Table 27-1: Regional observed changes in temperature, precipitation, river runoff and climate extremes in various sectors of CA and SA. Additional information on changes in observed extremes can be found in the IPCC SREX (Seneviratne *et al*., 2012) and Chapter 2 IPCC WGI AR5 [2.4, 2.5, 2.6]

Region	Period	Observed trends	References
CA and Northern SA			
Increase of precipitation in the NAMS during the onset season	1943-2002	+0.94 mm/day/58 years	Englehart and Douglas (2006)
Delay in the entire cycle of the summer NAMS reinfall in SW USA	1948-2004	-10 to -20 days/57 years	Grantz *et al*. (2007)
Positive rainfall trends during the summertime NAMS on the core region in the Southwest of USA.	1931-2000	17.6 mm century^{-1}	Anderson *et al*. (2010)
Positive trends in rainfall extremes (P95), mainly due to intense precipitation from tropical cyclones (TCs) in the NAMS	1961-1998	+1.3% decade^{-1}	Cavazos *et al*. (2008)
Increase of precipitation in the NAMS core region	1979-2008	+ 2 mm/day decade^{-1}	Wang *et al*. (2012)
Reduction in cold days and nights in CA and Northern SA	1951-2000	Cold days: -1 day decade^{-1} · Cold nights: -2 day decade^{-1}	Donat *et al*. (2013)
Increase warm days and nigts in Northern SA	1951-2000	Warm days: +2 to +4 day decade^{-1} · warm nights: +1 yo +3 day decade^{-1}	Donat *et al*. (2013)
Increase in heavy precipitation (R10) in Northern SA	1951-2000	+1 to +2 day decade^{-1} ·	Donat *et al*. (2013)
Reduction in consecutive dry days (CDD) in Northern SA	1951-2000	-2 day decade^{-1} ·	Donat *et al*. (2013)
Positive runoff trends of the Magdalena river in Colombia	1948-2008	+0.5 mm/day/50 years	Dai *et al*. (2009)
West Coast of SA			
SST and air temperatures off coast of Peru and Chile (15S-35S)	1960-2010	-0.25C/decade	Gutiérrez *et al*. (2011a; 2011b), Falvey and Garreaud (2009)
Cooling, reduction of precipitation, cloud cover, and number of rainy days since the middle 1970´s off coast of Chile (18S-30S)	1920-2009	-1 C/40 years, -1.6 mm/40 years, -2 octs/40 years, and -0.3 days/40 years	Schulz *et al*. (2011)
Reduction in the % of wet days until 1970, increase after that, reduction in the precipitation rate in southern Chile (37S-43S)	1900-2007	-0.34% until 1970 and +0.37 after that, -0.12 %	Quintana and Aceituno (2012)
Decrease in cold days and nights in all South American coast,	1951-2000	Cold days: -1 days decade^{-1}; cold nights: -2 days decade^{-1}	Donat *et al*. (2013)
Decrease in warm nights in all South American coast, increase in warm days in the northern coast of South America, decrease of warm days off the coast of Chile	1951-2000	Warm night: -1 days decade^{-1}; warm days: +3 days decade^{-1} ; warm days: -1 days decade^{-1}	Donat *et al*. (2013)
Increase of warm nights in the coast of Chile	1961-1990	+5 to +9%/31 years	Dufek *et al*. (2008)
Increase dryness as estimated by the Palmer Drought Severity Index (PDSI) for most of the west coast of SA (Chile, Ecuador, Northern Chile)	1950-2008	-2 to -4 / 50 years	Dai (2011)
Decrease in heavy precipitation (R95) in northern and central Chile	1961-1990	-45 to -105 mm/31 years	Dufek *et al*. (2008)
SESA			

Increase in mean annual air temperature in southern Brazil	1913-2006	+1.7 C/100 years	Sansigolo and Kayano (2010)
Decrease in the frequency of cold days and nights, increase in warm days in Argentina and Uruguay	1935-2002	-1.2%/decade, -1%/decade/, +0.2%/decade	Rusticucci end Renom (2008)
Increase in the highest annual maximum temperature and in the lowest annual minimum air temperature in Argentina and Uruguay	1956-2003	+0.8 C/47 years, +0.6C/47 years	Rusticucci and Tencer (2008)
Increase in the frequency of warm nights in Argentina and Uruguay and southern Brazil	1960-2009	10-20%	Rusticucci (2012)
Increase in warm nights in most of the region	1961-1990	+7 to +9%/31 years	Dufek *et al*. (2008)
Decrease in cold nights in most of the region	1961-1990	-5 to -9%/31 years	Dufek *et al*. (2008)
Decrease in cold days and nights in most of the region	1951-2000	warm nights: +3 days decade^{-1}; warm days: +4 days decade^{-1}	Donat *et al*. (2013)
Increase in warm days and nights in most of the region	1951-2000	Cold nights: -3 days decade^{-1}; cold days: -3 days decade^{-1}	Donat *et al*. (2013)
Increase of consecutive dry days (CDD) in northern Argentina, northern Chile, Bolivia and Paraguay and decrease of CDD in SA South of 30 S	1961-1990	+15 to +21 days/31 years, -21 to -27 days/31 years	Dufek *et al*. (2008)
Reduction in the number of dry months during the warm season October-March in the Pampas region between 25S-40S	1904-2000	From 2-3 months in 1904-1920 to 1-2 months from 1980-2000	Barrucand *et al*. (2007)
Increase in moister conditions as estimated by the Palmer Drought Severity Index (PDSI) in most of SESA	1950-2008	0 to 4/50 years	Dai (2011)
Positive rainfall trends in the Parana River	1948-2008	+1.5 mm/day/50 years	Dai *et al*. (2009)
Positive rainfall trends in the Parana River Basin	1948-2008	+1.5 mm/day/50 years	Dai *et al*. (2009)
Increase in number of days with precipitation bove 10 mm (R10) in most of the region	1951-2000	+2 days/decade^{-1}	Donat *et al*. (2013)
Increase in heavy precipitation (R95) in most of the region	1951-2000	+1% decade $^{-1}$	Donat *et al*. (2013)
Increase in consecutive dry days	1951-2000	-4 days decade $^{-1}$	Donat *et al*. (2013)
Increase in heavy precipitation (R95) in most of the region	1961-1990	+45 to +135 mm/31 years	Dufek *et al*. (2008)
Increase in heavy precipitation (R95) in the state of Sao Paulo	1950-1999	+50 to +75 mm/40 years	Dufek and Ambrizzi (2008)
Decrease in consecutive dry days (CDD) in the state of Sao Paulo	1950-1990	-25 to-50 days/40 years	Dufek and Ambrizzi (2008)
Lightning activity increases significantly with increasing temperature in the state of Sao Paulo	1951-2006	+40% per 1_C for daily and monthly timescales and approximately 30% per 1_C for decadal timescale	Pinto and Pinto (2008)
Increase in the number of days with rainfall above 20 mm in the city of Sao Paulo	2005-2011	+5 to +8 days/11 years	Marengo *et al*. (2012a), Silva Dias *et al*. (2012)
Increase in excess rainfall events duration after 1950	1901-2003	+ 21 months/53 yars	Krepper and Zucarelli (2010b)
Decrease in dry events and events of extreme dryness from 1972 to 1996	1900-2005	-29 days/24 years	Vargas *et al*. (2011)
Andes			
Increase in mean maximum temperature along the Andes, and increase in the number of frost dates	1921-2010	+0.10-12 C /decade in 1921-2010, and +0.23-0.24 C/decade during 1976-2010; 8	Marengo *et al*. (2011b)

		days/decade during 196-2002	
Increase in air temperature and changes in precipitation Northern Andes (Colombia, Ecuador)	1961-1990	+0.1 C to +0.22 C/decade, -4 to +4 %/decade years	Villacís (2008)
Increase in temperature and precipitation in northern and central Andes of Peru	1963-2006	+0.2-0.45C/decade, -20 to -30%/40 years	SENAMHI (2005; 2007; 2009a; 2009c; 2009d)
Increase in temperature and changes in precipitation in the southern Andes of Peru	1964-2006	+0.2 to 0.6 C/decade, -11 to +2 mm/decade	SENAMHI (2007; 2009a; 2009b; 2009c; 2009d); Marengo *et al*. (2011b)
Increase in air temperature and rainfall reduction Argentinean and Chilean Andes and Patagonia	1950-1990	+0.2 to 0.45 C/decade, -10 to -12%/decade	Falvey and Garreaud (2009), Masiokas *et al*. (2008), Villalba *et al*. (2003)
Decrease in number of days with rainfall above 10 mm (R10)	1950-2000	-3 days decade^{-1}	Donat *et al*. (2013)
Increase in dryness in the Andes between 35.65 S-39.9 S using the PDSI	1950-2003	-7 PDSI/53 years	Christie *et al*. (2011)
Strong rainfall decrease in the Mantaro Valley, central Andes of Peru	1970-2005	-44 mm/decade	SENAMHI (2009c)
Increase in air temperature in Colombian Andes	1959-2007	+1 C/20 years	Poveda and Pineda (2009)
Amazon region			
Decadal variability of rainfall in northern and southern Amazonia	1920-2008	-3 STD/30 years in northern Amazonia and +4 STD/30 years in southern Amazonia since the middle 1970's	Marengo *et al*. (2009a), Satyamurty *et al*. (2010)
Decrease in rainfall in all the region	1975-2003	-0.32 %/28 years	Espinoza *et al*. (2009a; 2009b)
Delay on the onset of the rainy season in southern Amazonia	1950-2010	-1 month since 1976 to 2010	Butt *et al*. (2011), Marengo *et al*. (2011b)
Increase of precipitation in the SAMS core region	1979-2008	+ 2 mm/day decade^{-1}	Wang *et al*. (2012)
Onset becomes steadily earlier from 1948 to early 1970s, demise dates have remained later, and SAMS duration was longer after 1972.	1948-2008	SAMS from 170 days (1948–1972) to 195 days (1972–1982).	Carvalho *et al*. (2011)
Spatially varying trends of heavy precipitation (R95), increase in many areas and insufficient evidence in others	1961-1990	+100 mm/31 years in western and extreme eastern Amazonia,	Marengo *et al*. (2009a)
Spatially varying trends in dry spells in (CDD), increase in many areas and decrease in others	1961-1990	+15 mm/31 years in western Amazonia, -20 mm/ in southern Amazonia	Marengo *et al*. (2009a; 2010)
Negative runoff trends of the Amazon River	1948-1968	-1.5 mmday/50 years	Dai *et al*. (2009), Dai (2011)
Positive runoff trends of the Tocantins River	1948-1968	+0.5 mmday/50 years	Dai *et al*. (2009), Dai (2011)
Positive rainfall trends in most of Amazonia and negative trends in western Amazonia	1948-2008	+1 mm/day/50 years, -1.5 mm/day/50 years	Dai *et al*. (2009), Dai (2011)
Increased dryness as estimated by the Palmer Drought Severity Index PDI in southern Amazonia and moister conditions in western Amazonia	1950-2008	-2 to -4/50 years, +2 to +4 /50 years	Dai (2011)
Decrease of seasonal mean convection and cloudiness	1984-2007	+30 W/m2/23 years, -8 %/23 years	Arias *et al*. (2011)
Delayed onset of rainy season in southern Amazonia due to land use change	1970-2010	-0.6 days/30 years	Butt *et al*. (2011)

Northeast Brazil			
Negative runoff trends in the Sao Francisco River	1948-2008	-2 mm/day/50 years	Dai *et al*. (2009), Dai (2011)
Negative rainfall trends interior Northeast Brazil and positive trends in northern Northeast Brazil	1948-2008	-0.3 mm/day/50 years, +1.5 mm/day/50 years	Dai *et al*. (2009), Dai (2011)
Positive trends in heavy precipitation (R95) in some areas, negative trends in others in southern Northeast Brazil	1970-2006	-2 mm/24 years to + 6 mm/24 years,	Silva and Azevedo (2008)
Negative trends in consecutive dry days CDD in most of southern Northeast Brazil	1970-2006	-0.99 days/24 years	Silva and Azevedo (2008)
Increase in total annual precipitation in northern Northeast Brazil	1970-2006	+1 to +4 mm/year/24 years	Santos and Brito (2007)
Spatially varying trends in heavy precipitation (R95) in northern Northeast Brazil	1970-2006	-0.1 to +5 mm/yeas/24 years	Santos and Brito (2007)
Spatially varying trends in heavy precipitation (R95) and consecutive dry days (CDD) in northern Northeast Brazil	1935-2006	-0.4 to +2.5 mm/year/69 years, -1.5 to +1.5 days/year/69 years,	Santos *et al*. (2009)
Increase dryness in Southern Northeast Brazil as estimated by the PDSI, and moister conditions in northern Northeast Brazil	1950-2008	-2 to -4/50 years, 0 to +1/50 years	Dai (2011)

Table 27-2: Regional projected changes in temperature, precipitation, river runoff and climate extremes in different sectors of CA and SA. Various studies used A2 and B2 scenarios from CMIP3 and various RCPs scenarios for CMIP5, and different time slices from 2010 to 2100. In order to make results comparable, the CMIP3 and CMIP5 at the time slice ending in 2100 are included. Additional information on changes in projected extremes can be found in the IPCC SREX (see IPCC, 2012), and Chapters 9 and 14 from IPCC WG1AR5 [9.5, 9.6 and 14.2, 14.7]

Region	Models and scenarios	Projected changes	References
CA and Northern SA			
Decrease in LAI, increase in evapotranspiration by 2070-2099 in CA	23 CMIP3 models, A2	Evapotransp: +20%; LAI:-20%+0.94 mm/day/58 years	Imbach *et al*. (2012)
Increases in temperature by 2075 and 2100 in CA	9 CMIP3 models, A2	+2.2 C by 2075; +3.3 C by 2100	Aguilar *et al*. (2009)
Rainfall reductions in CA, and increases in Venezuela. Increase in air temperature in the region	20 km MRI JMA model, A1B	Rainfall decrease/increase of about -10%/+10%, by 2079. Temperature increases of about +2.5-+3.5 C by 2079	Hall *et al*. (2009)
Decrease in precipitation and increase of evaporation was projected to increase in most of the region. Soil moisture in most land areas were projected to decrease in all seasons.	20 km MRI JMA model, A1B	Precipitation decrease of about -5 mm/day, evaporation increase of about +3 to +5 mm/day; soil moisture to decrease by -5 mm/day.	Nakaegawa *et al*. (2013)
Rainfall reductions in Nicaragua, Honduras, Northern Colombia and Northern Venezuela, increases in Costa Rica and Panama. Temperature increases in all region by 2071-2100	PRECIS forced by the HadAM3, A2	Rainfall: -25 to -50%, and +25 to +50%. Temperature: +3 to +6 C	Campbell *et al*. (2011)
Increase of precipitation and temperature in northern SA, decrease in interior Venezuela, temperature increases by 2071-2100	Eta forced with HadCM3, A1B	Increases by +30 to 50%, and reductions between -10 to -20%; temperature: +4 to +5 C;	Marengo *et al*. (2011a)
Reduction in precipitation and temperature increases by 2100 in CA	PRECIS forced with HadAM3, A2	Precipitation: -24 to -48%; temperature: +4 to -5 C	Karmalkar *et al*. (2011)
Increase in warm nights, consecutive dry days and reduction in heavy precipitation in Venezuela, by 2100	PRECIS forced with HadAM3, A2	Increase by +12 to _18%, +15 to +25 days and reduction of 75 to 105 days	Marengo *et al*. (2009a; 2010)
Increase in temperature, decrease in precipitation by 2100	23 CMIP3 models, A1B	Incfease by +3 to +5 C; reduction by -10 to -30%	Giorgi and Diffenbaugh (2008)
Increase in consecutive dry days and in heavy precipitation by 2099	20 km JMA-MRI model, A1B	Increase by +5 days and bdtwen +2 to +8 %	Kamiguchi *et al*. (2006)
West Coast of SA			
Decrease of precipitation, runoff and increase of temperature at the Limari river basin in semi-arid Chile by 2100	PRECIS forced with HadAM3, A2	Precipitation: -15 % to -25%; runoff: -6 to -27%; temperature: + 3 to +4 C	Vicuña *et al*. (2011)

Warming and increase of surface winds in west coast of SA (Chile) by 2100	15 CMIP3 models, PRECIS forced with HadAM3, A2	Temperature: +1 C; coastal winds: +1.5 m/sec	Garreaud and Falvey (2009)
Precipitation increase in the bands 5N-10S, and 25S-30S, reduction between 10S-25S and 30S-50S; temperature increase between by 2100	Eta model forced with HadCM3, A1B	Increases of 30-40%, rediction of 10-20%; increases of 3-5 C	Marengo *et al*. (2011a)
Increase in warm nights, reduction in consecutive dry days, and increase in heavy precipitation in 5N-5S by 2100	PRECIS forced with HadAM3, A2	Increase of +3 to +18%, rediction of -5 to – 8 days, increase by +75 to +105 days	Marengo *et al*. (2009a; 2010)
Increase of air temperature, increase of precipitation between 0 and 10S, reduction between 20 and 40S by 2100	23 CMIP3 models, A1B	Increase of -2 to -3 C; increase by 10%, reduction by -10 to -30%	Giorgi and Diffenbaugh (2008)
Increase of consecutive dry days between 5 N and 10 S and south of 30S, increase of heavy precipitation between 5S-20S and south of 20S by 2099	20 km MRI JMA, A1B	Increase by 10 days and between +2 to +10%	Kamiguchi *et al*. (2006)
Decrease of precipitation between 15 and 35 S and increase south of 40S, increase of precipitation by 2100	MM5 forced with HadAM3, A2	Decrease of -2 mm/day, increase of 2 mm/day, increase of +2.5 C	Nuñez *et al*. (2009)
Decrease of precipitation in Panama and Venezuela, increase of heavy precipitation in Panama and reduction in Venezuela, reduction of consecutive dry days over Panama and Colombia by 2099	RCA forced with ECHAM5-MPI OM model, A1B	Reduction of -1 to -3 mm/day,	Sörensson *et al*. (2010)
SESA			
Increase in precipitation and runoff, an in air temperature by 2100	Eta forced with HadCM3, A1B	Precipitation: + 20 to +30%; Runoff: +10 to +20%; air temperature: 2.5 to 3.5 C	Marengo *et al*. (2011a)
Increases in precipitation and temperature in the La Plata basin by 2050	MM5 forced with HadAM3, A2	Precipitation: _+0.5 to 1.5 mm/day; temperature: +1.5 C to 2.5 C.	Cabré *et al*. (2010)
Increase in warm nights, consecutive dry days and heavy precipitation by 2100	7 CMIP3 models, A1B	Warm nights: +10 to +30%; Consecutive dry days: +1 to +5 days; Heavy precipitation: +3 to +9 %.	Menendez and Carril (2010)
Increase in precipitation during summer and spring, and reduction in fall and winter by 2100	9 CMIP3 models, A2	Increase pof + 0.4 to +0.6 mm/day, reduction of -0.02 to -0.04 mm/day	Seth *et al*. (2010)
Increase in warm nights, consecutive dray days and heavy precipitation by 2100	PRECIS forced with HadAM3, A2	Increase of +6 to +12%, +5 to +20 days, +75 to +105 days	Marengo *et al*. (2009a; 2010)
Increase in temperature and rainfall by 2100	23 CMIP3 models, A1B	Increase by +2 to _+4 C, increase by +20 to +30 %	Giorgi and Diffenbaugh (2008)
Increase in consecutive dry days and in heavy precipitation by 2099	20 km MRI-JMA model, A1B	Increase by +5 to +10% and by +2 to +8 %	Kamiguchi *et al*. (2006)

Increase of precipitation in north central Argentina, decrease in southern Brazil, increase of air temperature by 2100	MM5 forced with HadAM3, A2	Increase of +_0.5 to +1 mm/day, reduction of -0.5 mm/day, increase of +3 to +4.5 C	Nuñez *et al*. (2009)
Increase of precipitation, heavy precipitation, reduction of consecutive dry days in the eastern part of the region, increase in the western part of the region by 2099	RCA forced with the ECHAM5 mode, A1B	Increase of +2 mm/day, of +5 to +15 mm, reduction of -10 days and incrarse of +5 days	Sörensson *et al*. (2010)
Andes			
Reduction of precipitation and temperature, increase by 2100 in the Altiplano	11 CMP3 models, A2	Precipitation: -10 to -30 %; temperature:>3 C	Minvielle and Garreaud (2011)
Precipitation increase at 5N-5S, and 30S-45 S, decrease at 5-25 S; temperature increases by 2100	Eta forced with HadCM3, A1B	Increase between +10 and +30%, decrease by -20 t -30%, increase of +3.5 to 4.5 C	Marengo *et al*. (2011a)
Increase in warm nights, reduction of heavy precipitation and consecutive dry days south of 15 S by 2100	PRECIS forced with HadAM3, A2	Increase by +3 to +18%, reduction by -10 to -20 days, and -75 to -105 days	Marengo *et al*. (2009a)
Increase in temperature, rainfall increase between 0-10S and reduction between 10-40 S	23 CMIP3 models, A1B	Increase by +3 to +4 C, increase by 10% and reduction by -10%	Giorgi and Diffenbaugh (2008)
Reduction of consecutive dry days and increase of heavy precipitation by 2099	20 km MRI-JMA model, A1B	Reduction by -5 days, increase by +2 to +4 % south of 20S	Kamiguchi *et al*. (2006)
Increase in precipitation, heavy precipitation, and consecutive dry days by 2070-99	RCA forced with ECHAM5, A1B	Increases of +1 to +3 mm/day, +5 mm and of +5 to +10 days	Sörensson *et al*. (2010)
Reduction in summer precipitation and increase in surface air temperature in the Altiplano region by 2099	9 CMIP3 models, A2	Reduction in precipitation between -10% and -30%, an temperature increase of +3 C	Minvielle and Garreaud (2011)
Amazon region			
Rainfall reduction in central and eastern Amazonia, increase in western Amazonia, warming in all region by 2100	Eta forced with HadCM3, A1B	Precipitation: -20 top -30%, +20 to +30%; temperature: +5 to +7 C	Marengo *et al*. (2011a)
Reduction in the intensity of the South Atlantic Convergence Zone and in rainfall in the South American monsoon region, 2081-2100	10 CMIP3 models, A1B	Precipitation: -100 to -200mm/20 years	Bombardi and Carvalho (2009)
Small increases of precipitation in western during summer and decreases in winter in Amazonia by 2100	5 CMIP3 models, A2 and ANN	+1.6% in summer and -1.5% in winter	Mendes and Marengo (2010)
Increase in the number of South American Low Level Jet east of the Andes events (SALLJ), and in the moisture transport from Amazonia to the La Plata basin by 2090	PRECIS forced by HadAM3, A2	+50 events of SALLJ during summer, increase in moisture transport by 50%	Soares and Marengo (2009)
Increase of precipitation in the South American monsoon during summer and spring, and reduction during fall and winter by 2100	9 CMIP3 models, A2	Increase of +0.15 to +0.4 mm/, reductions of -0.10 to -0.26 mm/day	Seth *et al*. (2010)

Increase in warm nights, increase of consecutive dry days in eastern Amazonia, increase of heavy precipitation in western Amazonia and reduction in eastern Amazonia by 2100	PRECIS forced with hadAM3, A2	Increase of +12 to +15%, by 25-30 days in eastern Amazonia, increase in western Amazonia by 75-105 days and rediction by -15 to 75 days in eastern Amazonia	Marengo *et al*. (2009a)
Increase in air temperature, rainfall increase in western Amazonia and decrease in eastern Amazonia by 2100	CMIP3 models, A1B	Increase of +4 to +_6 C, increase of +10% and decresase between -10 to -30%	Giorgi and Diffenbaugh (2008)
Reduction of consecutive dry days and increase in heavy precipitation by 2099	20 km MRI-JAM model, A1B	Reduction of -5 to -10 days, increase by +2 to +8 %	Kamiguchi *et al*. (2006)
Early onset and late demise of the rainy season in SAMS by 2040-2050 relative to 1951-80	10 CMIP5 models, RCP8.5 (high emission)	Onset 14 days earlier than present, demise 17 days later than present	Jones and Carvalho (2013)
Increase precipitation in SAMS during the monsoon wet season in 2071-2100 relative to 1951-80	10 CMIP5 models, RCP8.5 (high emission)	Increase of 300 mm during the wet season	Jones and Carvalho (2013)
Increase of precipitation in western Amazonia, reduction of heavy precipitation in northern Amazonia and increase in southern Amazonia, reduction of consecutive dry days in western Amazonia and increase in eastern Amazonia by 2099	RCA forced with the ECHAM5 mode, A1B	Increase of +1 to +_3 mm/day, reduction of -1 to -3 mm, in crease of +5 to _10 mm, decrease of -5 to -10 days, increase by +20 to +30 days	Sörensson *et al*. (2010)
Northeast Brazil			
Rainfall reduction in the entire region, temperature increases by 2100	Eta forced with HadCM3, A1B	Precipitation: -20 to -20%; temperature: +3 to +4 C	Marengo *et al*. (2011a)
Increase of warm nights, of consecutive dry days, and reduction of heavy precipitation by 2100	PRECIS forced with HadAM3, A2	Increase by +18 to +24%, by +25 to +30 days and -15 to –75 days	Marengo *et al*. (2009a)
Increase in temperature, reductions in precipitation by 2100	23 CMIP3 models, A1B	Increase of +2 to +4 C, reduction of -10 to -30%	Giorgi and Diffenbaugh (2008)
Reduction of consecutive dry days and increase in heavy precipitation by 2099	20 km MRI-JMA model, A1B	Reduction of -5 to -10% and increase of +2 to +6 %	Kamiguchi *et al*. (2006)
Increase of precipitation, in heavy precipitation and consecutive dry days by 2099	RCA foeced with ECHAM5 model, A1B	Increase of +1 to +2 mm/day, increase by +5 to +10 mm, and increase by +10 to +30 days	Sörensson *et al*. (2010)

Table 27-3: Observed trends related to Andean cryosphere.
a) Andean tropical glacier trends since the Little Ice Age (LIA) maximum and, particularly, during the last decades

Country	**Documented massifs (latitude)**	**Significant changes recorded and reference** (dates in AD)	**References**
Venezuela	*Cordillera de Merida (10°N)*	Four glacial advances between 1250 and 1810. Glaciers have been rapidly retreating since at least 1870. Equilibrium Line Altitude (ELA) raised up by ~300-500m between LIA maximum and today. Accelerated melting since 1972. Remaining glaciers are at risk of disappearing completely in the next years since ELA lies near to the Pico Bolivar summit (4979m).	Polissar *et al*. (2006); Morris *et al*. (2006)
Colombia	*Parque Los Nevados (4°50N)* *Sierra Nevada del Cocuy 56°30N)* *Sierra Nevada de Santa Marta (10°40N)*	LIA maximum occurred between 1600 and 1850. Loss of 60-84% in glacierized areas during the 1850-2000 period and many small/low elevation glaciers have disappeared. In the past 50yrs, 50% of glacier areas have been lost, and in the past 15yrs 10-50%. Since 2000, glaciers retreated at a rate of 3.0km^2/yr. Glacier areas total 45km^2 in Colombia in 2011.	Ruiz *et al*. (2008); Ceballos *et al*. (2006); Poveda and Pineda (2009)
Ecuador	*Antisana (0°28S)* *Chimborazo and Carihuayrazo (1°S)* *Ecuadorian volcanoes*	LIA maximum occurred in around 1720 and 1830 (Chimborazo). Historical evidences of ELA at 4700±50m in around 1740. ELA raised up 300m between the middle 18th and the last decades of the 20th (~200m during only the 20thcentury). A slight glacier reduction was reported between 1956 and 1976, but in the 1976-2006 period, glacier areas lost ~45%. Glaciers at low elevation (<5300m) are in process of extinction. Glaciers in Ecuador total less than 50km^2 in 2011.	Francou (2004); Jordan *et al*. (2005); Jomelli *et al*. (2009); Cáceres *et al*. (2006)
Peru	*Cordillera Blanca (9°S)*	LIA maximum occurred in around 1630±27. Loss of 12-17% of glaciers during the 18th century, and 17-20% during the 19th. Rapid retreat in the 1930s-1940s and from 1976-80. ELA increased by ~100m from the LIA maximum to the beginning of the 20th century, and by more than 150m during only the 20th century. The lost of glacial area reported by several teams since the 1960s to the 2000s converge on a range of 20-35% Physical observations of the Yanamarey glacier show acceleration in frontal retreat at a rate of 8 m decade^{-1} since 1970, accompanied by total volume loss on the order of 0.022 km Increase of 1.6 (± 1.1) percent in the specific discharge of the more glacier-covered catchments (>20 percent glacier area) Seven out of nine watersheds exhibit decreasing dry-season discharge. Median (out of 9 glaciers analyzed) average ice area loss of 0.61% a^{-1}. Glaciers of Coropuna have retreated by 26% between 1962 and 2000	Kaser and Georges (1997); Georges (2004); Mark and Seltzer (2005); Silverio and Jaquet (2005); Raup *et al*. (2007) Jomelli *et al*. (2009); UGHR (2010); Bury *et al*. (2011) Mark *et al*. (2010); Baraer *et al*. (2012)
	Coropuna volcano (15°33S)	Glaciers of Coropuna receded by 26% between 1962 and 2000	Racoviteanu *et al*. (2007)
	Cordillera Vilcanota (13°55S)	Qori Kalis glacier receded in the 1991-2005 period 10 times faster than during the 1963-2005 period	Thompson *et al*. (2006; 2011)

Bolivia	*Cordillera Real and Cordillera Quimza Cruz (16°S)*	On the Telata glacier, strong melting after the maximum extent occurred from 10.8±0.9 to 8.5±0.4kyr ago, followed by a slower retreat until the Little Ice Age, about 200 years ago. The LIA maximum is dated between 1657±20 and 1686±20 in the north of Bolivia. Between the LIA maximum and the late 20th century, the ELA increased by 300m (180-200m during the only 20th century). Proxy of vertical englacial temperature in Bolivia (Illimani, 6340m, 16°S) shows two warming phases from AD 1900 to 1960 (+0.5±0.3 K) starting in 1920-1930 and from 1985 to 1999 (+0.6±0.2K), corresponding to a mean atmospheric temperature rise of 1.1±0.2 K over the 20th century. From 1956 to 1963-1976, glaciers were near the equilibrium, but the recession was very strong after 1976. Small glaciers at low elevation (<5300-5400m) are in process of extinction (Chacaltaya vanished in 2009). Since 1991, Zongo glacier (6000-4900m) has lost a mean of 0.4m we/yr and only 20% of the mass balances measured in the 1991-2011 period have been positive or near the equilibrium. Glaciers of the Cordillera Real have lost 43% of their volume between 1963 and 2006, essentially over the 1976-2006 period, and 48% of their surface area between 1976 and 2006. Studies of sensitivity have shown that during the October-March wet period, crucial for the year mass balance, +1°C temperature increases the ELA by ~200m.	Jomelli *et al*. (2011) Rabatel *et al*. (2005) Rabatel *et al*. (2006; 2008); Gilbert *et al*. (2010); Soruco *et al*. (2009)*;* Lejeune (2007)
	Sur Lipez, Caquella, 21°30S	Evidence of recent degradation of Caquella rock glacier	Francou *et al*. (1999)

b) Extra tropical Andean cryposphere (glaciers, snowpack, runoff effects) trends.

Region	Documented massifs/latitude	Significant changes recorded and reference	References
Andes of Chile, Argentina and Bolivia and Argentinan Patagiona	*Snow cover extent*	The 1979–2006 period shows a sinusoidal like pattern for both snow cover and snow mass, though neither trend is significant at the 95% level.	Foster *et al*. (2009)
Dessert Andes *(17°S-31°S)*	*Review on extra tropical glaciers*	Most areas in the Andes of extratropical SA have experienced a general pattern of glacier recession and significant ice mass losses	Masiokas *et al*. (2009)
	Huasco basin glaciers (29°S)	Glacier mass loss is evident over the study period, with a mean of –0.84m w.e. yr–1 for the period 2003/2004–2007/2008	Nicholson *et al*. (2009); Rabatel *et al*. (2011); Gascoin *et al*. (2011)
Central Andes *(31°S-36°S)*	*Review on extra tropical glaciers*	Most areas in the Andes of extratropical SA have experienced a general pattern of glacier recession and significant ice mass losses	Masiokas *et al*. (2009)
	Piloto/Las Cuevas (32°S)	Within the 24-year period, 67% of the years show negative net annual specific balances, with a cumulative mass balance loss of - 10.50 m w.e.	Leiva *et al*. (2007)
	Aconcagua basin glaciers (33°S)	Reduction in glacier area of 20% ($0.63 km^2 a^{-1}$) over last 48 years. Glaciar Juncal Norte, exhibits a smaller reduction (14%) between 1955 and 2006.	Nicholson *et al*. (2009); Bown *et al*. (2008)
	Central Andes glaciers (33–36 °S)	All studied glaciers exhibited a negative trend during the 20th century with mean frontal retreats between –50 and $–9 my^{-1}$, thinning rates between 0.76 and 0.56 my^{-1} and a mean ice area reduction of 3% since 1955.	Le Quesne *et al*. (2009)
	ELA across central Andes	Analysis of radiosonde data of central Chile shows mid-tropospheric warming with an elevation increase of the 0ºC isotherm of 122 ± 8 m and 200 ± 6 m in winter and summer, respectively, during the 27-year period between 1975 and 2001.	Carrasco *et al*. (2005)
	Snowpack (30 °S -37°S)	Marked interannual variability, and a positive, though nonsignificant, linear trend for period (1951–2005)	Masiokas *et al*. (2006)
	Morenas coloradas rock glacier (32 °S -33°S)	A significant change in the active layer and suprapermafrost possibly associated with warming processes.	Trombotto and Borzotta (2009)
	Mendoza river streamflow	Possible link to rising temperatures and snowpack/glacier effects. Not conclusive.	Vich *et al*. (2007)
	Aconcagua basin streamflow	Significant decrease in streamflow that could be explained by a progressive change in glaciers area and volume in the basin.	Pellicciotti *et al*. (2007)
	Streamflow from basins between 28 °S and 47 °S	Not significant increase in February run-off trends for period 1950–2007 that might suggest an increase of glacier melt in the Andes.	Casassa *et al*. (2009)
	Streamflow timing between 30 °S and 40 °S	Significant (95% confidence level) negative trend (CT date shifting towards earlier in the year) for 23 out of the 40 analyzed series. More relevant is precipitation rather than temperature.	Cortés *et al*. (2011)

Patagonian Andes *(36°S-55°S)*	*Review on extra tropical glaciers*	Most areas in the Andes of extratropical SA have experienced a general pattern of glacier recession and significant ice mass losses	Masiokas *et al*. (2009)
	Casa Pangue glacier (41°S)	Between 1961 and 1998, mean thinning rate of -2.3 ± 0.6 m a^{-1}. When ice thinning is computed for the period between 1981 and 1998, the resulting rate is 50%higher (-3.6 ± 0.6 m a^{-1}).	Bown and Rivera (2007)
	North Patagonian Icefield (NPI)	Glacial lake outburst flood (GLOF) interpreted as a delayed paraglacial response to the retreat of Calafate glacier during the twentieth century.	Harrison *et al*. (2006)
	Southern Patagonia Icefield (SPI)	Retreating glaciers with larger rates observed on the west side coinciding with lower elevations of the ELAs (relative to the east side).	Barcaza *et al*. (2009)
	NPI, SPI and the Cordillera Darwin Icefield (CDI)	The majority of glaciers have retreated between 1945 and 2005 with maximum values of 12.2 km for Marinelli Glacier in the CDI, 11.6 km for O'Higgins Glacier in the SPI and 5.7 km for San Rafael Glacier in the NPI	Lopez *et al*. (2010)
	Cordón Martial glaciers (54 °S)	Ice loss rate for the period April 2002-December 2006 of 27.9 ± 11 km3/year, equivalent to an average loss of -1.6 m/year of ice thickness.	Chen *et al*. (2007)
	Gran Campo Nevado (GCN) (53 °S)	Glaciers slowly reciding from Late Little Ice Age (LLIA). Acceleration started 60 years ago	Strelin and Iturraspe (2007)
		All major glaciers of the GCN show a significant glacier retreat during the last 60 yr. Some of the outlet glaciers lost more than 20% of their total area during this period. Overall glacier retreat amounts to 2.8% of glacier length per decade and the glacier area loss is 2.4% per decade in the period from 1942 to 2002.	Schneider *et al*. (2007)
	Proglacial lakes located in Andean Patagonia between ~40°S and ~50°S	Summertime negative trend on lakes with a direct influence of glaciers interpreted as an indication that melt water is decreasing because the ice volume reduction.	Pasquini *et al*. (2008)
	Northwestern Patagonia between ca. 38° and 45°S.	Recession of 6 glaciers based on areal photograph analysis.	Masiokas *et al*. (2008)
	Streamflow from basins between 28 °S and 47 °S	Not significant increase in February run-off trends for period 1950–2007 that might suggest an increase of glacier melt in the Andes.	Casassa *et al*. (2009)

Table 27-4: Synthesis of projected climate change impacts on hydrologic variables in large South American basins and major glaciers.

Region	Basins studied	Hydrologic Variable	Projected Change	Period	GCM	Scenarios	References
La Plata Basin and SESA	Paraná	Runoff	Runoff: + 4.9% (not robust) Runoff: +10 to +20%	2081-2100 2100	CMIP3 Eta forced with HadCM3	A1B A1B	Nohara *et al.* (2006) Marengo *et al.* (2011a)
	Carcarañá	ET, Recharge	Increase in ET not compensated with increase in precipitation, slight reduction in recharge.	2010-2030	HadCM3	A2	Venencio and García (2011)
	Grande (Parana)	Runoff	Range from +20 to -20%	Different periods	7 CMIP3 models	Prescribed temperature changes and emission scenarios	Todd *et al.* (2011) ; Gosling *et al.* (2011); Nóbrega *et al.* (2011)
	Itaipu (Parana)	Runoff	2010–2040: Left bank: –5 to –15%; Right bank: +30% 2070-2100: 0 to –30%	2010–2040 and 2070-2100	CCCMA-CGCM2	A2	Rivarola *et al.* (2011)
Amazon Basin	Peruvian Amazon–Andes basin	Runoff	Some basins increased, some reduced	Three time slices	BCM2, CSMK3 and MIHR	A1B, B1	Lavado Casimiro *et al.* (2011)
	Ecuador - Tomebamba/Paute	Runoff	Some scenarios increase and some reduction	2070-2100	CMIP3	A1B	Buytaert *et al.* (2011)
	Amazon at Obidos	Runoff	Average change + 5.4% (not robust)	2081-2100	CMIP3	A1B	Nohara *et al.* (2006)
		Runoff	+6%	2000-2100	ECBilt-CLIO-VECODE	A2	Aerts *et al.* (2006)
	Amazon -Orinoco	Runoff	-20%	2050s	HadCM3	A2	Palmer *et al.*(2008)
Tropical Andes	Colombian glaciers	Glacier extent	Glacier disappearance by 2020s	linear extrapolation			Poveda and Pineda (2009)
	Cordillera Blanca basins	Runoff	Increase for next 20-50 years, reduction afterwards	2005-2020	Temperature output only	B2	Chevallier *et al.* (2011)
		Glacier extent	2050: area is reduced by 38 to 60%. Increased seasonality 2080: area is reduced by 49 to 75%. Increased seasonality	2050 (climatology)	Not specified	A1, A2, B1, B"	Juen *et al.* (2007)
	Basins providing water to cities of Bogota, Quito, Lima and La Paz	Water availability	Inner tropics: Only small change because of an offset of an increase in precipitation by an increase in evapotranspiration. Outer tropics: severe reductions due to a decrease in precipitation and increase in evapotranspiration	2010-2039 and 2040-2069	19 CMIP3 models	A1B and A2	Buytaert and De Bièvre (2012)

Central Andes	Maipo	Runoff Unmet demand	Reduction up to 30% Unmet demand up to 50%	Three 30-year periods 2070-2090	HadCM3	A2, B2	Melo *et al*. (2010); ECLAC (2009a) Meza *et al*. (2012)
	Maule, Laja	Runoff	Reduction up to 30%	Three 30-year periods	HadCM3	A2, B2	McPhee *et al*. (2010); ECLAC (2009a)
	Bio Bio						Stehr *et al*. (2010)
	Limari	Runoff	Reduction range -20 to -40%. Change in seasonality	2070-2100	HadCM3	A2, B2	Vicuña *et al*. (2011)
	Limay	Runoff	Reduction range -10 to -20%.	2080s (climatology)	HadCM2	Not specified	Seoane and López (2007)
North East Brazil	Brazilian Federal States of Ceara´ and Piauı´	Runoff	No significant change up to 2025. After 2025: strong reduction with ECHAM4; slight increase with HadCM2.	2000-2100	HadCM2, ECHAM4	Not clear	Krol *et al*. (2006); Krol and Bronstert (2007)
	Paracatu (Sao Francisco)	Runoff	A2: +31 to +131%; B2: no significant change	2000-2100	HadCM3	A2, B2	De Mello *et al*. (2008)
	Jaguaribe	Demand	Increase in demand: +33 to +44%	2040	HadCM3	A2, B2	Gondim *et al*. (2008)
	Parnaiba	Runoff	-80%	2050s	HadCM3	A2	Palmer *et al*. (2008)
	Mimoso catchment	Runoff	Dry scenario: -25 to -75%; Wet scenario: +40 to + 140%; Similar changes in GW recharge	2010–2039, 2040–2069, and 2070–2099	CSMK3 and HadCM3	A2, B1	Montenegro and Ragab (2010)
	Tapacurá River	Runoff	Low emission: decrease by 4.89%, 14.28% and 20.58% High emission: increase by 25.25%, 39.48% and 21.95%	Three 30-year periods	CSMK3 and MPEH5	A2, B1	Montenegro and Ragab (2012)
	Benguê catchment	Runoff	-15% reservoir yield	Sensitivity scenario in 2100 selected from TAR and AR4 GCMs with good skill. + 15% PET, -10% Precip			Krol *et al*. (2011)
North SA	Essequibo (Guyana)	Runoff	-50%	2050s	HadCM3	A2	Palmer *et al*. (2008)
	Magdalena (Colombia)	Runoff	Not significant changes in near future. End of 21st not consistent trend but changes in seasonality.	2015–2035 and 2075–2099	CMIP3 multi-model ensemble (MME)	A1b	Nakaegawa and Vergara (2010)
	Sinu (Colombia)	Runoff	-2 to -35%	2010-2039	CCSRNIES, CSIROMK2B, CGCM2, HadCM3 (different runs of these models)	A2	Ospina-Noreña *et al*.(2009a; 2009b)
CA	Lempa	Runoff	Statistically significant reduction in the order of 13% (B1) and 24% (A2).	2000-2100 (results presented for 2070-2100)	CMIP3	A2, B1	Maurer *et al*. (2009)

	Grande de Matagalpa	Runoff	-70%	2050s	HadCM3	A2	Palmer *et al*. (2008)
	Mesoamerica (6.5-22 N and 76.5-99 W)	Runoff	Decrease across the region (different magnitudes and uncertainty associated) even in areas where precipitation increases	2070-2100	CMIP3	A2, A1b, B1	Imbach *et al*. (2012)

Table 27-7: Overview on local, regional, national and international adaptation programs, projects and initiatives relevant for the region.

Countries	Name of Project/ Case Study/ Business Case	Specification of Approach/ Strategy/ Adaptation Area	Platform- NWP (PSI;LCS;EbA;AP)/ weAdapt	Details on platform specification*
Argentina	Adaptation strategies for the Jujuy model forest in NW Argentina	Adaptation efforts in a forest model in Argentina	weAdapt	n.a.
Belize	Adapting to climate change in the Mesoamerican Reef	Assessment of vulnerability; Improvement in capacity, design and policy measures; Implementation of EBA measures	NWP- EbA	Marine and coastal (WWF)
Belize	Ecosystems, Development and Climate Adaptation: Improving the base for policies, planning and management	Mainstreaming EbA in Belize	weAdapt	n.a.
Bolivia	Qhuthañas in Bolivia Collecting and storing rainwater in small dams (qhuthañas)	Rainwater harvesting	NWP- LCS	Hazards: Drought, aridity/ Impacts: Loss of crops; Water shortage
Bolivia	Enhancing adaptive capacity in semi-arid mountainous regions, Bolivia	Assessment of vulnerability; Improvement in capacity design and policy measures; Implementation of EBA measures	NWP- EbA	Mountain; Forest and woodland (The Netherlands Climate Assistance Programme (NCAP))
Bolivia	Building Capacity in Vulnerable Mountain Regions	Water Scarcity in Mountain Regions	weAdapt	n.a.
Bolivia	Climate Change Adaptation in Practice; Rescuing the Past: Using Indigenous Knowledge to Adapt to Climate Change in Bolivia	Using Indigenous Knowledge to Adapt to Climate Change in Bolivia	weAdapt	n.a.
Bolivia	Understanding Adaptation and Mitigation Strategies of Andean People - Bolivia	INCA- Bolivia	weAdapt	n.a.
Bolivia	Adaptation strategies for the Chiquitano tropical dry forest in Eastern Bolivia	Adaptation efforts in the tropical dry forest of Bolivia	weAdapt	n.a.
Bolivia	Ecosystem-based strategies and innovations in water governance networks for adaptation to climate change in Latin American Landscapes	EcoAdapt	weAdapt	n.a.
Brazil	New technologies for climate change adaptation	Food security, agriculture, forestry and fisheries	NWP- PSI	Chemicals (BASF)
Brazil	Insuring against climate impacts and rewarding sustainable business practices	Business	NWP- PSI	Financial Services (Allianz)
Brazil	Disaster preparedness, local capacity building, and planning	Science, assessment, monitoring and early warning; Education and training	NWP- PSI	Consulting and Environmental Services (Riverside Technology)

Brazil	New insurance products and climate risk	Business; Transport, infrastructure and human settlements	NWP- PSI	Financial Services (HSBC)
Brazil	Community Reforestation in Rio de Janeiro, Brazil; Preventing soil erosion and landslides	Soil conservation; Natural resource management	NWP- LCS	Hazard: Floods/ Impact: Soil erosion
Brazil	Babassu Palms in Brazil Harvesting the fruits for oil and protein	Diet diversification	NWP- LCS	Hazards: Drought, aridity/ Impacts: Loss of crops
Brazil	Tires walls in Rio de Janeiro, Brazil Building retaining walls from crape tires	Soil conservation	NWP- LCS	Hazard: Floods/ Impact: Soil erosion
Brazil	Rio de Janeiro's Community Reforestation Project	Improvement in capacity; design and policy measures; Implementation of EBA measurres	NWP- EbA	Urban; Forest and woodland (City of Rio)
Brazil	Ecosystem-Based Adaptation in Marine, Terrestrial and Coastal Regions as a Means of Improving Livelihoods and Conserving Biodiversity in the Face of Climate Change	Assessment of vulnerability; Improvement in capacity, design and policy measures; Implementation of EBA measures	NWP- EbA	Marine and coastal; forest and woodland; agriculture; inland water (Federal Environment Ministry of Germany, Conservation International Foundation)
Brazil	Adaptive management of pirarucu (Arapaima gigas)	Adaptive management	weAdapt	n.a.
Brazil	Promotion of drought resistant native fruits	Resistance to droughts	weAdapt	n.a.
Chile	SMCE/NAIADE: Evaluating the effects of the Alumysa Project in the Aysen Region in Chile	Adaptation tools, case study SMCE/NAIADE	weAdapt	n.a.
Chile	Adaptation strategies for the Alto Malleco model forest in Chile	Adaptation efforts in a forest model in Chile	weAdapt	n.a.
Colombia	Adaptation program to support ecosystem services	Water resources	NWP- PSI	Water Management (EEAB-Bogotá Water and Sewage Company)
Colombia	Integrated National Adaptation Plan - Colombia highland ecosystems	Assessment of vulnerability; Improvement in capacity, design and policy measures; Implementation of EBA measures	NWP- EbA	Mountain; Inland Water (GEF; World Bank; Conservation International)
Colombia	Orito Ingi Ande Medicinal Plants Sanctuary	Improvement in capacity, design and policy measures; Implementation of EBA measures	NWP- EbA	Forest and woodland (Government of Colombia; local communities)
Colombia	Implementing Climate Adaptation Strategies in the World's Most Outstanding Natural Places	Delivering Adaptation	weAdapt	n.a.
Colombia	Building Capacity in the Colombian coastal area	Integrated Coastal Management for Adaptation	weAdapt	n.a.

Colombia, El Salvador, Nicaragua	Integrating Climate Change Risks and Opportunities into National Development Processes and United Nations Country Programming (UNDP)	not specified	NWP- AP	Academic, Governmental, Intergovernmental
Costa Rica	Flood preparedness in Costa Rica Implementing a community training programme	Disaster risk management	NWP- LCS	Hazard: Floods/ Impact: Damage to human settlements
Costa Rica	Hurricane-resistant housing in Costa Rica Constructing low-cost reinforced bamboo houses	Improved housing design	NWP- LCS	Hazard: Storms/ Impact: Damage to human settlements
Ecuador	Providing farming training and assistance	Education and training; Food security, agriculture, forestry and fisheries; Water resources	NWP- PSI	Food and Beverages (Nestlé)
Ecuador	Flood-Resistant Housing in Ecuador Constructing elevated bamboo houses	Improved housing design	NWP- LCS	Hazard: Floods/ Impact: Damage to human settlements
Ecuador and Peru	The CEIBA-PILARES project	Improvement in capacity, design and policy measures; Implementation of EBA measures	NWP- EbA	Forest and woodland (Nature and Culture International)
El Salvador	Vulnerability and Capacity Analysis of Communities Amando López and Octavio Ortiz in the Lower Lempa Valley	Vulnerability and Capacity Analysis of Communities in El Salvador	weAdapt	n.a.
El Salvador, Costa Rica, Panama	Climate Change Governance Capacity: Building Regionally and Nationally Tailored Ecosystem-Based Adaptation in Mesoamerica	Assessment of vulnerability; Improvement in capacity design and policy measures; Implementation of EBA measures	NWP- EbA	Marine and coastal; Agriculture; Inland waters (Federal Environment Ministry of Germany, International Union for Conservation of Nature)
El Salvador; Guatemala; Nicaragua	Coffee Under Pressure: Climate Change and Adaptation in Mesoamerica (CUP)	Food security, agriculture, forestry and fisheries	NWP- PSI	Food and Beverages; Agriculture (Green Mountain Coffee Roasters (GMCR); International Center for Tropical Agriculture (CIAT); Catholic Relief Services (CRS))
El-Salvador	Drought-resistant agriculture in El-Salvador	Improvement in capacity, design and policy measures; Implementation of EBA measures	NWP- EbA	Agriculture (Red Cross; World Food Programme)
Guatemala	Finding Points of Engagement to Integrate Climate Change Adaptation into Water Management Planning	Integrating Climate Adaptation into National Policy (NCAP)	weAdapt	n.a.
Guyana	Participatory school and community-based disaster preparedness	Community-based disaster preparedness	weAdapt	n.a.

28.6. Research and Data Gaps

Frequently Asked Questions
28.1: What will be the net socio-economic impacts of change in the Polar Regions?
28.2: Why are changes in sea ice so important?

References

Executive Summary

The physical, biological and socio-economic impacts of climate change in the Arctic have to be seen in the context of often interconnected factors that include not only environmental changes caused by factors other than climate change but also demography, culture and economic development. There is evidence that climate change has compounded some of the existing vulnerabilities caused by these other factors (*high confidence*). [28.2.5, 28.4]

The rate rather than the magnitude of changes in the polar regions may become more of a key factor leading to dramatic impacts on natural and social systems if it exceeds the rate at which systems can adapt (*low to medium confidence*). [28.4.2] The decline of Arctic sea-ice in summer is occurring at a rate that exceeds most model projections (*high confidence*). Evidence of similarly rapid rates of change is emerging in some regions of Antarctica, particularly the ice shelves. There is some evidence, for example in the reduction of sea-ice extent in the Arctic and in the west Antarctic Peninsula that the changes are non-linear, and may be accelerating. [IPCC AR5 WGI Chapter 14]

The primary conservation concern for polar bears over the foreseeable future or three generations is the recent and projected loss of annual ice over continental shelves, decreased ice duration, and decreased ice thickness (*high confidence*). Of the two subpopulations where data are adequate for assessing abundance effects, it is *very likely* that the recorded population declines are caused by reductions in sea ice extent.

Environmental changes and ecosystem responses in the marine environment differ between ecological regions within both the Antarctic and Arctic, largely as a result of differences in the changes to sea ice dynamics and sea surface temperature (*high confidence*). [28.2.2] The changing sea ice environments off the Western Antarctic Peninsula and in the Arctic have resulted in measurable changes in phytoplankton communities. In the Western Antarctic Peninsula region, krill production has been linked to sea ice extent and duration. Further sea ice changes are likely to have a negative effect on krill populations and on the species that depend on them (*high confidence*). [28.2.2.2]

Some marine species will shift their ranges in response to changing ocean and sea ice conditions in the Polar Regions. Responses will vary depending on the vulnerability of species to changing ocean conditions. Some marine species have shifted their spatial distribution in response to changing environmental conditions. The response rate and the spatial extent of range shifts will differ by species based on their vulnerability to change and their life history. [28.2.2; 28.3.2] Penguins and flying birds restricted to sub-Antarctic islands will have lower reproductive success because of the added cost of obtaining prey further to the south (*medium confidence*).

Loss of sea ice in summer is expected to enhance secondary pelagic production in the Arctic with associated changes in the energy pathways within the marine ecosystem (*medium confidence*). These changes are expected to alter the species composition and carrying capacity of pelagic and benthic marine habitats with associated impacts on the ability of the region to support marine fish and shellfish populations (*medium confidence*). [28.2.2.1]

Shifts in the timing of seasonal biomass production could disrupt matched phenologies in the food webs, leading to decreased survival (*medium confidence*). The breeding cycle of some shellfish and fish in the Arctic coincides with the spring bloom of ice algae and ocean phytoplankton and subsequent secondary production which is considered to enhance survival of the larvae. If the timing between peaks in primary production and secondary production are no longer matched to the timing of spawning or egg release, survival could be impacted with cascading implications to higher trophic level consumers. Higher predators have highly synchronized breeding phenologies in Polar Regions, requiring prey to be available near to land-based colonies at certain times of the year. This impact would be exacerbated if shifts in timing occur rapidly (*medium confidence*). [28.2.2, 28.3.2] Mismatch between the phenology of different trophic levels caused by climate change has also been suggested to be a potential problem for Arctic terrestrial mammals and birds [28.2.3.5], but the scientific documentation for this is weak.

Ocean acidification has the potential to inhibit egg development and shell formation of some zooplankton and krill in the polar regions with potentially far-reaching consequences to food webs in these regions (*medium confidence*). Eggs and larvae of Antarctic krill have been shown to be vulnerable to increased concentrations of CO_2 in the water (*high confidence*). As well, there is increasing evidence that pelagic mollusks (pteropods) are vulnerable to ocean acidification (*medium confidence*). If these effects result in widespread impacts on populations then they will be far reaching on regional foodwebs. [28.2.2, 28.3.2]

Future trends in populations of Antarctic marine mammals and birds will be a complex response to multiple stressors and indirect effects (*high confidence*). [28.3.2.2] Changes in populations of many Antarctic predators are well documented [28.2.2.2]. Some species, such as Antarctic fur seals and humpback whales, are increasing as they recover from past exploitation (*very high confidence*). Decreases in populations of other species (chinstrap and Adelie penguins on the Western Antarctic Peninsula) and Emperor penguins generally have been associated with long-term physical changes such as sea ice (*medium confidence*). [28.2.2.2]

Climate change is impacting terrestrial and freshwater ecosystems in some areas of the Antarctica and Arctic. This is due to ecological effects resulting from reductions in the duration and extent of ice cover and enhanced permafrost thaw (*very high confidence*), and through changes in the precipitation-evaporation balance (*medium confidence*). [28.2]

The primary conservation concern for polar bears over the foreseeable future or three generations is the recent and projected loss of annual ice over continental shelves, decreased ice duration, and decreased ice thickness (*high confidence*). Of the two subpopulations where data are adequate for assessing abundance effects, it is *very likely* that the recorded population declines are caused by reductions in sea ice extent.

The abundance and biomass of deciduous shrubs and grasses has increased substantially over large – but not all – parts of the Arctic tundra in recent years (*very high confidence)*. It is *very likely* that most of this increase in biomass can be attributed to longer growing seasons and higher summer temperatures.

The tree line has moved northwards and upwards in many, but not all, Arctic areas and significant increases in tall shrubs have been observed in many places (*high confidence)*. Other factors such as changes in herbivore grazing, anthropogenic disturbances and changes in precipitation and the snow/water regime also influence the tree line and structural vegetation changes in the northern boreal forest. [28.2.3.2, 28.2.3.3]

Increased energy availability (warming) in combination with increased water availability is expected to lead to increased productivity, biomass and the development of community complexity in native Antarctic terrestrial biota (*high confidence*). However, these responses are potentially confounded by multiple stressors, including human activities (research stations, tourism etc). [28.3.3.2] Climate change will increase the vulnerability of terrestrial ecosystems to invasions by non-indigenous taxa, the majority likely to arrive through direct human assistance, which poses the greatest threat to terrestrial plant and animal communities in the future (*high confidence*). [28.3.3.4]

Summer phytoplankton levels in many Antarctic lakes have increased significantly together with higher nutrient inputs from exposed fell field soils and thawed ground (*very high confidence*). [28.2.1.2] These lakes have experienced extended open-water periods allowing the water and sediments to absorb more solar energy which has further increased lake water temperature during winter. Lakes with a low lake depth to surface area ratio have been susceptible to inter-annual and inter-decadal variability in the water balance (*high confidence*).

Impacts on the health and well-being of Arctic residents from climate change are significant and projected to increase – especially for many indigenous peoples (*high confidence*). [28.2.4] Impacts include injury and risk from extreme and unpredictable weather including flooding, changing in ice and snow conditions endangering hunting, herding, and fishing; food insecurity and malnutrition due to decreased access to local foods and loss or compromised freshwater sources; permafrost and erosion damage to homes and infrastructure and loss of homelands as well as increased social and economic problems due to loss of traditional livelihood, language, culture and relocation of communities. These impacts are expected to vary among the diverse settlements that range from small, remote predominantly indigenous to large industrial settlements (*high confidence*). Many of these impacts are often related to the fact that a large percentage of northern settlements are along coastlines or beside rivers and lakes.

Food security of many indigenous and rural residents in the Arctic is being impacted by climate change, and when seen in combination with the effects of globalization and resource development these impacts are projected to increase significantly in the future (*high confidence*). [28.2.7.1, 28.2.4] There have been noticeable impacts on the livelihoods of indigenous peoples' ways of life particularly their access to traditional foods that have provided sustenance, cultural, religious, economic, and community well-being for many generations. However, Arctic indigenous people have a high adaptive capacity and have begun to develop novel solutions to adapt to climate changes, such as combining traditional and scientific knowledge and co-producing climate studies with scientific partners. [28.2.7.1, 28.2.7.2, 28.4.1]

Climatic and other large-scale changes can have potentially large effects on Arctic communities where relatively small and narrowly based economies leave a narrower range of adaptive choices. [28.2.6.1.5] Formal and market-based economic activity is projected to have both costs and benefits, with some commercial activities becoming more profitable while others will face decline. Increased economic opportunities along with challenges for culture, security and environment, are expected with the increased navigability of Arctic marine waters and the expansion of land- and fresh water-based transportation networks (*high confidence*). [28.2.6.1.4, 28.4.2]

Significant impacts on the availability of key subsistence marine and terrestrial species are projected as climate continues to change with the ability to maintain economic livelihoods being affected. The informal, subsistence-based economy will be impacted by changing climate (*high confidence*). Indigenous hunters, whalers, walrus hunters and herders are reporting non-predictable conditions resulting from more frequent occurrence of

unusual weather events. There *is high confidence* that changing sea-ice conditions will result in more difficult access for hunting marine mammals and greater risk for the long-term viability of polar bear populations. [28.2.6.1.7]

Rising temperatures, leading to the further thawing of permafrost, and changing precipitation patterns have the potential to affect all infrastructure types and related services in the Arctic (*high confidence*). Much of the infrastructure is dependent upon the frozen soil to provide stable surfaces for buildings and pipelines, contain waste, stabilize shorelines and provide access to remote communities in the winter. [28.2.6.5.1]

Although there is general agreement that both indigenous and non-indigenous people in the Arctic have a long history of adapting to change, the complex inter-linkages between societal, economic, political factors and climatic stresses represent unprecedented challenges for northern communities (*high confidence*). [28.4]

28.1. Introduction

Previous IPCC reports define the Arctic as the area within the Arctic Circle (66ºN), and the Antarctic as the continent with surrounding Southern Ocean south of the polar front, which is generally close to 58ºS (IPCC, 2001). For the purpose of this report we use the conventional IPCC definitions as a basis, while incorporating a degree of flexibility when describing the Polar Regions in relation to particular subjects, similarly to the approaches adopted in the Arctic Climate Impact Assessment (ACIA) and Antarctic Climate Change and the Environment (ACCE) report (ACIA 2005, Convey et al. 2009; Turner *et al*., 2009; Convey *et al*., 2009). Changes in the physical climate regime in the Polar Regions are addressed in detail in IPCC WG-1 report.

[INSERT FIGURE 28-1 HERE
Figure 28-1: Location maps of the North and South polar regions. Source: IPCC, 2007. [Note: WGII AR4 Figure 15.1 to be updated, including the addition of major currents. Credit: P. Fretwell, British Antarctic Survey.]]

Summary of Knowledge Assessed in other Reports (including IPCC, SWIPA, IPY etc.)

Several recent international climate assessments, including the IPCC (2007), the synthesis report on Snow, Water, Ice and Permafrost in the Arctic (SWIPA, 2011), the State of the Arctic Coast 2010 (2011) reports, the Antarctic Climate and the Environment (Turner *et al*., 2009), and reports summarizing the findings of the International Polar Year (IPY) draw a consistent pattern of climatic and environmental changes in the Polar regions, as well as climate-driven societal and economical changes in the Arctic in the beginning of the 21st century. Here we summarize the key findings of these assessments focusing on impacts of climate change and briefly addressing the relevant information about changes in the physical climate parameters, which are detailed in the report of the Working Group 1 to the Fifth IPCC assessment.

Arctic

In the past few decades Arctic was characterized by the highest regional rates of changes in selected parameters of the physical climate regime. Such changes are essential for understanding a cascade of the environmental and societal impacts addressed in this chapter. Since 1980 Arctic has been warming at approximately twice the global rate demonstrating the strongest temperature changes (~ 1 °C/decade) in winter and spring, and smallest in autumn (IPCC WG2 2007, SWIPA 2011). Sea ice declined at an unprecedented rate in all seasons reaching the absolute minimum of 3.41 million km^2 in September 2012, which is 18% lower than in 2007, when the previous record of 4.17 million km^2 was recorded. (IPCC WG1 2014; Arctic report card, 2012). The Arctic Ocean is projected to become nearly ice-free in summer within this century, while some models suggest it may happen within the next thirty to forty years (IPCC WG1 Fifth AR). According to SWIPA (2011), the duration of snow cover extent and snow depth are decreasing in North-America while increasing in Eurasia. Since late 1970s permafrost temperatures have increased typically between 0.5 to 2 °C, with warming rates being much smaller for warm ice-rich permafrost at temperatures close to 0 °C than for colder permafrost or bedrock.

These changes in the physical climate regime and cryosphere are already generating widespread ecological, human, and economic impacts, which are projected to intensify in the future. Changes in the cryosphere will cause fundamental changes to the characteristics of Arctic ecosystems and in some cases loss of entire habitats with consequences for people who receive benefits from these resources (SWIPA 2011). In the terrestrial ecosystems the dominant response of Arctic species to climate change will probably be relocation rather than on-site adaptation (IPCC WG2 2007). It is expected over time that forest will replace significant proportions of the tundra and that this again will have great effects on biodiversity which is projected to increase. According to SWIPA (2011), decreased multi-year sea ice and increased open water will enhance the overall marine production. Many marine ecosystems will be experiencing shifts from light limitation to nutrient limitations as well as shifting balance between the primary production by ice algae and phytoplankton with implications for Arctic food webs. Changing ice patterns and timing will affect mammals, including the polar bears, marine birds and some fish species. Pinniped species that depend on ice (i.e. seals and walrus) will be disadvantaged due to reductions in the sea ice extent. According to model projections, within 50-70 years loss of hunting habitats may lead to extirpation of the polar bears from seasonally ice-covered areas, where currently two thirds of their world population live. Sub-arctic seabirds will be competing with arctic species. Northward expansion of habitats for some temperate species will enhance foraging opportunities for their predators in the High Arctic, at a cost to endemic populations of the Arctic.

There are challenges for human systems, local communities and traditional ways of life. Infrastructure and settlements, particularly on the Arctic coasts, become more vulnerable with increased risks of damage due to the coastal erosion, permafrost degradation, and loss of sea ice (IPCC WG2 2007; SOAC 2011; SWIPA 2011). Human settlements and cities in the Russian Arctic are conventionally located along the rivers, and particular concerns are associated with floods caused by ice jams. This is exemplified by the catastrophic 2001 Lena River flood, which demolished most of the buildings in the city of Lensk. According to SWIPA (2011), floods due to ice jams on Siberian rivers in the coming decade are projected to become 1.2 to 1.5 times more frequent and more severe with 35 to 60% increase in peak break-up water levels. In north-European Russian rivers (Severnaya Dvina, Sukhon, Vyga, Pechora) maximum jam levels might increase by 10-12%, while the frequency of floods would increase by a factor of 1.2, at most. Such changes may have serious implications for settlements and infrastructure on the shores of these rivers, and many of the populated areas are expected to be periodically flooded. Transport options and access to resources are radically changed by differences in the distribution and seasonal occurrence of snow, water, ice and permafrost. Freshwater ice durations over much the circum-polar North have decreased since 1970s in response to earlier break-ups and later freeze-ups, on average 6.3 and 5.8 days/100 years, respectively, with rates in the high Arctic more than 4 times greater than those experienced in more southerly latitudes (SWIPA, 2011). Maximum ice thickness decreased up to 15 cm in rivers within Siberia. Statistically, a long-term mean increase of 2 to 3°C in autumn and spring air temperature produces an approximate 10 to 15 day delay in freeze-up and advance in break-up, respectively. As a result, many of the ice roads may become less viable option than the all-weather roads with implications for significantly increased costs (SWIPA, 2011). There will also be new opportunities such as increasingly navigable Northern Sea Route with up to 125 days per year suitable for navigation by 2050, and predicted up to 15% decline in the heating energy demand in the populated Arctic areas (IPCC WG2 2007). Reduced ice period and thickness of river ice is beneficial for hydropower generation during the low flow winter season, when the energy demand is at its annual maximum (SWIPA, 2011).

Arctic societies have a well-deserved reputation for resilience in the face of change. But today they are facing an unprecedented combination of rapid and stressful changes involving environmental processes, cultural developments, economic changes, industrial developments, and political changes. That may limit this resilience. As argued in the AR4, the most effective adaptation options will be those that recognize the nexus between adaptation and sustainable development (Yohe et.al., 2007 (IPCC WG2). One consequence of this observation is the potential of “mainstreaming” adaptation into existing policy processes and priorities (such as those for poverty alleviation, health standards, emergency planning and insurance) leading to “win-win” options.

Although climate change and other processes affecting the availability of natural resources impose large impacts on quality of life and economic activity for communities on the Arctic coast, other factors and processes will often be more important, especially in the short run. Where communities are already stressed, even small changes in the availability or quality of natural resources may be critical (SOAC 2011).

The holistic perspective of indigenous culture suggests that efforts to understand, manage, and respond to change in Arctic local communities and coastal systems may benefit from the integration of this knowledge with Western science. Recognizing the value of traditional ecological knowledge may contribute to enhanced resilience and adaptive capacity in local and coastal communities (E.g. SOAC 2011; SWIPA 2011).

Antarctic

While temperatures over the bulk of the Antarctic continent have not changed markedly in recent decades, the strongest rates of atmospheric warming seen in the Southern Hemisphere are occurring in the western Antarctic Peninsula region of West Antarctica and the islands of the Scotia Arc, where there have also been increases in oceanic temperatures and large regional decreases in winter sea ice extent and duration (Mayewski *et al*., 2009; Turner *et al*., 2009; Stammerjohn *et al*., 2012). Although not to the same extent, warming has also occurred in the continental margins near to Bellingshausen Sea, Prydz Bay and the Ross Sea, with areas of cooling in between (Bromwich *et al*., 2013). Land regions that have experienced significant warming have seen considerable glacial recession along with changes in the ice and permafrost habitats in the coastal margins, although changes in snow fall show no trends. The Southern Ocean continues to warm throughout its depth with increased freshening at the surface due to precipitation, leading to increased stratification. The Antarctic Circumpolar Current has moved to the south, the extent of which is regionally variable. Similarly, the magnitude and southward extent of increasing wind-driven mixing associated with increasing SAM is also regionally variable (Sallee *et al*., 2010). Aragonite undersaturation of the Southern Ocean at depths equivalent to the continental shelf will occur within decades, with some regions being affected sooner than others. Undersaturation of the surface waters is likely before 2100, reinforcing previous conclusions of threats to pteropods (pelagic marine molluscs).

Antarctic terrestrial systems have been documented to have changed with increasing habitat from reduction in snow and ice cover resulting in increased abundance of flowering plants. On subantarctic islands there have also been increases in abundance of alien species and consequent negative impacts on local biota.
Antarctic terrestrial ecosystems occur in three generally accepted biogeographic regions; the sub-Antarctic, maritime Antarctic and Continental Antarctica, with generally warmer temperatures, reduced extreme seasonality and greater biodiversity in the sub-Antarctic (Convey, 2006). On the continent, where biological diversity is limited to species that can take advantage of the short periods where temperatures and moisture availability are above physiological and biochemical thresholds, recent research has shown that there are 15 biologically distinct areas (Terauds *et al*., 2012). In many areas there is no visible vegetation with life often limited to endolithic (within rock) communities of algae, cyanobacteria, fungi, bacteria and lichens (Convey, 2006).

Antarctic freshwater systems are fewer and much smaller than Arctic freshwater systems, comprising lakes, ponds, short streams and seasonally wetted areas (Vincent *et al*., 2008). Antarctic freshwater biota are dominated by benthic microbial communities of cyanobacteria and green algae in a simple food web. Mosses occur in some lakes but higher plants are absent on the continent. Planktonic ecosystems are dominated by small algae, bacteria and colourless flagellates. There are few metazoans and no fish. Documented effects of climate change include changing microbial dynamics in lakes as a result of changing nutrients and contaminants. For subantarctic islands, such as Signy Island, increased icefree conditions and temperatures along with decreases in perennial snow cover have led to increased organic and inorganic nutrient inputs to lakes. Fur seal populations have increased dramatically and occupied the increasing available terrestrial areas, resulting in disruption of local systems, including increased nutrients into the areas.

Productivity and food web dynamics in the Southern Ocean are dominated by the extreme seasonal fluctuations of irradiance and the dynamics of sea ice, along with temperature, carbonate chemistry and light due to vertical mixing (Massom and Stammerjohn, 2010; Boyd *et al*., 2012; Constable *et al*., submitted). Diatoms are the dominant primary producers, particularly in the coastal waters, which are also the primary contributors to the annual carbon flux in the region. Antarctic marine food webs are dominated by Antarctic krill, *Euphausia superba* (hereafter termed 'krill'), which primarily consumes large phytoplankton (diatoms) and small zooplankton and are themselves food for many of the fish, squid, marine mammals, penguins and flying birds in the Southern Ocean. Other

secondary producers are salps and copepods, which can feed on smaller phytoplankton, and are consumed by smaller fish, such as myctophids. The relative importance of krill varies regionally, being dominant from the Bellingshausen Sea east through to the Weddell Sea and the Atlantic sector of the Southern Ocean (Rogers *et al*., 2012). In the Indian and southwest Pacific sectors of the Southern Ocean, the krill-dominated system lies to the south of the Southern Boundary of the Antarctic Circumpolar Current, while in the north the system is dominated by copepods and myctophid fish.

Around the Antarctic continent, the coastal systems are characterised by deep shelf areas (800m) broken by canyons and cross-shelf depressions (Grant *et al*., 2006). Banks of 300m depth or less are scoured by icebergs. Benthic communities are differentiated by these topographic features (Constable *et al*., submitted). Coastal polynyas are prevalent, caused by land forms, glacier tongues, bottom topography or grounded icebergs(Massom and Stammerjohn, 2010). These areas are high in productivity with a few areas being important for the formation of Antarctic Bottom Water, which sinks from the surface flowing over the shelf and into deep water, influencing the benthos with its water chemistry and organic particulates.

For these marine ecosystems, few studies were available in AR4 to document and validate the changes resulting from climate change. Those studies reported increasing sponges and their predators, declining abundances of krill, Adélie and Emperor penguins, and Weddell seals and a possible increase in salps in place of krill, noting regional differences in these trends. These changes may have been attributable to declining sea ice or as indirect consequences of recovery of whales and seals from past over-exploitation. The importance of climate change was not able to be determined. Future impacts of climate change included that increases in temperature and reduced sea ice were expected to negatively affect krill abundance and cause a shift in its distribution. As well, many cold-adapted species, though not all, may be vulnerable if water temperatures rise to 5-10oC. Overall, the direct and indirect effects of climate change were considered to be difficult to predict, particularly in relation to an increasing fishery for Antarctic krill.

Economic activities in the Antarctic have been limited to fishing and tourism (IPCC WG2 2007).

28.2. Observed Changes and Vulnerability under Multiple Stressors

28.2.1. Hydrology and Freshwater Ecosystems

28.2.1.1. Arctic

Rivers and lakes within the Arctic high latitudes continue to show pronounced changes to their hydrology, which can have cascading effects on their aquatic ecology. One of the most conspicuous hydrologic changes has been to river flow. Previously noted increases in Eurasian river flow (1936-1999)(Peterson *et al*., 2002) could not, for a similar period (1951-2000), be attributable with certainty to precipitation changes (Milliman *et al*., 2008), although decreases observed in the flow of major high-latitude Canadian rivers (1964-2000; average -10%) does match that for precipitation (Déry and Wood, 2005).

More recent discharge data (1977-2007) for 19 circumpolar rivers indicates an area-weighted average increase of +9.8% (range –7.1 to +47.0%; 15 of 19 exhibiting increases), with additional evidence of accelerating change in recent years for the combined domain of six selected large basins (Overeem and Syvitski, 2010). This has been accompanied by shifts in flow timing with the main month of snowmelt (May) increasing by an average 66% but flow in the subsequent month of peak discharge decreasing by ~7%. Across the Russian Arctic drainage basin, dates of spring maximum daily discharge have also become earlier, particularly in most recent [1960-2001] period analyzed (average -5d; range for four regions +0.2 to -7.1 d), although no consistent trend exists for changes in the magnitude (average -1%; range +21 to -24%) of these daily flows (Shiklomanov *et al*., 2007). Changes to earlier timing were most pronounced in eastern, colder continental climates that have experienced rises in air temperature. Such upward trends in air temperature, rather than flow regulation, have been identified as the dominant control of such timing shifts (Tan *et al*., 2011).

Changes have also occurred in winter flows with documented rises in the winter minimum flows for many Eurasian and North American rivers (Walvoord and Striegl, 2007; Smith *et al.*, 2007; St. Jacques and Sauchyn, 2009; Ye *et al.*, 2009) , the key exceptions being decreases in eastern North America and unchanged flow in small basins of eastern Eurasia (Rennermalm *et al.*, 2010). Most such studies suggest that winter flows have increased because of enhanced subsurface flow resulting from permafrost thaw (see WGI, Chapter 4), the concept supported in part by some satellite-gravity measurements (Muskett and Romanovsky, 2009). Others argue that the primary control is an increase in net winter precipitation minus evapotranspiration (Rawlins *et al.*, 2009a; Rawlins *et al.*, 2009b; Landerer *et al.*, 2010). Insufficient spatial coverage of Arctic precipitation stations precludes deciphering the relative importance of these two controlling factors.

Information about the changes to the hydrology and water budget of lakes is scarcer than that for rivers. Information from satellite thermal imagery, however, indicates that surface-water temperatures of large water bodies have been warming for the period 1985-2009 (Schneider and Hook, 2010). Greatest warming was observed for mid- and high latitudes of the northern hemisphere with the spatial patterns generally matching those for surface air temperature. Where water bodies warmed more rapidly than air temperature, decreasing ice cover was suggested as enhancing radiative warming.

Changes to terrestrial hydrologic and freshwater ice regimes have also produced a number of physical, geochemical and ecological effects on some arctic lake, wetland and river systems. Reduced ice cover accompanied by higher air temperatures and evaporation, have been identified as being responsible for the recent summer drying out of some Canadian High Arctic ponds, which had been permanent water bodies for millennia (Smol and Douglas, 2007a). Where water has persisted and lake-water temperatures increased, reductions in organic carbon burial has been attributed to a strong positive relationship with the mineralization of organic carbon in lake sediments (Gudasz *et al.*, 2010). Increasing water temperatures can also affect planktonic and benthic biomass in Arctic lakes and lead to changes in species composition (Heino *et al.*, 2009; Jansson *et al.*, 2010). In a study of a Greenland catchment, warmer conditions have been noted to increase nutrient and humic acid loadings leading to a higher abundance of phytoplankton and zooplankton (crustaceans) and altered species composition (Christoffersen *et al.*, 2008).

In the case of permafrost thermokarst lakes, new studies have documented changes in their size and number in various parts of the Arctic (Riordan *et al.*, 2006; Hinkel *et al.*, 2007; Marsh *et al.*, 2009). Their spatial patterns and rates of change, however, are not consistent and may be related to differing thawing state of the permafrost as well as spatial variations in warming (Prowse and Brown, 2010a). Thawing permafrost has also been identified as causing major changes to the biogeochemistry of water entering high-latitude lakes and rivers (Frey and McClelland, 2009), and to have implications for their ecological structure and function (Lantz and Kokelj, 2008; Mesquita *et al.*, 2010) , with some documented cases resulting in enhanced lake eutrophication through an ecological shift from pelagic-dominated to benthic-dominated production (Thompson, M., Wrona, F., Prowse,T., 2012).

The ecology of rivers has also been demonstrated to be dependent on changes to their freshwater ice regimes. Reductions in the physical severity of spring break-up (see WGI, Chapter 4) in the vast riparian zones of the Mackenzie River Delta has been observed to decrease the supply of ice-jam floodwaters and related nutrients and sediments to the delta's riparian zone, and hence, its ecological health (Lesack and Marsh, 2007). Such reductions in spring flood levels, combined with rising arctic sea level and sea ice recession, have also been proposed as the proximal drivers of biodiversity loss in this system. This is primarily related to the decline of lakes with short and variable hydrologic connection times, plus low and variable river water renewal (Lesack and Marsh, 2007). Because circumpolar river deltas act as biogeochemical processors of river water before its discharge to the Arctic Ocean (Emmerton *et al.*, 2008), changes in delta flooding could also affect primary production and food web processes in the coastal marine ecosystem, although these remain to be assessed. Changes to some near-coastal freshwater environments have been documented for the case of epishelf lakes (Veillette *et al.*, 2008). Such ice dependent freshwater lakes have become increasingly inundated with seawater as a result of the loss of integrity in their retaining ice dams (Vincent *et al.*, 2009), and as a result, the microbiologically rich ice shelve lakes are disappearing (Mueller *et al.*, 2008).

28.2.1.2. Antarctic

Recent compilations of single-year datasets have reinforced previous conclusions on the changing freshwater habitats in Antarctica (Verleyen *et al*., 2012). In regions where the climate has warmed the physical impacts on aquatic ecosystems include loss of ice cover, increasing periods of open water, increased water column temperatures and changes in water column stratification. Shifts in the water balance can also occur. In some areas a negative water balance has been established due to increased temperate and changes in wind strength driving enhanced evaporation and sublimation and leading to increased salinity in lakes (Hodgson *et al*., 2006a). In other areas, especially glacial forelands, increased temperatures lead to greater volumes of seasonal meltwater in streams and lakes together with increased nutrient fluxes. In both cases the balance between precipitation and evaporation can have detectable effects on lake ecosystems through changes in water body volume and lake chemistry (Lyons *et al*., 2006; Quesada *et al*., 2006). Non-dilute lakes with a low lake depth to surface area ratio are most susceptible to inter-annual and inter-decadal variability in the water balance, as measured by changes in specific conductance (Verleyen *et al*., 2012). In most cases warming is predicted to increase biological production in lakes. Other effects include dessication of moss banks due to increased evaporation and sublimation rates (Wasley *et al*., 2006), increases in the latitudinal ranges of extant species and increase the likelihood of invasive species becoming established together with increases in community biomass and complexity (Peck, 2005).

In summary, there is *high confidence* that increased temperatures will impact subaerial aquatic ecosystems in Antarctica. The exact nature of these impacts are likely to vary regionally depending on the magnitude of the temperature change, how much change in an area required for the temperature to rise above freezing, the depth to surface area of the lakes and the local hydrology. A great difficulty in documenting change is the absence of long term monitoring in most of Antarctica.

28.2.2. Oceanography and Marine Ecosystems

28.2.2.1. Arctic

Climate change is expected to affect physical and chemical properties of Arctic marine ecosystems by: (1) increasing temperatures, (2) altering the timing and extent of sea ice retreat, (3) changing sea water density through increased freshwater supply, (4) reducing sea ice thickness and multi-year ice formation which in turn changes the timing and duration of irradiance in the water column, and (5) ocean acidification (WG 1 Chapters 4 and 11). This section addresses the expected impacts of these physical and chemical changes on marine ecosystems.

Retrospective studies show the Arctic and its neighboring seas are influenced by interannual, decadal, and multi-decadal climate variations (WG 1). These variations in climate forcing are expected to continue in the future (Overland and Wang, 2010) and will continue to influence the ocean conditions in the Arctic (Ogi *et al*. 2010). For example, recent (2007-2012) ocean conditions in the Bering Sea have been cold (Stabeno et al. 2012), while the Barents Sea has been warm (Lind and Ingvaldsen, 2012).

Observations and model predictions indicate that the carbon cycle of the Arctic Ocean will be impacted by climate change. The processes that influence the inorganic carbon cycle in the Arctic are complex and differ seasonally and regionally (Bates and Mathis, 2009). The mechanisms underlying ocean acidification and the expected rates of change in ocean pH caused by increased CO_2 are documented in WG I Chapter 6 and II Chapters 5, 6, 19 and 30. If some regions in the Arctic become understaturated with respect to aragonite (the primary structural component of the shells of some marine calcifiers such as pteropods (small planktonic shelled mollusks), urchins, and clams the growth and survial of these organismswill be impacted (WG I, Chapter 6 Figure 6.28; Chierici and Fransson, 2009; Fabry *et al*., 2009; Yamamoto-Kawai *et al*., 2009). Additional monitoring and process studies are needed to fully understand how these processes will unfold in the future.

28.2.2.1.1. Overview of Arctic marine plankton and fish

Two sources of primary production include spring and fall ice algal blooms and pelagic blooms in response to the solar cycle and stratification (Wassmann, 2011). Large phytoplankton blooms can develop underneath the ice with implications for energy partitioning between pelagic and benthic ecosystems (Perrette *et al*., 2011; Arrigo *et al*., 2012). With the onset of the Arctic summer, sea ice begins to melt and the water column stratifies. The upper mixed layer of the Arctic Ocean is nutrient-rich and the combination of increased light and nutrients triggers spring bloom (Hirche *et al*., 2006; Zhang *et al*., 2010).

Copepods (small pelagic crustaceans) dominate the mesozoplankton community in the Arctic, where they are preyed upon by larger invertebrate predators, fish, seabirds and marine mammals. Four species of the genus *Calanus* are common, but only two, *C. glacialis* and *C. hyperboreus*, are true Arctic species (Ji *et al*., 2012). The other two, *C. finmarchicus* and *C. marshallae*, are boreal ex-patriot species that are brought north in the Atlantic and Pacific water inflows, respectively. All four Calanus species feed on phytoplankton, accumulating lipid (wax-esters) during the growth season, and spending some part of the year dormant (in diapause) below the surface layers. All four have reproductive cycles that take advantage of the spring bloom in some way and while the boreal species have annual life cycles, the Arctic species take two or more years to mature and reproduce. Other important large-bodied copepods are *Neocalanus cristatus* and *N. flemingeri* in the Bering Sea, which have life histories and feeding preferences similar to those of the *Calanus* species, and *Metridia longa*, which is abundant throughout the deep waters of the eastern and central Arctic (Kosobokova and Hirche, 2009), and which is active all year round, feeding omnivorously. In the Bering and Barents Seas, a large fraction of the phytoplankton biomass is retained in the pelagic system by zooplankton grazing (Riser *et al*., 2008), while farther north in the Chukchi Sea low grazing pressure results in underutilization of early spring production which in turn leads to export of carbon on the seafloor where it feeds a productive benthic ecosystem (Grebmeier *et al*., 2006; Riser *et al*., 2008).

Euphausiids (krill) are not endemic to the Arctic, but are brought into the region in the Atlantic and Pacific inflows. In the Barents Sea, krill (mainly *Thysanoessa inermis* and *T. raschii*) provide an important food source for several species of fish, including cod, haddock and capelin (Ressler *et al*. 2012; Dalpadado *et al*., 2008; Orlova *et al*., 2009; Dalpadado *et al*. 2009). In the west, euphausiids are transported north through the Bering Strait towards the Beaufort Sea, where aggregations are consumed by bowhead whales off Point Barrow, Alaska (Berline *et al*., 2008).

The broad shelf regions of the Barents and Bering Seas support abundant and diverse fish and shellfish populations. Farther north, fewer fish species are adapted to the short growing season, the delay in the emergence of copepods and the cold ocean conditions. In general, dominant pelagic species are smaller sized fish capable of rapid growth in the first year of life (e.g. capelin, *Mallotus villosus*) and in some cases antifreeze proteins to tolerate cold temperatures (e.g. polar cod, *Boreogadus saida*). Examination of the biogeography of species shows that potentially interacting species partition their habitat vertically and horizontally in response to competition, predation and environmental disturbance (Spebcer, 2008; Mueter and Litzow, 2008). Habitats are bounded by topographic features, fronts, currents or river plumes, and oceanographic features left by sea ice (including salinity fronts) (Ciannelli and Bailey, 2005). Over time fish and invertebrates have evolved life histories to reduce exposure to predation, maximize the probability of temporal and spatial overlap with prey concentrations, and support successful mating (Sundby and Nakken, 2008; Hunt *et al*., 2011; Mundy, 2011; Bouchard and Fortier, 2011; Hollowed *et al*., 2012).

Phenological responses (timing of spawning, timing of settlement, duration of growing season, age at maturity)

Changes in ocean temperature, wind-driven upwelling of deep nutrient-rich waters, sea ice thickness, the date of ice breakup and stratification will alter the timing, duration and magnitude of phytoplankton production (Zhang *et al*., 2010). During the period 1997-2009 a trend towards earlier phytoplankton blooms was detected in approximately 11% of the area of the Arctic Ocean (Kahru *et al*., 2011). This advanced timing of annual phytoplankton blooms coincided with the decreased sea ice concentration in early summer (Kahru *et al*. 2011). Given the short time series and limited studies, there is *medium confidence* that climate change will alter the bloom timing and the duration of phytoplankton trophic production in the Arctic.

There is *medium confidence* based on theoretical relationships and observations that rapid changes in physical and chemical changes in ocean conditions will alter the timing and duration of phytoplankton production. If shifts in timing disrupt the match between copepod hatch dates and spring production this would impact the survival of zooplankton and timing of spring prey availability for their predators (Søreide *et al*., 2010). However, simulation modeling of the Arctic Ocean and its surrounding Seas, showed longer growth seasons and increased summer temperature in the central Arctic favored endemic copepods (*Calanus glacialis* and *Calanus hyperboreus*) (Ji *et al*., 2012). Results from the cruises conducted during the International Polar Year in 2007 and 2008 on the Canadian shelf and adjacent open ocean and the southeast Beaufort Sea, suggest that longer ice free periods in the Arctic could provide for more opportunities for episodic nutrient pulses that would enhance secondary production through the growing season (Tremblay *et al*., 2012). Additional research is needed to understand how climate change will impact seasonal survival of Arctic zooplankton.

There is *medium* to *high confidence* based on observations of fish responses at lower latitudes, that climate change impacts on the physical and chemical environment in the Arctic will cause changes in phenology of some fish and shellfish species in the Arctic marine ecosystems. Several studies document that climate shifts and associated changes in ocean conditions impact the growth, spawning and feeding distribution and of marine fish (Gjosaeter et al 2009; Drinkwater eta l. 2011). The responses of fish to shifts in the timing and duration of growing seasons will vary by species. Some species exhibit an ability to adjust the timing of spawning and rates of growth to local conditions (Ormseth and Norcross, 2009; Kristiansen *et al*., 2011) however, these adjustments occurred over long time periods. However, compared to temperate regions, there is a general lack of long-term phenological studies from the Arctic Ocean and additional observations are needed.

Observed spatial shifts in response to climate

Considerable geographic variation in primary production has been observed (Lee *et al*., 2010; Grebmeier, 2012). Simulation studies revealed that longer growing seasons resulting from climate change will be insufficient to allow expatriate species to become endemic species in the Arctic Ocean (Ji *et al*., 2012). In the Barents Sea, simulation modeling experiments showed that summer loss of sea ice and increased temperature would impact the decrease the production of *C. glacialis* and increase the production of *C. finmarchicus* (Slagstad *et al*. 2011). In the Arctic Ocean, the observational record is often short or of limited spatial scale (Slagstad *et al*., 2011). Additional observations are needed to accurately predict shifts in the range of Arctic and sub-Arctic copepods in response to climate change.

Climate-related changes in the flow of currents into the Arctic will likely change the abundance and distribution of euphausiids. In the Barents Sea, in years when greater intrusions of Atlantic water occurred, higher temperatures and higher levels of euphausiids were observed, with varying species composition (Zhukova *et al*., 2009).

Numerous studies from the Bering Sea, Barents Sea, west Greenland Sea, and Chukchi Sea confirm that fish shift their spatial distribution in response to climate variability (i.e. interannual, decadal or multi-decadal changes in ocean temperature; (Mueter and Litzow, 2008; Sundby and Nakken, 2008; Hátún *et al*., 2009; Valdimarsson *et al*., 2012). Retrospective analysis of the spatial distribution of demersal fish species in the North Atlantic shows redistribution of some species along latitudinal and depth gradients that are consistent with bio-climate envelope models (Simpson *et al*., 2011). However, responses to climate change may follow nonlinear responses in the future because multiple factors influence the spatial distribution and abundance of marine fish throughout its life cycle including: suitable habitat availability, fidelity to spawning locations, diet diversity, physiological responses, spatial temporal overlap with prey, prey density, and competition (Planque *et al*., 2010; Kristiansen *et al*., 2011; Sigler *et al*., 2011). Coupled bio-physical models have been developed to assess the implications of climate change on the spatial distribution and abundance of multiple life stages of several marine species in the Bering and Barents Seas (Huse, 2008; Parada *et al*., 2010). These models have been successful in reproducing the observed spatial dynamics of the target species and in some cases studies are underway to evaluate their predictive skill. Qualitative vulnerability assessments indicate that the persistence of cold winter conditions in the Arctic coupled with the life history factors noted above will restrict or retard the movement of several sub-arctic fish and shellfish species into the Arctic (Hunt Jr. *et al*., 2013; Hollowed *et al*., In Press). In summary, there is *medium* to *high confidence* based

on observations and modeling of fish responses in the Barents and Bering Seas to climate shifts, that climate change impacts on the spatial distribution and volume of suitable habitat will cause shifts in the spatial distribution of some fish and shellfish species in the Arctic marine ecosystems. The spatial extent of these shifts and the time frame for change will depend on the vulnerability of different species to climate change and the strength of the species response. Compared to temperate regions, there is a general lack of long-term comprehensive monitoring of the spatial distribution of fish and shellfish stocks in the high Arctic Ocean.

Observed variations in fish and shellfish production in response to climate

Satellite derived estimates of primary production provide evidence of a 20% increase in primary production in the Arctic Ocean between 1998 and 2009 in response to extended ice free periods (Arrigo *et al.*, 2011). Other studies showed gross primary production increased with increasing air temperature in the Arctic Basin and Eurasian shelves (Slagstad *et al.*, 2011). Studies based on a short, 5 year (2004-2008), time series in the Canadian Basin found that after the spring bloom, increased warming, increased stratification, and decreased nutrients during the Arctic summer may favor smaller phytoplankton over large phytoplankton (Li *et al.*, 2009; Morán *et al.*, 2010). Additional observations over a broader spatial scale are needed to confirm this relationship. Additional observations will also help to resolve observed differences between in-situ and satellite derived estimates of primary production (Matrai *et al.*, 2013). In summary, climate change is expected to extend the duration of the growing season and upwelling is expected to bring nutrients to the surface which would favor phytoplankton production, however, these factors may be offset later in the year by increased stratification and nutrient depletion in summer. Based on this information, there is *medium confidence* that primary production will increase in the Arctic in response to climate change impacts on the duration of ice free periods in the Arctic Ocean.

In the Bering Sea, Observations over the most recent decade in the southeast Bering Sea showed *C. marshallae* were more abundant in cold years than warm years (Coyle *et al.*, 2011). Based on this study there is *low confidence* that climate change will reduce the abundance of C. *marshallae* in the Bering Sea. Additional observations are needed to confirm this response.

Numerous studies have identified statistical links between climate variability and the annual production of zooplankton and fish (Mueter *et al.*, 2007; Drinkwater *et al.*, 2010). The mechanisms underlying these statistical linkages are often well documented for commercially important species (Bakun, 2010). The vulnerability of different fish and shellfish species to the direct and indirect effects of climate change is governed by the exposure of the species to changing environmental conditions and fishing throughout its life history and across its geographic range (Beaugrand and Kirby, 2010) and the ability of the species to adapt or acclimate to changing conditions (Pörtner and Peck, 2010; Donelson *et al.*, 2011). In the eastern Bering Sea and Barents Seas, large interdisciplinary research programs have identified the mechanisms underlying these statistical relationships which provided the foundation for climate change projections for selected species (discussed in section 28.3.2; Brander, 2010; Wiese *et al.*, 2012). Observations of the condition of age-0 pollock in the Bering Sea during the last decade showed condition improved in cold years suggesting that overwintering success was higher in years when *C. marshallae* were abundant (Hunt *et al.*, 2011). Retrospective studies of ocean conditions and interannual variations in walleye pollock recruitment to the fishery over three decades revealed a dome-shaped functional relationship between temperature and recruitment (Mueter *et al.*, 2011).

Other stressors

If the expected changes in summer sea ice occur as described by WG 1, opportunities for increased oil and mineral extraction, shipping, fishing and tourism are expected to occur in the region. These activities will increase the risk of introductions of alien species to the region and the risk of regional pollution.

The implications of ocean acidification on the food web can be considerable. If regions of the Arctic become understaturated with respect to aragonite, and this inhibits shell formation for pteropods, this will have strong consequences on their predators. At the current time it is not possible to fully predict the consequences because it is

unclear whether other species, with a similar nutritive value, will replace pteropods. Laboratory experiments showed a decline in the calcification of a pteropod (*Limacina helicina*) in the Arctic under projected ocean warming and acidification (Comeau *et al.*, 2010). Additional studies are needed to scale up regional impacts to assess the population level impact of ocean acidification on *Limacina helicina* and other vulnerable species (Orr *et al.*, 2009). The lack of systematic sampling over large areas of the Arctic and the paucity of experimental studies examining the response of marine organisms to multiple stressors impede the ability to project when and where waters will become understaturated in aragonite in the Arctic and the vulnerability of calcifying marine organisms to understaturated waters

28.2.2.1.2. Current changes in Arctic seabird populations

Upwelling or convergence areas found in frontal zones and eddies, and the marginal ice zone, are associated with high marine productivity important to Arctic seabirds (e.g. (Irons *et al.*, 2008). Long-term or permanent shifts in convergence areas and the marginal ice-edge zone induced by climate change may cause mismatch between the timing of breeding and the peak in food availability and, thus, potentially have strong negative impacts on seabird populations (Gremillet D. and Boulinier T., 2009).

Such spatial mismatch between prey base and breeding has been documented for a few seabird populations. The percentage of important prey in the diet of a declining black guillemot (*Cepphus grylle*) colony in the western Beaufort Sea was highly negatively correlated throughout the breeding season with changes in the distance to the ice edge which was the habitat of the prey (Moline *et al.*, 2008). Since 1990, breeding success and population size have been negatively correlated with summer pack-ice extent.

Even though timing of breeding advanced for Brünnichs guillemots (*Uria lomvia*) in a colony in the southernmost part of its range in Arctic Canada between 1988 and 2007, it did not advance sufficiently to match the advance in break up of sea ice which is associated with high prey availability. Less ice cover was correlated with lower chick growth rates and lower adult body mass, suggesting that reduction in summer ice extent had a negative effect on reproduction (Gaston *et al.*, 2005; Gaston *et al.*, 2009). Current trends suggest that continued warming should benefit birds breeding on the northern limit of the species range, while adversely affecting reproduction for those on the southern margin (Gaston *et al.*, 2009).

In contrast, (Byrd *et al.*, 2008) could not document any significant correlation between productivity of brünnichs guillemots and common guillemots (*Uria algae*) breeding on the Pribilof islands in the Bering Sea and changes in sea ice extent 1976-2006. Kittiwakes (*Rissa tridactyla and Rissa brevirostris*), however, breeding in colonies on the same islands, advanced their timing of breeding by half to almost one day per year and reduced their productivity in correlation with less sea ice and higher Sea Surface Temperatures (SSTs). In the North-Atlantic Svalbard islands, kittiwakes responded differently - by showing a non-significant trend for later egg-laying when SSTs increased and ice cover was reduced (Moe *et al.*, 2009).

The circumpolar populations of the two closely related common guillemot and Brünnichs guillemot declined when the SST shift was large and increased when the shift was small, although the effect differed between the Arctic-breeding species and the more temperate-breeding congener (Irons *et al.*, 2008). A major ecosystem shift in the Northern Bering Sea starting in the mid 1990tiescaused by increased temperatures and reduced sea ice cover had a negative impact on benthic prey for diving birds like eiders and these populations in the area have declined (Grebmeier *et al.*, 2006).

Karnovksy et al. (2010) projected changes in SST in the Greenland Sea at the end of the 21st century and concluded that 4 of 8 little auk (*Alle alle*) breeding colonies in the North Atlantic may be negatively impacted as temperatures exceed the thermal range suitable for their preferred prey, the large lipid-rich Arctic copepods *Calanus glacialis and C. hyperboreus*. Little auks in Svalbard also responded by advancing the date for egg-laying when SSTs increased and sea ice cover was reduced (Moe *et al.*, 2009).

The contrasting results from the relatively few studies of impacts of climate change on arctic seabirds, demonstrates that it is likely that future impacts will be highly variable between species and between populations of the same species. Retreating sea ice and increasing SSTs have favored some species and been a disadvantage to others. While phenological changes and changes in productivity of some breeding colonies related to climate changes have been observed, changes in population size or projected expansion of the northern range accompanied by a contraction of the southern range is not well documented (Gaston and Woo, 2008).

The coupled oceanographic models and ice models project a significant reduction in sea ice extent in this century and increasing SSTs in the Arctic (Wang and Overland, 2009). The high Arctic seabird species partly or completely dependent on the productivity of the sympagic ecosystem or the cold Arctic waters close to the ice-edge, like the ivory gull, Brünnichs guillemots and little auks, will with *high confidence* be negatively impacted if the projected changes in these physical parameters occur. A moderate retreat of the marginal ice-zone and earlier break-up of sea ice may improve foraging conditions for some of these sea bird populations in the northernmost part of their range (Gaston *et al*., 2005). The distance to suitable nesting localities could be too great (within 200 km) for the birds to utilize the marine productivity in the ice edge zone if a main part of the zone stays over the deep Arctic Ocean during the breeding season.

A general increase in SSTs and retreat of the ice cover will with *medium confidence* improve the environmental conditions and food abundance for sea bird species that have their range in the southern part of the Arctic or south of the Arctic. A poleward expansion of the range of these species is expected during a continued warming (ACIA 2005). Several other factors than climate influence on the dynamics of sea bird populations (Regular *et al*., 2010), however, and projections of future changes during a continued Arctic warming are therefore highly uncertain. Pattern of change will be non-uniform and highly complex (ACIA 2005). At present, the resolution of AOGCMs is not detailed enough to project spatial changes in mesoscale oceanographic features like frontal zones and eddies of importance to sea birds in the Arctic.

28.2.2.1.3. Polar bears

Both empirical and modelling studies have been used to understand the impacts of climate change on polar bears (*Ursus maritimus*) (Hunter *et al*., 2010; Amstrup *et al*., 2010; Durner *et al*., 2011). Empirical studies provide the most direct insight into the mechanisms of change but modelling allows improved predictive capacity.

Polar bears evolved from brown bears (*U. arctos*) and despite episodic admixture, the polar bears genome shows Arctic adaptations (Miller *et al*., 2012). Sea ice is the primary habitat of polar bears and is used for migration, mating, some maternity denning, and access to prey. Annual ice over the continental shelves is preferred due to high prey density (Durner *et al*., 2009). There is *high confidence* that the primary conservation concern for polar bears, over the foreseeable future or three generations (ca. 36-45 years), is the recent and projected loss of annual ice over continental shelves, decreased ice duration, and decreased ice thickness (Stirling and Derocher, 1993; Derocher *et al*., 2004; Stirling and Parkinson, 2006; Durner *et al*., 2009; Amstrup *et al*., 2010; Hunter *et al*., 2010; Rode *et al*., 2012; Sahanatien and Derocher, 2012).

Subpopulation response varies geographically reflecting differences in ice change. Only 2 of the 19 subpopulations, Western Hudson Bay (Regehr *et al*., 2007) and the Southern Beaufort Sea (Regehr *et al*., 2010; Rode *et al*., 2010a) have data series adequate for clear identification of abundance effects related to climate change. Other subpopulations lack adequate time series, but show characteristics associated with decline. For example, between 1977 and 2010, declining body condition in Baffin Bay and Davis Strait was associated with ice loss although high bear density was an alternate cause in the case of Davis Strait (Rode *et al*., 2012). Similarly, late arrival of ice at one Barents Sea denning area was associated with lower body mass of both mothers and their cubs (Derocher *et al*., 2011). There is *high confidence* that the primary conservation concern for polar bears is ice change that result in habitat loss and fragmentation causing reduced food intake, increased energy expenditure, and increased fasting (Stirling and Derocher, 1993; Stirling, I. *et al*. 1999; Mauritzen *et al*., 2003; Derocher *et al*., 2004; Regehr *et al*., 2007; Amstrup *et al*., 2010; Sahanatien and Derocher, 2012). There is *high confidence* for declining ice causing lower body condition that can reduce individual growth rates (Rode *et al*., 2010a; Rode *et al*., 2012) and *very high*

confidence that reduced body condition is a precursor to demographic change. Reduced body condition may result in lower fasting endurance, lower reproductive rates, and lower survival (Regehr *et al*., 2007; Regehr *et al*., 2010; Molnar *et al*., 2011) and these changes can reduce subpopulation growth rate or cause subpopulation decline (Derocher and Stirling, 1996; Derocher and Stirling, 1998; Stirling et. al., 1999; Regehr *et al*., 2010; Hunter *et al*., 2010; Rode *et al*., 2010a; Robinson *et al*., 2011). The Southern Beaufort Sea is projected to decline by 99% by 2100 with a probability estimated at 0.80-0.94 under A1B (Hunter *et al*., 2010). The Northern Beaufort Sea is currently stable although decline is predicted with warming (Stirling *et al*., 2011). There is *medium confidence* for subpopulation decline by 21% between 1987 and 2004 in Western Hudson Bay related to climate change (Regehr *et al*., 2007). Projected extirpation of approximately two-thirds of the world's polar bears was predicted for mid-century due to ice loss under A1B (Amstrup *et al*., 2008). Aspects of this study were criticized (Armstrong *et al*., 2008) but refuted (Amstrup *et al*., 2009). The two-thirds decline is consistent with other studies and has *robust evidence* with *medium agreement*. Projected extinction of polar bears has *low confidence*. There is *very high confidence* that subpopulation extirpation will occur with the projected climate change for the Arctic

Multiyear ice is used by some polar bears at maximal ice melt (Ferguson *et al*., 2010). Replacement of multiyear ice by annual ice could increase polar bear habitat (Derocher *et al*., 2004) but there is *low confidence* in habitat improvement. Increasing the distance to terrestrial refugia and multiyear ice at maximal melt may have negative consequences such as drowning, cub mortality, and high energetic costs (Monnett and Gleason, 2006; Durner *et al*., 2011; Pagano *et al*., 2012). Loss of multiyear ice may pose difficulties for some subpopulations although there is *limited evidence*.

There is *high confidence* in *robust evidence* of changes in sea ice conditions changing polar bear distribution (Fischbach *et al*., 2007; Schliebe *et al*., 2008; Gleason and Rode, 2009; Towns *et al*., 2010). Later formation and arrival of autumn ice at a Svalbard denning area reduced access to pregnant females (Derocher *et al*., 2011). Increased human-bear interactions were associated with distribution shifts and declines in body condition (Towns *et al*., 2009). There is *high confidence* that the number of human-bear interactions will increase with warming (Stirling and Derocher, 1993; Derocher *et al*., 2004; Stirling and Parkinson, 2006; Towns *et al*., 2009).

An increasingly terrestrial niche for polar bears was postulated (Dyck *et al*., 2007; Dyck and Romberg, 2007; Armstrong *et al*., 2008; Dyck *et al*., 2008; Dyck and Kebreab, 2009; Rockwell and Gormezano, 2009; Smith *et al*., 2010). However, such terrestrial feeding is not new (Lønø, 1970; Lunn and Stirling, 1985; Derocher *et al*., 1993; Derocher *et al*., 1993; Derocher *et al*., 2000). Assertions of an increased terrestrial niche for polar bears have been challenged because resources are inadequate to replace the high-energy content of marine prey (Derocher *et al*., 2004; Stirling *et al*., 2008b; Amstrup *et al*., 2009; Slater *et al*., 2010; Rode *et al*., 2010b). *Very low confidence* exists that polar bears can adapt to an increase in terrestrial foods. There is *very high confidence* that polar bears will not adapt to climate change in many subpopulations. Studies have also tentatively linked changing environmental conditions to cannibalism (Amstrup *et al*., 2006), altered feeding (Cherry *et al*., 2009), unusual hunting behaviour (Stirling *et al*., 2008a), and diet change (Iverson *et al*., 2006; Thiemann *et al*., 2008). There is *medium confidence* that these observations of polar bear may be related to changing ice conditions.

28.2.2.1.4. Arctic and subarctic marine mammals

Empirical studies on responses of Arctic and subarctic marine mammals to climate change are limited (Kelly, 2001; Laidre *et al*., 2008) . Understanding of climate change effects on marine mammals varies according to insight into their habitat requirements and trophic relationships. Many Arctic and subarctic marine mammals are highly specialized, have long-life spans, and are poorly adapted to rapid and directional environmental change (Moore and Huntington, 2008). Predicted changes, however, may not be evident until significant sea ice loss has occurred (Freitas *et al*., 2008; Laidre *et al*., 2008). Two Arctic ice-dependent seals (ringed seals, *Pusa hispida*, and bearded seals, *Erignathus barbatus*) and four ice-associated subarctic species (spotted seal, *Phoca largha*, ribbon seal, *P. fasciata*, harp seal, *Pagophilus groenlandicus*, and hooded seal, *Cystophora cristata*) use ice but none year-round (Lydersen and Kovacs, 1999). Similarly, walrus (*Odobenus rosmarus*) rely on ice for part of their life cycle but commonly retreat to land when ice is unavailable. Three cetaceans remain in the Arctic year-round (bowhead whale,

Balaena mysticetus, narwhal, *Monodon monoceros*, and beluga, *Delphinapterus leucas*) with narwhal the most ice-associated.

There is *high confidence* that climate change effects on Arctic and subarctic marine mammals will vary. Depending on life history characteristics, distribution, and habitat specificity, climate change will improve conditions for a few species, have minor negative effects for others, and some will suffer major negative effects (Ragen *et al.*, 2008; Laidre *et al.*, 2008). Resilience to climate change will vary and some ice-obligate species should survive in regions with sufficient ice and some may adapt to ice-free conditions (Moore and Huntington, 2008). Moore and Huntington (2008) suggest that less ice-dependent species may be more adaptable and could benefit from a longer feeding period but an increase in seasonally migrant species could increase resource competition.

Arctic and subarctic marine mammal vulnerability to climate change was associated with feeding specialization, ice dependence, and ice reliance for prey access and predator avoidance (Laidre *et al.*, 2008). There is *medium agreement* on which species' life histories are most susceptible to climate change. Hooded seals and narwhal were identified as most at risk and ringed seals and bearded seals as least sensitive (Laidre *et al.*, 2008). Kovacs *et al.* (2010) shared concern for hooded seals and narwhal but had serious concerns for ringed seals and bearded seals. Physiological specialization by narwhal suggests they may have limited ability to respond to habitat alteration (Laidre and Heide-Jørgensen, 2005); Williams *et al.* 2011). Species that spend only part of the year in the Arctic, such as the gray whale (*Eschrichtius robustus*) and killer whale (*Orcinus orca*) may benefit from reduced ice cover due to increases in prey availability (Moore, 2008; Laidre *et al.*, 2008; Higdon and Ferguson, 2009; Matthews *et al.*, 2011; Ferguson *et al.*, 2012). Expansion of killer whales into the Arctic could cause a trophic cascade with the polar bear-seal predator-prey linkage replaced with killer whales as the top predator (Higdon and Ferguson, 2009) although there is *limited evidence* at this time.

There is *limited evidence* although *moderate agreement* that generalists and pelagic feeding species may benefit from increased marine productivity resulting from reduced ice while benthic feeding ice-dependent species near continental shelf habitats may do poorly (Bluhm and Gradinger, 2008). There is *limited evidence* but *high agreement* that dietary or habitat specialists such as walrus will do poorly with reduced ice Changes in ice dynamics can cause walrus calves to become separated from their mothers during rapid ice retreat and may effect recruitment (Cooper *et al.*, 2006). Reduction of summer/autumn ice was identified as the primary extrinsic factor affecting Pacific walrus with predictions of distribution changes and longer-term predictions of high extinction probability (Maccracken, 2012). Retreat of summer ice was suggested to make migration to such habitats energetically unprofitable for ringed seals (Freitas *et al.*, 2008). Further, loss of ice in the Baltic Sea was identified as the primary threat to the Baltic ringed seal (Kovacs and Lydersen, 2008). Earlier break-up in the eastern Beaufort Sea had negative impacts on ringed seal pup growth and condition, and possibly on pup survival (Harwood *et al.*, 2000). Similarly, in Hudson Bay, earlier spring break-up and changes in snow cover over lairs used for reproduction has reduced ringed seal recruitment in recent years (Ferguson *et al.*, 2005). Further, changes in snowfall over the 21st century were projected to reduce the area of ice with sufficient snow for ringed seal lairs by 70% (Hezel *et al.*, 2012). Similarly, harp seal breeding habitat was affected by reduced ice duration and shifts in reproductive habitats, and an increase in the frequency of poor ice years could reduce survival of young (Bajzak *et al.*, 2011). While there is *limited evidence*, there are concerns that climate change may cause indirect effects on Arctic marine mammals' health (e.g., pathogen transmission, food web changes, toxic chemical exposure, shipping, and development) (Burek *et al.*, 2008).

There is *high confidence*that the effects on Arctic and subarctic marine mammals will vary spatially and temporally, with some populations affected earlier than others and thereby making trends and effects difficult to detect (Kelly, 2001; Laidre *et al.*, 2008). There is *high agreement* that many Arctic and subarctic ice-associated marine mammals will be affected by ice loss with altered species distributions, migration patterns, behaviour, interspecific interactions, demography, population declines, and vulnerability to extinction but there is *limited evidence* of changes for most species.

28.2.2.2. Antarctic

28.2.2.2.1. Vulnerability and change

Evidence is accumulating to conclude that the distributions of Southern Ocean pelagic species (phytoplankton and zooplankton) have moved south with the frontal systems (Hinz, Poulton et al. 2012; Mackey, Atkinson et al. 2012). This is also confirmed by observed range expansion into the Southern Ocean from the north by the coccolithophorid, Emiliania huxleyii (Cubillos, Wright et al. 2007), and the red-tide dinoflagellate Noctiluca scintillans (McLeod, Hallegraeff et al. 2012).

The observed occurrence of lithodid crabs on the continental shelf of the west Antarctic Peninsula (WAP) has been attributed to movement south of warmer waters (Smith, Grange et al. 2012). These crabs will potentially impact the structure and diversity of benthic assemblages because of their ability to crush echinoderms and other taxa along with their bioturbating behaviour. However, direct evidence of the invasion of these crabs or the magnitude of impacts that they may have in the region has yet to be observed. There is no evidence to date of climate change impacts on the distributions of cold-adapted fish, although this remains a valid expectation for many species (Constable et al., submitted).

Physiological responses will vary among polar organisms (Constable et al., submitted) but an important response of many biota will be to ocean acidification (Byrne 2011). Shell thickness in foraminifera in the Southern Ocean are thinner than in the Holocene and there is evidence of a relationship between shell thickness and atmospheric CO2, supporting the hypothesis that ocean acidification will affect this abundant protozoan in the Southern Ocean (Moy, Howard et al. 2009). Recent studies of arogonite-shelled pteropods indicate that they are vulnerable to the effects acidification (Comeau, Alliouane et al. 2012; Comeau, Gattuso et al. 2012) and that shells are thinner from sediment traps in aragonite under-saturated water (below the aragonite saturation horizon - ASH) compared to those captured above the ASH in Subantarctic waters (Roberts, D. et al. 2011). However, the absence of time-series of samples related to change in the depth of the ASH and aragonite saturation generally makes it difficult to conclude how shell composition will be affected by changes to oceanic aragonite saturation (Roberts, D. et al. 2011). There is evidence that shell dissolution has already been observed in surface waters in the Atlantic sector as a result of both upwelling and atmosperhic changes in CO2 (Bednarsek, Tarling et al. 2012). Other impacts of acidification on Southern Ocean organisms are currently uncertain, but short term negative impacts need to considered together with an organism's capacity to adapt in the longer term (Watson, Peck et al. 2012).

Collapse of ice shelves may alter the dynamics of benthic assemblages by opening up areas previously covered by ice shelves and allowing increased primary production as well as colonisation and establishment of new assemblages, such as occurred with the collapse of the Larson A/B ice shelves (Peck, Barnes et al. 2009; Gutt, Barratt et al. 2011). Increased production of icebergs may increase the number of grounded icebergs causing changes in local oceanography and declines in productivity that consequently affects productivity of benthic assemblages (Thrush and Cummings 2011), or they may result in increased scour on shallow banks, disrupting resident benthic assemblages (Barnes and Souster 2011; Gutt, Barratt et al. 2011).

28.2.2.2.2. Productivity and krill

Primary production is expected to be changing regionally in the Antarctic in response to changes in sea ice, glacial melt and oceanography (Arrigo, van Dijken et al. 2008; Boyd, Arrigo et al. 2012). To date, the most compelling results of the effects of change in the physical environment on primary production and microbial assemblages is from the west Antarctic Peninsula region where (Montes-Hugo et al., 2009) reported decreased phytoplankton stocks and productivity (based on time-series of satellite-derived and measured chlorophyll concentrations) north of 63°S i.e., around the Antarctic Peninsula, and increases in these properties to the south of 63°S (see WGII Chapter 6 for discussion). They also indicated a change from diatom-dominated assemblages to ones dominated by smaller phytoplankton.

Densities of Antarctic krill have been estimated to have declined by approximately 30% in the Scotia Sea since the 1980s (Atkinson, Siegel et al. 2004), in parallel with declines in the extent and season duration of winter sea ice in the region (see (Flores, Atkinson et al. 2012) for review). The degree to which the overall abundance of krill has declined is still a matter of conjecture because the results are based on densities measured using different nets and different times, with results often biased downwards, particularly in krill swarms (Nicol and Brierley 2010). However, the observed dependence of Antarctic krill on the annual extent of winter sea ice (Nicol, Worby et al. 2008) indicates strong grounds for concern that the krill population in this key area where 70% of the population is found (Atkinson, Siegel et al. 2009) may have already changed and will be subject to further change.

Analyses of krill population dynamics suggest that changes in recruitment of post-larval krill across the Scotia Sea are linked to variations in surface temperature and sea-ice extent. Recent simulation modelling of krill productivity and dynamics show the plausibility of the positive relationship between sea ice extent and recruitment of krill in the Antarctic Peninsula region (Wiedenmann, Cresswell et al. 2009). However, such a decline may be offset by increased productivity arising from increased water temperature in that area (Wiedenmann, Cresswell et al. 2008). That said, the latter study also showed that krill productivity may decline in the South Georgia area as a result of the increased metabolic costs of increasing temperatures. The combined effects of changing sea ice, temperature and food have not been investigated.

Recently, krill have been discovered to be sensitive to ocean acidification. Experiments have shown that krill larval development (Kawaguchi, Kurihara et al. 2011) and post-larval krill metabolic physiology (Saba, Schofield et al. 2012) may be impeded by elevated CO2 concentrations.

28.2.2.2.3. Food web effects

The switch from a krill-based food web to a copepod- and fish-based food web in times of low abundance of krill in around subantarctic islands in the southwest Atlantic suggests that the latter may become more dominant around these islands in the future (Trathan, Forcada et al. 2007; Shreeve, Collins et al. 2009; Waluda, Collins et al. 2010). Also, salps have been postulated to be competitors with krill for phytoplankton around the Antarctic Peninsula when oceanic conditions displace shelf and near-shelf waters during times of low sea ice (Ducklow, Clarke et al. 2012). The trophic efficiency of these longer food webs in the absence of krill is less (Murphy, J. et al. 2013) and the long-term implications of this for higher trophic levels are unknown.

The changes in the physical habitat to the west of the Antarctic Peninsula (WAP), including the movement south of the sea ice extent, are believed to be resulting in a shift of the krill-dominated food web (krill, Adélie penguins and ice-breeding seals) to higher latitudes (Forcada, Trathan et al. 2012) and the replacement of this food web at lower latitudes with one composed of species that that do not depend on sea ice and are more able to exploit a range of prey items, for example gentoo penguins and elephant seals (Costa, Huckstadt et al. 2010; Trivelpiece, Hinke et al. 2011; Ducklow, Clarke et al. 2012; Murphy, Watkins et al. 2012b). The mechanisms driving these changes are currently under review and may be more complex than a simple association with sea ice (Lynch, Naveen et al. 2012; Melbourne-Thomas, Constable et al. 2013). This shift may be accompanied by an overall decline in the productivity of the WAP shelf (Montes-Hugo, Doney et al. 2009), although this may be tempered by increased inputs of iron through changes to ocean processes in the region (Dinniman et al., 2012).

28.2.2.2.4. Marine mammals and birds

The response of marine mammals, penguins and flying birds will be a complex response to a number of direct and indirect effects and may result either increasing or decreasing abundance depending on the regional effects of climate change on their habitats and food. In general, many Southern Ocean seals, penguins and flying birds are exhibiting strong responses to a variety of climate indices, with many, but not all, species showing a negative response to warmer conditions (Barbraud *et al.*, 2012; Forcada *et al.*, 2012). Adelie and chinstrap penguins have been declining in the north of the Antarctic Peninsula (Lynch *et al.*, 2012) while gentoo penguins are increasing in that region. In contrast, Adelie penguins may be increasing in east Antarctica (Constable *et al.*, submitted). There is

increasing evidence that emperor penguins may be declining throughout the Antarctic (Barbraud *et al.*, 2008; Jenouvrier *et al.*, 2009; Trathan *et al.*, 2011). Declines in seal and seabird populations in the subantarctic of the Indian sector of the Southern Ocean have been interpreted as a region-wide shift to a system with lower productivity (Weimerskirch *et al.*, 2003; Jenouvrier *et al.*, 2005a; Jenouvrier *et al.*, 2005b).

Direct effects on penguins include changes in location and conditions of foraging habitats as a result of shifting ocean conditions and sea ice extent near to breeding colonies, as well as increased precipitation in the colonies. Some of these responses may be dependent on local populations or colonies (Lynch *et al.*, 2012; Barbraud *et al.*, 2012) or may be regional differences. For example, Adelie and emperor penguins are postulated to have dome-shaped relationships between their demographic success and sea ice extent (see (Barbraud *et al.*, 2012) for review) rather than a simple monotonic relationship but the nature of such a relationship remains to be determined. A contributing factor to the reduction in Adélie penguins may be increased snow precipitation which accumulates in the breeding colonies and, when accompanied by reduced food supply, can decreases survival of chicks (Chapman *et al.*, 2011).

Movement south of the frontal systems, and therefore movement of productive foraging areas, in the Indian sector have been attributed to causing declines in King penguin colonies on subantarctic islands in that sector(Peron *et al.*, 2010), while the shift in wind patterns may be causing changes to the demography of albatross(Weimerskirch *et al.*, 2012).

As identified in the last assessment, change in some species may be a result of incidental mortality in fisheries or recovery from past over-exploitation, both of which may confound interpretation of the response of these species and their food webs to climate change. The recovery of Antarctic fur seals has been well documented. More recently, there has been confirmation of some Antarctic whale populations recovering, such as humpback whales(Nicol *et al.*, 2008; Zerbini *et al.*, 2010), suggesting that food is currently not limiting. In contrast, albatross and petrel colonies are declining as a result of incidental mortality in longline fisheries in southern and temperate waters where these birds forage (Croxall *et al.*, 2012).

28.2.3. Terrestrial Ecosystems

Arctic terrestrial ecosystems have undergone dramatic changes throughout the late Pleistocene and Holocene (last 130 000 years) mainly driven by natural climate change. Significant altitudinal and latitudinal advances and retreats in tree line have been common, animal species have gone extinct, and animal populations have fluctuated significantly throughout this period e.g. (Lorenzen *et al.*, 2011; Salonen *et al.*, 2011; Mamet and Kershaw, 2012).

28.2.3.1. Phenological Responses

Phenological responses attributable to warming are apparent in Arctic terrestrial ecosystems (*medium confidence*). Compared to temperate regions, there is a general lack of long-term phenological studies from the Arctic. Phenological responses to warming vary from little overall trend in the Swedish sub Arctic (Molau *et al.*, 2005), despite accelerated recent warming (Callaghan *et al.*, 2010), to dramatic earlier onset of plant reproductive phenophases of up to 48 days in west Greenland (Post *et al.*, 2009a; Callaghan *et al.*, 2011a). Other substantial changes include earlier clutch initiation dates in birds and earlier emergence of arthropods in northeast Greenland (Figure 28-2) (Høye *et al.*, 2007).

[INSERT FIGURE 28-2 HERE
Figure 28-2: Advancement of phenological events in high-Arctic Greenland. a) location of the study area Zackenberg, North-east Greenland. b) Temporal change in onset of flowering (plants), median date of emergence (arthropods) and clutch initation dates (birds). Red dots are statistically significant, blue dots are not (Høye et al., 2007).]

28.2.3.2. Observed Changes in Tundra Vegetation

The abundance and biomass of deciduous shrubs and graminoids (grasses and grass-like plants) have increased substantially over large – but not all – parts of the Arctic tundra in recent years (*very high confidence*). Most of this increase in deciduous shrubs can be attributed to Arctic warming (*very likely*), but in some parts of northwest Eurasia a portion of the graminoid increase seems tied to steadily intensifying reindeer grazing/trampling coupled with large-scale hydrocarbon extraction in recent decades(Forbes and Stammler, 2009; Kumpula *et al.*, 2011; Kumpula *et al.*, 2012) .

Recent assessments of changes in NDVI (Nomrlaized Difference vegetation Index, a proxy for plant productivity) from satellite observations between 1982 and 2010 show a substantial greening over large parts of the Pan-Arctic (Zhang *et al.*, 2008; Bhatt *et al.*, 2010; Walker *et al.*, 2011; Xu et al. 2013) (Figure 28-3) with the greatest increases in the North American high Arctic and along the Beaufort Sea, and in northern Canada (Pouliot et al. 2009). In contrast, decreases in NDVI were generally observed in South-western Alaska and easternmost Russia and occurred locally in the western Russian Arctic.
However, the east European Arctic (Nenets Autonomous Okrug) registers a significant increase in NDVI during this same time period (Macias-Fauria *et al.*,2012 ; Raynolds *et al.*, 2008; Bhatt *et al.*, 2010; Forbes *et al.*, 2010; Xu et al. 2013).

[INSERT FIGURE 28-3 HERE
Figure 28-3: Significant changes ($p < 0:05$) in aboveground tundra phytomass from 1982 to 2010 (Epstein et al. 2012).]

The positive trends (1982-2010) in NDVI are associated with increases in the summer warmth index (sum of the monthly-mean temperatures above freezing expressed as ºC per month) that have increased on average by 5ºC per month for the Arctic as a whole(Xu et al. 2013). However, the even greater 10 to 12ºC per month increase for the land adjacent to the Chukchi and Bering Seas (Figure 28-3) was associated with decreases in NDVI, indicating that other factors than increased warming also affect NDVI and plant growth. On the Yamal Peninsula in Russia the pattern of NDVI is partly due to surface disturbance, such as landslide activity particularly in the central and northern portions (Walker *et al.*, 2009). Small rodent cycles reduce NDVI in sub Arctic Sweden, by decreasing biomass and changing plant species composition (Olofsson *et al.*, 2012). This indicates that the changing NDVI signal should be interpreted with care in general. Increases in land surface temperatures and NDVI in some areas have been related to earlier retreat of coastal sea ice in early summer (Bhatt *et al.*, 2010), but the relationship between sea ice and NDVI is restricted to early spring in northwest Eurasia (Macias-Fauria et al. 2012).

Since IPCC AR4, increasing evidence from studies that range in scale from landscape to experimental plots, shows that one of the greatest vegetation changes is the areal expansion, in-filling (densification) and increased growth of woody plants (trees and shrubs) (Myers-Smith *et al.*, 2011a; Callaghan *et al.*, 2011b; Elmendorf *et al.*, 2012 aand b) Observations extend back 100 years but most evidence comes from changes that have occurred over approximately the past 20 years.. Shrubs have generally expanded their ranges (Myers-Smith *et al.*, 2011a; Callaghan *et al.*, 2011b; Elmendorf *et al.*, 2012b) and/or growth for example in Alaska (Tape et al. 2001; Sturm et al. 2006), the Yukon region of Canada (Myers-Smith *et al.*, 2011a), southeast Yukon (Danby and Hik, 2007), the Canadian high Arctic (Hudson and Henry, 2009; Hill and Henry, 2011), the Swedish sub Arctic (Hallinger *et al.*, 2010; Rundqvist *et al.*, 2011; Hedenås *et al.*, 2011), and the northwestern Russian Arctic(Macias-Fauria *et al.*,2012 ; Forbes *et al.*, 2010). Changes in growth of shrubs have varied from dramatic, i.e. 200% area increase in study plots (Rundqvist *et al.*, 2011) in sub arctic Sweden to early invasion of a fell field community on west Greenland plots by low shrubs (Callaghan *et al.*, 2011a). Structural changes within the tundra zone can result when low erect shrubs (e.g. *Salix*, *Alnus* spp.) increase significantly in height *in situ*. There is strong evidence that this has occurred in the past in Beringia (Edwards *et al.*, 2005) and is in progress now in the northwestern Russian Arctic (Macias-Fauria *et al.*, 2012).

Changes in species diversity could not be detected in the long-term study from Ellesmere Island in Canada (Hudson and Henry, 2009; Hill and Henry, 2011). However, other multi-decadal studies (see references in Callaghan and Tweedie, 2011) show small changes in plant community composition at sites in Canada, Greenland and Sweden that

indicate responses to warming and drying. Furthermore, aspen tree invasion has been recorded at a sub Arctic tree line (Van Bogaert *et al*., 2010).

Snow bed habitats have decreased in sub arctic Sweden (Björk and Molau, 2007; Hedenås *et al*., 2011). In other plant communities, changes have been less dramatic, ranging from small increases in species richness in the south west Yukon of the Canadian sub Arctic (Danby *et al*., 2011), through subtle changes in plant community composition in west and southeast Greenland (Daniëls and De Molenaar, 2011; Callaghan *et al*., 2011a) to 70 year stability of a plant community on Svalbard (Prach *et al*., 2010).

Early experimental studies projected that mosses and lichens would be disadvantaged by climate warming (Cornelissen *et al*., 2001; Van Wijk *et al*., 2004). Lang et al. (2012) showed that Arctic warming on two continents had consistent negative effects on lichen diversity and mixed effects on bryophyte diversity and Tømmervik et al. (2009) documented a significant decrease in lichens in northern Norway in the period 1957-2000 and a slight increase again in the period 2000-2006. Hudson and Henry (2009) reported significant increases in bryophyte biomass between 1981 and 2008 on Ellesmere Island. In contrast, moss communities on Iceland were stable during experimental summer warming and growth (Jonsdottir et al. 2005) and photosynthetic activity of a bryophyte was significantly reduced by simulation of acute mid-winter warming events in a sub-Arctic heath (Bjerke *et al*., 2011). Although significant recovery of lichens has been recorded recently in Finnmarksvidda (Tømmervik *et al*., 2012), Forbes and Kumpula (2009) recorded long-term and widespread lichen degradation in northern Finland attributed more to trampling of dry lichens by reindeer in summer than winter consumption as forage. Lichens, unlike bryophytes, were unaffected by extreme warm events in winter in the sub Arctic (Bjerke *et al*., 2011).

A meta-analysis (11 sites: (Walker *et al*., 2006) and a synthesis (61 sites: (Elmendorf *et al*., 2012a) of experimental warming studies of up to 20 years duration in tundra sites worldwide, showed, overall, increased growth of deciduous shrubs and graminoids, decreased cover of mosses and lichens, and decreased species diversity and evenness. Elmendorf et al. (2012a) point out that the groups that increased most in abundance under simulated warming were graminoids in cold regions and primarily shrubs in warm regions of the tundra. However, strong heterogeneity in responses to the experimental warming suggested that other factors could moderate the effects of climate warming significantly like herbivory, differences in soil nutrients and pH, precipitation, winter temperatures and snow cover, and species composition and density. Intersite comparisons indicated an association between the degree of summer warming and change in vascular plant abundance, with shrubs, forbs and rushes increasing with warming. However, the association was dependent on the climate zone, the moisture regime and the presence of permafrost.

28.2.3.3. Changes in Tree Line

Palaeorecords of vegetation change indicate that the northern tree line should extend upwards and northwards during current climate warming (IPCC FAR) because tree line is related to summer warmth (e.g. (Harsch *et al*., 2009). Although the tree line has moved northwards and upwards in many Arctic areas, there is *high confidence* that the tree line has not shown a general circumpolar expansion in recent decades. The existing evidence suggests varying patterns of re-location resulting from several co-occurring drivers.

An expansion of the tree line as a response to warming has been observed in many areas e.g. (Chapin III, 2005; Lloyd, 2005; Shiyatov *et al*., 2007; Kullman and Öberg, 2009) but in some areas, the location of the tree line has not changed or has changed very slowly (Masek, 2001; Holtmeier *et al*., 2003; Payette, 2007; MacDonald *et al*., 2008). A global study by Harsch et al. (2009) showed that only 52% of all 166 global tree line sites had advanced over the past 100 years. In many cases the tree line has even retreated (Vlassova, 2002; Dalen and Hofgaard, 2005; Kullman, 2005; Cherosov *et al*., 2010).

This diversity of response is also seen at the small scale. Within one area undergoing the same degree of climate warming (sub arctic Sweden and Siberian taiga), the tree line has shown increase, decrease and stability in neighboring locations (Van Bogaert *et al*., 2011; Lloyd *et al*., 2011). These variable responses clash with process-

based understanding in model projections and relate to local drivers of change that interact with or negate direct effects of climate warming (see below).

Model projections that suggest a displacement of between 11 and 50% of tundra by forest by 2100 (see references in Callaghan et al 2005) and shifts upslope by 2 to 6 m per year (Moen *et al*., 2004) and northwards by 7.4–20 km per year (Kaplan and New, 2006) might be overestimating rate of tree line advance by a factor of up to 2000 (Van Bogaert *et al*., 2011). The fastest upslope shifts of tree lines recorded during 20th century warming are in the range of 1 to 2 m year (Shiyatov *et al*., 2007; Kullman and Öberg, 2009) whereas the fastest so-far recorded northward-migrating tree line replaces tundra by taiga at a rate of 3–10 m year (Kharuk *et al*., 2006).

Evidence for densification of the forest at the sub Arctic tree line is robust and consistent within Fennoscandia (Tømmervik *et al*., 2009; Rundqvist *et al*., 2011; Hedenås *et al*., 2011) and Canada (Danby and Hik, 2007). Dendroecological studies indicated enhanced conifer recruitment during the twentieth century in the northern part of the Siberian taiga (Briffa *et al*., 2008) and tree growth was well correlated with warm summer temperature (Macdonald *et al*., 2008; Lloyd *et al*., 2011; MacDonald et al. 2008). Some of the changes are dramatic, such as an increase in area of mountain birch in study plots in northern Sweden by 600% between 1977/8 and 2009/10 (Rundqvist *et al*., 2011) and a doubling of tree biomass in Finnmarksvidda in northern Norway since 1957 (Tømmervik *et al*., 2009). Also, in at least one location, a tree species not present in 1977 has invaded the tree line (Van Bogaert *et al*., 2010; Rundqvist *et al*., 2011). However, model projections of displacement of deciduous forest by evergreen forest (Wolf *et al*., 2008; Wramneby *et al*., 2010) have not so far been validated.

Even where the mountain birch tree line has increased in elevation and shrub (e.g. willow, dwarf birch) abundance has increased, the response can be an interaction between climate warming, herbivory pressure and earlier land use (Olofsson *et al*., 2009; Hofgaard *et al*., 2010; Van Bogaert *et al*., 2011). There is evidence from Fennoscandia and Greenland that heavy grazing by large herbivores may significantly check deciduous low erect shrub (e.g. dwarf birch) growth (Post *et al*., 2008; Kitti *et al*., 2009; Olofsson *et al*., 2009). However, in cases where tall willow shrubs are already above the reindeer browse line of ≈1.8 m, their transformation into tree size individuals is likely to track warming temperatures rather than grazing intensity (Macias-Fauria *et al*.,2012 ; Forbes *et al*., 2010).

Climate warming might also have negative impacts on northern forests where growth is largely made possible by moisture supplied from melting of the winter snowpack (Yarie, 2008). In most of the boreal forest region, temperature increases have made the snow-accumulation season shorter, particularly in spring, and the warm season longer(Callaghan *et al*., 2011c), so that less of the annual water budget is from the spring pulse of snowmelt. Less moisture from snow and more rain now favors broadleaf trees over conifers and mosses in some areas (Juday, 2009) while moisture deficits are reducing the growth of some northern forests (Goetz *et al*., 2005; Verbyla, 2008) and making them more susceptible to insect pest outbreaks (see references in (Callaghan *et al*., 2011c)). Death of trees through drought stress or insect pest activity will increase the probability of fire that will have positive feedbacks on the climate from reduced carbon dioxide uptake, increased carbon dioxide loss from soils and decreased albedo as in tundra fires (Mack et al., 2011). There is evidence that recent warming in combination with snow anomalies has caused increased drought stress and insect damage to northern forests (see references in Callaghan et al. 2011c).

28.2.3.4. Changes in Animal Population Cycles

High-amplitude population cycles of herbivores like lemmings, voles, snowshoe hares and forest Lepidoptera (caterpillars of moths and butterflies) are characteristic processes of tundra and boreal forest ecosystems, influencing considerably the dynamics of vegetation and other animal populations in these ecosystems (Rydgren *et al*., 2007; Ims *et al*., 2007; Berg *et al*., 2008; Gilg *et al*., 2009; Krebs, 2011; Olofsson *et al*., 2012; Kausrud et al. 2009;).

The documented collapse or dampening of population cycles of voles and lemmings over the last 20-30 years in parts of Fennoscandia and Greenland (Scmidt et al. 2012), can be attributed with *high confidence* to climate change (Ims *et al*., 2007; Gilg *et al*., 2009; Ims *et al*., 2011; Kausrud et al. 2009). A shortening of the snow season and more thaw and/or rain events during the winter season have the potential to increase overall mortality and decrease winter reproduction because snow hardness increases and influence on the subnivean space which provides thermal

insulation, access to food, and protection from predators to high latitude rodents (Berg *et al*., 2008; Johansson *et al*., 2011; Kausrud et al. 2009).However, the causes of the changes in the lemming and vole cycles are still being debated as other factors than climate change may also be of importance(Brommer *et al*., 2010; Krebs, 2011).

Both the boreal forest and the mountain birch forest of Fennoscandia are regularly subject to large-scale tree mortality from insect outbreaks. Climate-mediated range expansion both in altitude and latitude of insect pests, and increased survival due to higher winter temperatures, has been documented for bark beetles in North America (Robertson *et al*., 2009; ACIA 2005) and for geometrid moths in Fennoscandia (Jepsen *et al*., 2008; Callaghan *et al*., 2010; Jepsen *et al*., 2011), causing more extensive forest damage than before. Outbreaks of insect pests like geometrid moths may even be of a magnitude that reduces the strengths of CO_2 sinks in some areas (Heliasz *et al*., 2011).

The latitudinal and altitudinal expansion of the range of the red fox (*Vulpes vulpes*) into the tundra and alpine areas is likely to be a response to warming which has strengthened interspecific competition with the much smaller arctic fox (*Alopex lagopus*) and most likely has contributed to the decline of this species and its population cycles in many Arctic regions (Fuglei and Ims, 2008; Henden *et al*., 2010; Killengren et al. 2007).

28.2.3.5. Changes in Reindeer and Muskox Populations

The decline in wild reindeer and caribou (both *Rangifer tarandus*) populations in certain regions of about 30 percent over the last 10-15 years have been linked both to climate warming and anthropogenic landscape changes (Post et al. 2009; Vors and Boyce 2009; Russell and Gunn 2010). Even though most of the Arctic has warmed, the decline in the populations has not been uniform. Some of the North American large herds have for example declined by 75-90 percent, while other wild herds there and semi-domestic herds in Fennoscandia and Russia have been stable or even increased (Gunn et al. 2009; Vors and Boyce 2009; Joly et al. 2011; Forbes et al. 2009; Forbes 2010; Kumpula et al. 2012).

A trophic mismatch causing increased calf mortality and drop in female productivity has been documented when timing of parturition in a population of caribou in Greenland did not keep pace with advancement of the plant-growing season and peak forage availability and quality caused by a warmer climate (Post and Forchhammer, 2008; Post *et al*., 2009a; Post *et al*., 2009b). It is suggested that similar warming-induced trophic mismatches have a role in the decline of circumpolar reindeer and caribou populations (Post et al. 2009a). This trophical mismatch has, however, been disputed as well as their extension of their study in Greenland to circumpolar populations (Griffith *et al*., 2010).

The increased primary productivity of Arctic tundra (see above) may potentially increase the supply of food for Arctic ungulates, although new biomass already above the browse would be inaccessible and therefore superfluous (Forbes *et al*., 2010). The overall quality of forage may decline during warming, for example if the nitrogen content of key fodder species for ungulates were to drop during warming (Turunen *et al*., 2009; Heggberget et al. 2010). As mentioned above, there are indications that lichen biomass, and important winter fodder for reindeer, is decreasing over much of the Arctic region. Arctic lichens have been shown experimentally to be vulnerable to icing events (Bjerke *et al*., 2011). Herbivory also changes the vegetation itself in concert with the warming, further complicating the prediction of vegetation changes on the ungulate populations (van Der Wal *et al*., 2007; Turunen *et al*., 2009).

More frequent icing events and thicker snow-packs caused by warmer winters and increased precipitation may restrict access to vegetation and have profound negative influences on the population dynamics of Arctic ungulates (Berg *et al*., 2008; Forchhammer *et al*., 2008; Miller and Barry, 2009; Stien *et al*., 2010; Hansen *et al*., 2011; Stien et al. 2012). Behavioural plasticity may partly buffer such icing events (Hansen et al. 2010). In contrast, warmer winters were shown to enhance the abundance of reindeer in a population in Svalbard because access to vegetation became easier (Tyler *et al*., 2008), and ice on the grazing areas was not the main reason in 31 declines of 12 different reindeer and caribou populations (Tyler, 2010). Over the period 1970 to 2006, reindeer calf production in Finland increased by almost one calf per 100 females for each day of earlier snow melt (Turunen *et al*., 2009). More frequent icing events have caused heavy mortality in domestic reindeer herds (Forbes et al. 2009) and some of the herders in Yamal in Siberia have lost as much as 25% of the herds in one winter season due to icing (Bartsch et al.

2010). Despite this, the indigenous Nenets inhabiting the area, stressed hydrocarbon development as the main long-term threat to their existence (Forbes and Stammler 2009; Forbes et al. 2009; Kumpula et al. 2012).

28.2.3.6. Long-Term Trends and Event-Driven Changes in Ecosystems

Changes in vegetation and animal populations are driven relatively slowly by long-term climate change but tipping points may be reached quickly by events such as extreme weather, fire, insect pest and disease outbreaks. While the impacts of winter thaw events are well-documented for animals (see above), the severe impacts of tundra fires on vegetation and biospheric feedbacks have been described only recently (Mack *et al*., 2011). Similarly, experimental and observational determinations of the impacts of extreme winter thaw events on plants, soil arthropods and ecosystem processes have become evident since IPCC 2007 (e.g.(Bokhorst *et al*., 2011)). For example, results from experimental thaws during winter were validated by a natural thaw in northern Norway and Sweden in 2007 that reduced NDVI by almost 30% over an area of at least 1400 km^2 (Bokhorst *et al*., 2009). Studies on relationships between climate change and plant disease are almost totally lacking but a new study demonstrated the effect of increased snow accumulation on a higher incidence of fungal growth on sub Arctic vegetation (Olofsson *et al*., 2011).

28.2.3.7. Antarctic Terrestrial Systems

Climate change will impact Antarctic terrestrial habitats in all three biogeographic regions through changes in air temperature, wind speed, precipitation (rain and snowfall), permafrost and exposure of new habitat through glacial/ice retreat. There are no documented trends in changing surface areas of different habitats or in the exposure of new habitat, a major gap in this assessment.

Few robust studies of biological responses to observed climatic changes in natural Antarctic terrestrial ecosystems are available. Most attention has been given to rapid population expansion and local-scale colonisation by the two native flowering plants (*Deschampsia antarctica* and *Colobanthus quitensis*) in the maritime Antarctic (Parnikoza *et al*., 2009; Convey *et al*., 2011), which remains the only published repeat long-term monitoring study of any terrestrial vegetation or location in Antarctica. Radiocarbon techniques are now also demonstrating long-term biological effects of Antarctic climate change on moss beds (Clarke *et al*., 2012). One important aspect underlying these changes is thought to be that air temperatures have increased past the critical temperature at which successful sexual reproduction (seed set) can now take place, changing both the dominant mode of reproduction, and increasing the potential distance for dispersal. Similar changes in the local distribution and development of typical cryptogamic vegetation of this region have been reported (Convey, 2011), including the rapid colonisation of ice free ground made available through glacial retreat and reduction in extent or previously permanent snow cover (Olech and Chwedorzewska, 2011). As these vegetation changes creates new habitat, there are concurrent changes in the local distribution and abundance of the invertebrate fauna that then colonises them. Such hypotheses remain to be confirmed through the establishment of robust baseline survey and monitoring studies (Convey, 2006; Convey, 2010), which are now an urgent priority (Wall *et al*., 2011). A critical part of such studies will be to link well-described large-scale climatic trends with that of microclimates experienced by terrestrial biota at much smaller and relevant physical scales (Turner *et al*., 2009).

28.2.4. Human Populations

Although humans have been present in the Arctic for thousands of years, Antarctica has no permanent human settlements; instead, only temporary residents who are either visiting scientists or staff at research facilities. Therefore, this Human Populations Section assesses the risks and impacts of Arctic warming on the diverse human communities across the Arctic where people have been addressing change for centuries. While it is recognized that several large industrial Arctic cities in Russia and elsewhere have serious climate change-related challenges, this section focuses on indigenous, isolated, and rural populations because they are especially vulnerable to climate change due to their dependence on the environment for food, culture, transportation, security, and ultimate survival;

their political and economic marginalization; and existing social, health, poverty, and other disparities. (Larsen *et al*., 2010; [AR5 12.3]) In addition, a large amount of literature documenting the impacts of climate change on the health and well-being of Arctic indigenous residents has been published since the last report.

The warming Arctic and the significant changes in the cryosphere are impacting residents across the region through a complex set of physical, environmental, cultural, economic, political, and socio-cultural factors operating on and within Arctic communities, which have important implications for the health and well-being of all Arctic populations. These influences are expected to vary significantly among the highly diverse communities which range from small, remote, predominantly indigenous to large northern, industrial settlements. (Larsen and Fondahl, 2010) It is estimated that there are between 4 and 9 million people living in the Arctic depending upon geographic delineation of Arctic which includes original residents (indigenous peoples) as well as a broad spectrum of more recent settlers ranging from subsistence hunters to oil industry personnel to urban office workers, scientists, military, and tourists. (Hovelsrud *et al*., 2011) Approximately two-thirds of Arctic people live in relatively large settlements of over 5,000 residents, the other one-third is scattered in small and often very remote, isolated communities. (Bogoyavlensky and Siggner, 2004; Larsen and Fondahl, 2010) During the past century, the composition of Arctic communities and settlements has been shifting dramatically due to seasonal and permanent immigration into the Arctic driven by the development of resources such as oil and gas, fishing, and mineral resources or the necessity to escape problems in homelands outside the Arctic, including some population declines from 2000 to 2005, especially in Russia. (Hovelsrud et al, 2011)

Climate change and globalization, environmental contamination, resource development, plus the new activities and residents competing for lands and resources traditionally used by Indigenous peoples, are especially impacting the Indigenous populations of the North and are projected to increase in the future. (Abryutina, 2009; Larsen *et al*., 2010). The estimated indigenous populations in the Arctic are between 400,000 and 1.3 million. (Hovelsrud et al, 2011) Approximate numbers of Indigenous residents are: Canada, 66,000; Denmark, Greenland, 50,000; Norway, Sweden, and Finland, 50,000; Russia, 90,000; and USA, 110,000 (Galloway McLean, 2010) The percent of the populations of indigenous peoples in the Arctic range from 3-4 % in Russia to 80% in Greenland. (Galloway McLean, 2010) Indigenous peoples have been sustained by the region's terrestrial, marine and freshwater renewable resources, including mammals, birds, reindeer, fish and plants for sustenance, cultural, religious, economic, medicinal, and community health for many generations. (Nuttall *et al*., 2005; Parkinson, 2009) However, the ability of Indigenous peoples to maintain traditional livelihoods such as hunting, harvesting, fishing, and herding is increasingly being threatened by climate change and associated multiple stressors.

Human health and well-being may be defined as the mental, physical, spiritual, and social well-being plus the absence of disease and infirmity, and includes cultural and social practices as critical contributing factors. (Larsen and Huskey, 2010) To fully understand the potential for projected impacts of climate change on the health and well-being of the diverse communities in the Arctic, it is necessary to take into account a complex suite of underlying interconnected factors including not only additional stressors such as contaminants like POPs (persistent organic pollutants), radioactivity, and heavy metals such as mercury, but also the complicated social, cultural, political, and economic forces operating in these communities such as persistent poverty and lack of health and other services. (Abryutina, 2009; Ford and Furgal, 2009; Larsen and Huskey, 2010; AMAP, 2009; UNEP/AMAP, 2011) Climate change alone is not always the most important factor determining vulnerability in polar communities, but it can be a force that exacerbates other stresses. (Ford *et al*., 2010) A significant amount of research has been carried out on the health and well-being of Arctic indigenous populations and, therefore, this section emphasizes both the direct and indirect impacts of climate changes on these more vulnerable segments of the population.

28.2.4.1. Direct Impacts of a Changing Climate on the Health of Arctic Residents

Direct impacts of climate changes on the health of Arctic residents include extreme weather events, rapidly changing weather conditions, and increasingly unsafe hunting conditions (physical/mental injuries, death, disease), temperature-related stress (limits of human survival in thermal environment, cold injuries, cold-related diseases), and UV-B radiation (immunosuppression, skin cancer, non-Hodgkin's lymphoma, cataracts). (IPCC Special Report: Managing Risk of Extreme Events, 2012; AMAP, 2009) Intense precipitation events and rapid snowmelt are

expected to impact the magnitude and frequency of slumping and active layer detachment resulting in rock falls, debris flow, and avalanches. (Kokelj *et al*., 2009; Ford *et al*., 2010) Other impacts from weather, extreme events, and natural disasters are the possibility of increasingly unpredictable, long duration and/or rapid onset of extreme weather events and storms, which, in turn, may create risks to safe travel or subsistence activities, loss of access to critical supplies and services to rural or isolated communities (e.g., food, fuel, telecommunications), and risk of being trapped outside one's own community. (Laidre *et al*., 2008; Brubaker *et al*., 2011b). Changing river and sea ice conditions affect the safety of travel for indigenous populations especially, and inhibit access to critical hunting, herding and fishing areas. (Andrachuk and Pearce, 2010; Derksen *et al*., 2012) For example, reductions in land-fast ice plus increased open water area cause less predictable fog and sea-ice conditions, creating treacherous coastal travel conditions and more difficult communications among communities. (Barber *et al*., 2008)

Cold exposure has been shown to increase the frequency of certain injuries (e.g. hypothermia, frostbite) or accidents, and diseases (respiratory, circulatory, cardiovascular, musculoskeletal skin). (Revich and Shaposhmikov, 2010) Studies in Northern Russia have indicated an association between low temperatures and social stress and cases of cardiomyopathy, a weakening of the heart muscle or change in heart muscle structure. (Revich and Shaposhnikov, 2010) It is estimated that 2,000 to 3,000 deaths/yr occur from cold-related injury and diseases during the cold season in Finland. Respiratory diseases among children in Northern Russia are 1.5 to 2 times greater than the national average. It is expected that winter warming in the Arctic will reduce winter mortality rates, primarily through a reduction in respiratory and cardiovascular deaths (Shaposhnikov *et al*., 2010). It is also believed that a reduction in cold-related injuries may occur, assuming that the standard for protection against the cold is not reduced (including individual behavior-related factors) (Nayha, 2005). Conversely, some Arctic residents are reporting respiratory and cardio stress associated with extreme warm summer days which has not previously been experienced. (Revich and Shaposhnikov, 2010).

28.2.4.2. Indirect Impacts of Climate Change on the Health of Arctic Residents

Indirect effects of climate change on the health of Arctic residents include a complex set of impacts such as changes in animal and plant populations (species responses, infectious diseases), changes in the physical environment (ice and snow, permafrost), diet (food yields, availability of country food), the built environment (sanitation infrastructure, water supply system, waste systems, building structures), drinking water access, contaminants (local, long-range transported), and coastal issues (harmful algal blooms, erosion). (Maynard and Conway, 2007; Brubaker *et al*., 2011a; Parkinson and Evengard, 2009). Local and traditional knowledge in communities across the Arctic are observing extremes not previously experienced and increasingly unusual environmental conditions (e.g., (Laidler *et al*., 2009; Ignatowski and Rosales, 2012)). There also appears to be an increase in injuries related to climate changes among residents of northern communities associated with 'strange' or different environmental conditions, such as earlier break-up and thinning of sea ice. (Ford and Pearce, 2010) These climate-driven disruptions in the physical environment are increasingly being shown to cause a variety of serious mental and psychological conditions in many Arctic communities, particularly in vulnerable, already disadvantaged populations. (AR5 Chapter 11; Portier et al, 2010; USARC, 2010)

Underlying all climate change impacts and processes, are the complicated impacts from contaminants such as POPs (persistent organic pollutants), radioactivity, and heavy metals (e.g., mercury) which create additional and/or synergistic impacts on the overall health and well-being of the communities. (UNEP/AMAP, 2011) Contaminants and human health in the Arctic are tightly linked to the climate and Arctic ecosystems by factors such as contaminant cycling and climate (increased transport to and from the Arctic), exposure to contaminants, the risk of infectious diseases in Arctic organisms, and the related increased risks of transmission to residents through subsistence life ways, especially indigenous peoples. (AMAP, 2010; UNEP/AMAP 2011) The consumption of traditional foods by indigenous peoples places these populations at the top of the Arctic food chain and through biomagnification, therefore, they may receive some of the highest exposures in the world to certain contaminants. (UNEP/AMAP, 2011) These contaminants such as POPs are known for their adverse neurological and medical effects on humans, particularly, the developing fetus, children, women of reproductive age and the elderly. Thus, contaminants must be a significant part of any climate impact assessment as their potential health effects include

serious conditions such as nervous system and brain development problems, interference with hormones and sexual development, weakened immune systems, organ damage, cardiovascular disease and cancer. (UNEP/AMAP, 2011)

There are additional concerns regarding radioactivity and climate change because contamination can remain for long periods of time in soils and some vegetation, and because the terrestrial environment can create high exposures for people. (AMAP, 2010) Furthermore, climate changes not only have the ability to mobilize radionuclides throughout the Arctic environment, but can also potentially impact infrastructure associated with nuclear activities by changes in permafrost, precipitation, erosion, and extreme weather events. (AMAP, 2010) Additionally, there is a very high density of potential and existing radionuclide sources in some parts of the Russian Arctic and the risk for accidents is a significant cause for concern. (AMAP, 2010)

Warming temperatures are enabling increased overwintering survival and distribution of new insects that sting and bite as well as many bird and insect species that can serve as disease vectors and, in turn, causing an increase in human exposure to new and emerging infectious diseases. (Parkinson *et al*., 2008; Epstein and Ferber, 2011). Examples of new and emerging diseases are tick-borne encephalitis (brain infection) in Russia and Canada (Ogden *et al*., 2010; Tokarevich *et al*., 2011) and Sweden (Lindgren and Gustafson, 2001), *Giardia* spp. and *Cryptosporidium* spp. infection of ringed seals (*Phoca hispida*) and bowhead whales (*Balaena mysticetus*) in the Arctic Ocean. (Hughes-Hanks *et al*., 2005) It is also expected that temperature increases will increase the incidence of zoonotic diseases that can be transmitted to humans. (Revich *et al*., 2012) Many Arctic zoonotic diseases which currently exist in local host species (e.g., tularemia in rabbits, muskrats and beaver, and rabies in foxes) can spread through climate-related mechanisms such as relocation of animal populations. (Revich et al, 2012;)

Harmful algal blooms (HABs), are increasing globally and are known to be influenced directly by climate change related factors such as temperature, winds, currents, nutrients and runoff. (Portier *et al*., 2010) These HABs contain biotoxins with significant neurotoxic effects and can be a serious health hazard to humans or animals (paralysis, death) when the toxin is ingested through seafood, direct contact, or sea spray aerosols. (Portier *et al*., 2010; Epstein and Ferber, 2011). Increasing ocean temperatures have caused an outbreak of a cholera-like disease, Vibrio parahaemolyticusin, in Alaskan oysters (McLaughlin *et al*., 2005). Finally, there are concerns that the warmer temperatures may raise the possibility of anthrax exposure in Siberia from permafrost thawing of historic cattle burial grounds. (Revich and Podolnaya, 2011)

The impacts of climate change on food security and basic nutrition are critical to human health because subsistence foods from the local environment provide Arctic residents, especially, indigenous peoples, with unique cultural and economic benefits necessary to well-being and contribute a significant proportion of daily requirements of nutrition, vitamins and essential elements to the diet (Ford and Berrang-Ford, 2009; Ford, 2009). However, climate change is already posing an important threat to food security and safety for indigenous peoples and the availability of country food because of the impacts on traditional subsistence hunting, fishing and herding. (Ford *et al*., 2010) The decrease in predictability of weather patterns as well as low water levels and streams, timing of snow, ice extent and stability are impacting the possibilities for successful hunting, fishing and access to food sources and increasing the probability of accidents. (Ford and Furgal, 2009) Populations of marine and land mammals, fish and water fowl are also being reduced or displaced by changing temperatures, ice state, habitats and migration patterns reducing the traditional food supply. (Gearheard *et al*., 2006; West and Hovelsrud, 2010)

Furthermore, traditional food preservation methods such as drying of fish and meat, fermentation, and ice cellar storage are being compromised by warming temperatures, thus reducing food available to the community. (Brubaker *et al*., 2011b) For example, food contamination problems are becoming important wherever thawing of permafrost "ice cellars" is occurring for communities and families and increasingly wet conditions make it harder to dry food for storage. (Hovelsrud *et al*., 2011) These reductions in the availability of traditional foods plus general globalization pressures are forcing indigenous communities to increasingly depend upon expensive, non-traditional and often less healthy western foods, increasing the rates of modern diseases associated with processed food, such as cardiovascular diseases, diabetes, dental cavities, and obesity. (Berrang-Ford *et al*., 2011; Brubaker *et al*., 2011b) A complicating factor in evaluating trade-offs between traditional and market food is that wild foods – especially those at the top of the food chain - represent the most significant source of exposure to environmental contaminants. (AMAP, 2011)

Climate change is beginning to threaten community and public health infrastructure, often in communities with no central water supply and treatment sources. This is especially serious in low-lying coastal Arctic communities (e.g., Shishmaref, Alaska, USA; Tuktoyaktuk, Northwest Territories, Canada) through increased river and coastal flooding and erosion, increased drought and thawing of permafrost, resulting in loss of reservoirs, damage to landfill sites, or sewage contamination. (GAO, 2009) Salt-water intrusion and bacterial contamination may also be threatening community water supplies. (Parkinson *et al.*, 2008; Virginia and Yalowitz, 2012) Quantities of water available for drinking, basic hygiene, and cooking are becoming limited due to damaged infrastructure, drought, and changes in hydrology. (Virginia and Yalowitz, 2012) Disease incidence caused by contact with human waste may increase when flooding and damaged infrastructure such as sewage lagoons or inadequate hygiene, spreads sewage in villages where the majority of homes have lower water availability because of no in-house piped water source. This, in turn, can result in higher rates of hospitalization for pneumonia, influenza, and respiratory viral infections. (Parkinson and Evengard, 2009) This suggests that reduced water availability because of climate change impacts may result in increase rates of hospitalization among children for respiratory infections, pneumonia, and skin infection.(Parkinson *et al.*, 2008; Virginia and Yalowitz, 2012)

Finally, it is now well-documented that the many climate-related impacts on Arctic communities are causing significant psychological and mental distress and anxiety among the residents. (Portier *et al.*, 2010; Coyle and Susteren, 2012; AR5 Chapter 11; Levintova, 2010) The changes in the physical environment which threaten certain communities (e.g., through thawing permafrost and erosion) and which may lead to forced or voluntary relocation of residents or changes or declines in resources resulting in reduced access to subsistence species are often a pathway to rapid and long-term cultural change including loss of traditions. (Galloway-MacLean, K., 2010) These types of losses are, in turn, causing mental health impacts among indigenous and other vulnerable, isolated populations. (Curtis *et al.*, 2005; Albrecht *et al.*, 2007; Coyle and Susteren, 2012) Psychological impacts are especially acute for individuals and communities who feel intimately connected with the environment and those experiencing cumulative effects from repeated impacts such as natural disasters and extreme weather. (Portier *et al.*, 2010; AR5) A specific psychological condition called “solastalgia”- a strong feeling of loss and dislocation when people feel that changes to their environment are harmful - is becoming more common globally. (Albrecht *et al.*, 2007; Portier *et al.*, 2010) Special concern has been expressed by many communities concerning the unusually high and increasing numbers of suicides in the Arctic especially among indigenous youth, and efforts are under way to try to develop a thorough assessment as well as establish effective intervention efforts. (Albrecht *et al.*, 2007; Portier *et al.*, 2010; USARC, 2010)

28.2.5. Economic Sectors

Economic activity takes place in both of the Polar Regions. In the Arctic, economic sectors are confronted with multiple stressors of which climate change is just one (Larsen, 2010; Forbes, 2011; Hovelsrud *et al.*, 2011).

The Arctic economy consists of a combination of formal and informal sectors. Formal and market-based economic activity is projected to have both costs and benefits, with some commercial activities becoming more profitable while others will face decline. Outside of the urban areas indigenous and non-indigenous peoples often mix activities of the formal sector (e.g. commercial fish harvesting, oil and mineral resource extraction, forestry, and tourism) with traditional or subsistence activities, which include harvesting a variety of natural renewable resources to provide for human consumption. Hunting and herding, and fishing for subsistence, as well as commercial fishing, all play an important role in the mixed cash-subsistence economies (Nuttall *et al.*, 2005; Poppel and Kruse, 2009; Larsen and Huskey, 2010; Crate *et al.*, 2010; Poppel 2006; Aslaksen et al 2009). Significant impacts on the ability of key subsistence marine and terrestrial species are being observed and are expected to continue as climate continues to change, and the ability to maintain one’s economic well-being may be affected. In the early 1990s – initially in western Canada, and later elsewhere - indigenous communities started reporting climate change impacts (Berkes and Armitage, 2010). According to some herders, whalers and walrus hunters non-predictable conditions resulting from more frequent occurrence of unusual weather events are the main effect of recent warming (Forbes and Stammler, 2009; Ignatowski and Rosales, 2012; Forbes et al. 2009; www.Aksik.org).

In the Antarctic, economic activities include fisheries and tourism. Commercial mining activity does not take place in Antarctica, and fisheries remain the only large-scale resource exploitation activity.

28.2.5.1. Arctic

28.2.5.1.1. Agriculture and forestry

Climate change is very likely to have positive impacts for agriculture, including extended growing season, although variations across regions are expected (Hovelsrud *et al.*, 2011). Tree limits in Iceland, for example, are now found at higher latitudes than before, and the productivity of many plants has increased (Björnsson et al, 2011). Climate change is likely to have economic costs and benefits for forestry (e.g. Aaheim, et al. 2009). The accessibility to logging sites is (an already observed) concern for the forestry industry. There is an observed vulnerability of forestry to changes that affect the condition of roads and thus accessibility during thawing periods (Keskitalo, 2008). Grain production in Iceland has increased in the last two decades, and work on soil conservation and forestry has benefited from warming (Björnsson et al, 2011). Agricultural opportunities in the Arctic are likely to expand because of a warmer climate, but are likely to remain of minor importance to the Arctic economy (Eskeland and Flottorp 2006). In areas with a reduction in snow cover, the growing season may be extended (Grønlund, 2009; Falloon and Betts, 2009; Tholstrup and Rasmussen 2009).

Climate change is very likely to have costs and benefits for agriculture and forestry (*high confidence*).

28.2.5.1.2. Open water fisheries

The impacts of climate change will occur within the context of other anthropogenic activities including commercial fishing. Fish stocks have been exploited for centuries in the polar region (Geffen *et al.*, 2011). Commercial fisheries in the polar region of the northern hemisphere are sharply divided between regions of high yield and commercial value such as the southern Bering Sea, Baffin Bay, the east and west Greenland Seas, the Iceland Shelf Sea, the deep Norwegian/Greenland Sea, and the Barents Seas and low volume subsistence fisheries in the coastal regions of the Arctic Ocean (Figure 28-4).

[INSERT FIGURE 28-4 HERE
Figure 28-4: Fishing vessel activity. Source: AMSA, _____.]

In high yield regions, complex management strategies have been developed to build sustainable fisheries and rebuild overfished stocks (Froese and Proelß, 2010; Hollowed *et al.*, 2011; Livingston *et al.*, 2011). The performance of these strategies relative to the goal of preventing overfishing and rebuilding overfished stocks differs by region for a variety of reasons including: data quality, enforcement, management policies and strategies for community based management (Worm *et al.*, 2009; Hutchings *et al.*, 2010; Gutierrez *et al.*, 2011). Sustainable fishing practices are expected to continue in the future and may improve as managers strive to implement an ecosystem approach to management and overfished stocks are expected to rebuild (*medium confidence*). Successful spatial management of shared resources under shifting ocean conditions will require an understanding of the mechanisms underlying observed range shifts (Hannesson, 2013).

The relative absence of commercial fishing activity in the Arctic Ocean results from a combination of environmental policy, the abundance of the resource and infrastructure for capturing and processing fish. The remote location, difficulties in accessing fishing grounds especially during winter, and relatively low stock sizes all serve as deterrents to the development of commercial activities in the Arctic Ocean. In the Beaufort Sea, some evidence of range extensions of commercial species including Pacific cod and walleye pollock were observed in the Beaufort Sea (Rand, 2011). However, in the U.S. portion of the Chukchi Sea and Beaufort Sea, a recent analysis showed only three species were found in sufficient densities to support a modest commercial fishery: snow crab (*Chionoecetes opillio*), Polar cod (*Boreogadus saida*) and saffron cod (*Elegins gracilis*) (Stram and Evans, 2009; Wilson, 2009).

28.2.5.1.3. Freshwater fisheries

Several Arctic coastal fishes are targeted for subsistence and commercial use in the Arctic including: chum salmon (*Oncorhynchus keta*), Dolly varden (*Salvelinus malma*), Arctic char (*Salvelinus alpinus*), Arctic grayling (*Thymallus arcticus*) lease cisco (*Coregonus sardinella*) and Arctic cisco (*Coregonus autumnalis*). Commercial transactions from fishing are typically for local markets (Reist *et al*., 2006). The survival of Arctic coastal fishes depends on a complex suite of environmental conditions (Reist *et al*., 2006). Recent studies show that factors that influence the marine exit are critical for survival of salmon and cisco (Moulton et al. 2010; Mundy, 2011). Climate change related factors that influence the water level and freshening of rivers will influence run size of these species (Fechhelm et al 2007).

28.2.5.1.4. Marine transportation in the Arctic Ocean

Climate change is expected to lead to an increasingly ice free Arctic Ocean and increased navigability of Arctic marine waters. This is expected to bring economic opportunities to northern, more remote regions (e.g. (Prowse *et al*., 2009) Peters et al. 2011). New possibilities for shipping routes and extended use of existing routes may result from increased melting of sea ice (Paxian *et al*., 2010; Corbett *et al*., 2010; Khon *et al*., 2010; Peters et al., 2011). Observations and climate models indicate that in the period between 1979-1988 and 1998-2007 the number of days with ice free conditions (less than 15% ice concentration) increased by 22 days along the Northern Sea Route (NSR) in the Russian Arctic, and by 19 days in the North-West Passage (NWP) in the Canadian Arctic, while the average duration of the navigation season in the period 1980-1999 was 45 and 35 days, respectively (Mokhow and Khon, 2008).The increased shipping associated with the opening of the NSR will lead to increased resource extraction on land and in the sea, and with two-way commodity flows between the Atlantic and Pacific The frequency of marine transportation along the NSR is at its highest during the most productive and vulnerable season of natural resources, which is the late spring/summer. In this period, vulnerable natural resources are spread throughout the NSR area in the Arctic (Østreng 2006), which may negatively affect the future status of marine, terrestrial and freshwater biota since there will be substantial coastal infrastructure to facilitate offshore developments (Meschtyb, N., Forbes, B., Kankaanpää,P., 2010). Coastal terrestrial and freshwater habitats are especially critical for maintaining the large reindeer herds managed by indigenous Nenets along the Barents and Kara seashores and the loss of access to these pastures and fishing lakes and rivers would likely have knock-on effects throughout the region (Kumpula *et al*., 2011; Forbes et al. 2009). Thus, the combined actual and potential socio-economic and social-ecological footprint of commercial shipping is likely to be significant (e.g. (Mikkelsen and Langhelle, 2008)). In the case of Svalbard, oil spills on have increased due to the growth in activities related to tourism and research. Dangers of a cruise ship or cargo ship running a ground and with subsequent oil spillage is the biggest environmental risk connected to marine transportation at Svalbard (NorAcia 2010). Peters et al. (2011) find by using a bottom-up shipping model and a detailed global energy market model to construct emission inventories of Arctic shipping and petroleum activities in 2030 and 2050, that based on estimated sea-ice extent: there will be rapid growth in transit shipping; oil and gas production will be moving into locations requiring more ship transport; and this will lead to rapid growth in emissions from oil and gas transport by ship.

Increased economic opportunities along with challenges associated with culture, security and environment, are expected in Northern Canada with increased navigability of Arctic marine waters together with expansion of land- and fresh water-based transportation networks (Furgal C., 2008). Based on a study using four water level scenarios, a base case with only seasonal and annual variation in water levels and three climate change scenarios, results suggest that Great Lakes rivers will be impacted by climate change affecting both shipping and nonindigenous species due to expected lower water levels, shorter times of ice cover, and higher surface water temperatures (Millerd, 2007). An increase in the length of the summer shipping season, with sea-ice duration expected to be 10 days shorter by 2020 and 20-30 days shorter by 2080, is likely to be the most obvious impact of changing climate on Arctic marine transportation (Prowse *et al*., 2009). The reduction in sea ice and increased marine traffic could offer opportunities for economic diversification in new service sectors supporting marine shipping. These possibilities however also come with challenges including their predicted contribution to the largest change in contaminant movement into or within the Arctic, as well as their significant negative impacts on the traditional ways of life of

northern residents (Furgal C., 2008). Added shipping and economic activity will increase the amount of black carbon and reinforce warming trends in the region (Lack and Corbett 2012, Levitsky 2011), leading to additional economic activity. (Lack, D. A.; Corbett, J. J., 2012).

28.2.5.1.5. Infrastructure

Much of the physical infrastructure and the hunting activities in the Arctic rely on and are adapted to local sea-ice conditions, permafrost, snow and the seasonal and behavioral patterns of the harvested fish and animals, which will be affected by the changing sea-ice condition, rendering them especially climate sensitive (Huntington *et al*., 2007; Sundby and Nakken, 2008; West and Hovelsrud, 2010; Forbes, 2011) Martin et al. 2009; Sherman et al., 2009). Damage from ice action and flooding to installations such as bridges, pipelines, drilling platforms, and hydropower poses major economic costs and risks, which are more closely linked to the design lifetime of the structure than with thawing permafrost. Still, current engineering practices are designed to help minimize the impacts (Prowse *et al*., 2009). Climatic and other large-scale changes have potentially large effects on Arctic communities, where relatively simple economies (depending heavily on resource extraction and subsidies) leave a narrower range of adaptive choices (Anisimov and Vaughan, 2007; Ford and Furgal, 2009; Andrachuk and Pearce, 2010; Ford *et al*., 2010; Forbes, 2011; Berkes et al 2003).

In Northern Canada climate warming presents an additional challenge for northern development and infrastructure design. While the impacts of climate change become increasingly significant over the longer time scales, in the short term of greater significance will be the impacts associated with ground disturbance and construction (Prowse *et al*., 2009); Smith and Risebrough 2010).

28.2.5.1.6. Resource exploration

The Arctic has large reserves of minerals (Lindholt, 2006; Peters et al. 2011) and potentially large reserves of undiscovered sources of raw materials, and oil and gas. About one-fifth of the world's undiscovered oil and gas reserves are located within the Arctic region (Gautier *et al*., 2009). While oil and gas production has declined in some fields, there have been new discoveries in others (AMAP, 2010). Due to high costs and difficult access conditions, and despite future reductions in sea-ice, it is not clear that future oil and gas production in the Arctic will increase (Peters et al., 2011). Predicted new access to offshore energy resources is hypothesized to be a significant share of the global supply of oil and gas (Gautier *et al*., 2009; Berkman and Royal United Services Institute for Defence and Security Studies., 2010).The socio-economic impacts on the Arctic region and local communities of oil and gas exploration activity can be positive or negative (Duhaime *et al*., 2004; Huntington *et al*., 2007; Forbes, 2008; Kumpula *et al*., 2011)Forbes et al. 2009). Arctic resources will *likely* play a growing role in the world economy. At the same time, increased accessibility is expected to create challenges for extraction, transport, engineering, search-and-rescue needs and responses to accidents (Hovelsrud *et al*., 2011). Increased emissions due to rapid growth in Arctic Ocean transportation of oil and gas are projected (Peters et al. 2011).

About 50% of oil and gas production in the Arctic is oil; in Canada (59%), Alaska (87%), East Russia (9%), West Russia (46%), and in Norway (84%) (Peters et al., 2011). Projected declines in sea-ice covers leading to development of integrated land and marine transportation networks in Northern Canada, may stimulate further mine exploration and development (Prowse *et al*., 2009). Reduced sea ice extent is projected to lead to increased Arctic shipping of oil and gas with projections of increased future emissions of short-lived pollutants, ozone pre-cursors, and long-lived greenhouse gases (Peters et al., 2011)

28.2.5.1.7. Informal, subsistence-based economy

Inuit and Saami have expressed strong concern about how a rapidly warming climate will affect their livelihoods (Forbes and Stammler, 2009). For Inuit, the issues revolve around sea ice conditions, such as later freeze-up in autumn, earlier melt-out and faster sea ice retreat in spring, and thinner, less predictable ice in general (Krupnik and

Jolly, 2002). Diminished sea ice translates into more difficult access for hunting marine mammals, and greater risk for the long-term viability of polar bear populations (Laidre *et al.*, 2008). Most Inuit communities depend to some extent on marine mammals for nutritional and cultural reasons, and many benefit economically from polar bear and narwhal hunting. A reduction in these resources represents a potentially significant economic loss (Hovelsrud *et al.*, 2008). Among Fennoscandian Saami, the economic viability of reindeer herding is threatened by competition with other land users coupled with strict agricultural norms (Forbes, 2006). Reindeer herders are concerned that more extreme weather may exacerbate this situation (Oskal et al., 2009).

Climate change is affecting the reindeer herding communities through greater variability in snow melt/freeze, ice, weather, winds, temperatures (especially warmer winters), and precipitation, which, in turn are affecting snow quality and quantity – the most critical environmental variables for reindeer sustainability (Magga *et al.*, 2011; Eira *et al.*, 2012). Reindeer must forage continually and any significant impediment to their ability to access the plants (e.g. lichens) under the snow cover each day can threaten their very survival (Kitti *et al.*, 2009; Magga *et al.*, 2011). Increasing temperature variations in wintertime, with temperatures rising above freezing with rain, followed by refreezing ("rain-on-snow" conditions), are becoming more frequent, forming ice layers in the snow which then block the animals' access to their forage and subsequent starvation (Maynard *et al.*, 2011; Eira *et al.*, 2012; Bongo *et al.*, 2012). Annual migration patterns between summer and winter pastures are being challenged due to changes in the freeze-thaw cycles of rivers and lakes, with spring thaws occurring earlier and soft ice no longer able to support the reindeer as they try to cross (Klein *et al.*, 2005; Abryutina, 2009; Vuojala-Magga *et al.*, 2011). Warmer Arctic temperatures have increased insect harassment causing major interference with foraging (Kitti *et al.*, 2006). Indirect climate change impacts are also occurring, which have major implications for reindeer pasture availability and migration routes. With the lack of land-fast ice along the Arctic coasts in recent years, longer summers, and intense pressure to develop oil, gas and minerals in the North, the Arctic regions are becoming far more accessible to humans and industrial development, resulting in additional sources of increasing and irreversible loss of pasturelands (Kitti *et al.*, 2006; Bongo *et al.*, 2012).

The increasing global demand for energy and mineral resources plus an aggressive development of oil and gas fields as well as mining of other resources are encouraging rapid development with its associated infrastructure, pipelines, drill pads, roads, and pollution all across the once-rich pasture lands of the reindeer seasonal migration routes. (Forbes and Stammler, 2009; Magga *et al.*, 2011) In many locations, the associated infrastructure is being built across migration routes in Northern Russia, often blocking pathways to seasonal pastures and eliminating camping and fishing site for herders (Rees *et al.*, 2008; Bongo *et al.*, 2012; Forbes et al, 2009; Kumpula et al. 2012).

28.2.5.2. Antarctica and the Southern Ocean

The primary economic activities that currently take place in Antarctica are fisheries and tourism. Scientific activity by a number of nations is also taking place and has the potential to impact upon local habitats and communities. Mineral resource activity is currently prohibited south of 60°S until at least 2048 under the Protocol on Environmental Protection to the Antarctic Treaty. All activities in the region are currently regulated under the governance regimes described in Section 28.2.7, unless sovereign activities in subantarctic territories are exempted from those regulations. Patterns of fisheries and tourism and the vulnerabilities of the ecosystems to these activities are likely to be affected by climate change (Kawaguchi *et al.*, 2009; Constable, 2011; Chown *et al.*, 2012).

28.2.5.2.1. Fisheries

Fisheries in Antarctica were reported in AR4. Further analyses since then have shown that the current fishery in the southwest Atlantic, if it were to take the Total Allowable Catch of 5.6 million tonnes, could amount to approximately 6% of existing marine capture fisheries; current catches have been between 100-200,000 tonnes but are now increasing (Nicol *et al.*, 2011). The pattern of the krill fishery has been affected by changes in the sea ice extent around the Antarctic Peninsula. In recent years, the fishery has been taking advantage of the ice-free conditions and taking more of its catch during winter in that region (Kawaguchi *et al.*, 2009) . This changing pattern in the krill fishery will need to be accounted for by CCAMLR in the management strategy for the fishery. Catch

levels are expected to be larger than at present but this will depend more on economic rather than environmental constraints in the short to medium term.

CCAMLR aims to develop an ecosystem-based feedback management procedure for krill fisheries based on indicators of the status of krill and its predators (Constable 2011). This work has not yet factored in measures to account for climate change impacts on the ecosystem, including whether the ecosystem effects of climate change can be differentiated from the effects of fishing (Trathan and Agnew, 2010; Constable, 2011).

28.2.5.2.2. Tourism

Ship-based tourism is a significant industry in Antarctica. The large majority of tourists visit Antarctica aboard ships, and the industry does not involve permanent shore-based infrastructure. Over recent decades, the number of tourists visiting Antarctica has risen, with tourist numbers landing on shore having increased from 7322 in 1996/1997 to 32,637 in 2007/2008 , with one of the busiest sites being at Goudier Island to the west of the Antarctic Peninsula experiencing at least half of the visits (IAATO 2012). Tourists visit Antarctica in order to view scenery, wildlife, and historic sites, and to experience wilderness. As the numbers of tourists have increased, concerns have been expressed about the potential disturbance caused by visitors, e.g. visitors approaching too close to wildlife either on foot or by cruising in small boats. Risks exist of accidental pollution from maritime accidents (a number of groundings and one foundering are recorded), although no significant pollution incidents have occurred in recent decades. Tourism activity is expected to continue to increase, and as more ice-free areas become available as a result of climate change, there is an increasing likelihood of the introductions of alien species to terrestrial environments from tourism and other vectors (Chown, Lee et al. 2012). A combination of mandatory and voluntary management measures are in place under the Antarctic Treaty's Protocol on Environmental Protection (the Protocol) and measures of the Antarctic Treaty Consultative Meeting, aimed at minimizing the impact of such activities. Discharge from vessels is regulated under the Protocol and instruments of the International Maritime Organization.

28.2.6. Governance in the Polar Regions

Dealing with the stresses of climate change and other changing factors in the Polar Regions requires robust governance regimes. The Arctic and Antarctic Regions are governed by quite different regimes that reflect their geographic and political contexts. The Arctic is essentially an ice-covered ocean surrounded by sovereign states whereas the Antarctic is a continental landmass, surrounded by ocean, that has remained unpopulated except for isolated research stations.

The Antarctic is governed by a number of conventions, collectively called the Antarctic Treaty system. The number of States parties to the Treaty has grown from the original 12 nations that were involved in the Antarctic during the International Geophysical Year of 1957-58, to 50 parties today. The Treaty, negotiated during the Cold War tensions, was signed in December 1959 and entered into force on June 1961. The primary purpose of the Antarctic Treaty is to ensure "in the interests of all mankind that Antarctica shall continue forever to be used exclusively for peaceful purposes and shall not become the scene or object of international discord" and "freedom of scientific investigation in Antarctica." The Treaty effectively holds in abeyance all claims to territorial sovereignty in Antarctica. It is generally seen as one of the "success stories" of contemporary international law (Rothwell, 2012). The Protocol on Environmental Protection to the Antarctic Treaty was signed in 1991 and entered into force in 1998. Its objective is the comprehensive protection of the Antarctic environment and dependent and associated ecosystems. The Protocol designates Antarctic Treaty area as a "natural reserve devoted to peace and science", prohibits any activity relating to mineral resources other than scientific research, requires the prior environmental impact assessment of proposed activities, and establishes a range of other environmental standards and requirements. The other active component of the Antarctic Treaty System is the Convention for the Conservation of Antarctic Marine Living Resources, which applies to all marine areas south of the Antarctic Convergence overlapping in jurisdiction with the Antarctic Treaty. Both of these conventions provide mechanisms for managing the effects of climate change in their areas of jurisdiction.

The parallel for the Arctic is the Arctic Council which was formally established in 1996 as a high level intergovernmental forum to provide a means for promoting cooperation, coordination and interaction among the eight Arctic States and the Arctic Indigenous peoples' organizations on common issues such as sustainable development and environmental protection. The Arctic Council is supported by several Working Groups. The International Arctic Science Committee (IASC) which preceded the Arctic Council, being established in 1990, like SCAR is also under the umbrella of the International Council of Science (ICSU). The Arctic Council and the IASC carried out the Arctic Climate Impacts Assessment (ACIA, 2004). The most recent activity of the Arctic Council, in conjunction with IASC, was the Snow, Water, Ice and Permafrost Assessment (SWIPA, 2012). An Aeronautical and Maritime Search and Rescue agreement, signed in 2011, is the first legally-binding agreement negotiated under the auspices of the Arctic Council. Despite such achievements, the Arctic Council is still regarded by some as tentative – a "soft law regime" (Rothwell, 2012).

Since climate change, particularly in the Arctic, has been observed to be occurring faster than the global trend, it is not surprising that it has been a priority subject for the international organisations established under the Antarctic Treaty system and the Arctic Council (Rayfuse, 2007; Byers, 2010). In 2010 the Antarctic Treaty parties convened an Antarctic Treaty Meeting of Experts (ATME) on Climate Change Implications for Antarctic Management and Governance, which examined the ACCE report (Turner *et al*., 2009) and identified 30 recommendations for consideration by the Antarctic Treaty Consultative Meeting (ATCM). The majority of the recommendations related to actions that could be taken by the Parties in Antarctica and within the scope of the Antarctic Treaty system, but several recognised the importance of conveying information about Antarctic climate change to international bodies discussing and climate change. Accordingly, the Parties have begun to contemplate the scope of their role in addressing the implications of climate change for management of the Antarctic Treaty area, possibly including opportunities for enhanced engagement with international organisations discussing climate change action.

Retreating sea-ice in the Arctic is expected to open up new commercial opportunities for gas, petroleum and mineral activities (Borgerson, 2008; Paskal, 2010); UNDP, 2009). The establishment of Exclusive Economic Zones has proceeded in peaceful fashion and the provisions of the United Nations Convention on the Law of the Sea (UNCLOS) and the UN Commission on the Limits of the Continental Shelf have generally been respected (Gleditsch, 2011). Such regimes can be expected to be important in addressing any competition between the Arctic coastal states for control over outer continental shelf claims. Retreating ice will also open up new opportunities for shipping as well for a more intensive use of the Northern Sea Route and North-West Passage (Konyshev V.N., 2011). This may increase competition for the control of these passages and, at the same time, emphasize the need for effective pollution prevention regulations such as the Government of Canada's Arctic waters Pollution Prevention Act of 1970 (Pharand, 1988). Some scholars have argued that there could be sovereignty-related disputes in support of broad economic interests (Konyshev V.N., 2011) although most observers seem to agree with Haftendorn (2010) that this is not expected, nor is a military conflict among the contenders (Gleditsch, 2011).

These issues and others illustrate the importance of science-based innovation in the conservation, management and governance of Arctic resources.

28.2.6.1. Indigenous Peoples, Climate Change, and Traditional Knowledge

Arctic indigenous peoples – the original Native inhabitants of the region – are estimated to number between 400,000 and 1.3 million. (Bogoyavlensky and Siggner, 2004; Galloway McLean, 2010). The percentages of the populations of indigenous peoples in the Arctic range from 3-4 % in Russia to 80% in Greenland. (Galloway McLean, 2010) Indigenous populations in the Arctic are considered especially vulnerable to climate change, due to their close relationship with the environment and its natural resources for physical, social, and cultural well-being (Nuttall *et al*., 2005; Parkinson, 2009). Arctic residents in general depend heavily on the region's terrestrial, marine and freshwater renewable resources, including fish, mammals, birds, and plants; however, the ability of indigenous peoples to maintain traditional livelihoods such as hunting, harvesting, and herding is increasingly being threatened by the unprecedented rate of climate change. (Nakashima *et al*., 2011) The risks are spatially and temporally heterogeneous and encompass potential synergies with other, non-climatic drivers, such as general globalization and

resource development (e.g., oil and gas extraction, mining) (Vuojala-Magga *et al*., 2011), and the prevalence in many indigenous communities of poverty, marginalization, and resulting health disparities. (Abryutina, 2009).

Indigenous and local communities as well as scientists are therefore forced to think in terms of multiple stressors, since in any one area there may be significant synergies resulting from combinations of rapid climate and/or land use change coupled, in the worst cases, with non-adaptive forms of governance. (Sydneysmith *et al*., 2010; Kumpula *et al*., 2011). In habitats across the Arctic, climate changes are affecting these livelihoods through decreased sea ice thickness and extent, less predictable weather, severe storms, changing seasonal melt/freeze-up of rivers and lakes, changes in snow type and timing, increasing shrub growth, permafrost thaw, and storm-related erosion which, in turn, are causing such severe loss of land in some regions that a number of Alaskan villages are having to relocate entire communities (Mahoney *et al*., 2009; Forbes and Stammler, 2009; Bartsch *et al*., 2010; Weatherhead *et al*., 2010; Brubaker *et al*., 2011b; Bongo *et al*., 2012; Eira *et al*., 2012; McNeeley, 2012; Huntington and Watson, 2012)Bronen, 2011)

The historical, accumulated knowledge of indigenous peoples (also known as indigenous, traditional, or local knowledge which also includes "traditional ecological knowledge" or TEK) is increasingly emerging as a critical source of information for comprehensively addressing the impacts of environmental and other changes as well as the development of appropriate adaptation and response strategies for indigenous communities. (Nakashima et al 2012;Vuojala-Magga *et al*., 2011) Reflecting the importance of the incorporation of this knowledge for adaptation and response strategies, the IPCC Fourth Assessment Report acknowledged indigenous knowledge as "an invaluable basis for developing adaptation and natural resource management strategies in response to environmental and other forms of change" and this IPCC Fifth Assessment includes a number of sections on indigenous knowledge in several chapters. (e.g., Polar Regions, 28.2 – 28.4 and Human Security, 12, 12.3.2) Indigenous Knowledge has also been recognized at the global level in a recent report prepared by UNESCO for the IPCC AR5, which pays special attention to the systematic observations provided by Arctic indigenous communities (Nakashima *et al*., 2011)

Indigenous knowledge has been characterized as "knowledge and know-how accumulated across generations, and renewed by each new generation, which guide human societies in their innumerable interactions with their surrounding environment" (Nakashima et al 2012) and can be considered traditional due to its origins in traditional cultures.(Vuojala-Magga *et al*., 2011) Indigenous knowledge and TEK consist of beliefs, rituals, and understandings about the dynamic relationships between living entities and the environment, and is a body of knowledge that has evolved through adaptive processes and handed down through generations (Berkes, 2008; Reinert *et al*., 2009; Nakashima *et al*., 2011) Indigenous knowledge and TEK are useful for detecting and adapting to climate change impacts because climate models often have low resolution at local and even regional scales, and this is precisely the scale at which indigenous observations emerge. Examples include Sámi reindeer herders' knowledge of dynamic snow conditions, which mediate access to forage on autumn, winter and spring reindeer rangelands (Roturier and Roué, 2009; Riseth *et al*., 2011; Eira *et al*., 2012). While indigenous knowledge is important for climate assessments (Huntington *et al*., 2004; Salick and Ross, 2009; Green and Raygorodetsky, 2010) Ford et al., 2011), not all indigenous community members share the same expert and indigenous knowledge; hence, they face the need to conceptualize their adaptation strategies within their own social, political, and cultural contexts (Ford *et al*., 2011).

In many cases, indigenous knowledge, traditional ecological knowledge, and Western science detect the same climate change impacts, thereby increasing confidence about the effects of climate change on Arctic environments and societies. In some instances, however, the interpretations differ and caution is recommended before drawing firm conclusions (Huntington *et al*., 2004). The perception of change at the community level can be as important as scientifically detectable or measurable change in determining whether and how to respond to indirect environmental or more direct anthropogenic drivers (Alessa et al. 2008). Indigenous knowledge and TEK have long been incorporated into co-management regimes in the North American Arctic (Forbes and Stammler, 2009). Its application to date in Eurasian renewable resource management institutions has been mostly limited to marine fisheries (Jentoft 2000). In both North America and northernmost Europe, the results to date are mixed and there is ample room for improvement (Berkes and Dyanna, 2001; Kofinas, 2005; Ulvevadet, 2008; Meek *et al*., 2008; Berkes, 2009; Dowsley 2009).

At a more basic level, indigenous knowledge and TEK have proven applications in broadening our understanding of ongoing climate and land use changes and their combined ecological and social implications across the circumpolar North (Sydneysmith *et al.*, 2010; Riseth *et al.*, 2011; Kumpula *et al.*, 2012). At Clyde River, Nunavut, Canada, Inuit experts and scientists note that wind speed has increased in recent years and that wind direction changes more often over shorter periods (within a day) than it did during the past few decades (Gearheard *et al.*, 2010). In Norway, Sámi reindeer herders and scientists are both observing direct and indirect impacts to reindeer husbandry such as changes in snow and ice cover, forage availability and timing of river freeze-thaw patterns from increasing temperatures. (Maynard and Conway, 2008; Eira *et al.*, 2012). On the Yamal Peninsula in West Siberia, detailed Nenets observations and recollections of iced over autumn and winter pastures due to rain-on-snow events have proven suitable for calibrating the satellite-based microwave sensor SeaWinds (Bartsch *et al.*, 2010) and NASA's AMSR-e sensor (Bongo *et al.*, 2012).

In the Canadian Arctic, there is agreement between Inuit knowledge and scientific studies about the thinning of multiyear sea ice; the shortening of the sea ice season; the declining extent of sea ice cover, with Inuit experts reporting less predictability in the sea ice and more hazardous travel and hunting at ice edges; a decrease in the quantity of multiyear and first-year sea ice; an increasing distance of multiyear ice from the shore; and variability and uncertainty in sea ice during transition months of the year, when freeze-up and breakup occur. (Ford et. al., 2009; Aporta *et al.*, 2011).

While Arctic indigenous peoples are facing unprecedented impacts to their life ways from climate change and resource development (oil and gas, mining, forestry, hydropower, tourism, etc.), they have already implemented some creative ways of adapting (Cruikshank, 2001; Forbes, 2006; Krupnik and Ray, 2007; Salick and Ross, 2009; Green and Raygorodetsky, 2010; Cullen-Unsworth *et al.*, 2011; Alexander *et al.*, 2011; Bongo *et al.*, 2012)). For example, they are combining indigenous knowledge with western scientific knowledge about the ecology and its interrelationships with economic and cultural systems to develop the resilience of ecological and social systems and to identify those factors which can enhance that system's potential for self-sufficiency and sustainable development (Forbes, 2006; Maynard *et al.*, 2010; Gearheard *et al.*, 2011). Examples of indigenous adaptation strategies have included changing resource bases, shifting land use and/or settlement areas, combining technologies with Indigenous knowledge, changing timing and location of hunting, gathering, herding, and fishing areas, and improving communications and education (Galloway McLean, 2010; Bongo *et al.*, 2012). Local and state governance regimes or other institutions too rigid to accommodate relevant Indigenous knowledge or local knowledge are likely to increase vulnerability to rapid change, whereas, flexible institutions responsive to indigenous and local knowledge in real time can enhance resilience (Meek *et al.*, 2008; Sydneysmith *et al.*, 2010; Kumpula *et al.*, 2012)

28.2.6.2. Reindeer, Climate Change, Development, and Adaptation

Reindeer husbandry has had a long important history in the Arctic, especially for the many indigenous people in Norway, Sweden, Finland, Russia, Mongolia, China, US, Canada, and Greenland. (Magga et al, 2011) Reindeer husbandry as a livelihood now involves about 100,000 herders and approximately 2.5 million semi-domesticated reindeer. (Oskal, 2008) Interactions between reindeer (*Rangifer tarandus* L.) and humans date from the late Pleistocene onward and wild and semi-domestic animals continue to be essential to indigenous peoples throughout the Arctic for a diversity of purposes. (Oskal, 2008; Forbes and Kumpula, 2009) Contemporary reindeer management functions as a coupled social-ecological system characterized by a nomadic or semi-nomadic lifestyle undertaken by family- or shift-based, indigenous and mixed ethnicity communities (Vuojala-Magga *et al.*, 2011;Forbes, 2006). Migration routes within and among seasonal pastures vary widely from tens to several hundred kilometres. The reindeer lies at the very core of these communities, providing primary food, economic base, way of life, clothing, mythologies, and worldviews, but is facing increasing challenges from unprecedented changes in their climate and weather as well as accelerating changes in land use, (Stammler, 2005; Forbes, 2006; Oskal, 2008; Paine, 2009; Vuojala-Magga *et al.*, 2011),

Such changes in the climate are already affecting the reindeer herding communities through greater variability in temperature, and precipitation. This increased variability affects overall weather patterns and exerts strong influence on snow quality, quantity and duration (Bulygina *et. al.*, 2009; Bulygina *et. al.*, 2010; Callaghan *et al.*, 2011b) –

very critical environmental variables for reindeer sustainability (Eira *et al*., 2012). Reindeer must forage continually and any significant impediment to their ability to access forage under the snow cover each day during winter can threaten their survival (Vuojala-Magga *et al*., 2011). Increasing temperature variations in wintertime, with temperatures rising above freezing with rain, followed by refreezing ("rain-on-snow" conditions), are becoming more frequent, forming ice layers in the snow which then block the animals' access to their forage and subsequent starvation. (Bartsch *et al*., 2010; Bongo *et al*., 2012; Eira *et al*., 2012) Annual migration patterns between summer and winter pastures are being challenged due to changes in the freeze-thaw cycles of rivers and lakes, with spring thaws occurring earlier and soft ice no longer able to support the reindeer as they try to cross and by the appearance of new infrastructure such as oil and gas pipelines, roads, and buildings (Vuojala-Magga *et al*., 2011). Warmer Arctic temperatures have increased insect harassment causing major interference with foraging (Kitti *et al*., 2006). Other climate change impacts are also occurring, which have similarly important implications for reindeer pasture availability and migration routes. (Maynard et al, 2010) With the lack of land-fast ice along the Arctic coasts in recent years, longer summers, and intense pressure to develop oil, gas and minerals in the North, the Arctic regions are becoming far more accessible to humans and industrial development, resulting in additional sources of increasing and irreversible loss of pasturelands (Kitti *et al*., 2006; Forbes and Stammler, 2009; Bongo *et al*., 2012).

Over the millennia, wild and semi-domestic reindeer populations have developed a strong resiliency to climate change and variability because, in fact, it is a species which has constantly been subjected to extensive weather-related variations on a day-to-day basis as well as during seasonal migrations. (Klein *et al*., 2005; Turi, 2008). However, in recent years, these successful adaptation strategies which have guided their survival have been challenged by unprecedented rates of climate change and additional external factors such as changing government policies, sharply increasing oil and gas development and mining activities, overall pasture loss, and blocking of migration routes. (Forbes, 2006; Bongo *et al*., 2012). In fact, the increasing global demand for energy and mineral resources plus an aggressive development of oil and gas fields as well as mining of other resources are encouraging rapid development with its associated infrastructure, pipelines, drill pads, roads, and pollution all across the once-rich pasture lands of the reindeer seasonal migration routes (Forbes and Stammler, 2009; Kumpula *et al*., 2012). In many locations, the associated infrastructure is being built across migration routes in Northern Russia, often blocking pathways to seasonal pastures and eliminating camping and fishing site for herders (Rees *et al*., 2008; Kumpula *et al*., 2011; Kumpula *et al*., 2012; Degteva et al, 2010). This is especially important as it is well-known that female reindeer and their calves will avoid humans and their activities as well as physical infrastructure (Vuojala-Magga *et al*., 2011).

Of particular concern today, it is estimated that the Arctic may contain approximately 25 % of the world's remaining undeveloped petroleum resources and climate warming is accelerating access to northern lands for development. (Forbes, 2009). For example, Yamal in Western Siberia has approximately 90 % of Russia's gas reserves, but at the same time represents the largest area of reindeer herding in the world (Jernsletten and Klokov, 2002; Stammler, 2005; Forbes and Kumpula, 2009). Development activities to obtain these resources would shrink the grazing lands, and have been characterized as one of the major human activities in the Arctic contributing to the loss of "available room for adaptation" for reindeer husbandry (Forbes et al. 2009; Nuttal et al, 2005). Furthermore, it is anticipated that there will be sharp increases in future oil and gas and other resource development in the Russian North and other Arctic regions – along with its associated infrastructure, pollution, and other by products of development – which will, in turn, reduce the availability of available pasturelands for the reindeer and the indigenous communities associated with them. (Derome and Lukina, 2010). Together with the symptoms of ongoing climate warming cited above, the combination of these factors presents major concerns for the future of reindeer husbandry, the well-being of the Arctic indigenous and other communities, especially the reindeer herding communities, and the ability to adapt to future changes (Forbes *et al*., 2009; Kumpula *et al*., 2011; Vuojala-Magga *et al*., 2011; Kumpula *et al*., 2012).

28.3. Key Projected Impacts and Vulnerabilities under Different Climate Pathways

28.3.1. Hydrology and Freshwater Ecosystems

28.3.1.1. Arctic

Accompanying projected increases in Arctic river flow (see WGII Chapter 3) is a shift to earlier timing of spring runoff (Dankers and Middelkoop, 2008; Pohl *et al.*, 2009; Hay and McCabe, 2010) and an increase in the magnitude of spring snowmelt, particularly in areas with winter temperatures <-30ºC (Adam *et al.*, 2009). Based on the results of a study on the Canadian Archipelago (Lewis and Lamoureux, 2010), spring fluxes of sediment are also projected to increase with spring flows (+100 to 600% by the end of the 21st century based on CGCM3 A1b and A2 scenarios, respectively). Such estimates are considered conservative, however, because the modelling did not consider the potential for enhanced permafrost thaw.

Projected increases in permafrost thaw (see WGI Chapter 4) will also continue to affect the dynamics of thermokarst lakes (e.g., appearance of new lakes and drainage of some existing ones) and related ecological effects as outlined in Section 28.2.1.1. Similarly, the loss of glacier ice masses will alter spatial and temporal dynamics in runoff accompanied by changes to sediment loads, water chemistry and thermal regimes, and related channel stability, habitat and biodiversity (Milner *et al.*, 2009; Moore *et al.*, 2009).

Although snow, freshwater ice and permafrost affect the morphology of arctic alluvial channels, their future combined effects remain unclear (McNamara and Kane, 2009). In the case of small permafrost streams, however, even if the thickness of their hyporheic zones does not substantially deepen, longer projected periods of flowing water will modify nutrient and organic matter processing in this important biological stratum (Greenwald *et al.*, 2008; Zarnetske *et al.*, 2008). In terms of broader aquatic productivity, long-term negative impacts of increased sediment load could outweigh any positive effects associated with increased nutrient loading (Bowden *et al.*, 2008).

Thawing permafrost and changes in the hydrological regime of the Arctic rivers, particularly those traversing regions affected by industrial developments, will increase the contaminant flow (Nikanorov *et al.*, 2007). Studies in the Lena and Kolyma rivers indicated that water pollution by oil is one of the key factors currently affecting the pelagic ecosystems in the coastal zone, which is likely to increase under warmer climatic conditions (Nikanorov *et al.*, 2007; Nikanorov *et al.*, 2011a; Nikanorov *et al.*, 2011b)

Changes to the dynamics of spring freshet on large Arctic rivers is also projected to change from a reduction in their south to north thermal gradients and, hence, severity of river-ice breakup and ice- jam flooding (Prowse et al., 2010). Such a conclusion is based on GCM-ensemble projections of air temperatures (SRES A2 scenario; 2041–2070 & 2071–2100) along the 4 largest arctic rivers, Lena, Ob, Yenisei and Mackenzie compared to current (1979–2008) conditions. One caveat made on such a projection is the, as yet to be fully evaluated, complicating effect on break-up dynamics of the above noted increases in the magnitude of spring snowmelt.

A reduction in ice-jam flooding would have positive benefits for river-side northern communities and infrastructure but it could also alter the ecology of delta-riparian (Lesack and Marsh, 2010) and coastal-marine (Emmerton *et al.*, 2008) ecosystems. The quality of river water entering the marine environment during the spring period is also projected to be affected with the reduction or loss of stamukhi lakes and their distinct microbial assemblages, which play a key functional role in processing river inputs to the marine ecosystems (Dumas *et al.*, 2006; Galand *et al.*, 2008).

Future changes to lake-ice regimes are also projected to affect lentic ecology. Based on a modelling study of hypothetical 20-m deep lakes in the Northern Hemisphere (between 40° and 75°N), projections from a one-dimensional lake model driven by output from the CGCM3 indicate that future (SRES A2 scenario; 2040–2079 compared to 1960–1999) lake conditions will be characterized by an overall increase in lake-water temperature, and earlier and longer-lasting summer stratification (Dibike *et al.*, 2011). Other projections include: freeze-up delayed 5-20 days, break-up advanced by 10-30 days, thickness decreased 10-50 cm, and cover composition modified by changes in snow loads with white ice changing by -20 to +5 cm – the higher latitudes being an area most increase

because of the combination of increases in winter snowfall and thinner ice cover that would promote enhanced white-ice formation.

The loss or reduction in duration of ice cover on lakes and corresponding changes in their thermal regimes can affect a number of aquatic processes (Prowse and Brown, 2010a). Paleolimnological research has shown for a site in the Siberian Arctic that periods of highest primary productivity were associated with warm, ice-free summer conditions, while the lowest rates were coincident with periods of perennial ice (Melles *et al.*, 2007). The projected changes in snow and white ice coverage can also affect levels of secondary productivity, such as in fish e.g., (Borgstrøm and Museth, 2005; Prowse *et al.*, 2007). Patterns of species richness and diversity are also projected to change with alterations to ice and open-water durations, with increased open water periods favouring the development of new trophic levels and colonization of new aquatic species assemblages (Vincent *et al.*, 2009). For some lakes, however, the loss of ice will result in the loss of suitable habitat, both in availability and quality (Vincent *et al.*, 2008). For example, lake-ice duration has a controlling influence on the levels and mixing of dissolved oxygen (e.g. (Laurion *et al.*, 2010). The above-noted projected shifts to increased summer stratification will increase the possibility of oxygen depletion and even anoxia in the bottom waters and reduce the habitat availability for high oxygen-demanding biota during such periods. By contrast, with greater atmosphere-water gas exchange resulting from longer open-water periods, the occurrence of winter kills of resident fish are expected to be reduced and produce cascading effects on lower trophic levels (Balayla *et al.*, 2010).

In addition to habitat alterations, geochemical responses of Arctic lakes will be altered. As observed for certain Arctic thermokarst lakes, the loss of ice cover and associated warming can greatly increase methane production (Metje and Frenzel, 2007; Laurion *et al.*, 2010). Because temperature sensitivity has a stronger control over methane production than oxidation (Duc *et al.*, 2010), elevated water temperatures will enhance methanogenesis, causing increased methane release from sediments. The net balance of these two processes operating under a broad range of future changing environmental factors, however, remains to be quantified (Walter *et al.*, 2007; Walter *et al.*, 2008; Laurion *et al.*, 2010).

As well as methane, increased water temperatures are projected to lead to reduced organic carbon (OC) burial. Projections, based on a range of six climate warming scenarios (IPCC, 2007), indicates that there will be a 4-27% decrease (0.9-6.4 TgC yr-1) in OC burial in lake sediments across the entire northern boreal zone by the end of the 21st Century as compared to rates for the approximately last half-century (Gudasz *et al.*, 2010). Although these estimates are based on an assumption that future organic carbon delivery will be similar to present-day conditions, even with enhanced delivery as to be generated by thawing permafrost, higher water temperatures will increase organic carbon mineralization and thereby lower burial efficiency. The amount of burial will also depend on lake depth and mixing regimes. In the case of warming shallow lakes that are not thermally stratified, there will be a greater opportunity for water-sediment mixing and hence, greater carbon recycling back into the water column. Alternatively, in lakes that become increasingly thermally stratified lakes, carbon sinking below the thermocline tends not to return to surface waters until the fall turnover, thereby decreasing the probability of sediment-stored carbon being returned to the water column (Flanagan *et al.*, 2006).

Changes in ice cover, thermal regimes and stratification patterns will also affect the fate of contaminants in northern lakes. Higher water temperatures can enhance, for example, the methylation of mercury and modify food-web and energy pathways, such as through enhanced algal scavenging (a major foodweb entry pathway for mercury) resulting in increased mercury bio-availability to higher trophic levels (e.g., predatory fish) (Outridge *et al.*, 2007; Carrie *et al.*, 2010;AMAP, 2011).

28.3.1.2. Antarctic

Previous assessments have been reinforced in this assessment. The most vulnerable region for change in Antarctic freshwater systems are the northern Antarctic Peninsula and maritime Antarctic islands in the southern Scotia Arc, which are within a few degrees of the melting point, so a small shift in temperature regimes can have widespread ecosystem impacts. These range from catastrophic and immediate impacts such as loss of bounding ice masses causing drainage of freshwater and epishelf lakes (Smith *et al.*, 2006; Hodgson, 2011), to more gradual impacts

associated with changes in the amount and duration of catchment ice and snow cover, accelerated glacier melting, and declining volumes of precipitation falling as snow.

As in Arctic lakes, the most marked changes are expected to be associated with changes in the thickness and duration of seasonal ice cover, longer melt seasons and larger volumes of water flowing into the lakes (Lyons *et al.*, 2006). A longer ice free season may cause changes in a lakes mixing regime and release of solutes from the sediments, increased light (including ultraviolet), higher water temperatures, increased CO_2 exchange and conditions more favorable for the growth of the plankton, periphyton and benthic communities (Hodgson and Smol 2008). However in some systems the very high light irradiances experienced during the summer can substantially inhibit algal blooms under ice free conditions (Tanabe *et al.*, 2007). In shallow lakes this favors the growth of benthic cyanobacteria species that can synthesise a number of light screening compounds (Hodgson *et al.*, 2005). In other lakes, increases in meltwater supply may reduce light penetration due to an increase in suspended solids, and it remains uncertain whether this will offset the increases in the underwater light regime predicted as a result of extended ice free periods (Quesada *et al.*, 2006).

Under a warming climate an increase in catchment microbial biomass is likely because of the increased water supply from glacial melt and warmer temperatures, and could result in further development of soils and elevated nutrient and dissolved organic carbon delivery to lakes. This organic supply will promote growth and reproduction in the benthos and plankton. Another observation is that where more melt water is available, input of freshwater into the mixolimna of deeper lakes can increase stability and this, associated with increased primary production, will lead to higher organic carbon flux. Such a change will have follow–on effects including potential anoxia, shifts in overall biogeochemical cycles and alterations in the biological structure and diversity of ecosystems (Lyons, Laybourn-Parry et al. 2006). Conversely, in shallow lakes where water is heated above the 3.98°C maximum density only very moderate winds will be required to cause wind–induced mixing through the ice free periods influencing plankton communities, gas exchange and biogeochemical processes.

Away from glacial forelands, future regional patterns of water availability are unclear, but increasing aridity is likely in some areas of the continent in the long-term (Hodgson *et al.*, 2006b) and on subantarctic islands (Smith Jr *et al.*, 2012). Lakes can dry up completely causing local extinctions or retreat into cryptic or resistant life-cycle stages, as experienced in Arctic lakes (Smol and Douglas, 2007b).

Studies have also shown that once cold freshwater habitats in Antarctica can be colonised by biota from northern refuges in maritime and sub-Antarctic areas (Barnes *et al.*, 2006). There is *medium confidence* that future elevated temperatures will allow the sub- and maritime Antarctic taxa to re-invade and establish self-maintaining populations on the Antarctic continent (Hodgson *et al.*, 2006b).

For other organisms with lower dispersal capabilities there is increasing evidence of endemism, particularly in microbial groups (Vyverman *et al.*, 2010) whichhave evolved on the continent over multiple glacial interglacial cycles (Vyverman *et al.*, 2007; Vyverman *et al.*, 2010; Fernandez-Carazo *et al.*, 2011) and allows for the possibility that Antarctic lakes may contain species that are relicts of Gondwana (cf. (Convey and Stevens 2007)). These species cannot be replaced from lower latitudes if they were to experience continental extinction as a result of climate changes.

As in previous assessments, expanding fur seal populations in some breeding areas will increase nutrient enrichment of the freshwater habitats. As well, alien species may be more easily introduced into these environments through human activities and poses a greater threat than colonisation across the natural barriers of the Southern Ocean. increase, even though no reports of alien freshwater species have been reported to date (Frenot *et al.*, 2005).

28.3.2. Oceanography and Marine Ecosystems

28.3.2.1. Arctic

Arctic marine ecosystems are complex and thus predicting their future under climate change is challenging. In the Bering Sea and Barents Seas, there is *high confidence* based on a long history of observed responses of species to interannual and decadal variability in climate that climate change will impact marine ecosystems. While there is abundant evidence that climate induced shifts in ocean conditions impact marine ecosystems, predictions of the magnitude and spatial extent of ecosystem change are uncertain. Regions at lower latitudes have a rich basis of scientific literature and long time series from which to provide the foundation for scientific conclusions. Farther north, the cost and infrastructure needed to conduct research in the region results in fewer researchers working in the area and fewer empirical observations for drawing statistical inference and conclusions.

In the Arctic Ocean, a coupled bio-physical model was used to simulate changes in lower trophic levels under changing climate conditions for the period 1988 – 2007 (Zhang *et al.*, 2010). This model projected increased marine primary productivity consistent with satellite observations.

There is *medium confidence* that in the deep basins of the Arctic Ocean changes in stratification and the number of ice free days will lead to a greater drawdown of nutrients and higher pelagic primary production. It is unclear whether the large-bodied copepods (*Calanus* spp.) may have the capacity to graze this down phytoplankton levels in summer (Olli *et al.*, 2007).

28.3.2.1.1. Projected impacts on phenology
(timing of spawning, timing of settlement, duration of growing season, age at maturity)

Historical records show Atlantic cod can adapt to local conditions by shifting key vital rates (diet, growth rate, maturity schedule and survival rate) and reproductive periods to accommodate differences in regional prey availability, predator avoidance and environmental conditions (Ormseth, 2007; Sundby and Nakken, 2008;Vikebo et al., 2007). Efforts to project how these physiological and behavioral responses will impact marine ecosystems are the focus of a large interdisciplinary ecosystem modeling effort in the Bering Sea (Wiese *et al.*, 2012).

28.3.2.1.2. Projected spatial shifts in response to climate

In the northern Bering Sea, reduced sea-ice and warmer temperatures in the late 1990s and early 2000s led to a northward movement of benthic feeders (e.g. walrus, grey whales). This is thought to have been related to a reduced flux of particulate organic material to the benthos, because of increased pelagic grazing (Grebmeier *et al.*, 2006). Further climate warming may lead to an extension of these conditions farther north (e.g. into the Chukchi Sea). If this occurred this would provide higher levels of prey for pelagic planktivores and baleen whales, but could have a negative impact on the benthic planktivores. In addition, some planktonic predators may suffer if the large lipid-rich Arctic Calanus species (*C. glacialis, C. hyperboreus*) are displaced by the smaller boreal forms (*C. finmarchicus, C. marshallae*) (Karnovsky *et al.*, 2010).

Modeling studies project that climate change will shift the bio-climate envelopes of marine fish stocks resulting in an increase in biodiversity in the Arctic (Cheung *et al.*, 2009). Qualitative data synthesis and modeling shows that the response of fish stocks to changes in bio-climatic envelopes may be more complicated.

There is *medium confidence* that the waters off the coasts of Europe will provide the potential for increased production because of the combined effects of intrusion of Atlantic water over the relatively broader shelf regions and advective corridors for larval drift and range expansion of spawners. In the Barents Sea, Huse and Ellingsen (2008) used a spatially explicit coupled bio-physical model forced with future climate scenarios to project the implications of climate change on the spawning distribution of capelin in the Barents Sea. Projections show that the

spawning distribution of capelin will shift to the east and new spawning grounds will be colonized. A key factor governing this expansion will be the availability of pelagic prey.

In the Bering Sea, there is *medium confidence* based on observations that planktivorous species like walleye pollock in the eastern Bering Sea will shift their distribution in response to shifts in ocean temperature (Kotwicki *et al*. In Press). However, in the northern Bering Sea the persistence of cold winter conditions in the Arctic coupled with the life history factors will restrict or retard the movement of several sub-arctic fish and shellfish species into the Arctic (Sigler *et al*., 2011; Stabeno *et al*., 2012; Hunt Jr. *et al*., 2013; Hollowed *et al*., In Press). There is *medium confidence* based on qualitative data synthesis that fewer commercial fish species from the Pacific are expected to colonize the Arctic because of the shallow depth of the Bering Strait, the continued formation of the cold pool in the northern Bering Sea, and the comparatively weaker flow into the Arctic.

28.3.2.1.3. Projected impacts on fish and shellfish production in response to climate

In the Bering Sea there is *medium confidence* based on observations, that increased summer sea surface temperatures will cause a decrease in the abundance of energy rich zooplankton in the eastern Bering Sea. Decreased availability of energy rich zooplankton is expected to result in lower survival of walleye pollock stocks in the eastern Bering Sea (Hunt *et al*., 2011). Mueter et al. (2011) incorporated this relationship between ocean zooplankton into a single species stock projection model to assess the implications of future climate scenarios on the future production of Bering Sea walleye pollock. Results showed that walleye pollock stocks were projected to decline by 2050 due to reduced survival in the first year of life although there is considerable uncertainty in the projections. Efforts to extend these models for use in projecting annual production in the Arctic are under development.

28.3.2.1.4. Cumulative effects

The cumulative effects of climate change on the phenology, spatial distribution and production of fish and shellfish are uncertain and the projected outcomes will differ by species and region. While changes in the distribution and abundance of fish and shellfish have been observed in the Arctic and its surrounding seas, the absence of a historical baseline in the Arctic Ocean inhibits attribution of observed changes in that region to climate change.

28.3.2.2. Antarctica and the Southern Ocean

Continued increasing temperatures in the Southern Ocean are likely to result in increased metabolic costs in many pelagic species and movement south of the northern distribution of polar species and southern distribution of temperature and subantarctic species. Movement of the frontal systems and associated oceanographic mesoscale features such as eddies and filaments where increased productivity attracts top predators may not only cause a shift southward of many pelagic taxa but also make it energetically inefficient for some land-based predators to pursue those prey from their more northerly subantarctic breeding sites (Péron *et al*., 2012; Weimerskirch *et al*., 2012).

For Antarctic krill, the prognosis overall is ambigous. Krill will naturally respond to warming with an increased metabolic rate but its overall growth rate is dependent on having enough food to support it. The changes in temperature at the Antarctic Peninsula will enhance the productivity of krill but the response is likely to be negative at South Georgia because of the already warmer temperatures in that area (Wiedenmann *et al*., 2008). Models of recruitment and population dynamics indicate that the biomass of krill will decline if surface warming continues, but preliminary projections are highly uncertain (Murphy *et al*., 2012b). Recruitment success of krill may also decline in the long term as a result of impacts of ocean acidification on larval development (Kawaguchi *et al*., 2011). Overall, regional variation of factors that could impact directly on krill both positively and negatively will likely result in region-specific responses and depend on the ability of krill to adapt physiologically and behaviourally. Recently, it has been shown that krill can exploit the full depth of the ocean, thus their potential habitat is far greater than once thought and might provide avenues to escape further warming (Schmidt *et al*., 2011) but may make them less accessible to predators (Constable *et al*., submitted). These factors could lead to the marine food webs around the

South Atlantic islands with their current krill-based systems becoming more like the fish-based ecosystems of the Indian Ocean sector (Trathan *et al.*, 2012; Murphy *et al.*, 2012a; Murphy *et al.*, 2012b).

Projections show that the loss of summer sea ice from the west Antarctic Peninsula are expected to result in ice-dependent seals declining in WAP and being replaced by southern elephant seals and/or other seal species that are not dependent on sea ice (Costa *et al.*, 2010). Importantly, the change in duration of the winter sea ice season and a possible continued change in timing of the season could impact on the potential productivity of phytoplankton because of the mismatch in timing of optimal growing conditions at the time of sea ice melt and the available light (Trathan and Agnew, 2010). This mismatch in timing can also propagate through the food web to impact on krill and upper trophic levels that depend upon krill.

Coastal environments will be impacted by the dynamics of fast ice, ice shelf and glacier tongues. These factors will positively affect local primary production and food web dynamics (Peck *et al.*, 2009) but negatively affect benthic communities (Barnes and Souster, 2011). Projections of the response of Emperor penguins and Southern Ocean seabirds based on AR4 model outputs for sea ice and temperature indicates that general declines in these populations are to be expected if sea ice habitats decline in the future (Barbraud *et al.*, 2011; Jenouvrier *et al.*, 2012) but these responses are also expected to be regionally specific because of the regionally different expectations of change in the ice habitats.

28.3.3. Terrestrial Environment and Related Ecosystems

28.3.3.1. Arctic

Projections of future ecosystem distribution and production are based on one of two approaches: field experiments that simulate future environments such as increases in summer air temperature, soil temperature, precipitation, UV-B radiation, atmospheric CO2 concentrations, soil nutrients, snow depth, snow cover duration and or facilitation/competition from pre-existing species, and mathematical models. Both approaches have uncertainties. However, both approaches concur that climate warming will result in a generally northward migration of vegetation zones dominated by the particular responsiveness of woody plants – both shrubs and trees.

Model projections include equilibrium models based on climate and vegetation zone distributions and also dynamic vegetation models based on physiological and ecological processes.

Many models project a general northward movement of the boreal forest under a warming climate, that will displace between 11% and 50% of the tundra within 100 years (Callaghan *et al.*, 2005; Wolf *et al.*, 2008; Vygodskaya et al., 2007; Sitch et al., 2008; Tchebakova et al., 2009) in a pattern similar to that which occurred during the early Holocene climatic warming

The BIOME 3 equilibrium model applied to Europe and northern Asia projected general displacement of tundra by forest that amounted to between 10 and 35% (the minimum in Scandinavia and the maximum in central-Northern Siberia) (Harding et al. (2001). Estimates of displacement of tundra by forest from similar models varied up to a maximum of 50% (ACIA 2005). A recent model for Russia projected that as early as the first quarter of the 21st Century, changes will occur in the boreal zones of the European part of Russia and the Western region (Anisimov et al., 2011). By 2060, tundra vegetation will be displaced from the mainland and from further towards the East where it will remain only in the Far East and Primorye.

Dynamic vegetation models applied to Europe and the Barents Region project a general increase in net annual primary production of particularly woody plant functional types stimulated by climate warming and CO_2 fertilization together with a north-easterly shift of vegetation zones (Wramneby *et al.*, 2010): boreal needle-leaved evergreen coniferous forest replaces tundra and expands into the mountain areas of Fennoscandia. The most dramatic changes in vegetation structure were projected to occur in the Scandes Mountains where the succession progresses from tundra vegetation through deciduous forest to evergreen forest (Wramneby *et al.*, 2010). Another projection for the Barents Region included more plant functional types, particularly various shrub growth forms and plant

communities associated with open ground that are more characteristic of northern regions (Wolf *et al*., 2008). Over the next 100 years, this transient model also projected an increase in the northwards and upwards ranges of boreal needle-leaved evergreen forest and an increase in net primary production and leaf area index. As in the study by Wramneby et al. (2010), shade intolerant broadleaved summergreen trees were projected to extend to higher latitudes and altitudes. However, in contrast to these expected results, shrubs, currently expanding in area in many Arctic locations, were modelled to decrease in extent over the next 100 years after an initial increase (Wolf et al. (2008). This is thought to be a result of displacement by forest at their lower /southern limits and restriction of appropriate land at higher altitudes. Also counter-intuitively, tundra areas increased in the projections. This was a result of changes at the highest latitudes that opened land for colonisation at a rate exceeding displacement of tundra by shrubs in the south. A discrepancy in the model was an overestimation of forest in the Kola Peninsula that cannot be explained by climate alone.

Both studies calculated the magnitude of the effects of vegetation change on biospheric feedbacks to the climate system. These included the negative feedbacks of CO_2 sequestration and increased evapo-transpiration and the positive feedback of decreased albedo (Wramneby *et al*., 2010; Wolf et al., 2010).

Although the models generally agree qualitatively with expectations from historic vegetation changes, recent changes and results of climate change simulation experiments in the field, there are considerable uncertainties in the projected rates of change. Van Bogaert et al. (2010) compared maximum rates of annual projected forest advance of 20 km with the maximum observed rate of 20 m. Furthermore, the models do not yet include vertebrate and invertebrate herbivory, extreme events such as tundra fire and extreme winter warming damage or changes in land use that either reduce the rate of vegetation change or open up niches for rapid change. However, projections suggest increases in the ranges of the autumn and winter moths that have outbreaks in populations resulting in the defoliation of birch forest (Ims reference) and a general increase in the “background” (non-outbreak) invertebrate herbivores that may consume more vegetation than the outbreak species in the longer term (Wolf *et al*., 2008).

28.3.3.2. Antarctica

Regional climate warming and associated environmental changes are expected to both increase the frequency at which new potential colonists arrive in Antarctica (particularly the Antarctic Peninsula region) from lower latitudes, and subsequent probability of their successful establishment (Chown, Lee et al. 2012). However, human-assisted transfers of biota overcome several of the barriers facing natural colonists, including the speed of transfer and avoidance of extreme environments such as altitude or oceans (Barnes *et al*., 2006). Analyses for two remote Southern Ocean islands (Gough Island, Marion Island) have shown that human-assisted introductions may be more important by two orders of magnitude than natural introductions (Frenot, Chown et al. 2005). A broader regional analyses has shown that introduced species can alter native biodiversity through both homogenization and differentiation (Shaw *et al*., 2010).

Anthropogenic introductions of alien species are a major threat to Antarctic terrestrial ecosystems (Convey *et al*., 2009; Hughes and Convey, 2010; Convey, 2011). Climate change is expected to increase the potential for anthropogenic introduction of non-indigenous species to the Antarctic terrestrial areas, which could have devastating consequences to the local biodiversity (Hughes and Convey, 2010; Braun *et al*., 2012). It is also expected to exacerbate the impacts on terrestrial habitats of increasing colonies of recovering whales and seabirds (Convey and Lebouvier 2009; Favero-Longo, Cannone et al. 2011). At present, the majority of non-indigenous species established in the sub- and maritime Antarctic are very restricted in their distributions (Frenot, Chown et al. 2005); however, several are invasive and widely distributed across the region. Climate change could result in increased rate of spread of invasive species through colonisation of areas exposed by glacial retreat, as has occurred at South Georgia (Cook *et al*., 2010) and in the maritime Antarctic (Olech and Chwedorzewska 2011). Biosecurity measures may be needed to help control dispersal of established non-indigenous species to new locations, particularly given the expected increase in human activities in terrestrial areas (Hughes and Convey, 2010; Convey *et al*., 2011). An important gap in understanding is the degree to which climate change (particularly relating to warming and water availability) may facilitate some established non-indigenous species switching to invasive status, (Frenot, Chown et

al. 2005; Convey 2010; Hughes and Convey 2010; Cowan, Chown et al. 2011), which has been shown for the sub-Antarctic (Chown *et al*., 2012).

Across terrestrial ecosystems of much of the Antarctic, and particularly of the Antarctic Peninsula and Scotia arc archipelagoes, current environmental change predictions lie within what is known of the ecophysiological capacities of the affected biota. In these areas further climate amelioration is expected to (as is already being seen) relax constraints on biological activity, leading to increases in biomass and extent of existing communities. At present there is no indication that the magnitude of these environmental changes will surpass any environmental boundaries for these biota, and hence result in any form of limitation of their occurrence from their current distribution (e.g. southwards movement of current northern boundaries). As noted earlier, in particular locations it is possible that specific combinations and synergies between different environmental parameters might result in local limitation.

Overall, the likely impacts of existing and new non-indigenous species on the native terrestrial ecosystems of Antarctica and the sub-Antarctic islands, along with the continued increased presence of Antarctic fur seals (see 28.2.3 above) are likely to have far greater importance over the timescale under consideration than are those attributable to climate change itself (Turner *et al*., 2009; Convey and Lebouvier, 2009; Convey, 2010).

28.3.4. Economic Sectors

Projections of the economic costs of climate change impacts for different economic sectors in the Arctic are limited, but current assessments suggest that there will be both economic benefits and costs (Forbes, 2011; SWIPA 2011). Non-Arctic actors are likely to receive most of the benefits from increased shipping and commercial development of renewable and non-renewable resources, while indigenous peoples and local Arctic communities will have a harder time maintaining their way of life (Hovelsrud *et al*., 2011).

Arctic communities are exposed to the effects of climate change thru multiple pathways such as changes in weather (temperature, wind, precipitation), via impacts on the natural systems and from their effects on infrastructure and the food sector. Contributing to the complexity of measuring the future economic effects of climate change is the uncertainty in future predictions and the rapid speed of change, which are linked with the uncertainty of the technological and ecological effects of such change (NorAcia 2010). Communities with the same eco-zone may experience different effects from identical climate-related events because of marked local variations in site, situation, culture and economy (Clark *et al*., 2008).

Economic cost estimates have been made for the case of the Alaska economy, and they suggest that heavy reliance on climate-sensitive businesses such as tourism, forestry, and fisheries, renders the economy vulnerable to climate change, and that Alaska Native peoples, reliant on the biodiversity of the Alaskan ecosystem, are being affected disproportionately (Epstein and Ferber, 2011). From the present to 2030, permafrost thawing, amplified flooding and coastal erosion from global warming could add considerably to future costs of public infrastructure in Alaska (SCEIGW 2010). Thawing tundra can cause oil pipelines to buckle and break, causing spills (Epstein et al. 2008).Whether or not there will be these impacts, will depend on the design which may allow for these differential movements (Grosse et al.. 2010). A significant part of Alaska's economy is tourism. Loss of wildlife and habitat, such as spruce tree forests, could lead to a loss of tourism income (NWF 2009). Reductions in seabird and marine mammal populations with unusually warm sea temperatures, and declining salmon harvests could negatively affect tourism, native peoples' way of life, and the Alaskan salmon industry (SCEIGW 2010). It has been estimated that the Shishmaref, Kivalina, and Newtok tribal lands will be unlivable due to storm damage and coastal erosion in a number of years. The cost to re-locate these communities is estimated to be significant (Williams and Hanson, 2007).

28.3.4.1. Fisheries

Predicting the impacts of climate change on future fisheries is difficult because it is unclear whether the responses of marine species observed in the past will continue in the future, and because it is difficult to predict the response of

fisheries to shifts in supply. O'Neill et al. (2010) simulated demand for a composite food commodity under global demographic projections. In dollar terms, food expenditures rise steadily in these scenarios, driven by economic growth and demographic factors of urbanization and population growth. In biophysical terms, population growth alone could account for a 50% increase in seafood demand by 2050 relative to current global production levels (Rice and Garcia, 2011).

Climate change will impact the spatial distribution and catch of some open ocean fisheries in the Barents and Bering Seas (medium certainty). There is strong evidence and considerable data showing links between climate driven shifts in ocean conditions and shifts in the spatial distribution and abundance of commercial species in the Bering and Barents Seas (Mueter and Litzow, 2008; Drinkwater, 2011;Section 28.2.2.2.1). In limited cases, coupled bio-physical models have been used to predict future commercial yield or shifts in fishing locations however these predictions are uncertain (Huse, 2008; Ianelli *et al.*, 2011). Adopting successful strategies for management of Arctic fisheries will be a high priority to ensure that fisheries are managed based on sound science and sustainable harvest practices in the future (Molenaar, 2009). In regions of high yield fisheries, strategies will be needed to modify existing management practices to account for the expected shifts in distribution and abundance of commercial species to prevent overfishing and sustain fishery resources. As discussed in section 28.2.2.1, several North Atlantic commercial fish species exhibited shifts in their spatial distribution and abundance in response to ocean warming (Valdimarsson *et al.*, 2012) which have lead to non-trivial challenges to international fisheries agreements (Arnason, 2012). Techniques are under development to project how harvesters will respond to changing economic, institutional and environmental conditions. These techniques track fishers choices based on revenues and costs associated with targeting a species in a given time and area with a particular gear given projected changes in the abundance and spatial distribution of target species (Haynie and Pfeiffer, 2012). Estimates of future revenues and costs will depend in part on future: demand for fish, global fish markets and trends in aquaculture practices (Merino *et al.*, 2012; Rice and Garcia, 2011). While attempts to project global changes in small pelagic (e.g. anchovy, sardine, capelin and herring) fish markets have been attempted, extending these to larger fish species will be more difficult.

28.3.4.2. Forestry and Farming

A warmer climate is likely to impact access conditions and plant illnesses. In the case of Northern Norway, about half of the arable land area is covered by forest and 40% of it is marsh (Grønlund, 2009). If these areas were to be harnessed for farming, it would be at the cost of forestry production or by drying up the marshlands, which would contribute to more greenhouse emissions. Larger field areas could contribute to land erosion through rainfall and predicted unstable winters, and would likely increase conditions for plant diseases and fungal infections (Grønlund, 2009). If the winter season continues to shorten as a result of climate change (Xu et al. 2013), this would negatively affect access to logging sites. Access is best when frozen ground makes transportation possible in sensitive locations or areas that lack road. If the weather changes when logging has already taken place, sanding of the road may become necessary in order to ensure transportation within a specific timeframe, which carries significant economic costs (Keskitalo, 2008). Impact on the carrying capacity of the ground or road accessibility will thus affect forestry economically. Challenges may include limited storage space for wood (Keskitalo, 2008). A warmer climate may also have positive effects on forestry: In the case of Finland where forestry is of great economic importance, the risk of snow damage to forest is estimated to decrease with about 50% towards the end of the century (Hovelsrud *et al.*, 2011).

28.3.4.3. Infrastructure

Northern safety, security, and environmental integrity are much dependent upon transportation infrastructure. Ice as a provisioning system provides a transportation corridor and a platform for a range of activities and access to food sources (i.e. subsistence hunting and fishing on and around ice, oil and gas development) in the Arctic (Eicken et. al., 2009). While much of the infrastructure in the Arctic, including railways, airports, roads, buildings, communications towers, energy systems, and waste disposal sites for communities, as well as large-scale facilities and waste-containment sites, have been built with weather conditions in mind, much of it remains vulnerable and inadequate to respond to environmental emergencies, natural disasters, and non-environmental accidents

(Governments of Yukon, Northwest Territories, and Nunavut, 2008. A Multi-Modal Transportation Blueprint for the North in National Round Table on the Environment and the Economy 2009, 51; NorAcia 2010).

Rising temperatures and changing precipitation patterns have the potential to affect all infrastructure types and related services, as much of the infrastructure in the North is dependent upon the cryosphere to, for example, provide stable surfaces for buildings and pipelines, contain waste, stabilize shorelines and provide access to remote communities in the winter. Structures built on ice-rich soils will be more vulnerable to thawing and a changing climate than those built on ice-poor soils or bedrock and impacts are likely to be negligible. Communications towers and energy transmission infrastructure located in remote permafrost areas are becoming increasingly susceptible to the risk of failure and, since accessibility may also be an issue and the cost of redundancy is prohibitive, the threat posed by this hazard will likely become increasingly significant. Energy pipelines built over permafrost could be at risk of rupture and leakage, and warmer temperatures are already resulting in shorter winter road seasons. Failure of frozen-core dams on tailing ponds due to thawing and differential settlement, or thawing of tailings piles associated with climate warming, could in its turn result in contaminants being released into the surrounding environment, causing subsequent disastrous and irreversible degradation of sensitive habitat and human health. In the long term marine and freshwater transportation will need to shift its reliance from ice routes to open-water or land-based transportation systems. Of appropriate community adaptations to the predicted changes relocation is one option to deal with persistent flooding and bank erosion (Furgal C., 2008;National Round Table on the Environment and the Economy 2009).The implications for the sea-ice system may prove to have other major impacts as well, including environmental and socio-economic or geopolitical change which may substantially modify types of services offered and their uses by competing interests. Changing sea-ice (multiyear) conditions are suspected i.e. to have a regulating impact on marine shipping and coastal infrastructure through possible hazards on them (Eicken *et. al*., 2009).

28.3.4.4. Inland Transportation, Communication, and Drinking Water

By adapting transportation models to integrate monthly climate model (CCSM3) predictions of air temperature, combined with datasets on land cover, topography, hydrography, built infrastructure, and locations of human settlements, estimates have been made about changes to inland accessibility for northern landscapes northward of 40ºN by mid-21st Century (Stephenson *et al*., 2011). Milder air temperatures and/or increased snowfall reduce the possibilities for constructing inland winter-road networks, including ice roads, with the major seasonal reductions in road potential (based on a 2000 kg vehicle) being in the winter shoulder-season months of November and April. The average decline (compared to a baseline of 2000-2014) for eight circumpolar countries was projected to be -14%, varying from -11 to -82%. In absolute terms, Canada and Russia (both at -13%) account for the majority of declining winter-road potential with ~1x10^6 km^2 being lost.

Climate change impacts have increased the demand for improved communication infrastructure and related services (e.g. cellular and improved citizens band radio (CB) service), and community infrastructure for the safety and confidence in drinking water (National Round Table on the Environment and the Economy 2009). The access, treatment and distribution of drinking water has been and is generally dependent upon a stable platform of permafrost for pond or lake retention, a situation that is currently changing. Several communities have reported the need for more frequent water-quality testing both municipal systems and untreated water sources to ensure its availability (Furgal C., 2008). Demands on infrastructure and building costs is likely to increase with the impact of warming and thawing permafrost.

28.3.4.5. Terrestrial Resource Management (Oil and Gas, Mining, Forestry in the Arctic)

Sea ice retreat and thawing permafrost will have potential direct and indirect impacts on resource exploitation. Longer shipping season and improved access to ports may lead to increased petroleum activities, although possible increased wave activity and coastal erosion may increase costs related to infrastructure and technology. Disappearance of ice roads may restrict onshore exploration activities

The most recent comprehensive assessment of undiscovered petroleum resources is the Circumpolar Arctic Resource Appraisal (CARA) completed in 2008 by US Geological Surveys. The USGS (2008) estimated the Arctic undiscovered petroleum resources to 413 billion barrels of oil equivalents (bboe), about 22 per cent of global undiscovered conventional oil and gas resources. The share of oil (including natural gas liquids) was estimated to 134 bboe (15 per cent of global oil resources) and 279 bboe of gas (30 per cent of global resources). Hence the Arctic contains vast resources of oil, which is hard to replace as transportation fuel, and vast resources of gas, a more climate benign fuel than coal. The petroleum resources are unevenly distributed among Arctic regions and states. Figure 28-5 shows the allocation of oil and gas on regions. Arctic Russia is the major petroleum region with about 40 per cent of total Arctic oil and 70 per cent of total Arctic gas resources. Alaska is second with 28 per cent of oil and 14 per cent of gas.

[INSERT FIGURE 28-5 HERE
Figure 28-5: (top) Regional distribution of Arctic undiscovered oil resources (including NGL), and (bottom) regional distribution of Arctic undiscovered natural gas resources (including NGL). Source: Statistics Norway, 2010.]

The USGS 2008 study revised its assessments with respect to regional resource allocation compared with its own 2000 assessment. USGS (2008) lowered their estimates for oil resources in Norway, Greenland and Russia and raised the estimates for Alaska and Canada. Gas estimates were lowered for Norway and raised for all other regions. For the Arctic as a whole, USGS (2008) assessed the undiscovered petroleum resources to 8.5 per cent below their previous estimate (USGS 2000), whereas Wood Mackenzie (2006) estimated petroleum resources at only 40 per cent of the USGS (2008). These different estimates illustrate the considerable uncertainty on the level of resources in the Arctic.

Tables 28-1 and 28-2 show arctic oil and gas production by 2010 and their share in global supply.

[INSERT TABLE 28-1 HERE
Table 28-1: Arctic oil production in relation to non-OPEC and global supply, reference scenario (%).]

[INSERT TABLE 28-2 HERE
Table 28-2: Arctic gas in relation to MENA and global supply, reference scenario (%).]

Arctic Russia and Alaska are the major producers of oil. Greenland has a large potential, but not yet any production.

The Arctic is also rich in other natural resources, such as minerals and fish. Figure 28-6 Illustrates the dominant contribution of natural resource based industries to regional GDP in the Arctic (2005)

[INSERT FIGURE 28-6 HERE
Figure 28-6: Value added in natural resource-based industries in Arctic regions, 2005 (% of regional GDP). Source: Statistics Norway, 2010.]

In Arctic Russia the extraction of energy alone contributes close to 60 per cent of regional GDP (see Figure 28-7). In Alaska and Arctic Canada the energy and minerals contribute 30-38 per cent, whereas fishing and fish processing are the major elements in Faroe Islands, Greenland and Iceland.

[INSERT FIGURE 28-7 HERE
Figure 28-7: (a) Arctic gas production, reference scenario (Mtoe); and (b) regional distribution of West Arctic gas production, reference scenario (Mtoe). Source: Statistics Norway, 2010.]

Among indirect impacts on resource exploitation are changes related to changing ecosystems and changes in distribution and abundance of species. This may lead to stricter environmental regulations and requirements (e.g. AMAP. Oil and Gas Activities in the Arctic 2007). Conservation management and protected areas designed to address the effects of human actions are well developed and extensive in the Arctic.

28.3.4.6. Anticipated New Resource Exploitation Development in the North

GCMs generally underestimate the duration of the ice-free period in the Arctic Ocean and simulate slower changes than those observed in the past decades (Stroeve *et al.*, 2007). Mokhow and Khon (2008) used a sub-set of climate models that better than other GCMs reproduce the observed sea ice dynamics to project the duration of the navigation season along the NSR and through NWP under the moderate SRES-A1B emission scenario. According to their results, by the end of the 21st century NSR may be open for navigation 4.5±1.3 months per year, while the NWP may be open 2-4 months per year (Figure 28-8). The models did not predict any noticeable changes of the ice conditions in the NWP until the early 2030s.

[INSERT FIGURE 28-8 HERE
Figure 28-8: Projected duration of the navigation period (days) over the North-West passage (1) and Northern Sea route (2). Source: Mokhow and Khon, 2008.]

Analysis indicated that by the end of the 21st century transportation costs from Europe to Asia along the NSR may be up to 15% less than the transit through Suez Canal (Mokhow and Khon 2008). Apart from the less restrictive requirements to the ice class of cargo vessels and decreased demand for ice-breaker's support due to longer open water season this will stimulate the development of the navigation along the NSR and in the longer term also through NWP (Peresypkin and Yakovlev, 2007 from Mokhow and Khon), although in the following two decades commercial shipping in the NWP is unlikely.

Three active proposals for arctic submarine fiber optic cables connecting Eastern Asia with Europe - one through the NSR and two through the NWP and all planned to be in operation before 2015- illustrate the non-shipping uses for sea routes that are being made possible by seasonal ice free periods and which will require at least periodic access for maintenance. (Source: http://www.extremetech.com/extreme/122989-1-5-billion-the-cost-of-cutting-london-toyko-latency-by-60ms).

28.4. Adaptation in the Polar Regions

There is general agreement that both indigenous and non-indigenous people in the Arctic have a long history of adapting to natural variability in climate and the natural resource base, as well as in recent decades rapid socio-economic, cultural and technological change (Forbes and Stammler, 2009; Wenzel, 2009; West and Hovelsrud, 2010; Ford and Pearce, 2010; Bolton *et al.*, 2011). Climate change exacerbates the existing stresses faced by Arctic communities (Rybråten and Hovelsrud, 2010; Crate and Nuttall, 2009), and is only one of many important factors influencing adaptation (Berrang-Ford *et al.*, 2011). Climate adaptation needs to be seen in the context of these inter-connected and mutually reinforcing factors (Tyler *et al.*, 2007; Hovelsrud and Smit, 2010). The complex inter-linkages between societal, economic, political factors and climatic change represent unprecedented challenges for northern communities (Ford *et al.*, 2010; Hovelsrud *et al.*, 2011; Keskitalo, et al 2010; Abele et al., 2009).
There is considerable evidence that changing weather patterns, declining sea-ice, thawing permafrost, and plant and animal species' abundance and composition have consequences for the wellbeing of communities in the Arctic (see 28.2.5.2 and 28.3.4). Sea-ice is particularly important for coastal communities which rely upon it for transportation between communities and hunting areas (Krupnik et al., 2010). Changing the duration and conditions of sea ice and the consequent changes to country food availability significantly impact the wellbeing of communities (Furgal and Seguin, 2006; Ford and Berrang-Ford, 2009; Ford *et al.*, 2010), outdoor tourism (Dawson *et al.*, 2010) and hunting and fishing (Wiig *et al.*, 2008; Brander, 2010).

Adaptation to climate change is taking place at the local and regional levels where the impacts are often felt most acutely and the resources most readily available (Hovelsrud and Smit, 2010). Such adaptation is often taking place despite the lack of national guidelines (Dannevig *et al.*, 2012; Juhola et al., 2012; Glaas et al., 2010). Current experiences and projections of future conditions often lead to technological adaptation responses such as flood and water management and snow avalanche protection (West and Hovelsrud, 2010; Hovelsrud and Smit, 2010) rather than policy responses (Hedensted Lund et al., 2012; Rudberg et al., 2012). Climate variability and extreme events,

such as floods, avalanches and mud slides, are found to be salient drivers of adaptation (Berrang-Ford *et al.*, 2011; Dannevig *et al.*, 2012; Amundsen et al., 2010).

National policies for adaptation are largely in their infancy in the Arctic (Keskitalo 2010a,b; Berrang-Ford et al., 2011; Yamineva 2012). The lack of local scale climate projections, combined with uncertainties in future economic, social and technological developments often act as barriers to adaptation. These barriers, together with other societal determinants such as ethics, cultures, and attitudes towards risk may cause inaction (Adger *et al.*, 2009; West and Hovelsrud, 2010). Resolving divergent values across and within different communities poses a challenge for the increasingly complex societies and governance regimes. A determining factor in building adaptive capacity is the flexibility of enabling institutions to develop robust options (Keskitalo et al., 2009; Hovelsrud and Smit 2010; Forbes et al. 2009; Ford and Goldhar, 2012). In the North American and Scandinavian context, adaptive co-management responses have been developed through land claims settlements and/or multi-scale institutional cooperation to foster social learning (Berkes, 2009; Armitage et al., 2008).

28.4.1. Adaptation and Indigenous Peoples

The adaptive capacity of Arctic indigenous peoples is largely due to an extensive traditional knowledge and cultural repertoire, and flexible social networks (see Chapter 12, section 12.3). The dynamic nature of traditional knowledge is valuable for adapting to current conditions (Tyler et al., 2007; Eira et al., 2012). The sharing of knowledge ensures rapid responses to crises (Ford et. al., 2007). In addition, cultural values such as patience, persistence, calmness, respect for elders and the environment are important for adaptation. Some studies suggest that traditional knowledge may not always be sufficient to meet rapid changes in climate and weather, or extreme events (see also Chapter 12), and it may be perceived to be less reliable because the changing conditions are beyond the current knowledge range (Ingram et al., 2002; Ford et al., 2006; Valdivia et al., 2010; Hovelsrud et al., 2010a). This has in some cases created a sense of a “loss of order in the world” (Turner et al., 2008,) and less confidence in the reliability of knowledge keepers (Chapin III et al., 2006; Hovelsrud and Smit, 2010).

Over the last half-century, the adaptive capacity in some indigenous communities has been challenged by the transition from semi-nomadic hunting groups to permanent settlements (Ford et al, 2010). Forced or voluntary migration as an adaptation response can have deep cultural impacts. The establishment of permanent communities can also led to increasing employment opportunities and income diversification for indigenous peoples, which in turn may cause social inequalities (Ford et al, 2010). However, the current level of skilled labour and formal education may limit the abilities to take advantage of such opportunities (Furgal C., 2008). On the other hand the intergenerational transfers of knowledge and skills through school curricula, land camps, and involvement in community-based monitoring programmes may strengthen adaptive capacity (Bolton et al., 2011; Hovelsrud and Smit, 2010; Ford et. al., 2007; Forbes 2007).

Renewable resource harvesting remains a significant component of Arctic livelihoods and with climate change hunting and fishing has become a riskier undertaking, and many communities are already adapting in a reactive manner (Gearheard *et al.*, 2011; Laidler *et al.*, 2011). Adaptation includes taking more supplies when hunting; constructing more permanent shelters on land as refuges from storms; improved communications infrastructure; greater use of global positioning systems (GPS) for navigation; synthetic aperture radar (SAR) to provide estimates of sea-ice conditions (Laidler *et al.*, 2011) and the use of larger or faster vehicles (Ford et al, 2010). Avoiding dangerous terrain can result in longer and time-consuming journeys which can be inconvenient to those with wage-earning employment (Ford et.al. 2007).

Reindeer herders have developed a wide range of adaptation strategies in response to changing pasture conditions. These include: moving herds to better pastures (Bartsch *et al.*, 2010); providing supplemental feeding (Helle and Jaakkola, 2008; Forbes and Kumpula, 2009); retaining a few castrated reindeer males to break through heavy ice-crust (Reinert et al., 2008); ensuring an optimal herd size (Forbes et al., 2009; Tyler et al., 2007); and creating multicultural initiatives combining traditional knowledge with scientific studies to create and distribute co-produced dataset (Vuojala-Magga *et al.*, 2011; Bongo *et al.*, 2012). Coastal fishers have adapted to changing climate by targeting different species and diversifying income sources (Hovelsrud et al., 2010b).

In some Arctic countries indigenous peoples have successfully negotiated land claims rights and have become key players in addressing climate change, as well as other issues related to education, health-care and economic development (Abele et al., 2009). In some instances this has given rise to tensions over land/water use between traditional livelihoods (e.g. reindeer herding, marine mammal hunting) and new opportunities (e.g. tourism and natural resource development) (Forbes, 2006; Hovelsrud and Smit, 2010). Some territorial governments in Northern Canada promote adaptation by providing hunter support programs (Ford et al., 2006; Ford et. al., 2010).

The health of many indigenous peoples is being affected by the interactions of changes in the climate with ongoing changes in human, economic and biophysical systems (Donaldson et al., 2010). The distribution of traditional foods between communities and the use of community freezers in the Canadian Arctic has improved food security, an important factor for health (Ford et al, 2010). While wage employment may enhance the possibilities for adaptive capacity, greater involvement in full time jobs can threaten social and cultural social cohesion and mental well-being by disrupting the traditional cycle of land-based practices (Berner et al., 2005; Furgal, 2008).

28.4.2. Adaptation and Industrial Development

Increasing access to minerals and fossil fuels and increased shipping, due to reduced sea ice, will bring both opportunities and challenges. The extraction of off-shore fossil fuels in areas where icebergs are a significant threat will require design changes to drilling platforms (McClintock et al, 2007). Some of the resources that will be extracted are expected to be transported by ship to southern markets; other resources may be transported by pipelines whose design requirements will need to take climate change into account. On shore processing plants and particularly waste containment facilities must be able to maintain their structural integrity over the expected long lifetime of a project (Prowse et al, 2009). Unless mines are located close to the coast and port facilities, resupply is generally limited to winter periods and the availability of ice roads, whereas exploration activities are usually restricted to short summer periods with access by air.

Box 28-1. Adapting Critical Infrastructure to Climate Change in Northern Canada

Climate change is increasingly recognized as a critical factor in the design of major infrastructure projects in northern Canada and has been incorporated in environmental impact assessments since the late 1990's (Hayley and Horne, 2008). A risk-based project screening tool has been developed for considering climate change in northern engineered facilities (CEAA, 2003). A study by Canada's National Roundtable on the Environment and the Economy (Government of Canada, 2009) reviewed the use of existing policy tools such as codes and standards, insurance and emergency/disaster management to support wise adaptation of critical infrastructure. The study concluded that there was inadequate technical (including monitoring) information and capacity as well as a systematic assessment of risks to take full advantage of these policy tools. This was in part because of limited interaction between scientists and decision-makers. The lack of systematic assessments meant that often there was unclear responsibility for infrastructure investment and operational decisions.

Adaptation of northern infrastructure to thawing permafrost will largely involve current solutions to reduce the impacts of ground disturbance (CSA, 2010). These include the use of pile foundations (that may need to be deeper to account for climate change), insulation of the surface (which may require thicker gravel pads), clearance of snow (to promote colder winter ground temperatures), adjustable foundations for smaller structures and increased use of artificial cooling with heat-pumps and thermosyphons to ensure that foundation soils remain frozen. Recently developed techniques, such as air-convection embankments may also be utilized. Where permafrost is thin, frozen ice-rich material may be excavated and replaced with thaw-stable material, or intentionally thawed by clearing vegetation and postponing construction for several years until the permafrost has completely degraded and the ground has settled. Finally, a critical adaptive response will be monitoring infrastructure performance; determine if changes in permafrost conditions deviate from those predicted; and decide whether additional adaptation measures are required (Burgess, et al, 2010).

Ice roads and ice bridges that are constructed and maintained each winter provide a relatively inexpensive way to supply northern communities and industry, particularly the rapidly expanding oil/gas and mining sector. In addition, these ice-roads link communities and facilitate social and cultural activities, and provide access to hunting, fishing, or trapping areas (Furgal and Prowse, 2008; Ford et al., 2008).

_____ END BOX 28-1 HERE _____

28.5. Arctic Pollution and Climate Change

Recent studies suggest that transport pathways, intercompartmental distribution, bioaccumulation and transformation of environmental contaminants such as persistent organic pollutants (POPs), mercury (Hg) and radionuclides in the Arctic and the globe as such may be affected by climate change (AMAP 2011, UNEP/AMAP 2011). Ambient temperature variability and temperature gradients directly affect the volatilization, remobilization, and transport pathways of mercury and POPs in the atmosphere, ocean currents, sea ice and rivers. Thus, the rate and efficacy of transport of these contaminants into the Arctic and their occurrence in the environment are expected to be significantly affected by climate change (Macdonald and Loseto, 2010; AMAP 2011).

An oxidized form of gaseous mercury in the Arctic atmosphere is deposited on ice and snow surfaces in episodic atmospheric mercury depletion events (AMDEs). The oxidation is enhanced by photochemical reactions involving halogens released from freezing sea ice. The extent of sea ice and changes in the timing of freezing will affect AMDE dynamics and the deposition of mercury in the Arctic (Steffen *et al*., 2007).

The fate of POPs and mercury in the terrestrial environment is mainly controlled by temperature and biogeochemical processes (Teng *et al*., 2012; AMAP 2011). Changes in the carbon cycle by thawing permafrost will affect the methylation of mercury and the bioaccumulation and release of POPs. Ma et al. (2011) and Hung et al. (2010) demonstrated that POPs are already being remobilized into the air from sinks in the Arctic region as a result of decreasing sea ice and increasing temperatures.

There is evidence that climate change will cause alterations in trophic structures, food sources and migratory patterns, which may influence bioaccumulation and biomagnification of some POPs. There is also concern about effects from multiple stressors, including exposure to POPs and climate change, in environments such as the Arctic where species are living at the edge of their physiological tolerance (Macdonald *et al*., 2005; Borgå *et al*., 2010; Teng *et al*., 2012; UNEP/AMAP 2011).

There is *high confidence* that climate change will affect the fate and impacts of anthropogenic contaminants in the Arctic, but the extent to which this will occur is uncertain.

28.6. Research and Data Gaps

Our understanding of a region of the globe as large and heterogeneous as the Polar Regions and with multiple human and development stresses is still imperfect. For example, ice-sheets in Greenland and Antarctica and sea-ice in the Arctic are declining faster than models predict. Many of the physical and biological systems in the Polar Regions are sensitive to rapid change and could tip into new regimes as they cross critical thresholds. Systematic monitoring will be essential for the early detection of these changes and remote-sensing will be particularly valuable in providing geographically comprehensive coverage.

Increasing evidence indicates that changes in the Polar Regions are having impacts on global-scale physical and human systems. These include: effects on the global climate system via changes in thermohaline and atmospheric circulation; the enhanced release of greenhouse gases, such as from land and ocean based sources of methane and carbon; and intensification of natural-resource exploitation and expansion of international trade. Understanding these changes will require international and interdisciplinary collaboration.

The combined effects of climate-change, globalization and other stresses are producing impacts on northern residents and these also need to be carefully monitored so there is adequate and relevant information for developing appropriate adaptation measures and policies such as new regulations governing infrastructure design and natural resource harvesting. Although there is a considerable body of traditional and western experience in adapting to changing climate and resource availability this may be inadequate if the magnitude and rate of the change is greater than in the past. Mechanisms will be required to develop, share and evaluate adaptation response options.

Frequently Asked Questions

FAQ 28.1: What will be the net socio-economic impacts of change in the Polar Regions?

Climate change will have cost and benefits for Polar Regions. In the Arctic, positive impacts include new possibilities for economic diversification, marine shipping, agricultural production, and forestry. Northern Sea Route is predicted to have up to 125 days per year suitable for navigation by 2050, while the heating energy demand in the populated Arctic areas is predicted decline by 15%. In addition, there could be greater accessibility to offshore mineral and energy resources although challenges related to environmental impacts as well as effects on traditional livelihoods of northern residents are possible. Changing sea ice condition and permafrost thawing may cause damage to installations such as bridges, pipelines, drilling platforms, hydropower and other infrastructure. This poses major economic costs and human risks, although these impacts are closely linked to the design of the structure. Furthermore, warmer winter temperatures will shorten the accessibility of ice roads that are critical for communications between settlements and economic development. Since 1970s maximum ice thickness decreased up to 15 cm in rivers within Siberia. Statistically, a long-term mean increase of 2 to 3°C in autumn and spring air temperature produces an approximate 10 to 15 day delay in freeze-up and advance in break-up, respectively. As a result, many of the ice roads may become less viable option than the all-weather roads with implications for significantly increased costs. Particular concerns are associated with projected increase in the frequency (by 20-50% in the coming decade) and severity (with 35 to 60% increase in peak break-up water levels) ice-jam floods on Siberian rivers. They may have potentially catastrophic consequences for the villages and cities located in the river plain, as exemplified by the 2001 Lena River flood, which demolished most of the buildings in the city of Lensk. Climatic, accecerbated by other large-scale changes can have potentially large effects on Arctic communities, where relatively simple economies leave a narrower range of adaptive choices. Changing sea ice conditions will impact indigenous livelihoods, and changes in resources, including marine mammals, could represent a significant economic loss for many local communities. Food security and health and well-being are expected to be impacted negatively. In the Antarctic, tourism is expected to increase, and risks exist of accidental pollution from maritime accidents, and an increasing likelihood of introductions of alien species to terrestrial environments. Fishing for Antarctic krill near to the Antarctic continent is expected to become more common during winter months in areas where winter sea ice extent reduces.

FAQ 28.2: Why are changes in sea ice so important?

Sea ice is a dominant feature of Polar Oceans. Shifts in the distribution and extent of sea ice during the growing season impacts the duration, magnitude and species composition of primary and secondary production in the Polar Regions. With less sea ice many marine ecosystems will be experiencing shifts from light limitation to nutrient limitations as well as shifting balance between the primary production by ice algae and phytoplankton with implications for Arctic food webs. Sea ice is also an important habitat for juvenile Antarctic krill, providing food and protection from predators. While the overall sea ice extent in the Southern Ocean has not changed markedly in recent decades, there have been increases in oceanic temperatures and large regional decreases in winter sea ice extent and duration in the western Antarctic Peninsula region of West Antarctica and the islands of the Scotia Arc. Changes in sea ice will have bottom up consequences for marine foodwebs. Mammals and birds utilize sea ice as haul-outs during foraging trips (seals, walrus, and polar bears in the Arctic and seals and penguins in the Antarctic). Some seals (e.g. Bearded seals in the Arctic and crabeater and leopard seals in the Antarctic) give birth and nurse pups in pack ice. Shifts in the spatial distribution and extent of sea ice will alter the spatial overlap of predators and their prey. According to model projections, within 50-70 years loss of hunting habitats may lead to extirpation of the polar bears from seasonally ice-covered areas, where currently two thirds of their world population live. The vulnerability of marine species to changes in sea ice will depend on the exposure to change, the sensitivity of the

species to changing environmental conditions and adaptive capacity of each species. More open waters and longer ice-free period in the northern seas enhance the effect of wave action and coastral erosion with implications for coastal communities and infrastructure.

29.8. Facilitating Adaptation and Avoiding Maladaptation

29.9. Research and Data Gaps

Frequently Asked Questions
29.1: Are small islands experiencing the impacts of climate change?
29.2: Why is it difficult to detect and attribute changes on small islands to climate change?
29.3: Why is the cost of adaptation to climate change so high in small islands?

References

Executive Summary

The distinction between *observed* and *projected* impacts of climate change is often not clear in the literature on small islands (*high agreement*). Many publications deal with both types of impact, often using a recent 'observed' impact relating to some extreme weather- climate- or ocean-related event as an analogy to what may happen in the future. Moreover, much of the literature on projected climate change impacts on small islands is not specific about the scenario (s) used, partly because of the difficulty in moving from global-scale scenarios and models to the scale of small islands. [29.4] Consequently, there is *low confidence* in the magnitude of projected impacts in some sectors and systems of small islands. However, there is evidence that this challenge can be partly overcome with continued improvements in downscaling, as is demonstrated by the use of downscaled SRES scenarios in a comprehensive assessment of the vulnerability of fisheries in 22 Pacific island countries. As these and other studies are duplicated elsewhere, confidence in projected impacts of climate change on small islands will increase. [29.3, 29.4.2]

Many impacts on small islands are generated from processes well beyond the borders of an individual nation or island and generally they have negative effects (*high confidence, robust evidence).* Trans-boundary impacts on small islands may originate in distant regions including continental countries and high latitudes. Examples of the former include airborne dust from the Sahara and Asia reaching small islands far down-drift from the desert source, and examples of the latter include large ocean swells generated by extra tropical cyclones and high latitude low pressure systems. [29.5.1, 29.5.2] Other trans-boundary impacts result from invasive plant and animal species that reach the warmth of tropical small islands and the spread of aquatic pathogens that may have implications for human health. For island communities the trans-boundary implications of existing and future 'invasions' and human health challenges are projected to increase in a changing climate. [29.3.3.2, 29.5.3, 29.5.5]

For most small islands climate change is just one of a series of multiple stresses that must be coped with, and often it is not the most important one *(medium agreement, medium confidence*). Increasingly there are arguments that priority in the short-term should be given to addressing immediate development problems such as water supply, waste management, deteriorating ecosystems and food security. [29.3.3] We agree that addressing the critical social, economic and environmental issues of the day will *likely* increase human and environmental resilience to the longer-term impacts of climate change. [29.6.1, 29.6.2.3, Figure 29-5]

Adaptation and mitigation on small islands are not trade-offs, but can be regarded as complementary components in the response to climate change (*medium confidence).* At least three key areas for adaptation-mitigation inter-linkages in small islands are identified here: energy supply and use, tourism infrastructure and activities, and coastal wetlands. The alignment of these sectors for potential emission reductions together with adaptation needs offers co-benefits and opportunities in small islands. [29.7.2, 29.8] Lessons learned from adaptation and mitigation experiences in one island may offer some guidance to other small island states, though we have *low confidence* in the wholesale transfer of adaptation and mitigation options when the lenses through which they are viewed differ from one island state to the next, based on cultural, socio-economic, ecological and political values. [29.6.2, 29.8]

Assistance from the international community is vital for supporting adaptation and mitigation programs in small islands, though there is increasing concern that some types of interventions may be maladaptive (*medium evidence*). Caution is needed to ensure that donors are not driving the climate change agenda in small islands, as there is a risk that donor-driven adaptation and mitigation aid may not address the critical challenges confronting island governments and communities, and may not be aligned with the sustainable development goals of small islands (*high agreement*). This may lead to inadequate adaptation or a waste of scarce resources and may unintentionally cause enhanced vulnerability by supporting inappropriate adaptation strategies that are externally derived, rather than optimizing the benefits of local practices that have proven to be efficacious through time. [29.8, Box 29-1, 29.6.2.3, 29.6.3]

Island vulnerability to climate change may be related to the experience and perceptions of islanders to both climate and non-climate stressors (*medium agreement*). Islands and islanders are recognized for their long experience of adapting to a range of hazards including extreme weather-climate- and ocean-related events and for their resilience in coping with such hazards. We have *medium confidence* that adaptive capacity is better when the frequency of hazards is greater, but there may be limits to this capacity when small islands are going through rapid socio-economic change. [29.3.3.1, 29.6.1, 29.6.2]

29.1. Introduction

It has long been recognized that greenhouse gas emissions from small islands are negligible in relation to global emissions, but that the threats of climate change and sea-level rise to small islands are very real. Indeed, it has been suggested that the very existence of some atoll nations are threatened by rising sea levels associated with global warming. Whilst such extreme scenarios are not applicable to all small island nations, there is no doubt that on the whole the impacts of climate change on small islands will have serious negative effects especially on socio-economic conditions and bio-physical resources – although impacts will be ameliorated by the extent and effectiveness of adaptation.

The small islands considered in this chapter are principally sovereign states and territories located within the tropics of the southern and western Pacific Ocean, central and western Indian Ocean, the Caribbean Sea, and the eastern Atlantic off the coast of west Africa, as well as in the more temperate Mediterranean Sea.

Although these small islands nations are by no means homogenous politically, socially, or culturally, or in terms of physical size and character or economic development, there has been a tendency to generalise about the potential impacts on small islands and their adaptive capacity. In this chapter we attempt to strike a balance between identifying the differences between small islands as well as recognising that small islands tend to share a number of common characteristics that have distinguished them as a particular group in international affairs. Also in this chapter we reiterate some of the frequently voiced and key concerns relating to climate change impacts, vulnerability and adaptation whilst emphasising a number of additional themes that have emerged in the literature on small islands since the IPCC Fourth Assessment. These include the relationship between climate change policy, activities and development issues; externally generated trans-boundary impacts; and the implications of risk in relation to adaptation and the adaptive capacity of small island nations.

29.2. Major Conclusions from Previous Assessments

Small islands were not given a separate chapter in the IPCC First Assessment (FAR) in1990 though they were discussed in the chapter on 'World Oceans and Coastal Zones' (Tsyban *et al*., 1990). Two points were highlighted. First, that a 30-50 cm sea-level rise projected by 2050 would threaten low islands, and that a 1 m rise by 2100 'would render some island countries uninhabitable' (Tegart *et al*., 1990: 4). Second, the costs of protection works to combat sea-level rise would be extremely high for small island nations. Indeed, as a percentage of GDP the Maldives, Kiribati, Tuvalu, Tokelau, Anguilla, Turks and Caicos, Marshall Islands and Seychelles were ranked among the ten nations with the highest protection costs in relation to GDP (Tsyban *et al*., 1990: 6. 4). Over twenty years later these two points continue to be emphasized. For instance, although small islands represent only a fraction of total global damage projected to occur due to a sea-level rise of 1.0 m by 2100 (SRES A1 scenario) the actual damage costs for the small island states is enormous in relation to the size of their economies (Anthoff *et al*., 2010: 328) with several small island nations (Nauru, Marshall Islands, Palau, Federated States of Micronesia) being included in the group of ten countries with the highest relative impact projected for 2100 (Anthoff *et al*., 2010: 328-330).

The Second Assessment (SAR) in 1995 confirmed the vulnerable state of small islands, now included in a specific chapter titled 'Coastal Zones and Small Islands' (Bijlsma, *et al*., 1996). However, importantly the SAR recognized that both vulnerability and impacts would be highly variable between small islands and that impacts were 'likely to be greatest where local environments are already under stress as a result of human activities' (Bijlsma, *et al*., 1996: 290-291). The report also summarized results from the application of a common methodology for vulnerability and adaptation analysis that gave new insights into the socio-economic implications of sea-level rise for small islands including: negative impacts on virtually all sectors including tourism, freshwater resources, fisheries and agriculture, human settlements, financial services and human health; protection is likely to be very costly; and, adaptation would involve a series of tradeoffs. It also noted that major constraints to adaptation on small islands included: lack of technology and human resource capacity, serious financial limitations, lack of cultural and social acceptability and uncertain political and legal frameworks. Integrated coastal and island management was seen as a way of overcoming some of these constraints.

The Third Assessment (TAR) in 2001 included a specific chapter on 'Small Island States'. In confirming previously identified concerns of small island states two factors were highlighted, the first relating to sustainability noting that 'with limited resources and low adaptive capacity, these islands face the considerable challenge of meeting the social and economic needs of their populations in a manner that is sustainable' (Nurse *et al*., 2001: 845). And the second, that there were other issues faced by small island states concluding that 'for most small islands the reality of climate change is just one of many serious challenges with which they are confronted' (Nurse *et al*., 2001: 846). Both of these themes are raised again and assessed in the light of recent findings in the present chapter.

Until the Fourth Assessment (AR4) in 2007, sea-level rise had dominated vulnerability and impact studies of small island states. Whilst a broader range of climate change drivers and geographical spread of islands was included in the 'Small Islands' chapter, Mimura *et al*. (2007) prefaced their assessment by noting that the number of 'independent scientific studies on climate change and small islands since the TAR' had been quite limited and in their view 'the volume of literature in refereed international journals relating to small islands and climate change since publication of the TAR is rather less than that between the SAR in 1995 and TAR in 2001' (Mimura *et al*., 2007: 690).

Since AR4 the literature on small islands and climate change has increased substantially. A number of features distinguish the literature we review here from that included in earlier assessments. First, the literature appears more sophisticated and does not shirk from dealing with the complexity of small island vulnerability, impacts and adaptation or the differences between island states. Second, and related to the first, the literature is less one-dimensional, and deals with climate change in a multidimensional manner as just one of several stressors on small island nations. Third, the literature also critiques some aspects of climate change policy, notably in relation to development and security of small islands, and suggests that adaptations for the future are being placed above

critical development needs of the present. As a result, it is argued, there is a reduction in resilience that will have serious ramifications for small island adaptation in the future.

29.3. Observed Impacts of Climate Change, including Detection and Attribution

The distinction between *observed* impacts of climate change and *projected* impacts is often unclear in the small islands literature and discussions. Publications frequently deal with both aspects of impacts interchangeably, and use observed impacts from, for instance an extreme seasonal event, as an analogy to what may happen in the future due to climate change (e.g. Lo-Yat *et al.,* 2011). The key climate and ocean drivers of change that impact small islands include variations in air and ocean temperatures, ocean chemistry, rainfall, wind strength and direction, sea-levels and wave climate and particularly the extremes such as tropical cyclones, drought and distant storm swell events. All have varying impacts, dependent on the magnitude and frequency and temporal and spatial extent, as well as on the bio-physical nature of the island and its social, economic and political setting.

[INSERT FIGURE 29-1 HERE
Figure 29-1: This schematic describes common tropical island typology from young high volcanic islands (left) through to atolls (submerged volcanics) on the far right. This simple overview highlights important components such as elevation and differing land and marine resources as well as the presence of coral reefs. On both high and low islands coastal settlement patterns predominate. Elevated limestone islands and islands comprised of 'continental' rocks are not included in this figure, but see Table 29-3.]

29.3.1. Observed Impacts on Island Coasts and Marine Biophysical Systems

29.3.1.1. Sea Level Rise, Inundation, and Shoreline Change on Small Islands

Sea-level rise poses one of the most widely recognized climate change threats to low-lying coastal areas (Church and White 2011; Cazenave and Llovel, 2010; Nicholls and Cazenave, 2010). This is particularly important in small islands where the majority of human communities and infrastructure are located in coastal zones with limited relocation opportunities especially on atoll islands (Woodroffe, 2008) (Figure 29-1). Rates of global average sea-level rise have continued at approximately 3.3 mm yr $^{-1}$ between 1993 and 2011 and acceleration is detected in longer records since 1870 (Merrifield *et al.,* 2009; Church and White, 2011) (See Chapter 13, Working Group 1). Rates of sea-level rise are however not uniform across the globe and large regional differences have been detected including in the south Indian Ocean and tropical Pacific, where rates have been significantly higher than the global average (Meyssignac *et al.,* 2012). In the tropical western Pacific where a large number of small island communities exist, rates up to four times the global average (approximately 12 mm yr $^{-1}$) have been reported between 1993 and 2009 and are generally thought to describe transient rates associated with natural cyclic climate phenomena such as ENSO (El Niño-Southern Oscillation) (Cazenave and Remy, 2011; Becker *et al*., 2012). Large interannual variability in sea level has also been demonstrated from the Indian Ocean (e.g Chagos Archipelago, Dunne *et.al.,* 2012) whilst in the Caribbean Palanisamy et al. (2012) found that over the last 60 years the mean rates of sea-level rise in the Caribbean region were similar to the global average ~ 1.8mm yr^{-1}.

There are few long-term sea level change trends for individual small island locations and the situation is hampered in many sites by the absence of adequate monitoring regimes. Furthermore, sea flooding and inundation is frequently associated with sea level extremes caused by transient phenomena, e.g.; surge, storm wave and routine lunar (tidal) cycles (Vassie *et al.,* 2004; Zahibo *et al*., 2007; Komar and Allan, 2008; Haigh *et al*., 2011). For example, high spring tide floods at Fongafale Island, Funafuti Atoll, Tuvalu, have been well publicized and study has shown that areas of the central portion of Fongafale are already below sea-level at high spring tide (Yamano *et al.,* 2007). Rates of relative sea level rise at Funafuti between 1950 – 2009 has been approximately three times higher than the global average (Becker *et al.,* 2012) and saline flooding of internal low-lying areas occurs regularly and is expected to become more frequent and extensive over time (Yamano *et al.,* 2007).

Documented cases of coastal inundation and erosion often cite extenuating circumstances such as vertical subsidence, engineering works, development activities or beach mining. Three examples can be cited. First, on the Torres Islands, Vanuatu communities have been displaced due to increasing inundation of low-lying settlement areas due to a combination of tectonic subsidence and sea-level rise (Ballu *et al.,* 2011). Second, on Anjouan Island, Comores in the Indian Ocean, Sinane et al. (2010) found beach aggregate mining was a major contributing factor influencing rapid beach erosion. Third, the intrinsic exposure of rapidly expanding settlements and agriculture in the low-lying flood prone Rewa Delta, Fiji is shown by Lata and Nunn (2012) to place populations in increasingly severe conditions of vulnerability to flooding and marine inundation.

Since the AR4 several studies have documented changes in island shorelines over the last few decades. Historical shoreline position change over 20 – 60 years on 27 central Pacific atoll islands showed that total land area remained relatively stable in 43 per cent of islands, whilst another 43 per cent had increased in area; and the rest showed a net reduction in land area (Webb and Kench, 2010). Dynamic responses were also found in a four year study of 17 relatively pristine islands on two other central Pacific atolls in Kiribati by Raney (2011) who concluded that sea-level rise was not likely to be the main influencing factor in these shoreline changes. On uninhabited Raine Island on the Great Barrier Reef, Dawson and Smithers (2010) also found that shoreline processes were dynamic but that island area and volume increased 6 per cent and 4 per cent, respectively between 1967 and 2007. Overall, these and other studies conclude that normal seasonal erosion and accretion processes appear to predominate over any long-term morphological trend or signal.

In many locations changing patterns of human settlement and direct impacts on shoreline processes present immediate erosion challenges in populated islands and coastal zones (Yamano *et al*., 2007; Storey and Hunter, 2010; Novelo-Casanova and Suarez, 2010) and mask attribution. A study of Majuro atoll (Marshall Islands) found that erosion was widespread but attribution to factors like sea level rise were masked by pervasive anthropogenic impacts to the coastal system (Ford, 2012). Similarly a study of three islands in the Rosario Archipelago (Colombia) reported shoreline retreat over a 50-55 year span and found Grande, Rosario, and Tesoro Islands had lost 6.7, 8.2 and 48.7 per cent of their land area respectively. Erosion was largely attributed to management issues on densely settled Grande Island, whilst sea level increase and persistent northeast winds enhanced erosion on uninhabited Rosario, and Tesoro (Restrepo *et al.,* 2012). Likewise, Cambers (2009) reported average beach erosion rates of 0.5 m yr^{-1} in eight Caribbean islands from 1985-2000 and whilst the study could not quantify the extent of attribution it did highlight that greater erosion rates were positively correlated with the number of hurricane events. Alternately, Etienne and Terry (2012) found the net shoreline impacts of a category 4 cyclone which passed within 30 km of Taveuni Island (Fiji) nourished shorelines with fresh coralline sediments despite localized storm damage. These studies contribute to improved understanding of island shoreline processes and change since AR4 though the vulnerability of small island shores and low-lying areas to increasing inundation and erosion in response to sea level rise and other potential climate change stressors provided in AR4, remains unchanged.

29.3.1.2. Coastal Ecosystem Change on Small Islands: Coral Reefs and Coastal Wetlands

Coral reefs are an important resource in small tropical islands and the culture and wellbeing of island communities is linked to their on-going function and productivity. They play a significant role in supplying sediment to island shores and in mediating wave energy this reducing potential at-shore erosion. They also provide habitat for a host of marine species upon which many island communities are dependent for subsistence diets as well as underpinning beach and reef-based touristic economic activity (Bell *et al.,* 2011; Perch-Nielsen, 2010). The documented sensitivity of coral reef ecosystems to climate change is summarized elsewhere (see Box CC-CR).

Increased coral bleaching due to thermal stress and reduced calcification rates due to increasing CO_2 concentration are expected to affect the function and viability of living reef systems (Hoegh-Guldberg *et al.,* 2007; Eakin *et al.,* 2009) and some studies are starting to observe impacts consistent with regional reef decline (De'ath *et al*., 2009; Tanzil *et al.,* 2009; Cantin *et al.,* 2010). Unprecedented bleaching events in small islands have been recorded iin the remote Phoenix Group (Kiribati) where there had been near 100 per cent coral mortality in the lagoon environment and 62 per cent mortality on the outer leeward slopes of the otherwise pristine reefs of Kanton Atoll during 2002 / 2003 (Alling *et al*., 2007). Similar patterns of mortality were observed in four other atolls in the Phoenix group and

temperature-induced coral bleaching was also recorded in isolated and unpopulated Palmyra Atoll during the 2009 ENSO event (Williams *et al*., 2010). In 2005 extensive bleaching was recorded at 22 sites around Rodrigues Island in the western Indian Ocean with up to 75% of the dominant species affected in some areas (Hardman *et al*., 2007). Studies of the severe 1998 El Niño bleaching event in the tropical Indian Ocean showed reefs in the Maldives, Seychelles and Chagos Islands were among the most impacted (Cinner *et al*., 2012; Tkachenko, 2012). In 2005 a reef survey around Barbados following a Caribbean regional bleaching event revealed the most severe bleaching ever recorded with approximately 70% of corals impacted (Oxenford *et al*., 2008). Globally, the incidence and implications of temperature-related coral bleaching in small islands is well documented and the synergistic effect of increasing ocean acidification can be considered a threat to the long-term persistence of island coral reef ecosystems (see Box CC-OA).

Island reefs have limited defences against thermal stress and acidification. However studies such as Cinner et al. (2012) and Tkachenko (2012) highlight that whilst recovery from bleaching is variable, some reefs show greater resilience that has important implications for reef protection and management regimes. Additionally, there is evidence that coral reef resilience is enhanced in the absence of other environmental stresses such as declining water quality. In Belize chronologies of growth rates in massive corals *Montastraea faveolata* over the past 75–150 years show that the bleaching event in 1998 was unprecedented but that the severity of the response also appeared to stem from reduced thermal tolerance resulting from the direct effect of human coastal development (Carilli *et al*., 2010). Likewise a study over a 40 year period (1960's – 2008) in the Grand Recif of Tulear, Madagascar concluded that severe degradation was mostly ascribed to direct anthropogenic disturbance of the near shore marine environment, despite an average 1^0C increase in temperature over this period (Harris *et al*., 2010). Coral recovery following the 2004 bleaching event in the central Pacific atolls Tarawa and Abaiang (Kiribati) was also noted to likely be improved in the absence of direct human impacts (Donner *et al*., 2010).

The loss of coral reef habitat has dire implications to coastal fisheries (Pratchett *et al*., 2009) in small islands where reef based subsistence and tourism activities are often critical to the wellbeing and economies of islands (Bell *et al*., 2011). In Kimbe Bay, Papua New Guinea 65% of coastal fish are dependent on living reefs at some stage in their life cycles and that there is a decline in fish abundance following reef degradation (Jones *et al*., 2004). Even where coral reef recovery occurs following bleaching, reef associated species composition may not recover to its original state (Pratchett *et al*., 2009; Donner *et al*., 2010). In reefs where bleaching has not been an immediate threat, SST anomaly events like that reported by Lo-Yat *et al*., (2011) between 1996 and 2000, showed an associated lag in larval supply of coral reef fishes of Rangiroa Atoll, French Polynesia. Higher temperatures have also been implicated in negative affects to spawning of adult reef species (Munday *et al*., 2009; Donelson *et al*., 2010).

Like coral reefs, mangroves and sea grass environments provide a range of ecosystem goods and services (Polidoro *et al*., 2010 and Waycott *et al*., 2009) and both habitats play a significant role in the wellbeing of small island communities. Mangroves in particular perform a host of commercial and subsistence uses as well as providing natural coastal protection from erosion and storm events (Ellison, 2009; Krauss *et al*., 2010; Waycott *et al*., 2011).

Sea-level rise is reported as the most significant climate change threat to the survival of mangroves (McKee *et al*., 2007; Waycott *et al*., 2011) and the loss of seaward edge of mangroves at Hungry Bay, Bermuda has been recorded by Ellison (1993) who attributes this to ongoing sea-level rise and the inability of mangroves to tolerate the increased inundation at the seaward margin. Elsewhere in the Caribbean and tropical Pacific observations vary in regards to the potential for sedimentation rates in mangroves forests to keep pace with sea-level rise (McKee *et al*., 2007; Krauss *et al*., 2003). In Kosrae and Pohnpei Islands (Federated States of Micronesia), Krauss *et al*., (2010) found significant variability in mangrove average soil elevation changes due to deposition from a deficit of 4.95 mm y^{-1} to a surplus of 3.28 mm y^{-1} relative to their sea-level rise estimates. This depositional potential is mostly reported from high island studies via the addition of terrigenous sediment inputs. However, Rankey's (2011) study of shoreline change in atolls in Kiribati also noted natural seaward migration (up to 40m) of some mangrove areas between 1969 and 2009 suggesting sediment accretion can also occur in the absence of terrigenous inputs. Otherwise, in the absence of vertical accretion landward migration may occur where accommodation space permits (Gilman *et al*., 2008) though in small islands accommodation space is seldom extensive as illustrated by Martinique in the Caribbean (Schleupner, 2008).

The response of sea grass to climate change stress is also likely to be complex, regionally variable and manifest in quite different ways. A study of seven species of sea grasses from tropical Green Island, Australia highlighted the variability in response to heat and light stress (Campbell *et al*., 2006). Light reduction may be a limiting factor to sea grass growth due to increased depth (Ralph *et al.,* 2007) and Ogston and Field (2010) observed that a 20 cm rise in sea level may double suspended sediment loads and turbidity in shallow waters on Hawaii's Molokai Island's fringing reefs, with negative implications to photosynthetic species such as seagrass. Otherwise, temperature stress is most commonly reported as the main expected climate change impact on sea grass (e.g. Marbá and Duarte 2010; Campbell *et al.,* 2006; Waycott *et al.,* 2011). Literature on seagrass diebacks in small islands is scarce but research in the Balearic Islands (Western Mediterranean) has shown that over a six-year study, sea grass shoot mortality and recruitment rates were negatively influenced by higher temperature (Marbá and Duarte, 2010).

29.3.2. Observed Impacts on Terrestrial Systems: Island Biodiversity and Water Resources

Climate change impacts on terrestrial biodiversity on islands, frequently interacting with several other drivers (Blackburn *et al*., 2004; Didham *et al*., 2005), fall into three general categories namely: (a) ecosystem and species horizontal shifts and range decline; (b) altitudinal species range shifts and decline mainly due to temperature increase on high islands; and (c) exotic and pest species range increase and invasions mainly due to temperature increase in high latitude islands. Due to the limited area and isolated nature of most islands, these effects are generally magnified compared to continental areas and may cause species loss especially in tropical islands high in endemics. For example, decline in the long-term persistence of freshwater-dependent ecosystems within two low-lying Caribbean carbonate islands in the Bahamas have been attributed to the synergistic impacts of increasing sea level and reduced rainfall. Greaver and Sternberg (2010) found that during periods of reduced rainfall the shallow freshwater lens subsides and contracts landward and ocean water infiltrates further inland below coastal strand vegetation. The combination of drier conditions and saline incursion in deeper soils negatively impacts vegetation formerly reliant on deeper freshwater reserves. Sea level rise has been observed to threaten the long-term persistence of freshwater-dependent ecosystems within low-lying islands in the Florida Keys in the northern end of the Caribbean (Goodman *et al*., 2012). On Sugarloaf Key, Ross et al. (2009) found pine forest area declined from 88 to 30 h from 1935 to 1991 due to increasing salinization and rising ground water, with vegetation transitioning to more saline tolerant species such as mangroves.

Whilst there are many studies that report observations associated with temperature increases in mid- and high-latitude islands, such as the Falkland Islands and Marion Islands in the south Atlantic and south Indian ocean respectively (Bokhorst *et al*., 2007; 2008; (Le Roux *et al*., 2005) and Svalbard in the Arctic (Webb *et al*., 1998) there are few equivalent studies in tropical small islands. One exception is a recent study of the tropical bird species the Mauritius kestrel that indicates changing rainfall conditions in the island of Mauritius over the last 50 years has resulted in this species having reduced reproductive success due to a mismatch between the timing of breeding and peak food abundance (Senapathi *et al*., 2011).

Increasing global temperatures also lead to altitudinal species range shifts and contractions within high islands with an upward creep of the tree line and associated faunal species (Benning *et al*., 2002). Comparative vegetation distribution and composition studies in sub-Antarctic Marion Island, found an altitudinal shift of 3.4 m per year for plant species (Parolo and Rossi 2008). Comparative effects also occur in the tropics such as the Hawaii Volcano National Park where comparison of sample plots over a 40 year period from 1966-67 to 2008 show climate change attributed adaptation of fire adapted grasses upward in elevation (Angelo and Daehler, 2012). Reduction in the numbers and sizes of endemic populations caused by such habitat constriction and changes in species composition in mountain systems may result in demise and possibly extinction of endemic species (Chen *et al*., 2009; Pauli *et al*., 2007; Sekercioglu *et al.,* 2008). Altitudinal temperature change has also been reported to influence the distribution for disease vectors such as mosquitoes potentially threatening biota unaccustomed to such vectors (Freed *et al*., 2005).

Freshwater supply in small island environments has always presented challenges and has been an issue raised in all previous IPCC reports. On high volcanic and granitic islands small and steep river catchments respond rapidly to rainfall events and watersheds generally have restricted storage capacity. On porous limestone and low atoll islands

surface runoff is minimal and water rapidly passes through the substrate into the ground water lens. Rainwater harvesting is also an important contribution to freshwater access and alternatives like desalination have mixed success in small island settings due to operational costs (White and Falkland, 2010).

Rapidly growing demand, land use change, urbanisation and tourism are already placing significant strain on the limited freshwater reserves in small island environments (Cashman *et al*., 2010; Emmanuel and Spence, 2009; White and Falkland, 2010). In the Caribbean where there is considerable variation in the types of freshwater supplies utilised concern over the status of freshwater availability has been expressed for at least the past 30 years (Cashman *et al*., 2010). There have also been economic and management failures in the water sector not only in the Caribbean (Mycoo, 2007) but also in small islands in the Indian (Payet and Agricole, 2006) and Pacific oceans (Moglia *et al*., 2008a; 2008b; White *et al*., 2007) .

These issues also occur on a background of decreasing rainfall and increasing temperature. Rainfall records averaged over the Caribbean region for 100 years (1900-2000) show a consistent 0.18 mm/year reduction in rainfall, a trend that is projected to continue (Jury and Winter, 2010), In contrast, analysis of rainfall data over the past 100years from the Seychelles has shown substantial variability related to ENSO though an increase in average rainfall from 1959 to 1997 and an increase in temperature of ~ 0.25 °C per decade has occurred (Payet and Agricole, 2006). Detection of long-term statistical change in precipitation is one prerequisite to understanding the impacts of climate change in small island hydrology and water resources.

Much recent literature has focussed on saline (sea-water) intrusion into fresh groundwater reserves on atoll islands which is frequently attributed to incremental sea-level rise though there is a paucity of empirical evidence to support this premise (e.g. Rozell and Wong, 2010). White and Falkland's (2010) review of existing small island studies indicates that a sea level increase of up to 1 m would have negligible salinity impacts on atoll island groundwater lenses so long as there is adequate vertical accommodation space, island shores remain intact, rainfall patterns do not change and direct human impacts are managed. However, wave overtopping and wash over can be expected to become more frequent with sea level rise and this has been shown to impact freshwater lenses dramatically. On Pukapuka Atoll, Cook Islands storm surge over-wash occurred in 2005 and caused the fresh water lenses to become immediately brackish and took some 11 months to recover to conductivity levels appropriate for human use (Terry and Falkland, 2010). The ability of freshwater lens' to float upwards within the matrix of the island in step with incremental sea level rise also means that in low-lying and central areas of many atolls the lens may pond at the surface. This phenomenon already occurs in very low-lying central areas of Fongafale Island, Tuvalu, and during extreme high 'king' tides large areas of the inner part of the island become inundated with brackish waters (Yamano *et al*., 2007; Locke, 2009).

29.3.3. Observed Impacts on Human Systems of Small Islands

29.3.3.1. Observed Impacts on Island Settlements and Tourism

Whilst traditional settlements on high islands were often located inland, the move to coastal locations was encouraged by colonial and religious authorities and more recently through the development of tourism. Now the majority of settlements, infrastructure and development is located on low-lands along the coastal fringe of small islands. In the case of atoll islands, all development and settlement is essentially coastal. It follows that populations, infrastructure, agricultural areas and fresh groundwater supplies are all vulnerable to extreme tides, wave and surge events and sea level rise (Walsh *et al*., 2012). Population drift from outer islands or from inland, together with rapid population growth in main centers and lack of accommodation space drives growing populations into ever more vulnerable locations. Additionally, without adequate resources and planning, engineering solutions such as shoreline reclamation also place communities and infrastructure in positions of increased risk (Schleupner, 2008; Yamano *et al*., 2007).

Many of the environmental issues that the media raise relating to Tuvalu, the Marshall Islands and Maldives are in fact only relevant to the major center and its surrounds, that is Funafuti, Majuro and Male respectively. As an example Storey and Hunter (2010) indicate the 'Kiribati' problem does not refer to the whole of Kiribati but rather

to the southern part of Tarawa atoll where preexisting issues of severe overcrowding, proliferation of informal housing and unplanned settlement, inadequate water supply, poor sanitation and solid waste disposal, pollution and conflict over land ownership are of concern. They argue that these problems require immediate resolution if the vulnerability of the South Tarawa community to the 'real and alarming threat' of climate change is to be managed effectively (Storey and Hunter, 2010).

On Majuro atoll, rapid urban development and the abandonment of traditional settlement patterns has resulted in movement from less vulnerable to more vulnerable locations on the island (Spennemann, 1996). Likewise, geophysical studes of Fongafale Island, the capital of Tuvalu, show that engineering works during World War II, and rapid development and population growth since independence, has lead to the settlement of inappropriate shoreline and swampland areas leaving communities in heightened conditions of vulnerability (e.g. Yamano *et al.*, 2007). Ascribing direct climate change impacts in such disturbed environments is problematic due to the existing multiple lines of stress on the island's biophysical and social systems. However, it is clear that such pre-existing conditions of vulnerability add to the threat of climate change in such locations.

The issue of 'coastal squeeze' remains a concern for many small islands as there is a constant struggle to manage the requirements for physical development against the need to maintain ecological balance (Fish *et al.,* 2008; Sano *et al.,* 2010; Gero *et al.*, 2011; Mycoo, 2011). Martinique in the Caribbean exemplifies the point, where physical infrastructure prevents the beach and wetlands from retreating landward as a spontaneous adaptation response to increased rates of coastal erosion (Schleupner, 2008). Moreover, intensive coastal development in the limited coastal zone combined with population growth and tourism have placed great stress on the coast and has resulted in dense aggregations of infrastructure and people in potentially vulnerable conditions.

Tourism is an important sector on many small islands. Linkages between weather, climate and tourism in small islands have been assessed on several occasions, including in IPCC assessments. There is currently no evidence that observed climatic changes in small island destinations or source markets have altered patterns of demand for tourism to small islands (Scott *et al.,* 2012a). There is also no systematic analysis of how recent extreme storm events have impacted tourism operations (costs of evacuations, damages, recovery interruption, insurance) in small islands (UNWTO, 2010).

Climate can also impact directly on environmental resources that are major tourism attractions in small islands. Beach erosion is widespread and has been found to negatively impact destination attractiveness and accommodation prices (Houston 2002, Cowell *et al.,* 2006, Buzinde *et al.,* 2010a, 2010b, Hamilton 2007). Erosion caused by Hurricane *Wilma* in 2005 at renowned coastal tourism destinations in Mexico is indicated of these impacts. Tourist perceptions of the beach erosion and restoration ranged from aesthetically unpleasant and feeling deceived by marketing of extensive beaches to focusing on new recreational opportunities provided by the erosion control structures in the water (Buzinde *et al.*, 2010a, 2010b). Visitation at Cancun declined roughly 50% in the year following the erosion, but as beach restoration continued, arrivals recovered to pre-erosion levels in 2007 (Scott *et al.,* 2012b). It is unclear whether the extent of this recovery would have occurred without the extensive investment in beach restoration.

Higher surface water temperatures continue to cause coral bleaching near many small islands. Severe bleaching caused several marine parks and dive sites in Southeast Asia and the Indian Ocean to close during 2010, in an attempt to try and reduce further damage (Sarnsamak, 2011). Studies reveal dive tourists are well aware of coral bleaching, particularly the experienced diver segment (Cesar, 2000; Westmacott *et al.,* 2000, Ngazy *et al.,* 2005, Gössling *et al.,* 2008, Kragt *et al.,* 2009, Klint *et al.,* 2012a, 2012b, Klinthong 2012), and therefore more acute impacts occur among tourism operators and resorts that cater to these markets. No information is available on how changes in marine ecology are influencing the sport fishing industry of small islands (Scott *et al.,* 2012b).
The availability of freshwater is limited on many small islands, and changes in the availability or quality during drought events linked to climate change have adverse impacts on tourism operations (Gössling *et al.,* 2012, UNWTO 2012). One aspect of this that cruise ships may cease coming to an island where there is not sufficient freshwater to restock their supplies. Tourism is a seasonally significant water user in many island destinations and in times of drought, concerns over limited supply for residents and other economic activities become heightened (Tapper *et al.,* 2011, Gössling *et al.,* 2012). As a consequence, some islands are investing in coral reef restoration,

beach rehabilitation, water demand management and desalination plants in attempts to reverse the negative publicity arising from those observed impacts. There is no analysis of how widespread these investments are or their capability to cope effectively with future climate change. The tourism industry and investors are also beginning to consider the climate risk of tourism operations (Scott *et al.,* 2012b).

29.3.3.2. Observed Impacts on Human Health of Island Populations

Globally, the effects of climate change on human health will be both direct and indirect, and are expected to exacerbate existing health risks, especially in the most vulnerable communities where the burden of disease is already high (refer to Chapter 11.3, 11.5 and 11.6.1, this volume).Many small island states currently suffer from climate-sensitive health outcomes, including morbidity and mortality from extreme weather events, certain vector- and food- and water-borne diseases (Barnett and Campbell, 2010; Cashman *et al.,*2010; Pulwarty *et al.,* 2010; McMichael and Lindgren, 2011). Extreme weather and climate events such as tropical cyclones, storm surges, flooding, and drought can have both short-and long-term effects on human health, including drowning, injuries, increased disease transmission, and health problems associated with deterioration of water quality and quantity. Most small island nations are in tropical areas with weather conducive to the transmission of diseases such as malaria, dengue, filariasis, and schistosomiasis.

The linkages between human health, climate variability and seasonal weather have been demonstrated in several recent studies. The Caribbean has been identified as a 'highly endemic zone for leptospirosis' with Guadeloupe, Barbados, and Jamaica representing the highest annual incidence (13 to 7.8 per 100,000 population) in the world with only the Seychelles being higher (43.2 per 100,000 population) (Pappas *et al.,* 2008). Studies conducted in Guadeloupe demonstrated a link between El Niño occurrence and leptospirosis incidence with rates increasing to 13 per 100,00 population in El Nino years as opposed to 4.5 cases per 100,00 inhabitants in La Niña and neutral years (Herrmann-Stock *et al.,* 2008). In addition, epidemiological studies conducted in Trinidad reviewed the incidence of leptospirosis during the period 1996-2007 and showed seasonal patterns in the occurrence of confirmed leptospirosis cases, with significantly ($P<0.001$) more cases or 75% of all cases occurring in the wet season, May to November (193 cases), than during the dry season, December to May (66 cases) (Mohan *et al*., 2009). Recently changes in the epidemiology of leptospirosis have been detected especially in tropical islands with the main factors being climatic and anthropogenic (Pappas *et al*., 2008) that are likely to be enhanced with increases in ambient temperature and changes in precipitation, vegetation and water availability as a consequence of climate change (Russell, 2009).

In Pacific islands the incidence of diseases such as malaria and dengue fever has been increasing, especially endemic dengue in Samoa, Tonga and Kiribati (Russell, 2009). While studies conducted so far in the Pacific have only established a direct link between malaria, dengue and climate variability, these and other health risks including from cholera, are projected to increase as a consequence of climate change (Russell, 2009; refer also to Chapter 11.2.4 and 11.2.5 this volume, for detailed discussion on the link between climate change and projected increases in the outbreak of dengue and cholera). Dengue incidence is also a major health concern in other small island countries, including Trinidad and Tobago, Singapore, Cape Verde, Comoros and Mauritius (Chadee *et al*, 2007; Chadee 2009; Koh *et al.,* 2008; Van Kleef *et al.,* 2010; Teles, 2011). In the specific cases of Trinidad and Tobago, the outbreaks have been significantly correlated with rainfall and temperature, respectively (Chadee *et al.,* 2007; Chadee 2009; Koh *et al.,* 2008).

Previous IPCC assessments have consistently shown that human health on islands can be seriously compromised by lack of access to adequate, safe, fresh water and adequate nutrition (Nurse *et al*., 2001; Mimura *et al*., 2007). Lovell (2011) notes that in the Pacific many of the anticipated health effects of climate change are expected to be indirect, connected to the increased stress and declining well-being that comes with property damage, loss of economic livelihood and threatened communities. There is also a growing concern in island communities in the Caribbean, Pacific and Indian Ocean, that fresh water scarcity, more intense droughts and storms could lead to a deterioration in standards of sanitation and hygiene (Cashman *et al*., 2010; McMichael and Lindgren, 2011). In such circumstances, increased exposure to a range of health risks including communicable diseases would be a distinct possibility.

Ciguatera fish poisoning (CFP) occurs in tropical regions and is the most common non-bacterial food-borne illness associated with consumption of fish. Distribution and abundance of the organisms that produce these toxins, chiefly dinoflagellates of the genus *Gambierdiscus*, are reported to correlate positively with water temperature. Consequently, there is growing concern that increasing temperatures associated with climate change could increase the incidence of CFP in the island regions of the Caribbean (Morrison *et al.,* 2008; Tester *et al.,* 2010), Pacific (Llewellyn, 2010; Rongo and van Woesik, 2011; Chan et al, 2011) and the Mediterranean *(Aligizaki and Nikolaidis, 2008; refer also to section 29.5.4)*. One of the objectives of the Caribbean study was to characterize the relationships between sea surface temperatures (SSTs) and CFP incidence rates. This was done in tandem with a series of experiments designed to determine the effects of temperature on the growth rate of organisms responsible for CFP. High rates in the Lesser Antilles occur in areas which experience the warmest water temperatures and which show the least temperature variability. There are also high rates in the Pacific in Tokelau, Tuvalu, Kiribati, Cook Islands and Vanuatu.

The influence of climatic factors on malaria vector density and parasite development is well established (Beguin *et al.,* 2011; Chaves and Koenraadt, 2010). Previous studies have assessed the potential influence of climate change on malaria, using deterministic or statistical models (Hay *et al.,* 2009; Martens *et al*., 1999; Parham and Michael, 2010; Pascual *et al*., 2006). While the present incidence of malaria on small islands is not reported to be high, favourable environmental and social circumstances for the spread of the disease are present in some island regions, and are expected to be enhanced under projected changes in climate in Papua New Guinea, Guyana, Suriname and French Guyana **(**Michon *et al.,* 2007**;** Rawlins *et al.,* 2008; Figueroa, 2008), In the Caribbean, the occurrence of autochthonous malaria in non-endemic island countries in the last ten years, suggests that all of the essential malaria transmission conditions now exist, and Rawlins et al. (2008) call for enhanced surveillance, recognizing the possible impact of climate change on the spread of anopheles and malaria transmission.

29.3.3.3. Observed Impacts of Climate Change on Relocation and Migration

Empirical evidence of human migration as a response to climate change is scarce for small islands – in terms of a lack of studies showing the direct impacts of climate change on human settlements, and how these impacts lead to changes in migration and resettlement attitudes and behaviours. Several authors highlight this lack of empirical studies of the effect of climate drivers such as sea level rise, on island migration (Lilleor and Van den Broeck, 2011: s78, Mortreux and Barnett, 2009). Further there is no evidence of any government policy that allows for climate 'refugees' from islands to be accepted into another country (Bedford and Bedford, 2010). This surprising finding contrasts with the early desk-based estimates of migration under climate change such as the work of Myers (2002). These early studies have been criticised as they fail to acknowledge: the reality of climate impacts on islands, the capacity of islands and islanders to adapt, or the actual drivers of migration (Barnett and O'Neill, 2012).

The majority of studies on island migration reveal that the key drivers are economic or cultural and not climatic. For example when looking at historical process of migration within the Mediterranean it appears that rising levels of income, coupled with a decreased dependence on subsistence agriculture has left the Mediterranean less vulnerable to all environmental stressors, resulting in a reduced need for mobility to cope with environmental or climatic change (de Haas, 2011). Studies from the Pacific have also shown that culture, lifestyle and a connection to place are more significant drivers of migration than climate (Mortreux and Barnett, 2009, Barnett and Webber, 2010). For example a Pacific Access Category of migration has been agreed between New Zealand and Tuvalu that permits 75 Tuvaluans to migrate to New Zealand every year (Kravchenko, 2008). Instead of enabling climate driven migration, this agreement is designed to facilitate economic and social migration as part of the Pacific island lifestyle (Shen and Gemenne, 2011). Thus, there is no evidence *yet* that reveals that migration from islands is being driven by climate change.

Nonetheless there is recognition that environmental change affects land use and land rights, which in turn are drivers of migration (Bedford and Bedford, 2010). In a survey of 86 case studies of community relocations in Pacific islands, Campbell et al. (2005) found that environmental variability and natural hazards accounted for 37 communities relocating. In the Pacific, where land rights are a source of conflict, climate change could increase levels of stress associated with land rights, and impact on migration (Campbell, 2010; Weir and Virani, 2011).

While there is not yet a climate fingerprint on migration and resettlement patterns in small islands, it is clear that there is the potential for human movement as a response to climate change. To better understand the impact of climate change on migration there is an urgent need for robust methods to identify and measure the effects of the drivers of migration on migration and resettlement.

29.3.3.4. Observed Impacts on Island Economies

The economic and environmental vulnerabilities of small islands states are well documented (Briguglio *et al.,* 2009, Bishop, 2012). Such vulnerabilities, which render the states at risk of being harmed by economic and environmental conditions, stem from intrinsic features of these states, and are not governance induced (although poor governance in this regard may aggravate the harm).

Economic vulnerability is the result of a high degree of exposure to economic conditions often outside the control of small island states, exacerbated by dependence on a narrow range of exports and a high degree of dependence on strategic imports, such as food and fuel (Briguglio *et al.,* 2009). This leads to economic volatility, a condition that is harmful for the economy of the islands (Guillaumont, 2010).

There are other economic downsides associated with small size and insularity. Small size leads to high overhead cost per capita, particularly in infrastructural outlays. This is of major relevance to climate change adaptation as this often requires upgrades and redesign of island infrastructure. Insularity leads to high cost of transport per unit, associated with purchases of raw materials and industrial supplies in small quantities, as well as high cost of storing and warehousing to ensure adequate supply of production inputs and consumer goods. These disadvantages are associated with the inability of small islands to reap the benefits of economies of scale resulting in a high cost of doing business in small islands (Winters and Martins, 2004).

The environmental vulnerability of small island states stems from various intrinsic features, including the high ratio of coastline to land mass, rendering these states highly exposed to ocean borne hazards and to sea-level rise (Barnett and Campbell, 2010, Nicholls and Cazenave, 2010). Small island states are also highly prone to natural disasters (Peduzzi *et al.,* 2009; Turvey, 2007). Other environmental problems associated with small territory size relate to the high population densities of many small island states, which leads to a high per capita cost of waste management, traffic congestion, relatively high degree of biodiversity loss, heavy strain on water resources and other environmental harm associated with population pressure.

These economic and environmental problems are exacerbated by climate change, particularly because government funds have to be diverted from the normal budget outlays to cover additional expenditures associated with mitigation and adaptation to climate change. In addition, a large proportion of economic activity of many small island states, particularly those associated with tourism and fisheries, are located right on the coastline and these are likely to be affected by sea-level rise and extreme weather events.

29.3.4. Detection and Attribution of Observed Impacts of Climate Change on Small Islands

While exceptional vulnerability of many small islands to future climate change is widely accepted, the foregoing analysis indicates that scientific literature on observed impacts is quite limited. Detection of past and recent climate change impacts is challenging due to the presence of other anthropogenic drivers, especially in the constrained environments of small islands. Attribution is further challenged by the strong influence of natural climate variability compared to incremental change of climate drivers. Notwithstanding these limitations we have prepared a summary of the relationship between detection and attribution to climate change of several of the phenomena described in the above sections. Figure 29-2 reflects our degree of confidence in the linkage between observed changes in several components of the coastal, terrestrial and human systems of small islands and the drivers of climate change.

[INSERT FIGURE 29-2 HERE
Figure 29-2: Based on available literature discussed in this chapter, the diagram shows a comparison of the degree of confidence in the detection of tropical small island impacts (horizontal axis) with the degree of confidence in attribution to climate change drivers (vertical axis). For example; the blue symbol No. 2 (Coastal Systems), indicates there is very high confidence in both the detection of "sea-level rise consistent with global means" and its attribution to climate change drivers; whereas the yellow symbol No. 17 (Human Systems) indicates whilst detection of "casualties and damage during extreme events" is very high, at this time there is low confidence in the attribution to climate change drivers. It is important to note that low confidence in attribution frequently arises due to the very limited research available for small island environments.]

29.4. Projected Integrated Climate Change Impacts

Small islands face many challenges in using climate change projections for policy development and decision-making. Primary among these is the absence of credible regional socio-economic scenarios relevant at the scale at which most decisions are taken. Scenarios are an important tool to help decision makers disaggregate vulnerability to the direct physical impacts of the climate signal from the vulnerability associated with socio-economic conditions and governance. Before building socio-economic scenarios to aid decision making, there has to be scientifically credible simulation of future small island climates. In this regard, there is a serious problem in generating climate scenarios at the scale of small islands since they are generally much smaller than the resolution of the global models. This is because the grid squares in the Global Circulation Models (GCMs) used in the SRES scenarios over the last decade, were between 200 and 600 km^2, which provides inadequate resolution over the land areas of virtually all small islands.

The scale problem has been usually addressed by the implementation of statistical downscaling models that relate GCM output to the historical climate of a local small island data point. The limitation of this approach is the need for observed data ideally for at least three decades for a number of representative points on the island, in order to establish the statistical relationships between GCM data and observations. In most small islands long-term quality-controlled climate data is generally sparse, so that in widely dispersed islands such as in the Pacific, observational records are usually supplemented with satellite observations combined with computer models (Australian Bureau of Meteorology and CSIRO, 2011a; Keener *et al*., 2012). However where adequate local data is available for several stations for at least 30 years, downscaling techniques have demonstrated that they can respond to the guidance of the GCMs to closely match the local domain and that they require less computational demand (e.g. Charlery and Nurse, 2010). Even so, most projected changes in climate for the Caribbean, Pacific, Indian Ocean and Mediterranean islands, generally apply to the region as a whole and this may f be adequate to determine general trends in regions where islands are close together.

29.4.1. Non-Formal Scenario-Based Projected Impacts

Scenarios are often constructed by using a qualitative climate projections approach based on expected changes in some physical climate signal from literature review rather than direct modelling. Sometimes this is proposed as a 'what if' question which is then quantified using a numerical method. For example, in the Caribbean, sea level projections superimposed on topographic maps have been used to estimate that 49-60% of resort properties would be damaged with a one metre sea-level rise, potentially transforming the competitive position and sustainability of coastal tourism destinations in the region (Scott *et al.,* 2012c). Another example of qualitative modelling from the Pacific is a case study from Nauru which uses local data and knowledge of climate to assess the GCM projections. It suggests that Nauru should plan for continued ENSO variability in the future with dry years during La Niña and an overall increase in mean rainfall and extreme rainfall events. Climate adaptation concerns which arise include water security and potential changes in extreme wet events which affect infrastructure and human health (Brown *et al., submitted*).

29.4.2. Projected Impacts for Islands based on Existing SRES Scenarios

Another approach to scenario development is to use the SRES projections more directly. The broad synthesis in the AR4 of climate scenario projections and impacts on small island regions (e.g. Mimura *et al.*, 2007) remains valid (see new RCP Projections in Figure 29-3). For example, Table 29-1 shows that in general for the SRES A1B more balanced medium emissions scenario, the projections suggest about a 2°C increase in temperature in the Caribbean, Indian Ocean and Pacific Ocean small islands regions by 2100 with an overall annual decrease in precipitation of about 12% in the Caribbean (see also AR5 WG 1, 14.7.4) and a 3-5% increase in the Indian and Pacific Oceans small island regions. There are important spatial differences however as for example among the more dispersed Pacific islands where the more equatorial regions are likely to get wetter and the sub-tropical high pressure belts drier as reported by AR5 WG I, however, in regions directly affected by the SPCZ and western portion of the ITCZ, the rainfall outlook is uncertain (AR5 WG 1, 14.7.13). The Mediterranean islands also have differences from the tropical small island pattern. Throughout the Mediterranean region, the length, frequency, and/or intensity of warm spells or heat waves are very likely to increase to the year 2100 (AR5 WG 1, 14.7.6).

[INSERT TABLE 29-1 HERE
Table 29-1: Small islands regions temperature and precipitation change projections for the SRES A1B scenario over the period 2080-2099 compared to 1980-1999. The table shows the minimum, median (50%), and maximum values of the mean temperature and precipitation responses from each of the 21 AR4 global models (adapted from WGI AR4 Table 11.1).

In the main regions in which most tropical or sub-tropical small island states are located, there are few independent peer reviewed scientific publications providing downscaled climate data projections, and virtually none illustrating the experience gained from their use for policy making. A projected 2ºC temperature increase by the year 2100 has potential far reaching consequences for sentinel ecosystems such as coral reefs that are important to tropical islands (see Chapter *6.2.2.4.4.*). This is because 'Degree Heating Months' (DHM) >2 ºC-month are the determined threshold for severe coral bleaching (Donner, 2009). For example Donner (2009) in a study of sea surface temperature (SST) across all coral reef regions using GCM ensemble projections forced with five different SRES future emissions scenarios, concluded that even warming in the future from the current accumulation of greenhouse gases in the atmosphere could cause over half of the world's coral reefs to experience harmfully frequent thermal stress by 2080. Further, this timeline could be brought forward to as early as 2030 under the A1B medium emissions scenario. He further states that thermal adaptation of 1.5 ºC would only delay the thermal stress forecast by 50–80 years. Donner (2009) also estimated the year of likelihood of a severe mass coral bleaching event due more than once every 5 years, to be 2074 in the Caribbean, 2074 in the western Indian Ocean, 2082 in the central Indian Ocean, 2065 in Micronesia, 2057 in the central Pacific, 2094 in Polynesia and 2073 in the eastern Pacific small islands regions.

Small island economies can also be objectively shown to be at greater risk from sea-level rise in comparison to other geographic areas. Such a study is the use of the FUND model to assess the economic impact of substantial sea-level rise in a range of socio-economic scenarios downscaled to the national level, including the four SRES storylines (Anthoff *et al.,* 2010). Although this study shows that in magnitude, a few regions experience most of the costs of sea-level rise by 2100, especially East Asia, North America, Europe and South Asia, these same results when expressed as percent of GDP show that most of the top ten and four of the top five most impacted are small islands from the Pacific (Micronesia, Palau, Marshall islands, Nauru) and Caribbean (Bahamas) (Anthoff *et al.,* 2010). The point is made that the damage costs for these small island states are enormous in relation to the size of their economies (Nicholls and Tol, 2006) and that together with deltaic areas they will find it most difficult to locally raise the finances necessary to implement protection (Anthoff *et al.*, 2010).

In the Caribbean, downscaled climate projections have been generated for some Caribbean islands using the Hadley Centre PRECIS regional model (Taylor *et al.*, 2007, Stephenson *et al.,* 2008). For the SRES A2 and B2 scenarios the PRECIS regional climate model projects an increase in temperature across the Caribbean of 1–4 °C with increasing rainfall during the latter part of the wet season from November–January, in the northern Caribbean (i.e. north of 22°N) and drier conditions in the southern Caribbean with a strong tendency to drying in the traditional wet season from June–October (Whyte *et al.*, 2008, Campbell *et al.,* 2011, Taylor *et al.,* 2013). Projected lengthening

seasonal dry periods, and increasing frequency of drought periods are expected to increase demand for water throughout the region under the SRES A1B scenario (Cashman *et al*., 2010). Decrease in crop yield is also projected in Puerto Rico for the SRES B1 (low), A2 (mid-high) and A1F1 scenarios during September although increased crop yield is suggested during February (Harmsen *et al*., 2009). Using a tourism demand model linked to the SRES A1F1 A2 B1 and B2 scenarios, the projected climate change heating and drying impacts are also linked to potential aesthetic, physical and thermal effects that are estimated to cause a change in total regional tourist expenditure of about +321, +356, -118 and -146 million US dollars from the least to the most severe emissions scenario respectively (Moore, 2010).

In the Indian Ocean, representative downscaled projections have been generated for Australia's two Indian Ocean territories the Cocos (Keeling) Islands and Christmas Island using the CSIRO Mark 3.0 climate model with the SRES A2 high emissions scenario (Maunsell Australia Pty Ltd., 2009). Future climate change projections for the two islands for 2070 include a 1.8°C increase in air temperature by 2070, probable drier dry seasons and wet seasons, a 40 cm rise in sea level and a decrease in intense tropical cyclones.

In the western tropical Pacific, extensive climate projections have been made for 15 small islands based on downscaling from an ensemble of 15 GCMs (Australian Bureau of Meteorology and CSIRO, 2011b). The temperature projections in this region dominated by oceans seem less than those seen globally ranging from +1.5 to 2.0 °C for the B1 low emissions scenario to +2.5 to 3.0 °C for the A2 high emissions scenario by the year 2090 relative to a 20 year period centred on 1990. Notably there is a expected trend of increasing rainfall as indicated by a projected increase in 20 year extreme rainfall events to an average of seven times per year, by 2090 under the A2 (high emissions) scenario (Australian Bureau of Meteorology and CSIRO, 2011b). In the tropical Pacific Ocean, another comprehensive assessment of the vulnerability of the fisheries and aquaculture sectors to climate change in 22 Pacific island countries and territories focussed on two future time-frames (2030 and 2100) and two SRES emissions scenarios, B1 (low emissions) and A2 (high emissions) (Bell *et al*., 2011). The results are not very different from the IPCC AR4 projections with projected temperature increases of about +1.0 to 1.5 ºC by 2100 and an increase in rainfall of 10-20% in equatorial regions. Estimates of the resulting projected changes in habitat area (mangroves, seagrasses, freshwater fish) coral reef cover, demersal fish production, skipjack and bigeye tuna for the two SRES scenarios are given in Table 29-2.

[INSERT TABLE 29-2 HERE
Table 29-2: Preliminary projected percentage changes in tuna catches relative to the 20 year average (1980-2000) and estimated percentage change to government revenue resulting from projected changes in the catch of skipjack tuna in 2030 and 2100 (Bell et al, 2011).]

Most anticipated changes in habitat and resource availability such as the commercial tuna catch are negative, with implications for government revenue and island food security (Bell *et al*., 2011, Bell *et al*., 2013).

In the Mediterranean islands of Mallorca, Corsica, Sardinia, Crete and Lesvos, Gritti et al. (2006) simulated the terrestrial vegetation biogeography and distribution dynamics under the SRES A1F1 and B1 scenarios. The simulations indicate that the effects of climate change are expected to be negligible within most ecosystems except for mountainous areas that are projected to be eventually occupied by exotic vegetation types from warmer, drier conditions. Cruz et al. (2009) report similar results for the terrestrial ecosystems of Madeira Island in the Mediterranean. Downscaled SRES A2 and B2 scenarios for the periods 2040 – 2069 and 2070 – 2099 suggest that the higher altitude native humid forest called the Laurissilva, may expand upwards in altitude, which could lead to a severe reduction of the heath woodland which because it has little upward area to shift may reduce in range or disappear at high altitudes resulting in the loss of rare and endemic species within this ecosystem.

29.4.3. RCP Projections and Implications for Small Islands

Utilizing updated historical greenhouse gas emissions data the scientific community has produced future projections for four plausible new global Representative Concentration Pathways (RCPs) in order to explore a range of global climate signals up to the year 2100 and beyond (e.g. Moss *et al.,* 2010; van Vuuren *et al*., 2010). The RCPs are

named according to their global warming potential (e.g. RCP 4.5 W/m^2) and in an ongoing process are matched to a global socio-economic scenario storyline (SSP) such that each RCP can respond to more than one SSP. Scientists have strongly cautioned against the specification of detailed sub-global conditions and local trends based on these coarser global datasets and models. With these caveats in mind, typical representations of RCP projections for temperature and precipitation for similar times of the year in some small island regions are presented in Figure 29-3 adapted from Annex I WGI AR5. Highlighted in Figure 29-3 is the output of one model that is the mid-projection representation of each RCP model ensemble. A more comprehensive compilation of global RCP projections can be found in Annex I of the WGI AR5 Report.

[INSERT FIGURE 29-3 HERE
Figure 29-3: RCP Scenario projections to the year 2100 for the four main small island regions (adapted from AR5 WG1, Annex 1).]

Small Island Developing States (SIDS) advocated that the Global Mean Surface Temperature (GMST) increase should be limited to 'well below' 1.5ºC above pre-industrial levels (Hare *et al.,* 2011; Riedy and McGregor, 2011). Inspection of column 1 in Figure 29-3 suggests that for Caribbean, Indian Ocean and Pacific SIDS in the tropics, that is only plausible under RCP 2.6 that in each case yields about a 1ºC regional increase by 2100. RCP 2.6 also suggests no significant change in mean rainfall in the Caribbean with a slight increase for Indian and Pacific Ocean SIDS. In the mid-latitude Mediterranean Sea region RCP 2.6 yields about a 2ºC increase in temperature by 2100 and no apparent change in rainfall.

By comparison with regard to temperature, RCP 4.5 in Figure 29-3 suggest a probable less than 2ºC but not less than 1.5ºC temperature increase in Caribbean, Indian Ocean and Pacific SIDS by 2100 and about a 3ºC increase in the Mediterranean. Associated with this, the Caribbean and Mediterranean regions may experience a decrease in mean rainfall while the Indian and Pacific Ocean SIDS may experience increased rainfall. These trends accelerate moderately for RCP 6.0 and steeply for RCP 8.5.

29.5. Inter- and Intra-Regional Trans-Boundary Impacts on Small Islands

Many impacts on small islands are generated by processes originating in another region or continent well beyond the borders of an individual archipelagic nation or small island. These are inter-regional trans-boundary impacts. Intra-regional trans-boundary impacts originate from a within-region source (e.g. within the Caribbean). Some trans-boundary processes may have positive effects on the receiving small island or nation, though most that are reported have negative impacts. Deciphering a climate change signal in inter- and intra-regional trans-boundary impacts on small islands is not easy and usually involves a chain of linkages tracing back from island-impact to a distant climate or climate-related bio-physical or human process. Some examples are given below.

29.5.1. Large Ocean Waves from Distant Sources

Unusually large deep ocean swells, generated from far distant sources in the mid- and high-latitudes by Extra-Tropical Cyclones (ETC) cause considerable damage on the coasts of small islands thousands of kilometers away in the tropics. Impacts include sea-flooding and inundation of settlements, infrastructure and tourism facilities as well as severe erosion of beaches. Examples from small islands in the Pacific and Caribbean are common though perhaps the most significant instance, in terms of a harbinger of climate change and sea-level rise, occurred in the Maldives in April 1987 when long period swells originating from the Southern Ocean some 6000 km away caused major flooding, damage to property, destruction of sea defences and erosion of reclaimed land and islands (Harangozo, 1992). The Maldives and several other island groups in the Indian Ocean have been subject to similar ocean swell events more recently, most notably in May 2007 (Department of Meteorology, 2007).

In the Caribbean northerly swells affecting the coasts of islands have been recognized as a significant coastal hazard ever since the 1950s (Donn and McGuinness, 1959). They cause considerable seasonal damage to beaches, marine ecosystems and coastal infrastructure throughout the Caribbean (Cambers, 2009; Bush *et al.*, 2009). These high-

energy events manifest themselves as long period, high-amplitude waves generated by extra-tropical cyclones and high latitude lows originating thousands of kilometers away in the North Atlantic. They occur during the northern hemisphere winter and often impact the normally sheltered, low-energy leeward coasts of the islands (Bush *et al.,* 2009; Cambers, 2009). Such swells have even reached the shores of Guyana on the South American mainland as illustrated by a swell event in October 2005 that caused widespread flooding and overtopping and destruction of sea defences (van Ledden *et al*., 2009).

Distant origin swells differ from the 'normal' wave climate conditions experienced in the Caribbean, particularly with respect to direction of wave approach, wave height and periodicity. Based on statistical analysis of wave data from voluntary observer ships (VOS), Gulev and Grigorieva (2006) suggest that significant wave heights have increased by between 10 – 40 cm/decade in both the North Atlantic and North Pacific, during the period 1958-2002. While significant wave height has been observed to increase in some regions, current model simulations project enhanced wave heights only in the Southern Ocean and the tropical South Pacific, and decreases in all other ocean basins (See AR5-WG1, 13.7.3.2). This may however be related to the challenge of downscaling 'future wind states from coarse resolution climate models into regional and global wave model projections' (AR5-WG1, 13.7.3).

Swell events of similar origin and characteristics also occur in the Pacific the best documented being in the Hawaiian island where there is evidence of damage to coral growth by swell from the north Pacific, especially during years with a strong El Nino signal (Fletcher *et al*., 2008). Hoeke et al. (submitted) describe inundation from mid-high latitude north and south Pacific waves respectively at Majuro (Marshall Islands) in November and December 1979 and along the Coral Coast (Fiji) in May 2011. They also describe in detail an inundation event in December 2008 that was widespread throughout the western and central Pacific and resulted in waves surging across low-lying islands causing severe damage to housing and infrastructure and key natural resources that affected about 100,00 people across the region. The proximate cause of this event was swell generated in mid-latitudes of the north Pacific Ocean, more than 4000 km from the furthest affected island (Hoeke *et al.,* submitted).

Whereas the origin of the long period ocean swells that impact small islands in the tropical regions come from the mid-and high-latitudes in the Pacific, Indian and Atlantic oceans, there are also instances of unusually large waves generated from tropical cyclones that spread into the mid- and high- latitudes. One example occurred during 1999 when tide gauges at Ascension and St. Helena Islands in the central south Atlantic recorded unusually large deep-ocean swell generated from distant Hurricane Irene (Vassie *et al*., (2004). The impacts of increasing incidence or severity of storms or cyclones is generally considered from the perspective of direct landfall of such systems, whereas all of these instances serve to show 'the potential importance of swells to communities on distant, low-lying coasts, particularly if the climatology of swells is modified under future climate change' (Vassie *et al*., 2004: 1095). From the perspective of those islands that suffer damage from this coastal hazard on an annual basis, this is an area that warrants further investigation.

Deep ocean swell waves and elevated sea-levels resulting from ETCs are examples of *inter-regional* trans-boundary processes; locally generated Tropical Cyclones (TCs) provide examples of *intra-regional* trans-boundary processes. Whilst hurricane force winds, heavy rainfall and turbulent seas associated with TCs can cause massive damage to both land and coastal systems in tropical small islands, the impacts of sea waves and inundation associated with far distant ETCs are limited to the coastal margins. Nevertheless both storm types result in a range of impacts covering island morphology, natural and ecological systems, island economies, settlements and human well-being (see Figure 29-4).

29.5.2. Trans-Continental Dust Clouds and their Impact

The transport of airborne Saharan dust across the Atlantic and into the Caribbean has engaged the attention of researchers for some time. The resulting dust clouds are known to carry pollen, microbes, insects, bacteria, fungal spores and various chemicals (Prospero *et al*., 2005; Middleton *et al*., 2008; Monteil, 2008). During major events, dust concentrations can exceed 100 $\mu g\ m^{-3}$ (Prospero, 2006; Griffin, 2007). Independent studies using different methodologies have all found a strong positive correlation between dust levels in the Caribbean and periods of drought in the Sahara, while concentrations show a marked decrease during periods of higher rainfall. Consequently, it is argued that higher dust emissions due to increasing aridity in the Sahel and other arid areas could enhance climate change effects over large areas, including the eastern Caribbean and the Mediterranean (Prospero and Lamb, 2003). Similar findings have been reported at Cape Verde where dust emission levels were found to be a factor of nine lower during the decade of the 1950s when rainfall was at or above normal, when compared to the 1980s, a period of intense drought in the Sahel region (Nicoll *et al*., 2011). Dust from the Sahara has also long been known to reach into the eastern Mediterranean (e.g., Santese *et al*., 2010) whilst dust from Asia has been transported across the Pacific and Atlantic oceans and around the world (Uno *et al*., 2009).

There is also evidence that the trans-boundary movement of Saharan dust into the island regions of the Caribbean, Pacific and Mediterranean is associated with various human health problems including asthma admissions in the Caribbean (Monteil, 2008; Monteil and Antoine, 2009; Prospero *et al*., 2008), cardiovascular morbidity in Cyprus in the Mediterranean (Middleton *et al.,* 2008) and is found to be a risk factor in respiratory and obstructive pulmonary disease in the Cape Verde islands (Martins *et al*., 2009). These findings underscore the need for further research into the link between climate change, airborne aerosols and human health in localities, such as oceanic islands far distant from the continental source of the particulates.

29.5.3. Movement and Impact of Introduced and Invasive Species across Boundaries

Invasive species are colonizer species that establish populations outside their normal distribution ranges and spread into natural or local areas. The spread of invasive alien species is regarded as a significant trans-boundary threat to the health of biodiversity and ecosystems, and has emerged as a major factor in species decline, extinction and loss of biodiversity goods and services worldwide. This is particularly true of islands, where both endemicity and vulnerability to introduced species tend to be high (Kenis *et al*., 2009; Reaser *et al*., 2007; Westphal *et al*., 2008; Rocha *et al*., 2009; Kueffer *et al*., 2010). The extent to which alien invasive species successfully establish themselves at new locations in a changing climate will be dependent on many variables, but non-climate factors such as ease of access to migration pathways, suitability of the destination, ability to compete and adapt to new environments, and susceptibility to invasion of host ecosystems are deemed to be critical. This is borne out for example by Le Roux et al. (2008) who studied the effect of the invasive weed *Miconia calvescens* in New Caledonia, Society Islands and Marquesas islands, by Gillespie and Pau (2008) in an analysis of the spread of *Leucaena leucocephala*, *Miconia calvescens*, *Psidium sp*. and *Schinus terebinthifolius* in the Hawaiian islands; and by Christenhusz and Toivonen (2008) who showed the potential for rapid spread and establishment of the oriental vessel fern, *Angiopteris evecta*, from the South Pacific throughout the tropics. Mutualism between an invasive ant

and locally honeydew-producing insects has been strongly associated with damage to the native and functionally important tree species, *Pisonia grandis* on Cousine island,Seychelles (Gaigher, *et al*., 2011).

Whilst invasive alien species constitute a major threat to biodiversity in small islands, the removal of such species can result in recovery and return to species richness. . This has been demonstrated in Mauritius by Baider and Florens, 2011) where some forested areas were weeded of alien plants and after a decade the forest had recovered close to its initial condition,. They concluded, given the severity of alien plant invasion in Mauritius, that their example can 'be seen as a relevant model for a whole swath of other island nations and territories around the world particularly in the Pacific and Indian Oceans' (Baider and Florens, 2011).

The movement of aquatic and terrestrial invasive fauna within and across regions will almost certainly exacerbate the threat posed by climate change in island regions, and could impose significant environmental, economic and social costs. Recent research has shown that the invasion of the Caribbean Sea by the Indo-Pacific lionfish (*Pterois volitans*), a highly efficient and successful predator, is a major contributor to observed increases in algal dominance in coral and sponge communities in the Bahamas and elsewhere in the region. The consequential damage to these ecosystems has been attributed to a significant decline in herbivores due to predation by lionfish (Schofield, 2010; Albins and Hixon, 2008; Lesser and Slattery, 2011; Green *et al.,* 2011). While there is no evidence that the lionfish invasion is climate-related, the concern is that when combined with pre-existing stress factors the natural resilience of Caribbean reef communities would decrease (Albins and Hixon, 2011; Green *et al*., 2012), making them more susceptible to climate change effects such as bleaching. Englund (2008) has documented the negative effects of invasive species on native aquatic insects on Hawai'i and French Polynesia, and their potential role in the extirpation of native aquatic invertebrates in the Pacific. Similarly, there is evidence that on the island of Oahu introduced slugs appear to be 'skewing species abundance in favour of certain non-native and native plants', by altering the 'rank order of seedling survival rates', thereby undermining the ability of preferred species (e.g. the endangered *C. Superba*) to compete effectively (Joe and Daehler, 2008).

29.5.4. Spread of Aquatic Pathogens within Island Regions

The mass mortality of the black sea urchin, *Diadema antillarum*, in the Caribbean basin during the early 1980s demonstrates the ease with which ecological threats in one part of a region can be disseminated to other jurisdictions thousands of kilometres away. The die-off was first observed in the waters off Panama around January 1983, and within 13 months the disease epidemic had spread rapidly through the Caribbean Sea affecting practically all island reefs, as far away as Tobago some 2000 km to the south and Bermuda, some 4000 km to the east. The diadema population in the wider Caribbean declined between 90-95 per cent as a consequence of this single episode (Lessios, 1988, 1995;Rotjan and Lewis, 2008; Alvarez-Filip *et al*., 2009; Croquer and Weil, 2009a, 2009b). As *D. antillarum* is one of the principal grazers that removes macroalgae from reefs and thus promotes juvenile coral recruitment, the collateral damage was severe, as the region's corals suffered from high morbidity and mortality for decades thereafter (Carpenter and Edmunds, 2006; Myhre and Acevedo-Gutierrez, 2007; Idjadi *et al*., 2010).

There are other climate-sensitive diseases such as yellow, white and black band, white plague and white pox that travel across national boundaries and infect coral reefs directly. This is variously supported by examples from the Indo-Pacific relating to the role of bacterial infections in white syndrome and yellow band disease (Piskorska *et al*., 2007; Cervino *et al*., 2008), the impact of microbial pathogens as stressors on benthic communities in the Mediterranean associated with warming seawater (Ainsworth *et al*., 2007; Danovaro *et al*., 2009; Rosenberg *et al*., 2009), and an increasing evidence of white, yellow and black band disease associated with Caribbean and Atlantic reefs (Rosenberg *et al*., 2009; Brandt and McManus, 2009; Miller *et al*., 2009; Weil and Croquer, 2009; McClanahan *et al*,, 2009; Weil and Rogers, 2011).

29.5.5. Trans-Boundary Movements and Human Health

For island communities the trans-boundary implications of existing and future human health challenges are projected to increase in a changing climate. For instance, the aggressive spread of the invasive giant African snail,

Achatina fulica, throughout the Caribbean, Indo-Pacific islands and Hawaii is not only assessed to be a severe threat to native snails and other fauna (e.g. native gastropods), flora and crop agriculture, but is also identified as a vector for certain human diseases such as meningitis (Reaser *et al*., 2007; Meyer *et al*., 2008; Thiengo *et al*., 2010).

Like other aquatic pathogens ciguatoxins, that cause ciguatera fish poisoning, may be readily dispersed by currents across and within boundaries in tropical and sub-tropical waters. Ciguatoxins are known to be highly temperature-sensitive and may flourish when certain sea water temperature thresholds are reached, as has been noted in the South Pacific (Llewellyn, 2010), Cook Islands (Rongo and van Woesik, 2011), Kiribati (Chan *et al*., 2011), the Caribbean and Atlantic (Morrison *et al*., 2008; Otero *et al*., 2010; Tester *et al*., 2010) and Mediterranean (Aligizaki and Nikolaidis, 2008) (see also 29.3.3.3).

29.6. Adaptation and Management of Risks

For most islands, there is limited empirical evidence of changes in risk associated with climate change, largely due to: poor regional projections e.g. of sea level rise (Willis and Church, 2012), and a lack of long term baseline monitoring of changes in climatic risk (Voccia, 2012), such as risk of saline intrusion, risk of invasive species, risk of biodiversity loss, risk of large ocean waves, or risk of sea-level rise. Island adaptation studies therefore rely on analogues of responses to past and present weather extremes and climatic change, or assumed impacts of climate change based on island type, see Table 29-3. Until climate risks are better identified for islands, our ability to identify effective adaptations remains constrained.

[INSERT TABLE 29-3 HERE
Table 29-3. Type of island in the Pacific region and implications for hydro-meteorological hazards.**]**

29.6.1. Addressing Current Vulnerabilities and Adaptation Gaps on Small Islands

There is medium evidence of generic vulnerability of small islands to climate change, with some disagreement about the costs of adapting in small islands, and ultimately the potential need for migration from small islands (Nicholls *et al.,* 2011, Gemenne, 2011, Biermann and Boas, 2010, Voccia 2012). Islands are heterogeneous in geomorphology, culture, ecosystems, populations and hence also in their vulnerability to climate change (Wheeler, 2011). Vulnerabilities and adaptation needs are as diverse as the variety of islands between regions and even within nation states such as the Solomon Islands (see for example Rasmussen *et al.,* 2011).

Generic indices of national level vulnerability continue to emerge (Cardona, 2007) with a minority focused on small islands (e.g. Blancard and Hoarau, 2013). Many indicators suffer from lack of data, for example, Peduzzi et al. (2009) note that 18 small island states in the Pacific, Caribbean and Indian oceans are not included in their Disaster Risk Index due to lack of data. Other generic indices use indicators that are not relevant in all islands (Barnett and Campbell, 2010), or use data of limited quality for islands, such as sea level rise (as used in Wheeler, 2010). Park et al. (2012) attempt to produce relevant indicators of climate vulnerability and adaptive capacity for the Pacific Islands by adopting a three-stage participatory approach linking scientific knowledge with local visions of vulnerability. Their study concludes that all Pacific Island nations will be vulnerable to climate change in the next 40 years.

Following Smit et al. (2000), Brooks et al. (2005), and Yamano et al. (2007), Barnett and Campbell (2010) reinforce the point that island vulnerability to climate change is often a function of four key stressors: socio-economic, geo-physical, and socio-ecological vulnerabilities, as well as the climate stressor. Socio-economic vulnerabilities are related to on-going challenges of managing urbanisation, pollution and sanitation, both in small island states and non-sovereign islands as highlighted by Storey and Hunter (2010) in Kiribati, López-Marrero and Yarnal (2010) in Puerto Rico, and in Mayotte (France) (Le Masson and Kelman, 2011). Geo-physical characteristics of islands are varied, some low-lying atolls, some oceanic, some volcanic islands (see Table 29-3; Figure 29-1), each of which creates different vulnerabilities, for example the Azores (Portugal) face seismic, landslide and tsunami risks (Coutinho *et al*., 2009). Socio-ecological stresses, such as habitat loss and degradation, invasive species (described

in Sax and Gaines, 2008), overexploitation, pollution, human encroachment and disease can harm biodiversity (Caujape-Castells *et al*., 2010; Kingsford *et al.,* 2009), and reduce the ability of socio-ecological systems to bounce back after shocks. To understand climate vulnerability on islands, the impact of each of these non-climate stresses needs to be first understood and then integrated into climate vulnerability assessments (Rasmussen *et al*., 2011). For example, with individual ecosystems, such as coral reef ecosystems – those already under stress from non-climate factors are more at risk from climate change than those that are unstressed (Maina *et al*., 2011, Hughes *et al*., 2003). Evidence is starting to emerge that shows the same applies at the island scale. In Majuro (Marshall Islands), 34-37 years of aerial photography indicates that rural areas have experienced lower rates of erosion than urban areas (Ford, 2012). This could suggest that either the eroding urban coastal areas were initially more exposed, or that human activity in coastal areas and interventions in coastal ecosystems are exacerbating erosion associated with sea level rise. Additional empirical evidence is needed to confirm which explanation is accurate. In short, all aspects of vulnerability and climate risk assessment remain under-researched in islands; for most islands it is not possible to answer the key vulnerability questions unequivocally, i.e. who is at risk of what, where, and when?

29.6.2. Practical Experiences of Adaptation on Small Islands

Islands are often assumed to be generically vulnerable to climate change (Parks and Roberts, 2006, Myers, 2002). Yet islands and islanders are also recognized for their long experience of adapting to weather variability and climate hazards and for their resilience in the face of hydro-meteorological hazards (Barnett, 2001). Their resilience appears to come from both a belief in their own capacity (Kuruppu and Liverman, 2011; Adger and Brown, 2009), and a familiarity with their environment and understanding of what is needed to adapt (Tompkins et al., 2009; Le Masson and Kelman, 2011). For example, compared to communities in the larger countries of Madagascar, Tanzania and Kenya, the Indian Ocean islands – the Seychelles and Mauritius – were found to have comparatively high adaptive capacity (Cinner *et al.,* 2012). Adaptive capacity was assessed as: capacity to anticipate change and prepare strategies, self-awareness of human impact on environment; willingness to change occupation; livelihood diversity; social capital; material assets; access to technology and infrastructure. These studies all point to the importance of self-belief as well as culturally communicated knowledge of current risks and how to respond to them.

There are many ways in which climate adaptation can be undertaken: reducing socio-economic vulnerabilities, building adaptive capacity, enhancing disaster risk reduction, or building longer term climate resilience (e.g. see McGray *et al*., 2007, Eakin *et al*., 2009). Figure 29-5 highlights the potential benefits and risks associated with the various options. Not all adaptations will be equally appropriate in all contexts. Understanding the baseline conditions and stresses (both climate and other) are important in understanding which climate change adaptation option will generate the greatest benefits. On small islands where resources are often limited, recognising the starting point for action is critical to maximising the benefits from adaptation. The following section considers the benefits of pursuing the various options.

[INSERT FIGURE 29-5 HERE
Figure 29-5. Potential benefits and risks associated with alternative climate change adaptation actions or policies.]

29.6.2.1. Building Adaptive Capacity on Small Islands

Capacity to adapt to current risks on islands may be correlated to ability to adapt to future climate change, but there is limited evidence for this (such as Lefale, 2010). Consequently, this section can only assess evidence of adaptive capacity that: reduces vulnerability to existing stressors, enables adaptation to current stresses, or supports current disaster risk management, much of this relates to traditional practices.

As in previous IPCC Assessments, there is continuing strong support for the incorporation of indigenous knowledge into adaptation planning. For example, Samoans have their own seasonal calendar based on observations of local environmental and weather changes. Their ability to forecast the onset of extreme weather and climate events relying predominantly on local environmental changes are tools that could be incorporated in the formulation of climate change adaptation strategies (Lefale, 2010). Two discrete studies from the Solomon Islands highlight the

importance of traditional patterns of social organization within communities to support food security under social and environmental change (Reenberg *et al.,* 2008, Mertz *et al.,* 2010). In both studies the strategy of relying on traditional systems of organization for farming and land use management have been shown to work effectively – largely as there has been little cultural and demographic change. Evidence is inconclusive on the local capacity to observe long-term climate change. In the Solomon Islands, Lauer and Aswani (2010) found mixed ability to detect change in spatial cover of seagrass meadows. In Jamaica, Gamble et al. (2010) reported a high level of agreement between farmers' perception of increasing drought incidence and statistical analysis of precipitation and vegetation data for the area. In this case farmers perceptions clearly validated the observational data and vice versa. Despite some claims that the vulnerability of indigenous groups in small islands may be best tackled by combining indigenous and Western knowledge in a culturally compatible and sustainable manner (Mercer *et al.,* 2007), given the small number of studies in this area, there is not sufficient evidence to determine the benefits and limits to the use of traditional knowledge in building adaptive capacity to climate change on small islands.

There is a growing literature, but a lack of agreement on the role of traditional technologies and skills for climate adaptation. In coastal Samoa participatory village consultation and capacity building that take into account traditional practices, can be vital to the success of adaptation initiatives in island communities (Daly, 2010). Campbell (2009) identified that traditional disaster reduction measures used in Pacific islands focussed around maintaining food security, building community cooperation, and protecting settlements and inhabitants. Examples of actions to maintain food security include: the production and storage of food surpluses – such as yam and breadfruit buried in leaf-lined pits to ferment; high levels of agricultural diversity to minimise specific damage to any one crop; and the growth of robust famine crops – unused in times of plenty which could be used in emergencies (Campbell, 2009). Nonetheless there are physical and cultural limits to the ability to store surplus production on atoll islands. On Rongelap in the Marshall Islands, surpluses are avoided, or are redistributed to support community bonds (Bridges and McClatchey, 2009). Further, traditional approaches that Pacific island communities have used for survival for millennia (such as building elevated settlements and resilient structures; and working collectively), have been abandoned or forgotten due to processes of globalisation, colonialism and development (Campbell, 2009).

Traditional construction methods have long been identified across the Pacific as a means of adapting to tropical cyclones and floods. In the Solomon Islands traditional practices include: elevating concrete floors on Ontong Java to keep floors dry during heavy rainfall events; building 'low, aerodynamic houses and sago palm leaves as roofing material on Tikopia' as preparedness for tropical cyclones; and in Bellona local perceptions are that houses constructed from modern materials and practices are more easily destroyed by tropical cyclones, implying that traditional construction methods are perceived to be more resilient in the face of extreme weather (Rasmussen *et al.,* 2009: 10). In parallel, Campbell (2009) documents the characteristics of traditional building styles (in Fiji, Samoa and Tonga) where relatively steep hipped roofs, well bound connections and joints, and airtight spaces with few windows or doors offer some degree of wind resistance. Traditional building measures can also reduce damages associated with earthquakes – as evidenced in Haiti (Audefroy, 2011). By reducing damage caused by other stresses (such as earthquakes), adaptive capacity is more likely to be maintained. The quality of home construction is critical to its wind-resistance. If inadequately detailed, home construction will fail irrespective of method. While some traditional measures could be challenged as potentially risky – for example using palm leaves, rather than metal roofs as a preparation for tropical cyclone impacts – the documentation of traditional approaches, with an evaluation of their effectiveness remains urgently needed.

Traditional systems appear less effective when multiple civilization-nature stresses are introduced. For example in the island of Makira, Solomon Islands, where there have been high levels of population growth and changing social objectives, these factors appear to have acted as inhibitors of adaptation (Fazey *et al.,* 2011). In Reunion and Mayotte, population growth, and consequent rises in land and house prices have lead low-income families moving closer to hazardous slopes that are prone to landslides and river-banks which are prone to flooding (Le Masson and Kelman, 2011). Traditional belief systems can also limit adaptive capacity, for example in two Fijian villages, approximately half of survey respondents identified divine will as the cause of climate change (Lata and Nunn, 2012). These findings reinforce earlier studies in Tuvalu (Mortreux and Barnett, 2009), and more widely across the Pacific (Barnett and Campbell, 2010). The importance of taking into account local interests and traditional knowledge in adaptation in small islands is emphasized by Kelman and West (2009) and McNamara and Westoby

(2011), yet research is also needed to identify its limits, such as in the context of rapid socio-ecological change, or the impact of belief systems on adaptive capacity.

There remains limited evidence of how traditional knowledge, technologies and skills are being used to support adaptation. To date research in the Pacific and Caribbean dominates small island climate change work. More detailed studies on small islands in the central and western Indian Ocean, the Mediterranean and the central and eastern Atlantic would improve understanding in this area.

29.6.2.2. Addressing Risks on Small Islands

Many of the future climate risks on small islands remain unknown due to: the lack of effective downscaling methods for small islands, the lack of baseline data to ground-truth model results, and the lack of model skill in projecting the climatic variables that matter to small islands, notably: tropical cyclone frequency and intensity, wind speed and direction, precipitation, sea level, ocean temperature and ocean acidification (Brown *et al.,* submitted). Therefore much of the research on climate risks on islands depicts either current hydro-meteorological risks and responses, or risk management for hypothesised risks. In terms of present disaster risks, reflected by global disaster statistics, islands rarely appear to be in the 'worst affected' category - this is due to their small size and population. Yet, when the relative impact of current natural hazards are considered, in terms of percentage of the population exposed or in terms of losses as a percentage of GDP, then islands appear to suffer disproportionately (see Table 29-4).

[INSERT TABLE 29-4 HERE
Table 29-4: Top ten countries in the Asia-Pacific region based on absolute and relative physical exposure to storms and impact on GDP (between 1998 and 2009).]

Much of the climate risks literature recognises the relatively severe impacts of current natural hazards on islands, and identifies a range of approaches for managing this risk. Again, it is worth highlighting that most of this literature considers present day risk as an analogue for future risk; yet there is little evidence of a correlation between the effectiveness of current and future risk management under climate change. Given this constraint, much of the work on addressing risk focuses on either risk transfer, risk spreading or risk avoidance. Risk transfer is often undertaken through insurance; risk spreading through access to and use of common property resources, livelihood diversification, or mutual support through networks; and risk avoidance through migration.

Risk transfer through insurance markets has limited uptake in small islands, as the markets do not function as effectively as they do in larger locations, in part due to a small demand for the insurance products (Heger *et al.*, 2008). In the case of insurance for farmers, researchers found that a lack of demand for insurance products (in their study countries: Grenada, Jamaica, Fiji and Vanuatu) meant an undersupply of customized food insurance products, which in turn contributed to a lack of demand for insurance (Angelucci and Conforti, 2010). Alternatives exist such as index-based schemes which provide pay outs based on the crossing of a physical threshold, e.g. when rainfall drops below a certain level, rather than on drought damage sustained, (Linnerooth-Bayer and Mechler, 2009). The potential for index-based insurance for climate stressors on islands is under-researched. Small island governments also face expensive climate risk insurance. The Caribbean Catastrophe Risk Insurance Facility (CCRIF) pools Caribbean-wide country-level risks into a central, more diversified portfolio – offering lower premiums for participating national governments. CCRIF has been operating since 2007 (CCRIF, 2008). The potential for a similar scheme in the Pacific is being explored (ADB, 2009, Cummins and Mahul, 2009), although there is limited evidence of the long-term effectiveness of index-based or pooled-risk insurance in supporting household level adaptation.

Risk spreading can take many forms from reliance on social networks and familial ties to creation of marine protected areas to enhance representation of habitat types and replication of species. In Fiji, after Cyclone *Ami* in 2003, households whose homes were not affected by the cyclone increased their fishing effort to support those whose homes were damaged (Takasaki, 2011). In this way, risk was spread among the households, and mutual support formed a central pillar for community-based adaptation. In the case of natural systems, risks can be spread through the creation of marine protected areas, around key refuges that protect a diversity of habitat, that cover an

adequate proportion of the habitat and that protect critical areas such as nursery grounds and fish spawning aggregation areas (McLeod *et al.,* 2009). In Fiji, Locally Managed Marine Areas – which involve the local community in the management and protection of their local marine environment – have proven to be effective in increasing biodiversity, and in reducing poverty in areas dependent on marine resources (Techera, 2008). By creating a network of protected areas supported by local communities there is medium evidence that risks associated with some forms of climate change can be spread and potentially reduced (Mills *et al*., 2010).

29.6.2.3. Working Collectively to Address Climate Impacts on Small Islands

More attention is being focused on the relevance and application of community-based adaptation (CBA) principles to island communities, to facilitate adaptation planning and implementation (Warrick, 2009; Kelman *et al*., 2011), and to tackle rural poverty in resource dependent communities (Techera, 2008). Warrick's work in Vanuatu focuses on empowerment that is 'helping people to help themselves', while addressing local priorities and building on local knowledge and capacity. This approach to adaptation is being promoted as an appropriate strategy for small states, since it is something done 'with' rather than 'to' communities (Warrick, 2009).

Nonetheless externally driven programmes to encourage community-level action have produced some evidence of effective adaptation. Both Limalevu et al. (2010) and Dumaru (2010) describe the outcomes of externally-led pilot community-based adaptation projects (addressing water security and coastal management) implemented in villages across Fiji, notably: more effective management of local water resources through capacity building; enhanced knowledge of climate change,-; and, the establishment of mechanisms to facilitate greater access to technical and financial resources from outside the community. Limalevu et al. (2010) recognise that more long term monitoring and evaluation of the effectiveness of community level action is needed.

There is medium evidence that collaboration between a variety of stakeholders can benefit communities through the introduction of technical expertise to avoid simple mistakes that can dampen the effectiveness of adaptation actions. Evidence from the Eastern Caribbean suggests that adaptations taken by individual households to reduce landslide risk – building simple retaining walls – can be ineffective compared to community level responses (Anderson et al., 2011). They argue better hillside drainage through construction of networks of drains to capture surface runoff, household roof-water and grey water, with community support to construct the networks, with input from engineers can significantly reduce landslide risk . Case studies from Fiji and Samoa in which multi-stakeholder and multi-sector participatory approaches were used to help enhance resilience of local residents to the adverse impacts of disasters and climate change (Gero *et al.,* 2011) further support this view. In the case of community based disaster risk reduction (CBDRR), Pelling (2011) notes that buy-in from local and municipal governments are needed, as well as strong pre-existing relationships founded on routine daily activities, to make CBDRR effective. In both the Solomon Islands and the Cayman Islands there is reasonable agreement that the factors that underpin resilience to hazards resonates with earlier work on successful governance of the commons, that is: community cohesion; effective leadership; and, community buy-in to collective action (Schwarz *et al.,* 2011, Tompkins *et al*., 2008). Where community organisations are operating in isolation, or where there is limited coordination and collaboration community vulnerability is likely to increase (Ferdinand *et al*., 2012). Strong local networks, and trusting relationships between communities and government appear to be key elements in adaptation, in terms of maintaining sustainable agriculture and in disaster risk management.

All of these studies reinforce the earlier work of Barnett (2001), providing robust evidence that supporting community-led approaches to disaster risk reduction and hazard management may contribute to greater community engagement with anticipatory adaptation. However, it is not yet possible to identify the extent to which climate resilience is a coincidental benefit of island lifestyle and cultural, or a purposeful approach, such as the community benefits gained from reciprocity among kinship groups (Campbell, 2009).

29.6.2.4. Addressing Long-Term Climate Impacts and Migration on Small Islands

Small island states have 16% of their land area in low elevation coastal areas (<10m) as opposed to a global average of 2%, and the largest proportion of low elevation coastal urban land area: 13% (along with Australia and New Zealand), in contrast to the global average of 8% (McGranahan *et al.,* 2007). Figures like these lead many to suggest that small islands could be overwhelmed by rising seas associated with sea level rise (Loughry and McAdam, 2008, Yamamoto and Esteban, 2010, Gordon-Clark, 2012, Berringer, 2012, Dema, 2012, Lazrus, 2012, Laczko and Aghazarm, 2009). Yet there remains limited evidence as to which regions (Caribbean, Pacific, Indian Ocean) will experience the largest sea level rise (Willis and Church, 2012), which islands will experience the worst climate impacts, or which, if any, islands might disappear completely. Nicholls et al. (2011) have modeled impacts of 4°C warming, producing a 0.5 to 2.0m sea level rise, to assess the impacts on land loss and on migration. With no adaptation occurring, they estimate that this could produce displacement of between 1.2 and 2.2 million people from the Caribbean, Indian Ocean and Pacific Ocean. More research is needed to produce robust agreement on the impact of sea level rise on small islands, and on the range of adaptation strategies that could be appropriate under those scenarios. Some authors highlight that the image of small islands as 'canaries in the coal mine' is a western discourse that could potentially hinder adaptation in islands (Farbotko and Lazrus, 2012). Research into the possible un-inhabitability of islands has to be undertaken sensitively to avoid short-term risks (i.e. to avoid depopulation and ultimately island abandonment) associated with a loss of confidence in an islands' future (McNamara and Gibson, 2009, McLeman, 2011).

Relocation and displacement are frequently cited as outcomes of sea level rise and consequent land loss on islands (Byravan and Rajan, 2006, Biermann and Boas, 2008, Kolmannskog and Trebbi, 2010). Recent examples of environmental stress driven relocation and displacement provide contemporary analogues of climate-induced migration. Evidence of post-natural disaster migration has been documented in the Caribbean in relation to hurricanes (McLeman and Hunter, 2010), and in the Carteret Islands, Papua New Guinea – where during exceptionally high inundation event in 2008 (see 29.5.1.1) islanders sought refuge on neighbouring Bougainville island (Jarvis, 2010). Drawing any strong conclusions from this literature is challenging as there is little understanding of how to measure the effect of the environmental signal in migration patterns (Afifi *et al.*, 2013, Krishnamurthy, 2012). While the example of the Carteret Islands cannot be described as evidence of adaptation to climate change, it suggests that under some scenarios entire island communities may need to relocate in the future (Gemenne, 2011). In reality, financial and legal barriers are likely to inhibit significant levels of international environmentally induced migration in the Pacific (Barnett and Chamberlain, 2010) (see also Box 29-1). In the event of entire island relocation, the international community could find itself confronted with other critical issues such as how to support the legal and political continuity of a state that has lost its territory (Cournil and Gemenne, 2010). The potential migration options open to islands are presented in Table 29-5.

[INSERT TABLE 29-5 HERE
Table 29-5: Climate migration options in the Pacific.]

Climate stress is occurring at the same time as the growth in rural to urban migration. The latter is leading to squatter settlements that strain urban infrastructure – notably: sewerage, waste management, transport and electricity (Jones, 2005, Connell and Lea, 2002). Urban squatters often live in highly exposed locations, lacking basic amenities, leaving them highly vulnerable to climate risks (Baker, 2012). There is however limited evidence of the impact of climate change on the growing number of urban migrants in islands.

29.6.3. Barriers and Limits to Adaptation in Small Island Settings

Since publication of the IPCC SAR in 1996, significant barriers to climate change adaptation strategies in island settings have been discussed in considerable detail. Barriers include inadequate access to financial, technological and human resources, issues related to cultural and social acceptability of measures, constraints imposed by the existing political and legal framework, the emphasis on island development as opposed to sustainability, and a tendency to focus on addressing short term climate variability rather than long term climate change, and community preferences for "hard" adaptation measures (seawalls i.e.) instead of "soft" devices (Sovacool 2012). Heger et al.

(2008) recognise that more diversified economies have more robust responses to climate stress, yet most small islands lack economies of scale in production, thus specialising in niche markets and developing monocultures (e.g. sugar or bananas). Non-sovereign island states face additional exogenous barriers to adaptation. For example, islands like Réunion and Mayotte experience French provision of social services, but not the French level of building codes and land use planning (Le Masson and Kelman, 2011). Owing to their nature and complexity, these constraints will not be easily eliminated in the short term and will require on-going attention if their impact is to be minimized incrementally over time. Exogenous factors, such as the comparatively few assessments of social vulnerability to climate change, adaptation potential or resilience for island communities (Barnett, 2010) limit current understanding and action. In part this is due to the particularities of islands – both their heterogeneity and their difference from mainland locations – as well as the limitations of climate models in delivering robust science for small islands. It remains the case that thirteen years after Nurse et al. (2001) noted that downscaled global climate models do not provide a complete or necessarily accurate picture of climate vulnerabilities on islands, there is still little climate impacts research that reflects local concerns and contexts (Barnett *et al.,* 2008).

While lack of access to adequate financial, technological and human resources is often cited as the most critical constraint, experience has shown that endogenous factors such as culture, ethics, knowledge and attitudes to risk are important in constraining adaptation. Translating the word 'climate' into Marshallese implies cosmos, nature and culture as well as weather and climate (Rudiak-Gould, 2012), such cultural misunderstandings can create both barriers to action and novel ways of engaging with climate change. The lack of local support (due to encroachment on traditional lands) for the development of new infiltration galleries to augment freshwater supply on Tarawa atoll, Kiribati, highlights the importance of social acceptability (Moglia *et al.,* 2008a, 2008b). Such considerations have led to the conclusion that there is still much to be learned about the drivers of past adaptation and how 'mainstreaming' into national programs and policies, widely acclaimed to be a virtually indispensable strategy, can practically be achieved (Mercer *et al.,* 2007; Adger *et al.,* 2009; Mertz *et al.,* 2009).

Notwithstanding the extensive and ever-growing body of literature on the subject, there is still a relatively low level of awareness and understanding at the community level on many islands about the nature of the threat posed by climate change (Nunn, 2009). Even where the threat has been identified, it is often not considered an urgent issue, or a local priority, as exemplified in Malta (Akerlof *et al.,* 2010), and Funafuti, Tuvalu (Mortreux and Barnett, 2009). Lack of awareness, knowledge and understanding can function as an effective barrier to the implementation and ultimate success of adaptation programs. This is borne out in both Fiji and Kiribati where researchers found that spiritual beliefs, traditional governance mechanisms, and a short term approach to planning were barriers to community engagement and understanding of climate change (Kuruppu, 2009, Lata and Nunn, 2012). Although widely acknowledged to be critical in small islands, few initiatives pay little more than perfunctory attention to the importance of awareness, knowledge and understanding in climate change adaptation planning. Hence, the renewed call for adaptation initiatives to include and focus directly on these elements on an ongoing basis (e.g., Crump, 2008; Kelman and West, 2009; Kelman, 2010; Kuruppu and Liverman, 2011; Gero *et al.,* 2011) is timely, if these barriers are to be eventually removed.

29.6.4. Mainstreaming and Integrating Climate Change into Development Plans and Policies

There is a growing body of literature that discusses the benefits and possibilities of mainstreaming or integrating climate change policies in development policies. Various mechanisms through which development agencies as well as donor and recipient countries can seek to capitalize on the opportunities to mainstream are beginning to emerge (see for example Klein *et al.,* 2007; Mertz *et al.,* 2009). Agarwala and van Aalst (2008) provide examples from Fiji and elsewhere, of where synergies (and trade-offs) can be found in integrating adaptation to climate change into development cooperation activities, notably: disaster risk reduction, community-based approaches to development, and building adaptive capacity. Boyd et al. (2009) urge for more rapid integration of adaptation into development planning, to ensure that adaptation is not side-lined, or treated separately from sectoral policies. Although there are synergies and benefits to be derived from the integration of climate change and development policies, care is needed to avoid institutional overlaps, and differences in language and approach – which can give rise to conflict (Schipper and Pelling, 2006). Overall however, there appears to be an emerging consensus around the views expressed by Swart and Raes (2007) that climate change and development strategies should be considered as complementary, and

that some elements such as land and water management and urban planning provide important adaptation, development and mitigation opportunities.

29.7. Adaptation and Mitigation Interactions

Greenhouse gas emissions from most small islands are negligible in relation to global emissions, yet small islands will most probably be highly impacted by climate change (Srinivasan, 2010). Since small islands' populations are not responsible for anthropogenic climate change there is little moral imperative for them to reduce greenhouse gas emissions, though most have chosen to do so because of the potential co-benefits and synergies. Malta and Cyprus are obliged to do so in line with EU climate and energy policies. This section considers some of the inter-linkages between adaptation and mitigation on small islands and the potential synergies, conflicts, trade-offs and risks. Unfortunately there is relatively little research on the emissions reduction potential of small islands, and far less on the inter-linkages between climate change adaptation and emissions reduction in small islands. Therefore in this section a number of assumptions are made about how and where adaptation and mitigation actions interact.

29.7.1. Assumptions/Uncertainties Associated with Adaptation and Mitigation Responses

Small islands are not homogeneous, they have diverse geo-physical characteristics and economic structures (see Table 29-3, Figure 29-1). Following Nunn (2009) we assume that the combination of island geography and economic types informs the extent to which adaptation and mitigation actions might interact. The geography and location of islands affect their sensitivity to hydro-meteorological and related hazards such as cyclones, floods, droughts, invasive alien species, vector borne disease, and landslides. On the other hand the capacity of island residents to cope is often related income levels, resources endowment, technology and knowledge (see 29.6.2).

The costs of adaptation in small islands are likely to be relatively large, mostly due to the problem of overhead cost indivisibilities (see 29.3.3) and also because of the potentially high climate change impacts. Bueno et al. (2008) examined the potential costs to the island nations of the Caribbean if greenhouse gas emissions continue unchecked and found that for just three categories—increased hurricane damages, loss of tourism revenue, and infrastructure damages—the Caribbean's annual cost of inaction is projected to total $22 billion annually by 2050 and $46 billion by 2100. These costs represent 10 per cent and 22 per cent, respectively, of the current Caribbean economy.

The potential for mitigation and emissions reductions in islands depends to a large extent on their size and stage of economic development. In the small and less developed islands key 'mitigation' sectors: including energy, transport, industry, built environment, agriculture, forestry, or waste management sectors are likely to be relatively small (Metz *et al.,* 2007, Swart and Raes, 2007). Hence opportunities for emissions reductions are usually quite limited and are mostly associated with electricity generation and utilization of vehicles. More mitigation opportunities should exist in more economically advanced and larger islands that rely on forms of production that utilize fossil fuels, including manufacturing, and where vehicle usage is extensive and electricity driven home appliances, such as air conditioners and water heaters, are extensively used. Table 29-6 presents an indicative assessment of potential areas for mitigation activity on small islands by island 'economy type'.

[INSERT TABLE 29-6 HERE
Table 29-6. Economic structure of small islands and areas of potential emissions reduction.]

In the absence of significant mitigation efforts at the global scale, adaptation interventions could become very costly and difficult to implement, once certain thresholds of change are reached. (Nelson, 2011; Rosenzweig and Wilbanks, 2010, Thornton *et al.,* 2011, Birkmann, 2011). Nicholls et al. (2011) make a similar observation with respect to coastal protection as a response to sea level rise. They suggest that if global mean temperatures increase by around 4^0 C (which may lead to sea level rise between 0.5 m and 2 m) the likelihood of successful coastal protection in some locations such as low-lying small islands, will be low. Consequently, it is argued that 'coastal abandonment' would be a likely outcome in such circumstances (Nicholls *et al.,* 2011).

29.7.2. Potential Synergies and Conflicts

Metz et al. (2007) suggest that adaptation and mitigation interactions occur in one of four main ways: adaptations that result in greenhouse emissions reduction,; mitigation options that facilitate adaptation; policy decisions that couple adaptation and mitigation effects; and, trade-offs and synergies between adaptation and mitigation. Each of these opportunities is considered using three examples: coastal forestry, energy supply, and tourism.

Small islands have relatively large coastal zones (in comparison to land area) and most development (as well as potential mitigation and adaptation activities) are located in the coastal zone. Coastal ecosystems (coral reefs, sea grasses and mangroves) play an important role in protecting coastal communities from wave erosion, tropical cyclones, storm surges, and even moderate tsunami waves (Cochard *et al*., 2008). Whilst coastal forests including both endemic and exotic species especially mangroves are seen as effective adaptation options ('bioshields' Feagin *et al*..2010) in the coastal zones, they also play an important role in mitigation as carbon sinks (van der Werf *et al*., 2009). Thus, the management and conservation of mangrove forests has the potential to generate synergies between climate change adaptation and mitigation. However, despite this knowledge population, development and agricultural pressures have constrained the expansion of island forest carbon stocks (Fox *et al*., 2010) while Gilman et al. (2008) note that such pressures can also reduce the buffering capacity of coastal vegetation systems.

Renewable energy resources on small islands have only recently been considered within the context of long-term energy security (Praene *et al*., 2012, Chen *et al*., 2007). Stuart (2006) speculates that the lack of uptake of renewable technologies to date might be due to historical commitments to conventional fossil fuel-based infrastructure, and a lack of resources to undertake research and development of alternatives. Those islands that have introduced renewable energy technologies have often done so with support from international development agencies (Dornan, 2011). Despite thisthere remain significant barriers to the wider institutionalization of renewable technologies in small islands. Research in Europe and the United States has shown the mitigation and cost savings benefits of Energy Service Companies (ESCOs): companies that enter into medium-to-long term performance-based contracts with energy users, invest in energy efficiency measures in buildings and firms, and profit from the ensuing energy savings measures for the premises (see for example Steinberger *et al*., 2009). Potential benefits exist in creating the opportunity for ESCOs to operate in small islands. Preliminary evidence from Fiji suggests that if the incentive mechanisms can be resolved, and information asymmetries between service providers and users can be aligned, ESCOs could provide an opportunity to expand renewable technologies (Dornan, 2009).

The transition towards renewable energy sources away from fossil fuel dependence has been partly driven by economic motives, notably to avoid oil price volatility and its impact. The development of hydro-power (in Fiji for example) necessitates protection and management of the water catchment zones, and thus could lead to improved management of the water resources – a critical adaptation consideration for areas expected to experience a decrease in average rainfall as a result of climate change. Whilst the cost effectiveness of renewable technologies is critical, placing it within the context of water adaptation could enhance project viability (Dornan, 2009). Cost-benefit analyses have shown that in southeast Mediterranean islands photovoltaic generation and storage systems may be more cost-effective than existing thermal power stations (Kaldellis, 2008; Kaldellis *et al*., 2009).

Energy prices in small islands are among the highest anywhere in the world, mainly due to their dependence on imported fossil fuel, and limited ability to reap the benefits of economies of scale including bulk buying. Recent studies show that the energy sectors in small islands may be transformed into sustainable growth entities mainly through the judicious exploitation of renewable energy sources, combined with the implementation of energy efficiency measures (van Alphen *et al*., 2008; Banuri, 2009; Mohanty, 2012; Rogers *et al*., 2012). Realising the potential for such transformation, the countries comprising the Alliance of Small Island States (AOSIS) launched SIDS Dock, which is intended to function as a 'docking station' to connect the energy sector in SIDS with the international finance, technology and carbon markets with the objective of pooling and optimizing energy efficiency goods and services for the benefit of the group. This initiative seeks to decrease energy dependence in SIDS, while generating financial resources to support low carbon growth and adaptation interventions.

Many small islands rely heavily on the foreign exchange from tourism to expand and develop their economies, including the costs of mitigation and adaptation. Tourism, particularly in small islands, often relies on coastal and terrestrial ecosystems o provide visitor attractions and accommodation space. Much has been made of the relationship between ecosystem services and tourism In Jamaica, Thomas-Hope and Jardine-Comrie (2007) suggest that sustainable tourism planning should include activities undertaken by the industry, that is tertiary treatment of waste, and re-use of water, as well as composting organic material and investing in renewable energy. Gossling and Schumacher (2010) and others who have examined the linkages between greenhouse gas emissions and sustainable tourism argue that the tourism sector (operators and tourists) should pay to promote sustainable tourism, especially where they benefit directly from environmental services sustained by these investments.

29.8. Facilitating Adaptation and Avoiding Maladaptation

While there is a clear consensus that adaptation to the risks posed by global climate change is necessary and urgent in small islands, the implementation of specific strategies and options is a complex process that requires critical evaluation of multiple factors, if expected outcomes are to be achieved (Kelman and West, 2009; Barnett and O'Neill, 2012). These considerations may include, *inter alia*, prior experience with similar or related threats, efficacy of the strategies or options and their co-benefits, costs (monetary and non-monetary), availability of alternatives and social acceptability. In addition, previous work (e.g. Adger *et al.,* 2005) has emphasized the relevance of scale as a critical factor when assessing the efficacy and value of adaptation strategies, as the extent to which an option is perceived to be a success, failure or maladaptive may be conditioned by whether it is being assessed as a response to climate variability (shorter-term) or climate change (longer-term).

As in other regions, adaptation in islands is locally delivered and context specific (Tompkins *et al.,* 2010). Yet, sectors and communities on small islands are often so intricately linked that there are many potential pathways that may lead to maladaptation, be it via increased greenhouse gas emissions, foreclosure of future options, burdensome opportunity costs on local communities, by unintentionally discouraging adaptation initiatives, or by fostering over-dependence on external support (see for example Box 29-1).

_____ START BOX 29-1 HERE _____

Box 29-1. Resettlement and Migration: Adaptation or Maladaptation?

Whilst there is agreement that assistance from the international community is vital for supporting adaptation programs in small islands, there is a concern that some types of interventions may actually be maladaptive. For example, Barnett and O'Neill (2012) suggest that strategies such as resettlement and migration should be regarded as options of 'last resort' on islands, as they may actually discourage viable adaptation initiatives, by fostering over-dependence on external support. They argue that in the Pacific islands

> "Relying on resettlement forecloses on all other adaptation options…if there is no future for people in the places in which they live, then there is no reason to manage those places sustainably…Thus, if the only answer to climate change is resettlement, then there is no need to do anything else but wait, all other adaptation options will become impossible, and incentives to reduce greenhouse gas emissions will be similarly reduced" (Barnett and O'Neill, 2012, p.10)

_____ END BOX 29-1 HERE _____

Notwithstanding the observations of Barnett and O'Neill (2012), there is a concern that early foreclosure of this option might well prove maladaptive, if location-specific circumstances show such action to be efficacious in the longer-term. States contemplating this option may wish to consider early proactive planning, as resettlement of entire communities might prove to be socially, culturally and economically disruptive (Campbell, 2010; McMichael *et al.,* 2012; refer also to 29.3.3.4). The case study of the residents of Nauru who contemplated resettlement in Australia after the collapse of phosphate mining (their only revenue source) in the1950s, provides helpful insight

about the complex social, economic and cultural challenges associated with environmentally triggered migration (Tabucanon and Opeskin, 2011). The challenge therefore is to find the middle ground between premature resettlement and objective assessment of other appropriate adaptation choices.

Similarly, while insurance is being promoted as an element of the overall climate change response strategy in some island regions, e.g. the Caribbean, where the Caribbean Catastrophe Risk Insurance Facility (a multi-country risk pooling facility established in 2007 and owned by Caribbean governments) has been implemented, concerns have also been expressed in various jurisdictions about possible linkages to maladaptation. The potential consequences include the imposition of exorbitant premiums that are beyond the capacity of resource-scarce governments as the perception of climate change risks increase, discriminatory coverage of sectors that may not align with local priorities, and tacit encouragement for the state, individuals and the private sector to engage in behavior that is not risk-averse, e.g. development in hazard-prone areas (Herweijer*et al.,* 2009; Linnerooth-Bayer *et al.,* 2009; Linnerooth-Bayer *et al.,* 2011; van Nostrand and Nevius, 2011; Thomas and Leichenko, 2011). Likewise, although the exploitation of renewable energy is vital to the sustainable development of small islands, more attention needs to be paid to the development of energy storage technologies, if rapid transition from conventional fuels is to be achieved in an efficient manner. This is especially important in the case of intermittent energy sources (e.g. solar and wind), as the cost of current storage technologies can frustrate achievement of full conversion to renewables. Thus to avoid the possibility of maladaptation in the sector, countries may wish to consider engaging in comprehensive planning, including considerations relating to energy storage (Krajačić *et al.,* 2008; Krajačić *et al.,* 2010; Bazilian *et al.,* 2011).

Recent studies have demonstrated that opportunities exist in island environments for avoiding maladaptation. Studies have shown for example that decisions about adaptation choices and their implementation are best facilitated where there is constructive engagement with the communities at risk, in a manner that fosters transparency and trust (Fazey *et al.,* 2008; Lopez Marrero, 2010; van Aalst et al., 2008). Further, some analysts argue that adaptation choices are often subjective in nature and suggest that participatory stakeholder involvement can yield valuable information about the priorities and expectations that communities attach to the sector for which adaptation is being sought. The point is underscored by Moreno and Becken (2009), whose study of the tourism sector on the Mamanuca islands (Fiji) clearly demonstrates that approaches which explicitly integrate stakeholders into each step of the process from vulnerability assessment right through to consideration of alternatives measures can provide a sound basis for assisting destinations with the implementation of appropriate adaptation interventions. This view is supported by Dulal *et al*. (2009), who argue that the most vulnerable groups in the Caribbean - the poor, elderly, indigenous communities and rural children – will be at greater risk of being marginalized, if adaptation is not informed by equitable and participatory frameworks.

Other studies reveal that new paradigms whose adoption can reduce the risk of maladaptation in island environments, are emerging across various sectors. In the area of natural resource management, Hansen *et al*. (2010) suggest that the use of protected areas for climate refugia, reduction of non-climate stressors on ecosystems, adoption of adaptive management approaches combined with reduction of greenhouse gas emissions wherever possible, may prove to be more effective response strategies than traditional conservation approaches. Other strategic approaches, including the implementation of multi-sectoral and cross-sectoral measures, also facilitate adaptation in a more equitable, integrated and sustainable manner. Similarly, '*no-regret'* measures such as wastewater recycling, trickle irrigation, conversion to non-fossil fuel based energy and transportation which offer collateral benefits with or without the threat of climate change, and '*low-regret'* strategies, which may only increase existing operational costs marginally, are becoming increasingly attractive options to island governments (Gravelle and Mimura, 2008; Heltberg *et al.,* 2009; Cashman *et al.,* 2010; Howard *et al.,* 2010). Together, these constitute valid risk management approaches, as they are designed to assist communities in making prudent, but necessary decisions, in the face of an uncertain future.

Caution is needed to ensure that donors are not driving the adaptation and mitigation agenda in small islands, as there is a risk that donor-driven adaptation or mitigation will not address the salient challenges on small islands, and may lead to inadequate adaptation or a waste of scarce resources (Barnett, 2010; Nunn, 2009). There is a concern that donor-led initiatives may unintentionally cause enhanced vulnerability by supporting adaptation strategies that

are externally derived, rather than optimizing the benefits of local practices that have proven to be efficacious through time (Reenberg *et al.,* 2008; Kelman and West, 2009; Campbell and Beckford, 2009).

29.9. Research and Data Gaps

Significant advances in our understanding of the actual impacts and potential effects of climate change on small islands have been made since the AR4. These advances cover a range of themes including: dynamic downscaling of scenarios appropriate for small islands; impacts of trans-boundary processes generated well beyond the borders of an individual nation or island; barriers to adaptation in small islands and how they may be overcome; the relationships between climate change adaptation and disaster risk reduction; and, the relationships between climate change adaptation, maladaptation and sustainable development.

It is also evident that much further work is required on these topics in small island situations, especially comparative research. There are also important information and data gaps and many uncertainties still exist on impacts, vulnerability and adaptation in small islands. These include:

- **Lack of climate change and socio-economic scenarios and data at the required scale for small islands**. For example, projected changes in climate for the Caribbean, Pacific, Indian Ocean and Mediterranean islands, generally apply to the region as a whole and not to specific countries. However, most socio-economic decisions are taken at smaller scales. There is need for credible simulations of future small island climates and socio-economic conditions at comparable scales
- **Difficulties in detecting and attributing past impacts on small islands to climate change processes.** Further investigation of the observed impacts of weather, climate and ocean events that may be related to climate change is required to clarify the relative role of climate change and non-climate change drivers.
- **Uncertainty about the potential impacts of climate change**. In several small islands adaptation is being progressed without adequate understanding of past or potential impacts and vulnerability. Whilst assessment of future impacts is hampered because of uncertainty in climate projections at the local island level, alternative scenarios could be used for vulnerability and sensitivity studies to guide adaptation strategies.
- **Need for a range of climate change-related projections beyond temperature and sea-level.** Generally climate-model projections of temperature and sea-level have been satisfactory, but there are strong requirements for projections for other variables that are of critical importance to small islands. These include rainfall and drought, wind direction and strength, tropical storms and wave climate, and recognition that trans-boundary processes are also significant in a small island context.
- **Need to acknowledge the heterogeneity and complexity of small island states and territories.** Although small islands have several characteristics in common, neither the variety or complexity of small islands is sufficiently appreciated. Thus, transferring data and practices from a continental situation, or from one small island state to another, needs to be done with care.
- **Need to develop a typology that classifies small island states into a few groupings based on their social, cultural, economic, physical and ecological characteristics relevant to climate change impacts and vulnerability**. This has been an elusive task to date noting the discussion on vulnerability indicators in 29.6.1. Notwithstanding that discussion as well as the foregoing point there is increasing evidence that such a typology could be developed in stages. For example, an improved understanding of the interactions between vulnerability and 'island type' could provide useful guidance for optimizing scarce adaptation resources at community and local levels.
- **Within country/territory differences need to be better understood**. Many of the environmental and human impacts we have reported have been attributed to the whole country, when in fact they refer only to the major centre or town or region. There is need for more work on rural areas, outer islands and secondary communities. Several examples of such research have been cited in this chapter. Also it should be noted that some small island states are single islands and others highly fragmented multiple islands.
- **Lack of investment and attention to climate and environmental monitoring frameworks in small islands**. A fundamental gap in the ability to improve empirical understanding of present and future climate change impacts is the lack of climate and environmental monitoring frameworks that in turn hampers the level of confidence with which adaptation responses can be designed and implemented.

- **Economic and social costs of climate change impacts and adaptation options are rarely known**. In small island states and territories the costs of past weather, climate and ocean events is poorly known and further research is required to identify such costs, and to determine the economic and societal costs of climate change impacts and the costs of adaptation options to minimize those impacts.
- **Need to integrate adaptation to climate change and development co-operation activities.** There is some evidence to indicate that longer-term climate change adaptation policies and programs in small islands are compromising more immediate development objectives. Avenues need to be developed to redress this situation perhaps through a combined focus on hazard risk reduction and community based approaches to development and adaptation. Synergies between adaptation and development need to be explored in a small island context.

The foregoing list is a sample of the gaps, needs and research agenda appropriate for small island states. If those gaps are filled, needs satisfied and research achieved, we feel that the general view that small islands are highly vulnerable to climate change, and, that they have low adaptive capacity, may well be challenged by some nations as well as in some sectors and/or regions within small island states.

Frequently Asked Questions

FAQ 29.1: Are small islands experiencing the impacts of climate change?

Observed impacts of climate change on small islands are not conclusive. Whilst the media and some researchers emphasize the vulnerability of small islands, there are few studies that have been able to isolate anthropogenically-induced climate change impacts from those associated with natural climate variability and/or human activities. Even in the case of atolls where inundation from sea-flooding, storm surges and shoreline erosion has occurred, sea-level rise specifically linked to climate change has not been definitively identified as a primary cause of these hazards, or of outmigration and resettlement of populations from such areas. This does not mean that small islands are not experiencing the physical and socio-economic impacts of climate change, but rather that the manifestation of any climate change impact is not easily distinguishable from impacts attributable to other possible causes. It also reflects the poor level of empirical monitoring which occurs in small island environments and represents a research gap that needs to be urgently filled if greater confidence in the attribution of climate change stress in both human and physical systems is to be achieved.

FAQ 29.2: Why is it difficult to detect and attribute changes on small islands to climate change?

In the last two or three decades many small islands have undergone substantial changes in human settlement patterns and in socio-economic and environmental conditions. Such changes may have masked any clear evidence of climate change. This has resulted in difficulties when attempting to detect and attribute changes on small islands to climate change. One example can be cited. In many small islands coastal erosion has been widespread and has adversely affected important tourist facilities, settlements, utilities and infrastructure. However, specific case studies from islands in the Pacific and Indian oceans and the Caribbean have indicated that attribution of such shoreline instability to factors like sea-level rise associated with climate change have been masked by pervasive human impacts as well as episodic extreme events. Whilst coastal erosion is consistent with models of sea-level rise resulting from climate change, it has not been possible to quantify the extent of attribution of past and on-going coastal erosion to that factor. Given the range of natural processes and human activities that could impact the coasts of small islands in the future, the role of climate change-related processes may continue to be difficult to quantify and attribute.

FAQ 29.3: Why is the cost of adaptation to climate change so high in small islands?

Adaptation to climate change often involves overhead costs, such as infrastructural changes and upgrades. These generally include ‘lumpy‘ costs and costs that cannot be downscaled in proportion to the size of the population or territory. This disadvantage, termed the ‘indivisibility’ problem, is a major socio-economic issue for many small islands. It can be illustrated by way of example. A seawall, intended as a shore protection measure, 100 m long, suitable for a small island, will cost much more than one-tenth of a seawall 1 km long (that is ten times as much), suitable for a larger territory. This means that the cost of the seawall to the small island will be higher per m than for the larger territory. This reality applies throughout much of a small island economy including the

indivisibility of public utilities and services. It also applies to all forms of development and redesign of the infrastructure, aimed at ensuring that it is more resilient to climate change and extreme weather events. The result is a relatively higher adaptation cost per capita in countries with small populations, such as small islands and especially those islands that are geographically isolated, have a poor resource base and high import and transport costs.

Table 29-2: Preliminary projected percentage changes in tuna catches relative to the 20 year average (1980-2000) and estimated percentage change to government revenue resulting from projected changes in the catch of skipjack tuna in 2030 and 2100 (Bell et al., 2011).

SRES Scenario		2035	2100	
		B1/A2	B1	A2
Skipjack tuna	Western fishery	+ 11%	-0.2%	-21%
	Eastern fishery	+37%	+43%	+27%
Bigeye tuna	Western fishery	-2%	-12%	-24%
	Eastern fishery	+3%	-4%	-18%
Skipjack tuna	Total	+19%	+12%	-7%
Bigeye tuna	Total	+0.3%	-9%	-27%
Change to Government Revenue (Percent)	FSM	0.8 to 1.7%	-0.9 to -1.9%	
	Solomon Is	0.01 to 0.16%	-0.03 to0.77%	
	Kiribati	+11 to 18.4%	+7.2 to12.0%	
	Tuvalu	+3.7 to 9.2%	+2.5 to6.2%	

Table 29-3: Type of island in the Pacific region and implications for hydro-meteorological hazards.

Island type and size	Island elevation, slope, rainfall	Implications for hazard
Continental - Large - High biodiversity - Well developed soils	- High elevations - River flood plains - Orographic rainfall	River flooding more likely to be a problem than in other island types. In PNG high elevations expose areas to frost (extreme during El Nino).
Volcanic High Islands - Relatively small land area - Barrier reefs - Different stages of erosion	- Steep slopes - Less well developed river systems - Orographic rainfall	Because of size few areas are not exposed to tropical cyclones. Streams and rivers subject to flash flooding. Barrier reefs may ameliorate storm surge.
Atolls - Very small land area - Small islets surround a lagoon - Larger islets on windward side - Shore platform on windward side - No or minimal soil	- Very low elevations - Convectional rainfall - No surface (fresh) water - Ghyben Herzberg (freshwater) lens	Exposed to storm surge, 'king' tides and high waves. Narrow resource base. Exposed to fresh water shortages and drought. Water problems may lead to health hazards.
Raised Limestone Islands - Concave inner basin - Narrow coastal plains - No or minimal soil	- Steep outer slopes - Sharp karst topography - No surface water	Depending on height may be exposed to storm surge. Exposed to fresh water shortages and drought. Water problems may lead to health hazards.

Table 29-6: Economic structure of small islands and areas of potential emissions reduction.

Type of economy	*Sectors with significant emissions reduction potential*						
	Energy supply	Transport	Buildings (commercial /residential)	Industry	Agriculture	Forestry	Waste management and sewage
Aid dependent	X	X	X	X	?	?	X
Services dependent	√	?	√	X	?	X	√
Natural resource exporting	?	X	√	?	√	√	?
Diversified with manufacturing	√	?	√	√	?	?	?

Notes:
X = low potential for emissions reduction due to excessive cost or limited effectiveness
? = possible area for emissions reduction, although may depend on capacities within the islands
√ = rich area for exploring emissions reduction

Island Typology

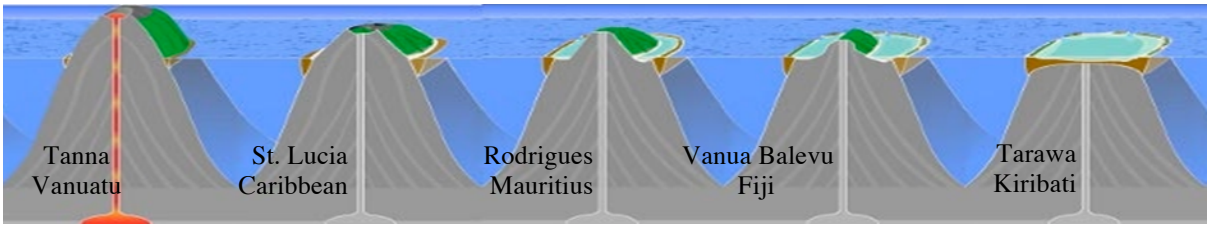

Figure 29-1: This schematic describes common tropical island typology from young high volcanic islands (left) through to atolls (submerged volcanics) on the far right. This simple overview highlights important components such as elevation and differing land and marine resources as well as the presence of coral reefs. On both high and low islands coastal settlement patterns predominate. Elevated limestone islands and islands comprised of 'continental' rocks are not included in this figure, but see Table 29-3.

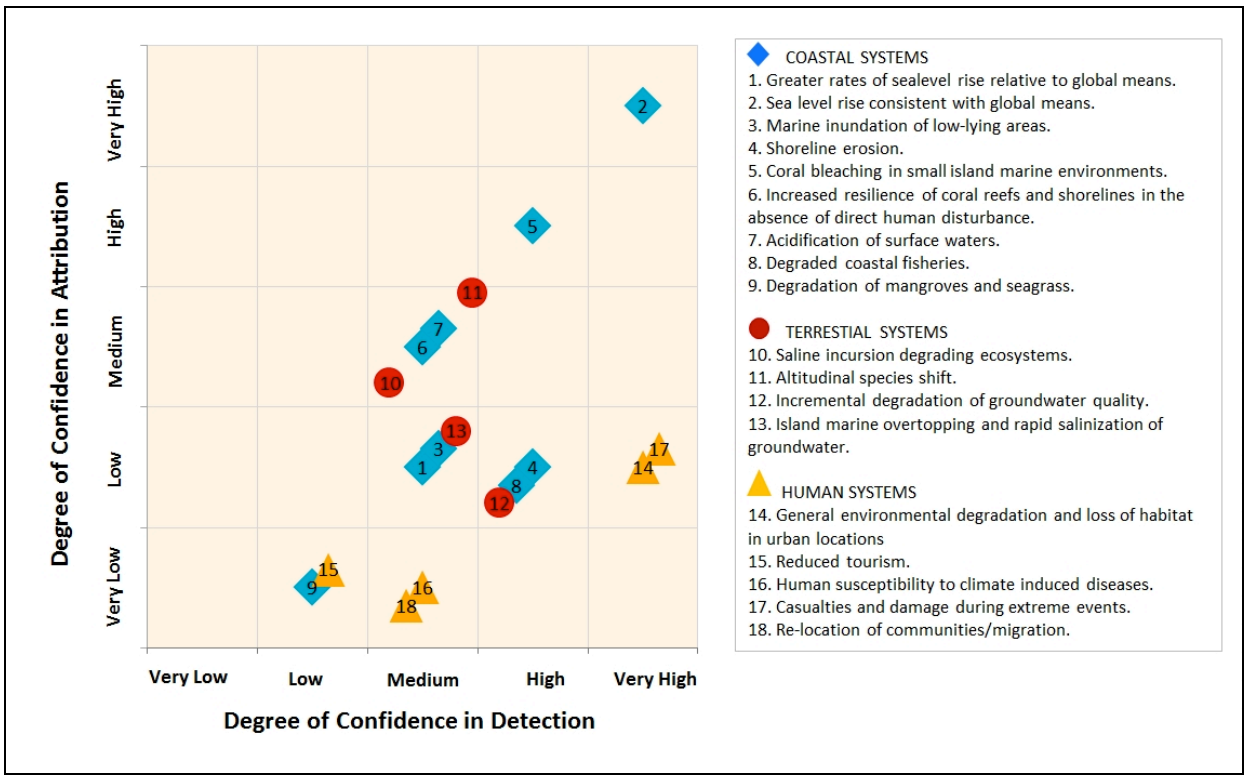

Figure 29-2: Based on available literature discussed in this chapter, the diagram shows a comparison of the degree of confidence in the detection of tropical small island impacts (horizontal axis) with the degree of confidence in attribution to climate change drivers (vertical axis). For example; the blue symbol No. 2 (Coastal Systems), indicates there is very high confidence in both the detection of "sea-level rise consistent with global means" and its attribution to climate change drivers; whereas the yellow symbol No. 17 (Human Systems) indicates whilst detection of "casualties and damage during extreme events" is very high, at this time there is low confidence in the attribution to climate change drivers. It is important to note that low confidence in attribution frequently arises due to the very limited research available for small island environments.

Executive Summary

The Ocean plays a central role in Earth's climate, absorbing over 90% of the heat added to the global climate system through the enhanced greenhouse effect. [WGI 3.2] The Ocean is also a major sink for anthropogenic CO_2 emissions. [WGI Box 3.2] Here, we assess the evidence for changes due to anthropogenic climate change (including acidification from rising atmospheric CO_2) on the Ocean as a region. It is *virtually certain* that anthropogenic climate change is already changing ocean temperature and acidity, as well as ocean productivity, trophic structure, and the distribution of species and ecosystems. The world's Ocean, however, encompasses a large variety of oceanographic and ecosystem structures and functions, and, hence, a wide variety of regional responses to climate change. We address this diversity by dividing the Ocean into eight sub-regions: High Latitude Spring Bloom Systems (HLSBS), Eastern Boundary Upwelling Ecosystems (EBUE), Coastal Boundary Systems (CBS), Equatorial Upwelling (EUS), Subtropical Gyres (STG), Semi-Enclosed Seas (SES), the Deep Sea (DS, >1,000 m), and Polar Seas. Dividing the Ocean into these sub-regions takes into account the diversity of marine environments and ecosystems at a large-scale although we acknowledge that any attempt is unlikely to be universally acceptable given the many bases by which this might be done (e.g. ecosystem, biogeochemical). Polar Seas (defined by the presence of sea ice) are not considered here as they are dealt with in Chapter 28. Our assessment reveals widespread impacts on organisms and ecosystems arising from the fundamental changes that have occurred within the physical and chemical conditions of the Ocean (*very high confidence*). Clear attribution of these changes to climate change depends on the sub-region and the physical, chemical or biological components involved. We discuss the implications of observed changes for different ocean sectors and sub-regions as climate change occurs.

The physical and chemical properties of the Ocean have changed significantly over the past 60 years (*very high confidence)*. Heat content has increased in the upper layers of the Ocean since 1950 consistent with the positive radiative imbalance of the climate system driven by anthropogenic greenhouse gas emissions. Temperatures in many sub-regions have been influenced by long-term variability (e.g. Pacific Decadal Oscillation, PDO, Atlantic Multidecadal Oscillation, AMO) as well as anthropogenic climate change, with the effects of variability being heightened at regional scales. Regional changes have also occurred in wind speed, surface salinity, ocean currents, solar irradiance, cloud distribution, and oxygen depth profile (*robust evidence, high agreement)*. Thermal expansion and melt water from glaciers and ice-caps have increased sea levels globally and to different extents regionally (*virtually certain)*. Surface warming of the Ocean and changes in wind speed have also increased the thermal stratification of the upper ocean in some regions (*high confidence*). Increased uptake of atmospheric carbon dioxide by the Ocean has decreased ocean pH and fundamentally changed the carbon chemistry of the Ocean *(very high confidence)*. The present state and rate of change of combined ocean pH and the concentration of carbonate ions are unprecedented in millions of years (*robust evidence, high agreement*). [30.3.1, 30.3.2; 6.1.1, 6.2.2.1; WGI 3.2 – 3.8, 10.41-10.4.4]

The Ocean is *virtually certain* to continue to warm and acidify as emissions continue to increase although differences between Representative Concentration Pathways (RCP) are likely to be minimal until 2035 (*high confidence, $p \leq 0.01$*). Projected temperatures of the surface layers of the ocean, however, diverge as the 21st century unfolds and will be 1-3°C higher by 2100 under RCP8.5 than RCP2.6 across most ocean sub-regions. Projected warming beyond 2100, however, is *very likely* to eventually reach average global temperatures and hence ocean temperatures that are 3-11°C above today. Ocean chemistry (pH, carbonate concentrations, and oxygen concentrations) is *virtually certain* to continue changing, with conditions approaching those not seen for 40 million years if atmospheric CO_2 continues to increase in the atmosphere (*very high confidence*). Based on the substantial response of ocean systems to the relatively small amounts of change so far, projected changes in atmospheric greenhouse gas concentrations and temperature are *virtually certain* to drive fundamental and far-reaching changes to the structure and function of ocean ecosystems (*high confidence*), and consequently the goods and services they provide for humanity (*medium confidence*). [30.3.1, 30.3.2, 6.3, 6.4; WGI 3.2, 3.8; Box 3.2, 12.4.7.1, 12.5]

Changes to ocean conditions have resulted in fundamental and extensive changes to organisms and ecosystems in the Ocean. Marine organisms are moving to higher latitudes consistent with warming trends (*high confidence*). Isotherms are migrating rapidly (10-20 km yr^{-1}) across the ocean surface in some regions, especially at lower latitudes causing marine organisms to move, acclimatise, or adapt evolutionarily. The greatest rates of movement of organisms to higher latitudes are seen amongst mobile organisms such as fish, crustaceans and

zooplankton assemblages, especially at higher latitudes *(robust evidence, high agreement)*. These changes have also been influenced by diverse factors such as the loss of sea ice, transcontinental shipping and the alteration of coastlines by rising sea levels (*medium evidence, medium agreement*). Increased sea temperatures have also significantly altered the phenology or timing of key life-history events such as plankton blooms, migratory patterns, and spawning in fish and invertebrates over recent decades (*medium confidence*). [30.4, 30.5; 6.2, 6.3, 6.5]

Ocean acidification resulting from the increased flux of atmospheric CO_2 into the Ocean represents a fundamental challenge to marine organisms and ecosystems, although the extent of its influence varies with the taxa and process involved (*high confidence*). The sensitivity of organisms to ocean acidification is highest in the earliest life history stages (*high confidence*). While there is *robust evidence*, *high agreement* and *high confidence* from controlled laboratory experiments and mesocosm studies that ocean acidification significantly impacts a large range of organisms (e.g. corals, fish, pteropods, coccolithophores, and macroalgae), physiological (e.g. skeleton formation, gas exchange, reproduction, growth and neural function) and ecosystem processes (e.g. productivity, reef building and erosion), there are fewer field studies that have shown (or not shown) direct ecosystem changes. Our understanding of synergies and interactions of increased ocean acidification with increased sea temperature is also limited and should be a priority of future studies. [30.3.1, 30.3.2, 30.4, Box CC-OA, 6.2, 6.3, 6.5, Box 5.1, 6.2]

Climate change, by increasing temperatures and altering surface winds, has influenced ocean mixing, nutrient levels and primary productivity. These changes are very likely to have positive consequences for some fisheries and negative ones for others through the de-oxygenation of deep water environment and associated spread of hypoxic zones (*medium evidence, medium agreement).* Changing surface winds have produced major changes in the supply of nutrients to the upper layers of the ocean. In regions where primary production has increased (or is predicted to increase), such as in the High Latitude Spring Bloom Systems (HLSBS), Eastern Boundary Upwelling Ecosystems (EBUE), and Equatorial Upwelling (EUS), energy transfer to higher trophic levels is *likely* to increase along with microbial activity. Increased primary productivity is *likely* to lead to an increased transfer of organic carbon to deep sea habitats stimulating respiration and drawing down oxygen levels in some areas. These changes are further influenced by the contribution of nutrients from coastal pollution, leading to the expansion of hypoxic (low in oxygen) zones in areas such as the Gulf of Mexico, North Sea, Arabian Sea, and coastal areas of many countries. Increasing temperatures will also reduce the solubility of oxygen, adding to oxygen stress (*very high confidence*). [30.5.2, 30.5.4, 30.5.6; 6.2, 6.3, 6.5]

Chlorophyll concentrations have decreased in the STGs in the North Pacific, Indian and North Atlantic Oceans by 9%, 12% and 11%, over and above the inherent seasonal and interannual variability from 1998 to 2010 (*high confidence; $p<0.05$*). Significant warming over this period has resulted in increased water column stratification and reduced mixed layer depth. This has reduced the vertical transport of nutrients into the upper layers of the Ocean and has reduced primary production by phytoplankton in these vast areas (as measured by chlorophyll, see 6.3.1 for associated uncertainties). Reducing primary production is *likely* to impact food availability for pelagic fish species (*limited evidence, medium agreement*). The influence of long-term variability complicates attribution of past changes directly to climate change. Changes in ocean primary productivity, chlorophyll, and other key biogeochemical processes are complex and our understanding how they are likely to change with climate warming is *limited*. [30.5.5.1, Table 30-2, 6.3, 6.1.3, 6.5]

Increasing ocean temperatures are driving a greater frequency of elevated temperature events that have had significant impacts on coastal ecosystems (*very high confidence*). In some cases (e.g. coral reefs, Mediterranean intertidal communities), the projected degradation of these marine ecosystems is *very likely* to pose substantial challenges for coastal societies where livelihood and food security may depend on ecosystem health. Many coastal ecosystems, however, are also affected by a wide range of non-climate change related human activities, making clear attribution of observed changes to climate change difficult. Reducing regional stressors represents an opportunity to strengthen the ecological resilience of these ecosystems which may help them survive projected changes in ocean temperature and chemistry. [30.4, 30.5.3; 30.5.6, 6.2.2.4, 6.3.2, 6.5.2; Box CC-CR]

High Latitude Spring Bloom systems (HLSBS) in the North Eastern Atlantic are changing in response to warming oceans (*high agreement, medium evidence).* These ecosystems are responding to rapid warming, with the greatest changes being observed since the late 1970s in the phenology, distribution and abundance of plankton

assemblages, and the reorganisation of fish assemblages. For example, the abundance of boreal species has decreased along the southern fringe and increased along the northern fringe of the HLSBS since cool phase of Atlantic Multidecadal Oscillation (AMO) in the 1960s and early 1970s. However, substantial natural variability over the past 30 years is embedded in the entire Northeast Atlantic region as part of the AMO (WG1 Chapter 14). These changes have both positive and negative implications for the future of the fisheries within the HLSBS. [30.5.1, 30.8.3]

The world's Semi-Enclosed Seas have been changing rapidly since 1982 with projected changes having important ramifications for surrounding countries (*medium confidence*). The upper layers of the world's Semi-Enclosed Seas (SES) show significant warming since 1982, although this warming signal is strongly influenced by long-term variability (e.g. AMO). Further warming is projected which is *very likely* to expose the SES to greater thermal stratification, which will lead *very likely* to reduced oxygen levels at depth and the spread of hypoxic zones, especially in the Baltic and Black Seas. These changes are *likely* to impact regional ecosystems as well as fisheries, tourism, and other human activities although the understanding of the potential impacts is relatively undeveloped. [30.3, 30.5.6]

Evidence that the world's most abundant habitat, the deep sea, is changing is compelling but requires further research (*medium agreement, limited evidence*). Deep sea habitats (>1000 m) occupy 60% of the planet's surface yet are little understood due to the difficulties of accessing them. Deep water coral communities are vulnerable to changes in ocean pH and carbonate chemistry. There is *medium evidence and agreement* that an increased nutrient supply through intensified upwelling in some regions (through intensified upwelling) threatens deep sea ecosystems with hypoxia by increasing the rate of metabolism (and hence oxygen use). Similarly, a decrease in primary productivity in some areas (e.g. subtropical gyres) may reduce the availability of organic carbon to deep sea ecosystems. These changes are *virtually certain* to increase due to the amplifying influence of rising deep water temperatures on microbial metabolism. Our understanding, however, of the changes in deep sea habitats that are currently occurring, and will occur, is limited. [30.5.7, 6.1.1.2, 6.1.1.3]

The observed and projected impacts on ocean ecosystems and processes reveal significant regional differences that will require differing policy responses and adaptation approaches (*medium agreement, medium evidence*). Changes to the distribution and abundance of fish species as waters warm and acidify will dictate the need for flexible and informed decision-making. For example, tuna, a key fisheries species, are highly sensitive to changes in sea temperature and changes in their distribution and abundance will provoke new technological and policy challenges. The cross-boundary migration of fish stocks (from the waters of one nation to another) will require international cooperation and evidence-based decision making. [30.5.5.2, 30.6.3]

Projected change to ocean ecosystems as a result of ocean warming and acidification will reduce access to food, and increase poverty and disease in many countries (*medium agreement, limited evidence*). Key fisheries throughout the world are being impacted by climate change, through direct physiological and ecological impacts. In many parts of the world (particularly in the tropical and subtropical regions), fisheries are in decline and will continue to do so under rapid anthropogenic climate change. Reduced access to food in some coastal regions as a result of declining fisheries will expose greater numbers of already vulnerable people to reduced access to food and will result in associated health impacts. Disease, impacts of harmful algal blooms, cholera, and ciguatera poisoning are also *likely* to increase as oceans warm and acidify. Understanding of these changes and their origin is important although limited. [30.6.3, 30.6.5]

Building dynamic fisheries management as well as sustainable aquaculture represent opportunities for adaptation to changes in the distribution and productivity of fish stocks (*high agreement, medium evidence*). The application of ecosystem-based management which includes climate change to manage the development and maintenance of fish stocks represents a key tool for adapting to changes resulting from climate change. Reducing non-sustainable fishing (e.g. bottom trawling, 'ghost' fishing) provides an avenue for adapting to climate impacts by reducing the impact of additional stressors. Changes to coastal fishing due to the loss of coastal ecosystems will require adaptation strategies such as marine protected areas, alternative livelihoods and/or the movement of people and industry sectors. Industries such as nature-based tourism will require similar strategies for decision-making. [30.6.3, 6.5, Ch7]

Changes to surface winds, sea level, wave height and storm intensity will increase the risks associated with coastal and ocean-based industries such as shipping, oil, gas and mineral extraction (*medium agreement, medium evidence*). Storm impacts on coastal areas will increase with sea level rise through greater storm surge impacts. [WGI, 3.7.4] Strategies will require consideration of these changes in the design and use of ocean-based infrastructure together with the evolution of policy for reducing risks to equipment and people. New opportunities for shipping, oil, gas and mineral extraction, as well as international issues over access and vulnerability, are likely to evolve as waters warm, particular in high latitude regions. [30.6, 6.5]

Adapting to the impacts of climate change within the Ocean is poorly developed but will benefit from improved forecasting and early warning systems (*medium agreement, limited evidence*). Given the reduced opportunity to mitigate ocean warming and acidification directly due to the scale of the problem, adapting fisheries strategies based on forecasting as well as developing ecosystem-based management strategies for fish stocks will help sustain many fisheries under climate change to some extent. Similarly, advanced warning systems can be used to help modify aquaculture management such as treating inflowing water to facilities during periods of low pH. While some examples exist of adaptation along these lines, the options are poorly developed for the broader set of impacts from climate change. [30.6]

Ocean ecosystems and associated sub-regions offer a large potential for carbon dioxide mitigation strategies (*medium agreement, limited evidence*). Ecosystems such as mangroves, seagrass and salt marsh represent potentially significant carbon sequestration strategies (e.g. 'blue carbon'). Reducing highly anoxic habitats through coastal restoration (and hence the emission of methane) also represent significant mitigation opportunities, although an understanding of these opportunities is limited. [30.7] There are also significant opportunities for ocean-based industries such as international shipping to continue to reduce their emissions intensity, as well as projects that source offshore wind and tidal power. Sequestration of anthropogenic CO_2 into deep ocean areas has been explored although studies indicate significant hurdles with respect to the expense and vulnerability of deep water marine ecosystems.

International frameworks for decision-making and collaboration represent vital tools for anticipating and responding to impacts of global climate change (including ocean acidification) on marine systems. UNCLOS, LOSC and other international frameworks provide the common basis for countries to recognise the common challenges arising from the impact of climate change on the ocean and to solve problems as diverse as creating sustainable fisheries across national borders, collaborative responses to the impacts of extreme events, and strengthening international food security through sustainable marine resources. Given the importance of the ocean to all countries, there is a need for the international community to progress rapidly to 'whole of ocean' strategies for responding to the challenges associated with anthropogenic climate change.

30.1. Introduction

The Ocean exerts a profound influence on the Earth, interacting with its atmosphere, cryosphere, land and biosphere to determine planetary conditions. It also directly influences human welfare through the provision and transport of food and resources, as well as cultural and economic benefits, and indirectly through the regulation of atmospheric gas content and distribution of heat and water across the planet. The present chapter evaluates the current impacts and future implications for Ocean sub-regions of increased concentrations of atmospheric greenhouse gases and other anthropogenic alterations to planetary radiative forcing. We also include the influence of changes to the chemistry of the Ocean through its acidification by increasing atmospheric carbon dioxide concentrations. In doing so, this chapter assesses recent scientific evidence and examines the extent to which significant changes can be accurately detected and attributed to anthropogenic climate change. The impacts, risks and vulnerabilities associated with climate change are assessed within seven ocean sub-regions, and the impacts and adaptation options for key ocean-based sectors discussed. Polar oceans are not directly considered here as they are given detailed treatment elsewhere (WGII Ch28). It is also noteworthy that while the impact of climate change on ocean sub-regions directly influences the coastal and low-lying sub-regions of multiple nations, a detailed discussion of these potential impacts also occurs in the relevant chapters of this report (e.g. WGII Ch5, Ch29).

30.1.1. Major Sub-Regions within the Ocean

The Ocean represents a vast region which stretches from the high tide mark to the deepest oceanic trench (11,030 m), and occupies 71% of the earth's surface. There are considerable challenges in assessing the regional impacts of climate change on the Ocean. Not only is the Ocean vast but it also contains a very broad diversity of life forms and habitats, many of which are poorly documented and not easily studied due to the difficulty of visiting much of this enormous region. Devising an appropriate structure in order to explore the influence of climate change on the entire ocean system is consequently challenging. *Longhurst* [1998] identified over 50 distinct ecological provinces in the ocean, defined by physical forcing, and the structure and function of phytoplankton communities. Longhurst's scheme, however, yields far more sub-regions than could be sensibly discussed in the space allocated here. Consequently, we have used comparable principles but have divided the non-polar ocean into seven larger sub-regions similar to *Barber* [1988]. In this case, our sub-regions are unified by specific physical forcing and ecosystem structure that might be expected to respond to climate change in broadly distinct ways (Figure 30-1, Table 30-1). We recognize that these sub-regions do not always map perfectly over physical-chemical patterns or specific geographies, and that they interact with strongly with terrestrial regions through weather systems and the exchange of materials. We also recognize that different ocean sub-regions may have substantially different primary and fishery productivities. Notably, over 80% of fisheries production is associated with three ocean sub-regions Northern hemisphere High Latitude Spring-bloom (HLSBS), Coastal Boundary Systems (CBS), and Eastern Boundary Upwelling Ecosystems (EBUE; Table 30-1, Figure 30-1B). The Deep Sea (>1,000m) is included as separate category which overlaps the six other ocean sub-regions.

[INSERT FIGURE 30-1 HERE
Figure 30-1: A. The world's non-polar oceans have been separated into seven major sub-regions, with polar oceans being excluded due to treatment elsewhere (Ch28). The chlorophyll concentration averaged over the period from Sep 1997 – 30 Nov 2010 (NASA) is also shown. Together with key oceanographic features, primary production was the basis for separating the ocean into the sub-regions shown. The map insert shows the distribution of Deep Sea habitat (>1000 m; Bathypelagic and Abyssopelagic habitats combined). Numbers refer to: 1 = High Latitude Spring Bloom Systems (HLSBS), 2 = Equatorial Upwelling (EUS), 3 = Semi-enclosed seas (SES), 4 = Coastal Boundary Systems (CBS), 5 = Eastern Boundary Upwelling Ecosystems (EBUE), 6 = Subtropical gyres (STG), and 7 = Deep sea (>1000 m). B. relationship between fish catch and areas for Ocean sub-regions shown in A. Red columns: average fish catch (millions tons yr^{-1}) for the period 1970-2006. Blue columns: area (millions km^2).]

[INSERT TABLE 30-1 HERE
Table 30-1: Percent area of the ocean, primary productivity and fisheries catch (production) for major sub-regions of the ocean (for location of sub-regions, see Figure 30-1).]

30.1.2. Detection and Attribution of Climate Change within the Ocean

The primary goals of Chapter 30 were to assess recent literature with respect to the detection and attribution of climate change to the physical, chemical and biological components of the Ocean and its sub-regions. Within Chapter 3 of IPCC AR5 from Working Group I (WGI), detailed observations of changes to the physical and chemical characteristics of the Ocean are described, while Chapter 10 assesses the influence of anthropogenic climate change on ocean heat content, ocean salinity on freshwater fluxes, sea level, and oxygen (WG1 10.4). These observations are assessed relative to near and long-term projections generated by CMIP5 models (WGI Chapters 11-12). We extend assessment to the observed changes in the physical and chemical characteristics of the Ocean in response to anthropogenic climate change by assessing change on Ocean sub-regions.

Attribution follows the detection of a change by addressing the question as to whether climate change has significantly contributed to the observed change [18.2.1.1]. We attempt to do this for a wide range of changes within our defined sub-regions within the Ocean. There are a number of general limitations to the detection and attribution of impacts to climate change (including ocean acidification) that are discussed elsewhere [18.2.1.2]. Challenges with

respect to ocean temperature and heat content, acidification, salinity, sea level, and oxygen are dealt with in Chapter 10 (WGI). Generally, attribution to climate change occurs when the full range of possible forcing factors is considered and those related to climate change are found to be the most likely explanation for the change in question. Comparing detected changes to the expectations of well-established scientific evidence plays a central role in the successful attribution of detected changes. Approaches and 'best practice' guidelines are discussed in Chapters 10 and 18 (WGI), as well as several other places [*Hegerl et al.*, 2010; *Hegerl and Zwiers*, 2007; *Stott et al.*, 2010].

Achieving successful detection and attribution of recent changes in ocean systems is complicated, as is the case on land, by the influence of sources of long-term and complex variability such as the Pacific Decadal Oscillation (PDO) and Atlantic Multidecadal Oscillation (AMO). The fragmentary nature of ocean observing, uncertainty of model simulations, and confounding influences of anthropogenic factors unrelated to climate change represent significant challenges [*Hoegh-Guldberg et al.*, 2011a; *Parmesan et al.*, 2011]. Anthropogenic climate change (e.g. ocean warming and acidification) are co-mingled with other human driven changes (e.g. pollution, introduced species, overexploitation of fisheries, and disease, [*Halpern et al.*, 2008] thereby frustrating efforts to establish a clear climate change signal. Long-term records are essential for this task but are rare, especially in difficult to access oceanic environments. Stressors not related to climate change may also interact synergistically or antagonistically with each other and climate change, further vexing the process [*Hegerl et al.*, 2010; *Hegerl and Zwiers*, 2007].

30.2. Major Conclusions from Previous Assessments

An integrated assessment of the impacts of climate change on the Ocean as a region was not done during previous IPCC assessment reports, although a chapter devoted to the Ocean in the Second Assessment Report (SAR) did "attempt to assess the impacts of projected regional and global climate changes on the oceans" [*Ittekkot et al.*, 1996]. Notwithstanding, attempts to detect and attribute the impact of climate change on observed changes in ocean and coastal systems are spread throughout previous assessment reports, reducing an key opportunity to synthesize the physical, chemical and biological changes and their causes within the Ocean and its sub-regions. The IPCC Fourth Assessment Report (AR4) concluded, however, that while terrestrial sub-regions are warming faster than the oceans, "Observations since 1961 show that the average temperature of the global ocean has increased to depths of at least 3,000 m and that the ocean has been taking up over 80% of the heat being added to the climate system." AR4 also concluded that sea levels had risen due to the thermal expansion of the ocean but recognized that our understanding of the dynamics of glaciers and ice sheets was "too limited to assess their likelihood or provide a best estimate or an upper bound for sea level rise" (AR4 SPM).

Changes to ocean temperature and density also have the potential to alter large-scale ocean circulation. AR4 concluded, however, with respect to the Meridional Overturning Circulation (MOC) that "it is very likely that up to the end of the 20th century the MOC was changing significantly at interannual to decadal time scales" (AR4 WGI, CH5, Box 5.1), although definitive evidence of a slowing MOC was lacking. According to AR4, "sea-level rise over the last 100 to 150 years is probably contributing to coastal erosion in many places" including the east coasts of the United States and United Kingdom (AR4, WGII Chapter 1). The AR4 assessment was *virtually certain* (Table 7.3), however, that rising atmospheric CO_2 had changed ocean chemistry (buffering, carbonate), and that a decrease in surface pH of 0.1 had occurred over the global ocean, which was calculated from the uptake of anthropogenic carbon estimated to have occurred between 1750 and 1994 [*Raven et al.*, 2005; *Sabine et al.*, 2004] ; AR4, 5.4.2.3].

Large-scale changes to ocean salinity were also observed from 1955 to 1998, which were "characterised by a global freshening in sub-polar latitudes and salinification of shallower parts of the tropical and subtropical oceans" (AR4 WGI Chapter 5). In this case, freshening was observed in the Pacific, with increased salinity being observed in the Atlantic and Indian Oceans (AR4, WGI, and ES). These changes in surface salinity were qualitatively consistent with observed and expected changes to surface freshwater flux. Freshening of mid- and high-latitude waters together with increased salinity at low latitudes were seen as evidence "of changes in precipitation and evaporation over the oceans".

Substantial evidence indicated that changing ocean conditions have extensively influenced marine ecosystems (AR4, WGI, Table 1.4). The abundance and productivity of pelagic plankton assemblages have responded to regional changes in sea temperature, stratification, upwelling, iron deposition, and other physical and chemical changes [*Hayes et al*., 2001]. Changes in the distribution and timing of reproduction were also reported in a range of organisms, although a separate detection and attribution of changes to climate change (from terrestrial studies) was not done as part of AR4. AR4 noted that there is an "accumulating body of evidence to suggest that many marine ecosystems, including managed fisheries, are responding to changes in regional climate caused predominately by warming of air and sea surface temperatures (SSTs) and to a lesser extent by modification of precipitation regimes and wind patterns".

Observed changes in marine ecosystems and managed fisheries within AR4 included: changes to plankton community structure and productivity, pelagic phenology and biogeography, intertidal communities along rocky shores, kelp forests, and the distribution of pathogens and invasive species. Changes were also observed in coral reefs through increased mass coral bleaching and mortality, populations and biogeography, migratory patterns and trophic interactions of sea birds, marine reptiles and mammals, as well as a range of other marine organisms and ecosystems (AR4, WGII, Table 1.5).

30.3. Recent Changes and Projections of Ocean Conditions

Understanding the extent to which the physical and chemical environments of the Ocean and its sub-regions have changed is centrally important to the interpretation of how organisms and ecosystems are likely to change over the coming decades and century. Increasing concentrations of atmospheric CO_2 have increased average global temperature and subsequently the temperature of the Ocean, and have fundamentally altered its chemistry (AR5, WGI, Executive Summary). Expert archives such as HadISST1.1 contain sea surface temperature (SST) from a range of sources allowing an opportunity to explore monthly mean gridded, global SSTs from 1870 to present [*Rayner et al*., 2003]. The HadISST1.1 data set is used here to investigate regional trends in SST within six of the seven sub-regions (Table 30-1), along with a range of other expert data sets for other variables including sea level, wind speed, water movement, water column structure, oxygen concentration, biogeochemistry and salinity.

30.3.1. Physical Changes

30.3.1.1. Heat Content and Temperature

There is little disagreement that Ocean has been dominant sink for most (>90%) of the extra heat arising from the human influence on Earth's radiative balance (*virtually certain;* WGI Box 3.1). As a result, the upper layers of the Ocean (0-75 m) have warmed significantly (>0.1°C per decade) since global observations became available (*virtually certain*). The intensification of the warming signal is associated with an increased thermal stratification of the upper layers (0-200 m) of the Ocean of around 4% over a 40-year record. These changes have a significant (*virtually certain*, $p < 0.01$) anthropogenic signal [*Gleckler et al*., 2012]**.** Rates of warming decrease to 0.015°C per decade at 700 m and are likely to be small but positive at deeper depths (<0.01°C per decade; WGI 3.2.2, Figure 3.1). All three ocean basins are warming at rates that exceed that expected if there were no changes to greenhouse gas forcing over the past century (Figure 3.2).

We use published HadISST 1.1 to explore trends in historic SST with our sub-regions outlined in Figure 30-1. The .2median SSTs for 1871-1995 from the Comprehensive Ocean-Atmosphere Data Set (COADS) were merged with data from the Met Office Marine Data Bank (MDB) to produce monthly globally-complete fields of SST on a 1º latitude-longitude SST grid from 1870 to date. The higher resolution HadISST 1.1 dataset (as compared to HadSST3) is best suited for use in this chapter.

The surface waters of the three ocean basins are warming similarly, with the Atlantic Ocean warming faster (0.3ºC decade^{-1}), than the Pacific (0.20ºC decade^{-1}) and Indian (0.11ºC decade^{-1}) Oceans (Figure 30-2). All but one of the Ocean sub-regions (exception being SES) have warmed significantly over the period 1950-2009 (HadISST1.1 data,

Table 30-2) although trends in temperature vary at a finer scale (e.g. South versus North Pacific, Table 30-2, Figure 30-3A). Notably, the southern portions of the HLSBS also did not show significant warming over this period although the northern hemisphere HLSBS did (Table 30-2). The rates of warming observed for the North Atlantic are consistent with the analysis of Advanced Very High Resolution Radiometer (AVHRR) satellite data combined with *in situ* measurements from ships and buoys collected in the International Comprehensive Ocean–Atmosphere Data Set (ICOADS, icoads.noaa.gov)[*González-Taboada and Anadón*, 2012]. Among the Eastern Boundary Currents, the Canary and Californian currents exhibited significant warming (0.09°C.decade^{-1} and 0.12°C.decade^{-1} respectively; $p < 0.05$) while the Benguela and Humboldt currents did not show significant temperature changes ($p > 0.05$; Table 30-2). The Coastal Boundary Systems showed highly significant warming (from 0.09°C.decade^{-1} to 0.13°C.decade^{-1}, Table 30-2). All subtropical Gyres (except the North Atlantic sub-tropical gyre) exhibited significant warming although rates were lower than analyses done over shorter periods (e.g. 1998 to 2010 [*Signorini and McClain*, 2012] and based on NOAA_OI_SST_V2 data (Figure 30-12B). Trends from 1950-2009 were not significant within the five SES analyzed here, although studies done of shorter periods (e.g. 1982-2006, [*Belkin*, 2009] reveal significant increases in SST temperature of: Baltic (1.35°C), Black (0.96°C), Red (0.74°C) and Mediterranean (0.71°C) Seas. These more recent and shorter length studies are complicated by the influence of patterns of long-term variability, most probably influenced by their small and land-locked nature. Given the large sensitivity of coral reefs to temperature anomalies [*Eakin et al.*, 2010; *Strong et al.*, 2011], we also examined the temperature trends in key coral reef regions using the World Resources Institute's Reefs at Risk (www.wri.org) to identify HadISST1.1 grid cells containing coral reefs (Figure 30-4). Grouping the results into six major coral reef regions, we found that coral reef waters had increased in temperature over the 50 year period examined by 0.36-0.65°C (Table 30-2).

[INSERT FIGURE 30-2 HERE
Figure 30-2: Observed and simulated variations in past and projected future annual average sea surface temperature over various oceanic regions. The black line shows estimates from HadISST1 observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (62 simulations), historical changes in "natural" drivers only (25), the "RCP4.5" emissions scenario (62), and the "RCP8.5" (62). Data are anomalies from the 1986-2006 average of the HadISST1 data (for the HadISST1 time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.]

[INSERT FIGURE 30-3 HERE
Figure 30-3: Analysis of data from Hadley Centre (HadISST 1.1, [*Rayner et al.*, 2003]) for different ocean sub-regions. A. Rate of change in sea surface temperature over the past 30 years (°C. decade^{-1}). B. Velocity at which isotherms are moving (km.decade^{-1}) from 1960-2009. C. Shift in seasonal changes that drive natural history events (days.decade^{-1}) for April and D. for October. E.]

[INSERT FIGURE 30-4 HERE
Figure 30-4: Location of coral reef grid cells used in Tables 30.2 and 30.4 as well as in Figure 30-11. Each dot is centred over a 1x1 degree grid cell within which lies at least one coral reef. The latitude and longitude of each reef is derived from data provided by the World Resources Institute's Reefs at Risk (http://www.wri.org). The six regions are as follows: Red – Western Pacific; Blue – Eastern Pacific Ocean; Green – Caribbean & Gulf of Mexico; Yellow – Western Indian Ocean; Magenta – Eastern Indian Ocean; and Cyan – Coral Triangle & SE Asia.]

[INSERT TABLE 30-2 HERE
Table 30-2: Regional changes in sea surface temperature (SST) over the past 50 years for ocean sub-regions specified in Figure 30-1. A linear regression was fitted to all 1x1 degree monthly SST data extracted from the HadISST 1.1 data set (Rayner et al., 2003) for the period of 1950 to 2009 for each ocean sub-region. The Table includes the slope of the regression (ºC.decade^{-1}), p value of the slope being different to zero, Linear Change Over 50 Years (slope of linear regression multiplied by 5 to obtain the average change over 50 years, and the difference between the mean temperature (1950-1959) from the mean temperature 50 years later (2000-2009). The latter may be different to the linear change over 50 years if there is significant long-term variability around the trend line. The last column compares the linear trend with that calculated between the two means with significant deviations (<0.8 and > 1.2) shown in red. P values that exceed 0.05 are also shown in red.]

Burrows et al. [2011] examined the rate at which isotherms are migrating by calculating the ratio of the rate of temperature change (°C.year^{-1}) to the spatial gradient of temperature (°C.km^{-1}) over the period 1960-2009. Given the essential role that temperature plays in the biology and ecology of marine organisms [*Poloczanska et al.*, 2013; *Pörtner*, 2002], the speed of isotherm migration ultimately determines the speed at which populations must either move, adapt, or acclimatize to changing sea temperatures [*Burrows et al.*, 2011; *Hoegh-Guldberg*, 2012b; *Pörtner*, 2002]. This analysis and others (e.g. North Atlantic, *González-Taboada and Anadón* [2012]) reveals that isotherms are moving at high velocities (up to 20 km.yr^{-1}) across the ocean, especially at lower latitudes (Figure 30-3B; *high confidence*). Other sub-regions showed lower velocities with contracting isotherms (cooling) in some areas (e.g. the Central and North Pacific, and Atlantic, Oceans Figure 30-3B). There are also changes in the timing of seasonal temperature in both spring and fall/autumn (Figure 30-3 C, D). The timing of spring conditions has advanced by 2-5 day.decade^{-1} in many parts of the global ocean, although the extent of change varies geographically. These changes in thermal environments are likely to have impacts on a range of different biological processes including the migration of species to higher latitudes and the timing and synchrony of reproductive and other seasonal behaviors [*Burrows et al.*, 2011; *Poloczanska et al.*, 2013], although it is noteworthy that other variables (e.g. light, food, habitat) can play significant roles in determining the distribution and abundance of marine organisms.

Significant excursions of sea temperature above long-term summer temperature maxima (or below long-term temperature minima) have significant impacts on marine organisms and ecosystems [*Bensoussan et al.*, 2010; *Crisci et al.*, 2011; *Harley*, 2011; *Hoegh-Guldberg*, 1999]. Consequently, calculating heat stress as a function of exposure time and size of a particular temperature anomaly has proven useful in understanding recent changes to organisms and ecosystems [*Strong et al.*, 2011]. The total heat stress accumulated over the period 1981-2010 was calculated using the methodology of [*Donner et al.*, 2007] and a reference climatology based on 1985-2000 in which the highest monthly SST was used to define the thermal threshold, above which accumulated thermal stress was calculated as 'exposure time multiplied by stress' or Degree Heating Months (DHM). Thermal stress was calculated as the running total of four consecutive months. While most sub-regions of the ocean experienced an accumulation of heat stress (relative to a climatology based on the period 1985-2000), equatorial and high latitude sub-regions in the Pacific and Atlantic oceans have the greatest levels of the accumulated heat stress (Figure 30-5A). There was also a higher proportion of years that had had at least one stress event (DHM > 1) in the last 30 years (1981-2010) than in the preceding 30 years (1951-1980; Figure 30-5B). In the last 30 years, most sub-regions that have coral reefs have experienced heat stress sufficient to cause mass coral bleaching [*Strong et al.*, 2011] events every 2-3 years.

[INSERT FIGURE 30-5 HERE
Figure 30-5: Recent changes in thermal stress calculating using HadISST 1.1 data. A monthly climatology was created by averaging the HadISST monthly SST values over the period 1985-2000 to create twelve averages, one for each month of the year. The Maximum Monthly Mean (MMM) climatology was then created by selecting the hottest month for each pixel. Anomalies were then created by subtracting this value from each SST value, but only allowing values to be recorded if they were greater than zero (Donner et al., 2007). Three measures of thermal stress change were then created: (A) Total thermal stress for the period 1981-2010, calculated by summing all monthly thermal anomalies for each grid cell. (B) Proportion of years with thermal stress, which is defined as any year that has a thermal anomaly, for the periods 1951-1980 and (C) 1981-2010.]

Projections of future sea temperature changes were examined using ensemble averages from AOGCM simulations available in the CMIP5 archive (Table 30-3) for the four representative concentration pathways (RCP2.6, RCP4.5, RCP6.0, and RCP8.5; [*van Vuuren et al.*, 2011]). Ensemble averages for each RCP are based on simulations from 10 to 16 individual models (Table 30-3). Model hind-cast changes matched those observed for Ocean sub-regions for the period 1980-2009 (HadSST 1.1, Table 30-2, Figure 30-2), with the model ensemble slightly overestimating the extent of change across the different Ocean sub-regions (slope of observed/model = 0.81, $r^2 = 0.76$, $p < 0.001$). In this way, the absolute amount of change projected to occur in the ocean sub-regions was calculated for near-term (2010-2039) and long-term (2070-2099) periods (Table 30-4). In the near term (2010-2039), changes in the temperature projected for the surface layers of the ocean are largely indistinguishable between the different RCP pathways due to the similarity in forcing until 2035. By the end of the century, however, SSTs across the Ocean sub-

regions were 1-3°C higher under RCP8.5 than those projected to occur under RCP2.6 (Table 30-4). The implications of these projected changes on the structure and function of oceanic systems are discussed in later in this chapter.

[INSERT TABLE 30-3 HERE
Table 30-3: CMIP-5 models used to create the Chapter 30 RCP 2.6, 4.5, 6.0 and 8.5 SST ensembles.]

[INSERT TABLE 30-4 HERE
Table 30-4: Projected changes in sea surface temperature (SST, ºC) over the next 90 years for Ocean sub-regions (Figure 30-1) using model runs from the Coupled Model Intercomparison Project Phase 5 (CMIP-5, http://cmip-pcmdi.llnl.gov/cmip5/). Runs were divided up into their respective Representative Concentration Pathways (RCP) to form four groups; RCP2.6, RCP4.5, RCP6.0 and RCP8.5. The CMIP-5 models that were used in this analysis are listed in Table 30-3. For each region, a linear regression was fitted to all 1x1 degree monthly SST data extracted from the models for each of three periods; 2010-2039, 2040-2069 and 2070-2099. The average change in SST was calculated by multiplying the slope of each linear regression by 360 (months) to derive the average change over each successive 30 year period. The table is divided into two sections, "Near-term (2010-2039)" – the average change in SST over the next 30 years, and "Long-term (2010-2099)" – the total change from 2010-2099, which was calculated by adding the average change of the three 30 year periods from 2010 to 2099. This is a simplified method to account for slight non-linearity in SST change over the 90 year period.]

30.3.1.2. Sea Level

The Ocean has expanded as a result of its increased heat content (3.7.2) and has expanded in mass (reliable records begin in 2002) mainly as a result of water being added from melting glaciers and ice sheets on land. As a result of the thermosteric and mass components, it is *virtually certain* that Global Mean Sea Level (GMSL) has increased between 1.4 and 2.0 mm yr^{-1} over the 20th Century and between 2.7 and 3.7 mm yr^{-1} since 1993 [(99% confidence; WGI 3.7.6]. It is also considered *very likely* that sea level rise has accelerated over the past two centuries and that rates are tenfold higher than the relatively high rates that occurred during the late Holocene [WGI Chapter 3, Chapter 5, 13.2.1–2, Figure 13.3].

Measurement of sea level rise using satellite altimetry, oceanographic buoys and floats (e.g. Argo Program) and tidal gauges reveal that sea level rise varies geographically, with rates three times higher than the global average sea level rise in the Pacific Warm Pool (PWL) located in the Western Pacific and South-East Asian region, and rates that are close to zero in many parts of the eastern Pacific. The high rates of sea level rise associated with the PWL are a result of the intensification of trade winds while the lower rates of sea level rise in the western United States are associated with changes in wind stress, both of which are strongly influenced by PDO variability (WGI 3.7.3, Figure 3.11 and FAQ 13.1). These differences are expected to vary on decadal timescales although it is very likely (*high confidence*) that 95% of the Ocean will experience significant regional changes in sea level over and above this source of variability (WGI Section 13.6.5, Figures 13.15–13.17).

Global Mean Sea Level is likely to increase by 0.7 m to 0.95 m by 2100 for Representative Concentration Pathways (RCP) of 2.6 and 8.5, respectively (*medium confidence*). Semi-empirical approaches project that sea level will increase well above 1 m by the end of the century (up to 1.5 m, WGI Table 13.6) although there is some discussion around assumptions associated with these approaches (WGI 13.4.1, 13.4.5). It is significant to note that sea level rise under these scenarios does not stop at 2100 and continues to occur for hundreds of years into the future, depending on the scenario in question. Central to this analysis is the millennial scale commitment to further sea level rise that is likely to arise from the melting of the Greenland and Antarctic ice sheets.

The combined effects of sea level rise and other factors such as increased storm intensity are very likely to increase the occurrence of extreme flooding events (WGI 13.7.2, 18 Figure 13.19). Regional flood risk depends on local topology, oceanography and other factors. While complete understanding of the associated risks is relatively undeveloped, significant coastal and low-lying areas, particularly in the Pacific Ocean and North Atlantic, face increased in flood risk (5.5). Future impacts from sea level rise include increasing penetration of storm surge into coastal areas, changing patterns of shoreline erosion (5.2.2.1) as well as the inundation of saltwater into coastal

aquifers (5.3.2.2.). While habitat may be lost, some examples of habitat expansion have been reported [*Brown et al.*, 2011]. Overall, changes to sea level and storm intensity are very likely to modify the habitats and hence coastal ecosystems such as beaches, salt marsh, coral reefs and mangroves (5.4.1.5), especially where rates of sea level rise are highest (e.g. South East Asia and the Western Pacific).

30.3.1.3. Surface Wind and Ocean Circulation

Atmospheric and ocean circulation (and their interaction) are centrally important to the chemical, physical and biological characteristics of the Ocean, determining crucial properties such as intensity of ocean ventilation, coastal upwelling, primary production, carbon export, and the spatial distribution and trophic interaction of plankton populations. While water is the major conveyor for transporting nutrients to land plants, the critical factor for transporting nutrients to the marine primary producers is ocean mixing driven by wind. Wind stress measurements from satellite and *in situ* observations have been collated within a number of international projects to produce reliable data sets on historic global wind patterns. In addition to an expanding set of ocean observing systems (e.g. Global Drifter and Argo Programs), there is a smaller archive of ocean circulation measurements, the small size of which ultimately limits our understanding of how ocean circulation has changed (WGI 3.6).

The National Center for Environmental Prediction (NCEP) Reanalysis Project, [*Kalnay et al.*, 1996] provides an opportunity to explore regional changes that have occurred over the past 60 years (1951-2010, Figure 30-6). While there are large uncertainties associated with historic wind speed data generally (WGI 2.7.2) and overall confidence in wind trends is low (SREX 3.3), there are some specific trends that persist across multiple data sets and analyses. Wind stress (westerly winds) has increased since 1951 over the Southern Ocean (Figure 30-6A) which matches observations from satellites and island station data since the early 1980s (*medium confidence*, WGI 3.4.4). A progressive migration of the westerlies towards higher latitudes has also occurred over the past several decades [*Cai*, 2006.; *Cai and Cowan*, 2007]. These changes are affecting mixed-layer dynamics, nutrient flux, and ocean circulation. The transport of Indian Ocean waters into the South Atlantic has increased in response to latitudinal shifts in the Southern Hemisphere westerlies [*Bard and Rickaby*, 2009; *Biastoch et al.*, 2008a; *Biastoch et al.*, 2008b], with potential implications for the evolution of the MOC [*Friocourt et al.*, 2005] and consequently future climate.

Surface waves are influenced by wind stress although understanding trends remains a challenge due to the paucity of data sets. It is likely, however, that Significant Wave Height (SWH) has been increasing since the 1950s over the Southern Ocean (up to 5% per decade, WG1 3.4.6) and mid-latitudes of the North Pacific and Atlantic Oceans (winter season trends of 8-20 cm per decade; WGI 3.4.6, 2.7.2). Understanding how SWH will change over the coming decades and century remain *uncertain* over most of the ocean remains an important knowledge gap (WG1 3.4).

Parts of the tropical Pacific show a decrease in wind stress over the same period (Figure 30-6A) which is consistent with other studies [*Vecchi et al.*, 2006] and analyzes (WGI Figure 2.37). Reduced trade wind speed is consistent with Walker Circulation and appears to have a considerable anthropogenic forcing component [*Vecchi et al.*, 2006]. Winds speeds have increased within some Eastern Boundary Upwelling Systems (e.g. California Current, Figure 30-6A; WG1 2.7.2). Changing wind regimes have the potential to influence Mixed-Layer-Depth (MLD) and upwelling intensity in highly productive sub-regions of the world's oceans although agreement is low as to whether or not upwelling will intensify across all areas [*Bakun*, 1990; *Bakun et al.*, 2010]. While there are many uncertainties with how wind stress will change under future changes to global climate, evidence from the tropical Pacific is consistent with predictions of further weakening of tropical atmospheric circulation under the influence of anthropogenic forcing [*Vecchi et al.*, 2006]. These changes are closely linked to patterns (and are likely to influence) of long-term variability associated with ENSO, NAO and SAM although observations are too limited in space and time to be able to separate anthropogenic trends from natural variability (WGI 3.5).

There is growing evidence that major circulation systems have changed. It is very likely, for example, that the subtropical Gyres (STG)s within the three ocean basins have expanded and strengthened since 1993 (WGI 3.5), and it is *as likely as not* that these changes are associated with an anthropogenic driver [*Signorini and McClain*, 2012].

There is *limited evidence* for other large-scale trends in major features of ocean circulation (e.g. Atlantic Meridional Overturning Circulation, AMOC, Indonesian flow-through) at this point (WGI 3.6). Global climate models need firstly to capture the large-scale changes in wind in order to accurately predict changes in primary production. Primary production, however, is also strongly dependent on regional and local processes down to frontal and eddy-forming scales implying that high resolution predictions of wind stress are also needed and represent an essential knowledge gap.

30.3.1.4. Solar Radiation and Clouds

Solar radiation plays a crucially important role in the biology of marine organisms. Not only as a source of energy for photosynthesis but it is also as a potential co-stressor in temperature related stress such as seen during mass coral bleaching and mortality events [*Hoegh-Guldberg*, 1999]. Global surface solar radiation (from the NCEP/NCAR Reanalysis Project, *Kalnay et al.* [1996]) decreased 4.3 $W.m^{-2}decade^{-1}$ from the 1950s until 1991 after which it increased at 3.3 $W.m^{-2}decade^{-1}$ until 1999 [*Ohmura*, 2009; *Wild*, 2009]. Changes in solar radiation and cloudiness from 1951 to 2010 vary regionally (Figure 30-6 B, C). The largest increases in solar radiation and decreases in cloudiness from 1951 to 2010 occurred in the tropical Pacific. These observations are consistent with the eastward shift in tropical convection and total cloud cover from the western to central equatorial Pacific over the 20th Century and with the long-term weakening of the Walker circulation (WG1 2.5.7.3). Decreases in cloud cover from 1951 to 2010 are also visible in the southern Indian, Pacific and Atlantic Oceans. Changes in cloud cover and solar radiation were correlated with broad changes in surface ocean salinity as a result of associated changes in heating of the ocean surface, cloud, and rainfall [*Deser et al.*, 2004]. Projections of how cloudiness, solar insolation and precipitation are likely to change as the planet warms have low levels of confidence due to the large interannual variability (ENSO, PDO), short observation time series and uneven spatial sampling, particularly early in the record (before 1950; WG1 2.5.8). Understanding these changes, however, represents a significant knowledge gap and area of future research.

[INSERT FIGURE 30-6 HERE
Figure 30-6: Absolute change over 50 years calculated using regression analysis of data from 1951-2010 (A) Wind Speed as the absolute change in $m.s^{-1}$; (B) Solar radiation as change at the surface of incoming solar insolation in Wm^{-2}; (C) Cloud Cover as the absolute change in total cloud fraction (i.e. If at the beginning of the period the cloud fraction was 0.6 and 0.5 at the end of the period, the change would be -0.1) using NCEP re-analyzed data (www.esrl.noaa.gov); and (D) Salinity as the percentage change from 1960-2010 [reproduced using the data of Durack and Wijffels, 2010]. Data for (A), (B) and (C) were derived from the NCEP/NCAR Reanalysis [*Kanamitsu et al.*, 2002]. Monthly mean values for wind speed, total cloud cover and downward solar radiation flux (solar insolation) were obtained from http://www.esrl.noaa.gov/psd/data/gridded/data.ncep.reanalysis.derived.html. At each 1x1 degree grid cell, a linear regression was calculated for each of wind, cloud and solar insolation. The slopes were then multiplied by 600 (months) to calculate the average change over a 50 year period.]

30.3.1.5. Storm Systems

Storm systems range from small atmospheric disturbances to large and violent cyclones, typhoons and hurricanes, and can have both positive and negative influences on ocean ecosystems. As agents of water column mixing, storms can remix nutrients from deeper areas into the photic zone of the ocean, stimulating productivity. Storms can also reduce local sea temperatures and associated stress by remixing heat into the deeper layers of the ocean [*Carrigan and Puotinen*, 2011]. Storms are often highly destructive, however, and can destroy coastal infrastructure and habitats such as coral reefs and mangrove forests which can take decades to recover [*De'ath et al.*, 2012].

There is *robust evidence* that the frequency of the most intense cyclones in the Atlantic has increased since 1987 (WG1 2.6.3) and *robust evidence* of inter-decadal changes in the storm track activity within the North Pacific and North Atlantic [*Lee et al.*, 2012]. There is also statistically significant evidence of a decrease in tropical cyclones that impacted the East Australian coast is the 19th century, with a significant interaction with long-term variability and land-falling cyclones being twice as common in La Niña versus El Niño years (*high confidence,* [*Callaghan and Power*, 2011]. There has been an increase in the number of intense wintertime extra-tropical cyclone systems since

the 1950s in the North Pacific. Similar trends have been reported for the Asian region although analyses are restricted by limitations in terms of the spatial and temporal coverage of reliable records (WG1 2.6.4).

Higher sea temperatures and specific humidities is *likely* to result in fewer yet more intense and damaging storm systems [*Bengtsson et al*., 2009; *Grinsted et al*., 2010]. Wind velocity of tropical cyclones is likely to increase under the influence of warming oceans although the frequency will either decrease or remain unchanged (WGI, 3.4.4). The number of extra-tropical and tropical storm events are *likely* to decrease while average storm intensity is likely to increase [*Bengtsson et al*., 2006; *Bengtsson et al*., 2009; *Landsea et al*., 2010], especially in the Western Atlantic, north of 20°N [*Bender et al*., 2010]. There is *medium confidence* that extra-tropical storm tracks will shift polewards (WGI, 3.4.5). Coastal ecosystems and human communities are likely to experience greater storm surge impacts as increased storm intensity interacts with rising sea levels [SREX 3.5.3, 3.5.5].

30.3.1.6. Thermal Stratification

Greater heat content has resulted in a 4% increase in thermal stratification of the upper layers of the Ocean (0-200 m, 40 year record) except in the case of the Southern Ocean (WG1 3.2.2). Increasing thermal stratification has reduced ocean ventilation and the depth of mixing in most ocean sub-regions (*medium confidence*, 6.3.2, 6.5.2). This in turn reduces the availability of inorganic nutrients and consequently limits primary productivity (*medium confidence*, 6.1.1, 6.2.2.1, 6.2.2.2.3). This has been observed in the STGs which dominate the three major ocean basins (30.5.6), and less so in high-latitude regions where winter convection and deep-water formation are dominant seasonally.

The continued warming of the surface layers of the ocean will *very likely* further enhance stratification and increasingly limit the nutrient supply to euphotic zone. There is *medium evidence* to suggest that the associated loss of primary productivity may be compensated for by enhanced upwelling at high latitudes and from the increasing input of nutrients from coastal systems from human activities (6.1.1.5). The response of upwelling to global warming is *likely* to vary between regions and represents a complex interplay between local and global variables and processes (Box 30-1).

_____ START BOX 30-1 HERE _____

Box 30-1. Upwelling Intensification, Stratification-Ventilation, and Primary Productivity

Bakun [1990] hypothesized that if atmospheric pressure gradients between land and sea expand due to global warming, meridional wind stress that causes upwelling could intensify (Figure 30-16). Empirical support for this hypothesis is equivocal *Bakun* [1990] found supporting trends in some EBUEs, but not others. Similarly, *Narayan et al*. [2010] found mixed results depending on the data sets used. *Garcia-Reyes and Largier* [2010] observed increasing winds and cooling for coastal locations off north-central California (from 36°N to 39°N), but no change to the north or south, while [*Perez et al*., 2010] found that upwelling clearly weakened in the northern Canary Current. Thus trends may vary spatially within systems. Upwelling-favorable winds could lead to increased nutrient input and primary productivity, increasing winds could also result in increased turbulence and offshore advection, factors that may reduce productivity on continental shelves [*Botsford et al*., 2003; *Cury and Roy*, 1989]. In this way, increased upwelling may be associated with increased nutrient input to the euphotic zone, but decreased primary and secondary production.

[INSERT BOX FIGURE HERE
Caption: Diagram illustrating the interaction between land and coastal sea temperature, wind direction and strength, and coastal upwelling.]

More recently, *Rykaczewski and Dunne* [2010] proposed the “stratification-ventilation” hypothesis which hypothesises that climate change could result in enhanced nutrient input and productivity at regional scales. Focusing on the California Current, GCMs were used to show that future increased stratification in the western and central North Pacific could alter the characteristics of waters upwelled in the California Current, with increasing

nitrate concentrations being a primary result. The basic argument in this case is that reduced ventilation and mixing of deep, nutrient-rich waters into the euphotic zone over much of the ocean allows continued accumulation of remineralized nutrients in subsurface waters. In sub-regions where these nutrient-enriched waters are forced into the euphotic zone by upwelling processes, nutrient supply and primary production may increase. Thus, primary productivity in the EBUEs may benefit from reduced utilization of nutrients in adjacent, well stratified sub-regions.

_____ END BOX 30-1 HERE _____

30.3.2. Chemical Changes

30.3.2.1. Surface salinity

Ocean salinity varies regionally and is an outcome of the balance between evaporation and the precipitation water from the atmosphere [*Durack and Wijffels*, 2010]; WG1 3.3). Evaporation-dominated regions such as the STGs, Atlantic (except in the Gulf of Mexico and South America; WG1 3.3.3.2) and Western Indian Oceans (Arabian Sea, WG1 3.3.3.1) have elevated salinity, while areas of high precipitation such as the North Pacific, north-eastern Indian Ocean and the eastern Pacific have relatively low salinities (WG1 3.3.3.1 Figure 30-5D). There is *very high confidence* (>99%) that most of these areas have continued to change in the same direction (i.e. a trend of increasing salinity in areas of high salinity and one of decreasing salinity in areas of low salinity (*Durack and Wijffels* [2010], Figure 30-6D).

Salinity trends are strongly consistent with the amplification of the global hydrological cycle [*Durack et al.*, 2012; *Pierce et al.*, 2012], a consequence of a warmer atmosphere producing greater precipitation, evaporation and extreme events (WG1 3.3.4, Figure 10.14a). These trends are consistent with increases in global temperature, and lead to the conclusion that "it is therefore *likely* that some of the observed changes in surface salinity in the 20th and the early 21st century are attributable to anthropogenic forcing" (WG1 10.4.3, Figure 10.14). Changes in salinity and temperature are consistent with changes expected due to anthropogenic forcing of the climate system and are inconsistent with the effects of natural climate variability, either internal to the climate system (e.g. ENSO, PDO) or external (e.g. solar forcing or volcanic eruptions, [*Pierce et al.*, 2012]. There are *high agreement* between CMIP3 climate models that these trends in ocean salinity are expected to continue as average global temperature [*Terray et al.*, 2012]. Ramifications of these changes are largely uncertain but are of great interest given the role of ocean salinity and temperature in fundamental processes such as the AMOC.

30.3.2.2. Ocean Acidification

Increased atmospheric CO_2 from human activities has increased the flux of CO_2 into the Ocean, resulting in decreased ocean pH as well as carbonate and bicarbonate ion concentrations (Box CC-OA). The extent to which the added influx of CO_2 into the Ocean has acidified and influenced the tendency for aragonite or calcite (polymorphs of calcium carbonate) to precipitate into the shells and skeletons of marine organisms depends mostly on the solubility of CO_2 and calcium carbonate, both of which decrease as temperature increases or depth decreases. Other factors such as atmosphere-ocean heat exchange, ocean circulation, and land-sea interactions (WG1 6.4) play significant roles in determining the saturation state of seawater for the polymorphs of calcium carbonate. Consequently, pH and the saturation states of aragonite and calcite are naturally lower at high latitudes and in upwelling areas (e.g. Eastern Pacific upwelling, Californian Current) which may be relatively more vulnerable to ocean acidification as a result [*Gruber et al.*, 2012](Figure 30-7 A, B). These two variables also decline with depth, calcite reaching its saturation horizon between 3,000 and 4,500 m, and aragonite reaching its saturation horizon between 1000 m and 2500 m in the Pacific and Atlantic oceans respectively [*Orr et al.*, 2005].

Surface ocean pH has declined by approximately 0.1 pH units since the beginning of the Industrial Revolution (*very high confidence*, WG1, 3.8.2, Box 3.2) with significant shoaling of the saturation horizons of both polymorphs of calcium carbonate [*Orr et al.*, 2005]. Oceanographic studies have measured the ongoing decline in ocean pH (–0.0015 and –0.0024 pH units per year; WGI 3.8.2, Figure 3.17) and the saturation state of calcium carbonate

polymorphs (WG1 Figure 3.17). These changes can be strongly attributed to the increase in anthropogenic CO_2 emissions to the atmosphere (*very high confidence*, WGI 3.8.2, Box 3.2 and Table 10.1) and are at least 10 times faster than accumulation of atmospheric CO_2 than during the Paleocene-Eocene Thermal Maximum (PETM; 6.1.2, *high confidence*). The impacts of ocean acidification on marine organisms and ecosystems has emerged as a major concern especially given the *robust evidence* that the current chemistry of the ocean is outside where it has been for million years [*Pelejero et al.*, 2010; *Zeebe*, 2012]. At current rates of atmospheric CO_2 increase, changes to the chemistry of the ocean will surpass any seen over the last 40 million years [*Hoegh-Guldberg et al.*, 2007; *Raven et al.*, 2005; *Tyrrell and Zeebe*, 2004] and possibly 300 million years (6.1.2).

Observations from a wide range of laboratory, mesocosm, and field studies reveal that marine organisms and ocean processes are sensitive to levels of ocean acidification projected under elevated atmospheric CO_2 (Box CC-OA, 6.2.2, 6.3.4, [*Kroeker et al.*, 2013], *high confidence*). Ecosystems that are characterised by high rates of calcium carbonate deposition (e.g. coral reefs, plankton communities) are sensitive to decreases in the saturation states of aragonite and calcite (*high confidence*). These changes are *very likely* to have broad consequences such as the loss of three-dimensional coral reef frameworks [*Dove et al.*, 2013; *Hoegh-Guldberg et al.*, 2007] and restructuring of food webs at relatively low concentrations of atmospheric CO_2. Similarly, organisms sensitive to changes in pH with respect to physiological processes such as respiration and neural function are also expected to respond to the rapid changes in pH and ocean chemistry (6.3.4). Due to the relative short history of ocean acidification studies, and the current expanding effort to understand this problem, there are a growing number of organisms and the processes that are being identified as sensitive to the influence of anthropogenic changes to ocean chemistry.

Projected changes to the atmospheric CO_2 will further acidify the ocean and change its chemistry (Figure 30-7; WG1 Figure 6.28). Doubling CO_2 will decrease ocean pH by another 0.1 pH units and decrease carbonate ion concentrations by approximately 100 mmol kg^{-1} (from an average of 250 mmol kg^{-1}; *high confidence, Orr et al. [2005]*)(WG1 6.4, Figure 6.28). The saturation horizons will also become significantly shallower in all oceans, with the aragonite saturation horizon line between 0 and 1500 m in the Atlantic and, 0 and 600 m (poles versus equator) in the Pacific Ocean [*Orr et al.*, 2005] WG1 6.4, Figure 6.28). Trends towards under-saturation of aragonite and calcite will also depend on ocean temperature, with polar waters expected to be undersaturated with respect to aragonite and calcite within a couple of decades (Box CC-OA; 6.4.4). These changes will also be accompanied by a shoaling of the aragonite and calcite saturation horizons that is *very likely* to have serious ramifications for deep water communities such as deep water scleractinian corals and other benthic organisms [*Guinotte et al.*, 2006].

[INSERT FIGURE 30-7 HERE
Figure 30-7: A. Surface pH and B. aragonite saturation state of the Ocean at different atmospheric CO_2 levels simulated by the University of Victoria Earth System Model. The fields of pH and aragonite saturation state are calculated from the model output of dissolved inorganic carbon concentration, alkalinity concentration, temperature, and salinity, together with the chemistry routine from the OCMIP-3 project (http://www.ipsl.jussieu.fr/OCMIP/phase3).]

30.3.2.3. Oxygen Concentration

Dissolved oxygen is a major determinant of the distribution and abundance of marine organisms (6.2.2.1.). Oxygen concentrations vary across the ocean basins, tending to be lower in the eastern Pacific and Atlantic basins, and northern Indian Ocean (Figure 30-8; 6.1.1.3). By contrast, some of the highest concentrations of oxygen are associated with cooler high latitude waters (WG1 Figure 3.19). Long-term records of oxygen concentrations in ocean waters are rare. However, there is high agreement that open ocean oxygen concentrations in the thermocline have declined by 0.09 to 0.34 μmol kg^{-1} $year^{-1}$ since 1960 and it is *very likely* that the tropical oxygen minimum zones have expanded over recent decades (WG1 3.8.3; *Stramma et al.* [2008]). These changes are consistent with the solubility of oxygen declining with higher temperatures and with increased water column stratification reducing ocean-atmosphere ventilation. Analysis of ocean O_2 trends over time [*Helm et al.*, 2011a] reveals that the basic phenomenon of O_2 solubility decreasing with increased temperature is responsible for no more than 15% of the observed change. The remaining 85%, consequently, must be attributed to increased deep-sea microbial respiration and reduced O_2 supply from increased ocean stratification (WG1 Box 6.5 Figure 1). Eutrophication of coastal areas,

for example, can lead to increased transport of organic carbon into ocean habitats where microbial metabolism is stimulated resulting in a rapid drawdown of oxygen [*Bakun et al*., 2010; *Rabalais et al*., 2009; *Weeks et al*., 2002].

It is *likely* (*limited evidence, medium agreement*) that areas of low O_2 concentrations in deep water are expanding in many parts of the world (WGI 3.8.3) with impacts on marine life including mass mortality and the subsequent exclusion of fish and other metazoans from expanding "dead zones" (*high confidence*, [*Diaz and Rosenberg*, 2008](6.2.2, 6.3.3). These areas are rapidly expanding due to regional human drivers not directly related to climate change (i.e. eutrophication of coastal areas) in addition to drivers that are (e.g. increasing sea temperature, increasing stratification, changes in terrestrial run-off and reduced ventilation from changing wind stress). Climate change at a decadal time scales is also driving the widespread increase in hypoxia through the reduction in oxygen concentrations arising due to reduced solubility, temperature effects on microbial respiration, and increased water column stratification. The subarctic Pacific is perhaps the best example of an ocean basin where physical forcings are clear, where Siberian warming leads to reduced ice formation, a reduction in dense water formation and a weakening oxygen transport into the interior ocean [*Nakanowatari et al*., 2007].

The development of hypoxic conditions (generally defined as O_2 concentrations below 60 μmoles kg^{-1}) over recent decades has been documented across a wide array of ocean sub-regions including SES (Black and Baltic Seas), the Arabian Gulf, and the California, Humboldt and Benguela current systems (Figure 30-8), where eruptions of hypoxic, sulfide-laden water have occurred [*Weeks et al*., 2002]. Localized seasonal hypoxic zones have emerged in economically valuable coastal areas such as the Gulf of Mexico [*Rabalais et al*., 2010; *Turner et al*., 2008], the Baltic Sea [*Conley et al*., 2009] and Black Sea [*Kideys*, 2002; *Ukrainskii and Popov*, 2009], in connection with nutrient fluxes from land. Over a vast region of the Eastern Pacific stretching from southern Chile to the Aleutian Islands, the minimum pO_2 threshold (< 2 $mg.l^{-1}$ or 60 mmol kg^{-1}) is found at only 300-m depth and upwelling of increasingly hypoxic waters is well documented [*Grantham et al*., 2004]. Hypoxic waters in the northern Arabian Sea and Bay of Bengal are located close to continental shelf depths. Long-term measurements are revealing that oxygen concentrations are declining in these waters, with *medium evidence* that economically significant mesopelagic fish populations are being threatened [*Koslow et al*., 2011]. The Atlantic Ocean differs from the Pacific and Indian Ocean as hypoxic conditions in this respect are largely limited to the regions at and adjacent to the two EBUE due to its better ventilation. The calculation of hypoxia profiles according to an assumed critical threshold of 60 mmol kg^{-1} are illustrative although this can convey an overly simplistic message given that critical concentrations of O_2 are species and life history stage specific, showing a great dependence on body size and/or temperature. This variability in sensitivity is critical to how ecosystems are likely to respond to this aspect of climate change (6.3.3).

It is *very likely* that further increases in ocean temperature will lead to decreased oxygen concentrations due to the effect of temperature on O_2 solubility and water column stability (reduced ocean ventilation). There is *high agreement* among modelling studies that the total oxygen within the ocean will decline under future scenarios (WG1 Table 6.14). The outcomes of these global changes will be influenced by regional differences in wind stress, coastal processes, and the production and consumption of organic matter by microbes.

[INSERT FIGURE 30-8 HERE
Figure 30-8: Map of the depth [*Hofmann et al*., 2011] at which a critical value of partial pressure of O_2 of 60 matm occurs which is widely accepted as threatening to marine life on continental shelves (200m depth). Conventional maps of oceanic oxygen values report simple mass properties with no temperature or depth dependence; a better rendition of the availability of O_2 to marine life is provided by the partial pressure, which includes the temperature terms. Critical sub-regions in the eastern and northern Pacific and in the northern Indian ocean stand out. In these areas quite modest upward expansion of the depth at which the critical pO_2 level occurs can have negative effects on major fish populations. Note: not all areas have been included – for example, significant hypoxia in the Gulf of Mexico is not been shown.]

30.4. Global Responses by Marine Organisms to Climate Change (including Ocean Acidification)

There has been a rapid increase in studies that focus on climate change impacts on marine ecosystems since AR4 ([*Hoegh-Guldberg and Bruno*, 2010; *Poloczanska et al*., 2013] representing an opportunity to examine and

potentially attribute detected changes within the Ocean to climate change. *Poloczanska et al*. [2013] applied the 'vote-counting' approach used by *Parmesan and Yohe* [2003]; *Root et al*. [2003] and *Rosenzweig et al*. [2008] to show a coherent pattern in responses of ocean life to recent climate change across regions and taxonomic groups using a global database of observed responses (1735 responses in 857 species or assemblages from 208 peer-reviewed papers). (Figure 30-9; [*Poloczanska et al*., 2013]. Observations were defined as those where the authors of a particular paper assessed the consistency of change in a biological parameter (namely distribution, phenology, abundance, calcification, demography or community composition) with climate change. Studies from the peer-reviewed literature were selected using three criteria: (1) authors inferred or directly tested for trends in biological and climatic variables; (2) data after 1990 were included; and (3) observations spanned at least 19 years, to minimize bias resulting from short-term biological responses to natural climate variability. Approximately 90% of the studies identified temperature as the primary driver of change, with the remainder focusing on sea ice, pH and climate oscillation, where changes have been explicitly linked to global warming.

[INSERT FIGURE 30-9 HERE
Figure 30-9: (A) 1735 observed responses to climate change from 208 single- and multi-species studies showing responses that are consistent with climate change (blue), opposite to expected (red) and are equivocal (yellow). Each circle represents the centre of a study area. Where points fall on land, it is because they are centroids of distribution that surround an island or peninsula. Pie charts show the proportions within regions bounded by red squares and in the Mediterranean; numbers indicate the total (consistent, opposite plus equivocal) observations within each region. (B) Frequency of observations by latitude. (C) South-west Pacific. (D) North-east Atlantic. (E) California Current. (F) North-west Pacific (Poloczanska et al 2013).]

The results of this meta-analysis suggest that climate change is having an impact on species in many different ways across a broad range of taxonomic groups (plankton to top predators). Of the observations that showed a response in either direction, 84% were in a direction that was consistent with climate change (Fig. 30-10). For these, consistency was variable according to taxonomic group (Figure 30-10A), latitudinal band (Figure 30-10B), and biological response parameter (Figure 30-10C). Despite remaining knowledge gaps, especially in equatorial sub-regions and the Southern Hemisphere, it is clear that recent climate change has already had widespread impacts on marine organisms and ecosystems.

[INSERT FIGURE 30-10 HERE
Figure 30-10: Percent of responses consistent with climate change predictions. Mean and standard error of responses by (A) taxa, (B) latitudinal region and (C) response measure show significantly higher consistency than expected from random (dashed line at 50% consistency). Solid line is the mean across all observations. Significance of results is listed next to labels (***: $p < 0.001$; **: $p < 0.01$; *: $p < 0.05$). Sample sizes are listed to the right of each row.]

The overall mean (± SE) rate of re-distribution for marine biota was 72.0 ± 13.5 km decade^{-1} measured at leading range edges and 15.8 ± 8.7 km decade^{-1} at trailing edges, with most of the data collected from 1950 onwards (Figure 30-10B) revealing much higher rates of migration than reported for terrestrial species. The average rate of change on land was 6.1 ± 2.4 km decade^{-1} when calculated across taxa [*Parmesan and Yohe*, 2003] or 19.7 ± 3.7 km decade^{-1} calculated across regional taxonomic groupings [*Chen et al*., 2011]. Similarly, spring timing showed advances of -4.4 ± 0.7 day.decade^{-1} in marine systems (Figure 30-11A [*Poloczanska et al*., 2013]), contrasting with -2.8 ± 0.35 day.decade^{-1} for terrestrial species [*Parmesan*, 2007]. Similar trends are seen for the delayed arrival of fall/winter in both hemispheres.

[INSERT FIGURE 30-11 HERE
Figure 30-11: Rates of change in (A) phenology (days.decade^{-1}) measured during spring (red) and summer (brown); and (B) distribution (km.decade^{-1}) for marine taxonomic groups, measured at the leading edges (red), and trailing edges (brown). O (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward) and negative phenological changes are consistent with warming (generally earlier). Means ± standard error are shown, with number of observations and significance (*p<0.1, **p<0.05, ***p<0.01); Poloczanska et al, 2013).]

The faster expansion rates of leading edges compared to contraction of trailing edges can be partly explained by the speed and direction at which isotherms propagate across the Ocean's surface [*Burrows et al*., 2011; *Loarie et al*., 2009] in study regions. Both the leading and trailing range edges for ectothermic marine organisms are likely to be equally responsive to warming temperatures [*Sunday et al*., 2012]. The velocity of isotherm migration in the ocean over 1960-2009 [*Burrows et al*., 2011] varies considerably, with locally fast and slow sub-regions. Rapid velocities (>50 km.decade^{-1}) were observed in the North Sea, the sub-Arctic Pacific and Atlantic, and within 15° of the equator, implying a risk of large ecological responses (Figure 30-3B, [*Burrows et al*., 2011]). Rates of climate change, such as climate velocity, over longer time periods can help to explain both present-day distribution patterns and shifts in biodiversity [*Sandel et al*., 2011].

Poloczanska et al. [2013] reveal that climate change is resulting in changes to organisms and ecosystems within the world's oceans (*robust evidence, high agreement,* and *high confidence*). Diagnostic fingerprints, uniquely predicted by twentieth century climate trends, provide convincing evidence that climate is the primary driving force behind the observed biological changes, strengthening the attribution of detected changes to climate change (Parmesan and Yohe 2003). These include concurrent increases of 'warm-water' species and decreases of 'cool-water' species, as expected with climate change, within regions. Consistent responses were recorded across multiple poleward or equatorward edges of distributions that were widely separated (such as for fish populations in north-west Atlantic and north-east Atlantic, and discussed in regional assessments below).

30.5. Regional Impacts, Risks, and Vulnerabilities: Present and Future

This section explores the impacts, risks and vulnerabilities of climate change for the seven sub-regions within the Ocean. There is considerable variability from region to region, especially in the extent and interaction of climate change and non-climate change stressors. While the latter may complicate attribution attempts in many sub-regions, interactions between the two types of stresses may also represent opportunities to reduce the overall impact on marine organisms and processes by environmental changes being driven by climate change (including ocean acidification).

30.5.1. High-Latitude Spring Bloom Systems

High-latitude Spring Bloom Systems (HLSBS) stretch from 35º N and S to the edge of the winter sea ice and provide 36% of world's fishery catch (Table 30-1, Figure 30-1). Strong seasonal cycles of primary productivity are pronounced at high latitudes, which create phytoplankton spring-bloom dynamics, and follow the latitudinal gradient in light intensity [*Racault et al*., 2012]. Efficient transfer of marine primary and secondary production to higher trophic levels, including commercial fish species, is influenced by the magnitude and spatial and temporal synchrony between successive trophic production peaks [*Beaugrand and Reid*, 2003; *Beaugrand et al*., 2003; *Cushing*, 1990; *Hjort*, 1914].

30.5.1.1. Observed Changes and Potential Impacts

30.5.1.1.1. North Atlantic

The North Atlantic is one of the most intensively fished ocean sub-regions. The major areas for harvesting marine living resources span the eastern American, European and Icelandic shelves [*Livingston and Tjelmeland*, 2000]. In addition, the Deep Sea regions of the Nordic Seas and the Irminger Sea contain large resources of pelagic and mesopelagic fish such as herring, blue whiting, mackerel and redfish. The region covers a wide latitudinal range from 35º to 80ºN, and, hence, a large span in thermal habitats. This is reflected in the latitudinal gradients from subtropical/temperate species along the southern fringe to boreal/arctic species along the northern fringe.

The North Atlantic HLSBS shows prominent and robust warming trend resulting in an increase in temperature of 3.97ºC from 1955 to 2005 (Table 30-2). Since the 1970s, the Atlantic Ocean has warmed more than any other Ocean

basin (0.3ºC decade^{-1}; Table 30-2; WGI Chapter 3) with greatest warming rates over European continental shelf areas such as the southern North Sea, the Gulf Stream front, the sub-polar gyres and the Labrador Sea [*González-Taboada and Anadón*, 2012; *Lee et al*., 2011; *Levitus et al*., 2009; *Mackenzie and Schiedek*, 2007a; b]. Nearly half of the basin-wide warming in the North Atlantic since the mid-1990s has been driven by global warming, with the rest being contributed by the Atlantic Multi-decadal Oscillation [*Wang and Dong*, 2010].

Observations and modeling indicate increased primary production with increasing temperature [*Mueter et al*., 2009; *Steinacher et al*., 2010], and poleward displacement of species [*Cheung et al*., 2011; *Stenevik and Sundby*, 2007]. The subsequent examples, mainly from the Barents, Nordic, and North Seas how warming from the early 1980s has influenced North Atlantic ecosystems where substantial biological impacts have been observed including large-scale modification of the phenology, abundance and distribution of plankton assemblages and reorganization of fish assemblages [*Beaugrand et al*., 2002; *Edwards*, 2004; *Edwards and Richardson*, 2004; *Nye et al*., 2009; *Simpson et al*., 2011; *Tasker*, 2008] Changes are also evident towards the southern fringe of North Atlantic HLSBS where southern species of molluscs and fish have expanded into the Bay of Biscay [*Bañón et al*., 2010; *Guerra et al*., 2002] and juvenile Bluefin Tuna (*Thunnus thynnus*) and Albacore Tuna (*Thunnus alalunga*) on summer feeding migrations are arriving earlier from 1967-2005 due to warming and subsequent shifts in prey assemblages [*Dufour et al*., 2010].

The past decade has been the warmest decade ever recorded in the Barents Sea resulting in large populations of krill, shrimp, pelagic and demersal fish stocks linked to the Atlantic and boreal ecosystem of the Barents Sea [*Johannesen et al*., 2012]. The relatively warm Atlantic waters have advanced northward and eastward [*Årthun et al*., 2012] and sea-ice has retreated along with the Arctic water masses. As a result, boreal euphausiids, which are mainly confined to the Atlantic water, have increased in biomass and distribution [*Dalpadado et al*., 2012] enhancing growth of young cod *Gadus morhua* (boreal) as well as the more Arctic (arcto-boreal) capelin (*Mallotus villosus*). The amphipods of more Arctic origin have decreased, resulting in poorer feeding conditions for polar zooplankton predators such as polar cod (*Boreogadus saida*). Blue whiting (*Micromesistius poutassou*) which spawn west of the British Isles, feed on zooplankton in the Norwegian Sea during the summer. During the recent warming period, the summer feeding distribution of the whiting extended into the Barents Sea. In summary, the long-term trend of pelagic fish species has increased in the Barents Sea, although with pronounced decadal-scale oscillations superimposed over long-term climate trends. The recruitment to boreal fish stocks like cod, haddock, and herring has increased in the Barents Sea [*Eriksen et al*., 2012]. Climate change by 2100 is *virtually certainly going* to impact the northern fringes of the Atlantic HLSBS with increases in zooplankton production of 20 % in the Barents Sea [*Ellingsen et al*., 2008] as temperatures increase and Atlantic species replace the Arctic ones (*medium evidence, high agreement,* and *high confidence*). Together with poleward shifts of fish species, a substantial increase in fish biomass and catch is also *very likely* [*Cheung et al*., 2011]. However, the continuous temperature increase is *very likely* to cause discontinuous changes in life cycle conditions for some species like the capelin which feeds in summer at the ice edge and spawns in spring at the southern Atlantic Norwegian/Murman coast of the Barents Sea. The limited migration potential for this small pelagic fish is *likely* to cause it to switch spawning areas to the similar, but far separated spawning grounds at the Novaja Semlja coast with the only alternative to go extinct [*Huse and Ellingsen*, 2008].

The Norwegian Sea is one of the two core regions for the herbivore copepod *Calanus finmarchicus* that is an important prey species for pelagic fish and early life-stages of all fish around the rim including the North Sea and the Barents Sea [*Sundby*, 2000]. *C. finmarchicus* is the main food item for some of the world's largest fish stocks such as the Norwegian spring-spawning herring (*Clupea harengus*), blue whiting (*M. poutassou*) and Northeast Atlantic mackerel (*Scomber scombrus*). These stocks have increased considerably during the recent warming from the early 1980s [*Huse et al*., 2012]. Also, the individual size of herring has increased enabling longer feeding migration routes to utilize zooplankton closer to more distant Arctic water masses towards northwest. Mackerel has advanced northward and westward into Icelandic waters [*Astthorsson et al*., 2012]. Since 2008, however, biomass of the pelagic fishes has decreased along with a decreasing biomass of the *C. finmarchicus*, indicating a switch in the system to a top-down control. This demonstrates that even though fish stocks are expected to increase in high latitude regions under climate change this increase is limited by the productivity in zooplankton.

There is *high confidence* that observed changes in the phenology of plankton groups in the North Sea is being driven by regional warming [*Edwards and Richardson*, 2004; *Lindley and Kirby*, 2010; *Lindley et al.*, 2010; *Schluter et al.*, 2010; *Wiltshire and Manly*, 2004; *Wiltshire et al.*, 2008]. Phenological responses of zooplankton were species-specific with substantial variation within functional groups. For example, the peak maximum abundance of the copepod *Calanus finmarchicus* advanced by 10 days from the 1960s to the 2000s, but it's warm-water equivalent, *C. helgolandicus,* did not advance [*Bonnet et al.*, 2005]. The appearance of larvae of benthic fauna in the meroplankton corresponds to the timing of adult reproductive cycles, so shifts in adult phenology [*Beukema and Dekker*, 2005; *Philippart et al.*, 2003] have implications for biological linkages between benthic and pelagic ecosystems [*Kirby et al.*, 2007; *Lindley et al.*, 2010]. The ranges of some cold-water zooplankton assemblages in the North-east Atlantic have contracted towards the Arctic since 1958, and many warm-water zooplankton assemblages (specifically copepods) have replaced them (*high confidence*), moving up to 1000 km northward [*Beaugrand*, 2009; *Beaugrand et al.*, 2002].

Fish communities from both the North-west and North-east Atlantic show distributional shifts (*high confidence*) although the direction of these changes varies among species. Fish communities are also shifting to greater depths due to warming [*Dulvy et al.*, 2008; *Nye et al.*, 2009; *Perry et al.*, 2005; *Tasker*, 2008]. In the North Sea, bottom temperatures in winter have warmed by 1.6°C (1980- 2004, [*Dulvy et al.*, 2008]. The whole demersal fish community shifted deeper by 3.6 m decade^{-1} over the period 1980-2004, although mean latitude of the whole community did not show net displacement [*Dulvy et al.*, 2008]. Within the community, cool-water specialists generally shifted northwards while abundant warm-water species shifted southwards reflecting winter warming of the southern North Sea. The cold winter temperatures of the shallow regions of the southern North Sea have acted to exclude species with warm-water affinities. Trawl survey data from the rapidly-warming southern North Sea suggests waves of immigration by southern species, such as red mullet (*Mullus surmuletus*), anchovy (*Engraulis encrasicholus*) and sardines (*Sardina pilchardus*), linked to increasing population sizes and warming temperatures [*Beare et al.*, 2005]. In the high-latitude North Atlantic diversity of zooplankton and fish has increased, as more diverse warm-water assemblages extend northward in response to changing environmental conditions [*Beaugrand*, 2009; *Hiddink and ter Hofstede*, 2008; *Kane*, 2007; *Mountain and Kane*, 2010; *ter Hofstede et al.*, 2010]. Southern (warm-water) species of fish have increased in abundance on both sides of the North Atlantic (*medium confidence*) [*Beare et al.*, 2005; *Collie et al.*, 2008; *Hermant et al.*, 2010; *Lucey and Nye*, 2010; *Simpson et al.*, 2011].

Range expansions and contractions linked to changing climate have also been found in benthic crustaceans, bivalves, gastropods, and polychaetes [*Berke et al.*, 2010; *Beukema et al.*, 2009; *Mieszkowska et al.*, 2007]. For example, the southern range of the common intertidal barnacle *Semibalanus balanoides* in the North-east Atlantic has been contracting at a rate of 15-50 km decade^{-1} since 1872, and the retreat is attributed to reproductive failure as winter temperatures warm [*Southward et al.*, 2005; *Wethey and Woodin*, 2008]. The warm-water competitor *Chthamalus montagui* of *S. balanoides* has increased in abundance to replace the niche vacated by *S. balanoides* [*Poloczanska et al.*, 2008; *Southward et al.*, 1995]. Changes in the distribution of seaweed species have been observed along the coastline of the Iberian Peninsula where a latitudinal gradient in temperature is observed all year despite summer upwelling. In particular, some large seaweeds with a cold-water affinity have contracted their distribution limits [*Díez et al.*, 2012; *Fernández*, 2011; *Lamela-Silvarrey et al.*, 2012] while species with a warm-water affiliation have expanded [*Lima et al.*, 2007].

Most of the longest and most comprehensive time series used to investigate the ecological consequences of climate fluctuations and fishing are from this region [*Edwards et al.*, 2010; *Poloczanska et al.*, 2013; *Southward et al.*, 2005; *Sundby and Nakken*, 2008; *Toresen and Østvedt*, 2000]. Meta-analysis of 288 long-term datasets of zooplankton, benthic invertebrates, fish and seabirds from the OSPAR Commission Maritime Area in the north east Atlantic showed wide-spread changes in distribution, abundance and seasonality that were consistent (75%) with expectations from enhanced greenhouse warming [*Tasker*, 2008]. The study bought together evidence of changes in ocean climate, and ecological responses across a range of species that encompassed both exploited and unexploited species from a variety of information types including peer-reviewed reports from ICES Working Groups [*Tasker*, 2008]. In particular, observations showed polewards shifts in zooplankton communities, increasing abundance of fish species in the northern part of their ranges and decreases in southern parts, and the expansion of benthic species into more northerly or less coastal areas.

The major part of the literature on climate impacts for the North Atlantic region covers time spans longer than for most other sub-regions of the Oceans. Even here, however, most of the literature is limited to the recent 30 to 50 years. The few publications covering the first half of the 20th century represent an important longer-term perspective to the impacts of climate change [*Astthorsson et al.*, 2012; *Bañón*, 2009; *Drinkwater*, 2006; *Sundby and Nakken*, 2008; *Toresen and Østvedt*, 2000]. For example, distinct changes in fauna were associated with a pronounced warming period of 1920-1940 [*Wood and Overland*, 2010] when fish and other fauna moved northward [*Drinkwater*, 2006; *Hátún et al.*, 2009; *Iversen*, 1934; *Southward et al.*, 1995]. The major lesson from these reports is that an almost similar large-scaled temperature increases occurred in the high-latitude North Atlantic from 1910s to the 1940s as that which occurred during the last 30 years, with similar basin-scale impacts on marine ecosystems. The former event was of great concern within the scientific community, particularly during the late 1940s and early 1950s [*Iversen*, 1934; *Tåning*, 1949; *Tåning*, 1953]. With the subsequent long-term cooling in the 1970s, however, discussion around climate impacts has unfortunately discontinued. The present centennial-long perspectives indicate that the major fraction of the impacts from the recent 30-year temperature increase is part of multidecadal changes with the crucial message that understanding the scenarios for the anthropogenic climate change over the next century is particularly important. We are only beginning to see the early contours of this development. Under the assumption that the long-term natural climate variability continues through 21st century with the same frequency and amplitude as during the 20th century we could expect that we have already reached a culmination of the multidecadal signal with only limited temperature increase over the next 20 years until again the anthropogenic and natural climate signal are adding up in the same direction. Under such a scenario, the climate of the North Atlantic climate is projected to change more rapidly around 2050 than ever recorded (*high confidence*).

30.5.1.1.2. North Pacific

Sub-decadal variability in the North Pacific HLSBS is dominated by ENSO [*Trenberth*, 1990], WGI Chapter 14). Like the North Atlantic HLSBS, the North Pacific HLSBS has shown high rates of warming, with an increase in average sea temperature of 4.62ºC from 1955 to 2005 (based on data from 1950 to 2009, Table 30-2). Decadal and longer periods of variability in the North Pacific are reflected in two principal modes; the Pacific Decadal Oscillation (PDO) with periodicities at both 15-25 y and 50-70 y in SST [*Mantua and Hare*, 2002; *Minobe*, 1997], and the Victoria Pattern [*Bond et al.*, 2003] and the North Pacific Gyre Oscillation (NPGO). The PDO exhibits SST anomalies of one sign along the eastern boundary and the opposite sign in western and central Pacific (WGI 14.6.6), The PDO has been reported to have an anthropogenic component thus confounding statistical approaches aimed at removing natural variability from ecological time-series [*Bonfils and Santer*, 2011]. The interplay of the phases of these modes of variability has strong influence on high-latitude Pacific ecosystems. In the space of three years, the eastern North Pacific fluctuated from one of the warmest years in the past century (2005) to one of the coldest (2008) [*McKinnell and Dagg*, 2010; *McKinnell et al.*, 2010]. This rapid change was accompanied by large changes in primary productivity, zooplankton communities and fish and seabirds [*Batten and Walne*, 2011; *Bi et al.*, 2011; *Keister et al.*, 2011; *McKinnell and Dagg*, 2010; *McKinnell et al.*, 2010].

Periods of broad-scale environmental regime shifts are observed across high-latitude ecosystems in the North Pacific (eastern Bering Sea and Gulf of Alaska) during 1976-78, 1987-89 and 1998-99. These periods were associated with regime shifts in forage fish that occurred in 1979-82, 1988-92 and 1998-2001. These changes indicate of how basin-scale variability such as PDO can manifest across distinct ecosystems [*Link et al.*, 2009a; *Link et al.*, 2009b; *Overland et al.*, 2008]. Climate regime shifts are characterized by abrupt reorganization of the ecosystems as dynamic trophic relationships among species alter [*Alheit*, 2009; *Hunt et al.*, 2002; *Litzow and Ciannelli*, 2007; *Litzow et al.*, 2008]. Phenological shifts have been observed in the zooplankton communities of the North Pacific in response to decadal climate cycles with distinct changes noted after the climate regime shifts of the 1970s and 1990s [*Chiba et al.*, 2006; *Mackas et al.*, 1998]. In the North-west Pacific, springtime copepod abundance also increased linearly over the period 1960-2002 [*Chiba et al.*, 2006]. Regime shifts in the mid-1970s and late-1980s were also reported in the Kuroshio-Oyashio Extension (KOE) in the North-west Pacific with dramatic changes in pelagic ecosystems and sardine and anchovy stocks [*Chiba et al.*, 2008; *Yatsu et al.*, 2008]. Climate change model simulations show global warming could further alter the dynamics of the Kuroshio Current and the Kuroshio Extension dynamics over the coming century [*Sakamoto et al.*, 2005] that will alter timing, magnitude and structure

of spring-blooms in the western Pacific with implications for pelagic fish production and biogeochemical cycles [*Hashioka et al.*, 2009].

Commercial catches of salmon species in the North Pacific follow decadal climate changes [*Hare and Mantua*, 2000; *Mantua and Hare*, 2002]. Catches peaked in the warm periods of the 1930s-1940s and 1990s-2000s with 2009 yielding the highest to date, and warming trends may have contributed to recent peak in some sub-regions [*Irvine and Fukuwaka*, 2011; *Morita et al.*, 2006]. Anticipating ecological responses to future anthropogenic climate change also requires evaluation of the role changes to climate beyond warming *per se*. For example, declining sea level pressure (SLP) in the North Pacific is anthropogenically forced [*Gillett et al.*, 2003], and SLP in turn is related to atmospheric climate parameters (e.g., turbulent mixing via wind stress) that regulate commercially significant fish populations [*Wilderbuer et al.*, 2002].

The Bering Sea region is among the most productive of marine sub-regions, and includes the world's largest single-species fishery which fishes for walleye Pollock *Theragra chalcogramma* [*Hunt et al.*, 2010]. This region has undergone major changes in recent decades as a result of climate variability, climate change and fishing impacts [*Hunt et al.*, 2010; *Jin et al.*, 2009; *Litzow et al.*, 2008; *Mueter and Litzow*, 2008]. SSTs have increased at a rate of 0.23°C.decade^{-1} over 1982-2006 [*Mueter and Litzow*, 2008] but since 2006 it has been colder than the long-term average [*Coyle et al.*, 2011]. Seasonal sea ice cover strongly influences the Bering Sea ecosystem through regulating the spring bloom and extent of the "cold pool" ; an area of reduced water temperature <2°C on the northern Bering Sea shelf that is formed as a consequence of sea ice and is maintained over summer [*Hunt et al.*, 2010]. Seasonal sea ice has declined since the 1990s (to 2006), although there is no linear trend 1953-2006, and the initiation of spring ice retreat over the south-eastern Bering Sea shelf occurred earlier [*Wang et al.*, 2007a; *Wang et al.*, 2007b]. Concurrent with a retreat of the cold pool, bottom trawl surveys of fish and invertebrates show a significant community-wide northward distribution shift and a colonization of the former cold pool areas by subarctic fauna [*Mueter and Litzow*, 2008; *Wang et al.*, 2006a]. Total biomass (mean catch per unit effort) has increased dramatically in the northern survey area, including the area around the Pribilof Islands [*Mueter and Litzow*, 2008]. The shallow waters of the eastern Pacific Ocean are low in oxygen (Figure 30-8). Coastal upwelling along the continental shelf can cause mortality of coastal fishes and invertebrates [*Grantham et al.*, 2004], whereas decreasing oxygen concentrations at depth in the subtropics are explained by changes in the gyre circulation in response to 20th century climate change. The role of climate change in decreasing the oxygen concentration at higher latitudes remains unclear although changes in ocean mixing and ventilation are likely to be contributing factors [*Deutsch*, 2005].

30.5.1.1.3. Southern Hemisphere

The seasonal peaks in phytoplankton productivity in the southern hemisphere are much less pronounced and of smaller magnitude as those in northern hemisphere high-latitudes [*Yoder et al.*, 1993]. The southern hemisphere HLSBS is broadly bounded by the sub-tropical front (STF) and sub-Antarctic front. Associated with the STF is intense biological activity by bloom-forming coccolithophores (phytoplankton) [*Brown and Yoder*, 1994]. The calcifying plankton assemblages play a key role in carbon cycles in the region and the transport of carbon to deep ocean sediments. The coccolithophore *Emiliania huxleyi* has extended its range south of 60° in the south-west Pacific (141-145°E) over the two decades since 1983 [*Cubillos et al.*, 2007]. Although the drivers for this range extension are not clear, it is proposed that the extension is facilitated by surface warming or changes in the abundance of grazing zooplankton.

While the South Pacific HLSBS has not shown warming overall (1950 to 2009, Table 30-2), some areas within the HLSBS have warmed very significantly. There is *high confidence*, for example, that the western Tasman Sea has shown enhanced warming since 1900 as compared to average global trends. This has been driven by changes in large-scale wind-forcing leading to a southward expansion of the South Pacific STG and intensifying the southward-flowing East Australian Current (EAC) [*Cai*, 2006; *Hill et al.*, 2008; *Wu et al.*, 2012]. Model simulations suggest both stratospheric ozone depletion and greenhouse forcing contribute equally to the observed trend in wind stress [*Cai and Cowan*, 2007]. Coinciding with this warming and intensified EAC is the observation that a number of benthic invertebrates, fish and zooplankton are now found further south compared to mid-20th century [*Last et al.*,

2011; *Ling*, 2008; *Pitt et al.*, 2010]. We have *very high confidence* that warming has facilitated the establishment of the grazing urchin *Centrostephanus rodgersii* in eastern Tasmania during the late 1970s which has resulted in deleterious effects on macroalgal beds [*Banks et al.*, 2010; *Ling*, 2008; *Ling et al.*, 2008; *Ling et al.*, 2009].

30.5.1.2. Key Risks and Vulnerabilities

Projected changes to the temperature of surface waters matched those of the past 50 years, with average sea temperatures in the HLSBS increasing by 0.41-1.17°C in the near term (2010-2039) and by 1.91-4.84°C over the long term (2010-2099) under the 'Business-as-usual' (BAU) RCP8.5 scenario. Under the lower-case scenario considered here (RCP2.6), projected rates of warming are much lower: 0.13 - 0.79 °C in the near term (2010-2039) and -0.09 - 1.46 °C by 2100. Risks to HLSBS from even modest warming of surface waters include changes to basin- and regional-scale ocean circulation which is *very likely* to affect the transport of organisms and water masses, primary production with implications for food webs and carbon cycling, changes in distribution, phenology and productivity of species leading to reorganization of ecosystems, and the loss of subsurface habitat to hypoxia. An additional risk exists for sub-polar areas from the loss of seasonal sea-ice. Ocean acidification will produce additional and large-scale challenges. Both primary productivity and timing of the spring bloom in this region are very sensitive to environmental change. The magnitude of planktonic production is central to higher trophic level production. Climate induced changes in stratification strength and mixed layer depth can lead to decreased or increased phytoplankton production [*Behrenfeld et al.*, 2006]. The onset of spring warming within high latitude sub-regions is advancing by 2-2.5 days.decade^{-1} [*Burrows et al.*, 2011]. Latitudinal shifts in the distribution of phyto- and zooplankton communities will change the day-length regimes experienced with impacts on growth and survival [*Beaugrand*, 2009; *Ito et al.*, 2010; *Shoji et al.*, 2011]. Alteration of the structure and composition of plankton communities will propagate through food webs because of tight trophic linkages, [*Beaugrand and Kirby*, 2010; *Beaugrand et al.*, 2010; *Edwards and Richardson*, 2004]. Mechanisms are complex and tend to be non-linear, with impacts on ecosystems, fisheries and biogeochemical cycles. Climate shifts can also result in abrupt changes or rapid regime shifts in ecosystems [*Alheit*, 2009]. Climate change in the Gulf of Alaska associated with the 1976/77 PDO regime shift produced a very rapid shift in target species for commercial fisheries [*Litzow et al.*, 2008]. A sudden reorganization of commercial fisheries, with attendant social and economic disruption, is a key risk and vulnerability of ongoing climate change in the region.

Alteration of thermal regimes and declining seasonal sea ice could produce changes in high latitude ecosystems that exceed those observed during the climate oscillations of the 20th century. Decreases in seasonal sea-ice in sub-polar regions are *very likely* to lead to increases in the length of the growth season and the intensity of the light available to fuel phytoplankton growth and hence to enhanced primary production and modifications of ecosystem structure [*Arrigo et al.*, 2008]. In the long-term, however, primary production may decrease due to the reduced supply of nutrients to the surface layers. The decline in Arctic sea ice will open dispersal pathways between the North Atlantic and the North Pacific; large numbers of the Pacific diatom *Neodenticula seminae* were found in the North Atlantic in 1999 [*Reid et al.*, 2007]. High latitude sub-regions are also vulnerable to rapid changes in ocean chemistry. There is *medium agreement* that calcifying organisms in these regions will be impacted by ocean acidification with substantial impacts on higher trophic levels although there is *limited evidence* at this point.

30.5.2. Equatorial Upwelling Systems

The largest upwelling systems are found in the equatorial regions of the eastern Pacific and Atlantic oceans (Fig. 30.1). Equatorial Upwelling Systems (EUS) produce a highly productive 'cold tongue' that stretches westward across equatorial areas. The associated upwelling is a consequence of the Earth's rotation and Easterly (westward) winds and currents which drive water northwards and southwards at the northern and southern edges of these sub-regions. As result, cold, nutrient-rich and high CO_2 waters are transported from deep waters into the surface waters, driving high levels of primary productivity which supports 4.7% of total global fisheries productivity (Table 30-1, Figure 30-1). Inter-annual and inter-decadal modes of variability (e.g. ENSO) dominate EUS, particularly in the Pacific [*Barber et al.*, 1994; *Christian and Murtugudde*, 2003; *Le Borgne et al.*, 2002; *McCarthy et al.*, 1996; *Mestas-Nuñez and Miller*, 2006; *Pennington et al.*, 2006; *Signorini et al.*, 1999; *Wang et al.*, 2006b]. Upwelling is reduced during

El Niño years when the trade winds cease, or even reverse, and is strengthened during the strengthened La Niña events. ENSO-periodicity controls primary productivity consequently has a strong influence over associated fisheries production [*Mestas-Nuñez and Miller*, 2006]. ENSO influences the position of the InterTropical Convergence Zone (ITCZ) at the edges of the equatorial upwelling zone and also plays a key role in determining the habitats, productivity, fisheries, and precipitation in these regions.

30.5.2.1. Observed Changes and Potential Impacts

The two EUS show similar behavior and hence are dealt with together in the one section. The average sea temperature associated with the EUS has increased significantly (0.35 and 0.45°C from 1955 to 2005 in the Pacific and Atlantic EUS, respectively; based on data from 1950 to 2009, Table 30-2). Wind speed and cloudiness have decreased in both EUS regions, with the opposite happening along the northern and southern edges (convergence zones) where cloud and wind have increased from 1955 to 2005. In the Pacific, spatial variation in SST is related to frequent El Niño Modoki or Central Pacific El Niño events [*Ashok et al.*, 2007; *Lee and McPhaden*, 2010]. The faster warming of the Atlantic EUS has been associated with a weakening of upwelling [*Tokinaga and Xie*, 2011]. Sea level rise in the eastern equatorial Pacific has been minimal, with the annual rate of change <1 $mm.yr^{-1}$ since 1950 [*Church et al.*, 2006].

Coral reefs in the EUS (e.g. Galápagos and Cocos islands) have relatively low species diversity and poorly developed carbonate reef frameworks in the eastern Pacific, due to the low pH and aragonite saturation of recently-upwelled waters [*Glynn*, 2001; *Manzello*, 2010; *Manzello et al.*, 2008]. Prolonged periods of elevated temperature associated with El Niño have impacted corals, kelps and associated organisms, and induced several possible local extinctions [*Glynn*, 2011]. Since 1985, coral reefs from South America west to the Gilbert Islands of Kiribati have experienced the highest levels of thermal stress [*Donner et al.*, 2010]. In 1982/1983, mass coral bleaching and mortality affected most of the reef systems within the eastern equatorial Pacific [*Baker et al.*, 2008; *Glynn*, 1984]. Subsequent canonical El Niño and Central Pacific El Niño events in 1997/8, 2002/3, 2004/5, and 2009/10 triggered mass coral bleaching by adding to the background increases in sea temperatures due to climate change [*Donner et al.*, 2010; *Obura and Mangubhai*, 2011; *Vargas-Angel et al.*, 2011]. Impacts of El Niño have also interacted with other anthropogenic impacts such as fishing pressure [*Edgar et al.*, 2010] further complicating the attribution of recent ecological changes to climate change.

30.5.2.2. Key Risks and Vulnerabilities

Climate models indicate that ENSO will continue to be a major driver of oceanic variability over the coming century. Consequently, superposition of a warming ocean and future ENSO activity (possibly modified frequency and intensity) may result in oceanic conditions that are different from those experienced during past El Niño and La Niña events [*Power and Smith*, 2007]. Temperatures within equatorial upwelling sub-regions are projected to continue to warm significantly, with temperatures increasing by approximately 0.8°C in the near term (2010-2039), and by approximately 3°C over the long term (2010-2099) under the BAU RCP8.5 scenario (Table 30-2). For Pacific and Atlantic EUS, differences between RCPs become clear beyond mid-century, with warming of SST under RCP2.6 being 0.43°C and 0.46°C to the much higher changes 3.01°C and 3.03°C under RCP8.5, respectively (Table 30-4). These projected increases in sea temperature will cause increasing stress and may largely eliminate key marine ecosystems such as coral reefs from this region (Box 30-1; Figure 30-12), with the temperature associated with these specific ecosystems increasing by more than 3°C by the end of the century. Further increases in atmospheric CO_2 will decrease pH and aragonite saturation of upwelling waters further. These changes in ocean chemistry will impact marine calcifiers, although many of the species from this region have already adapted to the low aragonite and calcite saturation states that result from equatorial upwelling [*Friedrich et al.*, 2012; *Manzello*, 2010]. A substantial risk exists with respect to the synergistic interactions between sea temperature and declining pH, especially as to how they influence a large number of key biological processes (Box CC-OA).

There is a *low confidence* in the current understanding of how (or if) climate change will influence the behavior of ENSO and other long-term climate patterns [*Collins et al.*, 2010], WG1 12.4.4.2). There is also *low agreement*

between different CMIP5 models on how ocean warming will affect ENSO, with no significant change in half the models examined, and both increasing and decreasing activity in others [*Guilyardi et al*., 2012]. These differences appear to be a consequence of the delicate balance within ENSO between dampening and amplifying feedbacks, and the different emphasis given to these processes within the different CMIP5 models [*Collins et al*., 2010]. Other studies have looked at the interaction between the subtropical gyres (STG), EUS, and the warming of surface waters in the Pacific, with at least one study projecting the possible expansion of the STG at the expense of the EUS [*Polovina et al*., 2011]. In the latter case, the area of equatorial upwelling within the North Pacific would decrease by 28%, and primary production and fish catch by 15%, by 2100. Many of the projected changes imply additional impacts on pelagic fisheries due to the migration of fishing grounds deriving from changing distribution of particular sea temperatures [*Bell et al*., 2013a; *Cheung et al*., 2010; *Lehodey et al*., 2008; *Lehodey et al*., 2011; *Lehodey et al*., 2006; *Sumaila et al*., 2011]. These projections suggest that fisheries within EUS will experience increased vulnerability due to elevated variability in space and time as a result of climate change.

30.5.3. Semi-Enclosed Seas

Semi-enclosed seas (SES) represent an subset of ocean sub-regions which are largely land-locked and consequently heavily influenced by surrounding landscapes and climates [*Healy and Harada*, 1991]. In most cases, they support fisheries significant fisheries (3.3% of global production, Table 30-1, Figure 30-1) and opportunities for other industries such as tourism. Five SES (all over 200,000 km^2 with single entrances < 120 km wide) are considered here. This particular geography has reduced circulation and exchange with ocean waters, and water bodies whose jurisdictions are shared by two or more neighbouring states. In many cases, the small volume and disconnected nature of SES (relative to coastal and oceanic environments) makes them highly vulnerable to both local and global stressors, especially with respect to the much reduced options for the migration of organisms as conditions change.

30.5.3.1. Observed Changes and Potential Impacts

30.5.3.1.1. Arabian Gulf

The Arabian Gulf (also referred to as the Persian Gulf), along with Red Sea, is the world's warmest sea with both extreme negative and positive temperature excursions (annual temperature range, 12-35°C). Like other SES, the Arabian Gulf is particularly vulnerable to changing environmental conditions given its landlocked nature. Trends in SST were not significant over the period 1950 to 2009 (Table 30-2) despite a large amount of variability. This may be part of larger regional and abrupt changes that occurred in the late 1980s [*Conversi et al*., 2010]. In keeping with this, recent (1985-2002) localised analyses (e.g. Kuwait Bay) show strong and significant warming trends based, in this case, on AVHRR (NOAA) satellite data of 0.6ºC decade^{-1} [*Al-Rashidi et al*., 2009]. There is *limited evidence* and *limited agreement* as to how this variability influences the marine ecosystems and human activities within the Arabian Gulf, although some ecosystem components (e.g. coral reefs) have been explored to some extent. The mass coral bleaching and mortality associated with 1996 and 1998 was a direct result of the sensitivity of reef-building corals to elevated sea temperatures [*Riegl*, 2002; *Riegl and Piller*, 2003], *high confidence*, Box CC-CR). These changes to coral reefs have resulted in a loss fish species that eat invertebrates while herbivorous and planktivorous fish abundances have increased [*Riegl*, 2002], *medium confidence*). Despite ecosystems there being adapted to some of the highest shallow water temperatures on earth, anthropogenic climate change is driving higher frequencies and intensities of mass coral bleaching and mortality [*Riegl et al*., 2011]. Other biological changes (e.g. harmful algal blooms and fish kills, [*Heil et al*., 2001]) have been associated with the increasing sea temperatures of the Arabian Gulf although attribution to increasing temperatures as opposed to other factors (e.g., water quality) is *uncertain* [*Bauman et al*., 2010; *Sheppard et al*., 2012].

30.5.3.1.2. Red Sea

Few studies have focused on attributing recent changes in the Red Sea to climate change (including ocean acidification). The Red Sea has warmed by 0.74°C from 1982-2006 [*Belkin*, 2009; *Raitsos et al*., 2011] although

trends over the period from 1950-2009 were not significant ($p > 0.05$, Table 30-2) due to a high degree of variability when longer periods are examined (supplementary material, [*Belkin*, 2009]. Regional trends within the Red Sea may also differ with at least one other study reporting higher rates of warming for the Central Red Sea (1.5°C [1950–1997, NOAA Extended Reconstructed SST, ERSST, v3b climatology, [*Cantin et al.*, 2010]. Long-term monitoring of coral community structure and size over 20 years has shown that average coral size has declined [*high confidence*] and species latitudinal limits may have changed [*moderate confidence*]. The decline in average coral size is ascribed to significant heat-mediated bleaching in 1998, and again in 2010 [*Riegl et al.*, 2012]. The patterns of this decline correlate well with the pattern of heating in the Red Sea [*Raitsos et al.*, 2011] with the biggest changes being seen in the southern part of the Red Sea. Skeletal growth of the long-lived massive coral *Diploastrea heliopora* has declined significantly, very likely as a consequence of warming temperatures ($p < 0.05$, *medium confidence*).

Cantin et al. [2010] proposed that corals in the central Red Sea will cease to grow by 2070 (*medium confidence*) although this may not hold for all coral species (e.g. *Porites* and *Cyphastrea*; Cantin et al., in review, PLosOne). For example, an increase in linear extension of *Porites* corals, beginning in the 1980s was recorded in the northern Red Sea [*Heiss*, 1996], where the present local warming rate is ~0.037ºC y^{-1}, suggesting that these corals are living in sub-optimal (cooler waters) conditions and may still benefit from elevated temperature before reaching their thermal threshold, at which point growth rates would be predicted to decline as they are in many oceans. *Riegl and Piller* [2003] concluded that coral habitats at moderate depths in the Red Sea might provide important refugia from some aspects of climate change in the future. *Silverman et al.* [2007] quantified the sensitivity of net coral reef ecosystem calcification to changes in carbonate system chemistry (pH, aragonite saturation). Their results demonstrate a strong negative impact of ocean acidification on ecosystem scale calcification and decalcification, and that small changes in carbonate dissolution could have large-scale implications for the long-term persistence of carbonate coral reef systems within the Red Sea [*Silverman et al.*, 2007; *Silverman et al.*, 2009].

30.5.3.1.3. Black Sea

The surface waters of the Black Sea have increased by 0.96ºC from 1982 to 2006 [*Belkin*, 2009] which is consistent with other studies [*Bozkurt and Sen*, 2011; *Buongiorno Nardelli et al.*, 2010] *high confidence*). As with other SES, longer data sets do not reveal a significant trend due to large-scale variability prior to 1980 which may be associated with AMO, NAO and other long-term sources of variability (Table 30-2; supplementary material, *Belkin, 2009*). *Buongiorno Nardelli et al.* [2010] observed that short-term SST variability (week-month) is strongly influenced by interactions with the overlying atmosphere, which itself is strongly influenced by the surrounding land temperatures. Freshwater discharge from rivers draining into the Black Sea has remained more or less constant since the early 1960s [*Ludwig et al.*, 2009]. Increased water temperature has steadily eliminated the Cold Intermediate Layer (CIL; with temperatures below 8°C) throughout the Black Sea basin [*Oguz et al.*, 2003], *high confidence*). Reduced water column mixing and upwelling during warmer winter periods has resulted in a reduced supply of nutrients to the upper layers of the Black Sea [*Oguz et al.*, 2003] and expanded areas of low oxygen in the deeper parts of the Black Sea, which is the world's largest anoxic marine basin [*Murray et al.*, 1989], *high confidence*). These changes have coincided with the collapse of fish stocks and the invasion by the ctenophore *Mnemiopsis leidyi* in the 1980s [*Oguz et al.*, 2008], while at the same time, inputs of nutrients such as phosphate from the River Danube have decreased strongly since 1992-1993. Environmental perturbations explain the declining levels of primary productivity, phytoplankton, bacterioplankton, and fish stocks in the Black Sea from the mid-1990s [*Oguz and Velikova*, 2010; *Yunev et al.*, 2007]. The Black Sea system is very dynamic and is strongly affected by non-climate stressors in addition to climate change, making attribution of detected trends to climate change difficult.

30.5.3.1.4. Baltic Sea

Temperatures in the highly dynamic Baltic Sea have increased substantially since the early 1980s, with increases of 1.35°C (1982-2006) being among the highest for SES [*Aleksandrov et al.*, 2009; *Belkin*, 2009]). This increase is parallel to the increase in the adjacent North Atlantic driven mainly by AMO. Increases of this magnitude are not seen in longer records throughout the Baltic Sea (1861-2001, [*Mackenzie and Schiedek*, 2007a; b; *Mackenzie et al.*,

2007]; from 1900 to 1998, [*Madsen and Hojerslev*, 2009]). The salinity of the surface and near bottom waters of the Baltic Sea (e.g. Gdansk Basin, [*Aleksandrov et al.*, 2009]; central Baltic [*Fonselius and Valderrama*, 2003; *Mollmann et al.*, 2003] decreased from 1975 to 2000, due to changing rainfall and river run-off and a reduction in the pulses of sea water (vital for oxygenation and related chemical changes) from the North Sea through its opening to the North Sea via Kattegat [*Conley et al.*, 2009; *Hanninen and Vuorinen*, 2011; *Samuelsson*, 1996] high confidence). There is a strong vertical zonation within the Baltic Sea in terms of the availability of oxygen. The shallow sub-regions of the Baltic are relatively well oxygenated. However, oxygen levels are low in the deeper basins, producing conditions where organisms and ecosystems are exposed to prolonged hypoxia.

The annual biomass of phytoplankton has declined almost threefold in the Baltic Transition Zone (Kattegat, Belt Sea) and Western Baltic Sea since 1978. The decrease in phytoplankton abundance and primary productivity since 1978 is very likely to be a response to increasing sea temperature [*Madsen and Hojerslev*, 2009], although the decreased nutrient input to the Danish Straits has almost certainly played a role ([*Henriksen*, 2009] *medium confidence*). Reduced phytoplankton production by increasing sea temperatures is expected to have a negative impact of the productivity of fisheries in the Western Baltic Sea and the transition zone [*Chassot et al.*, 2007]. Decreasing salinity in the Baltic deep basins may also affect zooplankton reproduction, especially of the copepod, *Pseudocalanus acuspes,* contributing to density-dependent decrease in growth of the commercially significant herring and sprat stocks [*Mollmann et al.*, 2003; *Möllmann et al.*, 2005], *high confidence*). The strong relationship between phytoplankton and fish production, and increasing sea temperature, decreasing salinity and other environmental factors, suggests that major changes in fisheries production may occur as sea temperatures increase and the hydrological cycle in the Baltic region is changed (*high confidence*).

A combination of climate-change-induced oceanographic changes (i.e. decreased salinity and increased temperatures) and eutrophication and overfishing have resulted in major structural changes at all trophic levels (particularly, an ecosystem regime shift [*Möllmann et al.*, 2005]) in the deep basins of the Baltic Sea. The strong relationship between primary and secondary production, and oceanography, suggests that major changes in Baltic fisheries production are very likely to occur as temperatures increase and salinities decrease. This has been demonstrated by examples such as that of the commercially important top-predator cod [*Lindegren et al.*, 2010](*medium confidence*).

30.5.3.1.5. Mediterranean Sea

The Mediterranean Sea is strongly linked to the climates of North Africa and Central Europe. SSTs within the Mediterranean SES have increased 0.43ºC from 1957 to 2008 (supplementary material, *Belkin 2009*) although analysis of data from 1950-2009 does not exhibit a significant trend ($p > 0.05$, Table 30-2) due to large fluctuations of SSTs prior to the 1980s. Increasing SST trends have been reported at a number of monitoring sites in the Mediterranean Sea (e.g. [*Calvo et al.*, 2011; *Coma et al.*, 2009; *Conversi et al.*, 2010]. In the western Mediterranean Sea, water temperatures, over the past 30–40 years, have also increased at depth [*Bethoux et al.*, 1990; *Rixen et al.*, 2005; *Vargas-Yanez et al.*, 2010]. Natural sources of variability such as the AMO and NAO, can obscure or accentuate the overall warming trend [*Marullo et al.*, 2011]. Relatively warm episodes in the 1870–1890s, 1930–1940s and since the 1990s, for example, exhibit an influence of the AMO [*Kerr*, 2000; *Moron*, 2003]. Reported temperature anomalies in the Mediterranean, often locally manifesting themselves as periods of low wind, increased water column stratification and deepening thermocline, are associated with positive phases of the NAO index [*Lejeusne et al.*, 2010; *Molinero et al.*, 2005].

Sea levels have increased rapidly in some areas over the last decades and are also strongly influenced by NAO phases. These rates have been approximately 3.4 $mm.yr^{-1}$ (1990-2009) in the NW Mediterranean [*Calvo et al.*, 2011], *high confidence*). These influences are reduced when measurements are pooled over longer time-scales resulting in a lower rate of sea level rise [*Massuti et al.*, 2008]. If the positive phase of the NAO is more frequent in the future [*Kuzmina et al.*, 2005; *Terray et al.*, 2004], then the future sea level rise may be slightly suppressed due to atmospheric changes [*Jorda et al.*, 2012]. As temperatures have increased, the Mediterranean has become more saline (+0.035 to 0.040 psu over 1950-2000, [*Rixen et al.*, 2005]) and the length of the stratification period persisted twice as long in 2006 than it did in 1974 [*Coma et al.*, 2009].

Conditions within the Mediterranean Sea changed abruptly and synchronously with similar changes across the North, Baltic, and Black Seas in the late 1980s [*Conversi et al*., 2010], which possibly explains the lack of trend in SES Sea surface data when examined over 50-60 years (Table 30-2). These changes in physical conditions (increased temperature, higher sea level pressure, positive NAO index) also coincided with step-changes in the diversity and abundance of zooplankton, decreases in stock abundance of anchovies, and the frequency of red tides and, increases in mucilage outbreaks [*Conversi et al*., 2010]. Mucilage outbreaks are strongly associated with warmer and more stratified water columns (*high confidence*), and lead to a greater abundance and diversity of marine microbes and potentially disease organisms [*Danovaro et al*., 2009]. Increasing temperatures are also driving the northward spread of warm-water species (*medium confidence*) such as the sardine, *Sardinella aurita* [*Sabates et al*., 2006; *Tsikliras*, 2008], and contributed to the fast spread of the coral *Oculina patagonia* [*Serrano et al*., submitted]. The recent spread of warm-water species that have invaded through the Straits of Gibraltar and through the Suez Canal, into cooler northern areas is leading to "tropicalisation" of Mediterranean fauna [*Ben Rais Lasram and Mouillot*, 2008; *Bianchi*, 2007; *CIESM*, 2008; *Galil*, 2008; 2011] (*high confidence*). Warming since the end of the 1990s has accelerated the spread of tropical invasive species from the eastern Mediterranean basin [*Raitsos et al*., 2010]

In addition to general patterns of warming, periods of extreme temperatures have had large-scale impacts on Mediterranean marine ecosystems. Unprecedented mass mortality events that affected at least 25 prominent invertebrate species occurred during the summers of 1999, 2003 and 2006 across hundreds of kilometres of coastline in the NW Mediterranean Sea [*Calvo et al*., 2011; *Cerrano et al*., 2000; *Crisci et al*., 2011; *Garrabou et al*., 2009] *very high confidence*). Events coincided with either short periods (2-5 days, 2003, 2006) of high sea temperatures (27°C) or longer periods (30-40 days) of modestly high temperatures (24°C, 1999; [*Bensoussan et al*., 2010; *Crisci et al*., 2011]). Impacts on marine organisms have been reported in response to the extreme conditions during events such as those in 1999, 2003 and 2006 in the Mediterranean (e.g. gorgonian-corals mortality [*Coma et al*., 2009], shoot mortality and anomalous flowering of seagrasses [*Diaz-Almela et al*., 2007; *Marba and Duarte*, 2010], *high confidence*). Increasing sea temperatures are very likely to increase the frequency and intensity of these types of heat stress events (*high confidence*).

Long-term data series (over several decades) to measure the rate of acidification in the Mediterranean Sea are scarce [*Durrieu de Madron et al*., 2011]. Recent re-analysis, however, has concluded that the pH of Mediterranean waters has decreased by 0.05-0.14 pH units since the preindustrial period [*Luchetta et al*., 2010; *Touratier and Goyet*, 2011], medium confidence). Even the deepest Mediterranean water is contaminated by anthropogenic CO_2, which the greatest relative changes in pH for an entire water column [*Touratier and Goyet*, 2011]. Studies that have explored the impact of ocean acidification on the biology and ecology of the Mediterranean Sea are rare although insights have been gained by studying natural CO_2 seeps at Mediterranean sites such as Ischia in Italy [*Hall-Spencer et al*., 2008]. Major changes to Mediterranean organisms and ecosystems were revealed for high CO_2 environments with calcifying organisms (e.g. molluscs, calcareous algae) being negatively affected while seagrasses and some macroalgae appeared to benefit.

30.5.3.2. Key Risks and Vulnerabilities

SES are highly vulnerable to changes in global temperature on account of their small volume and landlocked nature. Consequently, SES are *virtually certain* to respond faster than other parts of the ocean (*high confidence*). Risks to ecosystems within SES are *very likely* to increase as water columns become further stratified under increased warming, promoting hypoxia at depth and reducing nutrient supply to the upper water column (*medium evidence, high agreement*). The impact of rising temperatures on SES is exacerbated by their vulnerability to other human impacts such as overexploitation, pollution and enhanced run-off from modified coastlines. Due to a mixture of global and local human stressors, key fisheries have undergone fundamental changes in their abundance and distribution over the past 50 years. A major risk exists for SES from projected increases in the frequency of temperature extremes that drive mass mortality events, increasing water column stabilisation leading to reduced mixing, and resulting changes to the distribution and abundance of marine organisms. The vulnerability of marine

ecosystems, fisheries and human communities associated with the SES will continue to increase as global temperatures increase.

There is *very high confidence* that sea temperatures within the five SES will increase further under even moderate Representative Concentration Pathways (RCP). Under BAU (RCP 8.5; Table 30-4), sea temperatures in the SES are projected to increase by 0.93-1.24°C by 2039 and by 3.45-4.37°C by the end of the century (Table 30-4). The greatest increases are projected for the surface waters of the Baltic Sea (4.26°C) and Arabian Gulf (4.33°C), with lower yet substantial amounts of warming in the Red Sea (3.45°C). The heat content added to these small oceans is *very likely* to increase stratification of the water column, which will reduce the nutrient supply to the upper layers of the water column, reducing primary productivity and driving major changes to the structure and productivity of fisheries. Reduced mixing and ventilation, along with increased microbial metabolism, will *very likely* expand hypoxia and increase the size and number of 'dead zones'. Changing rainfall intensity is likely to also have strong influences on the physical and chemical conditions within SES, in some cases combining with climate change to transform these areas. These changes are likely to increase the risk of reduced O_2 levels to Baltic and Black Sea ecosystems, which is *very likely* to affect fisheries. Based on responses to temperature extremes seen over the past 30 years, these changes will increase the frequency and intensity of impacts arising from heat stress, such as the mass mortality of benthic organisms in the Mediterranean during the summers of 1999, 2003 and 2006, and the Arabian Gulf in 1996 and 1998. Similar projections to those seen in 30.8.4 can be applied to the coral reefs of the Arabian Gulf and the Red Sea, where temperatures are *very likely* to increase above established thresholds for mass coral bleaching and mortality (*high confidence*; Figure 30-12).

30.5.4. Coastal Boundary Systems

The Coastal Boundary Systems (CBS) are highly productive regions, comprising 10.6% of primary production and 28.0% of global fisheries production (Table 30-1, Figure 30-1). CBS regions are also bounded by the sub-regions of the Pacific, Atlantic and Indian oceans, except in coastal areas associated with the EBUEs. Within these sub-regions, the CBSs are dominated by powerful currents such as the Kuroshio (Pacific) and the Gulf Stream (Atlantic), and are strongly influenced by monsoons (e.g. Asian-Australian and African monsoons). The CBS includes the marginal seas of the NW Pacific, Indian, Atlantic and comprises Bohai/Yellow Sea, East China Sea, South China Sea and South-east Asia seas (e.g. The Timor, Arafura, Sulu, and northern coast of Australia) in the Pacific, and the Arabian Sea, Somali Current system, East Africa coast, small archipelagic states, Mozambique Channel and Madagascar in the Indian Ocean, and the Caribbean Sea and Gulf of Mexico in the Atlantic Ocean.

30.5.4.1. Observed Changes and Potential Impacts

Many ecosystems within the CBS are strongly affected by the local activities of often dense coastal human populations. Activities such as the overexploitation of fisheries, unsustainable coastal development and pollution have resulted in the wide-spread degradation of CBS ecosystems [*Burke et al*., 2002; *Burke et al*., 2011]. These influences have combined with steadily increasing ocean temperature and acidity to drive major changes to a range of important ecosystems over the past 50 years. Understanding the interactions between climate change and non-climate change drivers is a central part of the detection and attribution process within the CBS.

Overall, CBSs have warmed by 0.46-0.67°C from 1955 to 2005 (Table 30-2), although changes within the Gulf of Mexico/Caribbean sub-region were not significant over this period. Key sub-regions within the CBS such as Coral Triangle and Western Indian Ocean have warmed by 0.65 and 0.50°C respectively from 1955-2005 (calculated using data from 1950-2009, Table 30-2). Rates of sea level rise vary from low (2-3 mm $year^{-1}$, Caribbean) to very high rates (10 mm $year^{-1}$, SE Asia; 30.3.1.2). Ocean acidification also varies from region to region, influenced by oceanographic and coastal processes (Figure 30-6 A-D, Figure 30-7) which often have a large human component.

30.4.4.1.1. Bohai/Yellow Sea/East China Sea

Bohai/Yellow Sea and East China Sea (ECS) are shallow marginal seas along the edge of the NW Pacific that are strongly influenced by Kuroshio, the East Asian Monsoon (EAM), and major rivers such as Yellow River and Changjiang (Yanktze) River. The Kuroshio intrusion influences the associated marginal seas [*Matsuno et al*., 2009], providing abundant nutrients which support high levels of primary productivity [*Chen et al*., 1996; *Wong et al*., 2001; *Wong et al*., 2000]. The ecosystems of the ECS are heavily impacted by anthropogenic pressure factors (e.g., overfishing and pollution) which tend to compound the impacts of climate change.

SST within the ECS increased rapidly since the early 1980s [*Cai et al*., 2011.; *Jung*, 2008; *Lin et al*., 2005; *Tian et al*., 2012]. The largest increases in SST have occurred in the ECS in winter (1.96°C, 1955-2005) and Yellow Sea in summer (1.10°C, 1971-2006 [*Cai et al*., 2011.]. These changes in SST are closely linked to the weakening of the EAM (e.g. [*Cai et al*., 2011.; *Cai*, 2006.; *Tang et al*., 2009], and increasing warmth of the Kuroshio Current [*Qi*, 2010; *Wu et al*., 2012; *Zhang et al*., 2011]. At the same time, dissolved oxygen has decreased [*Jung*, 2008; *Lin et al*., 2005; *Qi*, 2010] with an associated increase in the size of the hypoxic areas (≤60 mmol kg^{-1}) in coastal areas of Yellow Sea/ECS [*Jung*, 2008; *Ning et al*., 2011; *Tang*, 2009].

There is *robust evidence* and *high agreement* that primary productivity, biomass yields and fish capture rates are declining within the ECS [*Lin et al*., 2005; *Tang*, 2009; *Tang et al*., 2003]. There is *medium evidence and medium agreement* that these are being driven by climate change and human pressures. Warm-water zooplankton species have expanded northward in the Changjiang River Estuary as water temperatures have increased [*Ma et al*., 2009]. Fluctuations in herring abundance also appear to closely track SST regime shifts within the Yellow Sea [*Tang*, 2009]. The proportion of warm water species relative to warm temperate species from plankton to fish species in the Changjiang River Estuary (extending to the south Taiwan Strait) have changed in the past decades [*Lin and Yang*, 2011; *Ma et al*., 2009; *Zhang et al*., 2005]. Meanwhile, the frequency of harmful algal blooms (HAB) and blooms of the Giant Jellyfish (*Nemopile manomurai*) in the offshore area of ECS have increased and have been associated with ocean warming and other factors such as eutrophication [*Cai and Tan*, 2010; *Tang*, 2009; *Ye and Huang*, 2003]. While attribution of these changes to anthropogenic climate change is complicated by the increasing influence of non-climate related human activities, many of these changes are consistent with those expected as sea temperatures increase.

30.5.4.1.2. South China Sea

The South China Sea (SCS) is surrounded by continental areas and a large number of islands, and is connected to the Pacific, ECS, and Sulu Sea by straits such as the Luzon and Taiwan Strait. The region is greatly influenced by cyclones/typhoons, and by the Pearl, Red and Mekong Rivers. The region has a distinct seasonal circulation and is greatly influenced by the southwest monsoon (in summer), the Kuroshio Current and northeast monsoon (in winter). The SCS includes significant commercial fisheries areas and includes coral reefs, mangroves and seagrasses.

The surface waters of the SCS have been warming steadily from 1945-1999 [*Li et al*., 2002; *Liu et al*., 2007] with the annual mean SST in the central SCS increasing by 0.92°C (1950-2006) [*Cai et al*., 2008,], a rate similar to that observed for the entire Pacific CBS from 1955-2005 (calculated using data from 1950-2009, 0.67°C, Table 30-2). Significant freshening in the SCS intermediate layer since the 1960s has been observed [*Liu et al*., 2007]. The temperature change of the upper layers of the SCS has made a significant contribution to sea level variation which is spatially non-homogeneous and varies in time [*Cheng and Qi*, 2007; *Li et al*., 2002].

Identifying a clear climate change impact within the SCS is difficult due to complexity of other factors and their interactions (e.g. local human stressors, and 'natural' climate variability such as EAM, ENSO and PDO). There is *limited evidence* and *medium agreement*, however, that changing sea temperatures have influenced the abundance of phytoplankton, benthic biomass, cephalopod fisheries and the size of demersal trawl catches in northern SCS [*Ning et al*., 2008]. Coral reefs and mangroves are degrading rapidly as a result of both climate change and non-climate change factors (Box CC-CR)[*China-SNAP*, 2011]. Elevated SSTs have triggered mass coral bleaching and mortality of coral reefs within the SCS in 1998 and 2007 [*Li et al*., 2011; *Yu et al*., 2006]. On the other hand, warming of

ocean waters has very likely favourably influenced the establishment of a high latitude, non-carbonate coral community in Daya Bay in the northern SCS, although this community has recently degraded due to local anthropogenic stresses [*Chen et al*., 2009; *Qiu et al*., 2010].

30.5.4.1.3. Southeast Asian seas

The South-east Asian Seas (SASs) have a complex island and archipelago domain which interacts with the westward flow of the North Equatorial current and the Indonesian through-flow (Figure 30-1). A large part of this region is referred to as the 'Coral Triangle' [*Veron et al*., 2009] and is the world's most biologically diverse marine area and includes parts of Malaysia, Indonesia, Philippines, Timor L'este, Solomon Islands, and Papua and New Guinea. Sea temperatures increased significantly over the period 1985-2006 [*McLeod et al*., 2010; *Peñaflor et al*., 2009] although with considerable spatial variation. Trends examined over longer periods (1955-2005) also show significant warming (+0.65°C, $p < 0.05$; Table 30-2, calculating using data from 1950-2009). Sea level is increasing by 10 $mm.yr^{-1}$ in a significant proportion of this region [*Church et al*., 2006; *Church et al*., 2004; *Green et al*., 2010]. Like other tropical areas in the world, coral reefs within SASs have experienced periods of elevated temperatures which have driven several mass coral bleaching and mortality events since the early 1980s (Figure 30-12), with the most recent occurred during the warm conditions associated with 2010 [*Krishnan et al*., 2011; *McLeod et al*., 2010]. There is *robust evidence* and *high agreement* that these changes are the result of increasing ocean temperatures and are very likely to be a consequence of anthropogenic climate change (*high confidence*, Box CC-CR; WG1 10.4.1). Calcification rates of some key organisms (e.g., reef-building corals [*Tanzil et al*., 2009] have slowed over the past two decades with increased sea temperature although the cause remains uncertain due to the possible influence of ocean acidification in these changes. While a large part of the decline in coral reefs has been due to rising local stresses (principally destructive fishing, declining water quality, and overexploitation of key reef species), there is high agreement that projected increases in SST represent a major challenge for these valuable ecosystems [*Burke and Maidens*, 2004; *Burke et al*., 2002].

30.5.4.1.4. Arabian Sea and Somali Current

The Arabian Sea and Somali current are relatively productive ocean areas, being strongly influenced by upwelling and the monsoonal system. Wind-generated upwelling enhances primary production in the western Arabian Sea [*Prakash and Ramesh*, 2007]. Several key fisheries within this region are under escalating pressure from both fishing and climate change. Sea water temperature has increased by 0.18ºC and 0.26ºC in the Arabian Sea and Somali current, respectively, over the period 1982-2006 (HadSST2, [*Belkin*, 2009; *Rayner et al*., 2003], which is consistent with the overall rate of warming of the Western Indian Ocean portion of the CBS from 1955-2005 (0.50ºC, using data from 1950-2009, Table 30-2). Salinity of surface waters in the Arabian Sea has also increased by 0.5-1.0% over the past 60 years (Figure 30-6D) due to increased evaporation from warming seas and contributions from the outflows of the saline Red Sea and Arabian Gulf.

The aragonite saturation horizon in the Arabian Sea and Bay of Bengal is now 100 to 200 m shallower than it was in preindustrial times as a result of ocean acidification [*Feely et al*., 2004]. More than 50% of oxygen minimum zones (OMZs) and dead zones in the world oceans [*Diaz and Rosenberg*, 2008] occur in the Arabian Sea (Figure 30-8) and Bay of Bengal [*Helly and Levin*, 2004] where, unlike other sub-regions, OMZs have not expanded since the 1960s [*Karstensen et al*., 2008]. As in other tropical sub-regions, increasing sea temperatures have increased the frequency of mass coral bleaching and mortality within this region [*Goreau et al*., 2000; *Wilkinson*, 2004; *Wilkinson and Hodgson*, 1999]. Shoaling of the aragonite saturation horizon is likely to affect a range of organisms and processes, such as the depth distribution of pteropods in the western Arabian Sea [*Hitchcock et al*., 2002; *Mohan et al*., 2006]. The information regarding the impacts of climate change within this region is undeveloped and suggests that important physical, chemical and biological responses to climate change need to be the focus of further investigation.

30.5.4.1.5. East Africa coast and Madagascar

Oceanic conditions within the East Africa and Madagascar region influence on the coastal conditions associated with Kenya, Mozambique, Tanzania, Madagascar, La Réunion, Mayotte, and three archipelagos (Comores, Mauritius and the Seychelles). Like the north-west section of the Indian Ocean, sea temperatures are increasing rapidly (*high confidence*, $p < 0.05$). Changes in surface salinity vary with the location along the East African coastline. Periods of heat stress over the past 20 years has triggered mass coral bleaching and mortality on coral reef ecosystems with within this region [*Ateweberhan and McClanahan*, 2010; *Ateweberhan et al*., 2011; *McClanahan et al*., 2009a; *McClanahan et al*., 2009b; *McClanahan et al*., 2009c; *McClanahan et al*., 2007]. Steadily increasing sea temperatures have also produced anomalous growth rates in long-lived corals such as *Porites* (*high confidence,* $p < 0.05$)[*McClanahan et al*., 2009b]. Differences in the susceptibility of reef-building corals to stress from rising sea temperatures has also resulted in changes to the composition of coral (*high confidence,* $p < 0.05$, [*McClanahan et al*., 2007] and benthic fish communities (*high confidence*, $p < 0.05$, [*Graham et al*., 2008; *Pratchett et al*., 2011a], which is *very likely* to alter species composition and potentially the productivity of coastal fisheries (*robust evidence, high agreement*, *high confidence*)[*Jury et al*., 2010], although there may be a significant lag between the loss of coral communities and the subsequent changes in the abundance and community structure of fish ($p < 0.05$, [*Graham et al*., 2007]. Attempts to slow these impacts have included the establishment of marine protected areas and changes to fishing management [*Cinner et al*., 2009; *Jury et al*., 2010; *MacNeil et al*., 2010; *McClanahan et al*., 2008].

30.5.4.1.6. Gulf of Mexico and Caribbean Sea

The Caribbean Sea and the Gulf of Mexico form a semi-contained maritime province within the Western Atlantic. These areas are dominated by a range of activities including mineral extraction, fishing and tourism which provide employment and opportunity for over 100 million people who live in coastal areas of the US, Mexico and a range of other Caribbean nations [*Adams et al*., 2004]. The Caribbean Sea and the Gulf of Mexico have warmed by 0.50°C and 0.31°C respectively from 1982 to 2006 [*Belkin*, 2009; *Sherman et al*., 2009]. Warming trends are not significant from 1950-2009 (Table 30-2) which may be partly due to warming being spatially heterogeneous and the enclosed nature of this region making it strongly influenced by long-term variability in a similar way to that seen with respect to the SES sub-regions (30.5.3.1). The Caribbean region has experienced a sustained decrease in the aragonite saturation state from 1996 to 2006 [*Gledhill et al*., 2008]. Sea levels within the Gulf of Mexico and Caribbean Sea have increased at the rate of 2-3 mm y^{-1} from 1950 to 2000 [*Church et al*., 2004; *Zervas*, 2009].

Understanding influences of climate change on ocean ecosystems in this region is complicated by confounding influence of growing human populations and activities. The recent expansion of the seasonal hypoxic zone has been attributed to nitrogen inputs driven by land management [*Donner et al*., 2004; *Turner and Rabalais*, 1994] and changes to river flows, wind patterns, and thermal stratification of Gulf waters, which are likely to increase the size of the Gulf of Mexico "dead zone" [*Justic et al*., 1996; *Justic et al*., 2007; *Levin et al*., 2009; *Rabalais et al*., 2009; *Rabalais et al*., 2010]. Coastal pollution and fishing have also had increasing impacts that have potentially interacted with the influence of climate change on ocean ecosystems within this region (WGII's Ch5, Ch29).

A combination of local and global disturbances has driven the large-scale loss of reef-building corals across the Caribbean Sea since the late 1970s [*Gardner et al*., 2003; *Hughes*, 1994]. Record thermal stress in 2005 triggered the largest mass coral bleaching and mortality event on record for the region, damaging coral reefs across hundreds of km^2 in the eastern Caribbean Sea [*Donner et al*., 2007; *Eakin et al*., 2010]. Similar conditions and impacts on coral reefs occurred in 2010. Increasing sea temperatures has also been implicated in the spread of disease organisms in the Caribbean [*Harvell et al*., 2002b; *Harvell et al*., 1999; *Harvell et al*., 2004] and some introduced species [*Firth et al*., 2011]. As in other sub-regions, pelagic fish species are sensitive to changes in sea temperature and modify their distribution and abundance [*Muhling et al*., 2011]. Ocean acidification may also be altering patterns of fish recruitment although direct evidence for impacts on Caribbean species is lacking [*Dixson et al*., 2010; *Dixson et al*., 2008; *Munday et al*., 2009].

30.5.4.2. Key Risks and Vulnerabilities

At least 850 million people live within 100 km of CBS regions (i.e. number living within 100 km of coral reefs is 850 million and is therefore a minimum estimate given there are other ecosystems other than coral reefs, *Burke et al.* [2011]) from where they derive a range of benefits from food, coastal protection, cultural services, and income from industries such as fishing and tourism. Marine ecosystems within the CBS are sensitive to increasing sea temperatures (Figure 30-12), although detection and attribution is complicated by the significant influence and interaction with non-climate change stressors (water quality, over-exploitations of fisheries, coastal degradation; Box CC-CR). Warming is *likely* to have changed the primary productivity of ocean waters, placing valuable ecosystems and fisheries at risk within the ECS. Other risks include the expansion of hypoxic conditions and associated dead zones in many parts of CBS. Given the impact on coastal ecosystems and fisheries, these changes are *very likely* to increase the vulnerability of coastal communities throughout the CBS.

Sea temperatures are rapidly increasing within many parts of the CBS ecosystems, which will continue over the next few decades and century. Sea temperatures are projected to change by 0.34-0.50°C in the near–term (by 2039) and by 0.23 - 0.74°C in the long –term (by 2099) under the lowest RCP scenario (RCP2.6). Under BAU RCP8.5, CBS sea temperatures are projected to increase 0.62-0.85°C by 2039 and 2.44 – 3.32°C by 2099 (Table 30-4). Given the large-scale impacts (e.g. mass coral bleaching and mortality events) have occurred in response to much smaller changes in the past over the CBS regions (0.10-0.67°C from 1955 to 2005, Table 30-2), the projected changes of 2.44 – 3.32°C by 2099 are *very likely* to have large-scale and negative impacts on structure and function of many CBS ecosystems (Figure 30-12). It is *virtually certain* that fishery composition will change with *robust evidence* and *high agreement* that catch rates and productivity of many fisheries will be *very likely* to decrease as waters warm, acidify and stratify, and as crucial habitat associated with ecosystems such as coral reefs degrades. These changes are *very likely* to increase the vulnerability of millions of people who live in coastal communities and depend directly on fisheries and other ecological goods and services.

It is *very likely* that coral reef ecosystems will not survive changes in sea temperature beyond an additional increase of 1°C (Box CC-CR; Figure 30-12). Combining the known sensitivity of coral reefs within the Caribbean and Coral Triangle sub-regions [*Hoegh-Guldberg*, 1999; *Strong et al.*, 1997; *Strong et al.*, 2011], with the exposure to higher temperatures that are projected under medium (RCP4.5) to high (RCP8.5) scenarios, reveals that both coral reef rich regions are *virtually certain* to experience levels of thermal stress that cause coral bleaching every 1-2 years by the mid to late part of this century (*robust evidence, high levels of agreement, very high confidence,* Figure 30-5 A,B; Figure 30-12A,B). The frequency of mass mortality events (DHM > 5; Figure 30-11 A,C) climbs towards events that occur every 1-2 years by mid to late of this century under low to high climate change scenarios (*robust evidence, high levels of agreement, very high confidence,* [*Donner et al.*, 2005; *Frieler et al.*, 2012; *Hoegh-Guldberg*, 1999]. Mass mortality events that impact coral reefs will result in changes to community composition in the short-term (2010-2039)[*Adjeroud et al.*, 2009; *Berumen and Pratchett*, 2006] and a continuing downward trend in reef-building coral stocks in the longer term [*Baker et al.*, 2008; *Bruno and Selig*, 2007; *Gardner et al.*, 2003].

[INSERT FIGURE 30-12 HERE
Figure 30-12: Annual maximum proportions of reef pixels with Degree Heating Months (Donner et al. 2007; DHM) ≥ 1 (coral bleaching) and DHM ≥ 5 (bleaching across 100% of affected areas with significant mortality, Eakin et al. 2010) for each of the six coral regions (Figure 30-3) have been depicted as bar graphs for the period 1870-2009. This part of the graph is derived from the HadISST 1.1 data set. The black line plotted on top of the bar graphs is the maximum annual area value for each decade over the period 1870-2009. This value is continued through 2010-2099 using CMIP-5 data and splits into the four Representative Concentration Pathways (RCP 2.6, 4.5, 6.0 and 8.5). DHMs were produced for each of the four RCPs using the ensembles of CMIP models. From these global maps of DHMs the annual percentage of grid cells with DHM ≥ 1 and DHM ≥ 5 were calculated for each coral region. These data were then grouped into decades from which the maximum annual proportions were derived. The plotted lines for 2010-2099 are the average of these maximum proportion values for each RCP. Monthly SST anomalies are derived using a 1985-2000 maximum monthly mean (MMM) climatology derived in the calculations for Figure 30-4. This was done separately for HadISST 1.1 and each of the CMIP-5 models and each of the four RCPs, at each grid cell for each region. DHMs are then derived by adding up the monthly anomalies using a 4 month rolling sum.]

30.5.5. Eastern Boundary Upwelling Ecosystems

The Eastern Boundary Upwelling Ecosystems (EBUE) includes the California, Peru/Humboldt, Canary/NW Africa, and Benguela. They are highly productive sub-regions involving primary productivity that may exceed 1,000 g C m^{-2} y^{-1}. Although these provinces comprise <2% of the world ocean area, they contribute nearly 7% of marine primary production (Table 30-1, Figure 30-1) and more than 20% of the world's capture fisheries [*Pauly and Christensen*, 1995], which are dominated by planktivorous sardine, anchovy, and horse/jack mackerel, and piscivorous benthic-fish such as hake. This level of productivity is a result of large-scale atmospheric pressure gradients and wind systems which advect surface waters offshore (Box 30-1), which are then replaced with cold, nutrient-rich waters upwelled from depth into coastal euphotic zones [*Chavez*, 2011; *Chavez and Messie*, 2009; *Chavez et al.*, 2011]. At the same time, upwelling waters also have high concentrations of CO_2 as well as low pH and reduced concentrations of oxygen, trends that are likely to increase as atmospheric CO_2 increases [*Feely et al.*, 2008; *Gruber*, 2011]. Nutrient input stimulates primary production from phytoplankton blooms that are transferred to mid and upper trophic levels, resulting in substantial fish, seabird and marine mammal populations. As a result, EBUEs are considered "hotspots" of biodiversity [*Block et al.*, 2011].

30.5.5.1. Observed Changes and Potential Impacts

The historical importance of EBUE fisheries has resulted in extensive studies of their coupled climate-ecosystem dynamics (e.g. California Current). Decadal variability poses challenges to the detection and attribution of changes within the EBUEs to climate change although there are a number of long-term studies that have been able to provide insight into the patterns of change and their causes. Like other ocean sub-regions, EBUEs are projected to warm under climate change, experiencing increased stratification as well as periods of intensified upwelling, and altered wind fields as westerly winds shift polewards. However, cooling is also predicted for some EBUEs, resulting from the intensification of wind-driven upwelling [*Bakun*, 1990]. There is *limited* agreement on a broad response by EBUEs to climate change over past decades with considerable variability in warming and cooling both within and among systems [*Burrows et al.*, 2011; *Demarcq*, 2009], see 30.3.1.1 Table 30-2). The California and Canary Currents have warmed by 0.61 and 0.45°C ($p \leq 0.05$, 1950-2009; Table 30-2) respectively, while there has been no significant change in the temperature of the surface waters of the Benguela and Humboldt Currents since from 1950-2009 ($p > 0.05$, Table 30-2). These trends match shorter term trends (or lack of trends) for EBUs using Pathfinder version 5 data (Table 1, [*Demarcq*, 2009]. These differences between EBUEs are *likely* to be the result of differences in the influence of long-term variability and the specific responses of coastal wind systems to warming (Figure 30-6A) although an analysis of wind data over the same period did not pick up clear trends [*Demarcq*, 2009].

How climate change is likely to influence ocean upwelling is central to resolving ecosystem and fishery responses within each EBUE. There is considerable debate, however, as to whether or not climate change will drive an intensification of upwelling (e.g. [*Bakun et al.*, 2010; *Narayan et al.*, 2010]) in all regions. Discussion of the various hypotheses for how climate change is likely to affect coastal upwelling is presented in Box 30-1. EBUEs are also areas of naturally low pH and high CO_2 concentrations due to upwelling, and consequently may be vulnerable to ocean acidification and its synergistic impacts. A full understanding of the impacts of ocean acidification is discussed elsewhere (Box CC-OA; 6.2.2, 6.3.4, [*Kroeker et al.*, 2013], WG1 6.4).

30.5.5.1.1. Canary Current

Part of the North Atlantic STG, the Canary Current extends from northern Morocco southwestward to the North Atlantic Equatorial Current. It is linked with the Portugal Current (which is sometimes considered part of the Canary Current) upstream and extends downstream to the Atlantic Equatorial Current. The coastal upwelling system, however, is limited to a narrow belt along the Saharan west coast to the coast of Guinea, with the most intense upwelling centrally, along the coast of Mauretania (15-20ºN) and Morocco (21-26°N). Total fish catches, comprising mainly coastal pelagic sardines, sardinellas, anchovies and mackerel, have fluctuated around 2 million

tons.yr^{-1} since the 1970s (http://www.seaaroundus.org/lme/27.aspx). Contrasting with the other EBUEs, fishing productivity is modest, probably due to the legacy of uncontrolled fishing in the 1960s [*Arístegui et al.*, 2009].

Most observations suggest that the Canary current is warming at both local [*Demarcq*, 2009] and regional [*Belkin*, 2009] scales since the early 1980s with analysis of HadSST 1.1 data from 1950-2009 indicating warming of 0.45°C from 1955 to 2005 ($p<0.05$; Table 30-2) with a 20% and 45% decrease in the strength of upwelling in winter and summer respectively from 1967 to 2006 [*Gómez-Gesteira et al.*, 2008]. This is consistent with a decrease in wind strength over the past 60 years (Figure 30-6A), which reduces the upwelling and nutrient concentrations, and the supply of iron-laden dust from the Sahara [*Alonso-Pérez et al.*, 2011]. There is *medium evidence* and *agreement* that primary production in the Canary Current has decreased over the past two decades [*Arístegui et al.*, 2009; *Demarcq*, 2009], Table 1) contrasting trends apparent of nearby region of NW Spain [*Bode et al.*, 2011]. Satellite chlorophyll records (SeaWifs, MODIS) are relatively short, making it difficult to distinguish longer-term patterns of variability from the influence of climate change (*low confidence*)[*Henson et al.*, 2010]. There is also substantial interannual to decadal-scale variability in the fish catches in this system, and catch trends (1950-2007), which is not entirely consistent with these patterns of change in temperature, upwelling, or nutrient supply [*Arístegui et al.*, 2009; *Zeeberg et al.*, 2008].

30.5.5.1.2. Benguela Current

The Benguela Current originates from the eastward-flowing, cold South Atlantic Current, flows northward along the African southwest coast, and is bounded north and south by the warm-water Angola and Agulhas Currents, respectively. Upwelling is strongest and most persistent toward the center of the system in the Lüderitz-Orange River upwelling cell [*Hutchings et al.*, 2009]. Fish catch reached a peak in the late 1970s at 2.8 million tons.yr^{-1} (http://www.seaaroundus.org/lme/29/1.aspx), before declining to around 1 million tons.yr^{-1} (present) as a combined result of overfishing and inter-decadal environmental variability [*Cury and Shannon*, 2004; *Heymans et al.*, 2004; *Hutchings et al.*, 2009]. Commercial fisheries currently comprise sardine, anchovy and horse mackerel, and hake.

Most research in the Benguela Current has focused on fisheries and oceanography, with little emphasis on climate change. As with the other EBUEs, strong inter-annual and inter-decadal variability in physical oceanography make the detection and attribution of biophysical trends to climate change difficult. Nevertheless, physical conditions of the Benguela are highly sensitive to climate variability over a range of scales, and especially to atmospheric teleconnections that alter local wind stress [*Hutchings et al.*, 2009; *Leduc et al.*, 2010; *Richter et al.*, 2010; *Rouault et al.*, 2010]). Consequently, there is *medium agreement* that the Benguela system will change as a result of climate change [*Demarcq*, 2009].

There is no significant trend in the temperature of the surface waters of the Benguela Current from 1950 to 2009 ($p > 0.05$; Table 30-2) although shorter records show a decrease in the temperature of the south-central Benguela (0.35–0.55 ºC.decade^{-1} [*Rouault et al.*, 2010] or the whole Benguela region (total decrease of 0.24ºC, *Belkin* [2009]). These differences between short versus long records indicate the substantial influence of long-term variability on the Benguela system, reflected by the index of variability shown in Table 30-2. Information on other potential climate-change impacts within the Benguela is sparse. Sea-level rise is similar to the global mean, although it has not been measured rigorously within the Benguela [*Veitch*, 2007]. Although upwelling water in the northern and southern portions of the Benguela exhibits elevated and suppressed pCO_2, respectively [*Santana-Casiano et al.*, 2009]), the consequences of changing upwelling intensity remain poorly explored with respect to ocean acidification. Finally, while periodic hypoxic events in the Benguela are driven largely by natural advective processes, these may be exacerbated by future climate change [*Bakun et al.*, 2010; *Monteiro et al.*, 2008].

Despite its apparent sensitivity to environmental variability, there is no published evidence from the Benguela EBUE that attributes marine ecological impacts to climate change with any degree of confidence [*Poloczanska et al.*, 2013]. For example, pelagic fish [*Roy et al.*, 2007], benthic crustaceans [*Cockcroft et al.*, 2008] and seabirds [*Crawford et al.*, 2008] have demonstrated general eastward range shifts around the Cape of Good Hope. Although these may be associated with increased upwelling along the South African south coast, specific studies that attribute these changes to anthropogenic climate change are lacking.

30.5.5.1.3. California Current

The California Current spans ~23° of latitude from central Baja California, Mexico, to central British Columbia, linking the North Pacific Current (Westwind Drift) with the North Equatorial and Kuroshio currents, to form the North Pacific Gyre. High productivity driven by advective transport and upwelling [*Checkley and Barth*, 2009; *Chelton et al.*, 1982; *Hickey*, 1979] supports well-studied ecosystems and fisheries. Fish catch data from the California Current since 1950 is about 0.6 million tons.yr^{-1} (http://www.seaaroundus.org/lme/3.aspx) which makes it the lowest catch of the four EBUEs. However, a major fraction of the catches is on one higher trophic level than in the other EBUEs, i.e. more on piscivores than planktivores. Sardine (~47,000 metric tons.yr^{-1}) and squid (~65,000 metric tons.yr^{-1}) dominated the commercial catch of lower trophic level fisheries in the California Current (2000-2009) while anchovy contributed only ~10,000 metric tons.yr^{-1}. Further north, Pacific Hake and salmonids dominate the higher trophic-level fisheries. The ecosystem supports the foraging and reproductive activities of 2-6 million seabirds from around 100 species [*Briggs and Chu*, 1987]. Marine mammals are diverse and relatively abundant, including recovering populations of Humpback whales, among others [*Barlow et al.*, 2008].

The average temperature of the California Current has warmed by 0.61°C from 1955 to 2005 (1.1, $p < 0.05$, Table 30-2) and from 0.14 to 0.80 ºC (1985-2007, [*Demarcq*, 2009]. Like other EBUEs, the California Current is characterised by large-scale inter-annual and inter-decadal climate-ecosystem variability [*Chavez et al.*, 2003; *Checkley and Barth*, 2009; *Hare and Mantua*, 2000; *McGowan et al.*, 1998]. During an El Niño, coastally-trapped Kelvin waves from the tropics deepen the thermocline, thereby severely reducing upwelling and increasing ocean temperatures from California to Washington [*King et al.*, 2011]. Atmospheric teleconnections to the tropical Pacific alter wind stress and coastal upwelling. Therefore, the ENSO is intimately linked with Bakun's (1990) upwelling intensification hypothesis (Box 30-1). Inter-decadal variability in the California Current stems from variability in the Pacific-North America pattern [*Overland et al.*, 2010], which is influenced by the PDO [*Mantua et al.*, 1997] and the NPGO [*Di Lorenzo et al.*, 2008]. The major effects of the PDO and NPGO appear north of 39°N [*Di Lorenzo et al.*, 2008; *Menge et al.*, 2009].

Increasing upwelling has implications for productivity which is driven primarily by "bottom-up" trophic mechanisms [*Fleeger et al.*, 2006; *Ware and Thomson*, 2005], with upwelling, transport, and chlorophyll concentrations showing strong interannual couplings. These, in turn, influence trophic transfer up the food chain, affecting zooplankton [*Hooff and Peterson*, 2006; *Keister et al.*, 2011], forage fish [*Brodeur et al.*, 2008], seabirds [*Abraham and Sydeman*, 2004; *Ainley et al.*, 1995], and marine mammals [*Barlow et al.*, 2008; *Thompson et al.*, 2012]. Ecosystem dynamics are therefore sensitive to and may be strongly masked or accentuated by natural variability. For instance, the distribution for many species of larval fish in the Californian Current is strongly related to natural variability. However, many species are also moving polewards over long time-spans, an observation which is consistent with observed warming in the region [*Hsieh et al.*, 2009].

There is *robust evidence* that the California Current has experienced a decrease in the number of upwelling events (23-40%) while the duration of each upwelling event has increased such that the overall magnitude of upwelling events has increased from 1967 to 2010 [*Iles et al.*, 2012], which is consistent with changes expected under climate change [*Iles et al.*, 2012]. Oxygen concentrations have also undergone large and consistent decreases from 1984-2006 throughout the California current, with the largest relative decreases occurring below the thermocline (21% at 300 m). The hypoxic boundary layer ($\leq$60 mmol kg^{-1}) has also shoaled up to 90 m in some regions [*Bograd et al.*, 2008]. These changes are consistent with the increased input of organic carbon into deeper layers from enhanced productivity, which stimulates microbial activity and results in the drawdown of oxygen [*Bakun et al.*, 2010]. These changes are likely to reduce the available habitat for key benthic communities as well as fish and other mobile species [*Stramma et al.*, 2012]. Increasing microbial activity will also increase the partial pressure of CO_2, decreasing pH and the carbonate chemistry of seawater. Together with the shoaling of the saturation horizon, these changes have increased the incidence of undersaturated, low pH and corrosive water flowing onto portions of the continental shelf (40-120 m, [*Feely et al.*, 2008] with consequences for industries such as the shellfish aquaculture industry [*Barton et al.*, 2012].

30.5.5.1.4. Humboldt Current

The Humboldt Current is the largest of the four EBUEs, covering an area larger than the other three combined. It comprises the eastern edge of South Pacific Gyre, linking the northern part of the Antarctic Circumpolar Current with the Pacific South Equatorial Current. Although the primary productivity per unit area is modest compared to that of the other EBUEs, the Humboldt Current system has very high levels of fish production. Current catches are in line with a long-term average (since 1960s) of 8 million tons.yr^{-1} (http://www.seaaroundus.org/lme/13/1.aspx) although decadal-scale variations range from 2.5 to 13 million tons.yr^{-1}. While the anchoveta currently contributes 80% of the total catch, they alternate with sardines on a multi-decadal scale, with their dynamics mediated by the approach and retreat of subtropical waters to and from the coast [*Alheit and Bakun*, 2010] in a cycle that does not appear to be due to anthropogenic climate change. Thus, from the late 1970s to early 1990s, sardines were more important [*Chavez et al.*, 2003]. The other major commercial fish species are jack mackerel among the pelagic fish, and hake among the demersal fish.

The Humboldt Current has not shown a warming trend in SST over the last 60 years (Table 30-2) which is consistent other data sets (1982-2006, HadISST1.1, [*Belkin*, 2009]; 1985-2007, Pathfinder [*Demarcq*, 2009]. Wind speed has increased in the central portions of the Humboldt Current although wind has decreased in its southern and northern sections (Figure 30-6A, [*Demarcq*, 2009]. The lack of a consistent warming signal may be due to the strong influence of adjacent ENSO activity, which may be exerting opposing drivers on upwelling which (if they intensify) would decrease temperatures.

Primary production is suppressed during warm El-Niño events and amplified during cooler La-Niña phases. These changes affect primary production that propagates through to higher trophic levels [*Chavez et al.*, 2003; *Tam et al.*, 2008; *Taylor et al.*, 2008]. However, in addition to the trophic impacts, there is also a significant thermal impact directly on organisms, which varies depending on thermal adaptation window for each species. A 37-year zooplankton time series for the coast of Peru showed no persistent trend in abundance and diversity [*Ayón et al.*, 2004], although observed shifts coincided with the shifts in the regional SST. As for the other EBUEs, there is lack of studies that have rigorously attempted to detect and attribute changes to anthropogenic climate change, although at least one study [*Gutierrez et al.*, 2011] provides additional evidence that the northern Humboldt Current has cooled (due to upwelling intensification) since the 1950s, a trend matched by increasing primary production. This is not entirely consistent with the lack of significant change over the period from 1950-2009 (Table 30-2). Nevertheless, these relationships are likely to be complex in their origin, especially in their sensitivity to the long-term changes associated with ENSO and PDO.

30.5.5.2. Key Risks and Vulnerabilities

There is *robust evidence* and *high agreement* that EBUEs are vulnerable to changes that influence the intensity of currents, upwelling and mixing (i.e. SST, wind strength and direction), oxygen content, ocean chemistry, and the supply of organic carbon to deep offshore locations. Extent to which particular EBUEs are vulnerable to these factors depends on their location [*Gruber*, 2011] Figure 3) and other factors such as other sources of nutrient input and fishing pressure [*Bakun et al.*, 2010]. This complex interplay between regional and global drivers means that our understanding of how factors such as upwelling within the EBUEs are likely to respond to further climate change is uncertain (Box 30-1).

In the GCM ensembles examined (Table 30-3), modest rates of warming (0.22 – 0.91°C) occur within the four EBUEs, with the differences between the four RCP models examined being minimal in the near term (2010-2039) and range from 0.22ºC to 0.93ºC. By the end of the century, however, EBUE temperatures range from 0.07ºC to 1.02ºC warmer than today under RCP 2.6, and 2.52ºC to 3.51ºC under RCP8.5 (Table 30-4). These high temperatures have the potential to increase stratification of the water column and substantially reduce overall mixing in some areas and sometimes. Contrary to this, is the potential strengthening of coastal wind systems which would intensify upwelling and stimulate primary productivity through the increased injection of nutrients into the photic zone within the EBUEs (Box 30-1). *Garreaud and Falvey* [2009] explored how wind stress along the South

American coast would change by 2100 under B2 and A2 IPCC scenarios. Using an ensemble of 15 coupled atmosphere–ocean Global Circulation Models (GCMs), upwelling favorable southerly wind systems along the subtropical coast of South America increased, extending and strengthening conditions required for upwelling.

Changes in the intensity of upwelling within the EBUEs are *very likley* to drive fundamental changes to the abundance, distribution and viability of their resident biota although their nature and direction is *uncertain*. In some cases, large-scale decreases in primary productivity and dependent fisheries are projected to occur for EBUEs [*Blanchard et al.*, 2012] while other projections question the strong connection between primary productivity and fisheries production [*Arístegui et al.*, 2009]. Increased upwelling intensity also has potential disadvantages. Elevated primary productivity may lead to decreasing trophic transfer efficiency, thus increasing the amount of organic carbon exported to the seabed (Figure 30-16), where it is *virtually certain* to increase microbial respiration and hence increase oxygen stress [*Bakun et al.*, 2010; *Weeks et al.*, 2002]. Increased wind stress may also increase turbulence, breaking up food concentrations (affecting trophic transfer), or causing excessive offshore advection, which could remove plankton from shelf habitats.

The central issue for the EBUEs is therefore whether or not upwelling will intensify, and if so, whether the detrimental impacts of upwelling intensification on O_2 and CO_2 will outweigh its benefits to primary production and associated fisheries. These changes need to be considered together with the many other changes that are *likely*. As projected atmospheric CO_2 concentrations increase, upwelling waters will become increasingly corrosive (*very high confidence*). Although there is substantial evidence from other systems that these changes are likely to impact the biota of EBUEs, there are many uncertainties.

30.5.6. Subtropical Gyres

Subtropical gyres (STG) dominate the Pacific, Atlantic and Indian Oceans and consist of large stable water masses that circulate clockwise (northern hemisphere) and anticlockwise (southern hemisphere) due to the Coriolis Effect (Figure 30-1, Figure 30-13A). The oligotrophic areas at the core of the STGs represent one of the largest habitats on Earth, contributing 21.2% of the ocean primary productivity and 8.3% of the global fish catch (Table 30-1). A number of small island nations are found within this region. While many of the observed changes within these nations have been described in previous chapters, region-wide issues and impacts are discussed here given the strong linkages between ocean and coastal issues (e.g. Chapters 5 and 29).

30.5.6.1. Observed Changes and Potential Impacts

The central portions of the STG are oligotrophic (Figure 30-13A). Temperatures within the STGs of the North Pacific (NPAC), South Pacific (SPAC), Indian Ocean (IOCE), North Atlantic (NATL) and South Atlantic (SATL) have increased at rates of 0.024, 0.0236, 0.0322, 0.0248, and 0.0266°C.yr^{-1} from 1998 to 2010 respectively [*Signorini and McClain*, 2012](Figure 30-13B). This is consistent with changes observed from 1955 to 2005 (0.21-0.53ºC, Table 30-2). Salinity has decreased across the North and South Pacific STGs (Figure 30-6D; WGI 3.3.3.1), consistent with warmer sea temperatures and an intensification of the hydrological cycle [*Boyer*, 2005].

It is *very likely* that the tropical gyres in the North and South Pacific have expanded since 1993 (*high confidence*), with these changes being *as likely as not* consequences of changes in wind forcing and long-term variability (WG1 3.6.3). Chlorophyll levels have decreased in NPAC, IOCE and NATL by 9%, 12% and 11%, respectively over and above the inherent seasonal and interannual variability from 1998 to 2010 [*Vantrepotte and Melin*, 2011] Figure 30-13 C). Chlorophyll levels did not change statistically in the remaining two gyres (SPAC and SATL; which has been confirmed for SPAC by [*Lee and McPhaden*, 2010; *Lee et al.*, 2010]). Further, over the period 1998-2007, median cell diameter of key species of phytoplankton exhibited statistically significant linear declines of about 2% in the North and South Pacific, and 4% in the North Atlantic Ocean [*Polovina and Woodworth*, 2012]. Changes in chlorophyll and primary productivity in these sub-regions have been noted before [*Gregg et al.*, 2005; *Polovina et al.*, 2008] and are influenced by seasonal and longer term sources of variability (e.g. ENSO, PDO, 6.3.1, Figure 6-10). These changes represent a significant expansion of the world's most unproductive waters, although caution must

be exercised given the limitations of satellite detection methods (6.2, 6.3) and the shortness of records relative to longer-term patterns of climate variability. There is *high confidence* that changes that reduce the vertical transport of nutrients into the euphotic zone (e.g. decreased wind speed, increasing surface temperatures and stratification) will reduce the rate of primary productivity and hence fisheries.

[INSERT FIGURE 30-13 HERE
Figure 30-13: A. Map of SeaWiFS chl-a climatology. The white polygons define the sub-regions that were analyzed and represent the major sub-regions considered as sub-tropical gyres by Signorini and McClain (2012). B. Time series of anomalies in chl-a and B. Sea Surface Temperature SST for STGs in North Pacific (NPAC), South Pacific (SPAC), Indian Ocean (IOCE) North Atlantic (NATL) and South Atlantic (SATL) Oceans.]

30.5.6.1.1. Pacific Ocean STGs

Pacific climate is heavily influenced by the position of the Inter-tropical Convergence Zone (ITCZ) and the South Pacific Convergence Zone (SPCZ), which are part of the ascending branch of the Hadley circulation. These features are also strongly influenced by inter-annual to inter-decadal climate patterns of variability including the ENSO and PDO. The current understanding of how ENSO and PDO are likely to change as average global temperatures increase is *uncertain* [*Collins et al.*, 2010], WG1 12.4.4.2). The position of both ITCZ and SPCZ vary seasonally and with influences such as ENSO [*Lough et al.*, 2011], with a northward migration during the northern hemisphere summer and a southward migration during the southern hemisphere summer. These changes determine the timing and extent of the wet and dry seasons in SPAC and NPAC sub-regions, along with the West Pacific Monsoon [*Ganachaud et al.*, 2011]. Tropical cyclones are prominent in the Pacific (particularly the western Pacific), and CBS sub-regions between 10°-30° north and south of the equator, although the associated storm systems may occasionally reach higher latitudes. Spatial patterns of cyclones vary with ENSO, spreading out from the Coral Sea to the Marquesas Islands during El Niño and contracting back to the Coral Sea, New Caledonia and Vanuatu during La Niña [*Lough et al.*, 2011]. Historically, there has been almost twice as many land falling tropical cyclones during La Niña as opposed to El Niño years off the East coast of Australia, with a declining trend in the number of severe tropical cyclones from 0.45 per year in the early 1870s to 0.17 per year in recent times [*Callaghan and Power*, 2011].

The Pacific Ocean underwent an abrupt shift to warmer sea temperatures in the mid-1970s as a result of both natural (e.g. PDO) and climate forcing [*Meehl et al.*, 2009] (*high confidence*). This change coincided with a similarly sharp change in rainfall observed across the Pacific [*Griffiths et al.*, 2003], especially from 150-180°W. Countries such as the Cook Islands, Tonga, Samoa and American Samoa and Fiji tend to experience drought conditions as the SPCZ (with cooler sea temperatures) moves toward the north-east during El Niño (*moderate confidence*). The opposite is true during La Niña conditions. The impact of changing rainfall on the countries of the Pacific STGs discussed in greater detail elsewhere (5.3.2.5, 5.3.2.6, 29.3.2.2, Table 29-1). While these changes are due to different phases of long-term variability in the Pacific, they illustrate the ramifications and sensitivity of the Pacific to changes in climate change.

Elevated sea temperatures within the Pacific Ocean have increased the frequency of widespread mass coral bleaching and mortality since the early 1980s [*Baker et al.*, 2008; *Donner et al.*, 2010; *Hoegh-Guldberg*, 1999; *Hoegh-Guldberg and Salvat*, 1995; *Mumby et al.*, 2001]. There are few if any scientific records of mass coral bleaching and mortality prior to this period [*Hoegh-Guldberg*, 1999]. Rates of decline in coral cover on coastal coral reef ecosystems range between 0.5 and 2.0% per year depending on the location within the Indo Pacific region [*Bruno and Selig*, 2007; *De'ath et al.*, 2012; *Hughes et al.*, 2011; *Sweatman et al.*, 2011]. The reasons for this decline are complex and involve non-climate change related factors (e.g. coastal pollution, overfishing) as well is global warming and possibly acidification. A recent comprehensive analysis of the impacts of coral bleaching and mortality concluded "that bleaching episodes have resulted in catastrophic loss of coral reefs in some locations, and have changed coral community structure in many others, with a potentially critical influence on the maintenance of biodiversity in the marine tropics" [*Baker et al.*, 2008]. Increasing sea levels have also caused changes in seagrass and mangrove systems. *Gilman et al.* [2007] found a reduction in mangrove area with sea level rise, with the observed mean landward recession of three mangrove areas over four decades being 25, 64, and 72 $mm.yr^{-1}$, 12-37

times faster than the observed rate of sea-level rise. Significant interactions exist between climate change and coastal development, where migration shoreward depends on the extent to which coastlines have been modified or barriers to successful migration have been established.

Reduced ocean productivity of the STGs [*Sarmiento et al*., 2004; *Signorini and McClain*, 2012] reduces the flow of energy to higher trophic levels, such as those of pelagic fish and sharks [*Le Borgne et al*., 2011]. The distribution and abundance of fisheries stock such as tuna is also sensitive to changes in sea temperature and hence long-term variability such as ENSO and PDO. The redistribution of tuna in the Western central equatorial region has been related to the position of the oceanic convergence zones, where the warm pool meets the cold tongue of the Pacific. These changes have been reliably reproduced by population models that use temperature as a driver of the distribution and abundance of tuna [*Lehodey et al*., 1997; *Lehodey et al*., 2006].

30.5.6.1.2. Indian Ocean STG

Like the Pacific Ocean, the Indian Ocean plays a crucial role in the global weather patterns with teleconnections throughout Africa, Australasia, Asia and the Americas (e.g. [*Clark et al*., 2000; *Manhique et al*., 2011; *Meehl and Arblaster*, 2011; *Nakamura et al*., 2011]. Increasing sea level, temperature, storm distribution and intensity, and changing ocean chemistry set to influence the broad range of physical, chemical and biological aspects of the Indian Ocean. Coral reef ecosystems in the Indian Ocean gyre system were heavily impacted by record positive sea temperature anomalies seen in the southern hemisphere February-April 1998 [*Ateweberhan et al*., 2011] *robust evidence, high agreement, high confidence*). Coral cover across the Indian Ocean region has declined from 37-39% coral cover in the period 1987 to 1997 to approximately 22% coral cover (1999-2000). Responses to the anomalously hot conditions in 1998 varied between sub-regions, with the central Indian Ocean islands (Maldives, Seychelles, Chagos, and Lakshadweep) experiencing major decreases coral cover from 40 to 53% (1977 to 1997) to 7% (1999-2000) after the 1998 event (*high confidence*, [*Ateweberhan et al*., 2011]). Coral reefs lining islands in southern India and Sri Lanka experienced similar decreases in coral cover (45% to 13%). Islands in the South West Indian ocean (Comoros, Madagascar, Mauritius, Mayotte, Reunion, and Rodrigues) experienced much lower impacts (44%, 1977-1997 to 40%, 1999-2000). Recovery from these impacts has been variable with sites such as those around the central Indian Ocean islands exhibiting fairly slow recovery (13% by 2001-2005) while those around southern India and Sri Lanka showing much higher rates (achieving a mean coral cover 37% by 2001-2005; [*Ateweberhan et al*., 2011]. These impacts on key reef-building species are likely to drive major changes in the abundance and composition of fish populations in coastal areas, and affect other ecosystem services that are important for underpinning tourism and coastal protection (Box CC-CR).

Pelagic fisheries that involve tuna and other pelagic species are very valuable to many small island states within the Indian Ocean (Chapter 29). As with Pacific pelagic fisheries, the distribution and abundance of pelagic fisheries in the Indian Ocean is greatly influenced by sea temperature. The anomalously high sea temperatures of 1997-98 (leading to deep mixed layer anomalies) coincided with anomalously low primary production in the Western Indian Ocean and a major shift in tuna stocks within the Indian Ocean [*Menard et al*., 2007; *Robinson et al*., 2010], *high confidence*). Fishing grounds in the Western Indian Ocean were deserted and fishing fleets underwent a massive shift toward the eastern basin, which is unprecedented for the tuna fishery. As a result of these changes, many countries throughout the Indian Ocean lost significant tuna related revenue. In the case of the Seychelles in 1998, direct, indirect and induced economic effects of the tuna industry expenditure declined by 58, 26 and 35%, respectively [*Robinson et al*., 2010]. Observations over the period 1991 to 2007 reveal interactions between depth of the mixed layer and depressed chlorophyll concentrations. In 2007, tuna fishing revenue was again reduced by strong surface warming, the deepening of the mixed layer, and associated with modest reduction in primary productivity. These trends highlight the overall vulnerability of tuna fishing countries to climate change, which is similar for many other countries in the other major oceans of the world.

30.5.6.1.3. Atlantic Ocean STGs

The SST have increased within the STGs of the Atlantic Ocean (Figure 30-13, [*Belkin*, 2009; *Signorini and McClain*, 2012]. The strength of surface winds has also declined over a large portion of the STGs in the Atlantic Ocean (Figure 30-6A, *high confidence*). These changes have influenced the distribution of key fishery species as well the ecology of coral reefs in Bermuda [*Baker et al*., 2008; *Wilkinson and Hodgson*, 1999] and in the eastern Caribbean [*Eakin et al*., 2010]. Small island nations such as Bermuda depend on coral reefs for fisheries and tourism and are vulnerable to further increases in sea temperature that cause mass coral bleaching and mortality (Box CC-CR; Figure 30-12). As with the other STGs, phytoplankton communities and pelagic fish stocks are sensitive to temperature changes that have occurred over the past several decades. Observations to the changes have enabled models to be developed which have a high degree of accuracy in projecting the distribution and abundance of these elements within the Atlantic region generally [*Cheung et al*., 2011].

30.5.6.2. Key Risks and Vulnerabilities

The vast STGs of the Atlantic, Pacific and Indian oceans are responsive to increasing temperature which is *very likely* to increase water column stratification which is *likely* to reduce surface concentrations of nutrients, and consequently, primary productivity (*medium confidence*). Warming is projected to continue (Table 30-4), with substantial increases in the risk and vulnerability associated with systems that have been observed to change so far (*high confidence*; Figure 30-12). Under RCP2.6, the temperatures of the STGs are likely to increase by 0.20-0.55°C warmer in the near term (2010-2039) and between 0.00-0.87°C by the end of the century (Table 30-4). Under RCP8.5, however, surface temperatures of the world's STGs are projected to be 0.49-0.90°C warmer in the near term (2010-2039) and 2.05-3.44°C warmer by the end of the century (Table 30-4). These changes in temperature are *very likely* to increase water column stability, reduce the depth of the mixed layer, and influence key parameters such as nutrient availability and oxygen concentrations. It is *uncertain* how longer term sources of variability such as ENSO and PDO will change and ultimately influence these trends.

The world's most oligotrophic ocean sub-regions will continue to expand over coming decades with consequences for ecosystem services such as gas exchange, fisheries and carbon sequestration if a large part of recent changes have an origin in climate change. *Polovina et al*. [2011] explored this question for the North Pacific using a climate model that included a coupled ocean biogeochemical component to investigate potential changes under an SRES A2 scenario (~RCP 6.0 – 8.5). Model projections demonstrated that the STG expanded by approximately 30% by 2100, driven by the northward drift of the mid-latitude westerlies and enhanced stratification of the water column. The expansion of the STG occurred at the expense of the equatorial upwelling and other regions within the North Pacific. The total primary production and fish catch of the new enlarged STG is projected to increase by 26% although primary production per area declined slightly [*Polovina et al*., 2011].

Understanding how storm frequency and intensity is likely to change represents a significant question for many countries within the STGs. Projections of increasing sea temperature are *likely* to change the behavior of tropical cyclones. At the same time, the maximum wind speed and rainfall associated with cyclones is *likely* to increase, although future trends in cyclones and severe storms are *very likely* to vary from region to region (WG1 Box 14.2). Patterns such as "temporal clustering" can have a strong influence on the impact of tropical cyclones on ecosystems such as coral reefs [*Mumby et al*., 2011], although how these patterns are likely to change within the STG is uncertain at this point. There is, however, *medium to high confidence* that an intensifying hydrological cycle is likely to increase precipitation in many areas (WG1 2.6.3, 14.2.5), although longer droughts are also expected in other STGs (*medium confidence*). Improving our understanding of how weather systems associated with features such as the South Pacific Convergence Zone (14.3.1.2) are likely to vary is critical to climate change adaptation of a large number of nations associated with the STGs. Developing an understanding of how water temperature, climate systems such as SPCZ and ITCZ, climate change, and long-term cycles such as ENSO interact will be essential in this regard.

The impacts of projected sea temperatures on the frequency of coral bleaching and mortality within two key sub-regions within the STG are outlined in Box CC-CR and Figure 30-12. As with other sub-regions dominated by coral

reefs, mass coral bleaching and mortality becomes an annual risk under all scenarios, with mass mortality events beginning to occur every 1-2 years by 2100 (Box CC-CR, Figure 30-12). Coral dominated reef ecosystems (areas with more than 30% coral cover) are *very likely* disappear under these circumstances by the mid to late part of this century [*Bell et al.*, 2013a; *Donner et al.*, 2005; *Dove et al.*, 2013; *Frieler et al.*, 2012]. The loss of substantial coral communities has implications for the three-dimensional structure of coral reefs (Figure 30-12; Box CC-CR), and the role of the latter as habitat for organisms such as fish [*Bell et al.*, 2013a; *Hoegh-Guldberg*, 2011; *Hoegh-Guldberg et al.*, 2011b; *Pratchett et al.*, 2011a]. The impacts of increasing sea temperature can be exacerbated by increasing ocean acidification with potential impacts on calcification [*Doney et al.*, 2009; *Hoegh-Guldberg et al.*, 2007; *Kleypas et al.*, 1999] *medium confidence*), reef metabolism and community calcification [*Dove et al.*, 2013], and other key ecological processes [*Munday et al.*, 2009; *Portner et al.*, 2007; *Portner et al.*, 2001], 6.2.2.4.4). Ocean pH within the STGs will continue to decrease as atmospheric carbon dioxide increases, bringing pH within the STGs to 7.7 (800 ppm) and 7.9 (450 ppm, Figure 30-7A; Box CC-OA). Aragonite saturation states will decrease to around 1.6 (800 ppm,) and 3.3 (450 ppm, Figure 30-7B). Decreasing carbonate ion situations and saturation states pose serious risks to other marine calcifiers such as encrusting coralline algae, coccolithophores, and a range of invertebrates [*Doney et al.*, 2009; *Feely et al.*, 2009]. Increasing sea temperatures and sea level are also likely to influence other coastal ecosystems (e.g. mangroves, seagrass meadows) in the Pacific although significant gaps and uncertainties exist (6.4.1.2.2, 29.3.1.4, [*Waycott et al.*, 2007]. There is *medium confidence* that many of the negative consequences for coral reefs, mangroves and seagrass meadows are *likely* to have negative consequences for dependent coastal fisheries (through destruction of habitat) and tourism industries [*Bell et al.*, 2011; *Pratchett et al.*, 2011a; *Pratchett et al.*, 2011b]Table 29.3, WGII Ch29, *medium confidence*).

Changes to sea temperature also lead to changes in the distribution of key pelagic fisheries such as Skipjack Tuna (*Katsuwonus pelamis*), Yellowfin Tuna (*Thunnus albacares*), Big-eye Tuna (*T. obesus*) and South Pacific Albacore Tuna (*T. alalunga*), which make up the majority of key fisheries in the Pacific Ocean. Changes in the distribution and recruitment in response to changes in sea temperature as result of ENSO demonstrate a close association of pelagic fish stocks and water temperature. As a result, populations of key pelagic fishery species are projected to move many hundreds of km east from where they are today [*Lehodey et al.*, 2008; *Lehodey et al.*, 2010; *Lehodey et al.*, 2011], *high confidence*) with implications for income, industry and food security across multiple Pacific Island nations [*Bell et al.*, 2011; *Cheung et al.*, 2010; *McIlgorm et al.*, 2010], 7.4.2.1, Table 29.2:, Table 29.3, *high confidence*). Our understanding of the impacts of reduced oxygen on pelagic fish populations is uncertain although there is a *high agreement* on the potential physiological impacts (6.3.3). Those species that are intolerant to hypoxia, such as tuna, will have their depth range compressed, which may reduce their vulnerability to being caught (positively) and overall fisheries habitat and productivity (negatively, [*Stramma et al.*, 2010; *Stramma et al.*, 2011]; *high confidence*). Despite the importance of these potential changes, our understanding of the full range of impacts is limited at this point.

The shift in habitat for top predators in the Pacific was examined by *Hazen et al.* [2012] who used tracking data from 23 marine species and associated environmental variables to predict increases and decreases of up to 35% in core habitat for many species within the Pacific. Potential habitat contracted for Blue Whales, Salmon Sharks, Loggerhead Turtles, Blue Shark and Make Sharks, while potential habitat expanded for Sooty Shearwaters, Black Footed Albatross, Leatherback Turtles, White Sharks, Elephant Seals, Albacore, Bluefin and Yellowfin Tuna [*Hazen et al.*, 2012]. These directional changes represents an opportunity to participate and apply anticipate change and to apply large-scale management strategies to preserve these valuable species.

30.5.7. Deep Sea (>1000 m)

Assessments of the influence of climate change on the deep sea are challenging due to difficulty of access and scarcity of long-term, comprehensive observations [*Smith et al.*, 2009]. The size of this habitat is also vast, covering well over 60% of the earth's surface and stretching from top of the mid-oceanic ridges to bottom of deep ocean trenches. The fossil record in marine sediments reveals that the deep ocean environment has undergone large changes due to climate change in the past [*Knoll and Fischer*, 2011]. The paleo-skeletal record shows it is the rate, not simply magnitude, of climate change (temperature, oxygen and carbon dioxide) that is critical to marine life. The rate of change today in key parameters *very likely* exceeds that of other major events in Earth history. Two primary

time scales are of interest. The first is the slow rate (century scale) of ocean circulation and mixing and consequently the slow rate at which deep-sea ecosystems experience physical climate change. The second is the rapid rate at which organic matter enters the deep ocean from primary productivity generated at surface of the ocean, which represents a critical food supply to deep-sea animals [*Smith et al*., 2009; *Smith et al*., 2008]. Since the upper ocean is currently experiencing warming, increased stratification, and changing productivity (WG1 3.2.2) there is evidence (*medium confidence*) of impacts on quite different time scales between the slow warming at depth and the more rapidly changing (decreasing/increasing) food supply to deep-sea animals that falls from above.

30.5.7.1. Observed Changes and Potential Impacts

The greatest rate of change of temperature is occurring in the upper 700 m of the ocean (WG 1 3.2, *very high confidence*), although smaller yet significant changes are occurring at depth. The deep-sea environment is typically cold (~ 1-4°C) although abyssal temperatures in SES can be higher (e.g. Mediterranean ~12°C, Red Sea ~22°C). In the latter case, deep-sea populations can thrive in these environments as well, illustrating the variety of temperature conditions that differing species of abyssal life have adapted to. Individual species, however, are typically constrained within a narrow thermal and oxygen-demand window of tolerance [*Portner*, 2010] and therefore it is *very likely* that major shifts in the distribution of deep-sea species will occur. Warming over multiple decades has been observed below 700 m [*Levitus et al*., 2005; *Levitus et al*., 2009], with warming being minimal at mid-range depths (2000-3000 m), and increasing towards the sea floor in some sub-regions (e.g. Southern Ocean) (WGI Ch3). For the deep Atlantic Ocean, the mean age of deep-waters (mean time since last exposure to the atmosphere) is ~250 years; the oldest deep waters of the Pacific Ocean are >1,000 years old. The patterns of ocean circulation are clearly revealed by the penetration of tracers and the fossil-fuel CO_2 signal itself into the abyss [*Sabine et al*., 2004]; the time scale for full equilibration of deep ocean waters and their ecosystems with modern warming and CO_2 levels is many centuries [*Wunsch and Heimbach*, 2008].

Temperature accounts for ~86% of the variance in the export of organic matter to the deep sea (*moderate confidence*)[*Laws et al*., 2000]. Consequently, upper-ocean warming will (*medium confidence*) reduce the export of organic matter to the deep sea, impacting the distribution and abundance of deep sea organisms and associated food webs and ecosystem processes [*Smith Jr and Kaufmann*, 1999; *Smith et al*., 2008]. Most organic matter entering the deep ocean is recycled by microbial systems at relatively shallow depths [*Buesseler et al*., 2007], at rates which are temperature dependent. Upper ocean warming will increase the rate of sub-surface decomposition of organic matter (*high confidence)*, thus intensifying the intermediate depth oxygen-minimum zones [*Stramma et al*., 2008; *Stramma et al*., 2010] and reducing food supply to the abyssal ocean.

Quantifying these effects is difficult since complex ecosystem responses are likely and information is sparse. Food supply to depths below the euphotic zone is about 20% of net primary productivity. The vast majority of this is recycled by microbes at depths shallower than 1,000. The net result is that with warming of the upper ocean food supply to the deep sea will decrease. If the temperature dependence assumed by models such as that of *Laws et al*. [2000] is correct, then warming of the ocean basins by 2.5ºC (Table 30-4) would reduce the fraction exported to the deep sea by about 5%. Warming of intermediate waters will increase respiration at mid-water depths. The temperature dependence of mid-water respiration rates is not well known, but is *likely* (*moderate confidence*) to be similar to microbial rates in environments such as soils and sediments with a Q_{10} of about 2.5 [*Thamdrup et al*., 1998]. This suggests that a reduction in food supply to the deep sea from 20% to 16% of global net primary production (7.2 Gt C yr-1) could occur (medium confidence) under a 2.5ºC warming of the upper ocean. The impacts of climate change on other deep sea communities such as hydrothermal vent ecosystems are unknown [*Van Dover*, 2012].

The oxygen concentrations of the deep areas of the Ocean are decreasing [*Helm et al*., 2011b; *Karstensen et al*., 2008; *Keeling et al*., 2010; *Stramma et al*., 2008]. The largest signals occur at intermediate water depths shallower than 1,000 m [*Nakanowatari et al*., 2007; *Whitney et al*., 2007], but some waters >1,000 m depth are also experiencing decline [*Falkowski et al*., 2011; *Jenkins*, 2008]. The quantity of dissolved oxygen will be reduced with ocean warming due to direct effects on solubility (*high confidence*) with these effects being widely distributed [Shaffer et al. 2009]. It is also *virtually certain* that metabolic rates of all animals and microbial respiration rates will

increase with temperature [*Brown et al.*, 2004]. Thus, increased microbial activity and reduced oxygen solubility at higher temperatures will have additive impacts on the decline of oxygen (*high confidence*). Deep-sea waters have relatively high pO_2 due to the thermodynamic effects of pressure, and also from low microbial consumption rates associated with the small supply of organic matter. Oxygen concentrations will be less well oxygenated at mid depths as compared to deepest sites within the ocean which experience the highest pO_2 on Earth due to the very high pressures *(very high confidence)*.

Increasing deep water under-saturation for calcite and aragonite will impact carbonate shell formation and dissolution as has happened many times in Earth's past ([*Zeebe and Ridgwell*, 2011](*high confidence)*. Some cold-water deep-sea corals (reported down to 3,500m) already exist in waters under-saturated with respect to aragonite [*Lundsten et al.*, 2009]. These corals will face reduced calcification and growth rates from decreased food supply and altered seawater carbonate concentrations and pH (*high confidence*) [*Guinotte et al.*, 2006].

30.5.7.2. Key Risks and Vulnerabilities

Rising atmospheric CO_2 poses a risk to deep-water communities through increasing temperature, and decreasing oxygen, carbonate chemistry, and pH (*high confidence*). The resulting changes to the flow of organic carbon to some parts of the deep ocean (e.g. STGs) are very likely to impact deep-ocean ecosystems (*medium confidence*). Changes in temperature and the supply of organic carbon from surface waters are likely to interact and increase the risk of impacts to deep-ocean ecosystems. Changes in temperature, oxygen, and CO_2 may also increase the vulnerability of the daily vertical migration of mid-water populations. As with the deep sea generally, there is a need to fill in the substantial gaps that exist in our knowledge and understanding of the world's largest habitat and its responses to rapid anthropogenic climate change.

30.5.8. Detection and Attribution of Climate Change Impacts with Confidence Levels

The preceding analysis has identified a wide range of physical, chemical and ecological components that have changes over the decades and the last century. In some cases, confidence in both the detection and attribution of the changes to climate change is high. In other cases, confidence varies in both elements leading to lower levels of certainty surrounding whether or not specific changes can be attributed to anthropogenic climate change. Figure 30-14 summarises a number of examples from the Ocean as a region together with the degree of confidence in the detection and attribution steps. Physical and chemical changes such as ocean warming and acidification, confidence is extremely high that changes are being detected and they are due to climate change. Several ecological responses also fall in the upper corner such as changes in the distribution of marine plants and animals, and with respect to climate change driving more intense and frequent mass coral bleaching and mortality events. Other areas are of lower confidence, either because the detection of changes has been difficult (e.g. field evidence of declining calcification) yet models are in strong agreement that there should be a relationship, or where confidence is high when it comes to detection yet our models are in conflict (e.g. wind-driven upwelling). This analysis is further explored in Ch18.

[INSERT FIGURE 30-14 HERE
Figure 30-14: Expert assessment of degree of confidence in detection and attribution across sub-regions and processes (based on evidence explored throughout Chapter 30).]

30.6. Sectoral Impacts, Adaptation, and Mitigation Responses

The Ocean supports numerous sectors, many of which have been discussed in previous regional chapters of this assessment. Discussion here is restricted to economic, environmental and social sectors that have a direct relevance to the Ocean such as fisheries, tourism, shipping, oil and gas, maritime security, and renewable energy, as well as sectors that have significant non-market values such as ecosystem goods and services. The impacts of climate change on ocean sectors will be mediated through simultaneous changes in multiple environmental and ecological

variables (Figure 30-15). Many climate change impacts can be avoided, reduced or delayed by mitigation, yet both short-term and longer-term adaptation are necessary to address impacts that result from warming, even under the lowest stabilization scenarios assessed.

[INSERT FIGURE 30-15 HERE
Figure 30-15: A. Summary of regional impacts and opportunities associated with climate change on the world's ocean region. B. Example of changes occurring within fisheries across the Ocean.]

Sectoral approaches dominate resource management in the Ocean (i.e. shipping tends to be treated in isolation from fishing within an area), yet cumulative and interactive effects of individual stressors are known to be ubiquitous and substantial [*Crain et al.*, 2008]. Climate change consistently emerges as a dominant stressor in regional to global-scale assessments [*Halpern and Floeter*, 2008; *Halpern et al.*, 2010; *Halpern et al.*, 2009a; *Halpern et al.*, 2009b; *Halpern et al.*, 2009c; *Selkoe et al.*, 2009], but land-based pollution, commercial fishing, invasive species, and commercial activities such as shipping all rank high in many places around the world, especially coastal waters [*Halpern et al.*, 2010; *Halpern et al.*, 2009a]. Such cumulative effects pose challenges to managing for the full suite of stressors to marine systems, but also present opportunities where mitigating a few key stressors can potentially dramatically improve overall ecosystem condition (e.g.[*Halpern et al.*, 2010]). The latter has often been seen as a potential strategy for reducing climate impacts on marine ecosystems by increasing ecosystem resilience, thus buying time while the core issue of reducing greenhouse gas emissions is tackled [*Hughes et al.*, 2003].

30.6.1. Natural Ecosystem Services

Human welfare is highly dependent on ecosystem services provided by the Ocean. Many of these services are provided from coastal and shelf areas, and are consequently addressed in other chapters. Oceans contribute provisioning (e.g. food, raw materials; see 30.6.3.1), regulating (e.g. gas exchange, nutrient recycling, carbon storage, climate regulation, water flux), supporting (e.g. habitat, genetic diversity) and cultural (e.g. recreational, spiritual) services [Millennium Ecosystem Assessment, 2005]. The accumulating evidence fundamental ecosystem services within the ocean are shifting rapidly should be of major concern, especially with respect to the ability of regulating and supporting ecosystem services to underpin current and future human population demands [Rockstrom et al., 2009].

Supporting, regulating and cultural ecosystem services tend to transcend the immediate demands placed on provisioning services, and are difficult to value in formal economic terms due to their complexity, problems such as double counting and the value of non-market goods and services arising from marine ecosystems generally [*Beaudoin and Pendleton*, 2012; *Fu et al.*, 2011]. Pursuing a formal valuation of ecological services from the Ocean, however, has the potential to provide adaptation options for stimulating more effective governance, regulation and ocean policy while at the same time potentially improving the management of these often vulnerable services through the development of market mechanisms and incentives [*Beaudoin and Pendleton*, 2012]. Other strategies have involved placing larger areas of the ocean under management in order to protect and maintain the health and function of ocean ecosystems [*Agardy et al.*, 2011; *Edgar*, 2011; *Game et al.*, 2009]. The planetary scale changes that are currently occurring, however, require concerted international action on the fundamental drivers of change (anthropogenic greenhouse gas emissions) otherwise many of the proposed adaptation options will fail.

Adaptation strategies that reduce the impact of climate change on ocean ecosystems and their services include managing local factors not related to climate change. Overfishing, pollution, deteriorating water quality, and habitat loss often interact with climate change to produce greater effects than if each were to occur on their own (i.e. producing synergistic interactions). Coral reefs, for example, will recover three times faster from mass coral bleaching and mortality if healthy populations of herbivorous fish are maintained [*Hughes et al.*, 2003], indicating that controlling overfishing will help maintain coral-dominated reef systems while the international community reduces the emissions of greenhouse gases and stabilises global temperature. In a similar way, 'Blue carbon' provides opportunities for mitigation and by extension to other ecosystems services, adaptation. Blue carbon is defined as the organic carbon trapped and stored within marine ecosystems such as phytoplankton, mangrove, seagrass and salt marsh ecosystems. Destroying and removing these ecosystems exposes organic carbon to the

atmosphere, leading to the oxidation and release into the atmosphere. Combining data on global area, land-use conversion rates and near surface carbon stocks for marshes, mangroves and seagrass meadows, *Pendleton et al.* [2012] revealed that the destruction of these three ecosystems was equivalent to 3-19% of the emissions generated by deforestation globally with economic damages estimated to be US$6-42 billion annually. In driving the preservation of coastal ecosystems, strategies involving Blue Carbon and other strategies can also enhance adaptation against sea level rise and storm damage, as well as maintaining habitat for fisheries species. The current understanding of Blue Carbon is uncertain given limited knowledge, methodologies and policies for measuring and implementing blue carbon strategies.

30.6.2. Economic Sectors

30.6.2.1. Fisheries

Capture fisheries and aquaculture supplied the world with 148 million tonnes of fish and shellfish in 2010. This production was valued at US$217.5 billion, and supplied 18.8 kg of protein-rich food per person in 2011 [*FAO*, 2012]. The world's oceans provided 64% of the total world fisheries in 2011. Production from marine aquaculture increased from 16 million tonnes in 2006 to 18 million tonnes in 2010 whereas marine capture fisheries declined over the same period from 80 to 77 million tonnes per year [*FAO*, 2012]. The significance of marine capture fisheries is also illustrated powerfully by the number of people engaged in small-scale marine fisheries in developing countries. These small-scale fisheries account for 28 million of the ~80 million tonnes of fish caught from the ocean, and provide jobs for more than 47 million people – about 12.5 million fishers and another 34.5 million people engaged in post-harvest activities [*Mills et al.*, 2011].

The stagnation of marine capture fisheries production is attributed to full exploitation of 60% of the world's fisheries, and overexploitation of another 30% of fisheries [FAO, 2012]. The main problems with industrial fisheries include illegal, unreported and unregulated fishing; ineffective implementation of monitoring, control and surveillance and overcapacity in fishing fleets [*World Bank/FAO,* 2008; *FAO*, 2012].]. Such problems are being progressively addressed in several developed and developing countries [*Hilborn;* 2007; *Worm et al.,* 2009][*Pitcher et al.*, 2009], where investments have been made in stock assessment, strong management and application of the FAO Code of Conduct for Responsible Fisheries and the FAO Ecosystem Approach to Fisheries Management.

A different governance approach is needed in most cases for small-scale fisheries, which are often characterised by large numbers of politically weak fishers operating from decentralized localities, poor governance and insufficient data to monitor catches effectively [*Kurien and Willmann*, 2009; *Cochrane et al.* 2011; *Pomeroy and Andrew*, 2011]. For these fisheries, management that aims to avoid further depletion of overfished stocks is likely to be more appropriate in the short term than management aimed at maximising sustainable production. These aims can be achieved through (1) 'primary fisheries management', which uses simple harvest controls (e.g. size limits, closed seasons and areas, gear restrictions and protection of spawning aggregations) to avoid irreversible damage to stocks in the face of uncertainty [*Cochrane et al.* 2011], and (2) investing in the social capital and institutions needed for communities and governments to manage small-scale marine fisheries [*Hall et al.*, 2013; *Pomeroy and Andrew*, 2011].

Changes to sea temperature and other factors as a result of anthropogenic climate change is generating new challenges for fisheries as coastal and oceanic environments experience the loss of habitat, the spread of disease and invading species, and changes in the availability of food. There is *medium evidence* and *robust agreement* that these changes will change both the nature of fisheries and their ability to provide food and protein for hundreds of millions of people. These risks for ecosystems and fisheries vary from region to region (Figure 30-15, Chapter 7), with potential increases in fisheries production over the short term at high latitudes, and potential decreases at lower latitudes.

The challenges of optimising the economic and social benefits of both industrial and small-scale marine fisheries, which already include strategies to adapt to climatic variability [*Salinger et al.*, 2013], are now made more complex by climate change [*Cochrane et al.*, 2009; *Brander*, 2010; 2013]. Nevertheless, vulnerability assessments have

identified practical adaptations to assist enterprises, communities and households to reduce the risks from climate change and capitalise on the opportunities. The diversity of these adaptation options, and the policies needed to support them, are illustrated by the following examples.

30.6.2.1.1. Tropical fisheries based on top predators

Fisheries for Skipjack, Yellowfin, Big-eye and Albacore Tuna provide substantial economic and social benefits to the people of Small Island Developing States (SIDS). For example, tuna fishing license fees contribute substantially (up to 40%) to the government revenue of several Pacific Island nations [*Gillett*, 2009; *Bell et al.,* 2013b]. Tuna fishing and processing operations also contribute up to 25% of gross domestic product in some of these nations and employ over 12,000 people [*Gillett*, 2009; *Bell et al*., 2013b]. Considerable economic benefits are also derived from fisheries for top pelagic predators in the Indian and Atlantic oceans [*Bell et al*., 2013b; *FAO*, 2012]. Increasing sea temperatures and changing patterns of upwelling are projected to cause shifts in the distribution and abundance of pelagic top predator fish stocks (30.5.4, 30.5.5), with potential to create 'winners' and 'losers' among island economies as catches of the trans-boundary tuna stocks change within their exclusive economic zones [*Bell et al*., 2013b].

A number of practical adaptation options and supporting policies to minimize the risks and maximize the opportunities associated with the projected changes in distribution of the abundant Skipjack Tuna in the tropical Pacific have been identified [*Bell et al*., 2011; *Bell et al*., 2013a](Table 30-5). These adaptation and policy options include: (1) full implementation of the regional 'vessel day scheme' designed to distribute the economic benefits from the resource in the face of climatic variability, and other schemes to control fishing effort in subtropical areas; (2) strategies for diversifying the supply of fish for canneries in the west of the region as tuna move progressively east; (3) continued effective fisheries management of all tuna species; (4) energy efficiency programs to assist domestic fleets to cope with increasing fuel costs and the possible need to fish further from port; (5) the eventual restructuring of regional fisheries management organizations to help coordinate management measures across the entire tropical Pacific; and (6) provision of operational-level catch and effort data from all industrial fishing operations to improve models for projecting redistribution of tuna stocks during climate change [*Salinger et al.* 2013].

[INSERT TABLE 30-5 HERE
Table 30-5: Examples of priority adaptation options and supporting policies to assist Pacific Island countries and territories to minimize the threats of climate change to the socio-economic benefits derived from fisheries and aquaculture, and to maximize the opportunities. These measures are classified as 'win-win' (W-W) adaptations, which address other drivers of the sector in the short term and climate change in the long term, or 'lose-win' (L-W) adaptations, where benefits exceed costs in the short term but accrue under longer-term climate change (Modified from *Bell et al.* 2013a).]

Other adaptation options and policies have been recommended to increase access to tuna caught by industrial fleets for people in rapidly-growing urban centers. These options center on amending licensing conditions to ensure that sufficient high-quality tuna and by-catch are landed locally to provide the large quantities of fish needed for food security in Pacific Island nations [*Bell et al*., 2011; *Bell et al.,* 2013a]. Similar adaptation options and policy responses are expected to be relevant to the challenges faced by tuna fisheries in the tropical and subtropical Indian and Atlantic oceans.

30.6.2.1.2. Coral reef fisheries

Coral reefs provide habitats for a wide range of harvested fish and invertebrate species. Despite their importance to many developing countries, these ecosystems are under serious pressure from human activities that include deteriorating coastal water quality, sedimentation, ocean warming and acidification (30.3, 30.5, 7.2.13, Box CC-CR). These pressures are translating into a steady decline in live coral cover which is very likely to continue over the coming decades, even where integrated coastal zone management is practiced well. For example, coral losses around

Pacific Islands are projected to be as high as 75% by 2050 [*Bell et al.*, 2013a]. Even under the most optimistic projections (a 50% loss of coral by 2050), changes to state of coral reefs (Box CC-CR; Figure 30-12) are *very likely* to reduce the availability of associated fish and invertebrates that support many of the coastal fisheries in the tropics (*high confidence*). In the Pacific, the productivity of coral reef fisheries has been projected to decrease by at least 20% by 2050, which is also likely to occur in other coral reef areas globally given the similar and growing amounts of stress in these other regions (Table 30-2, 30.4). Other economic activities based on coral reef species, e.g. pearl farming, may also be impacted by changing sea temperature and ocean chemistry. Survival and growth of wild spat used to supply the pearl oysters for farms in Polynesia could decline as shells are weakened by lower aragonite concentrations [*Bell et al.*, 2011]. Reduced availability of aragonite may also affect pearl quality [*Welladsen et al.*, 2010].

Adaptation options and policies for building the resilience of coral reef fisheries to climate change suggested for the tropical Pacific include: (1) strengthening the management of catchment vegetation to improve water quality along coastlines: (2) reducing direct damage to coral reefs; (3) maintaining connectivity of coral reefs with mangrove and seagrass habitats; (4) sustaining and diversifying the catch of coral reef fish to maintain their replenishment potential; and (5) transferring fishing effort from coral reefs to near-shore Skipjack and Yellowfin Tuna resources by installing anchored fish aggregating devices close to shore [*Bell et al.*, 2011, 2013a] (Table 30-5). These adaptation options and policies represent a 'no regrets' strategy in that they provide benefits for coral reef fisheries and fishers irrespective of the impacts of climate change.

30.6.2.1.3. Northern Hemisphere HLSBS fisheries

The high latitude fisheries in the northern hemisphere span from around 30/35 ºN to 60ºN in the North Pacific and 80 ºN in the North Atlantic covering a wide range of thermal habitats from subtropical/temperate species to boreal/arctic species. The characteristics of these HLSBS environments as well as warming trends are outlined in 30.5.1 and Table 30-4. As a result of 30-years increase in temperature (Table 30-2; [*Belkin*, 2009; *Sherman et al.*, 2009], there has been a boost in fish stocks in high latitude fisheries in the northern hemisphere, particularly in the Norwegian spring-spawning herring which recovered from nearly extinction caused by a combination overfishing and cooler climate during the 1960s [*Toresen and Østvedt*, 2000]. The major part of high-latitude fish stocks, pelagic as well as demersal, are boreal species located north of 50ºN. Climate change is projected to increase high latitude plankton production and displace zooplankton and fish species poleward. As a combined result of these changes future, the abundance of fish (particularly boreal species) may increase in the northernmost part of the high latitude region [*Cheung et al.*, 2011] although moderately in some regions.

Both demersal and pelagic fish have shown considerable variation in abundance and distribution with climate fluctuation and climate change, but the changes in distribution and migration of the pelagic fishes are considerably larger. These changes have increased tensions leading to what many consider the first climate change related conflicts between fishing nations (30.6.5), which has emphasized the importance of developing international collaboration and frameworks for decision making (30.6.7, 15.4.3.3). The Atlantic mackerel has been a shared stock between EU and Norway due to its newer historical distribution. The recent advancement of the Atlantic mackerel into the Icelandic EEZ during summer has resulted in fishing from Iceland outside internationally agreed fishing quotas. Earlier records of mackerel during first half of 20th and second half of 19th century show, however, that mackerel has been present in Icelandic waters also in the earlier warming periods [*Astthorsson et al.*, 2012]. In the Barents Sea, the Northeast Arctic cod reached record-high abundance during 2012 and also reached its northernmost distribution, 82 ºN, ever recorded. A further northward migration is impossible since this would be into the deep-sea Polar Basin beyond the habitat of shelf species. A further advancement eastwards on the Siberian shelf is, however, possible. The Northeast Arctic cod is shared exclusively by Norway and Russia. Up to now there has been a good agreement between those two nations on the management of the stock.

The HLSB fisheries make up a large-scale high-tech industry with large investments in highly mobile fishing vessels, equipment and land-based industries. Knowledge on how climate fluctuations and change impacts growth, recruitment and distributions in fish stocks is presently not utilized in management strategies for fisheries. These strategies are vital for fisheries that hope to cope with the challenges of a changing ocean environment, and are

centrally important for any attempt to develop ecosystem-based management and sustainable fisheries under climate change. The large pelagic stocks with their climate-dependent migration pattern are shared among several nations. Developing equitable sharing of fish quotas is a needed adaption for a sustainable fishery. Factors presently taken into account in determining the shares of quotas are the historical fishery, bilateral exchanges of quotas for various species, and occupation time of the stocks in the various EEZs. Some of the problems and options are discussed further in 30.6.7.

30.6.2.2. Tourism

Tourism recreation represents one of the world's largest industries, accounting for 9% (> US$6 trillion) of global GDP and employing over 255 million people. A large proportion of tourism occurs within coastal and marine settings. It is expected to grow by an average of 4% annually and reach 10% of global GDP within the next 10 years [*WTTC*, 2012]. As with all tourism, that which is associated with the ocean is heavily influenced by climate change, global economic and socio-political conditions, and their interactions [*Scott et al.*, 2012a]. Climate change by impacting ecosystems negatively (e.g. coral reefs) is reducing destination appeal, increasing operating costs and bringing increased uncertainty into a highly sensitive business environment [*Scott et al.*, 2012a].

Several facets of the influence of climate change on the Ocean directly impact tourism. Sea level rise through its influence on coastal erosion and submergence, salinization of water supplies, and changes to storm surge increase the vulnerability of coastal tourism infrastructure, tourist safety and iconic ecosystems (*high confidence*, 30.3.1.2, 5.3.2.4, [*IPCC*, 2012],Table SPM.1). Approximately 29% resorts in the Caribbean are within 1 m of the high tide mark, with 60% being at risk of beach erosion from rapid sea level rise [*Scott et al.*, 2012b]. Extreme events such as violent storms, long periods of drought, and/or extreme precipitation events can decrease the attractiveness and reputation of tourist destinations (5.3.2.4, [*IPCC*, 2012]).

Increasing sea temperatures (30.3.1.1) through their influence on the movement of organisms and the health of ecosystems such as coral reefs can change the attractiveness of locations and the opportunities for tourism (Box CC-CR, [*UNWTO and UNEP*, 2008]. Mass coral bleaching and mortality (triggered by elevated sea temperatures) also has the potential to decrease the appeal of diving related tourism, although the awareness by tourists (e.g. < 50% of tourists were concerned about coral bleaching during 1998) and expected economic impacts has been found to be uncertain [*Scott et al.*, 2012a]. Some studies, however, have picked up reduced tourists satisfaction and the identification of 'dead coral' being one of the reasons for disappointment at the end of the holiday [*Westmacott et al.*, 2001]. Other forms of nature-based tourism are also vulnerable to climate change. For example, the whale watching businesses ($1 billion worldwide in 2001) will be affected by climate change impacts on whale distributions, abundance, and species composition [*Lambert et al.*, 2010]. Anticipated changes include a decline of deep-water whale species diversity in the tropics and increases at higher latitudes [*Whitehead et al.*, 2008].

Tourists respond to changes in factors such as weather and opportunity by expressing different preferences. For example, preferred conditions and hence tourism are projected to shift towards higher latitudes with climate change, or from summer to cooler seasons [*Amelung et al.*, 2007]. Options for adaptation by the marine tourism sector include: (1) identifying and responding to inundation risks with current infrastructure, and planning for projected sea level rise when building new tourism infrastructure (5.6; Scott et al. 2012); (2) promote shoreline stability and natural barriers by preserving ecosystems such as mangroves, salt marsh and coral reefs (5.6, Scott 2012); (3) deploying forecasting and early warning systems in order to anticipate challenges to the structure, appeal, and visitors [*IPCC*, 2012; *Strong et al.*, 2011]; (4) preparation of risk management and disaster preparation plans in order to respond to extreme events; (5) reducing the impact of other stressors on ecosystems and build resilience in iconic tourism features such as coral reefs and mangroves, and (6) educating tourists to improve understanding the impacts of climate change over those stemming from local stresses [*Scott et al.*, 2012a; *Scott et al.*, 2012b].

30.6.2.3. Shipping

International shipping accounts for > 80% of world trade by volume [*UNCTAD*, 2009a; b] and ~3% of global CO_2 emissions from fuel combustion (IMO, 2009), although emissions are expected to increase 2-3 fold by 2050 [*UNCTAD*, 2009b]. However, increased shipping, and the concurrent increase economic activity, will increase the emission of black carbon. The black carbon will in turn increase warming and ice-melt that further increases economic activity and shipping [*Lack and Corbett*, 2012]. Changing shipping routes [*Borgerson*, 2008], shifts in grain production and global markets, as well as new fuel and weather-monitoring technology, may alter these emission patterns. Higher temperatures and extreme weather events, intensified by climate change, may interrupt ports and transport routes more frequently, damage infrastructure, and introduce additional dangers to ship, crew and the environment [*UNCTAD*, 2009a; b].

Climate change may benefit maritime transport by reducing Arctic sea ice, shortening sailing distances between key ports [*Borgerson*, 2008] and thus decreasing total GHG emissions from ships. Currently, reliability of this route limits its use [*Schøyen and Bråthen*, 2011], and the potential full operation of the Northwest Passage and Northern Sea Route would require a transit management regime, regulation (e.g. navigation, environmental, safety and security) and a clear legal framework to address potential territorial claims that may arise, with a number of countries having direct interests in the Arctic.

30.6.2.4. Offshore Energy and Mineral Resource Extraction and Supply

The marine oil and gas industry is a key driver of energy and climate scenarios due to its role in supplying the liquid fossil fuels that are key contributors to greenhouse gas emissions. The industry also faces potential impacts from climate change on its ocean-based activities. Over 100 oil and gas platforms were destroyed in the Gulf of Mexico by the unusually strong hurricanes, Katrina and Rita. Other impacts to oil pipelines and production facilities ultimately reduced US refining capacity by 20% (AR5 SREX). The increasing demand for oil and gas has pushed operations to waters 2,000 m deep or more, far beyond continental shelves. The very large-scale moored developments involved are exposed to greater hazards and higher risks, most of which are not well understood by existing climate/weather projections. Although there is a strong trend towards seafloor well completions with a complex of wells, manifolds and pipes that are not exposed to surface forcing, these systems face different hazards from instability and bottom scouring from deep sea currents of the unconsolidated sediments [*Randolph et al.*, 2010]. Impacts from warming oceans on sea floor stability are widely debated due largely to uncertainties about the effects of methane and methane hydrates [*Archer et al.*, 2009; *Geresi et al.*, 2009; *Sultan et al.*, 2004]. The principle threat to oil and gas extraction in maritime settings is the impact of extreme weather on oil and gas extracting infrastructure [*Kessler et al.*, 2011], and this threat is likely to increase given that future storm systems are expected to have greater energy [*Emanuel*, 2005; *Knutson et al.*, 2010; *Trenberth and Shea*, 2006]. Events such as Hurricane Katrina in 2005 have illustrated challenges likely to arise for this industry with projected increases in storm intensity [*Cashell et al.*, 2005; *Cruz and Krausmann*, 2008]. In this regard, early warning systems and preparation planning offer some potential to reduce the impact of extreme events [*IPCC*, 2012].

30.6.3. Health and Social Vulnerability

30.6.3.1. Disease

Changing patterns of disease, water and food security, human settlements, extreme climatic events, and population growth and migration are the major threats to public health related to climate change [*Costello et al.*, 2009]. Evidence of linkages between climate change, the Ocean and disease are *limited*, although there is *medium agreement* that climate change has and will influence the frequency and incidence of disease in corals, molluscs and a range of other invertebrates [*Bruno et al.*, 2007; *Harvell et al.*, 2002a]. The predominately negative impacts are likely to be more serious in low-income countries such as southeast Asia, southern and east Africa, and various sub-regions of South America [*Patz et al.*, 2005], countries which also have under-resourced health systems [*Costello et al.*, 2009]. Many of the influences are directly or indirectly related with basin-scale changes in the Ocean (e.g.

temperature, rainfall, plankton populations, ocean circulation; 11.2.5.1)[*McMichael et al.*, 2006], which include the spread of pathological diseases, seafood diseases, biological invasion and ballast-water discharge. Climate change impacts on the Ocean may influence the distribution of vector-borne diseases like Cholera, malaria and salmonella. The frequency of cholera outbreaks induced by *Vibrio cholerae* and other enteric pathogens show correlated multi-decadal fluctuations of ENSO and plankton blooms which may provide insight into how these disease may change with projected rates of ocean warming (11.2.5.1, [*Colwell*, 1996; *Myers and Patz*, 2009; *Pascual et al.*, 2000; *Patz et al.*, 2005; *Rodo et al.*, 2002]. The incidence of diseases such as ciguatera also shows a link to ENSO, with ciguatera becoming more prominent after periods of elevated sea temperature (e.g. ENSO). This indicates that ciguatera may become more frequent in a warmer climate [*Llewellyn*, 2010].

30.6.3.2. Security of Social Benefits and Fisheries

Climate change impacts on open-ocean fish populations are expected to affect the economics of fishing and the livelihood security of fishing nations because of changes in the price and value of catches, fishing costs, income to fishers and fishing companies, national labour markets, and industry re-organisation [*Sumaila et al.*, 2011]. A study of the potential vulnerabilities of national economies to the effects of climate change on fisheries concluded that Malawi, Guinea, Senegal, Peru, Columbia, Bangladesh, Cambodia, Pakistan, and Yemen are most vulnerable [*Allison et al.*, 2009]. In contrast, countries at high latitudes are likely to experience increases in their potential fisheries catch [*Cheung et al.*, 2010] although there are many uncertainties (*medium confidence*; 30.5.1). Fisheries provides 50 to 90% of dietary animal protein in rural areas of many Pacific countries, providing up to 20% of the GDP of some countries, with licence fees from foreign fishing fleets providing up to 40% of government revenue [*Bell et al.*, 2013a]. Tuna are very responsive to changing sea temperatures. In the western equatorial Pacific, nations with the greatest dependence on tuna fisheries (e.g. Kiribati, Nauru, Tuvalu, Tokelau) are likely to benefit as tuna distributions shift eastward as global and ocean temperature change [30.5.1]. Climate change on the other hand will decrease food security through impacts on fisheries associated with coral reefs and mangroves (estimated loss of 20% by 2050)[*Bell et al.*, 2013a].

30.6.4. Ocean-Based Mitigation

30.6.4.1. Deep Sea Carbon Sequestration

The economic impact of deliberate CO_2 sequestration beneath the sea floor has earlier been reviewed [*Metz et al.*, 2005]. Active CO_2 sequestration from co-produced CO_2 into sub-sea geologic formations is proceeding in the North Sea, and in the Santos Basin offshore Brazil. It is likely that these activities will increase as off shore oil and gas production increasingly produces fields with high CO_2 in the source gas and oil. Significant risks from the injection of high levels of CO_2 into deep ocean waters have been identified for deep sea organisms and ecosystems. These risks are similar to those discussed previously with respect to ocean acidification and are also likely to exacerbate declining oxygen levels and trophic networks in deep water areas [*Seibel and Walsh*, 2001].

There are significant issues within the decision frameworks regulating these activities. Dumping of any waste or other matter in the sea including the seabed and its subsoil is strictly prohibited under the 1996 London Protocol (LP) except for those few materials listed in Annex I. The direct injection of CO_2 into sub-surface geological formations is generally considered to fall under the exception to the definition of "dumping" under the LP as "placement for a purpose other than the mere disposal thereof." The LP was amended in 2006 to permit storage of CO_2 under the seabed. Specific Guidelines for Assessment of Carbon Dioxide Streams for Disposal into Sub-Seabed Geological Formations were adopted by the parties to the LP in 2007. The Guidelines take a precautionary approach to the process requiring Contracting Parties under whose jurisdiction or control such activities are conducted to issue a permit for the disposal subject to stringent conditions being fulfilled [*Rayfuse and Warner*, 2012].

30.6.4.2. Blue Carbon: Sequestering and Maintaining Carbon in Marine Ecosystems

Marine and coastal ecosystems such as mangroves and salt marsh store significant amounts of organic carbon, which has been referred to as 'Blue Carbon' by analogy to the ocean equivalent of sequestered carbon within forests and other terrestrial ecosystems ('green carbon'). The measurements and recognition of the carbon sequestration value of marine ecosystems is in its infancy but may assume importance given that significant amounts of organic carbon are stored within ocean ecosystems such as sea grass beds and mangroves (e.g. sequestered carbon per square metre of mangrove is many times that of terrestrial forests). Assuming that the global trade in carbon matures, the strategy to protect and expand the sequestration of carbon within marine ecosystems may play an essential role in reducing the current higher flux of greenhouse gases such as carbon dioxide and methane to the atmosphere [*Mcleod et al*., 2011].

30.6.5. Maritime Security and Related Operations

Climate change and its influence on the Ocean has become an area of increasing concern in terms of the maintenance of national security and the protection of countries' citizens. These concerns have arisen as Nation States increasingly engage in operations ranging from humanitarian assistance in climate change related disasters to territorial issues exacerbated by changing coastlines, human communities, resource access and new seaways [*Kaye*, 2012; *Rahman*, 2012]. In this regard, increasing sea levels along gently sloping coastlines can have the seemingly perverse outcome that the territorial limits to the maritime jurisdiction of the State might be open to question as the distance from national baselines to the outer limits of the exclusive economic zone increases beyond 200 nm over time [*Schofield and Arsana*, 2012].

Changes in coastal resources may also be coupled with decreasing food security to compound coastal poverty and lead, in some cases, to increased criminal activities such as piracy, illegal fishing, and people smuggling and arms and drug trafficking [*Kaye*, 2012]. While the linkages have not been clearly defined in all cases, it is very likely that changes in the Ocean as result of climate change are likely to increase pressure on resources aimed at maintaining maritime security and countering criminal activity, disaster relief operations, and freedom of navigation. The size and shape of maritime security infrastructure may also require rethinking as new challenges present themselves as a result of climate change [*Rahman*, 2012]. Opportunities may also arise from changes to international geography such as formation of new ice free seaways through the Arctic, which may benefit some countries in terms of maintaining maritime security and access. On the other hand, new features such as these within the Ocean may also lead to increasing international tensions as States perceive new vulnerabilities from these changes to geography.

Like commercial shipping (30.6.2.3), Naval operations in many countries emit significant greenhouse emissions (e.g. US Navy emits around 2% of the national greenhouse gas emissions), [*Mabus*, 2010]. As a result, there are a number of substantial programs within navies around the world to reduce their greenhouse footprint through improved engine efficiency, reducing fouling of vessels, increasing the use of biofuels and nuclear technology for power generation, and other strategies. The push to reduce emissions by using renewable fuel sources has the very substantial and synergistic benefit of increasing independence from foreign sources of energy [*Rahman*, 2012].

30.6.6. Multi-Sector Synthesis, and Key Risks and Vulnerabilities

The Ocean interacts with almost all aspects of life on Earth. As a result, it is not instructive to assess the impacts of climate change on the Ocean as a series of isolated influences and impacts on sub-regions and sectors. Many aspects of the Ocean's chemical and physical characteristics are changing rapidly, triggering high levels of change within the Ocean's ecosystems. Given the direct dependence of hundreds of millions of people on ocean ecosystem services, many of the aspects of the changes discussed as part of this chapter are *very likely* to increase the risk of poverty, decrease food security, and increase social and economic dysfunction along coastlines throughout the world. At the same time, industries such as fishing and shipping will face increasing uncertainty concerning conditions within the Ocean, which may offer opportunities (e.g. increased access to Arctic resources and sea lanes) as well as significant challenges (e.g. rapidly moving and changing fisheries resources). Impacts from climate change are also *very likely* to interact with stressors not related to anthropogenic climate change. These changes may

be antagonistic (i.e. dampening the influence of each change) or synergistic, amplifying the influence that each change would have had on its own. Our understanding of these interactions and how they will play out under rapid climate change is incomplete and uncertain. A better understanding of these interactions between climate change and other human related stressors is, consequentially, of central importance to the understanding of how we might adapt to the changes that are occurring and will occur within the Ocean.

Key risks and vulnerabilities due to climate change across ocean sectors are synthesised in Table 30-6 and range from changing ocean productivity, ecosystem regime shifts, migration of organisms and ecosystems, reorganisation of fisheries composition, increases in disease and invading organisms, and the impacts of sea level rise and changing weather patterns on coastal processes, industries, and people. In addition to these risks and vulnerabilities, are the important implications of sea level rise and the loss of summer sea ice for the definition of maritime zones and aspects of national security. Issues have been discussed in previous chapters and section of the present chapter. The ramifications of these changes are also outlined in Table 30-6 including impacts on human communities and industries associated with coastal and oceanic sectors from fishing and tourism to maritime security.

30.6.7. Global Frameworks for Decisionmaking

As outlined here, there is little credible doubt that the Ocean is changing fundamentally as a result of the activities of humans at local and global scales (*very high confidence*). We are only just beginning to understand both the scale and complexity of these changes, highlighting the critical importance of rapidly reducing the emissions of greenhouse gases while at the same time seeking strategies to reduce the impact of changing physical and chemical circumstances and ecosystems across the planet. In the latter case, strong frameworks for global decision-making are critical for devising and implementing adaptation and mitigation strategies for reducing the impacts of climate change (Table 30-6, column 6). These frameworks if they continue to be successful, represent opportunities for global cooperation and the development of international, regional and national policy responses to the challenges posed by the changing ocean [*Kenchington and Warner*, 2012; *Tsamenyi and Hanich*, 2012; *Warner and Schofield*, 2012].

[INSERT TABLE 30-6 HERE
Table 30-6: Key risks and vulnerabilities, as well as ramifications, adaptation options and frameworks for decision-making within a number of areas discussed in chapter 30. Symbols are as follows: T = sea temperature; UW = upwelling; OA = ocean acidification; NU = nutrient concentration; IC = ice cover; SS = storm strength, SLR = sea level rise (↑ = Increased; ↓ = decreased; italics = uncertain). Acronyms are: CBD (Convention on Biological Diversity), CTI (Coral Triangle Initiative), GEF (Global Environment Facility), IHO (International Hydrographic Organization), ILO (International Labour Organisation), IOM (International Organisation of Migration), ISPS (International Ship and Port Facility Security), LOSC (1982 Law of the Sea Convention), MARPOL (International Convention for the Prevention of Pollution From Ships), PACC (Pacific Adaptation to Climate Change Project), PEMSEA (Partnerships in Environmental Management for the Seas of East Asia), RFMO (Regional Fisheries Management Organisations), SPREP (Secretariat of the Pacific Regional Environment Programme), UNCLOS (United Nations Convention on the Law of the Sea), UNHCR (United Nations High Commissioner for Refugees), and WHO (World Health Organisation).]

The United Nations Convention on the Law of the Sea (LOSC) was a major outcome of the third UN Conference on the Law of the Sea (UNCLOS III). The European Union and 164 countries have joined in the Convention although it is uncertain as to the extent to which the Convention codifies international maritime law. LOSC replaced earlier frameworks that were built around the 'freedom of the seas' concept and which limited territorial rights to 3 nm off a coastline. It provides a comprehensive framework for the legitimate use of the ocean and its resources, including maritime zones, navigational rights, protection and preservation of the marine environment, fishing activities, marine scientific research, and mineral resource extraction from the deep seabed beyond national jurisdiction. The relationship between climate change and LOSC is not clear and depends on interpretation of the key elements within the UNFCCC and Kyoto Protocol [*Boyle*, 2012]. However, the LOSC provides mechanisms to help structure adaptation in response to challenges posed by climate change. In a similar way, there is a wide range of other policy

and legal frameworks that structure and enable responses to the outcomes of rapid anthropogenic climate change in the oceans.

Global frameworks for decision-making are increasingly significant in the case of ocean areas, most of which fall outside national boundaries [*Elferink*, 2012; *Warner*, 2012]. While around 50% of the Earth's surface is occupied by ocean resources that are outside the exclusive economic zones and continental shelves of the world's nations (high seas and deep seabed beyond national jurisdiction), there are increasing calls for more effective decision frameworks aimed at regulating fishing and other activities (e.g. bioprospecting) within these ocean 'commons'. These international frameworks will become increasingly valuable as nations respond to changing fisheries resources and the state of ocean ecosystems that stretch across national boundaries. One such example is the multilateral cooperation that was stimulated by President Yudhoyono of Indonesia in August 2007 that led to the Coral Triangle Initiative on Coral Reefs, Fisheries, and Food Security (CTI) which involves region-wide (involving 6.8 million km^2 including 132,000 km of coastline) cooperation between the governments of Indonesia, Philippines, Malaysia, Papua New Guinea, Solomon Islands and Timor Leste on reversing the decline in coastal ecosystems such as coral reefs [*Clifton*, 2009; *Hoegh-Guldberg et al.*, 2009; *Veron et al.*, 2009]. Given that coral reefs, mangroves and key resources such as tuna stocks stretch across national boundaries, partnerships such as that begun in Southeast Asia have the potential to provide key frameworks to address issues such as interaction between the over-exploitation of coastal fishing resources and the recovery of reefs from mass coral bleaching and mortality, and the implications of the movement of valuable fishery stocks beyond waters under national jurisdiction. The recently announced World Bank Global Partnership for Oceans announced (March 28, 2012) aims to create a global framework in which to engage governments, international organisations, civil and public sector interests in both understanding and finding solutions to key issues such as overfishing, pollution, and habitat destruction [*GPO*, 2012]. Similarly, the Areas Beyond National Jurisdiction (ABNJ, Global Environment Facility) Initiative has been established to promote the efficient, collaborative and sustainable management of fisheries resources and biodiversity conservation across the open ocean.

Global partnerships are also essential for providing support to many nations that often do not have the scientific or financial resources to solve the challenges that lie ahead [*Busby*, 2009; *Mertz et al.*, 2009]. In this regard, international networks and partnerships are particularly significant in terms of assisting nations in developing local adaptation solutions to their ocean resources. By sharing common experiences and strategies through global networks, nations have the chance to tap into a vast array of options with respect to responding to the impacts of climate change on global resources.

30.7. Concluding Remarks: Emerging Issues, Data Gaps, and Research Needs

Our understanding of the changes that are occurring within the Ocean as a result of climate change is still forming, as is our ability to predict how future changes will unfold. We have *very high confidence* that many aspects of the Ocean have and will change over the coming decades in response to increasing levels of greenhouse gases in the atmosphere. The high rates of change in key variables such as temperature, pH, carbonate chemistry and oxygen levels (30.3) are *virtually certain* to drive fundamental changes in ocean ecosystem structure and function.

30.7.1. Major Conclusions

There is *robust evidence, high agreement and high confidence* that the physical, chemical and biological characteristics of the Earth Ocean are changing rapidly as a result of human activities that have increased the atmospheric concentrations of greenhouse gases such as carbon dioxide (30.3-30.5). Many of these changes are large-scale, interconnected and have no analogue in thousands if not millions of years (*very high confidence*), and involve changes to the physiology and ecology of the ocean, as well as ecosystem processes such as primary productivity, marine calcification and gas exchange (*high confidence*). A comprehensive analysis of recent literature, for example, reveals that 84% of recent changes reported in the peer-reviewed scientific literature are consistent with changes expected under climate change (*high confidence*). Organisms are rapidly moving to higher latitudes with 'mobile' organisms (phytoplankton, zooplankton and fish) moving at the most rapid rates (Figure 30-

11B). At the same time, seasonal changes that drive key events in organism life cycles are advancing by 2-5 days.decade^{-1}. These changes approach and exceed in many cases those seen for terrestrial organisms and ecosystems. These fundamental changes suggest increasing asynchrony between organisms and their competitors and food, as well as the increasing likelihood of ecosystem assemblages that have no recent analogue.

Many ocean sub-regions (e.g. SES, EBUE, EUS, and STG) are experiencing changes in the extent to which upper ocean waters mix with deeper layers (*high confidence*, Box 30-1). These changes affect the supply of nutrients to the surface waters in the ocean, and have serious ramifications for the primary production of ocean ecosystems as well oxygen concentrations in many parts of the ocean (*high confidence*). In several of the world's semi-enclosed oceans (Baltic, Black, and Mediterranean Seas), ocean warming is leading to greater water column stability, which in turn has reduced mixing and primary productivity, leading to increased hypoxia at depth. In the EBUE sub-regions, however, increasing wind strength may be driving increased upwelling and consequently greater levels of primary productivity. In the latter case, however, higher levels of primary productivity and a subsequently higher flux of organic carbon into the deep ocean is resulting in reduced oxygen levels at depth. While we do not have a complete understanding of the changes to the oxygen content of the Ocean, changes in such a fundamental variable should be of great concern.

Our understanding of the influence of climate change on ocean systems has been challenged by variability which operates on a variety of spatial and temporal scales, and which can amplify the impacts of ocean warming and acidification. While most ocean regions have experienced significant changes a few regions have not. Short to long-term patterns of variability such as ENSO, PDO, AMO and NAO have complicated the interpretation of recent changes within the ocean. Despite this variability, there is an undeniable trend in ocean temperature and the response of key marine organisms and ecosystems.

The impacts and implications of the current changes in the ocean differ from sector to sector. In many parts of the world, fisheries such as those associated with tropical coastlines are expected to continue to decline. In other regions, the distribution and abundance of key fish stocks such as tuna will change over time impacting fishing industries in regions such as the Pacific and Indian oceans. Some regions may benefit while others may find it increasingly hard to obtain fish stocks as they move to new parts of the Ocean in response to changing sea temperatures. HLSBS are critically important to 36% of the world's fisheries. Fundamental changes as a result of ocean warming and acidification are occurring in the composition of plankton communities which are driving changes to the species composition and abundance of key fisheries (30.14 B). Ecological regime shifts have occurred with substantial impacts on key fisheries and dependent industries (Figure 20.15B), and are *very likely* to continue as warming continues. Climate change may lead to greater productivity in some fisheries through warmer temperatures, increased upwelling and reduced sea ice.

The economic well-being of sectors such as tourism is *very likely* to be strongly influenced by changes in regional weather patterns, rising sea levels, extreme events and the perception of risk. In addition to changing weather patterns, heat stress events such as mass coral bleaching and mortality are likely to increase as temperatures increase, bringing the future of the highly productive coastal ecosystems such as coral dominated coral reefs into question (Figure 30-12; Box CC-CR). The impacts of losing these highly productive and biologically diverse ecosystems is *likely* to change the tourist attractiveness of some regions as well is the livelihoods of millions of people that live in close association with the world's coastal areas.

There are numerous other consequences of climate change on the Ocean. In some cases, there may be advantages for international shipping from warmer and less ice-prone waters. On the other hand, sectors such as fishing and tourism will have to deal with a greater level of uncertainty and change, which has ramifications for human health and security, as well as current and future tourist opportunities. The changing conditions within the world oceans also represent challenges for industries intent on exploiting offshore energy and mineral resources. Increasing storm strength along with larger wave heights and wind velocities present increasing risks to these industry sectors. These changes in turn impact maritime security operation as well as the capacity of these elements to respond to environmental impacts associated with anthropogenic climate change.

30.7.2. Emerging Themes

The rapid changes that have been observed within the world oceans are an emerging theme within our understanding of climate change. Until recently, the impacts of climate change on ocean systems gained much less attention than those being observed within terrestrial areas of the planet. From the detection and attribution analysis undertaken here, however, it should be clear that fundamental changes in the physical, chemical and biological characteristics of the ocean are occurring rapidly and have implications for people everywhere.

The decrease in the concentration of oxygen within the ocean core and across many parts of the ocean is an emerging theme. The decrease in oxygen levels is a consequence of warming and stratification of the water column in some areas, changes in local weather patterns in others, and temperature influences on the ratio of rate of metabolism. The decline in oxygen concentrations in large parts of the ocean is of great concern given the potential impacts that spreading hypoxia could have for marine species and ecosystems. In this respect, projected increases in sea temperature under the current Business-As-Usual scenarios are likely to rapidly enhance water column stratification, increase bacterial metabolism and consequently drive major expansion in deep-ocean areas that are currently low in oxygen. Based on the impacts experienced so far from the 0.8°C increase in average global temperature, future changes are *very likely* to threaten many significant ocean ecosystems and fisheries. There are also fundamental implications for the ability of the ocean to provide planetary services such as maintaining the oxygen content of the atmosphere.

The changes in wind stress and ocean-atmosphere exchange is another emerging theme. Changes to water column mixing and ventilation have driven changes to productivity and other aspects such as oxygen concentration in a number of key areas of the world's oceans. While there is considerable discussion about how climate change will affect upwelling systems, there is concern that changes to the increase in land-ocean thermal gradient could result in stronger upwelling in some areas while others decrease (Figure 30-15). At present, there is little information and understanding about the response of these important areas of fisheries production in the rapidly warming world.

The impacts of ocean acidification on marine organisms and ecosystems (Box CC-OA) has emerged as a major concern especially given the robust evidence that the current chemistry of the ocean is outside where it has been for at least 1 million years. At current rates of increase atmospheric CO_2, the acidity of the ocean will surpass any seen over the last 40 million years [*Hoegh-Guldberg et al*., 2007; *Raven et al*., 2005]. The growing literature from the past five years has increasingly documented a major array of changes from the reduced calcification of coral reefs and pteropods, to impacts on animal reproduction, navigation, and olfaction. Ocean acidification is rapidly emerging as a very serious yet uncharted risk for all ocean sub-regions, although the earliest demonstrated impacts of changing pH and carbonate ion concentrations are being felt at higher latitudes due to the colder temperatures and hence greater flux of CO_2 entering these waters.

Understanding how the productivity of the Ocean is likely to change in a warmer and more acidic ocean is a significant emerging theme. Changes to the physical and chemical nature of ocean waters are also driving changes in the distribution and abundance of primary production (Figures 30.15, 30.15). These changes are beginning to have fundamental and large-scale influences on the distribution and abundance of primary productivity, which has implications for both fisheries as well as the flux of organic carbon into the deep ocean. While the current decreases in productivity that have been reported in the major ocean basins need to be considered in the light of natural climate variability such as ENSO and PDO, it is necessary that we develop a greater understanding of the potential implications of these rapid changes in ocean productivity. In this respect, a serious decrease in ocean services may be underway if ocean productivity continues to decrease over and above the background variability within the ocean climate systems. Extending these changes over the coming decades and century would be the basis for serious global concern. In combination with changes to sea temperature, changes to the distribution of ocean productivity has serious implications for the productive pelagic top predator fisheries that many countries depend on (30.5.2, 30.5.6; Figure 30-15). Understanding these current changes should be an urgent priority of the international community.

30.7.3. Research and Data Gaps

Despite the fact that Earth is dominated by the Ocean, we are only beginning to understand the physical, chemical and biological processes that underpin its ability to provide a range of ecosystem and planetary services. This situation has arisen because of the relative difficulty of accessing ocean environments, which has meant that comprehensive measurements of many parameters and ocean regions have only been available for the past 50 years or less. Given the importance of the world's oceans, it is an imperative that we increase our understanding of how climate change (including ocean acidification) are likely to influence the structure and function of ocean systems.

Understanding how wind stress will change in a warmer world is particularly important given the role of wind in water column mixing and nutrient availability, and hence primary and fisheries production. This gap in our understanding is crucial given the reliance of humans on the fisheries associated with upwelling regions throughout the world. Similarly, improving our understanding of the changes that are occurring within the STGs of the major ocean basins is especially significant given the strong background influence of short to long-term natural climate variability such as ENSO, PDO, and AMO. Understanding how the variability that key fisheries currently face interacts with ocean warming and acidification represents a significant knowledge and research gap.

The deep ocean below 1000 m is the most abundant habitat on the planet yet it is the region about which we know the least. In this respect, increasing our understanding of deep-ocean habitats and how these may be changing under the influence of both climate change and non-climate change factors is of great importance. Linkages between changes occurring in the surface layers of the ocean and those associated with deep regions of the world's oceans are particularly important in the light of understanding how rapidly changes are occurring as well as implications for the metabolic activity and oxygen content of deep water habitats.

While research focused on the responses of marine ecosystems to climate change has increased substantially over the past decade, much of this effort is clustered in particular sub-regions (North Pacific and North Atlantic Oceans). It will be essential to expand the number and geographical spread of studies focused on how the Ocean and its ecosystems are changing with respect to global warming and acidification. Equally, many organisms are underrepresented in the studies. Bony fish, copepods and sea birds have received a lot of attention in the scientific literature (albeit located in heavily studied sub-regions), while macroalgae (particularly brown algae), benthic invertebrates (e.g. molluscs, barnacles, cnidarians), and dinoflagellates have been the focus of a moderate number of studies. Many other organisms have not received much attention, illustrating the need for an expansion of the focus of future studies to include these organisms, which are often crucial within ocean ecosystems and processes.

We are also in an early stage of understanding of how sectors such as fishing are likely to be affected by the current fundamental changes to the Ocean. In this respect, it is highly likely that the current structure, distribution, and abundance of fishery stocks and industries are going to be transformed as we head towards a much warmer world. Developing a better understanding of how to adapt fisheries infrastructure and strategy to these changing conditions is of enormous importance. In the broadest setting, it is an imperative that we also develop a greater understanding of how changes to storm strength, sea level and a range of other factors are going to influence other activities such as shipping, energy and mineral extraction, and other human activities, especially those located in the populous coastal sub-regions of the world.

Lastly, the current expansion of technologies that can allow the automated exploration of the ocean represents a very significant opportunity to rapidly improve our understanding of one of the most fundamentally important features of our planet. Given that our understanding of how ocean systems will respond to increased greenhouse gas concentrations has lagged behind our understanding of terrestrial and atmospheric change, it is vital that these new technologies be applied at a scale which can begin to understand and project how ocean systems are likely to change over the coming decades and century. When combined with the increasing opportunities offered by satellite-based remote sensing as well is an increasing set of research activities at all depths within the ocean, these technologies represent a significant opportunity to understand both our planet and the changes on it due to human activities. Hopefully these new insights and understanding will assist humanity to not only understand but ultimately solve the massive challenges presented by anthropogenic climate change (including ocean acidification) for the world’s Ocean.

Frequently Asked Questions

FAQ 30.1: Can we reverse the climate change impacts on the ocean?

Greenhouse gas emissions have resulted in major physical and chemical changes in our oceans. In less than 150 years, we have caused changes in the oceans not seen for millions of years. These changes can be reversed if emissions are stopped, but not in our lifetime. Oceans are warming slower than land because of their higher heat capacity and the slow mixing of warmer surface waters into the deep ocean (~2,000 yr). These different characteristics of the ocean mean that it will take centuries for ocean warming to reverse once greenhouse gas emissions are reduced. As CO_2 enters the oceans it also alters ocean chemistry (reducing pH). Chemical changes to the ocean will take thousands of years to reverse.

FAQ 30.2: How can we use non-climate factors to manage climate change?

Natural systems are exposed to a range of climate change and non-climate factors. We need to manage the combined impacts of climate and other human activities such as pollution, eutrophication, habitat destruction, invasive species and fishing. These activities combine in different ways with climate change, with some acting in opposition (antagonistic) while others act together to produce an enhanced effect (synergistic). Where we find synergistic interactions, we can devote our management efforts to reducing the non-climate activities thus minimizing degradation of natural systems. For example, maintaining coastal water quality will partially alleviate the impact of thermal stress and aid recovery of seagrass beds. Identifying the type of interactions between climate and human activities will be crucial for managing climate change impacts on natural systems. Developing ecosystem-based management of fishery resources where climate-induced changes in the productivity are implemented will help maintaining sustainable fishery under climate change.

FAQ 30.3: Does slower warming mean less impact on plants and animals?

The opportunities for adapting and accommodating climate change are generally higher at slower rates of environmental change. However, there are now many observations which suggest that even small amounts of warming will lead to significant changes in the structure and function of marine ecosystems. Despite less warming in equatorial sub-regions than elsewhere, many tropical species are under threat from future warming as they are already near their upper thermal tolerance limits. Similarly, despite slower warming over ocean than land, bands of equal temperature (isotherms) are migrating polewards at similar or faster rates in the ocean implying that marine species will have to move at rates comparable to, or faster than, land species to track thermal environments. Rates of change in seasonal temperature peaks are also similar over ocean and land, implying comparable shifts in timing of life history events such as earlier reproduction in spring. Therefore, even the slower warming in the tropics and in the oceans will pose challenges to species and reorganize natural systems.

FAQ 30.4: How will marine primary productivity change?

Changes in marine primary productivity in response to climate change remain the single biggest uncertainty in predicting the magnitude and direction of future changes in fisheries and marine ecosystems. Drifting microscopic (1-100 μm) plants known as phytoplankton are the dominant marine primary producers. Their photosynthetic activities provide approximately half the oxygen we breathe, supports most marine food webs, and influences global biogeochemical cycles. There is considerable uncertainty in observed changes in primary production globally, with some studies showing declines and others increases. Regionally, there is mounting evidence of productivity increases in the world's most productive (upwelling) systems, some evidence that productivity in the highest latitudes of the spring-bloom ecosystems and polar areas is increasing. Longer satellite time series, maintenance of in-water time series, and more emphasis on modeling future primary productivity are needed.

FAQ 30.5: Can we expect actual loss of marine life and/or the creation of true ocean dead zones under climate change?

Warming of the ocean by 2 degrees will reduce oxygen solubility by about 14 micromoles per kg at typical mid-water temperatures (5º - 7ºC). In some areas of the ocean such as those at a few hundred meters depth off the west coast of the Americas, and in the northern Arabian Sea, where oxygen levels are already low, we may expect conditions in which oxygen is virtually zero, with resulting loss of life. A smaller additional ocean oxidation

capacity is represented by the presence of dissolved nitrate which can be used by bacteria as a chemical resource thus delaying the absolute loss of oxygen. This process is occurring regionally today, and oceanic nitrate losses occurred in the pre-industrial ocean. But the combined oxidation capacity of oxygen and nitrate will be exceeded, and once this occurs, toxic hydrogen sulfide can appear in the ocean water column. This has not been seen in recorded history although short term sporadic eruptions of sulfide from the sea floor have been observed. There is evidence for the presence of sulfide oxidizing bacteria in the sub-oxic ocean today. The reduction of dissolved oxygen from solubility effects alone greatly underestimates the case. Ocean data shows that only ~15% of the observed changes can be attributed to solubility reduction from warming; ~85% is attributable to the effects of increased bacterial activity and reduced ventilation by the atmosphere in the more stratified upper ocean. If these trends hold then ~5x greater oxygen losses could occur at depth with more widespread true dead zones at depth and loss of marine life in affected ocean regions.

Cross-Chapter Boxes

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water structures made of calcium carbonate mostly secreted by reef-building (scleractinian) corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics. About 275 million people live within 30 km of a coral reef (Burke et al., 2011) and are likely to derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including those from provisioning (food, construction material, medicine), regulating (shoreline protection, water quality), supporting services (oxygen supply) and cultural (religion, tourism). This is especially true in small islands (29.3.3.1).

Most human-induced disturbances to coral reefs were local (e.g., coastal development, pollution, nutrient enrichment and overfishing) until the early 1980s when global and climate-related disturbances (ocean warming and acidification) began to occur. Temperature and seawater acidity are two of the most important environmental variables determining the distribution of coral reefs (Kleypas et al., 2001). As corals are centrally important as ecosystem engineers (Wild et al., 2011), the impacts on corals have led to widespread degradation of coral reefs.

A wide range of climatic and non-climatic stressors affect corals and coral reefs and negative impacts are already observed (5.4.2.4, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae (genus *Symbiodinium*), which live in the coral tissues and play a key role in supplying the coral host with energy and nutrients (Baker et al., 2008) (see 6.2.5 for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies, is the most widespread and conspicuous impact (Fig. 5X; see Sections, 5.4.2.4, 6.2.5, 25.6.2, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Elevated temperature along with ocean acidification reduces the calcification rate of corals (*high confidence*; 5.4.2.4), and may tip the calcium carbonate balance of reef frameworks towards dissolution (*medium evidence and agreement*; 5.4.2.4). These changes will erode fish habitats with cascading effects reaching fish community structure and associated fisheries (*robust evidence, high agreement*, 30.5).

Around 50% of all coral reefs have experienced medium-high to very high impact of human activities (30-50% to 50-70% degraded; Halpern et al., 2008), which has been a significant stressor for over 50 years in many cases. As a result, the abundance of reef building corals is in rapid decline (1 to 2% per year, 1997-2003) in many Pacific and SE Asian regions (Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner et al., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and coral bleaching have led to a decline in coral cover on the Great Barrier Reef (about 51% between 1985 and 2012; De'ath et al., 2012).

One third of all coral species exhibit a high risk of extinction, based on recent patterns of decline and other factors such as reproductive strategy (Carpenter et al., 2008). Although less well documented, non-coral benthic

invertebrates are also at risk (Przeslawski et al., 2008). Fish biodiversity is threatened by the permanent degradation coral reefs, including in a marine reserve (Jones et al., 2004). While many factors, such as overfishing and local pollution, are involved in the decline of coral reefs, climate change through its pervasive influence on sea temperature, ocean acidity, and storm strength plays a very significant role.

There is *robust evidence* and *high agreement* that coral reefs are one of the most vulnerable marine ecosystems (Chapters 5, 6, 25, and 30). Globally, more than half of the world's reefs are under medium or high risk of degradation (Burke et al., 2011) even in the absence of climatic factors. Future impacts of climate stressors (ocean warming, acidification and sea level rise) will exacerbate the impacts of non-climatic stressors (*high agreement*, *robust evidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9–60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation under the RCP3-PD scenario (Frieler et al., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30–88%, 68% uncertainty range). If present day corals have residual capacity to acclimatize and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*; Logan et al., sbm). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs produce 10-12% of the fish caught in tropical countries, and 20-25% of the fish caught by developing nations (Garcia & Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton et al. (2012) are already exploiting their coral reef fisheries in an unsustainable way (13.X.X).
- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke et al., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).
- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard et al., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4, 30.5).

Coral reefs make a modest contribution to the global domestic product but their economic importance can be high at the country and regional scales (Pratchett et al., 2008). For example, tourism and fisheries represent on average 5% of the GDP of South Pacific islands (Laurans et al., 2013). At the local scale, these two services provide at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans et al., 2013).

Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod et al., 2009). Although they are key conservation and management tools, they are less effective in reducing coral loss from thermal stress (Selig et al., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau et al., 2012). Controlling the input of nutrients and sediment from land is an important complementary management strategy because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann et al., 2012). There is also high confidence that, in the long term, limiting the amount of warming and acidity is central to ensuring the viability of coral reef systems and dependent communities (5.X.X and 30.5).

[INSERT FIGURE CR-1 HERE

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that

prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Introduction

Anthropogenic ocean acidification and climate change share the same primary cause at the global level, the increase of atmospheric carbon dioxide (WGI, 2.2.1). Eutrophication and upwelling contribute to local ocean acidification (5.3.3.6, 30.5.4). Past and futures changes in chemistry are well known in the surface open ocean (WGI, 3.8.2 and 6.4.4) but are more difficult to project in the more complex coastal systems (5.3.3.6 and 30.5.2).

Chemistry and Projections

The fundamental chemistry of ocean acidification has long been understood: the uptake of CO_2 into mildly alkaline ocean results in an increase in dissolved CO_2 and reductions in pH, dissolved carbonate ion, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of surface seawater can be projected at the global scale with high accuracy from projections of atmospheric CO_2 levels. Time series observations of changing upper ocean CO_2 chemistry support this linkage (WGI Table 3.2 and Figure 3.17; WGII Figure 30-5). Projections of regional changes, especially in coastal waters (5.3.3.6), and at depth are more difficult; observations and models show with high certainty that fossil fuel CO_2 has penetrated at depths of 1 km and more. Importantly, the natural buffering of increased CO_2 is less in deep than in surface water and thus a greater chemical impact is projected. Additional significant CO_2 increases and pH decreases at mid-depths are expected to result from increases in microbial respiration induced by warming. Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGII, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration).

Biological, Ecological, and Biogeochemical Impacts

The effects of ocean acidification on marine organisms and ecosystems have only recently been investigated. A wide range of sensitivities to projected rates of ocean acidification exists within and across organism groups and phyla with a trend for higher sensitivity in early life stages (*high confidence*; Kroeker et al., in press; 6.2.3-5, 6.3.4). A pattern of impacts, some positive, others negative, emerges for some processes and organisms (*high confidence*; Fig. X.C) but key uncertainties remain from organismal to ecosystem levels (Chap. 5, 6, 30). Responses to ocean acidification are exacerbated at high temperature extremes (*medium confidence*) and can be influenced by other drivers, such as oxygen concentration, nutrients, and light availability (*medium confidence*).

Experimental evidence shows that lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers such as reef-building corals (Box CC-CR, coralline algae (Raven, in press), bivalves and snails (Gazeau et al., in press) reducing their competitiveness compared to, e.g. seaweeds (Chap. 5, 6, 30). A reduced performance of these ecosystem builders would affect the other components of the ecosystem dependent on the habitats they create.

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*) and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may significantly stimulate nitrogen fixation in the oceans (*limited evidence, low agreement*; 6.2.3, 6.3.4). There are few known direct effects on early stages of fish and adult fish remain relatively undisturbed by elevated CO_2. Serious behavioral disturbances were reported, mostly on larval and juvenile coral reef fishes (6.2.4).

Projections of ocean acidification effects at the ecosystem level are limited by the diversity of species-level responses. Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities living on the sea-floor. Shifts in community structure have been documented in rocky shore environments (e.g., Wootton et al., 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012). Differential sensitivities and associated shifts in performance and distribution will change predator-prey

relationships and competitive interactions (6.2-3), which could impact food webs and higher trophic levels (*limited evidence, high agreement*).

There is *limited evidence* and *medium agreement* that some phytoplankton and mollusks can adapt to ocean acidification, indicating that the long-term responses of these organisms to ocean acidification could be less than responses obtained in short-term experiments. However, mass extinctions during much slower rates of ocean acidification in Earth history (6.1.2) suggest that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of change (*high confidence*).

The effect of ocean acidification on global biogeochemical cycles is difficult to predict due to the species-specific responses to ocean acidification, lack of understanding of the effects on trophic interactions, and largely unexplored combined responses to ocean acidification and other climatic and non-climatic drivers, such as temperature, concentrations of oxygen and nutrients, and light availability.

Risks

Climate risk is defined as the probability that climate change will cause specific physical hazards and that those hazards will cause impacts (19.5.2). The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, includes both the probability that ocean acidification will affect key processes, and the magnitude of the resulting impacts. The changes in key processes mentioned above present significant ramifications on ecosystems and ecosystem services (Fig. 19.3). For example, ocean acidification will cause a decrease of calcification of corals, which will cause not only a reduction in the coral's ability to grow its skeleton, but also in its contribution to reef building (*high confidence*; 5.4.2.4). These changes will have consequences for the entire coral reef community and on the ecosystem services that coral reefs provide such as fisheries habitat (*medium confidence*; 19.5.2) and coastal protection (*medium confidence*; Box CC-CR). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Socioeconomic Impacts and Costs

The biological, ecological and biogeochemical changes driven by ocean acidification will affect several key ecosystem services. The oceans will become less efficient at absorbing CO_2, hence less efficient at moderating climate change, as their CO_2 content will increase (*very high confidence*). The impacts of ocean acidification on coral reefs, together with those of bleaching and sea level rise, will in turn diminish their role of shoreline protection in atolls and small island nations as well as their direct and indirect benefits on the tourism industry (*limited evidence, high agreement*; Box CC-CR).

There is no global estimate of the observed or projected economic costs of ocean acidification. The production of commercially-exploited shelled mollusks may decrease (Barton et al., 2012) resulting in an up to 13% reduction of US production (limited evidence, low agreement; Cooley and Doney, 2009). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (Narita et al., 2012). The largest uncertainty is how the impacts on prey will propagate through the marine food webs and to top predators. Models suggest that ocean acidification will generally reduce fish biomass and catch (*limited evidence, high agreement*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (Branch et al., 2012; Griffith et al., 2012). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 500 billion USD, respectively for A1 and B2 SRES emission scenarios (Brander et al. 2012). Although this number is small compared to global GDP, it represents a large proportion of the GDP of some regions or small island states which rely economically on coral reefs.

Adaptation and Mitigation

The management of ocean acidification comes down to mitigation of the source of the problem and adaptation to the consequences (Rau et al., 2012; Billé et al., sbm). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts. Climate geoengineering techniques based on solar radiation management would have no direct effect on ocean acidification because atmospheric CO_2 would continue to rise (6.4.2). Techniques based on carbon dioxide removal could directly address the problem but their effectiveness at the scale required to ameliorate ocean acidification has yet to be demonstrated. Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep water oxygen levels (Williamson and Turley, 2012; 6.4.2; 30.3.2.3 and 30.5.7). Mitigation of ocean acidification at the local level could

involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Specific activities, such as aquaculture, could adapt to ocean acidification within limits, for example by altering the production process, selecting less sensitive species or strains, or relocating elsewhere. A low-regret approach is to limit the number and the magnitude of drivers other than CO_2. There is evidence, for example, that reducing a locally determined driver (i.e. nutrient pollution) may substantially reduce its synergistic effects with a globally determined driver such as ocean acidification (Falkenberg et al., 2013).

[INSERT FIGURE OA-1 HERE
Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.]

*** Not calculated (<0.5%)

Table 30-2: Regional changes in sea surface temperature (SST) over the past 50 years for ocean sub-regions specified in Figure 30-1. A linear regression was fitted to all 1x1 degree monthly SST data extracted from the HadISST 1.1 data set (Rayner et al., 2003) for the period of 1950 to 2009 for each ocean sub-region. The Table includes the slope of the regression ($^{o}C.decade^{-1}$), p value of the slope being different to zero, Linear Change Over 50 Years (slope of linear regression multiplied by 5 to obtain the average change over 50 years, and the difference between the mean temperature (1950-1959) from the mean temperature 50 years later (2000-2009). The latter may be different to the linear change over 50 years if there is significant long-term variability around the trend line. The last column compares the linear trend with that calculated between the two means with significant deviations (<0.8 and > 1.2) shown in red. P values that exceed 0.05 are also shown in red.

Region	Sub-region	oC/Decade	p Value	Linear Change Over 50 Years (1955-2005)	Mean (2000-2009) - Mean (1950-1959)	Index of Variability

Table 30-3: CMIP-5 models used to create the Chapter 30 RCP 2.6, 4.5, 6.0 and 8.5 SST ensembles. All models indicated were used in both the ensemble SSTs as well as the production of the DHMs, with the exception of 2 model outputs, denoted by a *. These two models were included in the ensembles but not in the production of the DHMs due to issues with the development of an appropriate Maximum Monthly Mean (MMM) climatology.

Table 30-4: Projected changes in sea surface temperature (SST, ºC) over the next 90 years for Ocean sub-regions (Figure 30-1) using model runs from the Coupled Model Intercomparison Project Phase 5 (CMIP-5, http://cmip-pcmdi.llnl.gov/cmip5/). Runs were divided up into their respective Representative Concentration Pathways (RCP) to form four groups: RCP2.6, RCP4.5, RCP6.0 and RCP8.5. The CMIP-5 models that were used in this analysis are listed in Table 30.3. For each region, a linear regression was fitted to all 1x1 degree monthly SST data extracted from the models for each of three periods; 2010-2039, 2040-2069 and 2070-2099. The average change in SST was calculated by multiplying the slope of each linear regression by 360 (months) to derive the average change over each successive 30 year period. The table is divided into two sections, "Near-term (2010-2039)" – the average change in SST over the next 30 years, and "Long-term (2010-2099)" – the total change from 2010-2099, which was calculated by adding the average change of the three 30 year periods from 2010 to 2099. This is a simplified method to account for slight non-linearity in SST change over the 90 year period.

Region	Sub-region	Near-term (2010-2039)				Long-term (2010-2099)				Diff RCP8.5 - RCP2.6
		RCP 2.6	RCP 4.5	RCP 6.0	RCP 8.5	RCP 2.6	RCP 4.5	RCP 6.0	RCP 8.5	
1. High Latitude Spring Bloom Systems (HLSBS)										
	Indian Ocean	0.13	0.29	0.18	0.41	-0.16	0.49	0.83	2.01	2.17
	North Atlantic	0.31	0.56	0.52	0.65	0.54	1.54	1.95	3.02	2.48

Table 30-5: Examples of priority adaptation options and supporting policies to assist Pacific Island countries and territories to minimize the threats of climate change to the socio-economic benefits derived from fisheries and aquaculture, and to maximize the opportunities. These measures are classified as 'win-win' (W-W) adaptations, which address other drivers of the sector in the short term and climate change in the long term, or 'lose-win' (L-W) adaptations, where benefits exceed costs in the short term but accrue under longer-term climate change (Modified from *Bell et al*. 2013a).

Adaptation options	Supporting policies
Economic development	
Full implementation of the vessel day scheme (VDS) to control fishing effort by the Parties to the Nauru Agreement[a] (W-W).	• Strengthen national capacity to administer VDS. • Adjust national tuna management plans and marketing strategies to provide flexible arrangements to buy and sell tuna. • Include implications of climate change in management objectives of the WCPFC. • Apply national management measures to address climate change effects for sub-regional concentrations of tuna in archipelagic waters beyond WCPFC's mandate. • Require all industrial tuna vessels to provide operational-level catch and effort data to improve models for projecting redistribution of tuna stocks during climate change.
Diversify sources of fish for canneries and maintain trade preferences (W-W).	
Continued conservation and management measures for all species of tuna to maintain stocks at healthy levels and maximize their resilience to climate change (W-W).	
Energy efficiency programmes to assist fleets to cope with oil price rises, minimise CO_2 emissions, and reduce costs of fishing further afield as tuna move east (W-W).	
Pan-Pacific tuna management through a merger of the Western and Central Pacific Fisheries Commission (WCPFC) and Inter-American Tropical Tuna Commission to co-ordinate management measures across the entire tropical Pacific (L-W).	
Food security and livelihoods	
Manage catchment vegetation to reduce transfer of sediments and nutrients to rivers and coasts to reduce damage to freshwater fish habitats, and coral reefs, mangroves and seagrasses supporting coastal fisheries (W-W).	• Strengthen governance for sustainable use of coastal fish habitats by: (1) building national capacity to understand the threats of climate change; (2) empowering communities to manage fish habitats; and (3) changing agriculture, forestry and mining practices to prevent sedimentation and pollution. • Minimise barriers to landward migration of coastal habitats during development of strategies to assist other sectors to respond to climate change. • Apply 'primary fisheries management' to stocks of coastal fish and shellfish to maintain their potential for replenishment. • Allocate the necessary quantities of tuna from total national catches to increase access to fish for both urban and coastal populations. • Dedicate a proportion of the revenue from fishing licences to improve access to tuna for food security. • Include inshore FADs as part of national infrastructure for food security, and undertake regular maintenance and replacement of FADs. • Provide incentives for aquaculture enterprises to assess risks to infrastructure so that farming operations and facilities can be 'climate-proofed' and relocated if necessary.
Foster the care of coral reefs, mangroves and seagrasses by preventing pollution, managing waste and eliminating direct damage to these coastal fish habitats (W-W).	
Provide for migration of fish habitats by: (1) prohibiting construction adjacent to mangroves and seagrasses and installing culverts beneath roads to help plants colonise landward areas as sea level rises; and (2) allowing floodplains to expand as rainfall increases (L-W).	
Sustain and diversify catches of coral reef fish to maintain the replenishment potential of all stocks (L-W).	
Increase access to tuna and by-catch caught by industrial fleets through storing and selling these fish at major ports to provide inexpensive fish for rapidly growing urban populations (W-W).	
Install fish aggregating devices (FADs) close to the coast to improve access to tuna and other large pelagic fish for rural communities as human populations increase and coral reef fish decline (W-W).	
Improve simple post-harvest methods to extend the shelf life of fish when good catches are made (W-W).	
Relocate pearl farming operations to deeper water and sites closer to coral reefs and seagrass/algal areas where water temperatures and aragonite saturation levels are likely to be more suitable for growth and survival of pearl oysters, and formation of high-quality pearls (L-W).	

a = The Parties to the Nauru Agreement (PNA) are Palau, Federated States of Micronesia, Papua New Guinea, Solomon Islands, Marshall Islands, Nauru, Kiribati and Tuvalu.

Table 30-6: Key risks and vulnerabilities, as well as ramifications, adaptation options and frameworks for decision-making within a number of areas discussed in chapter 30. Symbols are as follows: T = sea temperature; UW = upwelling; OA = ocean acidification; NU = nutrient concentration; IC = ice cover; SS = storm strength, SLR = sea level rise (□ = Increased; □ = decreased; italics = uncertain). Acronyms are: CBD (Convention on Biological Diversity), CTI (Coral Triangle Initiative), GEF (Global Environment Facility), IHO (International Hydrographic Organization), ILO (International Labour Organisation), IOM (International Organisation of Migration), ISPS (International Ship and Port Facility Security), LOSC (1982 Law of the Sea Convention), MARPOL (International Convention for the Prevention of Pollution From Ships), PACC (Pacific Adaptation to Climate Change Project), PEMSEA (Partnerships in Environmental Management for the Seas of East Asia), RFMO (Regional Fisheries Management Organisations), SPREP (Secretariat of the Pacific Regional Environment Programme), UNCLOS (United Nations Convention on the Law of the Sea), UNHCR (United Nations High Commissioner for Refugees), and WHO (World Health Organisation).

Primary driver(s)	**Biophysical change projected**	**Key risks and vulnerabilities**	**Ramifications**	**Adaptation options**	**Policy frameworks and initiatives (examples)**	**Key References**
↑T, ↑UW, *↑OA*	Changing primary productivity	Reduced fisheries production reduces important sources of income to some countries while others may see increase (e.g. as tuna stocks migrate eastwards in the Pacific with warming).	Reduced national income, increased unemployment, plus increase in poverty. Potential increase in disputes over national ownership of key fishery resources	Increased international cooperation over key fisheries. Improved understanding of linkages between ocean productivity, recruitment and fisheries stock levels. Implementation of the regional 'vessel day scheme', support industry as costs rise, stock characteristics change.	LOSC, PEMSEA, CTI, RFMO agreements	Tsamenyi and Hanich (2012); Bell et al. 2012, 2013; Section 30.6.1.1
↑T, *↑OA*	Ecosystem regime shifts (e.g. coral to algal reefs; structural shifts in phytoplankton community)	Reduced fisheries production as coastal habitats and ecosystems such as coral reefs and other coastal ecosystems degrade.	Decreased food and employment security and human migration away from coastal zone	Strengthen coastal zone management to reduce contributing stressors (e.g. coastal pollution, over-harvesting and physical damage to coastal resources). Promote blue carbon initiatives - restoration of coastal habitats such as mangroves, salt marshes and seagrass beds.	PEMSEA, CTI, PACC, MARPOL, UNHCR, CBD, IOM, GEF, ILO	Bell et al. 2012, 2013; Section 30.6.1.1
		Tourist appeal of coastal assets decreases as ecosystems change to less 'desirable' state reducing income to some countries.	Increased levels of coastal poverty in some countries as tourist income decreases.	As above, strengthen coastal zone management and reduce additional stressors on tourist sites; implement education programs and awareness among visitors. Diversify tourist activities to accommodate change in condition of local ecosystems.	CBD, PEMSEA, CTI, PACC, UNHCR, MARPOL	Kenchington and Warner (2012)
		Increased risk of some diseases (e.g. ciguatera may increase as temperatures increase shift and ecosystems shift away from coral dominance)	Increased disease and mortality; decreases in coastal food resources and fisheries income.	Increased monitoring and education surrounding key risks (e.g. ciguatera); develop alternate fisheries and income for periods when disease incidence increases.	National policy strategies as well as and regional cooperation needed	

Primary driver(s)	Biophysical change projected	Key risks and vulnerabilities	Ramifications	Adaptation options	Policy frameworks and initiatives (examples)	Key References
		Increased poverty and dislocation of coastal people (particularly in the tropics) as coastal resources such as fisheries degrade.	Increased population pressure on migration destinations (e.g. large regional cities), and reduced freedom to navigate in some areas (as criminal activity increases).	Develop alternative industries and income for affected coastal people. Strengthen coastal security both nationally and across regions. Increase cooperation over criminal activities.	LOSC, PEMSEA, CTI, ISPS, IMO, Bali Process on Transnational Crime ASEAN Mutual legal Assistance treaty and bilateral extradition and MLA agreements	Rahman (2012), Kaye (2012),
↑T	Migration of organisms and ecosystems to higher latitudes.	Sudden reorganization of commercial fisheries due arrival of novel organisms and ecological regime shifts.	Social and economic disruption over short periods of time.	Increased international cooperation and improve understanding of regime changes; provide increased monitoring of physical and biological variables; include related uncertainties into fisheries management; support industry as costs rise, stock characteristics change. change.	LOSC, CBD, RFMO agreements	
		Increased risks from pests and fouling as new species arrive at higher latitudes.	Increased damage to coastal ecosystems, aquaculture and fisheries. Income loss and increased costs associated with responding.	Increase monitoring of changes to community and ecosystem structure; provide assistance to industry impacted by pest and fouling organisms; control contributing factors such as the transport of invading organisms on ships hulls and in ballast water.	IMO, BWM, Anti Fouling Convention	
		Threats to human health increase due to the arrival of new pathogens at higher latitudes.	Increased disease and mortality in some coastal communities.	Reduce exposure through increased monitoring and education	UNICEF, WHO, IHOs, and national governments.	Myers and Patz (2009)
↑T, ↑NU, ↑*OA*	Increased incidence of harmful algal blooms (HABs).	Increased threats to ecosystems, fisheries and human health.	Reduced food and greater incidence of disease among some coastal communities.	Reduce nutrient run-off and other contributing issues; improve understanding of how related variables facilitate increased incidence of HABs.	CTI, PEMSEA, MARPOL	
↑T	Increased precipation as a result of intensified hydrological cycle in some coastal areas	Increased freshwater, sediment and nutrients flow into coastal areas.	Increasing damage to coastal reef systems with ecological regime shifts in many cases.	Improve management of catchment and coastal processes; expand riparian vegetation along creeks and rivers; improve agricultural retention of soils and nutrients.	CTI, PEMSEA, SPREP	

Primary driver(s)	Biophysical change projected	Key risks and vulnerabilities	Ramifications	Adaptation options	Policy frameworks and initiatives (examples)	Key References
↑T	Changing weather patterns (local climates, storm intensity)	Increased risk of damage to infrastructure such as that involved in shipping, and oil and gas exploration and extraction.	Increased damage and associated costs	Adjust infrastructure specifications for new conditions and developed more advanced monitoring and warning systems.	IMO	
↑SLR, ↑*SS*	Increased wave exposure of coastal areas	Exposure of coastal infrastructure and communities to damage and inundation	Increased costs to human towns and settlements, numbers of displaced people and human migration.	Develop integrated coastal plans that consider SLR in planning and decision making; increase understanding of the issues through education.	UNICEF, IHOs, and national governments.	Warner (2010)
		Inundation of coastal aquifers reduces water supplies and decreased coastal agricultural productivity.	Reduced food and water security leads to increased coastal poverty, reduced food security, and migration.	Assist communities to find alternatives for food and water, or assist in relocation from vulnerable areas.	UNICEF, IHOs, and national governments.	Warner (2010) CHAPTER 5 linkages
↑SLR	High tide mark moves inland, especially in low-lying countries.	UNCLOS defined limits of maritime jurisdiction will contract as national baselines shift inland. Potential uncertainty increases in some areas with respect to the international boundaries to maritime jurisdiction.	Lack of clarity increases as do disputes over maritime limits and maritime jurisdiction. Some nations at risk of major losses to their territorial waters.	Seek resolution of 'shifting national baselines' issue (retreat and redefinition, stabilization, or fixation of EEZ and other currently defined maritime jurisdiction limits.	LOSC, UNCLOS	Schofield and Arsana (2012); Warner and Schofield (2012)
↑T, ↓IC	Loss of summer sea ice	Access to northern coasts of Canada, USA and Russia increases security concerns.	Potential for increased tension on different interpretations.	Seek early resolution of areas in dispute currently and in the future.	LOSC, UNCLOS	WGII Chapter 28
		New resources become available as ice retreats, increasing vulnerability of international borders in some cases.	Tensions over maritime claims and ownership of resources.	International agreements need to be sort.	LOSC, UNCLOS

B

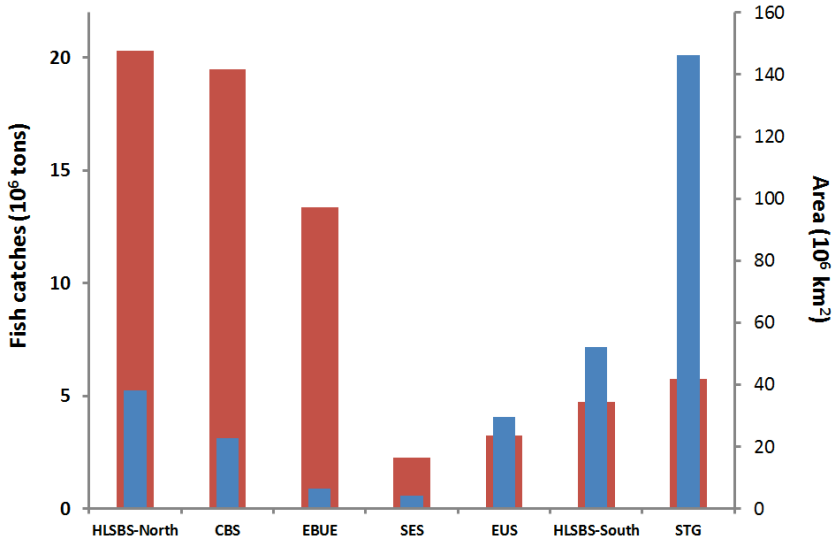

Figure 30-1: A. The world's non-polar oceans have been separated into seven major sub-regions, with polar oceans being excluded due to treatment elsewhere (Ch28). The chlorophyll concentration averaged over the period from Sep 1997 – 30 Nov 2010 (NASA) is also shown. Together with key oceanographic features, primary production was the basis for separating the ocean into the sub-regions shown. The map insert shows the distribution of Deep Sea habitat (>1000 m; Bathypelagic and Abyssopelagic habitats combined). Numbers refer to: 1 = High Latitude Spring Bloom Systems (HLSBS), 2 = Equatorial Upwelling (EUS), 3 = Semi-enclosed seas (SES), 4 = Coastal Boundary Systems (CBS), 5 = Eastern Boundary Upwelling Ecosystems (EBUE), 6 = Subtropical gyres (STG), and 7 = Deep sea (>1000 m). B. relationship between fish catch and areas for Ocean sub-regions shown in A. Red columns: average fish catch (millions tons yr^{-1}) for the period 1970-2006. Blue columns: area (millions km^2).

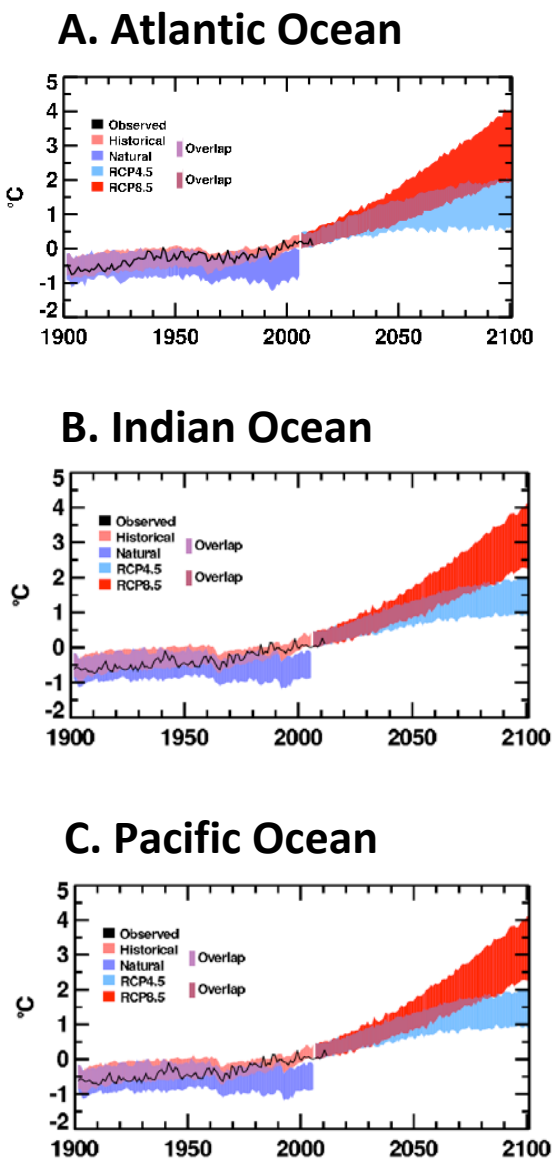

Figure 30-2: Observed and simulated variations in past and projected future annual average sea surface temperature over various oceanic regions. The black line shows estimates from HadISST1 observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (62 simulations), historical changes in "natural" drivers only (25), the "RCP4.5" emissions scenario (62), and the "RCP8.5" (62). Data are anomalies from the 1986-2006 average of the HadISST1 data (for the HadISST1 time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.

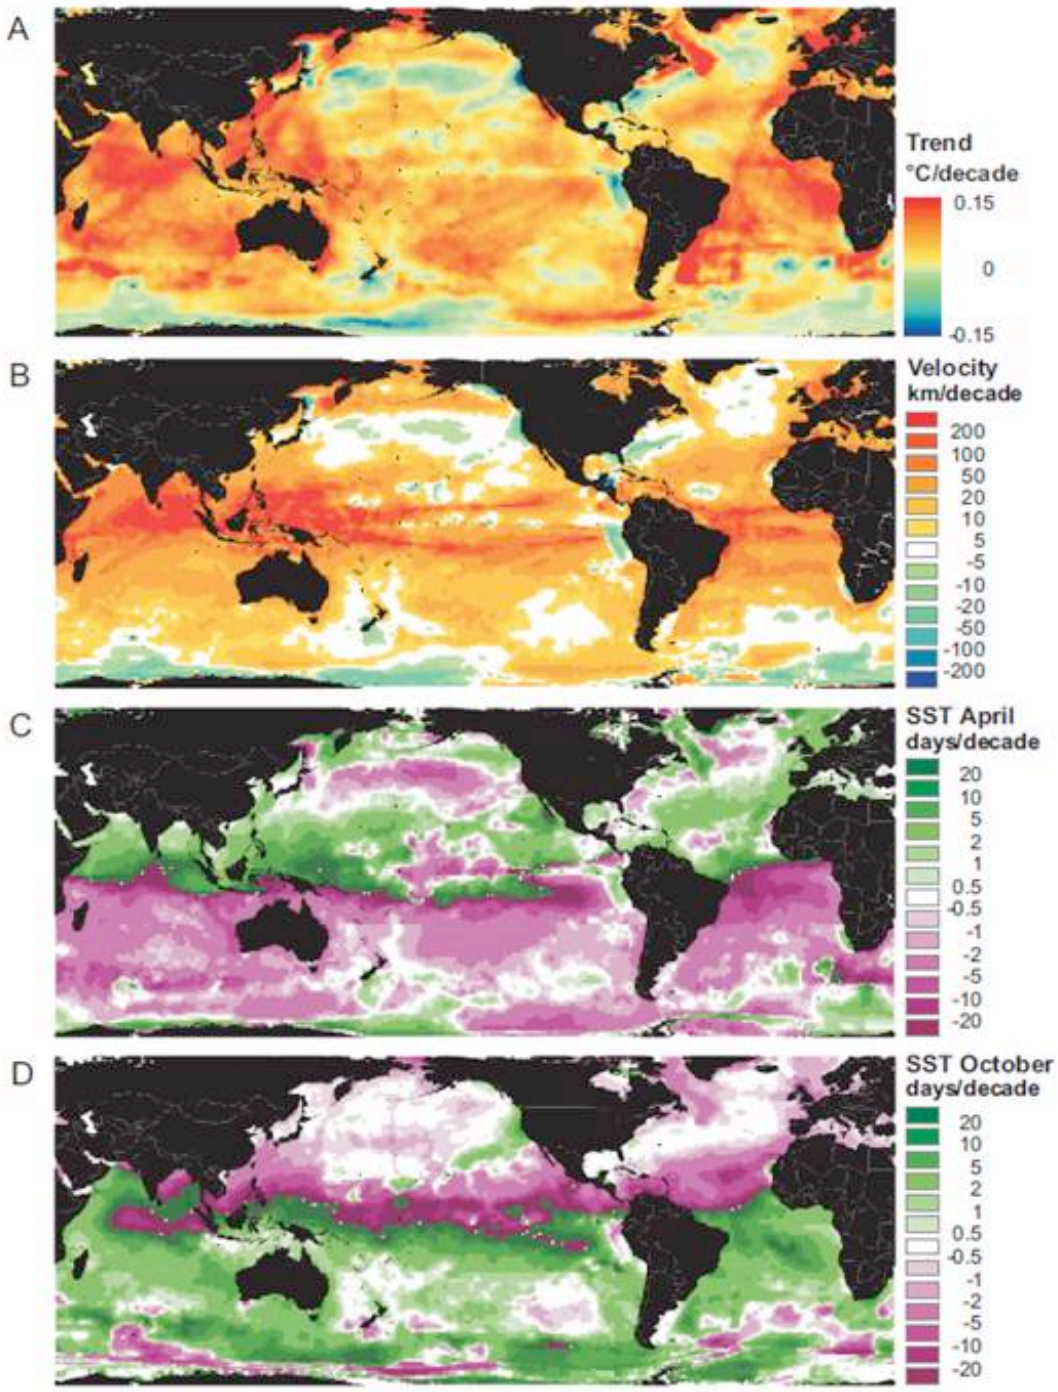

Figure 30-3: Analysis of data from Hadley Centre (HadISST 1.1, [*Rayner et al.*, 2003]) for different ocean sub-regions. A. Rate of change in sea surface temperature over the past 30 years (°C. decade^{-1}). B. Velocity at which isotherms are moving (km.decade^{-1}) from 1960-2009. C. Shift in seasonal changes that drive natural history events (days.decade^{-1}) for April and D. for October. E.

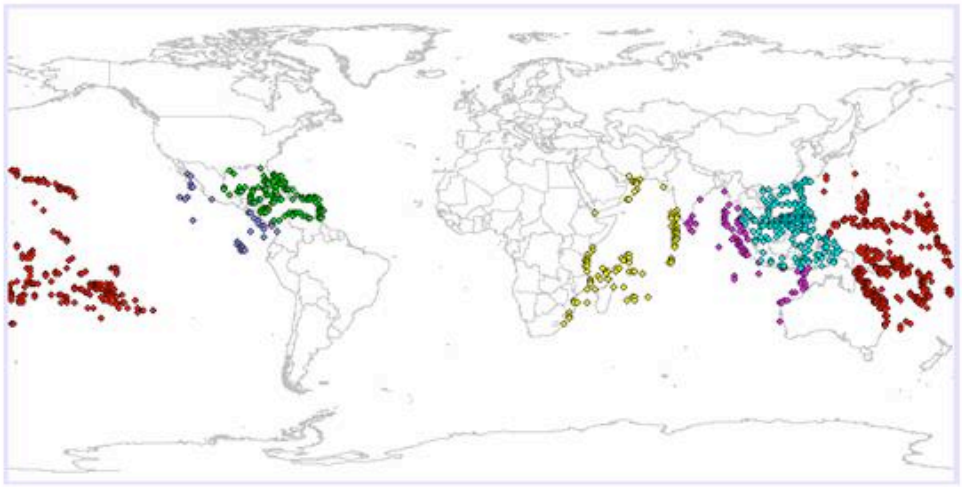

Figure 30-4: Location of coral reef grid cells used in Tables 30.2 and 30.4 as well as in Figure 30.11. Each dot is centred over a 1x1 degree grid cell within which lies at least one coral reef. The latitude and longitude of each reef is derived from data provided by the World Resources Institute's Reefs at Risk (http://www.wri.org). The six regions are as follows: Red – Western Pacific; Blue – Eastern Pacific Ocean; Green – Caribbean & Gulf of Mexico; Yellow – Western Indian Ocean; Magenta – Eastern Indian Ocean; and Cyan – Coral Triangle & SE Asia.

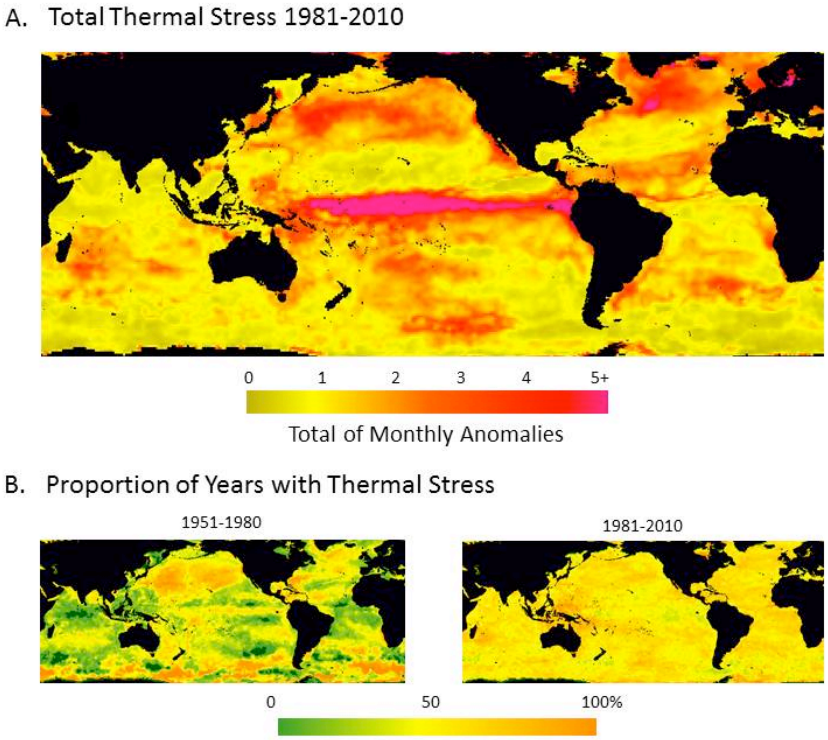

Figure 30-5: Recent changes in thermal stress calculating using HadISST 1.1 data. A monthly climatology was created by averaging the HadISST monthly SST values over the period 1985-2000 to create twelve averages, one for each month of the year. The Maximum Monthly Mean (MMM) climatology was then created by selecting the hottest month for each pixel. Anomalies were then created by subtracting this value from each SST value, but only allowing values to be recorded if they were greater than zero (Donner et al., 2007). Three measures of thermal stress change were then created: (A) Total thermal stress for the period 1981-2010, calculated by summing all monthly thermal anomalies for each grid cell. (B) Proportion of years with thermal stress, which is defined as any year that has a thermal anomaly, for the periods 1951-1980 and (C) 1981-2010.

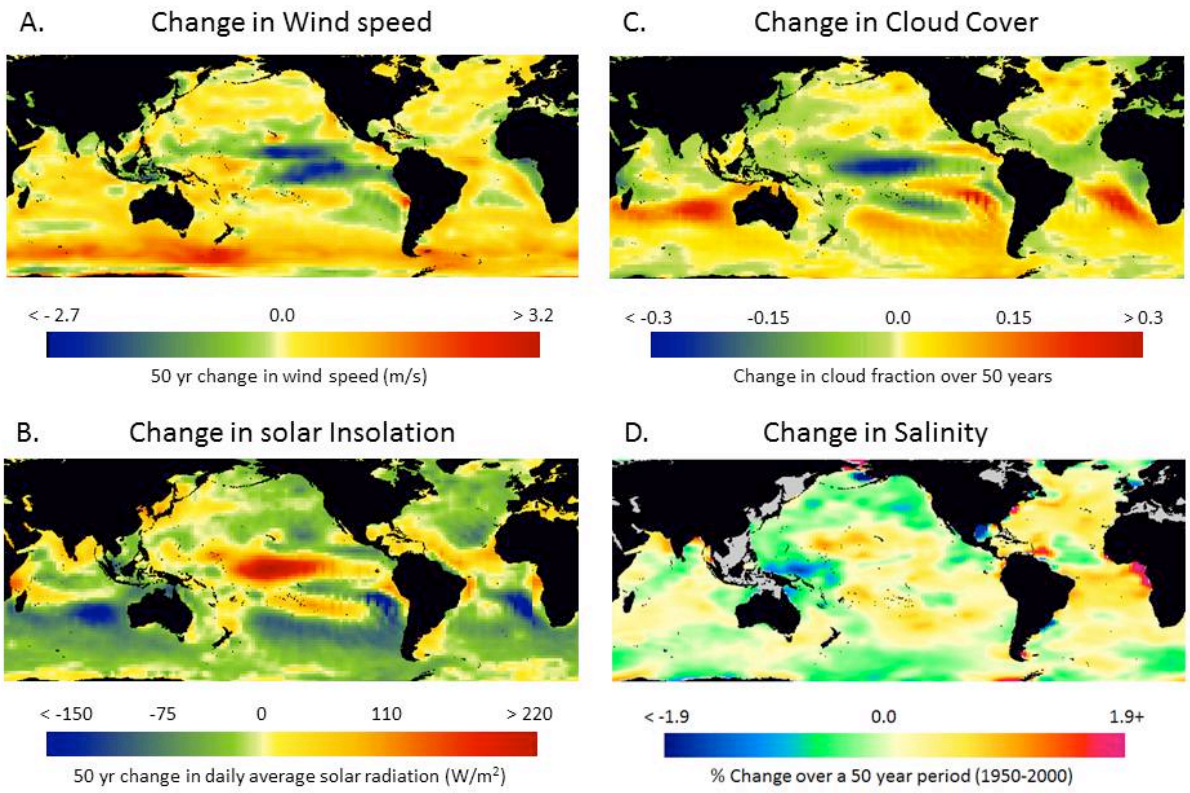

Figure 30-6: Absolute change over 50 years calculated using regression analysis of data from 1951-2010 (A) Wind Speed as the absolute change in $m.s^{-1}$; (B) Solar radiation as change at the surface of incoming solar insolation in Wm^{-2}; (C) Cloud Cover as the absolute change in total cloud fraction (i.e. If at the beginning of the period the cloud fraction was 0.6 and 0.5 at the end of the period, the change would be -0.1) using NCEP re-analyzed data (www.esrl.noaa.gov); and (D) Salinity as the percentage change from 1960-2010 [reproduced using the data of Durack and Wijffels, 2010]. Data for (A), (B) and (C) were derived from the NCEP/NCAR Reanalysis [*Kanamitsu et al*., 2002]. Monthly mean values for wind speed, total cloud cover and downward solar radiation flux (solar insolation) were obtained from http://www.esrl.noaa.gov/psd/data/gridded/data.ncep.reanalysis.derived.html. At each 1x1 degree grid cell, a linear regression was calculated for each of wind, cloud and solar insolation. The slopes were then multiplied by 600 (months) to calculate the average change over a 50 year period.

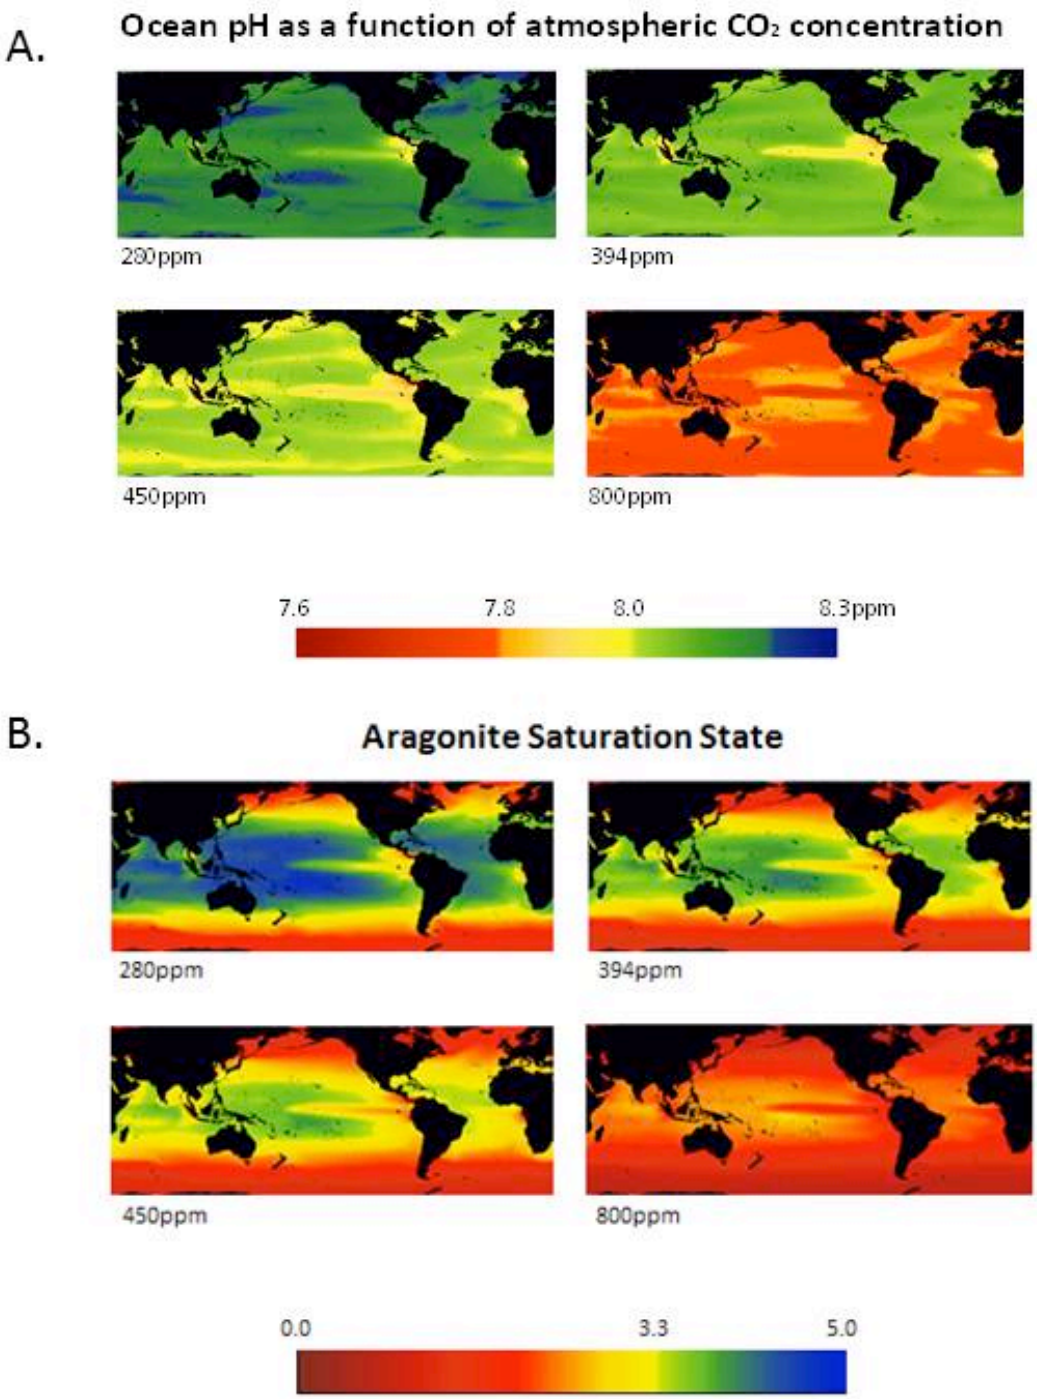

Figure 30-7: A. Surface pH and B. aragonite saturation state of the Ocean at different atmospheric CO_2 levels simulated by the University of Victoria Earth System Model. The fields of pH and aragonite saturation state are calculated from the model output of dissolved inorganic carbon concentration, alkalinity concentration, temperature, and salinity, together with the chemistry routine from the OCMIP-3 project (http://www.ipsl.jussieu.fr/OCMIP/phase3).

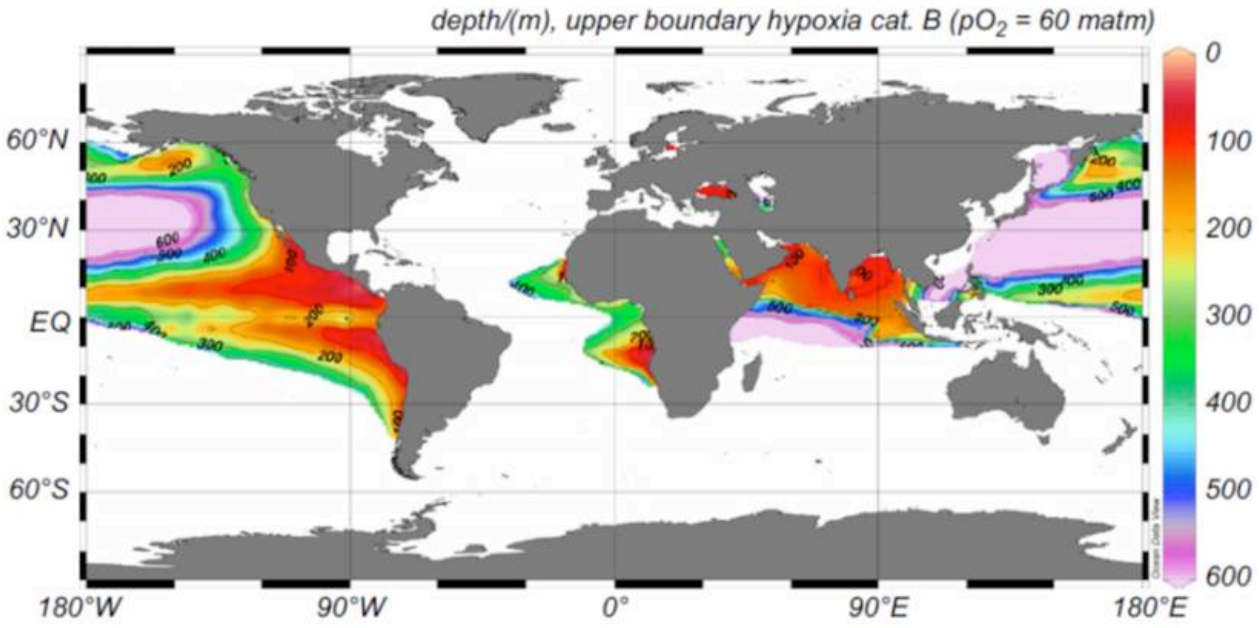

Figure 30-8: Map of the depth [*Hofmann et al.*, 2011] at which a critical value of partial pressure of O_2 of 60 matm occurs which is widely accepted as threatening to marine life on continental shelves (200m depth). Conventional maps of oceanic oxygen values report simple mass properties with no temperature or depth dependence; a better rendition of the availability of O_2 to marine life is provided by the partial pressure, which includes the temperature terms. Critical sub-regions in the eastern and northern Pacific and in the northern Indian ocean stand out. In these areas quite modest upward expansion of the depth at which the critical pO_2 level occurs can have negative effects on major fish populations. Note: not all areas have been included – for example, significant hypoxia in the Gulf of Mexico is not been shown.

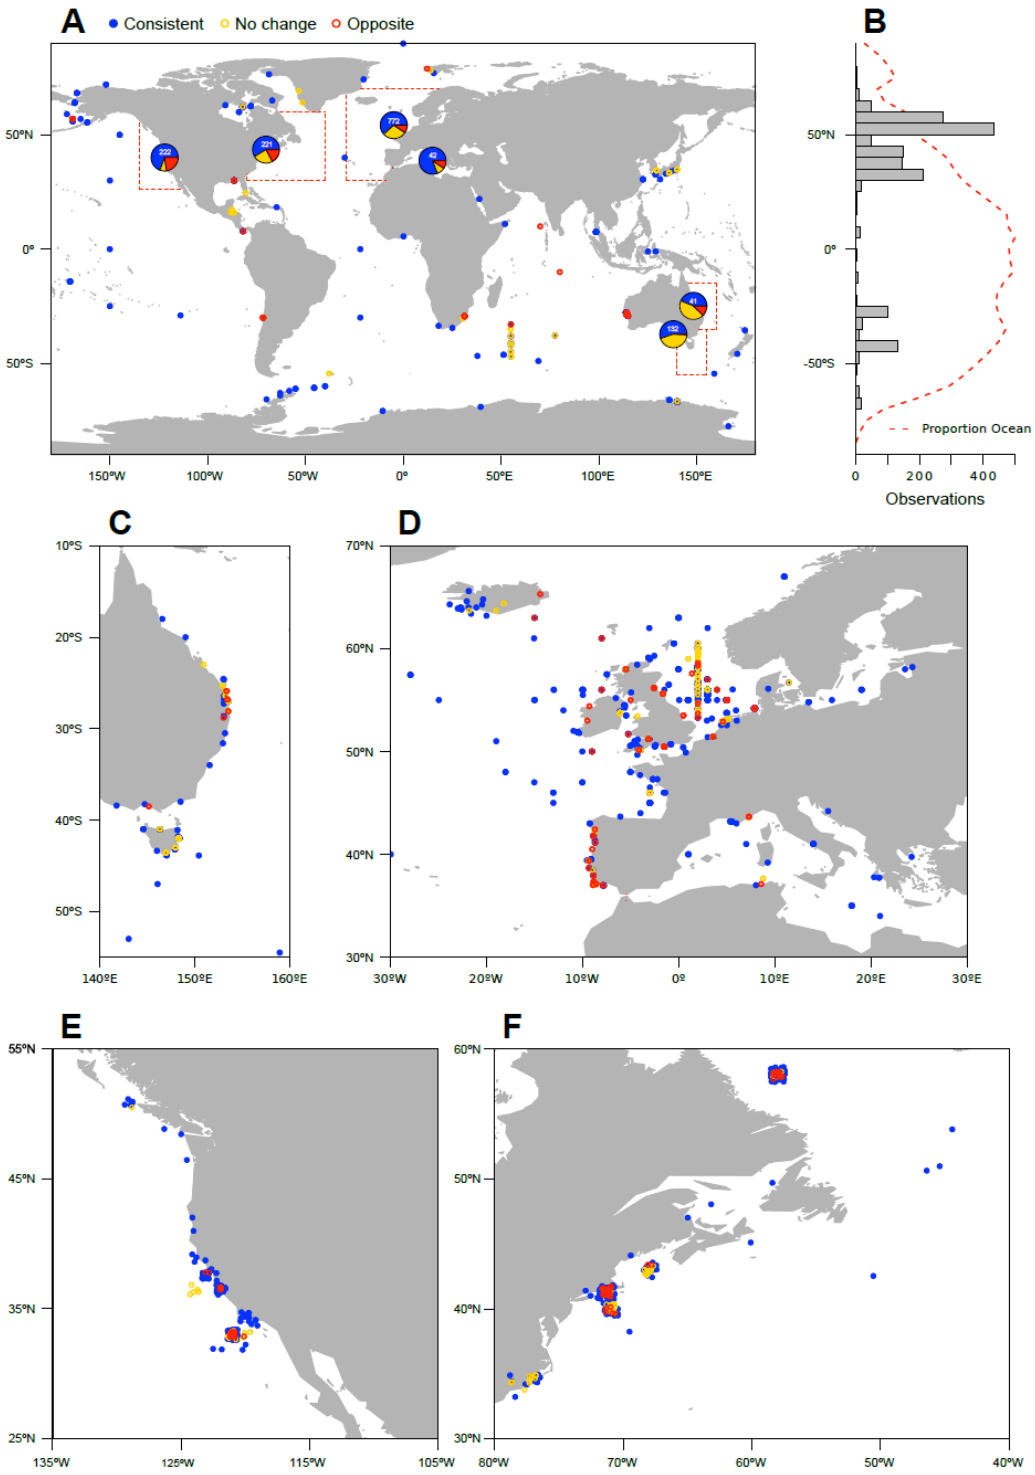

Figure 30-9: (A) 1735 observed responses to climate change from 208 single- and multi-species studies showing responses that are consistent with climate change (blue), opposite to expected (red) and are equivocal (yellow). Each circle represents the centre of a study area. Where points fall on land, it is because they are centroids of distribution that surround an island or peninsula. Pie charts show the proportions within regions bounded by red squares and in the Mediterranean; numbers indicate the total (consistent, opposite plus equivocal) observations within each region. (B) Frequency of observations by latitude. (C) South-west Pacific. (D) North-east Atlantic. (E) California Current. (F) North-west Pacific (Poloczanska et al 2013).

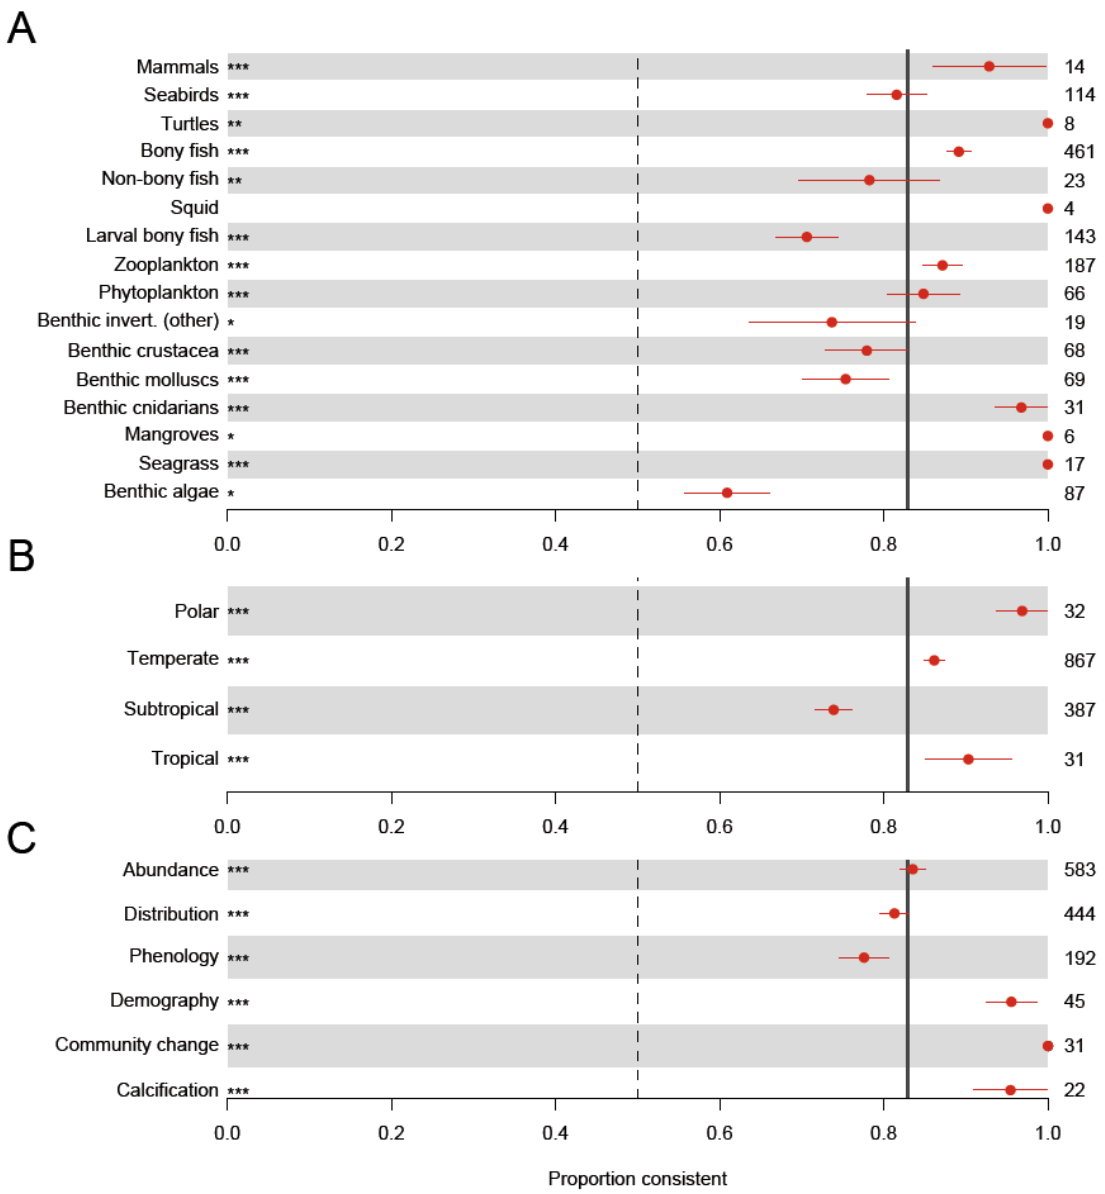

Figure 30-10: Percent of responses consistent with climate change predictions. Mean and standard error of responses by (A) taxa, (B) latitudinal region and (C) response measure show significantly higher consistency than expected from random (dashed line at 50% consistency). Solid line is the mean across all observations. Significance of results is listed next to labels (***: $p < 0.001$; **: $p < 0.01$; *: $p < 0.05$). Sample sizes are listed to the right of each row.

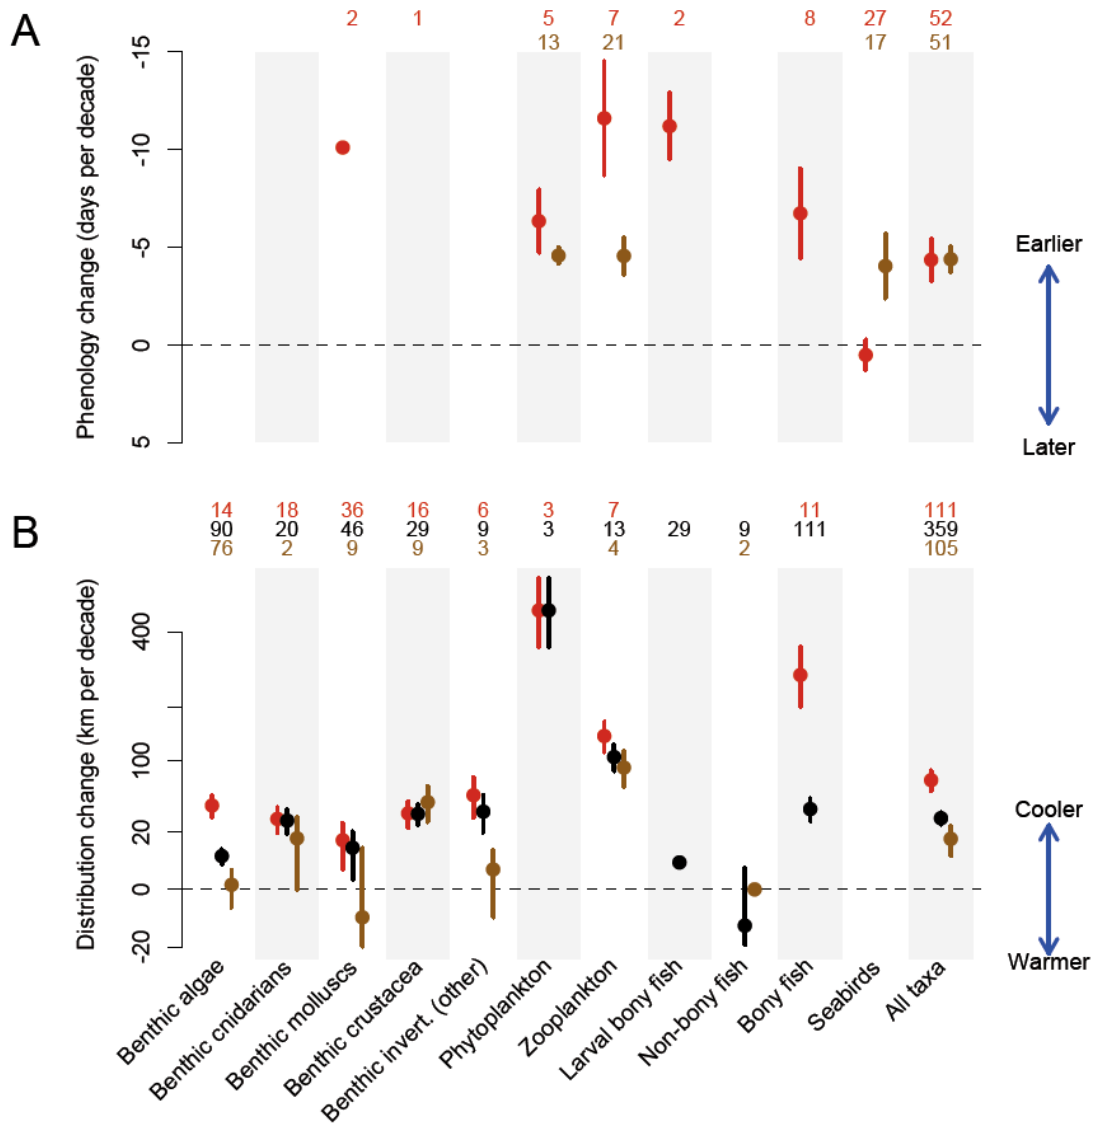

Figure 30-11: Rates of change in (A) phenology (days.decade^{-1}) measured during spring (red) and summer (brown); and (B) distribution (km.decade^{-1}) for marine taxonomic groups, measured at the leading edges (red), and trailing edges (brown). O (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward) and negative phenological changes are consistent with warming (generally earlier). Means ± standard error are shown, with number of observations and significance (*p<0.1, **p<0.05, ***p<0.01); Poloczanska et al, 2013).

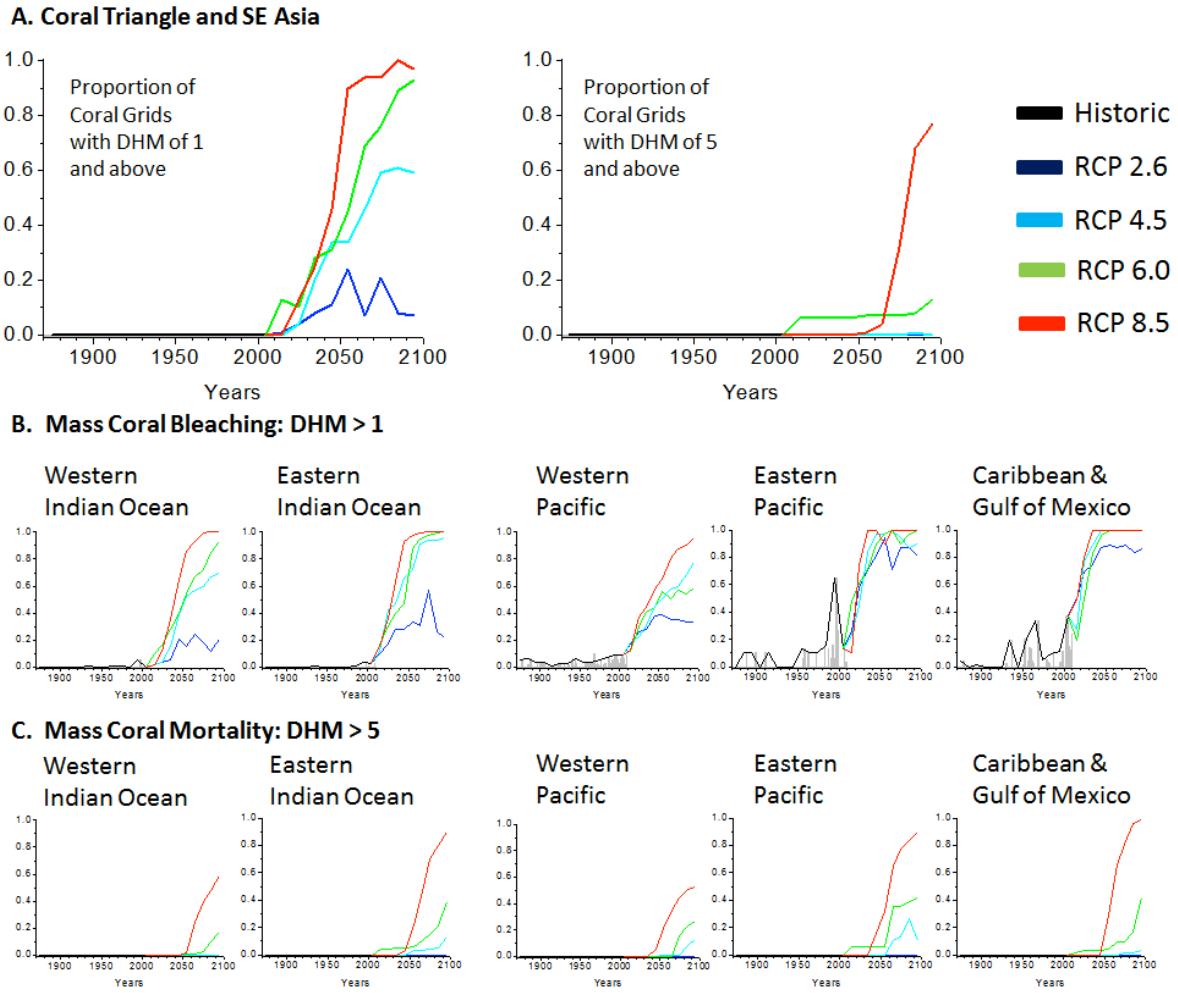

Figure 30-12: Annual maximum proportions of reef pixels with Degree Heating Months (Donner et al. 2007; DHM) ≥ 1 (coral bleaching) and DHM ≥ 5 (bleaching across 100% of affected areas with significant mortality, Eakin et al. 2010) for each of the six coral regions (Figure 30.3) have been depicted as bar graphs for the period 1870-2009. This part of the graph is derived from the HadISST 1.1 data set. The black line plotted on top of the bar graphs is the maximum annual area value for each decade over the period 1870-2009. This value is continued through 2010-2099 using CMIP-5 data and splits into the four Representative Concentration Pathways (RCP 2.6, 4.5, 6.0 and 8.5). DHMs were produced for each of the four RCPs using the ensembles of CMIP models. From these global maps of DHMs the annual percentage of grid cells with DHM ≥ 1 and DHM ≥ 5 were calculated for each coral region. These data were then grouped into decades from which the maximum annual proportions were derived. The plotted lines for 2010-2099 are the average of these maximum proportion values for each RCP. Monthly SST anomalies are derived using a 1985-2000 maximum monthly mean (MMM) climatology derived in the calculations for Figure 30.4. This was done separately for HadISST 1.1 and each of the CMIP-5 models and each of the four RCPs, at each grid cell for each region. DHMs are then derived by adding up the monthly anomalies using a 4 month rolling sum.

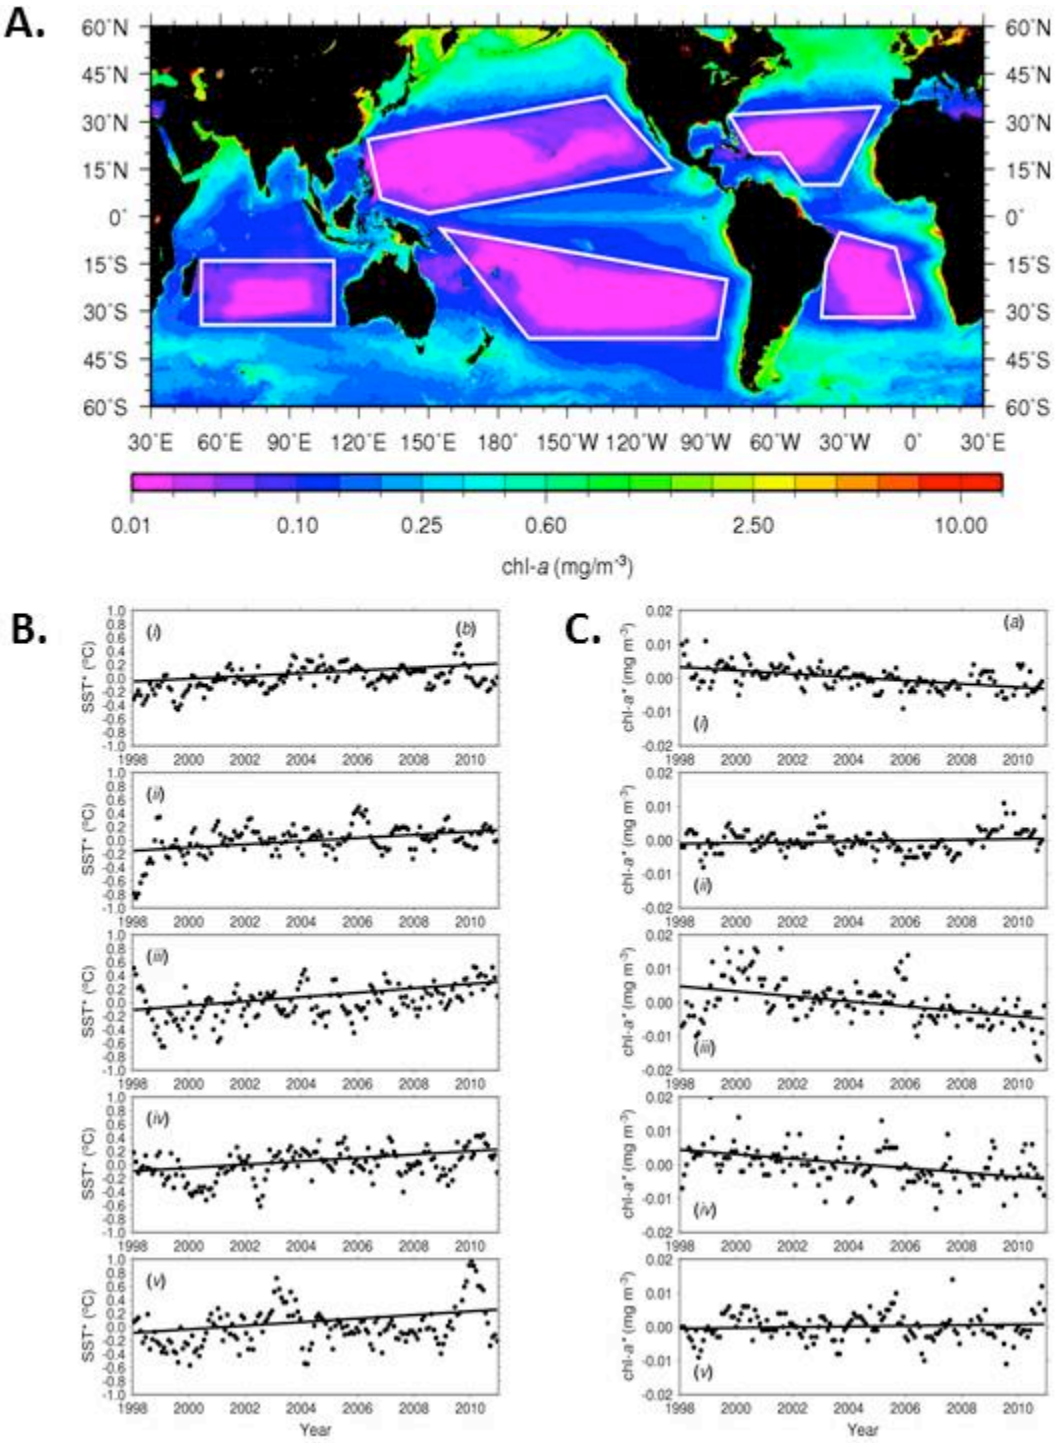

Figure 30-13: A. Map of SeaWiFS chl-a climatology. The white polygons define the sub-regions that were analyzed and represent the major sub-regions considered as sub-tropical gyres by Signorini and McClain (2012). B. Time series of anomalies in chl-a and B. Sea Surface Temperature SST for STGs in North Pacific (NPAC), South Pacific (SPAC), Indian Ocean (IOCE) North Atlantic (NATL) and South Atlantic (SATL) Oceans.

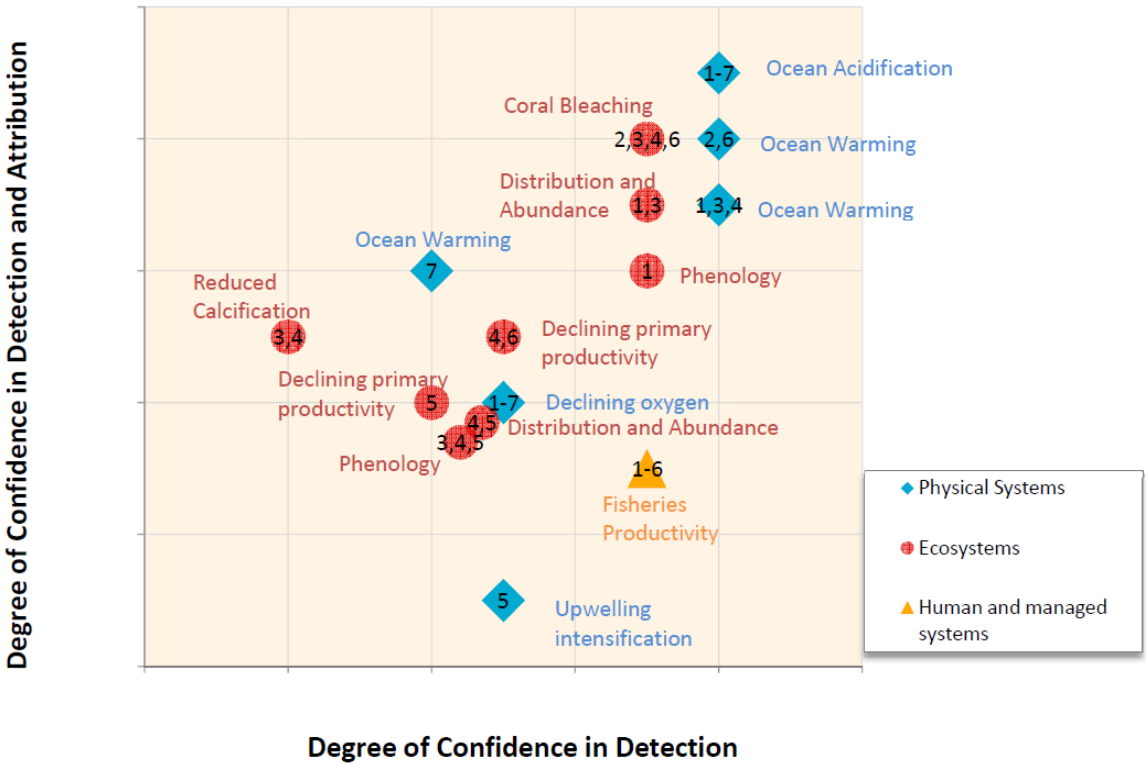

Figure 30-14: Expert assessment of degree of confidence in detection and attribution across sub-regions and processes (based on evidence explored throughout Chapter 30).

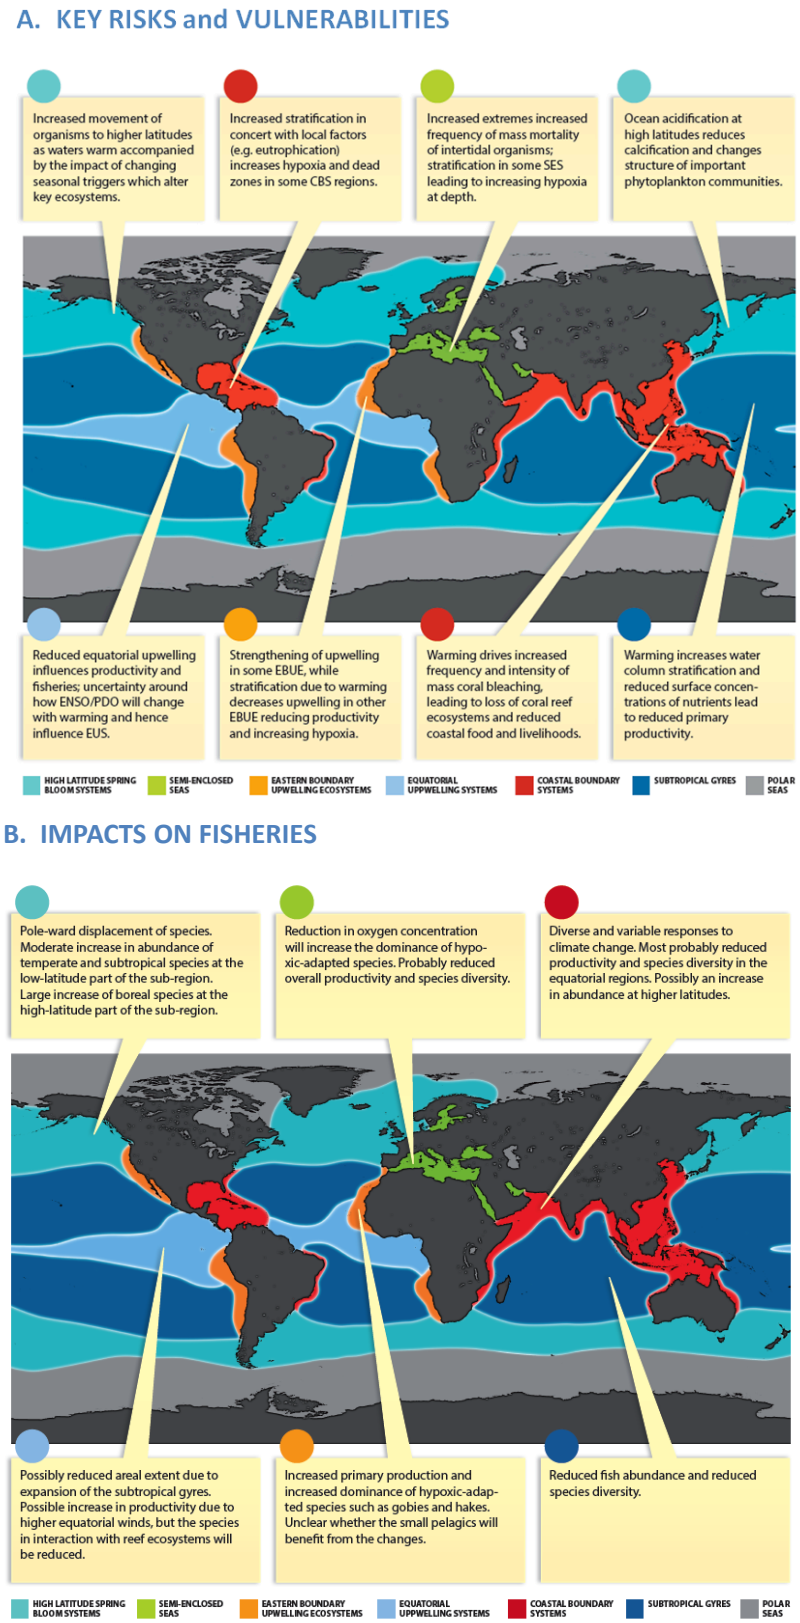

Figure 30-15: A. Summary of regional impacts and opportunities associated with climate change on the world's ocean region. B. Example of changes occurring within fisheries across the Ocean.

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

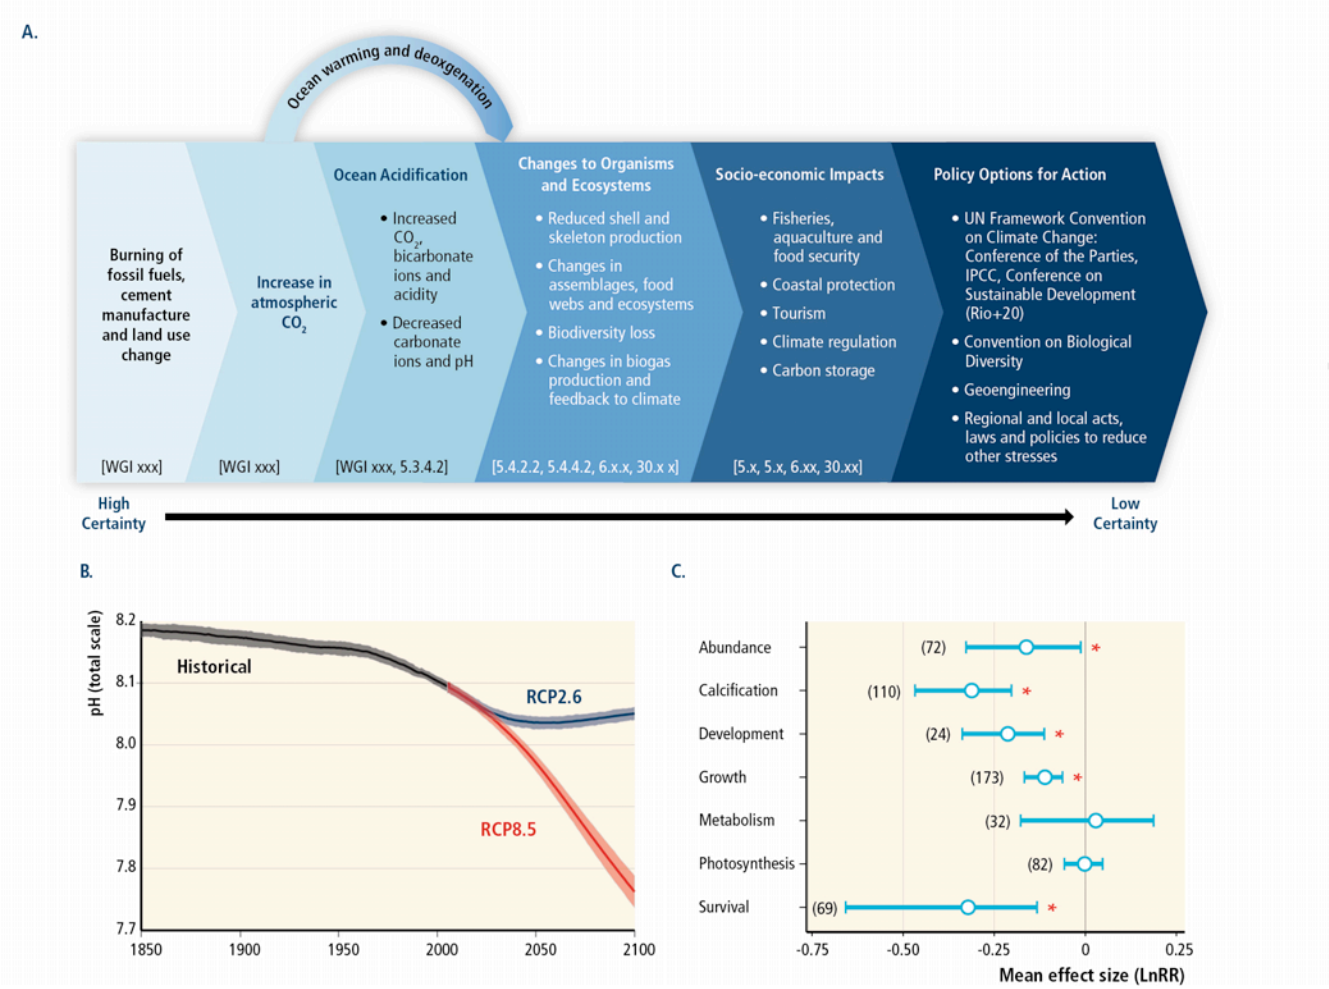

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.
