for developing countries; whereas, more implementation cases are documented at the local level in developing countries. Most national strategies appear to be based on potential impacts derived from international and national assessments without consistent and systematic use of regional climate scenarios (Biesbroek et al., 2010; Pulwarty et al. 2012; Chapter Regional Context). At the same time, as the social dimensions of adaptation have attracted more attention, it is emphasized to make the linkages between adaptation and development more explicit to link adaptation planning with co-benefits for development. Different sectors (e.g., disaster risk reduction, water resource planning, agriculture, urban planning) treat adaptation within their traditional context of planning to various degrees and a few are attempting to reconcile various model projects for risk analysis (e.g. Barsugli et al., 2012).

Separating investments that have been applied solely “adaptation” as opposed to “development” has proven difficult in many cases, particularly in defining or attributing the specific component that contributes to climate change adaptation funding beyond benefits to development per se. Studies comparing both formal adaptation plans and less formal adaptation studies several cities demonstrates that the focus is mostly on risk reduction and the protection of citizens and infrastructure, with very few such as Rotterdam seeing adaptation as opportunity for transformation (Heinrichs et al., 2011). Other sectors such as energy, transport, and built infrastructure remain less engaged.

Major investments in infrastructure projects designed to adapt to weather related hazards are being undertaken without awareness of the impacts of climate change on long-term sustainable development (Lasco et al., 2009). The reasons for the initial of attention have been identified as limited public awareness regarding practical links between poverty reduction and adaptation to climate change, and a perception of climate change adaptation as being, “expert driven” and limited to technological responses to identified changes in climate variables (Crabbé and Robin, 2006; Klein et al., 2007) although this is gradually changing (UNISDR, 2011; IPCC, 2012). Barriers to implementing climate change adaptation strategies in Mozambique resulted from differing perceptions of climate risk between farmers and policy-makers, and the perceived potential for negative consequences of the proposed adaptation plans.

Many climate-sensitive sectors in developing countries and marginalized communities in developed countries are currently not well adapted to the risks from current climate. For example, an area may have no or inadequate protection from current climate risks such as floods and drought. This has been termed the adaptation deficit (Burton and May, 2004). Most planning assessments do not include additional costs of reducing present vulnerability to a desired level. Most significantly lack of resources and analytical capabilities to deal with present risks has led to outsourcing of local adaptation plan development. These can generate acontextual recommendations, lacking both the social and historical contexts of a communities experience with climatic risks and more reliance on technological fixes (Crabbé and Robin, 2006; UNISDR, 2011; Pulwarty and Verdin, 2013). For example, despite the intention that city adaptation responses aim at an integrated approach, they tend to have sectoral responses, with limited integration of local voices.

Although national adaptation responses have diverse processes and outcomes in both developed and developing countries, the national level plays a key role in adaptation planning and implementation. NAPAs of developing countries are favorably viewed as being country-driven in their development. Many NAPAs propose adaptation strategies that are almost identical with standard development projects. Bottom-up approaches are particularly useful in efforts seeking to reduce social vulnerability and addressing adaptation to climate change as a process. However,

adaptation to climate change also requires complementary top-down strategies through different levels of governments. Another feature is that good practices have emerged in developing countries. Adaptation efforts in some countries, such as Bangladesh, Cambodia, Bhutan, and the Maldives, which are linked to development funding, provide a 'win-win' adaptation strategy that strengthens resilience to climate change while improving economic stability and environmental quality. However, securing the long-term financing for ongoing adaptation is rarely addressed beyond the project phase.

Urban areas are showing progress of CCA planning and implementation. A growing number of adaptation plans are reported, and urban areas are the focus of a number of local planning initiatives. Urban areas tend to formalize and institutionalize their work through the establishment of dedicated climate units, either within a relevant department or as a separate and cross-cutting office. However, with some exceptions, few local governments have had the resources, capability, and coordination to institutionalize adaptation to climate change.

Monitoring and early warning systems designed to inform social learning play important roles in helping to adjust adaptation implementation, especially on the local scale. Viewing risk communication as a social process allows for effective participatory approaches, network- building and the production of visual, compelling and engaging information for use by local stakeholders. The lack of coordination in the scale of governance together with unclear division of tasks and responsibilities of actors, especially under conflicting timescales of interventions e.g. emergency versus adaptive, are significant barriers to adaptation and future coordination of implementation.

A no-regrets approach based on co-benefits to emphasize on disaster risk management are increasingly advocated. However, climate change adaptation and disaster risk reduction are, at present, handled by separate agencies, although they share similar objectives and challenges. The experience on adaptation to date illustrates the need for better coordination and the development of collaborative networks. Developing frameworks and metrics for evaluating adaptation, that is cognizant of the experience in disaster risk, integrated watershed, coastal zone and the natural and social capita experience and literatures remain a central need. The potential for ecosystem-based approaches is also increasingly being realized (e.g. Munroe et al., 2011) offering opportunities that integrate with or even substitute for the use of engineered infrastructure or other technological approaches. Examples include sustainable water and habitat management, where river basins, aquifers, flood plains, and their associated vegetation are managed or restored to provide resilient water storage and enhanced base-flows, flood regulation services, reduction of erosion/siltation rates, and more ecosystem goods (e.g., Midgley et al., 2012; Opperman et al., 2009). The most significant contributions of ecosystem-based approaches may lie in allowing for flexibility as rapid transitions and thresholds are met, and in lowering the risk of maladaptation by substituting for or delaying the need for engineering solutions. Although the importance of evaluation of this area in adaptation is recognized, it is under-researched.

Most critical is the need for research to inform practice on the governance, including the leadership of and public engagement in adaptation. As a multidimensional concern involving many state and non-state actors and decisions, functioning on varying scales of global, national and local levels, improved multilevel governance offers the chance to identify options for moving from reactive to proactive adaptation processes.

Frequently Asked Questions

FAQ 15.1: What is the present status of climate change adaptation planning and implementation across the globe?

Climate change adaptation has been brought to people's attention due to the recent media coverage and various reports, leading to a growing number of adaptation plans both in developed and developing countries. The assessment of literature indicates adaptation planning is transitioning from a phase of awareness and promotion to the construction of concrete responses in societies. There is a wide range of adaptation plans reflecting the specific context, needs, values, and perceptions of societies. More national-level plans and adaptation strategies have been established in developed countries than in developing countries; whereas, more implementation cases are reported at the local level in developing countries. The plans developed by developing countries appear to focus more on climate change impacts and disaster risk management, where urban areas have become the focal point in local

planning initiatives. However, except for large cities, few local governments have the resources, capability, and coordination ability to institutionalize adaptation to climate change. In spite of these limitations, early discussions of the transformations needed in the structure and operational culture of institutions to address adaptation to climate change are occurring in both developed and developing countries. Monitoring, evaluating, and reviewing adaptation planning and implementation are critical aspects of complex adaptation planning as a social process.

FAQ 15.2: How are climate change policies operationalized at different scales (e.g., international, national, and local)?

National and subnational plans are developed by many developed countries and more and more plans are being produced by developing countries through the National Adaptation Programmes of Action (NAPA) and the National Adaptation Plans (NAPs). What lacks is the mechanism and institutional capacity to bridge between the national/sub-national level and the local level adaptation planning. NAPAs of developing countries are favorably viewed as being country-driven in their development. Many NAPAs propose adaptation strategies that are almost identical with standard development projects. Bottom-up approaches are particularly useful for reducing social vulnerability and addressing adaptation to climate change as a process. However, adaptation to climate change also requires complementary top-down strategies through different levels of governments to realize mainstreaming adaptation. Sustainable development and disaster risk management are two approaches to incorporate adaptation planning into these various levels, and these themes are particularly important and relevant at the local community in developing countries. In general, progress has been slow with regard to integrating disaster risk management and climate change adaptation at the national, subnational, and local level. To overcome such gaps, better coordination between risk management agencies and climate change adaptation efforts is needed.

FAQ 15.3: What capacities currently exist for implementing climate change adaptation?

In general there are two sources of adaptive capacity: institutional and organizational support, and science and technology. Adaptation capacity is supported by adaptation governance which occurs at multiple scales: international, national, sub-national, and local. Integrating and coordinating adaptation planning and implementation across these vertical levels of governance provides one big challenge while doing the same across different sectors (e.g., disaster risk reduction, water resource planning, agriculture, urban planning) and different sections or departments of a government provides yet another challenge. For successful implementation of adaptation plans, it is needed to promote both vertical and horizontal integration and coordination of adaptation planning across different governance levels and sectors. Science and technology provide another source of capacity. Development and diffusion of new technologies and management practices expands the range of adaptation possibilities by increasing opportunities or reducing costs. Knowledge development and sharing includes the development of science and new technologies, early warning systems, technology transfer and diffusion, education and training, and the use of local and traditional knowledge.

Cross-Chapter Box

Box CC-EA. Ecosystem Based Approaches to Adaptation - Emerging Opportunities

[Rebecca Shaw (USA), Jonathan Overpeck (USA), Guy Midgley (South Africa)]

Ecosystem-based approaches to adaptation (also termed Ecosystem-based Adaptation, EBA) integrate the use of biodiversity and ecosystem services into climate change adaptation strategies (e.g., CBD, 2009; Munroe *et al.*, 2011; Munroe *et al.*, 2011). EBA is implemented through the sustainable management of natural resources, as well as conservation and restoration of ecosystems, to provide and sustain services that facilitate adaptation both to climate variability and change (Colls *et al.*, 2009). The CBD COP 10 Decision X/33 on Climate Change and Biodiversity states further that effective EBA also "takes into account the multiple social, economic and cultural co-benefits for local communities".

The potential for EBA is increasingly being realized (e.g., Munroe *et al.*, 2011), offering opportunities that integrate with or even substitute for the use of engineered infrastructure or other technological approaches. Engineered defenses such as dams, sea walls and levees, may adversely affect biodiversity, resulting in maladaptation due to damage to ecosystem regulating services (Campbell *et al.*, 2009, Munroe *et al.*, 2011). There is some evidence that

the restoration and use of ecosystem services may reduce or delay the need for these engineering solutions (CBD, 2009). Well-integrated EBA is also more cost effective and sustainable than non-integrated physical engineering approaches, and may contribute to achieving sustainable development goals (e.g., poverty reduction, sustainable environmental management, and even mitigation objectives), especially when they are integrated with sound ecosystem management approaches. EBA also offers lower risk of maladaptation than engineering solutions in that their application is more flexible and responsive to unanticipated environmental changes.

EBA provides opportunities particularly in developing countries where economies depend more directly on the provision of ecosystem services (Vignola *et al.*, 2009), to reduce risks to climate change impacts and ensure that development proceeds on a pathways that are resilient to climate change (Munang *et al.*,). In these settings, ecosystem-based adaptation projects may be readily developed by enhancing existing initiatives, such as community-based adaptation and natural resource management approaches (e.g., Khan *et al.*, 2012, Midgley *et al.*, 2012; Roberts *et al.*, 2012)

Examples of ecosystem based approaches to adaptation include:

- Sustainable water management, where river basins, aquifers, flood plains, and their associated vegetation are managed or restored to provide resilient water storage and enhanced baseflows, flood regulation services, reduction of erosion/siltation rates, and more ecosystem goods (e.g., Midgley *et al.*, 2012, Opperman *et al.*, 2009).
- Disaster risk reduction through the restoration of coastal habitats (e.g., mangroves, wetlands and deltas) to provide effective measure against storm-surges, saline intrusion and coastal erosion;
- Sustainable management of grasslands and rangelands to enhance pastoral livelihoods and increase resilience to drought and flooding;
- Establishment of diverse and resilient agricultural systems, and adapting crop and livestock variety mixes to secure food provision. Traditional knowledge may contribute in this area through, for example, identifying indigenous crop and livestock genetic diversity, and water conservation techniques;
- Management of fire-prone ecosystems to achieve safer fire regimes while ensuring the maintenance of natural processes.

It is important to assess the appropriate and effective application of EBA as a developing concept through learning from work underway, and to build understanding of the social and physical conditions that may limit its effectiveness. Application of EBA, like other approaches, is not without risk, and risk/benefit assessments will allow better assessment of opportunities offered by the approach.

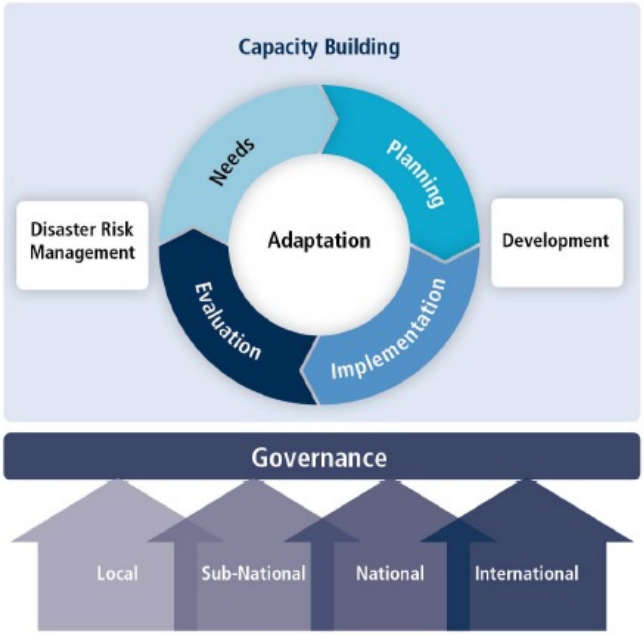

Figure 15-1: Four main phases of adaptation planning and implementation: needs, planning, implementation, and evaluation. This is a cyclic, iterative process. Building capacity to respond to change, whether expected or unexpected, creates resilience in societies to cope in the face of uncertainties in climate change projections. Efforts in adaptation need to be linked with development or disaster risk management. This is particularly true and important in developing countries. Adaptation governance underlies the capacity and governance takes place at multiple scales: international, national, sub-national, and local.

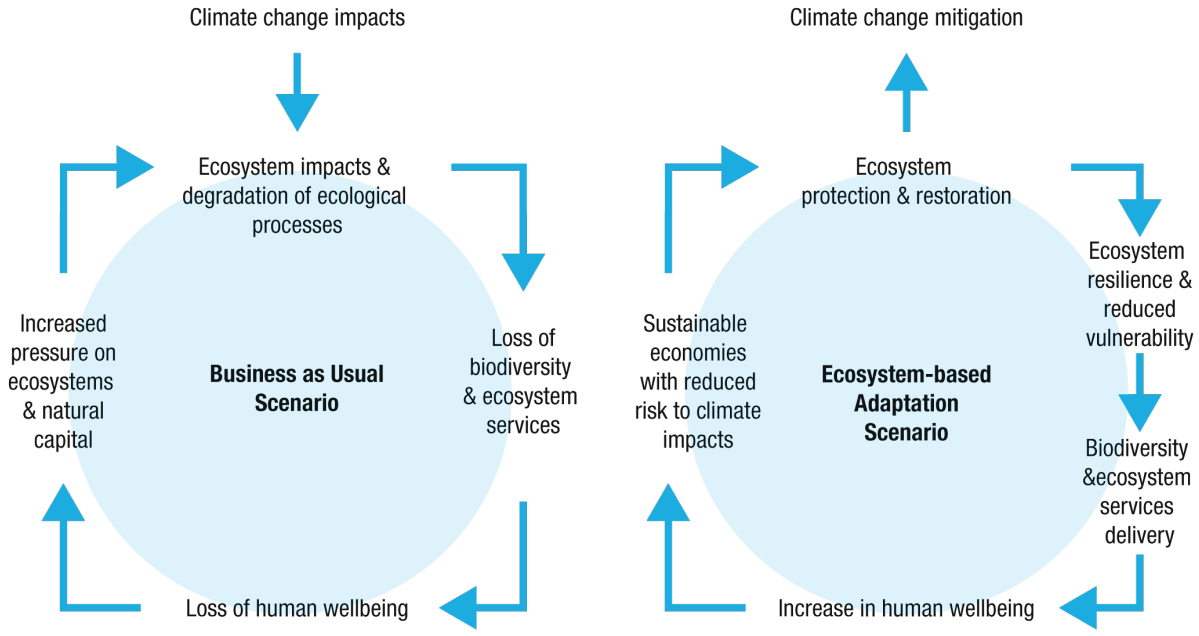

Figure EA-1: Adapted from Munang *et al*. (2013). Ecosystem based adaptation approaches to adaptation can utilize the capacity of nature to buffer human systems from the adverse impacts of climate change through sustainable delivery of ecosystems services. A) Business as Usual Scenario in which climate impacts degrade ecosystems, ecosystem service delivery and human well-being B) Ecosystem-based Adaptation Scenario which utilizes natural capital and ecosystem services to reduce climate-related risks to human communities.

Chapter 16. Adaptation Opportunities, Constraints, and Limits

Executive Summary

A range of factors constrain the planning and implementation of adaptation actions and potentially reduce their effectiveness (*high agreement, robust evidence)*. The availability of resources for adaptation continues to feature strongly in the adaptation literature as a significant constraint on adaptation, as does uncertainty regarding future climate and disaster risk at national and regional scales. However, there is increasing awareness within the literature of the dynamics of social processes and governance that mediate the entitlements of actors to resources and promote social learning regarding adaptation. The manner in which these constraints manifest and their implications for the capacity of an actor to achieve adaptation objectives vary significantly across different regions and sectors as well as across different social and temporal scales. Some constraints to adaptation are a consequence of inherent trade-offs among different perceptions of risk and the allocation of finite resources, and therefore, adaptation efficiency and effectiveness may often be less than optimal. [16.2, 16.3]

Evidence from both natural and human-managed systems demonstrates the existence of limits to adaptation to climatic and other related environmental and socio-economic risks (*high agreement, robust evidence*). Archeological and historical evidence is providing growing insights into periods of societal change, including catastrophic societal failures, in which climate change or variability may have been a contributory factor. Such evidence indicates that socioeconomic and cultural factors mediate societal responses to emergent risks such as changes in climate and influence the likelihood of limits to adaptation being reached and exceeded. [16.3, 16.5, 16.5.1, 16.5.2, 16.8, Box16-3]

Limits to adaptation emerge as a result of the interaction between climate change and other biophysical and socioeconomic constraints (*high agreement, robust evidence*). Recent studies have provided valuable insights regarding the presence of so-called 'tipping points', 'key vulnerabilities', or 'planetary boundaries' for the Earth system. While these biophysical thresholds represent an important determinant of limits to adaptation, particularly for natural systems, socioeconomic conditions and trends also contribute to the definition of limits in social systems. In particular, demographic change as well as economic development will influence future human vulnerability and adaptive capacity, but the externalities of these processes may reduce the resilience of natural systems to adapt to a changing climate. [16.2, 16.3, 16.4]

Much of the literature identifying limits to adaptation for specific systems and/or management objectives are associated with biophysical systems, particularly ecosystems and/or individual species that are dependent upon specific biophysical regimes (*high agreement, robust evidence*). Those species that already persist at the

edge of their thermal and/or hydrological limits are likely to be most vulnerable to a changing climate. Species do have the capacity to adapt through phenotypic and genetic responses. The physiological and/or ecological thresholds imposed by climate effectively represent 'hard' limits in that no adaptation options can be implemented to enable sustainability once thresholds are exceeded. As a broad range of human values and managed systems are dependent upon ecosystems goods and services, 'hard' limits in ecological systems have the potential to constrain or limit adaptation in socioeconomic systems. [16.4.1]

Social limits to adaptation are dynamic over space and time due to normative judgments and values of actors, technological change, and emergent properties of complex systems (*high agreement, low evidence*). Limits to adaptation are likely to be exceeded locally before being exceeded regionally and at larger spatial scales. This should provide regional, national and international actors with an early warning of possible future adaptation constraints and limits. Some adaptation limits may be removed over time due either to changing normative judgments and values of actors which lead to the abandonment of previously held objectives, or through technological advancement. However, some actors may find that transformational changes are required that necessitate trade-offs in some values in order to preserve others [16.4.1, 16.4.2]

The greater the magnitude of climate change, the greater the likelihood that adaptation will encounter limits (*high agreement, low evidence*). Mitigation and adaptation are complementary strategies. Greater adaptation efforts will be required to achieve the objectives of actors if mitigation efforts are not successful in avoiding high magnitudes of climate change. There are, however, limits to the extent to which adaptation could reduce the impacts not avoided by mitigation, and residual loss and damage is may occur despite adaptive action. Knowledge about limits to adaptation could therefore inform the level and timing of mitigation and might justify early mitigation action. However, as the future capacity of actors in different sectoral and regional contexts to adapt to climate change remains uncertain, the implications of adaptation for mitigation demand will be contingent upon economic development pathways and investments made to enhance the adaptive capacity of vulnerable actors. [16.3.1.2, 16.5, 19.6, 19.7, 20.5.3]

The capacity to describe and predict limits to adaptation is significantly impaired by the complexity of socio-ecological systems (*high agreement, low evidence*). While there is high agreement that limits to adaptation exist, detailed understanding of the level at which climate change impacts may impose an intolerable risk to social objectives (the definition of adaptation limits adopted here) is available only for a small number of ecosystems and crop species. Any assessment of limits to adaptation in human systems is preliminary because of uncertainty about the existence and level of adaptation limits, and whether these limits are hard or soft. Furthermore, social, economic and cultural trends and conditions, including uncertainty regarding actors' objectives and values and how they evolve over time further confound explicit definitions of limits. Thus while climate change raises 'reasons for concern' regarding the sustainability of various natural and human systems, there is little evidence to support climate thresholds, such as a 2°C increase in global mean temperature, as being robust definitions of limits to adaptation. [16.4.2]

Opportunities exist for actors at all geographical and institutional levels and in different development contexts to facilitate, initiate and implement effective adaptation action (*medium agreement, medium evidence*). Adaptation action at all levels – from households, firms or municipalities to national government agencies and regional economic integration organizations – is influenced by resources made available by third parties, including the sharing of knowledge and information, the transfer or technologies, and the provision of financial resources. In addition, national and international public policy can encourage the preparation and implementation of national adaptation strategies. Mainstreaming adaptation into planning and decision-making, including official development assistance, is an opportunity for enhancing the effectiveness and efficiency of adaptation investments. [16.6]

Avoiding limits to adaptation is a complex management challenge necessitating new integrative forms of risk governance (*medium agreement, low evidence*). Limits to adaptation are influenced by cultural, institutional and socio-economic factors. Consequently avoiding limits will necessitate policy responses and awareness that goes beyond greenhouse gas mitigation and adaptation responses alone. Driving forces such as inequality and the disproportionate vulnerability of marginalized actors to climate-related disasters and catastrophic losses will need to

be addressed. Hence, a portfolio of local, national, and international strategies will be needed to facilitate sustainable development that expands the range of climate to which socio-ecological systems can adapt. [16.4, 16.6, 16.7]

16.1. Introduction and Context

Since the IPCC's *Fourth Assessment Report* (AR4), demand for knowledge regarding the planning and implementation of adaptation as a strategy for climate risk management has increased significantly ((Park *et al.*, 2011; Preston *et al.*, 2011a). This chapter assesses the latest literature on biophysical and socioeconomic constraints on adaptation and the potential for such constraints to pose limits to adaptation. It also examines the circumstances that create opportunities for adaptation and the ancillary benefits that may arise from the implementation of adaptation policies and measures. Given increasing evidence of potential limits to adaptation, the chapter also examines the literature on transformation as a consequence of, or response to, adaptation limits.

To facilitate this literature assessment, this chapter provides an explicit framework for conceptualizing opportunities, constraints, and limits (16.2). In this framework, the core concepts including definitions of adaptation, vulnerability, and adaptive capacity are consistent with those used previously in the AR4. However, the material in this chapter should be considered in conjunction with that of other complementary AR5 WGII chapters. These include Chapter 14 (*Adaptation Needs and Options*), Chapter 15 (*Adaptation Planning and Implementation*), and Chapter 17 (*Economics of Adaptation*). Material from a range of other WGII chapters is also relevant to informing adaptation opportunities, constraints, and limits, particularly Chapter 2 (*Foundations for Decision-Making*) and Chapter 19 (*Emergent Risks and Key Vulnerabilities*). Furthermore, while this chapter synthesizes material from each of the sectoral and regional chapters, readers are encouraged to refer directly to those chapters for more detailed information.

In order to enhance the policy relevance of the assessment of adaptation opportunities, constraints, and limits, this chapter takes as its entry point the perspective of actors as they consider adaptation response strategies over near, medium and longer terms (Dow *et al.*, 2013; Dow *et al.*, In Press). Actors may be individuals, communities, organizations, corporations, NGOs, governmental agencies, or other entities responding to real or perceived climate-related stresses or opportunities as they pursue their objectives (Patt and Schröter, 2008a; Blennow and Persson, 2009; Frank *et al.*, 2011). These actors may seek to implement near-term adaptation policies and measures under constraining circumstances while simultaneously anticipating or working to alleviate those constraints to enable greater flexibility and adaptive capacity in the future. Therefore, it is necessary to consider diverse timeframes for possible social, institutional, technological and environmental changes. These timeframes also differ in the types of uncertainties that are relevant, ranging from those of climate scenarios and models, possible thresholds, nonlinear responses or irreversible changes in social or environmental systems, and the anticipated magnitude of impacts associated with higher or lower levels of climate change (Meze-Hausken, 2008; Hallegatte, 2009a; Briske *et al.*, 2010).

The range of adaptation options available to actors to achieve their objectives vary with capacities, social context and the dynamics of climate-environment interactions. Hence, a robust understanding of adaptive capacity is necessary to evaluate adaptation needs and options (Chapter 14) and the challenges associated with their implementation (Chapter 15). The manner in which actors frame adaptation and their objectives also influences adaptation processes. Much of the dialogue on adaptation has focused on incremental adaptation, wherein actors aim to make adjustments to management practice and behavior to secure status quo values and objectives (Garrelts and Lange, 2011). Such adaptation may include portfolios of responses as it may not be possible to completely 'climate proof' a system, making insurance or other support mechanisms important means of building resilience. However, some adaptations may encounter future constraints or limits by promoting lock-in to a technology or fostering path dependence around a set of strategies, which can lead to maladaptation (Berkhout, 2002; Barnett and O'Neill, 2010; Eriksen *et al.*, 2011). Hence, the adaptation discourse has recently expanded to consider more transformational framings of adaptation associated with fundamental changes in actors' objectives or values to shift from a position of increasing vulnerability to one of increasing opportunity (Stafford Smith *et al.*, 2011; Pelling, 2011; Park *et al.*, 2011; Kates *et al.*, 2012; O'Neill and Handmer, 2012).

To provide further background and context, this chapter proceeds by revisiting relevant findings on adaptation opportunities, constraints, and limits within the AR4 and the more recent IPCC *Special Report on Managing the Risks of Extreme Events and. Disasters to Advance Climate Change Adaptation* (SREX) (IPCC, 2012). The chapter then presents a framework for adaptation, opportunities, and limits with an emphasis on explicit definitions of these concepts to facilitate assessment. Key components of this framework are assessed in subsequent chapter sections including the synthesis of how these components are treated among the different sectoral and regional chapters of the AR5 WGII report. The chapter concludes with an assessment of the ethical implications of adaptation constraints and limits and a synthesis of what the adaptation literature suggests are pathways forward for research and practice to capitalize on opportunities, reduce constraints, and avoid limits.

16.1.1. Summary of Relevant AR4 Findings

The AR4 *Summary for Policymakers* of Working Group II concluded that there are "*formidable environmental, economic, informational, social, attitudinal and behavioural barriers to the implementation of adaptation*" and that for developing countries, "*availability of resources and building adaptive capacity are particularly important*" (IPCC, 2007a). These findings were based primarily on Chapter 17, *Assessment of Adaptation Practices, Options, Constraints and Capacity* (Adger *et al*., 2007). The key conclusion from Adger *et al*. (2007), as relevant to this chapter, was as follows: "*There are substantial limits and barriers to adaptation (very high confidence)*". The authors go on to identify a range of barriers including the rate and magnitude of climate change, as well as constraints arising from technological, financial, cognitive and behavioral, and social and cultural factors. The authors also noted both significant knowledge gaps and impediments to the sharing of relevant information to alleviate those gaps.

These findings were further evidenced by the sectoral, and particularly, regional chapters of the AR4 WGII report which provided information regarding the similarities and differences among regions with respect to the manner in which adaptation opportunities, constraints, and limits manifest. For example, the chapters assessing impacts and adaptation in Africa, Asia, and Latin America collectively emphasize the significant constraints on adaptation in developing nations. For Africa, Boko *et al*. (2007) suggest there is evidence of an erosion of coping and adaptive strategies as a result of varying land-use changes and socio-political and cultural stresses. For Asia, Cruz *et al*. (2007) note that the poor usually have very low adaptive capacity due to their limited access to information, technology and other capital assets, making them highly vulnerable to climate change. For Latin America, Magrin *et al*. (2007) find that socio-economic and political factors seriously reduce the capability to implement adaptation options. Meanwhile, the chapter on Small Islands by Mimura *et al*. (2007) identifies several constraints to adaptation including limited natural resources and relative isolation. For all of these regions, adaptation challenges are linked to governance systems and the quality of national institutions as well as limited scientific capacity and ongoing development challenges (e.g., poverty, literacy, and civil and political rights).

The AR4 also provided evidence that constraints on adaptation are not limited to the developing world. For example, Hennessy *et al*. (2007) find that while adaptive capacity in Australia and New Zealand has been strengthened, a number of barriers remain including tools and methods for impact assessment as well as appraisal and evaluation of adaptation options. They also note weak linkages among the various strata of government regarding adaptation policy and skepticism among some populations toward climate change science. Similarly for North America, Field *et al*. (2007) identify a range of social and cultural barriers, informational and technological barriers, and financial and market barriers. The chapter on Europe mentions the limits faced by species and ecosystems due to lack of migration space, low soil fertility and human alternations of the landscape (Alcamo *et al*., 2007). Finally, in the chapter on the Polar Regions, Anisimov *et al*. (2007) note that indigenous groups have developed resilience through sharing resources in kinship networks that link hunters with office workers, and even in the cash sector of the economy. However, they conclude that in the future, such responses may be constrained by social, cultural, economic, and political factors.

A few other AR4 chapters assessed literature relevant to this chapter. Chapter 18 - *Inter-Relationships between Adaptation and Mitigation* (Klein *et al*., 2007) discusses the possible effect of mitigation on adaptation (an issue also considered by Working Group III, in particular by (Fisher *et al*., 2007) and (Sathaye *et al*., 2007)). Finally, Chapter

19 -*Assessing Key Vulnerabilities and the Risk from Climate Change* (Schneider *et al*., 2007) outlines how the presence of adaptation constraints and limits is a contributing factor to vulnerability, possibly resulting in significant adverse impacts. Chapters that address similar themes ablso appear in the AR5, and cross-references are provided in this chapter to this more recent material as appropriate.

16.1.2. Summary of Relevant SREX Findings

The IPCC's SREX report assesses a broad array of literature on climate change, extreme events, adaptation, and disaster risk reduction. A central framing concept for the SREX was the assertion that (Lavell *et al*., 2012 pg. 37),

> *" . .while there is a longstanding awareness of the role of development policy and practice in shaping disaster risk, advances in the reduction of the underlying causes – the social, political, economic, and environmental drivers of disaster risk – remain insufficient to reduce hazard, exposure, and vulnerability in many regions (UNISDR, 2009, 2011) (high confidence)."*

As reductions in vulnerability can arise from either capitalizing on opportunities, relaxing constraints or removing limits to adaptation, this assessment of the relevant SREX material focuses on how the key findings of the SREX provide insights relevant to the treatment of opportunities, constraints and limits in this chapter.

With respect to opportunities, the linkages between development and disaster risk reduction provide a number of avenues for facilitating adaptive responses toward enhanced societal resilience to natural disasters and climate change. For example, the SREX highlights the benefits of considering disaster risk in national development planning and if strategies to adapt to climate change are adopted (Lal *et al*., 2012). The observed dependence of disasters at national and regional scales upon underlying patterns of development are indicative of the opportunities for increasing societal resilience through sustainable development. In particular, incorporating adaptation into multi-hazard risk management may be an effective strategy for the efficient integrated management of natural hazards and future climate risk (O'Brien *et al*., 2012). Disasters provide potential opportunities for reducing future weather- and climate-related risk through disaster response and recovery processes (Cutter *et al*., 2012). Capitalizing on this opportunity often necessitates careful planning for the staging of response efforts to ensure the demand for near-term recover does not jeopardize opportunities for enhanced resilience over the long-term. There may also be opportunities for enhancing international assistance for climate adaptation through more robust finance mechanisms for mainstreaming adaptation into disaster risk management and sustainable development (Burton *et al*., 2012).

The report also provides discussion of the constraints associated with enhancing disaster risk reduction as well as climate adaptation. In particular, ongoing development deficits as well as inequality in coping and adaptive capacities pose fundamental challenges to disaster risk management and adaptation (Cardona *et al*., 2012). Although such challenges can propagate from the bottom up, the SREX notes that national systems and institutions are critical to the capacity of nations to manage the risks associated with climate variability and change (Lal *et al*., 2012). Yet capacity at one scale does not necessarily convey capacity at other scales (Burton *et al*., 2012). Even in the presence of robust institutions, rates of socioeconomic and climate change can interact to constrain adaptation. For example, O'Brien *et al*. (2012) note that rapid socioeconomic development in vulnerable urban areas can increase societal exposure to natural hazards while simultaneously constraining the capacity of actors to implement policies and measures to reduce vulnerability. For many regions, such socioeconomic change may be a greater contributor to vulnerability than changes in the frequency, intensity, or duration of extreme weather events. Overcoming these constraints to achieve development objectives is challenged by a paucity of disaster data at the local level as well as persistent uncertainties regarding the manifestation of extreme events in future decades (Seneviratne *et al*., 2012; Cutter *et al*., 2012).

The SREX also cautioned that natural hazards, climate change and societal vulnerability can pose fundamental limits to sustainable development. Such limits can arise from the exceedance of biophysical and/or societal thresholds or tipping points (Lal *et al*., 2012; O'Brien *et al*., 2012; Seneviratne *et al*., 2012). Accordingly, the SREX concludes that adaptation actions must include not only incremental adjustments to climate variability and climate change but also transformational changes that alter the fundamental attributes of systems of value. Such

transformation may be aided by actors questioning prevailing assumptions, paradigms, and management objectives toward the development of new ways of managing risk and identifying opportunities (O'Brien *et al*., 2012).

16.2. A Risk-Based Framework for Assessing Adaptation Opportunities, Constraints, and Limits

Risk is an intrinsic element of any understanding of "*dangerous anthropogenic interference with the climate system*" (UNFCCC, 1992) and the associated assumptions about the capacity of biophysical systems, social groups and societies to adapt to climatic change. The UNFCCC refers specifically to adaptation of ecosystems, threats to food production and the sustainability of economic development. While there is evidence that there are opportunities to adapt to climate change impacts in natural and human systems, there is also evidence that the potential to adapt is constrained, or more difficult, in some situations, and faces limits in others (e.g. Adger *et al*., 2009b; Dow *et al*., In Press).

Consistent with for the development of risk management approaches to guide adaptation response to climate change (IPCC, 2012) this chapter utilizes a risk-based framework and a set of linked definitions of opportunities, constraints and limits to adaptation (see Box 16-1). A number of different meanings are ascribed to these key terms and these have worked to confuse an important scientific and policy debate. The AR4, for example, used the terms constraints, barriers, and limits interchangeably to describe general impediments to adaptation (Adger *et al*., 2007), and similar ambiguities are evident across the literature (O'Brien, 2009; Biesbroek *et al*., 2009; de Bruin *et al*., 2009a). The integrated set of definitions employed here aims to clarify discussions in this realm. The framework and definitions draw on a number of literatures (Dow *et al*., In Press), in particular vulnerability assessment (Füssel, 2006; Füssel and Klein, 2006a) and risk assessment (Jones, 2001; Klinke and Renn, 2002; Renn, 2008; NRC, 2010) as well as climate adaptation (Hulme *et al*., 2007; Adger *et al*., 2009b; Hall *et al*., 2012).

Building on the risk management approach, we present a set of definitions of opportunities, constraints and limits to adaptation. An explicit focus on risk is particularly useful to understanding climate adaptation. Adaptation is intended to reduce the risk to things we value (Adger *et al*., 2012b). The concept of risk integrates the dimensions of probability and uncertainty with the material and normative dimensions that shape societal response to threats. The framing is grounded in an actor-based perspective which acknowledges that social actors from individuals to agencies or governments, and biophysical entities from species to habitats to ecosystems have different objectives and resources with respect to adaptation.

Figure 16-1 relates judgement about risk and the ability to maintain risks at a tolerable level to the concept of adaptation and adaptation opportunities, constraints, and limits (Box 16-1). Drawing on the work of Klinke and Renn (2002)(2002), we view individual actors as addressing risks in one of three categories. Acceptable risks are risks deemed so low that additional efforts at risk reduction, in this case climate adaptation efforts, are not justified. Tolerable risks relate to situations where adaptive, risk reduction efforts are required and effective for risks to be kept within reasonable levels. The scope of risks that fall within the tolerable area is influenced by adaptation opportunities and constraints. As discussed further in sections 16.3 and 16.7, these opportunities and constraints may be physical, technological, economic, institutional, legal, cultural, or environmental conditions(Yohe and Tol, 2002; Meze-Hausken, 2008; Patt and Schröter, 2008a; Adger *et al*., 2009b; Moser and Ekstrom, 2010; Adger *et al*., 2012a; Adger *et al*., 2012b). Constraints may limit the range of adaptation options leaving the potential for 'residual damages' which nevertheless are deemed to remains at a tolerable level. There are also a host of perceptual, economic and institutional factors that determine whether or not organizations in the private or public sectors choose to adapt to reduce potential vulnerabilities or avoid climate change impacts (Ivey *et al*., 2004; Naess *et al*., 2005; Moser *et al*., 2008; Storbjork, 2010; Farley *et al*., 2011; Berrang-Ford *et al*., 2011; Berkhout, 2012) (Also see AR5 2.2; 14.4; 16.3.1.1; 17.3). In particular, the economic and other costs of adaptation may be perceived to outweigh the uncertain future benefits of adaptation. Within this category, some level of residual damage following adaptation may be tolerable (Stern *et al*., 2006; de Bruin *et al*., 2009a)

[INSERT FIGURE 16-1 HERE
Figure 16-1: Conceptual model of the determinants of acceptable, tolerable and intolerable risks and their implications for limits to adaptation (Dow *et al*., 2013); based on (Klinke and Renn, 2002).]

Intolerable risks to existing objectives and needs are those which, despite adaptive actions, pose threats of such combined frequency and intensity that an actor would avoid them or, if feasible and appropriate, act in the societal interest to prohibit them. Whether it is an individual's decision to relocate, an insurance company's decision to withdraw coverage, or a lack of managed adaption strategies for a species, these actions represent a discontinuity in behaviour symptomatic of reaching an adaptation limit. The alternative to such discontinuities of disposition or behaviour is escalating risk of losses (16.4.2). While actors have their own judgements of what are acceptable, tolerable or intolerable risks, collective responses often shape the constraints and opportunities to adaptation and responses to risk through the distribution of resources, institutional design, and support of capacity development (16.3). If these risks and discontinuities have global-scale consequences, they can be linked to 'key vulnerabilities' to climate change (see Chapter 19). Consistent with our framing of adaptation limits as being actor-centered, such key vulnerabilities would need to be assessed in terms of the adaptation limits which they imply for specific social actors, species and ecosystems.

_____ START BOX 16-1 HERE _____

Box 16-1. Definitions of Limits, Opportunities, and Constraints to Adaptation

Adaptation Limit: *The point at which an actor's objectives (or biophysical system needs) cannot be secured from intolerable risks through adaptive actions* (Dow *et al.*, 2013).
A limit to adaptation means that no adaptation options exist, or an unacceptable measure of adaptive effort is required to secure objectives, or to allow for a species or ecosystem to survive in an unaltered state. Examples of objectives include, for instance, standards of safety codified in laws, regulations, or engineering design standards (*e.g.,* 1 in 500 year levees), security of drinking water supplies as well as equity, cultural cohesion, and preservation of livelihoods. Requirements of biophysical systems might include a maximum temperature or precipitation levels. That ability to avoid adaptation limits is shaped by adaptation opportunities and constraints.

Adaptation Opportunity: *factors that make it easier to plan and implement adaptation actions.*
Opportunities are the opposite of constraints. Adaptation opportunities create new potential for an actor to secure their existing objectives, or for a biophysical system to retain productivity or functioning. New circumstances, such as public or private interventions, may make it possible or easier to pursue successful adaptation. Adaptation opportunities are distinct from co-benefits and from opportunities arising from climate change (e.g., longer growing seasons), which would commonly be referred to as potential benefits of climate change (see chapter 17) or adaptation options (see Chapter 14).

Adaptation Constraints: *factors that make it harder to plan and implement adaptation actions.*
Adaptation constraints restrict options for an actor to secure their existing objectives, or for a biophysical system to maintain productivity or functioning. These constraints commonly include lack funding, technology or knowledge, or institutional traits that restrict some actions (see 16.3) or lack of connectivity for ecosystems. The terms "barriers" and "obstacles" are frequently used as synonyms.

_____ END BOX 16-1 HERE _____

It is essential to evaluate opportunities, constraints, and limits with respect to the rate and magnitude of climate change and within the relevant time horizon for an actor, a species or an ecosystem. Opportunities, constraints and limits to adaptation develop along a dynamic continuum, together conditioning the capacity of natural and human systems to adapt to climate change. New opportunities may emerge through time, constraints may be loosened, and some, although not all, limits may be shifted or removed altogether. Climate variability and change and associated patterns of impacts are also changing at diverse and non-linear rates. For a given social actor, the timeframe for adaptation decisions usefully bounds an analysis of opportunities, constraints and limits. Each year, for example, US Great Plains farmers chooses if, when, and what to plant and how much insurance to purchase. While more drought-resistant crop varieties might become available in future, the choice in any given year is limited to the varieties currently available. A community that has suffered severe storm damage must act urgently to restore homes and infrastructure using the technologies, financial resources and institutions then available. Changing institutional

relationships may make greater amounts of disaster recovery aid available to support other adaptation choices in future, but if there are immediate safety needs, delay in expectation of these changes would be hard to justify. For natural ecosystems, the rate of species responses relative to change in environmental conditions bounds the capacity to adapt. The observed rate of evolutionary and other species responses ranges from rapid to inadequate to allow persistence (Hoffmann and Sgro, 2011), but the knowledge base is insufficient to permit clear general conclusions for ecosystem adaptation capacity.

Because adaptation limits relate to adaptation resources and attitudes to risk and threat which may change over time, some limits may be viewed as "soft". While a given adaptation option may not be available today or require impracticable levels of effort, it may become available through innovation or changes in attitudes in time. Soft limits may be shifted investments in research and development, changes in regulatory rules or funding arrangements, or by changing social or political attitudes. Other limits are "hard" in that there is no known process to change them. Examples of fixed limits include water supply in fossil aquifers, the range of a species, limits to retreat on islands, loss of genetic diversity, or the tolerance of coral species to temperature and ocean acidity.

16.3. Adaptation Capacities and Constraints

There is *high agreement and robust evidence* that different actors, sectors, and geographic regions have differential capacities to adapt to climate variability and change (Adger *et al*., 2007; IPCC, 2012), although those capacities can be difficult to measure (Tol *et al*., 2008; Hinkel, 2011). Since the AR4, the literature on adaptive capacity and adaptation constraints has deepened (Adger *et al*., 2009b; Moser and Ekstrom, 2010). This literature can be divided into two general categories of constraints (Figure 16-2). One focuses on interactions among biophysical and socioeconomic processes that may span multiple actors across different spatial or temporal scales. These processes evolve constantly over time and establish the context in societal context for adaptation. The second category focuses on the entitlements of actors to the assets and capital necessary for the implementation of specific adaptation policies and measures (Yohe and Tol, 2002; Paavola, 2008; Osbahr *et al*., 2010). These two categories of constraints as well as specific examples are discussed further in the following sections.

[INSERT FIGURE 16-2 HERE
Figure 16-2: Identification of key adaptation constraints considered in this chapter, which are categorized into two groups. One reflects constantly evolving biophysical and socio-economic processes that influence the societal context for adaptation. These processes subsequently influence the implementation of specific adaptation policies and measures that could be deployed to achieve a particular objective.]

Specific constraints associated with these two categories are common to multiple regions, sectors, communities, and actors. Nevertheless, the manner in which they manifest is context-dependent (Adger *et al*., 2007; Kasperson and Berberian, 2011; Weichselgartner and Breviere, 2011; IPCC, 2012). Therefore, one must be cautious in applying generic assumptions regarding adaptation constraints in assessments of vulnerability and adaptive capacity or in the identification of appropriate adaptation responses(Adger and Barnett, 2009; Barnett and Campbell, 2009; Mortreux and Barnett, 2009). The recent adaptation literature suggests significant work remains in understanding such context-specific determinants of vulnerability and adaptive capacity (Tol and Yohe, 2007; Klein, 2009; Smith *et al*., 2010; Hinkel, 2011; Preston *et al*., 2011b) and in effectively using the diversity of knowledge gained from the multitude of available case studies to facilitate adaptation more broadly.

16.3.1. Constraints Affecting the Context for Adaptation

16.3.1.1. Framing of Adaptation

Adaptation processes are influenced by the manner in which individuals and institutions frame adaptation including the perception of climate change risks and the mental models employed to structure decision-making regarding adaptation (Nisbet and Scheufele, 2009; Fünfgeld and McEvoy, 2011; Preston and Mustelin, 2013) (see also 15.4.3.1). Framing elements include definitions of adaptation and to what actors must adapt; objectives and

responsibilities of actors; the role of knowledge; appropriate adaptation responses; and constraints and limits associated with implementation (Smith *et al*., 2000; Nelson *et al*., 2008; Meinke *et al*., 2009; Preston and Stafford Smith, 2009; Fünfgeld and McEvoy, 2011; Gifford, 2011; Klein and Juhola, 2013; Arbuckle Jr. *et al*., 2013; Preston and Mustelin, 2013). In particular, recent literature identifies risk perception as a constraint on adaptation by conveying over-confidence in the ability of actors to manage risk (Wolf *et al*., 2010; Kuruppu and Liverman, 2011) or creating differences in the perception of climate risk between actors and governing institutions (Patt and Schröter, 2008a). However, Whitmarsh (2008) finds that motivation for adaptation is mediated indirectly through individual, environmental values rather than direct perceptions of climate risk. Meanwhile, van der Berg *et al*. (2010) suggest local leadership and normative values may be more critical drivers of adaptation than risk perception. The inconsistency among such case studies suggests risk perception may interact with other factors to shape adaptation responses and/or that other factors take precedence. A number of authors have commented on the potential constraints associated with the framing of adaptation as strictly a top down (i.e., government-led) or bottom up (i.e., community-based) process. Orlove (2009), for example, notes that indigenous herders in Peru frame adaptation differently than those working within NGOs and government agencies. Hence, there may be value in more integrated views of risk governance (16.3.1.4).

Recent studies have also investigated the science/policy interface with respect to how vulnerability and adaptation assessment shape understanding of adaptation (Füssel and Klein, 2006b; McGray *et al*., 2007; McEvoy *et al*., 2010; Eakin and Patt, 2011; Fünfgeld and McEvoy, 2011; Jones and Preston, 2011; Preston *et al*., 2011b; Yuen *et al*., 2012). Concerns have been raised in the literature that assessment tools and paradigms such as climatic prediction, risk management, cost/benefit analysis may obfuscate the need for and desirability of alternative approaches to adaptation (O'Brien *et al*., 2007; Hulme *et al*., 2009a; Eriksen and Brown, 2011; Eriksen *et al*., 2011; Pelling, 2011). Eisenack and Stecker (2012) and Klein and Juhola (2013) comment on the disconnect between adaptation research and policy that arises from limited consideration for the role of actors in shaping adaptation responses. Meanwhile, multiple authors have raised questions regarding the utility and legitimacy of vulnerability metrics for prioritizing adaptation interventions (Klein, 2009; Hinkel, 2011; Preston *et al*., 2011b). Greater incorporation of actors and communities into assessment processes and education interventions may be a pathway for increasing their potential to trigger effective adaptation responses(Kuruppu and Liverman, 2011; Klein and Juhola, 2013).

16.3.1.2. Rates of Change

There is *high agreement, robust evidence* that future rates of global change will have a significant influence on the demand for and costs of adaptation. Since, the AR4, new research has confirmed the commitment of the Earth system to future warming (Lowe *et al*., 2009; Armour and Roe, 2011) and elucidated a broad range of tipping points or 'key vulnerabilities' in the Earth system that would result in significant adverse consequences should they be exceeded (Lenton *et al*., 2008; Rockstrom *et al*., 2009); Chapter 19). While the specific rate of climate change to which different ecological communities or individual species can adapt remains uncertain (16.5), there is high agreement, robust evidence that more rapid rates of change constrain adaptation of natural systems (Hoegh-Guldberg, 2008; Gilman *et al*., 2008; Maynard *et al*., 2008; Allen *et al*., 2009; Malhi *et al*., 2009a; Malhi *et al*., 2009b; Thackeray *et al*., 2010; Lemieux *et al*., 2011), particularly in the presence of other environmental pressures (Brook *et al*., 2008). Therefore, if greenhouse gas mitigation policy is unable to reduce the rate of climate change, the effectiveness of some adaptation options may be reduced and higher costs for adaptation may be incurred (New *et al*., 2011; Stafford Smith *et al*., 2011; Peters, G.P., Andrew, R.M. *et al*., 2013).

Meanwhile, although rapid socioeconomic change, including economic development and technological innovation and diffusion, can enhance adaptive capacity, they can also pose constraints to adaptation. Globally, rates of economic losses from climate extremes are doubling approximately every one to two decades due to increasing human exposure (Pielke Jr. *et al*., 2008; Baldassarre *et al*., 2010; Bouwer, 2011; Gall *et al*., 2011; Munich Re, 2011; IPCC, 2012). These trends in losses are projected to continue in future decades (Pielke Jr., 2007; Montgomery, 2008; O'Neill *et al*., 2010; UN, 2011; Preston, Submitted);10.7.3). In addition, population growth and economic development can lead to greater resource consumption and ecological degradation (Alberti, 2010; Chen *et al*., 2010; Raudsepp-Hearne *et al*., 2010; Liu *et al*., 2012), which can constrain adaptation in regions that are dependent on natural resources (Badjeck *et al*., 2010; Marshall, 2010; Warner *et al*., 2010); CC-EA). Global trends toward

population aging can increase vulnerability by increasing net population sensitivity to climate extremes (O'Brien *et al*., 2008; Wolf *et al*., 2010; Bambrick *et al*., 2011). The adaptation literature also suggests that successful adaptation will be dependent in part upon the rate at which institutions can learn to adjust to the challenges and risks posed by climate change and implement effective responses (Adger *et al*., 2009b; Moser and Ekstrom, 2010; Stafford Smith *et al*., 2011).

16.3.1.3. Social and Cultural Dimensions

Adaptation can be constrained by social and cultural factors that are based on societal ideals regarding how a society should function and what is valued (O'Brien, 2009; Moser and Ekstrom, 2010; O'Brien and Wolf, 2010; Hartzell-Nichols, 2011). These social and cultural factors are the normative dimension of adaptation (O'Brien, 2009) (O'Brien, 2009), which determines what kind of adaptation is considered useful and feasible as well as when and by whom (Grothmann and Patt, 2005; Weber, 2006; Patt and Schröter, 2008b; Kuruppu, 2009; Adger *et al*., 2009b; Nielsen and Reenberg, 2010; Wolf and Moser, 2011; Wolf *et al*., 2013). Gender roles and identity, traditionally acceptable livelihoods, caste or class, land ownership systems, and religion can influence adaptation processes and hinder adaptive actions at individual, household and community levels (Ahmed and Fajber, 2009; Bryan *et al*., 2009; Codjoe *et al*., 2011; Jones and Boyd, 2011). Yet, values are not homogenous across society, which results in differential preferences for adaptation that can contribute to societal conflict (Wolf *et al*., 2013). Women in particular are often constrained by cultural and institutional pressures that favor male land ownership (Jones and Boyd, 2011) and constrain access to hazard information (Ahmed and Fajber, 2009). The lack of perception of vulnerability has left for example elderly people unprepared for heat waves in the UK (Sheridan, 2007; Wolf *et al*., 2009). Meanwhile, evidence suggests that chronic stresses such as poverty affect cognition and behavior, which influence adaptive capacity (Dias-Ferreira *et al*., 2009; Spears, 2011). Cultural constraints also include lack of oral history of disasters and risks, a prominent phenomenon in developed countries where highly vulnerable environments are built upon without adequate understanding of the landscape and its history (Heyd and Brooks, 2009). Studies indicate that cultural preferences regarding the value of traditional versus more formal scientific forms of knowledge influences that types of knowledge are considered legitimate (Jones and Boyd, 2011) and thus the way in which knowledge is used in adaptation (Box 16-2). Furthermore, social constraints can arise from governance arrangements which, for example, in the Arctic constrain individual's and communities' hunting and fishing practices and adaptation opportunities (Loring *et al*., 2011); 16.4.2.3).

Perceptions of the need for adaptation are also shaped by religion and sense of place. Religious beliefs can constrain adaptation as they reduce the perceived necessity and opportunities for adaptation while contributing to increase in vulnerability. Such constraints have emerged, for example, through religious institutions that have placed extensive financial commitments on their members reducing available capital for adaptation (Kuruppu, 2009). In Kiribati, Zanzibar, Tibet, Ecuador, and Mozambique, natural hazards are viewed as events controlled by God, supernatural forces, or ancestral spirits about which nothing can be done (Schipper, 2008; Byg and Salick, 2009; Mustelin *et al*., 2010; Kuruppu and Liverman, 2011; Artur and Hilhorst, 2012). In Tuvalu, God is attributed responsibility to take care of the people (Mortreux and Barnett, 2009). Adger *et al*. (2011; 2012a) and Fresque-Baxter and Armitage (2012) argue that sense of place, tied intimately to identity, shapes adaptation responses through sense of belonging, security, social connections, self-esteem, and emotional attachment. For example, Park *et al*. (2011) note that sense of place attachment among wine grape growers in Australia precludes consideration for migration to other growing areas. Further ethnographic explorations are needed to better grasp how and to what extent global climatic processes alter culture, values, and identity (Crate, 2011). Improved understanding is also needed regarding how gender, religious beliefs, land-use and rights can decrease vulnerability and enable individual, household and community adaptation.

16.3.1.4. Governance and Institutional Arrangements

Governance and institutional arrangements may both enable adaptation and act as potential constraints. Decision-making regarding adaptation is often undertaken within a context of multi-level governance including governmental administration at local to international levels as well as market actors and non-governmental organizations

(Rosenau, 2005). As a result, coordination or interplay among actors is crucial for facilitating adaptation decision-making and implementation (Young, 2006; van Nieuwaal *et al*., 2009; Grothmann, 2011). While some attention has been given quite recently to role of the private sector in adaptation governance (CDP, 2012; Taylor *et al*., 2012; Tompkins and Eakin, 2012), adaptation research and practice to date has largely focused on the public components of governance, particularly formal government institutions. Studies of the development of adaptation planning and policy at different levels of governance largely center on case studies (van Nieuwaal *et al*., 2009; Hunt and Watkiss, 2011), often by issue or level of government (Gagnon-Lebrun and Agrawala, 2006; Swart *et al*., 2009; Corfee-Morlot *et al*., 2009; Keskitalo, 2010; Biesbroek *et al*., 2010; Ford and Berrang-Ford, 2011; Preston *et al*., 2011a).

Multi-level governance of adaptation is challenged by the different regulatory and legal systems – including differing levels of decentralization – that exist across different geopolitical scales as well as differential authorities and power relationships. The NRC (2009) argued that U.S. institutions across scales lack the mandate, information, and/or professional capacity to select and implement adaptations for risk reductions. Similarly, Zinn (2007) and Preston (2009) suggest that effective responses to climate change would require levels of integrated environmental planning and management that governance systems have not been able to achieve consistently. Adger *et al*. (2009b), attribute such deficiencies to the complexity of governance systems that pose challenges to coordinating adaptation efforts, due in part to different objectives among actors (Preston *et al*., 2013). Similarly, Birkmann *et al*. (2010) observe that many urban adaptation plans depend on the involvement and interplay of formal and informal organizations, but these plans rarely address how this integration might be achieved (also see Chapter 15 on implementation). As binding legislation at national and in some cases subnational levels may create disincentives or potentially limit adaptation even in cases where adaptation per se is not the focus of legislation, adaptation decision-making at local level is partly shaped by higher levels as well as by the distribution of authority within the state (Urwin and Jordan, 2008; Huntjens *et al*., 2010a; Measham *et al*., 2011; Pittock, 2011; Westerhoff *et al*., 2011; Mukheibir *et al*., 2012; Amaru and Chhetri, 2013). The literature notes the challenges of changing legal principles to accommodate more forward-looking adaptation responses (Craig, 2010; McDonald, 2011). Preston *et al*. (2013), for example, identify cases in Australia and the United States where state government policies have impeded local governments from anticipatory adaptation for sea-level rise. A study of adaptation policy initiatives in the UK, Sweden, Finland and Italy, concluded that while initiatives at the central government level may play a significant role in supporting the development of adaptation policies at the local level, in cases where there is limited top down leadership or prioritization on adaptation, less centralized state structures could allow opportunities for local initiatives (Keskitalo, 2010). Transnational governance also influences adaptive capacity. For instance, in some cases in the European Union, funding programs have enabled local action on adaptation even in the absence of funding from the relevant EU member state (Keskitalo, 2010). The need for adaptation thus creates new challenges for the complex multi-national and multi-level governance of resources, particularly where there are ongoing disputes or conflicts (16.3.5). New institutions and bridging organizations will be needed to facilitate integration of complex planning processes across scales (National Research Council, 2010).

16.3.1.5. Monitoring and Evaluation

The AR4 provided little discussion of the role of monitoring and evaluation (M&E) of adaptation responses as a component of building adaptive capacity. Nevertheless, adaptation guidance, such as the guidelines for the preparation of National Adaptation Programmes of Action (UNFCCC, 2002), the United Nations Development Programme's *Adaptation Policy Framework* (Lim *et al*., 2005), and a range of climate change risk management frameworks (Jones, 2001; Willows and Connell, 2003; NZCCO, 2004a; NZCCO, 2004b; AGO, 2006; USAID, 2007; World Bank, 2008) all emphasize the importance of M&E for adaptation planning and implementation. The UK's Adaptation Sub-Committee, for example, recommends the monitoring of the implementation of the National Adaptation Programme and several agencies already have M&E protocols in place to track the effectiveness of responses to climate-related risks (Adaptation Sub-Commitee, 2012). In particular, M&E enables practitioners to develop robust adaptation practice through learning from policy successes and failures (GIZ, 2011a; GIZ, 2011b). Nevertheless, the long time scales associated with climate change and adaptation responses as well as uncertainty about the future pose significant challenges for evaluating success (GIZ, 2011b), particularly when there is a lack of consensus with respect to adaptation objectives (de Franca Doria *et al*., 2009; Osbahr *et al*., 2010). The literature on participatory M&E may offer guidance for how to overcome such conflicts by enhancing the incorporation of tacit

and local knowledge into M&E and the prioritization of management interventions (Brown *et al*., 2012; Harvey *et al*., 2012; Stringer and Dougill, 2013). Recent evidence suggests guidance on climate adaptation M&E is increasingly being translated into practice (GIZ, 2011a; GIZ, 2011b). However, Preston *et al*. (2011a) argue that adaptation M&E is more advanced in the developing world due to the close linkages between adaptation and development assistance (Global Environmental Facility, 2006), which has a long history of M&E. In contrast, the limited evidence from developed nations suggests that many organizations have yet to engage on adaptation (Wheeler, 2008); have yet to turn adaptation planning into practice (Berrang-Ford *et al*., 2011; Ford *et al*., 2011); or are limiting adaptation actions to capacity building efforts (Preston *et al*., 2011a). Yet, the UK Climate Change Act (2008) and U.S. Executive Order 13514 (CEQ, 2011) contain reporting provisions with respect to adaptation planning and implementation. This suggests that the policy foundation for M&E in developed nations is emerging, but additional development of objectives, methods, and metrics for M&E may be required.

16.3.2. Constraints Affecting the Implementation of Adaptation Policies and Measures

The various socioeconomic processes that influence the context for adaptation ultimately influence the entitlements of actors to the capacity and resources needed to support the implementation of adaptation policies and measures (Figure 16-2). The literature on vulnerability and adaptive capacity, for example, has traditionally focused on the availability of such resources and differential availability and access across different sectors, regions, and actors (Jantarasami *et al*., 2010; Moser and Ekstrom, 2010). For example, multiple studies have assessed adaptive capacity in sectors and communities using sustainable livelihoods framework (Paavola, 2008; Osbahr *et al*., 2010; Nelson *et al*., 2010a; Nelson *et al*., 2010b), which deconstructs adaptive capacity into five types of capital: financial, physical, natural, social, and human. Hence, adaptation efforts can be constrained by various factors including knowledge regarding climate change and adaptation (Deressa *et al*., 2011); Box 16-2); availability of adaptation finance (Hof *et al*., 2009; Smith *et al*., 2009b; Barr *et al*., 2010; Schultz, 2012); degradation of natural resources (Humphreys *et al*., 2007; Paavola, 2008; Thornton *et al*., 2008; Iwasaki *et al*., 2009; Badjeck *et al*., 2010; Côté and Darling, 2010; Nkem *et al*., 2010; Tobey *et al*., 2010); effectiveness of technology (UNFCCC, 2006; Adger *et al*., 2007; Dryden-Cripton *et al*., 2007; van Aalst *et al*., 2008); the degree of public engagement in adaptation (van Aalst *et al*., 2008; Burton and Mustelin, 2013); and the quality of human capital and leadership (Ebi and Semenza, 2008; Termeer *et al*., 2012). Such constraints have been identified and discussed in previous IPCC reports (Adger *et al*., 2007; IPCC, 2012), and are closely aligned to the discussion of adaptation needs in Chapter 14. Therefore, this chapter focuses on providing illustrative examples from the literature of how such constraints affect adaptation implementation (Table 16-1) and synthesizing key constraints across the regional and sectoral chapters (16.5). However, debates appear within the adaptation literature regarding the extent to which some types of resources constrain adaptation (Box 16-2).

_____ START BOX 16-2 HERE _____

Box 16-2. Is Knowledge a Constraint on Adaptation?

The generation and dissemination of knowledge regarding climate change and adaptive responses are important components of adaptation processes and, in particular, the effective implementation of specific policies and measures. The various types of knowledge most frequently examined in adaptation studies include a) knowledge regarding future biophysical and socioeconomic conditions and associated uncertainties (Keller *et al*., 2008; Wilby *et al*., 2009; Moss *et al*., 2010); b) knowledge regarding adaptation options and their associated costs and benefits (Prato, 2008; de Bruin *et al*., 2009b; Patt *et al*., 2010a); and c) knowledge regarding the various constraints on, or limits to, the implementation of those options and how they can be ameliorated (Mitchell *et al*., 2006; Smith *et al*., 2008; Moser, 2009; Moser and Ekstrom, 2010; Conway and Schipper, 2011). Although the pursuit of adaptation has been linked to education and awareness of climate change among actors (Deressa *et al*., 2011), the adaptation literature reflects different perspectives on the manner in which knowledge constraints adaptation. Adaptation practitioners and stakeholders continue to identify a deficit of information as a major constraint on adaptation

(Adger *et al*., 2009b; Jones and Preston, 2011; Preston *et al*., 2011a). This is evidenced by surveys and case studies in both developed (Tribbia and Moser, 2008; Jantarasami *et al*., 2010; Gardner *et al*., 2010; Ford *et al*., 2011) and developing nations (Bryan *et al*., 2009; Deressa *et al*., 2009). Discussions of knowledge deficits in the literature are often closely associated with the broader issue of uncertainty and its implications for adaptation. Key sources of uncertainty include scientific understanding of biophysical processes that influence future climate change; understanding of socioeconomic processes that influence the impacts of, and responses to, climate change; and understanding of the costs and benefits of different adaptation policies (Congressional Budget Office, 2005; Fankhauser, 2009; Hallegatte, 2009b; Arnell, 2010; Patt *et al*., 2010a; UNFCCC, 2011). Nevertheless, the AR4 concluded that knowledge in itself is not sufficient to drive adaptive responses (Adger *et al*., 2007). Recent literature has questioned, for example, the extent to which uncertainty and/or lack of information about future climate change is a constraint on adaptation (Dessai *et al*., 2009; Hulme *et al*., 2009b; Wilby and Dessai, 2010), particularly over the near-term. Approaches such as robust decision-making and so-called 'no regrets' or 'win-win' strategies may identify adaptation options that are insensitive to uncertainty (Lempert and Collins, 2007; Hallegatte, 2009a; Adger *et al*., 2009b; Wilby and Dessai, 2010). Other authors have also questioned the utility of vulnerability metrics and assessments for informing adaptation decision-making (Barnett *et al*., 2009; Preston and Stafford Smith, 2009; Klein, 2009; Hinkel, 2011; Preston *et al*., 2011a).

Studies also indicate that the role of knowledge in adaptation is closely tied to culture. For example, cultural preferences regarding the value of traditional versus more formal scientific forms of knowledge influence what types of knowledge are considered legitimate (Jones and Boyd, 2011). In the Arctic, however, Inuit traditional knowledge (*Inuit Qaujimajatuqangit,* IQ) encompasses all aspects of traditional Inuit culture including values, world-view, language, life skills, perceptions and expectations (Nunavut Social Development Council, 1999; Wenzel, 2004). While declining especially among youth (Pearce *et al*., 2011), IQ includes, for example, weather forecasting, sea ice safety, navigation, hunting and animal preparation skills that link together Inuit perception, knowledge, and values and are essential for managing climate risk. On the other hand, evidence suggests that increasing reliance on non-traditional forecasting (national weather office forecasts) and other technologies (GPS) in Arctic communities is in part responsible for increased risk taking when travelling on the land and sea ice (Aporta and Higgs, 2005; Ford *et al*., 2006; Pearce *et al*., 2011). As a result, the implications of relying upon traditional forecasting and skills are place and context-dependent. These various studies, and the inconsistency of conclusions that arise, indicates that the extent to which knowledge acts to constrain or enable adaptation is ultimately dependent upon how that knowledge is generated, shared and used to achieve desired adaptation objectives (Patt *et al*., 2007; Nelson *et al*., 2008; Tribbia and Moser, 2008; Moser, 2010).

_____ END BOX 16-2 HERE _____

16.3.3. Constraints across Spatial and Temporal Scales

Despite an emphasis in the adaptation literature on place-based adaptation, adaptation can be constrained by processes that transcend multiple spatial scales (Adger *et al*., 2005; Eakin and Wehbe, 2009; Preston and Stafford Smith, 2009; Adger *et al*., 2009a; Preston and Mustelin, 2013); 16.4.1.4). International efforts to reduce greenhouse gas emissions, for example, influence the magnitude and rate of change in climate at national, regional, and local scales (16.7). Adaptation constraints can also propagate from the bottom up. For example, global food commodity prices increased sharply in 2006–2008 and again in 2010–2011 due in part to the impacts of extreme weather events on food producing regions. The resulting increase in food prices benefited some producers in developed nations, but undermined food security in developing nations (FAO, 2011). Much of the literature on adaptation and spatial scales, however, focuses on climate impacts and adaptive responses that pose trans-boundary challenges, such as water resources management in multi-national or multi-state river basins (Iglesias *et al*., 2007; Goulden *et al*., 2009; Krysanova *et al*., 2010; Huntjens *et al*., 2010b; Timmerman *et al*., 2011; Wilby and Keenan, 2012).

Constraints on adaptation can also transcend temporal scales. Development of water management and allocation systems in both Australia and the U.S. Southeast occurred during periods of relatively favorable rainfall (Jones, 2010; Pederson *et al*., 2012), resulting in systems that have been challenged to cope with persistent drought in recent decades. Similarly, Libecap (2010) suggests that water infrastructure developed in the U.S. West in the late-19th and

early 20th centuries has resulted in path dependence that constrains management choice regarding water allocation in the present. Cherti *et al*. (2010) suggest similar challenges may exist for the U.S. agricultural industry in the future due to constraints on farmers' capacity to alter management practices and technology in response to a changing climate. Preston (Preston, Submitted) illustrates how the continuation of historical patterns of U.S. population growth and wealth accumulation will contribute to significant increases in future societal exposure to extreme events and associated economic losses. Attempts to rectify such path dependence come at significant costs. For example, the Australian Government has committed AUS$3.1 billion to purchase water entitlements in an attempt to restore water usage in the Murray Darling basin to sustainable levels (Commonwealth of Australia, 2010). Hence, the literature on flexible adaptation pathways emphasizes the implementation of reversible and flexible options (Stafford Smith *et al*., 2011; Haasnoot *et al*., In Press) as well as 'real options' that recognize that there may be value in delaying adaptation decisions until additional information is available (Dobes, 2008).

16.3.4. Constraints and Competing Values

Constraints on adaptation arise from the differential values of societal actors and the trade-offs associated with prioritizing and implementing adaptation objectives (Haddad, 2005; UNEP, 2011); Table 16-2). At international scales, for example, deliberation over how the adaptation needs of least developed countries will be financed has become central to the UNFCCC policy agenda (UNFCCC, 2007; Ayers and Huq, 2009; Dellink *et al*., 2009; Flåm and Skjærseth, 2009; Denton, 2010; Patt *et al*., 2010b). Yet the extent to which the developed world bears responsibility for compensating the developing world for climate impacts has been a contentious issue (Hartzell-Nichols, 2011). Brouwer *et al*., (2013) report that policy-makers in the EU may be reluctant to pursue climate adaptation, because such efforts may conflict with existing objectives with respect to maintain water quality. Even at local scales, Measham *et al*. (2011) report that some Local Government stakeholders in Australia find it difficult to pursue adaptation efforts to due perceived conflicts with an adaptation agenda with community values. Such differences among stakeholders with respect to the need for adaptation and appropriate adaptation responses may result in some actions being simultaneously perceived as adaptive and maladaptive (Bardsley and Hugo, 2010). Alternatively, whether an adaptation option represents an opportunity or a constraint may depend upon the manner in which it's implemented. Recognizing the potential for values conflicts to constrain adaptation, researchers and practitioners have advocated for so-called 'no regrets' or 'low regrets' adaptation strategies (Heltberg *et al*., 2009). However, Preston *et al*. (2011a) suggest such no regrets actions may reduce investments in more substantive adaptations necessary to protect highly vulnerable systems or avoid irreversible consequences. Meanwhile, Adger *et al*. (2009a) question whether incremental adaptation is sufficient to avoid consequences that directly impact human values and cultural identities that cannot be readily compensated. Addressing such risks through adaptation may necessitate deliberation among stakeholders regarding adaptation objectives and the manner in which competing or conflicting values can be reconciled to achieve outcomes (McNamara and Gibson, 2009; de Bruin *et al*., 2009b; McNamara *et al*., 2011; UNEP, 2011).

[INSERT TABLE 16-2 HERE
Table 16-2: Examples of potential trade-offs among adaptation objectives.]

16.3.5. Interactions among Constraints

Deconstruction of adaptation constraints into discrete factors assists with their identification and diagnosis, but, such constraints rarely act in isolation (Dryden-Cripton *et al*., 2007; Smith *et al*., 2008; Moser and Ekstrom, 2010; Shen *et al*., 2011); 16.4.6). Rather actors are challenged to navigate multiple, interactive constraints in order to achieve a given adaptation objective(Adger *et al*., 2007; Dryden-Cripton *et al*., 2007; Smith *et al*., 2008; Shen *et al*., 2008; Adger *et al*., 2009b; Jantarasami *et al*., 2010; Moser and Ekstrom, 2010; Shen *et al*., 2011). For example, while the cost of adaptation is frequently cited as a constraint on action, cost is a function of rates of climate change and greenhouse gas mitigation efforts (16.4.2.2), the availability of finance (16.4.1.3), and available technologies (16.4.1.4). Meanwhile, the perceived costs and benefits of a given adaptation option have strong intersections with governance as well as social and cultural preferences (Dryden-Cripton *et al*., 2007; Smith *et al*., 2009b; Engle, 2011; Shen *et al*., 2011). Multiple constraints can significantly reduce the range of adaptation options and opportunities

and therefore may pose fundamental limits to adaptation (16.5), and/or drive actors toward responses that may ultimately prove to be maladaptive (Barnett and O'Neill, 2010). As such, removing various constraints on adaptation, which in turn increases adaptation options and flexibility, is fundamental to the facilitation of adaptation processes (Smith *et al*., 2008; Moser and Ekstrom, 2010). Bottom up approaches have been credited with making adaptation constraints explicit and stimulating social learning (Preston *et al*., 2009; Yuen *et al*., 2012), but have yielded less evidence of substantive adaptation. Meanwhile, top down, index-based approaches have come under criticism due to concerns about robustness and relevance to adaptation decision-making (Hinkel, 2011; Preston *et al*., 2011a). Ongoing advances in comprehensive understanding of multiple, interacting constraints as well as the manner in which they influence adaptation and outcomes are needed to facilitate adaptation practice (Engle, 2011).

16.4. Limits to Adaptation

There is *high agreement and much evidence* that there are limits to the capacity of actors to adapt to climate change (Meze-Hausken, 2008; O'Brien, 2009; Adger *et al*., 2009b; Moser and Ekstrom, 2010; Dow *et al*., 2013); 16.4). Although constraints increase the challenges associated with implementing adaptation policies and measures, they do not necessarily pose a limit to adaptation in themselves. A limit is reached when adaptation efforts are unable to provide an acceptable level of security from risks to the existing objectives and values and prevent the loss of the key attributes, components or services of ecosystems (see Box 16-1). There is a variety of circumstances and associated terminology in the literature that relate to adaptation limits including 'thresholds' (Meze-Hausken, 2008; Briske *et al*., 2010; Washington-Allen *et al*., 2010); 'regime shifts' (Washington-Allen *et al*., 2010); 'tipping points' (Lenton *et al*., 2008; Kriegler *et al*., 2008); 'dangerous climate change' (Mastrandrea and Schneider, 2004; Ford, 2009a); 'reasons for concern' (Smith *et al*., 2009a); 'planetary boundaries' (Rockstrom *et al*., 2009); or 'key vulnerabilities' (Schneider *et al*., 2007; Johannessen and Miles, 2011; Hare *et al*., 2011); Chapter 19). In addition, terms such as barriers, limits, and constraints are sometimes used interchangeably. Due to this diversity in language, this discussion builds on recent efforts to develop a common lexicon to facilitate research and practice (Hulme *et al*., 2007; Adger *et al*., 2009b; Dow *et al*., 2013; Dow *et al*., In Press); 16.2; Box 16-1).

_____ START BOX 16-3 HERE _____

Box 16-3. Historical Perspectives on Approaching and Exceeding Limits to Adaptation

Does human history provide insights into societal resilience and vulnerability under conditions of environmental change? Archeological and environmental reconstruction provides useful perspectives on the role of environmental change in cases of significant societal change (sometimes termed 'collapse' (Diamond, 2005)). These may help to illuminate how adaptation limits were either exceeded, or where this was avoided to a greater or lesser degree. Great care is necessary to avoid over-simplifying cause and effect, or over-emphasizing the role of environmental change, in triggering significant societal change, and the societal response itself. Coincidence does not demonstrate causality, such as in the instance of matching climatic events with social crises through the use of simple statistical tests (Zhang *et al*., 2011), or through derivative compilations of historical data (deMenocal, 2001; Thompson *et al*., 2002; Drysdale *et al*., 2006; Butzer, 2012). Application of social theories may not explain specific cases of human behavior and community decision-making, especially because of the singular importance of the roles of leaders, elites and ideology (Hunt, 2007; McAnany and Yoffee, 2010; Butzer and Endfield, 2012; Butzer, 2012).

There are now roughly a dozen case studies of historical societies under stress, from different time ranges and several parts of the world, that are sufficiently detailed (based on field, archival, or other primary sources) for relevant analysis (Butzer and Endfield, 2012). These include Medieval Greenland and Iceland (Dugmore *et al*., 2012; Streeter *et al*., 2012); Ancient Egypt (Butzer, 2012); Colonial Cyprus (Harris, 2012); the prehistoric Levant (Rosen and Rivera-Collazo, 2012); Islamic Mesopotamia and Ethiopia (Butzer, 2012); the Classic Maya (Dunning *et al*., 2012; Luzzadder-Beach *et al*., 2012); and Colonial Mexico (Endfield, 2012). Seven such civilizations underwent drastic transformation in the wake of multiple inputs, triggers, and feedbacks, with unpredictable outcomes. These can be seen to have exceeded adaptation limits. Five other examples showed successful adaptation through the interplay of environmental, political and socio-cultural resilience, which responded to multiple stressors (e.g., insecurity, environmental or economic crises, epidemics, famine). Climatic perturbations are identified as only one

of many 'triggers' of potential crisis, with preconditions necessary for such triggers to stimulate transformational change. These preconditions include human-induced environmental decline mainly through over-exploitation. Avoidance of limits to adaptation requires buffering feedbacks that encompass social and environmental resilience. Exceedance of limits occurred through cascading feedbacks that were characterized by social polarization and conflict that ultimately result in societal disruption. Political simplification undermined traditional structures of authority to favor militarism, while breakdown was accompanied or followed by demographic decline. Although climatic perturbations did contribute to triggering many cases of breakdown, the most prominent driver at an early stage was institutional failure. Environmental degradation seldom played a pivotal role. Collapse was neither abrupt nor inevitable, often playing out over centuries.

These historical insights cannot be directly applied to contemporary problems of sustainability without adjustment for cumulative information and evolving developments such as increasing social possibilities for grassroots participation. For example, from the 14th to 18th centuries AD, Western Europe responded to environmental crises at great societal cost, with high nutritional stress and long-wave demographic fluctuations. This occurred through the consideration of traditional knowledge and the localized evaluation of new information to emphasize innovation, experimentation and intensification, sometimes under the stress of fresh environmental perturbations or social unrest. Resilience and adaptation depended on experience, communications, identification of alternative options, and a measure of consensus. Effective change in recent historical societies involved both the grassroots and the elites, with the key questions increasingly cybernetic, structural, and cultural.

Recent work on resilience and adaptation synthesizes lessons from extreme event impacts and responses in Australia (Kiem *et al*., 2010). This further emphasizes an institutional basis for resilience, finding that government intervention through the provision of frameworks to enable adaptation is beneficial. Furthermore, it was found that a strong government role may be necessary to absorb a portion of the costs associated with natural disasters. On the other hand, community awareness and recognition of novel conditions were also found to be critical elements of effective responses.

_____ END BOX 16-3 HERE _____

16.4.1. Hard versus Soft Limits

Although limits to adaptation are at times described in the literature as fixed thresholds(Adger *et al*., 2009b), recent studies have emphasized the need to consider the perspective of actors in defining adaptation limits (Adger *et al*., 2009b; Dow *et al*., 2013; Dow *et al*., In Press) as well as the dynamic nature of both biophysical and socioeconomic processes that influence adaptation decision-making and implementation (Dow *et al*., 2013; Dow *et al*., In Press). Informed by the distinctions drawn in the work of Meze-Hausken (2008), Adger *et al*. (2009b), and Moser and Eckstrom (2010), one can distinguish between "hard" limits, those that will not change, and "soft" limits, which could change over time. For human actors, whether a limit is hard or soft is usefully evaluated with respect to whether the capacity to implement an adaptation response to manage an intolerable risk could emerge in the future, even if that capacity is not immediately available in the present. For natural ecosystems, whether a limit is hard or soft is defined by the rate and capacity of species and ecosystem responses relative to environmental changes (Shaw and Etterson, 2012).

Discussions of hard limits in the literature are often associated with thresholds in physical systems that, if exceeded, would lead to irreversible changes or the loss of critical structure or function (Lenton *et al*., 2008; Adger *et al*., 2009b; IPCC, 2012; Preston *et al*., 2013). Such limits arise from the magnitude and/or rate of climate change (16.3.1.2). For example, a number of physical thresholds in the Earth system have been proposed as posing potential limits to adaptation, particularly large-scale events such as irreversible melting of the Greenland or Antarctic Ice Sheets, or collapse of the Atlantic Thermohaline Circulation (Schneider and Lane, 2006; Sheehan *et al*., 2008; Travis, 2010). Such physical thresholds, however, though relevant to understanding adaptation limits, are not necessarily limits in themselves as they neglect consideration for the adaptive capacity of natural and human systems(Leary *et al*., 2009; Adger *et al*., 2009b; Dow *et al*., 2013; Klein and Juhola, 2013; Preston *et al*., 2013; Dow *et al*., In Press).

For species and ecosystems, hard limits to adaptation are often associated with exceedances of the physiological capacity of individual organisms or communities to adapt to changes in the climate (i.e., temperature, rainfall, and/or disturbance regimes; (Peck *et al*., 2009)) or to climate-induced changes in the abiotic environment (e.g., ocean circulation and stratification, (Harley *et al*., 2006; Doney *et al*., 2012)). Such systems tend to be those that persist at the upper limit of climate tolerances (Sheehan *et al*., 2008; Dirnböck *et al*., 2011; Benito *et al*., 2011); those for which sustainability is closely tied to vulnerable physical systems (Johannessen and Miles, 2011); or those that are under significant pressure from non-climatic forces (Jenkins *et al*., 2011). For example, many species, including humans (Sherwood and Huber, 2010) and key food crops (e.g., wheat, maize, and rice) are known to have thermal limits to survival (IPCC, 2007a). Similarly, increased ocean acidity is expected to reduce the ability of some marine organisms, such as corals, to grow posing threats of significant ecosystem damage (CC-OA; CC-CR). However, even for unmanaged ecological systems, where there is robust evidence that limits exist, defining those limits remains challenging due to system complexity and lack of information regarding responses across different scales of biological organization (Steffen *et al*., 2009; Wookey *et al*., 2009; Lavergne *et al*., 2010; Preston *et al*., 2013). Furthermore, species have mechanisms for coping with climate change including phenotypic plasticity (Charmantier *et al*., 2008; Matesanz *et al*., 2010) genetic (evolutionary) responses (Gienapp *et al*., 17; Bradshaw and Holzapfel, 2006; Visser, 2008; Wang *et al*., 2013), and range shifts (Colwell *et al*., 2008; Thomas, 2010; Chen *et al*., 2011). Such mechanisms influence adaptation limits by extending the range of climate conditions with which individual organisms can cope in situ and/or enabling species to migrate over time to more suitable climates. Recent evidence suggests that range shifts and phenotypic plasticity, rather than evolutionary adaptation, may be a more common response to climate change (Merilä, 2012). Yet, more comprehensive assessments of such adaptive mechanisms are needed to develop robust understanding of ecological limits.

In contrast, limits within social systems are often soft as they are influenced by exogenous climate change as well as endogenous processes such as societal choices and preferences (Adger *et al*., 2009b). Various authors have noted that adaptation limits are socially-constructed by human agency in that economics, technology, infrastructure, laws and regulations, or broader social and cultural considerations can limit adaptation (Flåm and Skjærseth, 2009; O'Brien, 2009; Adger *et al*., 2009b; de Bruin *et al*., 2009b; Wilbanks and Kates, 2010; McNamara *et al*., 2011; Morrison and PICKERING, 2012). All of these factors, however, are dynamic and change over time. The Shared Socioeconomic Pathways, for example reflect different perspectives on future changes in the capacity of actors to adapt (Kriegler *et al*., 2012). Given rising incomes and advances in knowledge and technology, a greater number of adaptation options may become available to a greater number of actors over time. In contrast, impediments to development, constraints on investments in adaptation, or rapid escalations in risk may create more challenges for adaptation. Societal assessments of risk and willingness to invest in risk management are subject to many influences, such as experience of a recent disaster, some of which can result in rapid changes (Ho *et al*., 2008; Breakwell, 2010; Renn, 2011). Hence, Adger *et al*. (2009b; pg. 338), argue that many limits to adaptation are dependent on the changing goals, values, risk tolerances and social choices of society which may make them "*mutable, subjective, and socially constructed*." Similarly, Meze- Hausken (2008) views adaptation as being triggered in part by subjective thresholds including perceptions of change; choices, needs, and values; and expectations about the future (see also O'Brien, 2009). The influence of cognitive factors, culture, and ideology on judgments about risk is a well-documented element of risk management (Renn, 2008; IPCC, 2012); 14.3.1.1). Cost-benefit analyses and associated discount rates, for example, reflect a social value on investment returns (17.3.7.2). Yet, Morgan (2011) notes that adaptation planning based on cost-benefit analysis can pose limits to adaptation by discounting the future economic benefits of adaptation actions and excluding non-market benefits. Meanwhile, increasing loss and damage from societal exposure and climate change may pose economic limits to the insurability of disaster risks (10.7.3), which ultimately influences what activities can occur in certain locations.

Limits also have scale-dependent properties. A local community may not have the necessary resources to adapt but these constraints may be overcome by drawing in resources from regional, national, or international authorities as well as from NGOs. Adaptation finance and capacity building activities more broadly, for example, enable resources for adaptation to be transferred from developed nations to developing nations in order to overcome soft limits to adaptation. Nevertheless, the demand for adaptation finance is significantly larger than the current availability of resources represented through international adaptation funds (Flåm and Skjærseth, 2009; Hof *et al*., 2009), and there are challenges associated with developing a framework for the equitable and effective allocation of adaptation funds

(Barr *et al*., 2010; Smith *et al*., 2009b). Scale-dependence also manifests among different actors within sectoral supply chains. For example, climate change that poses limits to the sustainability of an individual farm enterprise may have little impact on a national or international agribusiness (Park *et al*., 2011). Such scale dynamics invariably arise within any complex networked system (e.g., energy, water resources, health), and they create inequities among actors with respect to who encounters limits and when.

When all options for managing a risk are exhausted, shifting or removing a soft limit can only occur through granting actors new entitlements to resources or technology (16.3.2); reform to governance systems and policies (16.3.1.4); and/or changes in values and risk tolerance (16.3.1.3). While some changes, such as global economic development, will occur autonomously, other changes are a function of social processes and human choice. In some instances, limits may arise from humans explicitly avoiding what would seem to be adaptive behaviors. Different communities and populations, for example, have different attitudes toward migration as a response to climate vulnerability (Acosta-Michlik and Espaldon, 2008; Locke, 2009; Mortreux and Barnett, 2009; Ford, 2009b). Yet, for some locations, such as low-lying islands in Torres Strait, adaptation in place is not a feasible option (Green *et al*., 2009), and thus sea-level rise poses a hard limit to those who view relocation as an intolerable risk. Foresight (2011) observes that staying in place when security continues to deteriorate can reflect a profound inability to pursue more positive adaptive options, which may be as significant a policy concern as migration. Therefore, while limits to adaptation may be soft in principle, in practice they can pose highly persistent obstacles to adaptation if the necessary societal changes to remove the limit are not forthcoming.

16.4.2. Limits and Transformational Adaptation

Adaptation has traditionally been viewed as a process of incremental adjustments to climate variability and change to maintain existing objectives and values (Burton *et al*., 2001). Reliance upon incremental adaptation, however, can create path dependence that ultimately leads to adaptation limits (Folke, 2006; Gallopin, 2006; Nelson *et al*., 2010; Pelling and Manuel-Navarrete, 2011).Once this point is reached, continuing to maintain those objectives and values can prove maladaptive resulting in chronic system underperformance or, in more severe instances, irreversible losses and system collapse (Box 16-3). Encountering an adaptation limit, however, does not necessarily result in the end of the adaptive process.Since the AR4, the adaptation and resilience literature has suggested that climate change may drive actors toward transformational changes (Dow *et al*., 2013), which include scaling-up of management efforts; introduction of new technologies or practices; geographic shifts in the location of activities, or fundamental changes in underlying objectives and values governing human and natural systems (Pelling, 2011; Stafford Smith *et al*., 2011; Kates *et al*., 2012; O'Neill *et al*., 2012; Park *et al*., 2012; 20.3). While transformational change is one pathway by which soft limits can be removed (16.4.1), they are also a means of adapting to hard limits. For example, transformation may involve accepting the loss of lower-order objectives (e.g., protection of existing vulnerable coastal property, or continuation of an agricultural practice in a given location) in order to continue to meet higher order objectives (e.g., resilient coastal communities or sustainable rural economies) (Pelling and Manuel-Navarrete, 2011). This suggests there are hierarchies of limits within systems (Park *et al*., 2012).Transformational adaptation, however, isn't without risks (Orlove, 2009; Kates *et al*., 2012), such changes can involve significant transaction costs and there are inherent uncertainties associated with the timing and magnitude of investment returns. Hence, the factors that constrain incremental adaptation also constrain transformation, but the greater scale of investment and/or shift in fundamental values and expectations required for transformational change may create greater resistance. Yet, the question of whether or not an adaptive response is in fact transformational is dependent how it is perceived by actors. Following on Davies and Hossain (1997), Preston and Stafford Smith (2009) argue that the feasibility of transformational change may be dependent upon whether it is perceived as a positive outcome (e.g., expansion of an industry into new locations; Park *et al*., 2012) or a negative (e.g., retreat from vulnerable locations; Kates *et al*., 2012).

16.4.3. Effects of Mitigation on Adaptation Constraints and Limits

Klein *et al*. (2007) in IPCC AR4 identified four ways in which adaptation and mitigation can inter- relate, one of which are mitigation actions that have consequences for adaptation. It follows that mitigation actions could have

consequences for adaptation constraints and limits. This section discusses the effects of alternative mitigation pathways on adaptation potential.

Klein *et al*. (2007) concluded that without mitigation, a magnitude of climate change may be reached that makes adaptation impossible for some natural systems, while for most human systems it would involve very high social and economic costs (see also Chapter 19). However, the literature aiming to establish at which magnitude of climate change, or at which levels of mitigation, such adaptation constraints and limits emerge, is scattered and inconclusive. Uncertainty about the location of both hard and soft limits is to a large extent due to the fact that these limits are determined not only by the degree and rate of climate change (and are therefore a function of mitigation pathways), but also by the degree and rate of non-climatic stresses affecting the resilience or adaptive capacity of natural and human systems. Little empirical information is available on the functional relationships between climate change, non-climatic stresses and the emergence of limits to adaptation, offering scant support to the idea that the 2°C global goal represents a limit.

Analysis by Christensen *et al*. (2011) shows that all emission scenarios – whether aggressive mitigation scenarios consistent with a 2°C stabilization pathway or medium-high emission scenarios such as SRES A1B or A1Fi – are very similar in terms of projected climate up to 2040. The effects of mitigation on overall adaptation potential will therefore arise in the medium to long term. Integrated assessment models (IAMs) can assess the relative damage-reducing effect of mitigation and adaptation, but in doing so these models assume the two strategies to be substitutes. However, mitigation and adaptation create benefits on different spatial, institutional and temporal scales and involve different actors with different interests. At the global level it requires the reconciliation of welfare impacts on people living in different places and at different points in time into a global aggregate measure of well-being. As highlighted in Chapter 17, defining the costs and benefits of adaptation is particularly difficult, limited by data, and depends on value judgments.

Furthermore, since AR4 the literature on tipping elements (Lenton *et al*., 2008; Kriegler *et al*., 2009; Levermann *et al*., 2012) has provided a greater separation of mitigation and adaptation, because only mitigation can avoid these discontinuities. These concerns have also been picked up in the economic literature, notably in relation to the plausible, if unknown, probability of catastrophic climate change (Weitzman, 2009) and 'fat tails', where uncertainty is so large that the tails of the probability distribution tend to dominate. Against this background, mitigation insures against catastrophic climate change, and thus mitigation has an additional objective to adaptation. While there could be potential for mitigation and adaptation substitutability under scenarios where catastrophic climate change is avoided, the thresholds for the onset of any tipping elements are not known.

[INSERT FIGURE 16-3 HERE]
Figure 16-3. Adaptation policy space as a function of mitigation pathways (Watkiss *et al*., 2013).]

Nonetheless, several studies using IAMs have investigated tradeoffs between mitigation and adaptation (De Bruin *et al*., 2009; Bosello *et al*., 2010), treating the two strategies as substitutes in order to find a balance or even an optimal mix. De Bruin *et al*. (2009) report that short-term optimal policies need to consist of a mixture of substantial investments in adaptation measures, coupled with investments in mitigation, even though the latter will only decrease damages in the longer term. They also find that the relative mix of the two depends critically on the assumptions, notably in relation to the discount rate and the parameterization of damages.

Such findings are preliminary, because the representation of adaptation in IAMs is very simple (Ackerman *et al*., 2009; Patt *et al*., 2010): the models adopt a highly aggregated and theoretical approach without considering any real-world constraints on adaptation. They also often assume perfect foresight, no uncertainty and no maladaptation (see also Watkiss, 2011; Berkhout, 2012). More recent models have attempted to address some of these issues. The PAGE09 model (Hope, 2011), for example, has less positive assumptions about adaptation than PAGE02 (assuming it to be about half as effective), which along with other factors leads to a strong increase in the economic costs of climate change.

16.5. Sectoral and Regional Syntheses of Adaptation Opportunities, Constraints, and Limits

THIS SECTION SYNTHESIZES MATERIAL AVAILABLE AT THE TIME OF WRITING FROM SECTORAL AND REGIONAL FIRST-ORDER DRAFTS – UPDATES WILL BE MADE WITH SUBSEQUENT INTERATIONS OF THOSE CHAPTERS

The adaptation literature since the AR4 reflects *high agreement and much evidence* that adaptation efforts can and will be constrained by multiple factors (16.3), and, in some cases, such constraints may effectively limit adaptation (16.4). However, there is also *high agreement and much evidence* that opportunities, constraints, and limits for adaptation vary significantly among different sectors and regional contexts (Adger *et al*., 2007). This heterogeneity arises from a range of sources including regional differences with respect to the rate and magnitude of climate change that is experienced, differential exposure and sensitivity of sectors or ecological systems, and differential capacity to adapt. In particular, a robust funding from the literature is the differential adaptive capacity of developed versus developing nations (Adger *et al*., 2007). Nevertheless, while developing nations face potential challenges for adaptation arising from development and adaptation deficits (2.3.2.2.; 15.4.3.1.; 15.6), challenges for adaptation planning and implementation have been reported for developed countries as well (NRC, 2009, 2010; Berrang-Ford *et al*., 2011; Preston *et al*., 2011a). Given this diversity in adaptation opportunities, constraints, and limits, it is important that they be considered in the specific context in which they arise. Therefore, this section draws on the various assessments of adaptation presented in the sectoral (Chapters 3-13) and regional (Chapters 22-30) chapters of the Working Group II report to synthesize knowledge regarding opportunities, constraints, and limits across these contexts.

16.5.1. Sectoral Synthesis

Each of the sectoral chapters in the Working Group II report addresses the opportunities for, and challenges associated with, the pursuit of adaptation (Table 16-3). Collectively, this represents a rich body of knowledge regarding understanding of adaptation processes and how they are evolving among different human and natural systems. Although each sectoral chapter assesses the relevant literature on adaptation somewhat independently, a common emphasis among these chapters is a need for integrated approaches to adaptation planning and implementation. For example, Integrated Water Resource Management (IWRM), Integrated Coastal Zone Management (ICZM), Community-Based Adaptation, and Ecosystem-Based Adaptation (CC-EA) are identified as cross-sectoral adaptation options, which are viewed as more effective than standalone efforts to reduce climate-related risks(Bijlsma *et al*., 1996); 3.6; 5.9). Such integration is important as many sectors experience threats not from by climate change, but also from a range of existing or emerging threats. The sectoral chapters also reflect the distinction between autonomous adaptation, which is particularly important for natural systems such as freshwater, terrestrial, and ocean ecosystems, and planned adaptation, which features strongly in the literature associated with human systems. Common constraints arise among different sectors, which resemble those addressed previously (16.3). These include institutional challenges, barriers to accessing resources for adaptation, as well as lack of or uncertain information (3.6.1). As such, many chapters emphasize the various opportunities for building capacity through development and increasing resilience to climate change by addressing other stresses to human and natural systems. While the sectoral chapters offer few explicit definitions of adaptation limits, they reflect the potential for soft limits to arise and the potential for them to be persistent due to interactions among multiple constraints (16.3.5). Meanwhile, the sustainability of individual species or ecosystems may experience hard limits in a change climate, as may ecosystem services for humans such as food crops and fisheries.

[INSERT TABLE 16-3 HERE
Table 16-3: Sectoral synthesis.]

16.5.2. Regional Synthesis

While the regional chapters assess the relevant literature on key sectors affected by climate change, those discussions are specific to the various regional contexts (Table 16-4). Mainstreaming climate change into national

development policies as well as regional and local planning and economic development has emerged as a unified theme across regions for addressing multiple, interacting, stresses (Dovers and Hezri, 2010; Tompkins *et al*., 2010). Most regional chapters reveal there is a significant mismatch between national adaptation planning on adaptation and local implementation to achieve substantive reductions in vulnerability. Just as there is a scale disconnect in adaptation planning and implementation, there is also a temporal disconnect. Adaptation interventions largely emphasize short-term risk management over long-term strategic planning, which potentially increases vulnerability and therefore the costs associated with future adaption efforts. Such short-sighted decision-making can also create the potential for maladaptation (Berrang-Ford *et al*., 2011). The regional chapters also reveal the fundamental disparities between developing and developed nations with respect to adaptive capacity. For example, Asia, Central and South America, and Africa reveal consistent weaknesses with respect to information on climate change and adaptation, access to other resources, and effective institutions for facilitating adaptation planning and implementation. Nevertheless, governance frameworks for incorporating adaptation are also identified in global regions such as North America and Europe, which are largely comprised of developed nations. A shift to risk-based approaches to adaptation offer opportunities for the development of approaches, tool and guidelines for the construction of adaptation plans with a long-term focus (16.7.2). In addition, ecosystem based adaptation (CC-EA) appears as another one adaptation opportunity to address short and long-term adaptation vulnerabilities in several regions (Africa, Australasia, Central and South America) (CC-EA).

[INSERT TABLE 16-4 HERE
Table 16-4: Regional synthesis.]

16.6. Ethical Dimensions of Adaptation Constraints and Limits

Hartzell-Nichols (2011, pg. 690) argues that "*Adaptation is fundamentally an ethical issue because the aim of adaptation is to protect that which we value*." This underlines the ethical dimensions of the framing of adaptation opportunities, constraints and limits adopted in this chapter as being concerned with risks to social objectives and values, and to needs of biophysical systems. However, defining what these values are and untangling the ethical issues is not straightforward. Defining general moral principles to clarify how to handle risks to objectives, values and needs, including where they are unavoidable and catastrophic, is difficult. According to Gardiner (2006, pg. 407), "*Even our best theories face basic and often severe difficulties addressing basic issues … such as scientific uncertainty, intergenerational equity, contingent persons, nonhuman animals, and nature. But climate change involves all of these matters and more"*. Complicating this picture further is the observation that social and personal values are not universal and nor are they static (O'Brien, 2009; O'Brien and Wolf, 2010). There may be different, equally well-founded values about an activity or value that is being put at risk by climate change. These are not limited to economic values, but include intangible cultural or spiritual values as well. Berkes (2008; pg. 163) documents that in Inuit culture, the loss of sea ice in summer months leaves some people 'lonely for the ice.' Whether the risk of such an irreversible cultural loss would be seen as intolerable remains a complicated question. The loss of traditional cosmologies and ways of seeing the world is a common occurrence throughout history. The ethical question is whether such non-material losses need to be acknowledged and whether there is a right to restitution.

One ethical principle that is widely applied in ethical discussions of climate is 'equity' (Gardiner, 2010). It is now well-established that nations, peoples and ecosystems are differentially vulnerable to current and future projected climate change impacts, which themselves are also almost certain to be unequally distributed across the world (IPCC, 2007b; Füssel, 2009; Füssel, 2010). This inequity is exacerbated by the fact that exposure to adverse impacts is involuntary for many societies (Paavola and Adger, 2006; Patz *et al*., 2007; Dellink *et al*., 2009; Füssel, 2010). Therefore, adaptation capacity and implementation constraints have the potential to create or exacerbate inequitable consequences due to climate change (*high agreement, robust evidence*). Linked to this is the complex question of the attribution of risks to anthropogenic forcing of climate change and whether there could be grounds for redress or compensation (Verheyen, 2005). Where limits to adaptation lead to catastrophic losses there are may be a strong need for humanitarian responses.

Inequity resulting from adaptation constraints and limits emerge across several dimensions; namely inter-country equity, inter-generational equity, inter-species equity (Schneider and Lane, 2005), and intra-country or sub-national equity (Thomas and Twyman, 2005). Adger *et al.* (2009b) propose that adaptation limits are endogenous to society and thus dependent on ethics, knowledge, attitudes to risk and culture. Inter-generational equity considerations are dominated by complex technical discussions about the time discount rate (Nordhaus, 2001; Stern *et al.*, 2006; Beckerman and Hepburn, 2007). This debate largely ignores the challenge of irreversible damages associated with limits to adaptation, especially those that may result from non-linear damage functions (Hanemann, 2008).

Inter-species equity is a complex topic and still the subject of evolving ethics unrelated to climate change considerations – value to human society increasingly serves as the most common metric for determining interventions affecting species (Balmford *et al.*, 2002). Clearly, differential ecosystem vulnerability is an important determinant of most species' vulnerability to climate change, with some species and ecosystems already severely threatened (IPCC, 2007b). Support for climate change adaptation interventions for species increasingly invokes human and societal benefits as a primary motivation (CBD, 2009).

Law codifies principles, norms and procedures for dealing with problems of risk and loss, including intolerable losses. National and international law will play a role in managing and sharing climate-related risks. The complexity of international law comprises a significant barrier to making the case for addressing the breaching of adaptation limits (Koivurova, 2007). At national and sub-national levels, cultural attitudes can contribute to stakeholder marginalization from adaptation processes, thus preventing some constraints and limits from being identified (such as gender issues and patriarchal conventions).

16.6.1. Ethics and the Externalities of Adaptation

There is a wide variety of potential positive and negative externalities associated with adaptation to climate change, and some of these have relevance in the context of constraints and limits. Externalities are important because they may allow 'free-riding' on the one hand, or, on the other hand, unintended adverse consequences that are not considered in implementing adaptation actions. Positive externalities can be projected at all levels of scale from international to local. Positive externalities may be associated with investments in public goods, but they may also arise from private investments in adaptation. Investments in health, food security and disaster risk reduction adaptive strategies may benefit neighbors most through reducing risks of social instability and resource demands. Negative externalities relate to adaptive strategies that reduce resource availability to neighbors, such as through water security strategies that may reduce availability to downstream neighbors (Eckstein, 2009), or generate new risks to neighbors, such as changing downstream flood risks as a result of raising river levees (te Linde *et al.*, 2011).

Positive distributional spill-overs of adaptation that aim to avoid limits are many and would benefit society through their monetization (Jack *et al.*, 2008). An example is the enhancement of ecosystem functions for local adaptation benefits (*e.g.,* restoration of wetlands to avoid the permanent loss of ecosystem services such as food and water security). The downstream externalized benefits would include a reduction in flood risk. Emerging concepts in the form of payments for ecosystem services would internalize these and provide further motivation for more integrated and equitable sharing of the burden and benefits of adaptation, but their implementation faces constraints relating to valuation and verification. There are few agreed international procedural arrangements for addressing or resolving these externalities, compounded by complex international law (Koivurova, 2007).

16.6.2. Ethics at the Limits of Adaptation

Historical reconstructions of societies that approach limits to adaptation involving a climate driver show that endogenous capabilities may determine whether limits are exceeded or avoided (Box 16-3). Ethical considerations are central to these endogenous responses. As real or perceived national or local limits to adaptation are approached, strategies may be encouraged that deprive neighbors of resources (FAO, 2011). Adaptation to water resource limitations may be particularly pernicious (Eckstein, 2009), with local strategies involving water table reductions that affect entire regions, and national strategies that impound water that would have previously flowed between or

across political boundaries. Intergenerational concerns are important for considering the ethics relating to avoiding adaptation limits. This is because several generations in the twenty-first century, at least, will experience progressively changing climates (Adger *et al*., 2009b), which could expose them to greater probabilities of exceeding adaptation limits.

16.7. Seizing Opportunities, Overcoming Constraints, and Avoiding Limits

16.7.1. Opportunities for Adaptation

We take adaptation opportunities to be factors that make it easier to plan and implement adaptive actions, or which ease adaptive responses to climate-related risks in ecosystems. An opportunity is distinct from an adaptation option, which is a specific means of achieving a social adaptation objective (such as an early warning system as a means of reducing vulnerability to tropical cyclones) or a strategy for securing a key ecological attribute (see Chapter 14.3.2 for discussion).We also do not consider here potential benefits of climate change, an issue addressed to varying degrees among the various sectoral and regional chapters.

Previous literature has focused especially on opportunities (and constraints) to build adaptive capacity and adaptation in national (Tompkins *et al*., 2010) and international policy contexts, while tending to neglect the important role of the private sector in facilitating adaptation (Tompkins and Eakin, 2012). The AR4 argues that public policy has a growing role in reducing vulnerability of people and infrastructure, providing information on risks for private and public investments and decision-making, and protecting public goods such as habitats, species and culturally important resources (Adger *et al*., 2007). Such roles include research and innovation support for adaptation options, creating the enabling environment for adaptation options to be implemented and ensuring that spillovers and externalities associated with adaptation options are managed. In a similar vein, the IPCC SREX report argues that (IPCC, 2012b: pg. 9),

> *"National systems are at the core of countries' capacity to meet the challenges of observed and projected trends in exposure, vulnerability, and weather and climate extremes. Effective national systems comprise multiple actors from national and sub-national governments, the private sector, research bodies, and civil society including community-based organizations, playing differential but complementary roles to manage risk, according to their accepted functions and capacities."*

In relation to ecosystem resilience, there is also a clear role for public policy (Vignola *et al*., 2009). Here too, common themes include information, mainstreaming, dialogue and participation. Special emphasis is placed on the transfer of power to local communities for adaptation decision-making. Given the great variability in social and ecosystem resilience, and the importance of local conditions and capacities in responding to these climate-related risks, there is often a rationale for local governance of adaptation. On the other hand, local resources, capacities and authority may not be sufficient to enable certain adaptation options to be realized.

16.7.1.1. Opportunities for Implementing Adaptation

There is evidence of public policy activity at the national and regional level in many parts of the world (see, for example, Chapter 15 for a discussion of National Action Plans for Adaptation (NAPAs)). Assessments of climate adaptation policies in Europe (Biesbroek *et al*., 2010; Massey and Bergsma, 2008) and North America (Luers and Moser, 2006; Moser and Luers, 2008; Moser *et al*., 2008) show that governments at different levels have recognized the importance of climate change and their potential role in adaptation. Accordingly, more structured policy frameworks and mechanisms to build capacity and advance adaptation are evident (16.8). Nevertheless, clear strategies for the implementation of substantive policies to reduce vulnerability to climate change and evaluate success are still lacking (Berrang-Ford *et al*., 2011; Ford *et al*., 2011; Preston *et al*., 2011a; Brouwer *et al*., 2013).

One of the primary strategies for enabling adaptation by private actors and securing public goods, such as ecosystem services, is through 'mainstreaming' climate vulnerability and adaptation into public policies (Urwin and Jordan,

2008; Dovers and Hezri, 2010). Mainstreaming involves a series of normative, organizational and procedural strategies that attempt to raise the profile of climate change at different stages of the policy cycle and to embed consideration of climate change impacts and adaptation in decision-making and policy evaluation (Mickwitz *et al.*, 2009; Rayner and Jordan, 2010). Mainstreaming is not without its challenges. For instance, there will be a question about whether 'principled priority' (Lafferty and Hoyden, 2003) should be given to climate adaptation goals over other goals, such as economic development or environmental protection. There is also a question over the extent of the coordination between policy domains that may be necessary. While key sectoral policy makers may accept the necessity for adaptive actions to ensure delivery of policy objectives into the long-term and adjust policies accordingly, they may fail to coordinate with efforts of other sectors. The result may be piecemeal approaches (Ellison, 2010) or incoherent, conflicting strategies (Pittock, 2011). For example, enhancing infrastructure for irrigation in arid areas to allow water-intensive agriculture to continue could hinder adaptation in other sectors, such as nature conservation.

A number of proposals have been made for public policy strategies that enable adaptation in the face of deep uncertainty. Hallegatte (2009b) describes five approaches to management decisions under conditions of uncertainty: "…*(i) selecting 'no-regret' strategies that yield benefits even in absence of climate change; (ii) favouring reversible and flexible options; (iii) buying 'safety margins' in new investments; (iv) promoting soft adaptation strategies, including (a) long-term (perspective); and (v) reducing decision time horizons*." By applying these principles, policymakers can create the conditions for better adaptation decisions by public agencies and in the private sector. In a similar vein, Stafford Smith *et al*. (2011) propose decision-making strategies for public policymaking, matching these strategies to the nature of uncertainty being faced in a specific decision context. They argue for a precautionary approach, risk-hedging against alternative futures and 'robust decision making' (see Chapter 2), where appropriate. Moser and Leurs (2008) suggest a series of enabling conditions for adaptation. These include taking account of the full range of adaptation options available (including apparently unattractive ones); making resources available for chosen options (singly or in portfolios) to be implemented; getting the institutional setting right in terms of incentives and penalties; making human and social capital available; enabling risk-spreading; and providing information allowing for good public understanding of stresses, risks and trade-off. In summary, adaptation opportunities are an outcome of an emphasis on flexibility, consistency and predictability, transparency and accountability in decision-making (Maddocks, 2012).

16.7.1.2. Ancillary Benefits of Adaptation

Adaptation in response to climate change vulnerabilities can achieve important co-benefits. While adaptation activities have often been developed and implemented in an *ad hoc* fashion (Ahmed and Fajber, 2009), adaptation efforts increasingly capitalize on complementarities by mainstreaming adaptation into existing policies and management activities (16.7.2). Although existing options provide a foundation to normalize adaptation (Dovers, 2010), it is important that the assessment and selection of adaptation responses consider a range of stressors, and, the need for adaptive management given future uncertainty.

Co-benefits may arise in three main ways – through improved implementation of adaptation to current climate variability; through exploiting new opportunities that arise as a result of the provision of climate adaptation goods and services; and through more general impacts on sustainable development.

- *Stimulating adaptation to current climate variability*: While it is generally assumed that physical, ecological and social systems are well-adapted to current climatic conditions; this is frequently not the case (Smit, 1993; Heyd and Brooks, 2009; Dugmore *et al*., 2009). Changes in observed climate, as well as the attention to such change, may lead currently maladapted actors and organisations to make changes that bring net benefits.
- *Provision of climate adaptation goods and services*: Adaptation will generally require additional investment and effort. It therefore represents an economic opportunity for some producers of goods and services. For example, the market for snow machines will be influenced by growing concerns about snow cover in more marginal ski resorts (Scott *et al*., 2006). In Arizona's high elevation, low latitude ski resorts by 2050, temperatures will may exceed technical thresholds in the shoulder seasons meaning that in years when natural snowfalls are poor the ski season may be curtailed. Higher elevation regions will see new

opportunities as a result of snow resort shifts (Bark *et al*., 2010). Likewise, new and innovative railway track and drainage systems may develop a market for dealing with track buckling caused by higher summer temperatures (Bark *et al*., 2010). The Stern Review suggested that huge market opportunities exist for new infrastructure and buildings resilient to climate change in OECD countries, with a potential value of between £9.5bn and £94.8bn per year (Stern *et al*., 2006). New services related to climate prediction and insurance also may emerge. Rising damage caused by climate change could provide new markets for innovative insurance products. Insurance can play an important role managing risks associated with climate-related damages (Botzen *et al*., 2009; Botzen *et al*., 2010).

- *Advancement of sustainability*: Economic development policies and strategies related to management of water and governance of natural resources, the development of water, transportation, and communication infrastructure, and the promotion of credit and insurance services can promote economic development, increase adaptive capacity and reduce the impacts of climate change on the poor (Hertel and Rosch, 2010).

16.7.2. Approaches to Overcoming Constraints and Avoiding Limits

There is a growing body of knowledge, including tools and guidelines, on the implementation of climate change adaptation responses which is addressing information and knowledge constraints on adaptation. This information provides a very wide range of views on how constraints may be overcome and opportunities taken. One of the important early initiatives in this area was the 'Assessment of Impacts and Adaptation to Climate Change' project under the START Program, which prompted an increase in research and policy interest and engagement in implementation (Mataki *et al*., 2006). In general, the information remains largely fragmented, although there is a major international effort underway to extract value from this knowledge through several actions of the Nairobi Work Program of the UNFCCC.

Opportunities for advancing implementation are becoming increasingly available through policies, tools and guidelines that are emerging throughout the developed and developing world addressing national, sub-national and local urban scales. For example, there is growing recognition of the potential for using disaster response and recovery processes as a means of increasing resilience to future extreme events (Lavell *et al*., 2012), although such opportunities require awareness and procedures to allow them to be taken. Examples of national responses include the USA '*Instructions for Implementing Climate Change Adaptation Planning in Accordance with Executive Order 13514*' (CEQ, 2011) and South Africa's '*National Climate Change Response White Paper*' (Government of South Africa, 2011). Many similar initiatives have been launched at sub-national and local levels with some early lessons about overcoming constraints to implementation being learned. For example Pickets (2012) states that many opportunities exist to incorporate adaptation-related principles and objectives into 'Official Community Plans', referring to storm-water management, water supply management, infrastructure planning, ecosystem mapping, and flood risk mitigation. Pickets (2012) also reports that incorporating climate change adaptation into existing plans and policies (i.e. mainstreaming) is effective in prioritizing implementation. However, there is far less information to assess how the theoretical body of adaptation knowledge has been applied, and the outcomes that have resulted, International networks of local governments (*e.g.,* Local Governments for Sustainability, ICLEI) will provide an important source of potential information on the effectiveness of implementation, and how constraints are being overcome and opportunities taken.

At present, the study of limits to adaptation is immature, with very few published data and little robust information available. As stated by the Australian National Climate Change Adaptation Research Facility (Jenkins *et al*., 2011; McNamara *et al*., 2011), the study of adaptation concerns mainly what adaptation can achieve, and not what is unachievable. Because limits to adaptation may be determined by a mix of physical, economic, technological and socially-related factors, and because history suggests behavioral responses affect the outcome of exceeding or avoiding limits, there is an urgent need to identify the social context that increases the chance of avoiding limits to adaptation.

Frequently Asked Questions

FAQ 16.1: Are there limits to adaptation to climate change?

Climate variations in the past sometimes went beyond what communities and societies at the time were able to cope with. Climate change during this century is also very likely to go beyond the limits of some of those needing to adapt. The greater the magnitude of climate change, the greater the likelihood that adaptation will encounter these limits. Limits exist both in the natural world and in society; some limits are hard while other ones are soft. For example, the rate of sea-level rise determines whether or not healthy coastal ecosystems can adapt by growing landwards or upwards. Beyond a certain rate these ecosystems will not be able to keep pace; this is a hard limit. Soft limits are reached when adaptation can no longer avoid a situation in which people's needs and values are compromised due to adverse effects of climate change. The location of both hard and soft limits is determined both by the degree and rate of climate change (and is therefore a function of mitigation pathways) and by the degree and rate of non-climatic stresses affecting the resilience or adaptive capacity of natural and human systems. Little empirical information is available on the functional relationships between climate change, non-climatic stresses and the emergence of limits to adaptation, offering scant support to the idea that the 2°C global goal represents a limit.

FAQ 16.2: To what extent can sustainable economic development, innovation, and technological change reduce adaptation constraints and contribute to the avoidance of limits?

There is a strong perception that economic development has enabled actors to deploy greater financial resources, technology, and human capital in managing risks due to climate change. However, the role of externalities of such development such as habitat degradation and, resource depletion, and climate change in increasing these risks has not been well quantified. A portfolio of local, national, and international strategies will be needed to facilitate sustainable development that expands the range of climate to which socio-ecological systems can adapt.

FAQ 16.3: Are limits to adaptation predictable?

Knowledge about limits to adaptation could inform the level and timing of mitigation and might justify early mitigation action. There is high confidence that limits to adaptation exist, but detailed understanding of the level at which climate change exceeds a limit is available only for a small number of natural systems and crop species. Research on adaptation by people often considers, explicitly or implicitly, technological change, financial resource availability, and other factors determining adaptive capacity, as well as physical and ecological impacts of climate change. However, any assessment of limits to adaptation in human systems is preliminary and of little use in decision-making, because of uncertainty about the existence and level of adaptation limits, and the soft nature of these limits. Furthermore, non-climatic trends and conditions, including uncertainty regarding actors' objectives and values and how they evolve over time, interact with climate change to further challenge the prediction of limits.

FAQ 16.4: What are the consequences of exceeding adaptation limits?

The exceedance of a socio-ecological system's limits to adaptation unavoidably results in a transformational change. This transformation may be adaptive through changes in management objectives, policy instruments, institutions and attitudes that enhance sustainability. Alternatively, transformation may be destructive resulting in loss and damage. As multiple values and objectives are often attached to biophysical and socioeconomic systems, transformation may involve trade-offs whereby some values are preserved while others are lost. As such, the exceedance of adaptation limits may raise ethical questions regarding how trade-offs are managed among different actors and, particularly, public versus private goods.

Cross-Chapter Box

Box CC-EA. Ecosystem Based Approaches to Adaptation - Emerging Opportunities

[Rebecca Shaw (USA), Jonathan Overpeck (USA), Guy Midgley (South Africa)]

Ecosystem-based approaches to adaptation (also termed Ecosystem-based Adaptation, EBA) integrate the use of biodiversity and ecosystem services into climate change adaptation strategies (e.g., CBD, 2009; Munroe *et al.*, 2011; Munroe *et al.*, 2011). EBA is implemented through the sustainable management of natural resources, as well as conservation and restoration of ecosystems, to provide and sustain services that facilitate adaptation both to climate

variability and change (Colls *et al.*, 2009). The CBD COP 10 Decision X/33 on Climate Change and Biodiversity states further that effective EBA also "takes into account the multiple social, economic and cultural co-benefits for local communities".

The potential for EBA is increasingly being realized (e.g., Munroe *et al.*, 2011), offering opportunities that integrate with or even substitute for the use of engineered infrastructure or other technological approaches. Engineered defenses such as dams, sea walls and levees, may adversely affect biodiversity, resulting in maladaptation due to damage to ecosystem regulating services (Campbell *et al.*, 2009, Munroe *et al.*, 2011). There is some evidence that the restoration and use of ecosystem services may reduce or delay the need for these engineering solutions (CBD, 2009). Well-integrated EBA is also more cost effective and sustainable than non-integrated physical engineering approaches, and may contribute to achieving sustainable development goals (e.g., poverty reduction, sustainable environmental management, and even mitigation objectives), especially when they are integrated with sound ecosystem management approaches. EBA also offers lower risk of maladaptation than engineering solutions in that their application is more flexible and responsive to unanticipated environmental changes.

EBA provides opportunities particularly in developing countries where economies depend more directly on the provision of ecosystem services (Vignola *et al.*, 2009), to reduce risks to climate change impacts and ensure that development proceeds on a pathways that are resilient to climate change (Munang *et al.*,). In these settings, ecosystem-based adaptation projects may be readily developed by enhancing existing initiatives, such as community-based adaptation and natural resource management approaches (e.g., Khan *et al.*, 2012, Midgley *et al.*, 2012; Roberts *et al.*, 2012)

Examples of ecosystem based approaches to adaptation include:

- Sustainable water management, where river basins, aquifers, flood plains, and their associated vegetation are managed or restored to provide resilient water storage and enhanced baseflows, flood regulation services, reduction of erosion/siltation rates, and more ecosystem goods (e.g., Midgley *et al.*, 2012, Opperman *et al.*, 2009).
- Disaster risk reduction through the restoration of coastal habitats (e.g., mangroves, wetlands and deltas) to provide effective measure against storm-surges, saline intrusion and coastal erosion;
- Sustainable management of grasslands and rangelands to enhance pastoral livelihoods and increase resilience to drought and flooding;
- Establishment of diverse and resilient agricultural systems, and adapting crop and livestock variety mixes to secure food provision. Traditional knowledge may contribute in this area through, for example, identifying indigenous crop and livestock genetic diversity, and water conservation techniques;
- Management of fire-prone ecosystems to achieve safer fire regimes while ensuring the maintenance of natural processes.

It is important to assess the appropriate and effective application of EBA as a developing concept through learning from work underway, and to build understanding of the social and physical conditions that may limit its effectiveness. Application of EBA, like other approaches, is not without risk, and risk/benefit assessments will allow better assessment of opportunities offered by the approach.

Table 16-1: Constraints affecting the implementation of adaptation policies and measures.

Constraint	Examples
Knowledge and Information	• Uncertainty regarding future climate change (Hulme *et al*., 2009; Dessai *et al*., 2009; Wilby and Dessai, 2010) • Uncertainty regarding future socioeconomic states and associated uncertainties (Preston et al., 2011b) • Lack of information regarding adaptation options and their costs and benefits (Prato, 2008; de Bruin *et al*., 2009b; Patt *et al*., 2010) • Incomplete information regarding the various constraints on, or limits to, the effectiveness of adaptation options (Mitchell *et al*., 2006; Moser, 2009; Smith *et al*., 2008b; Moser and Ekstrom, 2010; Conway and Schipper, 2011) • Lack of consensus regarding the appropriate balance between traditional and formal scientific knowledge (Box 16-2)
Natural Resources	• Growing consumption of water by humans is threatening the sustainable yield of surface and groundwater systems in a number of global regions (Bates *et al*., 2008; Shah, 2009; Goulden et al., 2009; Gober and Kirkwood, 2010; MacDonald, 2010; Taylor et al., 2012) • Non-climatic stresses to ecological systems can reduce their resilience to climate change (Malhi *et al*., 2009a,b; Diaz and Rosenberg, 2008; Kapos and Miles, 2008; Afreen *et al*., 2011). • Degradation of coastal wetlands and coral reef systems may reduce their capacity to buffer coastal systems from the effects of tropical cyclones (Das and Vincent, 2009; Tobey *et al*., 2010; Gedan *et al*., 2011; Keryn *et al*., 2011; CC-EA). • Soil degradation and desertification reduce crop yields and the resilience of agricultural and pastoral livelihoods to climate stress (Iglesias *et al*., 2011; Lal, 2011).
Financial Resources	• Financial capital is a key determinant of vulnerability and adaptive capacity of farmers and land managers to climate variability and change (Nhemachena and Hassan, 2007; Hassan and Nhemachena, 2008; Deressa *et al*., 2009, 2011; Jantarasami *et al*., 2010). • The costs of investigating and responding to climate change are perceived to be significant constraints on adaptation for local governments (Gardner *et al*., 2010; Smith *et al*., 2008b; Measham *et al*., 2011) • The reallocation of overseas development assistance to adaptation may divert resources away from programs and projects targeting development goals (Ayers and Huq, 2009) • Availability of adaptation finance through the clean development mechanism is declining (AFB, 2012)
Technology and Infrastructure	• Climate impacts to existing infrastructure and the needs for new infrastructure dominate aggregate estimates of adaptation costs (see Chapter 17, World Bank, 2006; Nicholls, 2007; UNDP, 2007; UNFCCC, 2007; Parry *et al*., 2009). • Inadequate technology and infrastructure is a key determining factor of the 'adaptation deficit' of particular regions and sectors (Burton 2004, 2005; Burton and May 2004). • Technological innovation and deployment is important for facilitating adaptation in agriculture (Hillie and Hlophe, 2007; Howden et al., 2007; Bates *et al*., 2008; Fleischer *et al*., 2011). • Technology is important for managing the risks of climate change and sea-level rise to coastal communities (Nicholls, 2007; van Koningsveld *et al*., 2008). • Awareness, uptake and use of technology is determined by multiple factors including education, financial resources, and cultural attitudes (Nhemachena and Hassan, 2007; Hassan and Nhemachena, 2008; Deressa *et al*., 2009, 2011).
Human Resources	• Lack of leadership on adaptation is a key constraint to adaptation planning and implementation (Gupta *et al*., 2010; Tompkins *et al*., 2010; Termeer *et al*., 2012; van der Berg *et al*., 2010) • Human resources influence the capacity of public health systems to manage climate risk (Ebi and Semenza, 2008) • Multiple stressors to mental health can impair cognition and effective decision-making around adaptation (Dias-Ferreira *et al*., 2009; Spears, 2011)

Table 16-2: Examples of potential trade-offs among adaptation objectives.

Sector	Strategy	Adaptation Objective	Real or Perceived Externality	References
Agriculture	Biotechnology and genetically modified crops	Enhance drought and pest resistance; enhance yields	Perceived risk to public health and safety; ecological risks associated with introduction of new genetic variants to natural environments	Howden *et al*. (2007); Nisbet and Scheufele (2009); Fedoroff *et al*. (2010)
	Subsidized drought assistance; crop insurance	Provide financial safety net for farmers to ensure continuation of farming enterprises	Creates moral hazard and inequality if not appropriately administered	Productivity Commission (2009); Pray *et al*. (2011); Trærup (2011); O'Hara (2012); Vermeulen *et al*. (2012)
	Increased use of chemical fertilizer and pesticides	Maintain or enhance crop yields; suppress opportunistic agricultural pests and invasive species	Increased discharge of nutrients and chemical pollution to the environment; increased emissions of greenhouse gases; increased human exposure to pollutants	Gregory *et al*. (2005); Howden *et al*. (2007); Boxall *et al*. (2009)
Biodiversity	Migration corridors; expansion of conservation areas	Enable natural adaptation and migration to changing climatic conditions	Unknown efficacy; concerns over property rights regarding land acquisition; governance challenges	Hodgson *et al*. (2009); West *et al*. (2009); Krosby *et al*. (2010); Levin and Petersen (2011)
	Anticipatory endangerment listings	Enhance regulatory protections for species potentially at-risk due to climate change	Addresses secondary rather than primary pressures on species; concerns over property rights; regulatory barriers to economic development	Clark *et al*. (2008); Ragen *et al*. (2008); Bernanzzani *et al*. (2012)
	Assisted migration	Facilitate conservation of valued species	Potential for externalities for ecological and human systems due to species relocation	Lovejoy (2005, 2006); McLachlan *et al*. (2007); Dunlop and Brown (2008)
Coasts	Sea walls	Protect assets from inundation and/or erosion	High direct and opportunity costs; equity concerns; ecological impacts to coastal wetlands	Nicholls (2007); Hayward (2008); Hallegatte (2009); Zhu *et al*., (2010)
	Managed retreat	Allow natural coastal and ecological processes; reduce long-term risk to property and assets	Undermines private property rights; significant governance challenges associated with implementation	Rupp-Armstrong and Nicholls (2007); Hayward (2008); Abel *et al*. (2011); Titus (2011)
	Migration out of low-lying areas	Preserve public health and safety; minimize property damage and risk of stranded assets	Loss of sense of place and cultural identify; erosion of kinship and familial ties; impacts to receiving communities	Hess *et al*. (2008); Helberg *et al*. (2009); McNamara and Gibson (2009); Adger *et al*. (2011)
Water resources management	Desalination	Increase water resource reliability and drought resilience	Ecological risk of saline discharge; high energy demand and associated carbon emissions; creates disincentives for conservation	Adger and Barnett (2009); Barnett and O'Neill (2010); Becker *et al*. (2010); Rygaard *et al*. (2011); Tal *et al*. (2011)
	Water trading	Maximize efficiency of water management and use; increases flexibility	Undermines public good/social aspects of water	Alston and Mason (2008); Bourgeon *et al*. (2008); Donohew (2008); Mooney and Tan (2012); Tan *et al*. (2012)
	Water recycling/reuse	Enhance efficiency of available water resources	Perceived risk to public health and safety	Hartley, 2006; Dolcinar *et al*., 2011

Table 16-3: Sectoral synthesis.

Sector	***Framing***	***Adaptation Objective***	***Rate of change***	***Opportunities***	***Constraint***	***Limits***	***Synthesis***
Freshwater resources [Chapter 3]	Major emphasis needs to be given to governance reform to build the capacity for climate change adaptation and design and implementation of resilient system. Adaptation involves measures to alter hydrological characteristics to suit human demands, and measures to alter demands to fit conditions of water availability [3.6.6]. Therefore, there is a concerted effort away from "predict and provide" to enhancement of adaptive water management techniques including Integrated Water Resource Management (IWRM) joined with Strategic Environmental Assessment (SEA)[3.6.1, 3.6.3].	Avoid adverse impacts (e.g. floods and droughts) to the economy (e.g. economic losses) and the society (e.g. affected population) through strategic water resource management by incorporating adaptation options in planning and implementation of best practices, and enhance adaptive water management techniques [3.6.1]. Move from "predict and provide" approach towards adaptive water management and the adoption of 'resilient' approaches [3.6.3], and investments in risk-based actions [3.6.4].	Intense precipitation events will become more frequently and droughts will be more severe [3.3.1.4] and rates of mass loss of glaciers is likely to increase [3.4.4.2]	Climate change is frequently cited as a key motivation for the adoption of adaptive water management [3.6.3 and Table 3.3] provides a list of Adaptation Options including improve information, improve water management practices, improve the design and operations of water services, reduce water demand and waste, increase water supply and reliability, prevent pollution, reduce impacts of natural disasters, IWRM. Opportunities for improvements include "no regret" actions - those that generate net social and/or economic benefits regardless of whether climatic change occurs [3.6.3 and FAQ 3.6].	Specific constraints include: Structural: Long-lived infrastructure and the prevailing of large infrastructure as prevailing design [3.6.1]. Governance/Institutional: Sectoral fragmentation, lack of reform to manage uncertainty and surprise [3.6.1]. Institutional structures that limit stakeholder engagement and the uncertainty in how climate change may affect the water management system [3.6.3]. Economic (Human and financial capital) constraints include high economic costs and the failure to estimate actual costs [3.6.2], the high cost of implementation. Lack of financial resources. Technological, Information and Science: Uncertainty in the projected future changes makes it impossible for practical purposes to construct quantitative probability distributions of climate change impacts [3.6.5]. Lack of guidance on how the adaptive water management approach works when addressing climate change over the next few decades [3.6.3]. Access constraints including technology, information, capacity, institutions and capital, particularly in the developing countries [Table 3.4]. Lack of technical capacity, financial resources, awareness, and communication in developing countries [3.6.4]. Social/Psychological/Cultural: *[Need specifics/update from SOD]* Other: *[Need specifics/update from SOD]*	Nothing mentioned explicitly; the subsection on limits to adaptation (3.6.4) discusses constraints.	Changes in precipitation patterns and reduction in glacier volume may lead to reductions in river flows and falling groundwater tables, and cause saline intrusion in rivers and groundwater in coastal areas and that reduction in local water sources will lead to increased demand on regional water supplies [3.5.1] and significant declines in freshwater species globally [3.5.5]. Costs will be ca. USD 531 billion through 2030 to provide a sufficient water supply, given present and future projected water demands and supplies in more than 200 countries, the adaptation (Kirshen 2007, [3.6.2].

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
Terrestrial and inland water systems [Chapter 4]	There is a potential for autonomous adaptation by ecosystems and species including the capacity to migrate and human assisted adaptation including adaptive management, assisted, migration and restoration [4.4.1, 4.4.2]	Increasing the capacity of target organisms, ecosystem or Social-Ecological System to survive and function at an acceptable level, in the presence of climate change [4.4.2].	Capacity of autonomous adaptation for ecosystem and their constituent organisms is insufficient to cope with the rate and magnitude of change under moderate and high climate change scenarios for this century [4.4.1-4.4.1.2, 4.4.3]	Opportunities to facilitate adaptation stems from the implementation of planned or "human-assisted" adaptation including reduction of non-climatic stresses [4.4.2.1], strategic number, location and connectedness of protected areas [4.4.2.2], landscape and watershed management [4.4.2.3], assisted migration and restoration [4.4.2.4] and ex-situ conservation [4.4.2.5]	*Specific constraints include*: Access: *[Need specifics/update from SOD]* Structural: Autonomous adaptation constrained by physical or topographic barriers (*e.g.,* valleys, mountain ranges and water bodies), human-created (fences, roads, croplands or settled areas), increasing habitat fragmentation of ecosystem. [4.4.3]; Lack of suitable habitat and dispersal pathways for species, inability to reduce or remove of other stressors, societal resistance Governance: Social and institutional factors including poor ecological understanding are constraints for successful adaptive management [4.4.2]. Economic (Human and financial capital): *[Need specifics/update from SOD]* Information and Science: Inadequate predictive theory for range shifts and extinction risk, combined with climate scenario uncertainty constrain conservation planning.	A clear consensus that climate change will result in shifts in species ranges, that constraints on migration for many species, in the context of highly fragmented habitats and other pressures, will greatly increase extinction risk over the coming century. [4.3.3] Phenotypic or genotypic evolution inadequate to ensure population persistence causing local to global extinction [4.4.1.2]	The most recent synthesis of range shifts indicates that terrestrial species have moved poleward which corresponds to predicted range shifts due to warming (Chen *et al*., 2011) and that range shifts for terrestrial species will accelerate over the coming century. [4.3.2.5] Significant proportion of coral reef species and terrestrial species at risk of extinction, as temperature change increases above 2 to 3 degrees. The cost of adaptation to ensure persistence in the wild increases due to land availability and translocation costs.
Coastal systems and low-lying areas [Chapter 5]	Adaptation occurs in the context of existing governance and social-ecological systems, regardless of types of adaptation (i.e. proactive and planned or reactive and ad hoc) the approach should be integrative and implemented through adaptive management [5.6.1]	Minimize risks and impacts from coastal hazards to ensure public safety and welfare; economic development and use of coastal resources; protection of coastal environmental resources, natural assets and ecosystems (5.6.1)	The coastal ecosystems are affected by higher sea level, increasing temperature, changes in precipitation, increased extreme events and reduction in ocean pH from climate change and rapid urbanization in coastal areas and growth of megacities with consequences on	Implementation of the many approaches on integration for better social, ecological, and economic outcomes including Integrated Coastal Management, Community-Based CoAdaptation, Ecosystem-Based Adaptation (EbA), and Disaster Risk Reduction and Management. [5.9.1]	Different constraints typically do not act in isolation but interact [5.9.4] Constraints are many and fall into many categories including the technological feasibility, resources, institutional (existing laws, regulations, procedural requirements or ineffective governance), social and psychosocial (place attachment, social support, social norms, identity), cultural-cognitive (beliefs, worldviews, values, awareness, education) and economic (livelihood, job mobility, investment), lack of awareness, knowledge or location-specific information, social justice concerns, or negative interactions between different policy goals. [Table	Managed retreat from coastal system as adaptation option implemented in response to a soft limit to adaptation FAQ 5.6. Limits to adaptation will be experienced by migrating species and habitat types as sea level rise	The most important effects of climate change on the coastal cities include the effects of sea-level rise, effects of extreme events on built infrastructure (such as wind storms, storm surges, floods, heat extremes and droughts), effects on health, food and water-borne disease, effects on energy use, and

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
			the coastal resources. [5.1]. Global mean sea level (MSL) has been rising since 1900 at a rate of 1.7 mm yr^{-1} and 3.2 mm yr^{-1} since 1993 (AR5, Chap 13).		5-7, 5.9.4] *Specific constraints include*: Access: *[Need specifics/update from SOD]* Structural: Continued development in high risk areas [5.6.1]. Governance/Institutional: The prevalence of mal-adaptation due to interactions across policy domains [5.6.4]. Economic (Human and financial capital): economic constraints at the individual level, institutional and government levels that prevent implementation [5.6.4]. Technological, Information and Science: *[Need specifics/update from SOD]* Social/Psychological/Cultural: *[Need specifics/update from SOD]* Other: *[Need specifics/update from SOD]*	meets human settlements [5.3.1] including coastal marshes [5.6.4]. The decline of seawater pH decreases the rate of calcification of most corals, presenting a limit to coral reef adaptation [5.3.1.6]. Physical limits to unassisted adaptation of coastal marshes as sea levels rise past A1B scenario (5.6.4)	effects on water availability and resources (Hunt and Watkiss, 2010) [5.4.2.1]. The total assets exposed in 2005 across all cities are estimated to be US$3 trillion, which would increase to US$35 trillion by 2070s (Nicholls *et al.*, 2008; Hanson et al., 2011) [5.4.2.1]
Ocean systems [Chapter 6]	Ecosystem resilience and marine ecosystem based adaptation [6.4] There is a potential for autonomous adaptation for species and population including through genotypic variation and migration [6.2.2.2]	Resilience of fisheries. *[Update for SOD as majority of adaptation discussion focused on species adaptation to increasing temperatures and changes in acidity]*	Over the last 43 years average warming has occurred by >0.1 °C/decade in the upper 75 m with increase of X% through 2070 [6.1.1.1]. The changes in ocean temperature and acidification will drive changes in nutrients con, salinity, underwater light regime net primary	Opportunities for adaptation of human populations dependent on ocean resources, particularly in developing countries, are limited [6.4.1.1.2]	Constraints are related to ocean temperature, acidification, etc that limit functions of ocean and supply of primary elements to living organism thus preventing autonomous adaptation [6.4]. *Specific constraints include:* Access: *[Need specifics/update from SOD]* Structural: *[Need specifics/update from SOD]* Governance/Institutional: *[Need specifics/update from SOD]* Economic (Human and financial capital): *[Need specifics/update from*	Marine species that already live close to their upper thermal and pH limits will be most sensitive to climate change. There have been reports on climate-induced changes in species abundances but not on climate-induced extinctions in the oceans [6.5.2].	Fisheries and ecosystem management in the future might have to deal not only with the traditional sustainability goals, but to increase the ecosystems resilience to climate variability and change [6.4.2.5] Adaptation and management of risks will build on successful detection and attribution. Ecosystem-based

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
			production and food availability [6.1, 6.2],		*SOD]* Technological, Information and Science: *[Need specifics from SOD]* Knowledge gaps on whether and to what extent species can undergo adaptation to progressive ocean acidification over generations [6.2]. Social/Psychological/Cultural Other: *[Need specifics from SOD]*	Evidence regarding limits to adaptation are scarce for ocean systems however one study finds a limit in which aragonite undersaturation is projected to occur by the year 2030 leading to a decrease rates of calcification and increasing ocean acidification [McNeil and Matear 2008]	management (EBM) with a focus on climate change impacts will need adopted to manage the multitude of anthropogenic pressures on marine ecosystems, [6.4.3]
Food production and food systems [Chapter 7]	Adaptation through reductions in risk and vulnerability by adjusting practices, processes and capital in response to current climate or threat of climate change [7.5.1],	Reduce and vulnerability by adjusting practices, processes and capital [7.5.1.1] to address the eight elements of the food security outcomes including income, employment, wealth, social capital, political capital, human capital, ecosystem stock and flows, ecosystem services and access to natural capital (Figure 7-1).	Crop yields are likely to fall by at least X% by the year 20XX [7.4.4.] with the highest rates of food insecurity are in Sub-Saharan Africa *[Need specifics/update from SOD]*	Opportunities include taking advantage of the increase in the growing season, the range expansion, and yields [7.5].	Constraints include inadequate information on climate, climate impacts, risks and benefits of options, lack of adaptive capacity, technical options, inadequate extension, institutional inertia, financial resources, infrastructure, functioning markets and insurance systems [7.5.1] *Specific constraints include:* Access: *[Need specifics/update from SOD]* Structural: Lack of infrastructure. Governance/Institutional: Institutional inertia and lack of adaptive capacity [7.5.1.2.1], lack functioning markets and insurance systems. Economic (Human and financial capital): Lack of financial resources, Inadequacy of required substantial investment to develop new varieties of crops or breeds of livestock [7.5.1.2.1] Technological, Information and	Physiological limits to performance and crop yields requirement to sustain critical backward and forward link infrastructure. [7.5.1]	Adaptation of food systems shows a wide range in effectiveness. With an increase in effective with adaptations aimed at temperature increases which leads to lower reductions in yields than in its absence with more effective adaption at higher latitudes [Executive Summary] However, most reduction in risk are incremental, not transformative, and do not take into account the competing stressors of water availability and increased demand for food

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
					Science: Inadequate information on climate, climate impacts, risks and benefits of option. Lack of technical options. [7.5.1.2.1]. Social/Psychological/Cultural: Other: *[Need specifics/update from SOD]*		[7.5] Many of the elements in the human food system will be adversely affected by projected climate change from about the mid-21st century onwards. Adaptation options have potential to reduce 20 percent yield reduction [ES]. Ongoing increases in potential yield across the globe due to crop improvements may act to mitigate negative impacts (7.4.1)
Urban areas [Chapter 8]	Building resilience of urban infrastructure and social system by integrated planning, investment and addressing structural drivers of social and urban vulnerability [8.3.2.1]	Integrate/mainstream climate change adaptation in urban areas through government led city planning and implementation and disaster risk reduction [8.3.2], coordination of investment from individuals, household and firms, and other levels of government [Executive Summary].	Great diversity exists among the world's urban areas with rates of change as informed by the scale and nature of the climate-related risks. *[Need specifics/update from SOD]*	Opportunities exist in taking advantage of 30 years of experience in municipal disaster risk reduction and in building on the relation between adaptation to climate change and development [8.3.2.2], including implementation of ecosystem-based adaptation to support a range of policy goals including food security, water purification, waste water treatment and flood risk reduction as well as mitigation [8.3.3.7, Box 8.1]]	Constraints include resource limitations, limited adaptive capacity with limited resources, weak institutions, poor/inadequate infrastructure and poor governance in global south [8.5.1] *Specific constraints include:* Structural/capacity: Lack of technical expertise, Lack of capacity of multi-levels of government to implement coordinated plans and responses [Executive Summary] Governance/Institutional: Municipal government priorities driven by short term priorities and nearer term concerns about economic growth and competitiveness [8.4]. Ill-designed institutional mechanisms (compartmentalization and fragmentation) at local level [8.4]. Lack of mandate and clarity at different levels, inadequate policy attention and recognition by national	Coastal system that are inundated as sea level rises and river systems that flood create a soft limit to adaptation [8.4.1.2] unless strategic and managed retreat is developed in advance.	Adaptation in a 4 degree world will have to be a "more substantial, continuous and transformative process" than for a 2 degree world, and will have to contend with the possibility of thresholds, that once crossed, will lead to abrupt, non-linear and unpredictable global environmental change. This will stretch the adaptive capacity not only of existing urban systems, but of the whole global system [8.5].

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
					government [8.4]. Disaster risk reduction is still not integrated into development plans and not drawing in all relevant departments and divisions of local government. Implementation of hard engineering solutions and effectiveness are constrained by technological, financial, institutional and skill [8.3]. Lack of coordinating poverty reduction with climate change responses and making adaptation plans locally relevant [8.5] Economic (Human and financial capital): Lack f financial resources for implementation [8.4] Technological, Information and Science: Uncertainty as to what climate change will bring (and when) in each locality [Executive Summary]. Limited technical expertise. Poorly developed Monitoring, Reporting and Feedback systems [8.5]. Substantial knowledge gaps need to be addressed to determine where the limits or thresholds lay, limits or thresholds to adaptation of various ecosystems. Knowledge about limits within existing systems will be vital in developing appropriate transformative planning responses to future climate challenges [8.3; 8.5] Social/Psychological/Cultural: *[Need specifics/update from SOD]* Other: *[Need specifics/update from SOD]*		
Rural Areas [Chapter 9]	Adaptation, and building capacity to adapt, is a dynamic process and should be linked to other development initiatives aiming for poverty reduction or improvement of rural	Development of resilient agriculture, economic and institutional development, improvements in health, education and infrastructure, growing	Prospects for adaptation depend on the magnitude and rate of climate change, adaptation strategies being inseparable from increasingly strong and complex	Opportunities to benefit rural communities come from expanding the use of seasonal forecast information for coordinating input and credit supply, food crisis	[*To be completed post-SOD]*	There are soft limits to the role of social capital in resilience which context specific and time bound [9.4.1].	Climate change in rural areas in developing countries will take place in the context of many important economic, social and land-use trends. In different regions,

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
	areas [9.4.1]	interconnectedness and technology transfers to help rural societies to develop their human and social capital and link adaptation to other development initiatives aiming for poverty reduction or improvement of rural areas.	global linkages [9.2].	management, trade and agricultural insurance [9.4.4]		Poverty, hunger, malnutrition are already significant challenges being exacerbated by climate variability in rural settings (mainly sub-Saharan Africa), attribution difficult because of the impacts of related and unrelated co-stressors, water supply, food production and agricultural income are seeing increasing residual damages, indicating the approach of limits in many regions [9.4.1].	rural populations have peaked or will peak in the next few decades [9.3.1]. Conservation agriculture and water management for agriculture is critical in rural areas under climate change and adjustment measures relating to there farming practices. Adaptation in marine ecosystems is also of relevance to rural areas. Need to discriminate between developing and developed country rural areas, with the latter at far higher risk of imminent limits, and heavily constrained by a number of factors.
Key economic sectors and services [Chapter 10]	To reduce the cost of adaptation.	*[To be completed post-SOD]*	*[To be completed post-SOD]*	*[To be completed post-SOD]*	*[To be completed post-SOD]*	*[To be completed post-SOD]*	*[To be completed post-SOD]*
Human health [Chapter11]	Climate change acts as a multiplier of risk – in most instances, changes in temperature; rainfall and extreme events compound health problems that are already present. [11.6.1]	Reducing background rates of disease and injury, improvements in public health and health care including access to heath care services for improvement of population resilience and minimizing poor health outcomes	There is a dearth of scientific evidence of the relationship between weather/climate and health in low- and middle-income countries [Box 11-2]	Cross-sectoral adaptation opportunities exists (transportation, building, landuse, forestry and agriculture (Younger et al., 2008). Reduction in disaster mortality through effective	Uncertainties of future climate and socioeconomic conditions, financial, technologic, institutional, social capital and individual cognitive limits, different knowledge and conceptual understanding by different actors/stakeholders, governance arrangements and the way institutions works (Huang, C, et al., 2010; Carmichael and Lambert, 2011) *Specific constraints include:*	Climate and/or health conditions that limit the body's ability to respond to stressful events [11.3.1.2].	Health is both a condition for, and a consequence of, development, and there is a similar inter-dependence between a country's social and economic progress and its ability to protect its population against adverse effects of

Sector	*Framing*	*Adaptation Objective*	*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
		resulting from climate change [11.6.1]		collaborations between government, local communities and non-governmental organizations (Khan 2008). Carbon abatement is an opportunity to achieve both climate mitigation and health benefits (UNEP, 2012).	Structural: *[To be completed post-SOD]* Governance/Institutional: *[To be completed post-SOD]* Economic (Human and financial capital): *[To be completed post-SOD]* Technological, Information and Science: Social/Psychological/Cultural: *[To be completed post-SOD]* Other: *[To be completed post-SOD]*		stressors such as climate change [11.1.1]
Human Security (Chapter 12)	Human security in the inverse of social vulnerability in that it implies the protection of people from severe shocks arising from changes in social or environmental conditions [Executive Summary].	Enhance human security through social and environmental policies and programs that ensure social protection and expand people's freedoms and opportunities necessary for survival, sustainable livelihoods, and dignity [12.1.2].	[*To be completed post-SOD]*	Opportunities include migration to enhance human security to climate change impacts [ES].	Lack of flexibility in where and when to relocate, access to resources, changes in the resource base, resource management, encroachment and institutional constraints, *Specific constraints include:* Structural: *[To be completed post-SOD]* Governance/Institutional: [*To be completed post-SOD]* Economic (Human and financial capital): [*To be completed post-SOD]* Technological, Information and Science: Neglecting local and traditional knowledge in policy and research [12.3.2] Social/Psychological/Cultural: Poverty widens disparities and lack of proper entitlements or rights for managing and using resources [12.3.4] Other: [*To be completed post-SOD]*	No hard limits identified but at very high rates of projected warming, all of the aspects of human security likely to be adversely effects creating soft limits that may be difficult to overcome [12.7]	Climate change seems likely to be an increasingly important driver of human insecurity in the future [12.7]
Synthesis	[*To be completed post-SOD]*	*[To be completed post-SOD]*	[*To be completed post-SOD]*	[*[To be completed post-SOD]*	[*To be completed post-SOD]*	[*To be completed post-SOD]*	[*To be completed post-SOD]*

Africa [Chapter 22] [22.3.4: adaptation section is forthcoming]	Mainstreaming adaptation to climate change into national development policies. Sub-regional organizations integrate climate change in their policies and economic management.	Strengthening adaptive capacity of rural and urban contexts by mainstreaming climate change into national development policies as well as sub-regional organizations integrate climate change in their policies and economic management.	*[To be completed post-SOD]*	Opportunities for adaptation include linking adaptation and development, and for low-regrets adaptation strategies that produce developmental co-benefits [22.4], including integrated programmes on desertification, water management and irrigation, promoting sustainable agricultural practices, developing alternative sources of energy [22.4.1] and implementing ecosystem-based adaptation [22.6.5] In addition, reducing health burdens through improving public health surveillance and monitoring, access to safe water and improved sanitation, hygiene education, and waste management strategies; and providing better access to health care and health insurance [22.3.3.2.3]	The constraints to adaptation in Africa interact in multiple and complex ways across scales influencing how local people both decide or are enabled to respond or not to changes in their environment [22.4.4]. *Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Corruption, inadequate extension services and top-down decision making. Institutional weakness, Over-emphasis of mitigation discourse, emphasis of short-term outcomes with a disaster/risk orientation. Economic (Human and financial capital): Lack of resources [22.4.4]. Technological, Information and Science: Lack of capacity, data and integrated analysis related to climate change. Lack of knowledge regarding what influences decision making [22.4.4]. Social/Psychological/Cultural: Cognitive, behavioral and cultural constraints exist regarding the need to adapt and the willingness to accept change [22.4.4]. Other: *[Need specifics/update from SOD]*	Neither autonomous nor planned adaptation to climate change is necessarily materialising neither in the ways expected nor at the pace desired, and that simply providing the right technology and sufficient funding to carry out local level programmes is not a guarantee for change on the ground (Ludi et al. 2012) [22.4].	A wide range of adaptation options, approaches and decision tools are being tested and implemented across Africa but additional efforts at scale are needed to address the complex identified vulnerabilities and needs [Executive Summary], including disaster risk reduction, early warning systems and disaster preparedness; social protection and index-based weather insurance; technological approaches and climate-resilient infrastructure; sustainable land management and ecosystem restoration; and livelihood diversification [Executive Summary], .

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
Europe [Chapter 23]	Integration of climate change into national, local and sectoral development plan and strategies [23.7] aiming at improving competitiveness, the environment, and the quality of life in rural areas [23.7.5].	Focus on cross-sectoral decision making for adaptation with respect to four main categories of impacts: (1) production systems and physical infrastructure; (2) agriculture, fisheries, forestry and bioenergy production; (3) health and social welfare and; (4) protection of environmental quality and biological conservation [23.1.1].	*[To be completed post-SOD]*	Individual and cross sector opportunities are highlighted in each of the four main categories (1) production systems and physical infrastructure; (2) agriculture, fisheries, forestry and bioenergy production; (3) health and social welfare and; 4) protection of environmental quality and biological With a focus on recreation and tourism, insurance and banking, food (fiber, livestock, fish) production, water resources, forestry, disaster risk reduction (drought, flood), infrastructure, water quantity and quality, human health, social and cultural. *[Need specifics/update from SOD]*	*Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Lack of institutional frameworks is a major constraint to adaptation governance [23.10.1] and cross-sector adaptation plans. A lack cross-sector impact and adaptation linkages as an important weakness in the city plans [23.7]. Economic (Human and financial capital): *[Need specifics/update from SOD]* Technological, Information and Science: *[Need specifics/update from SOD]* Social/Psychological/Cultural: *[Need specifics/update from SOD]* Other: Irrigation for agriculture will be constrained by reduced runoff, demands from other sectors, and by economic costs [23.4.1, 23.4.3]. Lack of integrated coastal zone management or climate change adaptation for the Baltic Sea Region.	In agriculture, there are limits to increasing crop yields and production through genetic modification [23.10.1] In natural systems, phenological mismatches will limit both terrestrial and marine ecosystem functioning and ecosystem service production [23.6.4, 23.6.5]. Drought-pest dynamics in forest systems may be a limit to forest persistent and productivity through a state change [23.4.4]. There are soft limits to how far communities can adapt to rapid and large sea-level rise.	Climate change impacts and vulnerability assessments have given rise to an adaptation decision-making framework, at the local, regional, national and pan-European levels leading to the development of a series of national plans and strategies to address adaptation [23.7]. The next step is cross-sectoral decision-making and planning [23.7] in arenas such as Coastal Zone Management [23.7.1]. Integrated Water Resource Management (IWRM) [23,7,2]), land use planning [23.7.4] and rural development [27.7.5].
Asia [Chapter 24]	Adaptive management and mainstreaming climate change into development planning at all scales, levels and sectors [24.2.2].	Adaptive management and mainstreaming climate change into development planning at all scales, levels and sectors including cross-sectorial collaborations for the development of sustainable adaptive measures (24.4.6.5)	*[To be completed post-SOD]*	Opportunities are described in 6 categories (1) Freshwater resources: applying water saving technologies in irrigation, changing to drought tolerant crops, increasing water supply, and improving management [24.4.1.5]. (2) Terrestrial and inland waters: conserving the geophysical stage;	Constraints are identified broadly as being ecological, social and economic, technical and political. *Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Lack of co-ordination in the formulation of responses [24.2.2]. High degree of	Limits are identified as biophysical limits in ecosystems, including limits to dispersal and climate tolerance will lead to species extinctions [24.4.2.3].	Mainstreaming adaptation into government's sustainable development policy portrays a potential opportunity for good practice to build resilience and reduce vulnerability depending on effective, equitable and legitimate actions

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
				protecting climatic refugia, and increasing landscape connectivity [24.4.2.5]. (3) Coastal system and low lying areas: Hard coastal defenses and acquisition of landward buffer zones [24.4.3.5] (4) Food production systems: crop breeding [24.4.4]conservation farming, change to drought-tolerant crops, water conservation efficiency, crop shifting and diversification and strategic food reserves [Table 24.8] (5) Human settlements, industry and infrastructure: migration, land use change, green infrastructure, flood proofing [Table 24.9] (6) Human Health, Security, Livelihoods, and Poverty: Win-win solutions for public health from the interaction of adaptation and mitigation measures that involve urban environments and air pollution [24.7]. Climate resilient livelihoods can be fostered through the creation of a bundle of capitals (natural, physical, human, financial and social capital) and poverty eradication [Table 24-11]. Community based approaches to address poverty and livelihoods [24.4.6.5]. Technologies and policy options that provide both mitigation potential as well as sustained income generation potential	centralization of the management regime and the lack of vertical integration result low adaptive capacity (24.4.1.5). Lack if information sharing of best practices across countries. Insufficient mainstreaming of adaptation into the broader policy frameworks. Insufficient integration of transboundary policy recommendations into national climate change plans and policies [24.9.1]. Absence of involvement of upstream and downstream stakeholders. Lack of prioritization of employment generation and education as issues at the national level [24.5.4]. Weak governance mechanisms and breakdown of policy and regulatory structures [24.5.4]. Lack of disaster risk reduction [24.5.4]. Economic (Human and financial capital): Lack of financial resources for adaptation implementation [25.5.4]. Lack of higher education in adaptation [24.5.4]. Technological, Information and Science: Spatial and temporal uncertainties associated with forecasts of regional climate, limited national capacities in climate monitoring and forecasting [24.2.2]. Lack of awareness on the impacts of climate change to sustainable development [24.5.4]. Lack of research [24.4.4] Social/Psychological/Cultural: *[Need specifics/update from SOD]*		to overcome barriers and limits to adaptation (24.5.3) Success will depend on promoting good governance including responsible policy and decision making; empowering communities and other local stakeholders so that they participate actively in implementation of adaptation; and mainstreaming climate change into development planning at all scales, levels and sectors [24.2.2], [24.4.6.5].

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
					Other: Existence of biophysical constraints to climate change [35.5.4]		
Australasia [Chapter 25]	The opportunities for and effectiveness of adaptation depend heavily on institutional and governance arrangements that enable decision-makers to consider climate change information [25.5.1]	Maintenance, enhancing resilience and rational use of natural resources (e.g. water, ecosystem) through policy reforms for mainstreaming climate change that comprises an interdependent mix of strategies. Ameliorating some impacts and delivering multiple benefits by reducing other environmental stresses.	*[To be completed post-SOD]*	Adaptation opportunities are highlighted in each of the nine main categories (1) Freshwater Resources: securing water augmentation, sewage recycling and stormwater use, reduction of demand, and integrated planning with consideration of flood risk and stormwater and wastewater infrastructures (2) Terrestrial and Inland Freshwater Ecosystems; increasing resilience, targeted relocation of at-risk species into new habitats (3) Coastal and Ocean Ecosystems: managed retreat from eroding coasts (Box 25-2), removal of human barriers to migration, beach nourishment, translocation of species, management of environmental flows, habitat provision, and modification [25.6.3.3] (4) Production Forestry, species or provenance selection, silvicultural options [25.6.4.2.] (5) Agriculture: crop switching [25.6.5.2] (6) Mining: *[Need specifics/update from SOD]* (7) Energy Supply, Transmission, and Demand: limit increasing urban energy demand [Box 25.9] (8) Tourism: strengthening ecosystem resilience, preparation for extreme	*Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Unclear legislative frameworks, institutional fragmentation, and limited vertical and horizontal integration of different actors with unclear responsibilities, contradictory policies and development goals [25.5.2]. Absence of a consistent information base and binding guidelines that clarify governing principles [25.5.2]. Economic (Human and financial capital): Lack of financial resources particularly at the community level. Limited of social and institutional capital. Technological, Information and Science: Uncertainty about the scale and timing of projected impacts, limited financial and human resources [25.5.2]. Lack of robust frameworks to deal with the uncertainties and dynamic change characteristic of climate change; magnitude and rate of climate change, together with fragmentation of habitat limit migration options for species [25.6.2.3]. Social/Psychological/Cultural: Perception of climate change as a risk, social and cultural values that place attachment	Collapse of coral reef systems in north-eastern and western Australia, driven by increasing sea-surface temperatures and ocean acidification; the natural ability of reefs to adapt to the projected rates of change is very limited [Box 5-3, 25.6.3] Loss of montane ecosystems and some endemic species in Australia [25.6.2], Individual species and ecosystems that occupy climatically constrained ecological niches and/or occur in fragmented habitats or locations where adaptive movement is not possible; e.g. coral reef systems in northeastern and west Australia and ecosystems in the Australian alpine zone currently covered by seasonal snow (25.6.2, 25.6.3).	Adaptation is already occurring and adaptation planning is becoming embedded in planning processes. Capacity to adapt is generally high in many human systems but implementation of effective adaptation measures faces major constraints especially at local and community levels. Some impacts have potential to be severe but can be moderated or delayed significantly by combined global mitigation and a portfolio of available adaptation measures while some cannot be. Two key challenges for adaptation are apparent in the region: identifying when and where a departure from incremental to transformative adaptation measures is needed; and, where specific policies to facilitate proactive adaptation are needed to overcome barriers to mainstreamed and

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
				events [25.6.8.2] (9) Human Health: reshaping government policy, improving healthcare services, developing early warning systems, preparing health system/emergency system, improving maintenance programs for key services, seeking behavioral changes and community awareness to reduce exposure, developing emergency response plan {25.6.9.3] (10) Indigenous: *[Need specifics/update from SOD]*	and differing values on near- versus long-term and private versus public costs and benefits [Box 25-1]. Individual and collective social and cultural values. Other: *[Need specifics/update from SOD]*		autonomous adaptation [25.8.3]
North America [Chapter 26]	*None. [Need specifics/update from SOD]*	Adjusting water infrastructure and institutional mechanism, improving climate resilience and adaptation for ecosystem and biodiversity though changes approach to protected area planning, institutional shift for addressing wildfire	The region is very likely to face increasing warming and extreme high temperatures, higher sea levels, more intense precipitation and droughts, more intense storms, and reduced snowpack and higher sea levels. [26.1.1, 26.2.2, 26.4.1, 26.5]	Opportunities are highlighted in the following 12 sectors: (1) Water Resources and Management: drought management plans, reduced water consumption, system interconnections, improved coordination with other organizations, holistic management of storm water, flood waters, water supply, and wastewater management, incorporating climate change impacts into municipal bond ratings, diversification of supplies and source protection, land use management, better alignment of revenues with fixed and variable costs [23.6.1.2], increased efficiency in farm systems, cooperative crisis management among user, and adjustment water infrastructure [26.3.3], For flooding, updating elevation and land use datasets every 10 years, improved	*Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Decentralized response frameworks focusing reactive measures to cope with rather than preventing problems. Lack of decision-making on priority between extreme events vs. changes in long-term average conditions [Box 26.4]. Lack of coordination and institutional fragmentation of the different tiers of government. Lack of mainstreaming climate change issues into decision-making. Lack of willingness to address adaptation issues [Box 26.4]. Existing deficits in infrastructure. Lack of services (health, education) and institutional capacity [Box 26.4]. Cities with existing deficits in infrastructure (e.g., insufficient coverage, need of major upgrades and climate proofing), services (health, education), and institutional	None identified.	*[Need specifics/update from SOD]*

				hydrologic and hydraulic modeling, predicting extent of future floodplains as the climate changes and uncertainties decrease, eventually charging pre NFIP buildings full rates to decrease repetitive loss (2) Ecosystems and Biodiversity: changes in the approach to protected area planning, establishment and management, breeding programs for resistance to diseases and insect pests, alignment of adaptation and mitigation [26.4.3] (3) Wildfires: changes in institutional management, communications of risk [26.5.3] (4) Food Security: Change varieties, crop diversification, capital for on farm improvement in irrigation efficiency, climate tolerant crops, adapt to shifting fish distribution [26.6] (5) Rural Communities: investments into rural adaptive capacity (6) Indigenous Communities: traditional culture with contemporary forms of knowledge, education and economic development [26.7.1.2] (7) Tourism-based Communities: restoration [26.7.2.3] (8) Forest-based Communities: assisted migration, economic diversification, (9) Human Health: none. (10) Infrastructure: none. (11) Urban: create synergies and overcome conflicts with	capacity. Economic (Human and financial capital): High cost, energy and time required to construct, develop and maintain infrastructures and services. Insufficient financial and human resources to address the underlying processes of environmental deterioration [Box 26.4] Technological, Information and Science: Lack of a warning systems and emergency preparedness; lack of regional-to-local spatial scales climate scenarios [Box 26.4] Social/Psychological/Cultural: low social capital and limited economic resources [Box 26.4] Other: *[Need specifics/update from SOD]*		

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
				mitigation and other development goals, Infrastructural upgrades, early warning systems, developing shared-risk schemes for agriculture and livestock activities, and creating insurance schemes against disasters. They also include campaigns for raising public awareness, green infrastructure (12) Key Economic Sectors: introducing and expanding the role of insurance in developing markets [26.11.4.1]			
Central and South America [Chapter 27]	Reducing exposure and vulnerability and increasing resilience to the potential adverse impacts of climate extremes, even though risks cannot be fully eliminated [27.1.1.2]	*[Need specifics/update from SOD]*	The projected mean warming for CA and SA by the end of the century ranges from 2°C to 4°C for the SRES emissions scenario B2, and from 4°C to 8°C for scenario A2. Changes in rainfall and in extremes are more uncertain, especially in CA and tropical SA	Opportunities are highlighted in the following 8 sectors: (1) Freshwater Resources: increase in water supply through groundwater pumping and fog interception, increase infrastructure, reservoirs and irrigation infrastructure capacity, increase irrigation efficiency practices and change crop patterns [27.3.1.2] (2) Terrestrial and Inland Water Systems: Adoption of ecosystem-based adaptation practices [27.3.2.2], restoration (3) Coastal Systems and Low-Lying Areas: marine protected areas, coastal planning, retreat and resettlement [27.3.2.2] (4) Food Production Systems and Food Security: diversification and shifting of crop types, changes in fertilizer use, changes in growing season, genetic	Adaptation is heavily constrained by limited funding available from central governments and lack of institutional capacity to mainstream climate change into policy [27.3.1.2]. Other constraints include: *Specific constraints include:* Structural: Settlements highly vulnerable. Governance/Institutional: Lack of capacity-building and appropriate political, institutional and technological frameworks. Planning efforts focused at the national and regional level while most of the final adaptation implementation actions are local. Lack of structural reforms to provide good governance. Lack of decision-maker capacity-building, absence of a synergetic development-adaptation planning and funding. Economic (Human and	None identified.	Adaptive capacity of developing and emergent countries is low and coping with new situations may require new approaches such as a multilevel risk governance (Corfee-Morlot *et al*., 2011; Young and Lipton, 2006) associated with decentralization in decision making and responsibility [27.4].

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
				techniques, specific scientific knowledge and land-use planning, irrigation and use of rain water, shading, genetic modification of crops, (5) Human Settlements, Industry, and Infrastructure: mainstreaming flood management and warning systems, urban tree planting (7) Renewable Energy: bioenergy production, management of land use change, development of policies for financing and management of science and technology renewable energy [27.3.6.2] (8) Human Health: none.	financial capital): limited financial resources. Income rates are low. Conflict between resources needed for long-term planning to ameliorate present social deficit in the welfare of the population and adaptation planning Technological, Information and Science: Lack of basic information, observation and monitoring systems. Inefficiency in transmission of information to decision makers. Vulnerability and disaster risk reduction does not always lead to long-term adaptive capacity Social/Psychological/Cultural: Perception of risk. Lack of awareness of environmental changes and the implications for livelihoods Other: *[Need specifics/update from SOD]*		
Polar Region [Chapter 28]	Mainstreaming adaptation into existing policy processes and priorities.	*[Need specifics/update from SOD]*	*[To be completed post-FOD]*	Opportunities include changing resource bases, shifting land use and/or settlement areas, combining technologies with Indigenous knowledge, changing timing and location of hunting, gathering, herding, and fishing areas, and improving communication and education; providing hunter support programs; distribution of traditional foods between communities and the use of community freezers; for the permafrost, use of pile foundations, insulation of the surface, clearance of snow, adjustable foundations for	*Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Lack of national policies [28.4] Economic (Human and financial capital): *[Need specifics/update from SOD]* Technological, Information and Science: uncertainties of climate projections, lack of local downscaling combined with uncertainties in future economic, social and technological developments [28.4]. Lack of technical information and capacity. Lack of a systematic assessment of	Fauna unable or poorly able to cope with temperature increases of as little as 1-3°C [28.1]. Polar bears are likely not able to adapt in face of sea ice loss [28.2.2.1.2].	The most effective adaptation options will be those that recognize the nexus between adaptation and sustainable development. Adaptation to climate change occurs in the context of, and is inextricably linked to societal change; and climate is not the most important driver of vulnerability in polar communities nor is it rarely the sole or primary stimulus for taking adaptive action [28.4]

Region	*Framing*		*Rate of change*	*Opportunities*	*Constraint*	*Limits*	*Synthesis*
				smaller structures, and increased use of artificial cooling, selective forest regeneration, sustainable management of ecosystems	risks [28.4] Social/Psychological/Cultural: Other: *[Need specifics/update from SOD]*		
Small Islands [Chapter 29]	Mainstreaming and integrating climate change into development plans is seen as a goal.	Coastal adaptation and protecting coastal ecosystems and communities is of critical importance (29.7.2.1)	*[To be completed post-SOD]*	Building shoreline resilience, island building [29/6/2]	*Specific constraints include:* Structural: *[Need specifics/update from SOD]* Governance/Institutional: Lack of financial resources. Uncertain political and legal framework Economic (Human and financial capital): Lack human resource capacity. Technological, Information and Science: Lack of technology. Lack of climate change and socio-economic scenarios and data at the required scale. Social/Psychological/Cultural: Lack of cultural and social acceptability and Other: *[Need specifics/update from SOD]*	None identified.	Lessons learned from adaptation experiences in one island may offer some helpful guidance to other states, wholesale transfer may not always be advisable, as the 'lenses' through which adaptation options are viewed differ from one community to the next, based on ecological, socio-economic, cultural and political values [29.8].
Synthesis	*[To be completed post-SOD]*	*[To be completed post-SOD]*	*[To be completed post-SOD]*	*[To be completed post-SOD]*	[*To be completed post-SOD]*	[*To be completed post-SOD]*	[*To be completed post-SOD]*

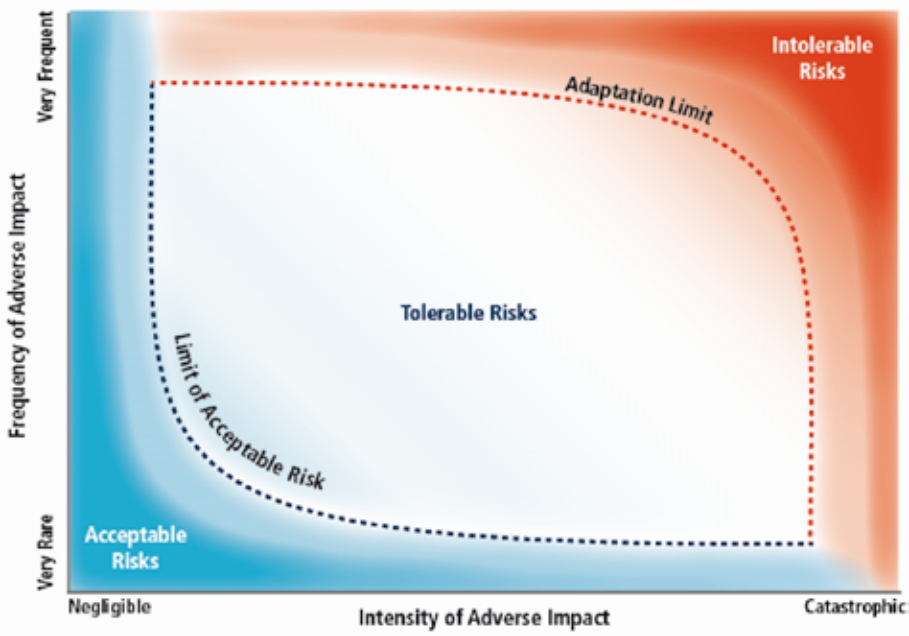

Figure 16-1: Conceptual model of the determinants of acceptable, tolerable and intolerable risks and their implications for limits to adaptation (Dow et al., 2013; after Klinke and Renn, 2002).

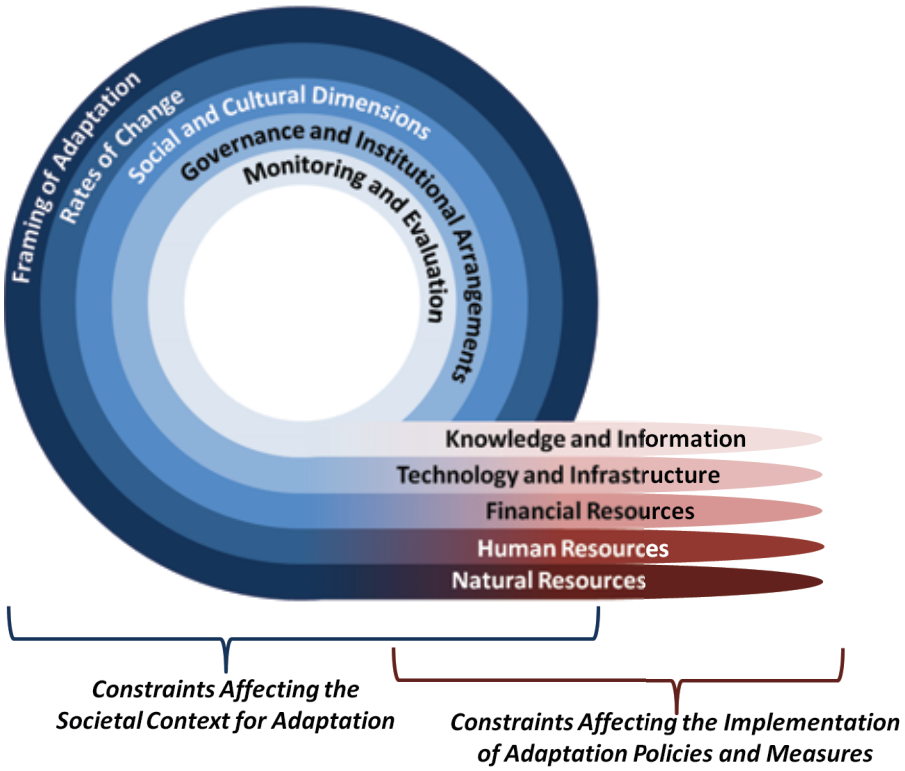

Figure 16-2: Identification of key adaptation constraints considered in this chapter, which are categorized into two groups. One reflects constantly evolving biophysical and socio-economic processes that influence the societal context for adaptation. These processes subsequently influence the implementation of specific adaptation policies and measures that could be deployed to achieve a particular objective.

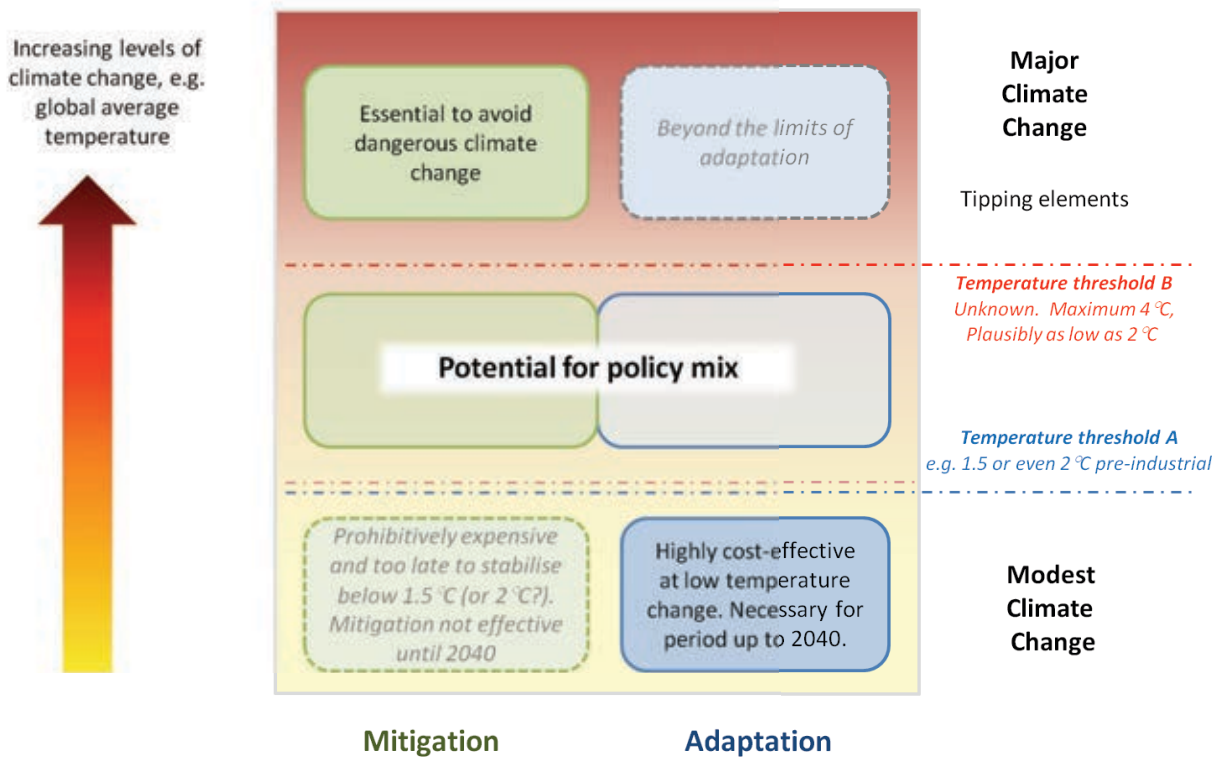

Figure 16-3: Adaptation policy space as a function of mitigation pathways (Watkiss et al., 2013).

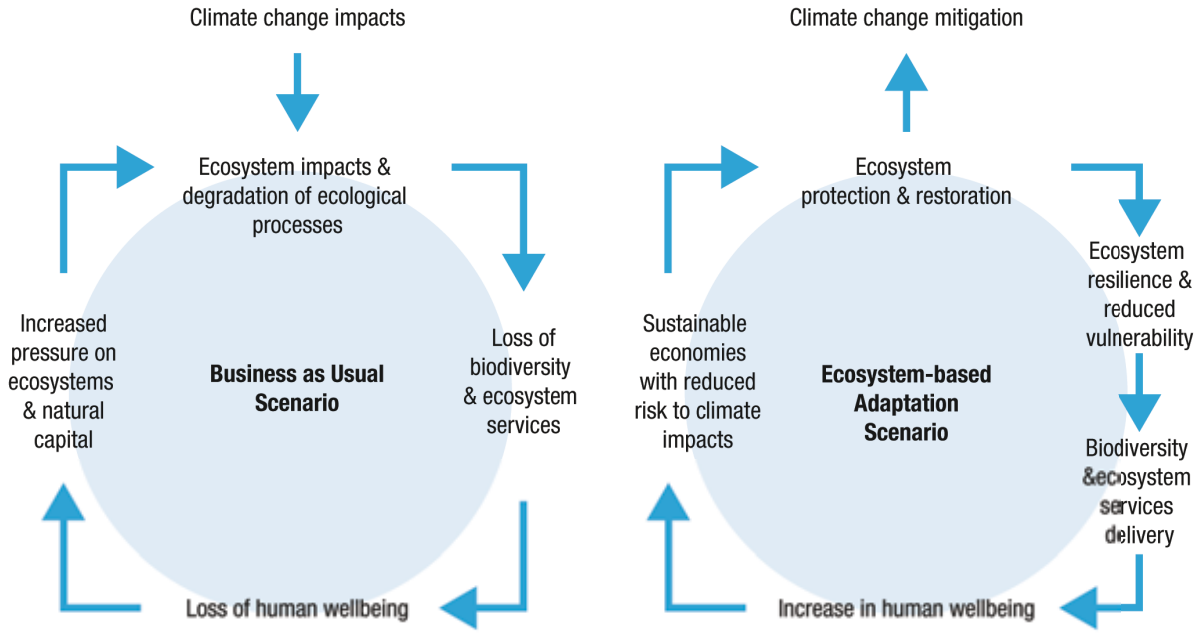

Figure EA-1: Adapted from Munang *et al*. (2013). Ecosystem based adaptation approaches to adaptation can utilize the capacity of nature to buffer human systems from the adverse impacts of climate change through sustainable delivery of ecosystems services. A) Business as Usual Scenario in which climate impacts degrade ecosystems, ecosystem service delivery and human well-being B) Ecosystem-based Adaptation Scenario which utilizes natural capital and ecosystem services to reduce climate-related risks to human communities.
