Table 4-1: Biome shifts from 1700 to the present from published field research that examined trends over periods > 30 y for biomes in areas where climate (rather than land-use change or other factors) predominantly influenced vegetation, derived from a systematic analysis of published studies (Gonzalez *et al.* (2010). Pre-AR4 publications are included to provide a comprehensive review. Shift type: elevational (E), latitudinal (L), examined but not detected (N). Biomes (and abbreviations), from poles to equator: tundra and alpine (UA), boreal conifer forest (BC), temperate conifer forest (TC), temperate broadleaf forest (TB), temperate shrubland (TS), tropical grassland (RG), tropical woodland (RW). Rate of change in temperature (Temp.) and fractional rate of change in precipitation (Precip.) are derived from linear least squares regression of 1901-2002 data (Mitchell and Jones, 2005; Gonzalez *et al.*, 2010). The table provides general regional climate trends at 50 km spatial resolution because the references do not give uniform site-specific climate data to compare across locations. The regional trends are consistent with local trends reported in each reference. * rate significant at $P \leq 0.05$).

Table 4-2: Summary of drivers and outcomes of land use / cover scenarios associated with Representative Concentration Pathways (Hurtt et al., 2011).

RCP	Key assumptions / drivers	Land use / cover outcomes
8.5-MESSAGE	No climate change mitigation actions; radiative forcing still rising at 2100 Strong increase in agricultural resource use driven by the increasing population (rises to 12 billion people by 2100) Yield improvements and intensification assumed to account for most of production increases	**Increase in cultivated land by about 305 million ha from 2000 to 2100** **Forest cover declines by 450 million ha from 2000 to 2100** **Arable land use in developed countries slightly decreased - all of the net increases occur in developing countries.**
6.0-AIM	Mitigation actions taken late in the century to stabilize radiative forcing at 6 Wm^{-2} after 2100 Population growth and economic growth Increasing food demand drives cropland expansion	**Urban land-use increases** **Cropland area expands** **Grassland area declines** **Total forested area extent remains constant**
4.5-GCM	Mitigation stabilizes radiative forcing at 4.5 Wm–2 before 2100 Assumes that global GHG emissions prices are invoked to limit emissions and therefore radiative forcing. Emissions pricing assumes all carbon emissions charged an equal penalty price, so reductions in land-use change carbon emissions available as mitigation Food demand met through crop yield improvements, dietary shifts, production efficiency and international trade.	**Preservation of large stocks of terrestrial carbon in forests** **Overall expansion in forested area** **Agricultural land declines slightly due to afforestation,**
2.6-IMAGE	Overall trends in land use and land cover mainly determined by demand, trade and production of agricultural products and bio-energy	**Much agriculture relocates from high income to low income regions** **Increase in bio-energy production, new area for bioenergy crops near current agricultural areas.**

Figure EA-1: Adapted from Munang *et al.* (2013). Ecosystem based adaptation approaches to adaptation can utilize the capacity of nature to buffer human systems from the adverse impacts of climate change through sustainable delivery of ecosystems services. A) Business as Usual Scenario in which climate impacts degrade ecosystems, ecosystem service delivery and human well-being B) Ecosystem-based Adaptation Scenario which utilizes natural capital and ecosystem services to reduce climate-related risks to human communities.

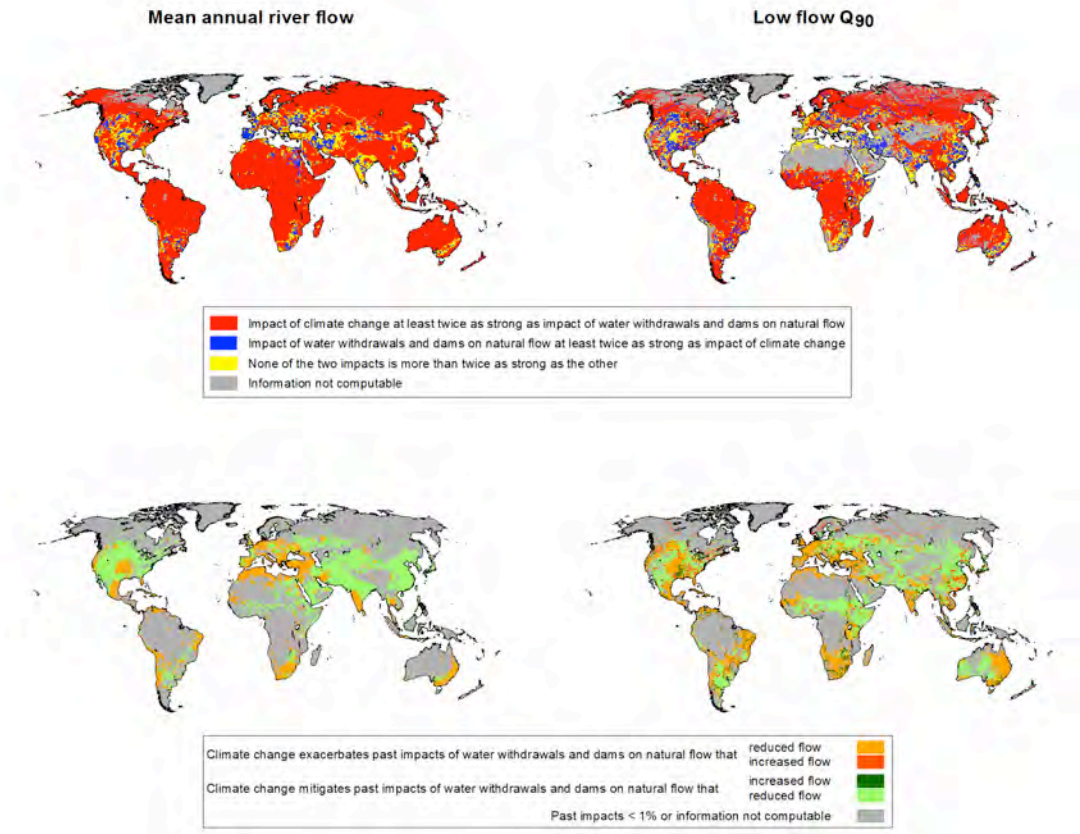

Figure RF-1: Impact of climate change on the ecologically relevant river flow characteristics mean annual river flow and monthly low flow Q_{90} as compared to the impact of water withdrawals and dams on natural flows, as computed by a global water model (Döll and Zhang, 2010). Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002.

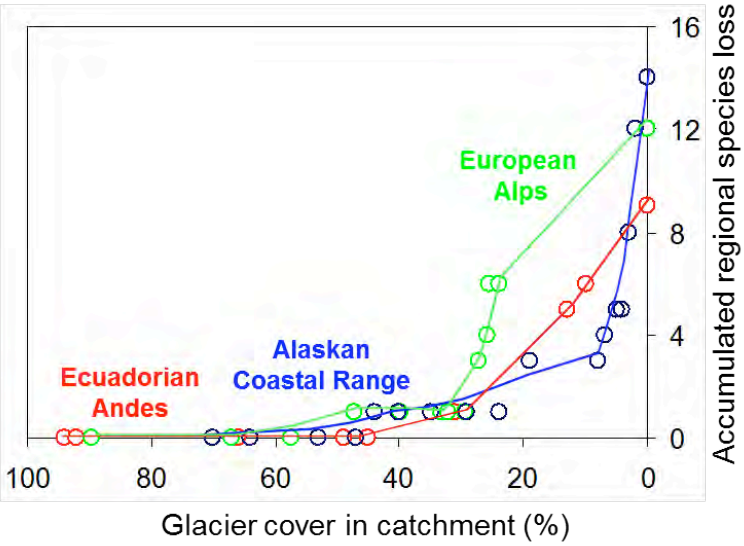

Figure RF-2: Accumulated loss of regional species richness (gamma diversity) as a function of glacial cover GCC. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%. Each data point represents a river site and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.

Executive Summary

Coastal systems and low-lying areas will increasingly experience adverse impacts associated with submergence and extreme sea level flooding due to relative sea level rise (*high confidence*). Large spatial variations in the projected sea level rise, together with local factors such as subsidence suggests that relative sea level rise can be considerably larger than projected GMSL and therefore is an important consideration in impact assessments (*very high confidence*) [5.3.1]. Changes in storms and associated storm surges may further contribute to changes in sea level extremes but the small number of regional storm surge studies, limited spatial coverage and different modelling approaches used means that there is *low confidence* in projections of storm surge [5.3.3.2].

Acidification and warming of coastal waters will continue with significant consequences for coastal ecosystems (***high confidence***). The increase in acidity will be higher in areas where eutrophication is an issue with negative consequences for many calcifying organisms (*high confidence*) [5.4.2.2, 5.4.2.4]. The interaction of acidification and warming exacerbates coral bleaching and mortality (*very high confidence*) [5.4.2.4, Box CC-OA]. Warming will cause a decline of vegetated coastal habitats across the temperate zone [5.4.2.3]. Temperate seagrass and kelp ecosystems will decline with the increased frequency of heat waves and sea temperature extremes as well as through the impact of invasive subtropical species (*high confidence*). The decline of seagrass and kelp habitats will affect food webs, biodiversity and biogeochemical cycling in these ecosystems (*very high confidence)*. In the absence of adaptation, beaches, sand dunes and cliffs currently eroding will continue to do so under increasing sea levels (*high confidence*) [5.4.2.1.-5.4.2.2.]. Increased human-induced drivers have been the primary drivers of change in coastal aquifers, lagoons, estuaries, deltas and wetlands (*very high confidence*). Climate-induced drivers will exacerbate currently existing problems in these natural systems (*very high confidence*) [5.4.2.3-5.4.2.7].

The population and assets exposed to coastal risk as well as human pressures on coastal ecosystems will increase significantly in the coming decades due to population growth, economic development, urbanization and coast-ward migration of people (*high confidence*). Under medium population projections, the population exposed to the 1 in 100 year coastal flood is expected to increase from 271 million in 2010 to 345 million in 2050 due to socio-economic development only [5.4.3.1]. This increase in coastal population is expected to further exacerbate human pressures on coastal systems resulting from excess nutrient input, reduced run-off and sediment delivery (*high confidence*) [5.3.4.3, 5.3.4.4, 5.3.4.5, 5.3.4.6].

The costs of inaction are larger than the sum of adaptation and residual damage costs for the 21st century and at the global scale (*high agreement*). Without adaptation, hundreds of million people will be affected by coastal flooding and be displaced due to land loss through submergence and erosion by 2100; the majority of these affected are from East, Southeast and South Asia (*high confidence*). [5.4.3.1]. Even with very extreme mean sea-level rise of 1.3m by 2100, protection is considered economically rational for most developed coastlines in most countries (*high agreement*) [5.5.3]. Under medium socio-economic development assumption, the expected direct global annual cost of coastal flooding (adaptation and residual damage costs) may reach US$300 billion per year in 2100 without adaptation and US$90 billion per year with adaptation under a 1.26 m sea-level rise scenario [5.5.3]

The impacts of climate change on coasts and the required level of adaptation vary strongly between regions and countries (*high confidence*). While developed countries are expected to be able to adapt to even high levels of sea-level rise, small island states and some low-lying developing countries are expected to face very high impacts and associated annual damage and adaptation costs of several percentage points of GDP (*high agreement*) [5.5.3]. Developing countries and small island states within the tropics relying on coastal tourism, are impacted not only directly by future sea-level rise and associated extremes but also by the impacts of coral bleaching and ocean acidification and reductions in tourist flows from other-regions **(***very high confidence*). [5.4.3.4]

Since AR4, the analysis and implementation of coastal adaptation has progressed significantly but much more effort is needed for a transition towards climate resilient and sustainable coasts (*very high confidence*). The analysis of adaptation has progressed towards novel approaches such as robust decision making and adaptation pathways that recognize that the deep uncertainty in projections of drivers does not have to be a barrier to adaptation (*high confidence*) [5.5.2.2]. Adaptation analysis and implementation have also progressed towards considering the institutional context and governance of adaptation, albeit many governance challenges related to vertical and horizontal policy integration, political will and power relations remain (*very high confidence*) [5.5.2.3, 5.5.2.4]. Many countries, sates/provinces, cities and communities are now carrying out adaptation activities including the mainstreaming of coastal adaptation into relevant strategies and management plans (*very high confidence*) [5.5.4].

5.1. Introduction

This chapter presents an updated picture of the impacts, vulnerability and adaptation of coastal systems and low-lying areas to climate change, with emphasis on sea-level rise. Unlike the coastal chapter in the previous assessment

(AR4), some materials pertinent to the oceans are not covered in this chapter but in two new ocean chapters (Chapters 6 and 30).

The topics covered in this chapter follow the outline for sectoral chapters approved by the IPCC. An Executive Summary summarizes the key messages with a line of sight to the supporting sections in the chapter.

This chapter comprises six sections with this first section dealing with progress in knowledge from AR4 to AR5 scope of chapter and new developments. Section 2 defines the coastal systems and climate and non-climate drivers. The coastal systems include both natural systems and human systems and this division is generally followed throughout the chapter. The climate and non-climate drivers are assessed in section 3, followed by the impacts, vulnerabilities and risks in section 4. Section 5 deals with adaptation and managing risks. Information gaps, data gaps and research needs are assessed in section 6. There are 8 boxes on specific topics or examples, including 3 cross-chapter boxes, distributed within the chapter.

In the AR4, the coasts chapter assessed the impact of climate change and global sea-level rise up to 0.6 m to 2100 The coastal systems were deemed be affected mainly by higher sea level, increasing temperature, changes in precipitation, larger storm surges and reduction in ocean pH. Human activities had continued to increase their pressure on the coasts with rapid urbanization in coastal areas and growth of megacities with consequences on the coastal resources. Regionwise, South, Southeast and East Asia, Africa and small islands were identified most vulnerable. The AR4 chapter offered a range of adaptation measures, many under the ICZM (integrated coastal zone management) framework that could be carried out in the developed and developing countries, but recognized that the latter would face more challenges. Various issues on increasing the adaptive capacity or increasing the resilience of coastal communities were discussed. The unavoidability of sea level rise in the long term, even with stringent mitigation was noted, and adaptation would become an urgent issue.

A number of key issues related to the coasts have arisen since the AR4. There is now better understanding of the natural systems, their ecosystem functions, their services and benefits to humanity and how they can be affected by climate change. Their linkages landward to the watersheds and seaward to the seas and oceans need to be considered for a more integrated assessment of climate change impacts. GMSL are projected to be 0.46 to 0.96 cm by 2100 although regional variations in sea level rise may see values vary by up to 20% of GMSL for most countries and as much as 50% for some (WG1 Chapter 13). This may have serious implications for coastal cities, deltas and low-lying states. While higher rates of coastal erosion are generally expected under rising sea levels, the complex inter-relationships between the geomorphological and ecological attributes of the coastal system and the relevant climate and oceanic processes need to be better established at regional and local scales.

Also of concern is ocean acidification and potential impacts of reduced calcification in shellfish and impacts on commercial aquaculture (Barton *et al.*, 2012). Together with warming, acidification also causes coral reefs to lose their structural stability with negative implications for reef communities and shore protection (Sheppard *et al.*, 2005; Manzello *et al.*, 2008; see also Box CC-OA). A significant number of new findings regarding the impacts of climate change on human settlements, key coastal systems such as rocky coasts, beaches, estuaries, deltas, salt marshes, mangroves, coral reefs and submerged vegetation have become available since the AR4 and are reviewed in this chapter. However, uncertainties regarding projections of potential impacts on coastal systems remain high.

This chapter also provides advances in both vulnerability assessments and the identification of potential adaptation actions, costs, benefits and tradeoffs. A larger number of new studies estimate the cost of inaction versus potential adaptation. Coastal adaptation has become more acceptable and a wider range of approaches and frameworks such as integrated coastal management, ecosystem-based adaptation, community-based adaptation and disaster risk reduction and management are being used.

Climate change will interact differently with the variety of human activities and other drivers of change along coastlines of developed and developing countries. For coastlines of developed countries, changes in weather and climate extremes and sea-level rise may impact for example, demand for housing, recreational facilities and construction of renewable energy infrastructure at the coast (Hadley, 2009). On coasts of developing countries,

weather and climate extremes put an additional risk to many of the fastest-growing coastal urban areas, such as in Bangladesh and China (McGranahan *et al.,* 2007; Smith 2011).

5.2. Coastal Systems

Coastal systems and low-lying areas, also referred to as simply coasts in this assessment are areas near to mean sea level. Generally, there is no single definition for the coasts and the coastal zone/area where the latter has an emphasis on area or extent. In relation to exposure to potential sea-level rise, the LECZ (low-elevation coastal zone) has been used in recent years with reference to specific area and population up to 10 m elevation (Vafeidis *et al.*, 2011). This chapter does not consider the polar coasts (chapter 28), small islands (chapter 29), many of which are low-lying, or the region beyond the continental shelf (chapters 6 and 30).

The coastal systems are conceptualized to consist of both natural systems and human systems (Figure 5-1). The natural systems include distinct coastal characterizations and ecosystems such as rocky coasts, beaches, barriers and sand dunes, estuaries and lagoons, deltas, wetlands and coral reefs. These elements help to define the seaward and landward boundaries of the coast. While they provde a wide variety of regulating, provisioning, supporting and cultural services (MEA, 2005) they have been altered and heavily influenced by human activities with climate change constituting only one amongst many pressures these systems are facing. The human systems include the built environment (settlements, infrastructure and transport networks), human activities (e.g., tourism, aquaculture, etc) as well as formal and informal institutions that organize human activities (e.g., policies, laws, customs, norms and culture). Both systems together form a tightly coupled social-ecological system (SES) (Berkes and Folke, 1998; Hopkins *et al.,* 2012).

[INSERT FIGURE 5-1 HERE

5.3. Drivers

5.3.1. Introduction

In TAR and AR4 changes in climate drivers (any climate-induced factor that directly or indirectly causes a change), including sea level rise, were projected for different SRES emissions scenarios (Nakicenovic and Swart, 2000). Consequently, to date, most of the impacts and vulnerability assessments of climate change in coastal areas are based on SRES A2, A1B, B2 and A1F1 scenarios. Since AR4 a new scenario process has been initiated to replace the SRES scenarios with Representative Concentration Pathways (RCPs) and Shared Socio-economic Pathways (SSPs) (Moss *et al.,* 2010). The RCPs are scenarios specifying concentrations, rather than emissions, thereby avoiding differences in concentrations of Long-Lived Greenhouse Gas and aerosol concentrations for the same emissions scenarios that can arise from the use of different models (van Vuuren *et al.,* 2011). For a comparison between RCP and SRES scenarios see WG1, Chapter 1, Box 1.2. In addition, Extended Concentration Pathways (ECPs) have been introduced for the period 2100-2300 (Meinhausen *et al.* 2009) providing the opportunity to assess the long-term commitment to sea-level rise, which is *very likely* to continue beyond 2500 unless global temperature declines (WG1, Chap.1, 13.5.2).

The SSPs provide representative qualitative story lines (narratives) of world development together with quantitative pathways of key socio-economic variables such as GDP and population (O'Neil *et al.*, 2011). A preliminary list of 5 SSPs have been proposed (Arnell *et al.*, 2011; O'Neil *et al.*, 2011) and will be discussed in 5.3.4.1 and work to further refine these is ongoing (Kriegler *et al.* 2012; Van Vuuren *et al.,* 2012). SSPs do not include assumptions about mitigation policy and are thus independent from RCPs in the sense that the same SSP may lead to different concentration levels and hence rises in sea-level depending on the level of mitigation reached (Arnell *et al.,* 2011; O'Neil *et al.*, 2011).

5.3.2. Relative Sea Level Rise

Relative sea level rise poses a significant threat to coastal systems and low-lying areas around the globe leading to inundation and erosion of coastlines, contamination of freshwater reserves and food crops (Nicholls, 2010). Sea level rise due to thermal expansion as the oceans warm, together with meltwater from glaciers, icecaps and ice sheets of Greenland and Antarctica are the major factors that contribute to relative sea level rise globally. However, the subsidence of coastal land due to sediment compaction, subsurface resource extraction (e.g. groundwater, gas and petroleum; Syvitski *et al.*, 2009), glacial isostatic rebound and tectonic movement may also contribute to relative sea level rise locally and therefore requires consideration in coastal impact studies. Sea level impacts are most pronounced during episodes of extreme sea levels and these are discussed in 5.3.3.

5.3.2.1. Global Mean Sea Level

Although sea level change can exhibit large regional variability on different time scales from factors such as climate variability and ocean circulation patterns, it is *very likely* that over the 20th Century, global mean sea level (GMSL) rose at a mean rate between 1.5 to 1.9 mm yr^{-1} and since 1993, at a rate between 2.8 to 3.6 mm yr^{-1}. Ocean thermal expansion and melting of glaciers have been the largest contributors, accounting for over 80% of the MSL rise over the latter period (AR5, Chapter 13). Future contributions to GMSL rise during the 21st century will *very likely* exceed the observed rate for the period 1971–2010 for all RCP scenarios. Sea levels will continue to rise beyond the 21st Century. Projections for sea levels are available for 2200 to 2500 although these are based on fewer and simpler models that include lower resolution coupled climate models for thermal expansion and ice sheet models coupled to climate models to project ice sheet contributions. The basis for the projections are the Extended Concentration Pathways (ECPs) and projections are provided for low, medium and high scenarios which relate to atmospheric GHG concentrations <500 ppm, 500-700 and > 700 ppm respectively (13.5.2). Projections of GMSL for a range of time horizons are summarized in Table 5-1.

[INSERT TABLE 5-1 HERE
Table 5-1: Projections of global mean sea level rise in metres relative to 1986–2005 based on ocean thermal expansion calculated from climate models, the contributions from glaciers, Greenland and Antarctica from surface mass balance calculations using climate model temperature projections, the range of the contribution from Greenland and Antarctica due to dynamical processes, and the terrestrial contribution to sea levels, estimated from available studies. For sea levels up to and including 2100, the central values and the 5-95% range is given whereas for projections from 2200 onwards, the range represents the model spread due to the small number of model projections available (source: WG1, Chapter 13).]

[INSERT TABLE 5-2 HERE
Table 5-2: Main climate-related drivers for coastal systems, their trends due to climate change, and their main physical and ecosystem effects (↑ increase; ↓ decrease; ⊄ no change; ? uncertain; ↔ regional variability).]

5.3.2.2. Regional Sea Level

The impacts of sea level rise will not be uniform in space and time. Natural modes of climate variability influence sea levels in different regions of the globe and this will affect the rate of rise on interdecadal time periods. For example in the equatorial Pacific, sea levels can vary from the global mean by up to 40 cm due to ENSO (e.g. Walsh et al, 2012) and this can strongly influence trends on decadal scales. Regional variations in the rate of sea level rise at the coast can arise from climate and ocean dynamical processes such as changes in winds and air pressure, air-sea heat and freshwater fluxes, ocean currents and their steric properties. Changes in gravitational processes due to the redistribution of water mass and changes in the shape of the sea floor also contribute. Although the vast majority of coastlines are experiencing sea level rise, coastlines near current and former glaciers and ice sheets are experiencing sea level fall. Under RCP4.5 and 8.5, it is *very likely* that about 72% and 77% respectively of the world's coastlines will experience a sea level change that is within ±20% of the GMSL change, although some coastlines may experience a rise of up to 50% above the GMSL (AR5, Chapter 13.6).

5.3.2.3. Local Sea Level

As well as long-term vertical land movements from GIA (glacial isostatic adjustment), relative sea level rise due to subsidence of coastal plains can occur through other natural causes. For example, tectonic movements, both sustained and abrupt, have brought about relative changes of sea level. The Tohoku earthquake in 2011 caused subsidence of up to 1.2 m along ~400 km of the Pacific coast of northeast Japan. The Sumatra-Andaman earthquake in 2004 and subsequent earthquakes in 2005 produced vertical deformation ranging from uplift of 3 m to subsidence of 1 m (Briggs *et al.*, 2006). These movements are especially important in coastal zones located near active plate margins.

Anthropogenic causes of relative sea level rise include sediment consolidation from building loads, reduced sediment delivery to the coast and extraction of subsurface resources such as gas, petroleum and groundwater. Subsidence rates may also be sensitive to the rates of oil and gas removal (e.g. Kolker *et al*., 2010). Syvitski *et al*., (2009) estimate that the majority of the world's largest deltas are currently subsiding at rates that are considerably larger than the current rates of sea level rise because of coastal sediment starvation due to substantial dam building over the 20th century or sediment compaction through natural or anthropogenic activities. Many large cities on deltas and delta plains have subsided during the last 100 years, by up to 5 m in eastern Tokyo, 3 m in Shanghai, 2 m in Bangkok, and 3 m in the Po delta (Nicholls, 2011; Teatini *et al.*, 2011). Loads from massive buildings and other large structures can also increase sediment compaction and subsidence (Mazzotti *et al.*, 2009). Relative sea level rise can exceed GMSL rise by an order of magnitude, reaching more than 10 cm/y and it is estimated that the delta surface area vulnerable to flooding could increase by 50% under projected sea-level rise in the twenty-first century (Syvitski et al, 2009).

5.3.2.4. Summary

Observed trends in mean sea level together with projected increases for 2100 and beyond means that coastal systems and low-lying areas will increasingly experience adverse impacts associated with submergence (*high confidence*). Large spatial variations in the projected sea level rise, together with local factors such as subsidence suggests that relative sea level rise can be much larger than projected GMSL and therefore is an important consideration in impact assessments (*very high confidence*).

5.3.3. Climate-related Drivers

Increasing greenhouse gases in the atmosphere produce changes in the climate system on a range of time scales that impact the coastal physical environment. On shorter time scales, physical coastal impacts such as inundation, erosion and coastal flooding arise from severe storm-induced surges, wave overtopping and erosion. On longer time scales, changes in wind and wave climate can cause changes in sediment transport at the coast that may also lead to erosion or accretion. Natural modes of climate variability, which can affect severe storm behaviour and wind and wave climate, may also undergo anthropogenic changes in the future. Ocean temperatures can affect species distribution and lead to declines in some species thereby leading to changes in coastal biodiversity. CO_2 uptake in the ocean increases ocean acidity and reduces the saturation state of carbonate minerals, essential for shell and skeletal formation in many coastal species. Past and future changes to these physical drivers are discussed in this section.

5.3.3.1. Severe Storms

Severe storms lead to strong winds and regions of low pressure which, over coastal seas can generate storm surges and high waves. The severity of these depends also on the storm's track, regional bathymetry and nearshore hydrodynamics. Tropical cyclones pose a significant threat to coastal population (see Box 5-2), mostly due to the

associated storm surge, which may combine with fresh water flooding due to extreme rainfall (Rappaport, 2000) and increase the extent of coastal flooding. Extratropical cyclones (ETCs) occur throughout the mid latitudes of both hemispheres and their development is linked to large-scale circulation patterns. Assessment of changes in large-scale climate circulation features indicate that there has been a widening of the tropical belt, poleward shift of storm tracks and jet streams and contraction of the polar vortex leading to the assessment that it is *likely* that, in a zonal mean sense, circulation features have moved poleward (Chapter 2). However, both Seneviratne *et al.* (2012) and AR5 concluded that there is *low confidence* regarding regional changes in intensity of extratropical cyclones. With regards to future changes, models tend to agree on a southward shift in the SH storm track and a global reduction of ETC numbers. However there is *high confidence* that the reduction in the global number of extra-tropical cyclones due to global warming will be small (less than a few percent) and hence small compared to natural interannual variability. There is *high confidence* that a small poleward shift is *likely* in the Southern Hemisphere (AR5 Chapter 14) but changes in the Northern Hemisphere are basin specific and of *lower confidencelower confidence*. There is also *low confidence* in the influence on extreme events of storm track changes.

5.3.3.2. Extreme Sea Levels

Extreme sea levels arise from combinations of factors that include astronomical tides, storm surges, wind and swell waves, sea level variations due to interannual variability and Tsunamis, although the latter are tectonic and therefore not related to climate. The frequency of extreme sea levels will be increased by relative sea level rise. Storm surges, caused by falling atmospheric pressures and surface wind stress associated with storms, may also change if storms are affected by climate change.

Recent global (e.g. Menendez and Woodworth, 2010) and regional studies (e.g. Marcos *et al.*, 2009; Haigh *et al.*, 2010, Losada *et al.* 2013) have found that observed trends in extreme sea levels are mainly consistent with mean sea level trends (SREX, indicating that the increasing frequency of extreme events observed so far is related to rising MSL and not to changes in the behaviour of severe storms. Observations of present sea level extremes due to variability of tides and storm surges have been combined with projections of MSL and their uncertainties, to estimate a "sea level allowance" (Hunter, 2012; Hunter *et al*., 2012) . Assuming that sea level extremes follow a simple extreme value distribution (i.e. a Gumbel distribution), projected MSL rises of 0.542 m (the projected MSL rise for 1990-2100 under an A1FI scenario) and 1.0 m require an additional allowance of 26% and 44% MSL respectively to preserve the current frequency of flooding events (Figure 5-2). Such an allowance can be factored into adaptive responses to rising sea levels. It should be noted however that extreme sea level distributions may not follow a simple Gumbel distribution (e.g. Tebaldi *et al.* 2012) due to different factors influencing extreme levels.

[INSERT FIGURE 5-2 HERE
Figure 5-2: Results of global analysis, indicated by dot diameter. a Factor by which frequency of flooding events will increase with a rise in sea level of 0.5 metres (key is left-hand column of dots in the bottom left-hand corner). b Sea-level rise allowance (metres) for 1990–2100 which conserves frequency of flooding events for the IPCC A1FI Projection based on A1FI emission scenario and AR4-adjusted TAR projections (normal distribution with Δz=0.542 m and σ=0.168 m); key is central column of dots in the bottom left-hand corner. c Sea-level rise allowance (metres) for 21st century which conserves frequency of flooding events for the 1.0/1.0 m Projection, based on post-AR4 results (raised cosine distribution with Δz=1.0 m and W/2=1.0 m); key is right-hand column of dots in the bottom left-hand corner.]

Several regional studies have assessed future changes to storm surges using hydrodynamic models forced by climate models. Extratropical studies show strong regional variability and sensitivity to the choice GCM or RCM (e.g. Debenard and Roed, 2008; Wang et al, 2008; Sterl et al, 2009 for the northeast Atlantic and Colberg and McInnes; 2012 for the southern Australian coastline. The effect of tropical cyclone changes on storm surges have also been investigated in a number of regions including Australia's tropical east coast (Harper *et al*.; 2009), Louisiana (Smith *et al*., 2010), Gulf of Mexico, (Mousavi *et al*., 2011), India, (Unnikrishnan *et al*.; 2011) and New York (Lin *et al*., 2012), and methods used and findings vary considerably between the studies. For example Mousavi *et al*., 2011 developed relationships between current climate cyclone intensities and SSTs and used the projected changes in SSTs from climate models to scale the cyclone intensity whereas Lin et al., (2012) use the cyclones simulated in

four climate models that were scaled-up to realistic cyclone numbers via a synthetic cyclone approach. Lin *et al*., (2012) found that 2 of their 4 models produced changes in storm surges comparable to the projected sea level rise while changes in the other two models were dominated by sea level rise. Non-linear interactions between the storm surge and increased sea level conditions were also highlighted in some studies (e.g. Smith *et al.*, 2010; Mousavi *et al.*, 2012).

The small number of regional storm surge studies combined with the different atmospheric forcing factors and modelling approaches means that there is *low confidence* in projections of storm surges. However, there is *high confidence* that extremes will increase with GMSL rise, thereby leading to large increases in the frequency of extreme sea level events by the end of the 21st century (see also Chapter 13).

5.3.3.3. Winds and Waves

In the context of coasts, wind climate determines large-scale wave climate change, which in turn shapes shorelines. Winds influence longshore current regimes and hence upwelling systems (Narayan *et al.*, 2010; Miranda *et al.*, 2012; see also Chapter 6). Energy dissipation via wave breaking contributes to beach erosion, longshore currents, and elevated coastal sea levels through wave set-up and run-up. Changes to wind and wave climate therefore can affect sediment dynamics and shoreline processes (e.g. Aargaard *et al*., 2004; Reguero *et al.*, 2012) while extreme winds and waves associated with storms are a threat to coastal populations. In addition to shorter period wind waves longer period swell, whose energy dominates the wave energy field, poses a significant danger to coastal and offshore structures, (Semedo *et al.*, 2011) and can causes flooding of coastlines with steep shelf margins (Hoeke *et al*. 2013). The coastal impacts of wave climate change are also a function of wave direction and period as well as the coastline itself, which can influence shoaling and refraction.

For observed changes in wind, Seneviratne *et al*., (2012) concluded that there is *low confidence* in trends calculated from measurements of mean and extreme winds and their causes due to the limited length of records and uncertainties associated with different wind measurement techniques. However, WG1 Chapter 3 notes increasing evidence for a strengthening of the wind stress field in the Southern Ocean since the early 1980s from atmospheric reanalyses, satellite observations and island station data. Regional wave climate is strongly related to modes of climate variability (Seneviratne, 2012) and it is *likely* that there have been positive trends in the North Atlantic, North Pacific and Southern Ocean (Chapter 3, see Table 5-1).

Projected changes in mean and extreme winds and waves were assigned *low confidence* (Seneviratne et al, 2012) owing to limited studies. Although there has been an increase in studies addressing wave climate change (Hemer *et al.*, 2013), generally *low confidence* remains in projected wave climate change (except for *medium confidence* over the southern ocean) and this is due to uncertainties in future winds, particularly those associated with storms (see also Chapter 13.7).

5.3.3.4. Sea Surface Temperature

Sea surface temperature has significantly warmed during the past 30 years along more than 70% of the world's coastlines, with highly heterogeneous rates of change both spatially and seasonally (Lima and Wethey, 2012). The average rate is 0.18 ± 0.16°C per decade and the average change in seasonal timing was -3.3 ± 4.4 days per decade. These values are larger than in the global ocean where the average of change is about 0.1°C per decade in the upper 75 m of the ocean during the period 1970-2009 (WGI, Chap. 3) and the seasonal shift is -2.3 days per decade (Lima and Wethey, 2012). Extreme events have also been reported. For example, the record high ocean temperatures along the Western Australian coast during the austral summer of 2010/2011, with nearshore temperatures peaking at about 5 °C above average, were unprecedented (Pearce and Feng, 2013). In summary, positive trends in coastal SST's are seen on the majority of coastlines and the rate of rise along coastlines is higher on average than the oceans (*high confidence*, *limited evidence*). Based on projected temperature increases there is *high confidence* that coastal SST's exhibiting positive trends will continue to do so.

5.3.3.5. Ocean Acidification

Anthropogenic ocean acidification refers to the changes in the carbonate chemistry primarily due to the uptake of atmospheric CO2 (Box CC-OA). Seawater pH exhibits a much larger spatial and temporal variability in coastal waters compared to open ocean due to the variable contribution of processes other than CO2 uptake (Duarte *et al.*, 2013) such as upwelling intensity (Feely *et al.*, 2008), deposition of atmospheric nitrogen and sulphur (Doney *et al.*, 2007), carbonate chemistry of riverine waters (Salisbury *et al.*, 2008; Aufdenkampe *et al.*, 2011), as well as inputs of nutrients and organic matter (Borges, 2011; Cai *et al.*, 2011). For example, pH (NBS scale) ranges from 6 to 9 in 24 estuaries (Borges and Abril, 2012) and short-term (hours to weeks) changes of up to 0.5 pH units are not unusual in coastal ecosystems (Hofmann *et al.*, 2011).

Few ocean acidification time series exceed more than 5 years in the coastal ocean (Wootton *et al.*, 2008; Provoost *et al.*, 2010; Waldbusser *et al.*, 2010). Some exhibit considerable differences with the open ocean stations illustrating the fact that anthropogenic ocean acidification can be lessened or enhanced by coastal biogeochemical processes (Borges and Gypens, 2010; Feely *et al.*, 2010).

In more recent years, a phosphorus removal policy limited primary production which led to a decrease in pH much larger than would be expected from the absorption of atmospheric CO_2 alone (-0.016 pH unit yr-1). Under the IS92a CO_2 emission scenario, the global pH (total scale) of coastal waters has been projected decrease from about 8.16 in the year 1850 to 7.83 in 2100 (Lerman *et al.*, 2011) but with considerable spatial variability. For example, using the same CO_2 emission scenario Cai *et al.* (2011) projected that the overall decline in 0.74 pH between pre-industrial time and 2100 in the Northern Gulf of Mexico, a value that is much greater than in the open ocean.

To summarise, seawater pH exhibits considerable temporal and spatial variability in coastal areas compared to open ocean due to additional natural and human influences (*very high confidence*). Coastal acidification is projected to continue but with large and uncertain regional and local variations (*high confidence).*

5.3.3.6. Freshwater Input

Changes in river runoff arise from changes in climate drivers such as precipitation and droughts, complex interactions between changing levels of CO_2, plant physiology and hence evapotranspiration (e.g. Gedney et al, 2006; Betts et al, 2007) and other human drivers such as land-use change, water withdrawal, dam building and other engineered modifications to waterways. Such changes can have multiple effects on coastal systems. Not only are changes in the quantity and quality of runoff relevant but also the temporal distribution. Sudden pulsed discharges of freshwater arising from meltwater or storm-induced runoff into marine systems may impact ecosystems unable to deal with low-salinity water and can affect the efficiency of estuaries to retain or filter material delivered by the rivers. This can result in the delivery of riverine nutrients to coastal sea systems that would otherwise have been processed during transit. Generally higher and more variable river runoff arises from lowered retention due to land clearing (Chapter 4) such as for agricultural purposes and this also associated with increased erosion and sediment yield.

An assessment of run-off trends in 925 of the world's largest ocean-reaching rivers, which account for about 73% of global total runoff, indicates that from 1948–2004 statistically significant trends were present in only one third of gauges and of these two thirds exhibited downward trends and one third upward trends (Dai *et al.*, 2009). Precipitation changes dominate the trends, which for flow discharging into the Pacific, Indian and Atlantic Oceans, is also correlated with ENSO. Positive trends in runoff are more prevalent in the Arctic in winter and spring associated with snow melt. While precipitation change dominates freshwater flows, decreasing trends in river discharge may be further enhanced by human pressures (Dai *et al.*, 2009; Chapter 3.2.3).

Average annual runoff is generally projected to increase at high latitudes and in the wet tropics and projected to decrease in most dry tropical regions (Chapter 3). Shifts to earlier peak flows are also projected in areas affected by snowmelt. However, there are some regions where there is considerable uncertainty in the magnitude and direction

of change, specifically south Asia and large parts of South America. Both the patterns of change and the uncertainty is largely driven by projected changes in precipitation.

To summarise, there is *medium confidence (limited evidence)* in a net declining trend in freshwater input globally although large regional variability exists. Trends are dominated by precipitation changes although human pressures on water supply may enhance downward trends (*medium confidence*). Uncertainty in future changes in run-off is linked to precipitation uncertainty. Runoff is generally projected to increase in high latitudes with earlier peak flows and in the wet tropics and decrease in other tropical regions but with large uncertainty (*medium confidence*).

5.3.4. Human Drivers

Coastal systems are subject to a wide range of non climate-related drivers (e.g., Crain *et al.*, 2009) the impacts of which can interact with climate-related drivers and confound efforts to attribute causes of changes. Some of the major human drivers, i.e. human-induced factors that directly or indirectly cause changes, are briefly reviewed below.

5.3.4.1. Socioeconomic Development

One of the most important drivers of coastal impacts is socio-economic development (SED). The current understanding of possible future SED pathways is described through a preliminary set of five shared socio-economic pathways (SSPs; Arnell *et al.*, 2011; O'Neil *et al.*, 2011). The highest GDP and lowest population numbers are attained under SSP1 (called "Sustainability"), which reflects a world progressing towards sustainability with reduced resource intensity and fossil fuel dependency, and SSP 5 (called "Conventional Development"), which reflects a world oriented toward equitable rapid fossil fuel-dominated development. GDP is lowest and population highest under SSP 3 ("Fragmentation"), which reflects a world fragmented into poor regions with low resource intensity and moderately healthy regions with a high fossil fuel dependency. GDP and population under SSP 4 (Inequality) which is a highly unequal world both within and across countries, follows a similar but less extreme trend compared to SSP 3. SSP 2 (Middle of the Road) reflects a world with medium assumptions between the other four SSPs.

There is *very high confidence* that SED has been one of the major drivers of increasing coastal flood damage through increasing exposure (IPCC SREX) and it is expected that this will also be a major driver of climate and sea-level rise impacts during the 21st century (Nicholls and Cazenave, 2010). Currently, the Low Elevation Coastal Zone (LECZ) constitutes 2% of world's land area but contains 10% of world's population (600 million) and 13% of world's urban population (360 million) based on 2000 estimates (McGranahan *et al.*, 2007). Although these estimates are subject to uncertainties (see Lichter *et al.*, 2011; Mondal and Tatem, 2012), they are indicative of the high exposure of low-lying coastal regions. About 65% of the world's cities with populations of over 5 million are located in the LECZ, including a large number of small island states and densely populated mega-deltas (McGranahan *et al.*, 2007). The top 10 exposed cities in terms of exposed population are Mumbai, Guangzhou, Shanghai, Miami, Ho Chi Minh City, Kolkata, Greater New York, Osaka-Kobe, Alexandria and New Orleans (Hanson *et al.*, 2011). In terms of assets exposed, 60% are from the USA, Japan and the Netherlands (Hanson *et al.*, 2011). Comparatively, Asia demonstrates the greatest exposure in terms of population, assets and productivity and the largest increases in exposure through socio-economic development is expected in Asia and Africa (Dasgupta, 2009; Hanson *et al.*, 2011; Kebede and Nicholls, 2012).

For many locations there is *high confidence* that coastal population and assets exposure is growing faster than the national average trends due to coastward migration, coastal industrialization and urbanization (e.g. McGranahan *et al.*, 2007; Smith, 2011; Seto, 2011; WG2 Ch. 8). Coastal net migration has largely taken place in flood- and cyclone-prone areas, which poses a challenge for adaptation (de Sherbinin *et al.*, 2012). These processes and associated land use changes are driven by a combination of many social, economic, and institutional factors including taxes, subsidies, insurance schemes, aesthetic and recreational attractiveness of the coast and increased mobility (Bagstadt *et al.*, 2007; Palmer *et al.*, 2011). In China, the country with the highest exposed population,

urbanization and land reclamation are the major drivers of coastal land-use change (Zhu *et al.*, 2012). Although coastal migration is expected to continue in the coming decades, it is difficult to capture this process in global scenarios as the drivers of migration and urbanization are complex and variable (Black *et al.* 2011).

Socio-economic development also determines the future capacity to adapt. Poor people living in urban informal settlements, of which there are about 1 billion worldwide, are particularly vulnerable to weather and climate impacts (Handmer *et al.*, 2012; de Sherbinin *et al.*, 2012). Of the top ten nations classified by population and proportion of population in coastal low-lying areas the majority are in developing countries (Bollman *et al.*, 2010). SED and associated land reclamation are also major drivers of the destruction of coastal wetlands, which also makes human settlements more vulnerable since wetlands act as natural buffers reducing wave and storm impacts on the coast (e.g., Crain *et al.*, 2009; Shepard *et al.*, 2011). Finally, socio-economic development is expected to further exacerbate a number of human pressures on coastal systems related to changes in freshwater input, water-diversion, nutrients and hypoxia, which will be discussed in the following sections.

[INSERT TABLE 5-3 HERE
Table 5-3: Top ten nations with the largest populations and the highest proportions of population in low-lying coastal areas (Countries with fewer than 100,000 inhabitants are not included; 15 SIDs (Small Island Developing States) with total of 423,000 inhabitants are also excluded). Source: Bollman *et al.*, 2010.]

5.3.4.2. Nutrients

Increased nutrient (i.e. nitrogen, phosphorus) loads to coastal systems in many world regions are observed and simulated by regional and global watershed models ((Alexander *et al.*, 2008; Howarth *et al.*, 1996; Seitzinger *et al.*, 2010). River transported anthropogenic nutrients are primarily due to increased fertilizer use for food production and fossil fuel emissions (NOx) (Bouwman *et al.*, 2009; Galloway *et al.*, 2004).

Anthropogenic global loads of biologically reactive dissolved inorganic N and P (DIN, DIP) are about 2 to 3 times larger than natural sources (Seitzinger *et al.*, 2010) resulting in degradation of coastal ecosystems, including hypoxia. Large variations exist between rivers in the magnitude of nutrient loads and their relative sources. Future trends depend on measures to optimize nutrient use in food production and minimize nutrient loss to rivers from agriculture, sewage, and NOx emissions. Using the Millennium Ecosystem Assessment (MEA) scenario with little emphasis on nutrient management, DIN and DIP global discharge increase by about 30% and 55%, respectively, between 2000 and 2050 (Seitzinger *et al.*, 2010). In the most ambitious MEA nutrient management scenario, global river DIN loads decrease slightly and DIP increases by 35%. In summary, nutrient loads have increased in many regions of the world (*high confidence*).

5.3.4.3. Hypoxia

The presence of excessive nutrients in coastal waters, which causes eutrophication and the subsequent decomposition of organic matter is the primary cause of decreased oxygen concentration (hypoxia). Upwelling of low oxygen waters (e.g., Grantham *et al.*, 2004) and ocean warming, which decreases the solubility of oxygen in seawater (Shaffer *et al.*, 2009) are secondary drivers. The oxygen decline rate is greater in the coastal rather than the open ocean (Gilbert *et al.*, 2010). Hypoxia poses a serious threat to marine life, which is exacerbated when combined with elevated temperature (Vaquer-Sunyer and Duarte, 2010). The number of so-called “dead zones” has approximately doubled each decade since 1960 (Diaz and Rosenberg, 2008). Fisheries catches from these areas are generally lower than predicted from nutrient loading alone (Breitburg *et al.*, 2009). Although non-climate anthropogenic factors are responsible for virtually all hypoxia in estuaries and inner continental shelves, climate drivers such as ocean warming, altered hydrological cycles and coastal currents shifts due to changes in wind patterns may interact with eutrophication in the next decades (Rabalais *et al.*, 2010) (*high confidence*).

5.3.4.4. Sediment Delivery

Human activities in drainage basins and coastal plains have impacted the coastal zone by changing sediment delivery to the coast. Sediment trapping behind dams, water diversion for irrigation, and sand and gravel mining in river channels all act to decrease sediment delivery, whereas soil erosion due to land-use changes acts to increase it. In the 1950s, before widespread dam construction, the global discharge of riverine sediment was estimated to have been ~20 Gt yr^{-1} (e.g., Syvitski *et al.*, 2005; Milliman and Farnsworth, 2011), and it has decreased to 12–13 Gt yr^{-1} (Syvitski and Kettner, 2011). Out of 145 major rivers, only 7 showed evidence of an increase in sediment flux while 68 showed significant downward trends (Walling and Fang, 2003). Two stages of drainage basin development have been identified in patterns of sediment delivery: an increase in the early stage due to soil erosion followed by a decrease in later stages due mainly to dam construction (Syvitski, 2008). The number of dams has increased continuously and their distribution has expanded globally. As of early 2011, the world has an estimated 16.7 million reservoirs larger than 0.01 ha with a combined storage capacity of approximately 8070 km^3 (Lehner *et al.*, 2011). Human pressure is the main driver of the observed declining trend in sediment delivery to the coast (*high agreement*). Reduction of sediment delivery to the coast has impacts on river deltas, contributes to shoreline erosion and threatens mangroves and wetlands (Syvitski, 2008) whereas increase delivery due to soil erosion impacts coastal ecosystems.

5.4. Impacts, Vulnerabilities, and Risks

5.4.1. Introduction

The distinction in the meaning of the terms vulnerability and risk is often unclear in current literature (Ch. 1; SREX; WG2 Glossary), with both terms used interchangeably to describe identical methodological approaches (Hinkel, 2010; Wolf, 2011). Therefore in this chapter, literature assessing vulnerability and risk will be treated together. Diverse approaches are applied for assessing impacts, vulnerability and risk. For impacts on natural systems, the key drivers considered are temperature, ocean acidification and sea level and a variety of approaches are applied including field observations of ecosystem features (e.g. biodiversity, reproduction) and functioning (e.g. calcification, primary production), remote sensing (e.g., extent of coral bleaching, surface area of vegetated habitats) and perturbation experiments in the laboratory and in the field. For impacts on human systems, most approaches focus on relative sea-level rise and can be distinguished in terms of the main biophysical impacts they address (Table 5-4).

[INSERT TABLE 5-4 HERE
Table 5-4: Main impacts of relative sea-level rise. Adapted from Nicholls 2002 and Nicholls *et al.* 2010.]

Sea-level rise exposure approaches are applied at all scales to assess values exposed to sea level rise (e.g., people, assets, ecosystems or geomorphological units). *Submergence exposure approaches* assess exposure to permanent inundation under a given level of sea level rise (e.g., Dasgupta *et al.*, 2008; Boateng, 2012) whereas *flood exposure approaches* assess exposure to temporary inundation during a coastal flood event by combining the extreme water level of the flood event with a given level of sea level rise (e.g., Dasgupta *et al.*, 2009; Kebede and Nicholls, 2012).

Indicator-based approaches are also used at all scales to aggregate data on the current state of the coastal systems into vulnerability indices (Hinkel, 2012), based on either biophysical exposure or hazard variables (e.g., Yin *et al.*, 2012; Bosom and Jimenez, 2011), socioeconomic variables representing a social group's capacity to adapt (e.g., Cinner *et al.*, 2012) or both kinds of variables (e.g., Bjarnadottir *et al.*, 2011; Yoo *et al.*, 2012; Li and Li, 2012).

At local scales (10-100 km coastal length), *process-based models* are applied to assess flooding, erosion and wetland impacts. Approaches include assessments of *flood damage* of single extreme water level events using *hydrodynamic/inundation models* (e.g., Xia *et al.*, 2011; Lewis *et al.*, 2011). M*orphodynamic models* are applied to assess impacts of RSLR on coastal erosion *(*Jiménez *et al. 2009;* Ranasinghe *et al. 2012).* For ecosystem impacts *ecological landscape simulation models* are used to predict habitat change due to sea level rise and other factors (e.g., Costanza *et al.*, 1990, Costanza and Ruth, 1998).

For assessing the impacts of sea level rise at regional to global scales (>1000 km coastal length), heuristic, statistical and economic models together with damage functions are used, as detailed process-based models are not available due to data and computational limits. Global scales assessments have been conducted with the Integrated Assessment Model FUND (Anthoff *et al.*, 2010) and the impact model DIVA (Hinkel and Klein, 2009). These models and their results are discussed in 5.4.3.1 and 5.5.3.

In the impacts on, vulnerabilities of and risks to biophysical systems (5.4.2) and for human systems (5.4.3) are covered. For biophysical systems, we start with impacts on smaller scale systems (e.g., beaches, wetlands, etc.) and proceed to larger scale and compound systems (estuaries and deltas). For human systems, we start with impacts on human settlements as a whole followed by impacts on key sectors that support human settlements. Where possible, all subsections address drivers, observed and projected changes.

5.4.2. Natural Systems

Coastal ecosystems are experiencing large cumulative impact of human activities (Halpern *et al.*, 2008) arising from both land- and ocean-based anthropogenic drivers. Anthropogenic drivers associated with global climate change are distributed widely and are an important component of cumulative impacts experienced by coastal ecosystems. There are few wetlands, mangroves, estuaries, rocky shores or coral reefs that are not exhibiting some degree of impact. Overexploitation and habitat destruction are often the primary causes of historical changes in coastal systems and eutrophication has largely followed rather than driven observed declines in diversity, structure, and functioning (Lotze *et al.*, 2006). Further, extreme climate events generate changes to both the mean and the variance of climatic variables over ecological time scales.

5.4.2.1. Beaches, Barriers, and Sand Dunes

Beaches, barriers and sand dunes constitute about one-third of world's coasts. These dynamic systems often exhibit distinct diurnal and seasonal changes. Due to their attractive attributes, they are highly valued for their recreational and residential value.

Observed impacts

Globally beaches and dunes have in general undergone net erosion over the past century or longer (e.g. see Bird, 2000 for an overview). This erosion is due to a variety of processes with some climate related: rising sea levels (Ranasinghe and Stive, 2009); increases in the frequency of extreme water levels with sea-level rise (Tebaldi *et al.*, 2012); wave propagation caused by sea-level changes realigning shorelines (Tamura *et al.*, 2010); sustained changes in the direction of mean wave energy (Reguero *et al.*, 2013); increased storm waves (Stutz and Pilkey, 2011) and changes in the loss of natural protective structures such as coral reefs (Grevelle and Mimura, 2008) or mangrove forests (Bongaerts *et al.*, 2010). These processes may act at different time scales.

Reasonably accurate maps have been available since about the mid-19th century to compare with more recent maps and imagery to quantify combined climate and non-climate changes. For example, along the U.S. Mid-Atlantic and New England coasts the long-term rate of erosion is 0.5 ± 0.09 m yr^{-1} and 68% showed net erosion based on over 21,000 measurement locations equally spaced along more than 1,000 km of coast (Hapke *et al.*, 2011). However, a survey using historical aerial photographs and satellite images of 27 atoll islands in the central Pacific showed that 86% of the islands have remained stable or increased in area over a 19 to 61 year period, contradicting the widespread perception that small islands are eroding with sea-level rise (Webb and Kench, 2010).

Attributing shoreline changes to climate change is still difficult due to the multiple natural and anthropogenic drivers contributing to coastal erosion. For example, rotation of pocket beaches (i.e. where one end of the beach accretes while the other erodes and then the pattern reverses) of Southeast Australia is closely related to interannual changes

in swell direction (Harley *et al.*, 2010). Additional processes, unrelated to climate change, that contribute to coastal change, include dams capturing fluvial sand (e.g., in Morocco, Chaibi and Sedrati, 2009). Statistically linking sea-level rise to observed magnitudes of beach erosion has been challenging as the coastal sea-level change signal is small relative to other processes (e.g. Sallenger *et al.*, 2000; Leatherman *et al.*, 2000a; 2000b). A Bayesian network incorporating a variety of factors affecting coastal change including relative sea-level rise, has been successful in hindcasting shoreline change, and, hence, may be useful in forecasting change (Gutierrez *et al.*, 2011).

One observed impact of net erosion is clear. Where an eroding shoreline approaches hard, immobile, structures like seawalls or resistant natural cliffs, the beaches will narrow due to coastal squeeze that removes the sands and associated habitats, and potentially steepens the beach slope, impacting the survivability of a variety of organisms (Jackson and McIlvenny, 2011). With coastal squeeze, sand dunes will ultimately be removed as the beach erodes and narrows. Extreme storms can erode and completely remove dunes, degrading land elevations and exposing them to inundation and further change if recovery does not occur before the next storm (Plant *et al.*, 2010).

Projected impacts

Projected sea-level rise may approach 1 m or more by 2100, and in the intervening time the resulting inundation and erosion may become detectable and progressively important. The impacts will *likely* be first apparent by sea-level rise adding to storm surge, making extreme water levels higher and more frequent to attack beaches and dunes (Tebaldi *et al.*, 2012).

Some investigators have used the Bruun rule to calculate erosion by sea-level rise (Bruun, 1962), although there is disagreement about whether the Bruun rule is appropriate (Cooper and Pilkey, 2004; Woodroffe and Murray-Wallace 2012). How to calculate the amount of retreat remains controversial (Gutierrez *et al.*, 2011; Ranasinghe *et al.*, 2012). An increase in storm intensity and ocean swell may accelerate erosion of beaches, barriers and dunes although in places beach response to sea-level rise could be more complex than simple retreat (Irish *et al.*, 2010).

Coastal squeeze will *likely* accelerate with a rising sea level. In many locales, locating sufficient sand to artificially rebuild beaches and dunes will *likely* become increasingly difficult as present supplies near to project sites are depleted. New generation models are emerging to estimate the costs of saving oceanfront homes through beach nourishment relative to the structures cost (McNamara *et al*, 2011). In the absence of adaptation measures, beaches and sand dunes currently affected by erosion will continue to do so under increasing sea levels (*high confidence*).

5.4.2.2. Rocky Shores

According to Davis and FitzGerald (2004) three-quarters of the world's coasts are rocky. They vary from consolidated sediments (lithified coasts) to unconsolidated sediments (unlithified coasts), with different strengths and typically having an abrasional shore platform at their base. They are characterized by very strong environmental gradients, especially in the intertidal zone where challenges are posed by both aquatic and aerial climatic regimes, such as temperature and desiccation

Observed impacts

Cliffs and platforms are erosional features and any change in the climate system that increases the efficiency of processes to act on them, such as relative sea level rise will lead to increased rates of erosion (Naylor *et al.*, 2010). Other significant climate drivers include mid-latitude storminess, wave climate and rainfall regime on cliff dynamics and retreat rates (Brooks and Spencer, 2012). Precipitation and frost appear to have a limited role in cliff retreat (Dornbusch *et al.*, 2008).

Cliffs and platforms have reduced resilience to climate change impacts; once platforms are lowered or cliffs retreat, it is difficult to rebuild them (Naylor *et al.*, 2010). For cohesive clay coasts, rising sea level will usually result in accelerated rates of bluff recession, especially if the rise is rapid (Trenhaile, 2010).

Changes in the abundance and distribution of rocky shore animals and algae in rocky shores have long been recognized (Hawkins *et al.*, 2008) and perturbation experiments provided information about environmental limits, acclimation and adaptation, particularly to changes in temperature (Somero, 2012). The challenge is to distinguish the response that are due to climatic drivers from those due non-climatic drivers, or to natural temporal and spatial fluctuations.

Helmuth *et al.* (2006) reported shifts of range limits of many intertidal species of up to 50 km per decade, much faster than most recorded shifts of terrestrial species. However, the geographical distribution of some species has not changed in recent decades, may be due to weak local warming (Rivadeneira and Fernández, 2005) or overriding effects of variables such as timing of low tide, hydrographic features, lack of suitable substrata, poor larval dispersal, and effects of food supply, predation and competition (Helmuth *et al.*, 2002, 2006; Poloczanska *et al.*, 2011).

The dramatic decline of biodiversity in mussel beds of the Californian coast, with a 59% loss in species richness between the 1960s and 2002, has been attributed to large-scale processes associated with climate change (*high confidence*; Smith *et al.*, 2002). A strong impact of temperature and food availability was shown in mussels on the coast of Oregon, with higher growth during warm than cool events (Menge *et al.*, 2008). Warming also reduced predator-free space on rocky shores, which lead to a decrease of the vertical extent of mussel beds by 51% in 52 years in the Salish Sea, and the disappearance of reproductive populations of mussels at several sites, illustrating the alteration of interspecific interactions by climate change (Harley, 2011).

Rocky shores are one of the few ecosystems for which field evidence of the effects of ocean acidification is available. Observational and modeling analysis have shown that the community structure of a rocky shore site of the NE Pacific shifted from a mussel to an algal-barnacledominated community between 2000 and 2008 (Wootton *et al.*, 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012).

Projected impacts

Based on contemporary and historic data for shoreline retreat the major driver appears to be sea-level rise (Brooks and Spencer, 2012). Soft-rock recession rates can be estimated by using square root of the relative change in sea-level rise rate while cliff retreat depends not only on total elevation change of sea level but also on the rate of sea-level rise (Ashton *et al.*, 2011).

In a modelling study, Trenhaile (2011) found sea-level rise to trigger faster rates of cliff recession, especially in coasts that are already retreating fast. However, results further suggested that coasts currently retreating slowly would experience the largest proportional increases in retreat rates. Increases in storminess appear to have smaller effects on rocky shores (Trenhaile, 2011; Dawson *et al.*, 2009). Using existing topographical data and a digital elevation model, the intertidal areas of rocky shore in Scotland are estimated to decrease by 10-27% with a 0.3 sea-level rise (Jackson and MacIlvenny, 2011).

Most projections of the effect of climate change on rocky shore ecosystems have used a climate envelope approach using environmental tolerances obtained in laboratory perturbation experiments and assuming that species will remain in their bioclimatic envelope as climatic stressors change. Few have considered the effects of direct and indirect species interactions (Poloczanska *et al.*, 2008; Harley *et al.*, 2011) and the effects of multiple stressors (Helmuth *et al.* 2006).

The abundance and distribution of rocky shore species will continue to vary in a warming world (*high confidence*). The likely long-term consequences of ocean warming on mussel beds of the NE Pacific are both positive (increased growth) and negative (increased susceptibility to stress and of exposure to predation)(*medium confidence*; Smith *et*

al., 2002; Menge *et al.*, 2008). Importantly, these projections are conservative as they do not consider hypoxia (Grantham *et al.*, 2004) or ocean acidification (Feely *et al.*, 2008) which is known to occur in this area.

Despite some shortcomings (Riebesell, 2008), observations performed near natural CO_2 vents in the Mediterranean Sea show that diversity, biomass, and trophic complexity rocky shore communities will decrease at future pH levels (*high confidence*; Barry *et al.*, 2011; Kroeker *et al.*, 2011). An abundant food supply tolerance appears to enable mussels of the Baltic Sea to tolerate low pH (Thomsen *et al.*, 2010, 2012) at the cost of increased energy expenditure. Model projections that assume a linear increase in temperature and ocean acidity, and include the interactive effects of temperature and pH suggests that a local population of a barnacle will become extinct in the English Channel 10 years earlier than would occur if there was only global warming and no concomitant decrease in pH (*medium confidence*; Findlay *et al.*, 2010).

Rising sea level is the major driver for rocky shores retreat (*robust evidence*). With coral reefs, rocky shores are the coastal ecosystem for which there is most evidence of the impacts of climate change. The most prominent effects are range shifts of species in response to ocean warming (*high confidence*) and changes in biodiversity (*high confidence*) in relation to ocean warming and acidification.

5.4.2.3. Wetland and Seagrasses Beds

Vegetated coastal habitats, including mangrove forests, salt marshes, seagrass meadows and macroalgal beds occur as a thin vegetation belt fringing the shoreline (Hemminga and Duarte 2000). Coastal wetlands are prominent features and important habitats in the intertidal zone along the coastline, including mangrove forests and tidal marshes. Seagrass meadows and macroalgal beds extend from the intertidal to the subtidal areas in coastal areas.

Observed impacts

Mangrove forests, salt marshes and seagrass meadows are declining globally (Duarte *et al.*, 2005), rendering shorelines more vulnerable to erosion due increased sea level rise and increased wave action (e.g., Alongi, 2008) and leading to the loss of carbon stored in sediments. Together, the loss of coastal wetlands and seagrass meadows results in the release of 0.04 to 0.28 Pg C annually from organic deposits (Pendleton *et al.* 2012). Recognition of the important consequences of the loss of mangrove forests, salt marshes and seagrass meadows for coastal protection and carbon burial, has led to large-scale reforestation efforts in some nations (e.g. Thailand, India, Vietnam).

The response of saltmarsh to sea level rise involves landward migration of salt marsh vegetation zones and submergence at lower elevations and drowning of interior marshes. Ocean warming is leading to range shifts in vegetated coastal habitats. The poleward limit of mangrove forests is generally set by the 20 ºC mean winter isotherm (Duke *et al.*, 1998). Accordingly, migration of the isotherm with climate change (Burrows *et al.*, 2011) should lead to a poleward expansion of mangrove forests, as observed in the Gulf of Mexico (Perry and Mendelssohn, 2009; Comeaux *et al.*, 2011, Raabe *et al.* 2012), and New Zealand (Stokes *et al.*, 2010), where it leads to increased sediment accretion (*medium confidence*).

Seagrass meadows are already under stress due to climate change (*high confidence*), particularly where maximum temperatures already approach their physiological limit. Heat waves lead to widespread seagrass mortality, as documented for Zostera species in the Atlantic (Reusch *et al.*, 2005), and Posidonia meadows in the Mediterranean Sea (Marbà and Duarte, 2010) and Australia (Rasheed and Unsworth, 2011) (*high confidence*). Warming also favours flowering of P. oceanica (Diaz-Almela *et al.*, 2007), but the increased recruitment rate is insufficient to compensate for the losses resulting from elevated temperature (Diaz-Almela *et al.*, 2009).

Kelp forests have been reported to decline in temperate areas in both hemispheres (Johnson *et al.* 2011, Wernberg *et al.* 2011a,b, Fernández *et al.* 2011), a loss believed to involve climate change (*high confidence*). Decline in kelp populations attributed to ocean warming has been reported in southern Australia (Johnson *et al.* 2011, Wernberg *et*

al. 2011a,b) and the North Coast of Spain (Fernández *et al.* 2011). The spread of subtropical invasive macroalgal species is believed to be facilitated by climate change, adding to the stresses temperate seagrass meadows experience from ocean warming (*medium evidence, high agreement*).

Projected impacts

Ocean acidification (5.3.34; Box CC-OA) is expected to enhance the production of seagrass (Duarte, 2000, McKee *et al.* 2012) and macroalgae (Wu *et al.*, 2008) through the fertilization effect of CO_2. Increased CO_2 concentrations may have already increased seagrass photosynthetic rates by 20% (Hemminga and Duarte, 2000; Hendriks *et al.*, 2010) (*limited evidence, high agreement*).

Coupling of downscaled model projections using the A1B scenario in the Western Mediterranean along with empirically-determined relationships between mortality rates and maximum seawater temperature led Jordá *et al.* (2012) to conclude that seagrass, Posidonia oceanica, meadows may become functionally extinct by 2050 to 2060 (*high confidence*). Poleward range shifts in vegetated coastal habitats is expected to continue with climate change (*high confidence*). Reduced ice cover and retreat of coastal glaciers may facilitate the expansion of seagrass meadows and kelp forests along the Arctic (Krause-Jensen *et al.* 2012; *medium confidence*), with cascading effects on the coastal Arctic ecosystem (Krause-Jensen *et al.* 2012).

Elevated CO_2 and ocean acidification are expected to lead to increased productivity of vegetated coastal habitats in the future (Duarte *et al.* 2000) (*high confidence*). However, there is *limited evidence* that elevated CO_2 may increase seagrass survival or resistance to warming (Alexandre *et al.*, 2012; Jordá *et al.*, 2012).

Coastal wetlands and seagrass meadows experience coastal squeeze in urbanized coastline, with no opportunity to migrate inland with rising sea levels. However, increased CO_2 and warming can stimulate marsh elevation gain, counterbalancing moderate increases in rates of sea-level rise (Langley *et al.*, 2009; Kirwan and Mudd, 2012). The net impact of climate change on salt-marsh accretion will be to increase carbon burial rates in the first half of the twenty-first century, with carbon–climate feedbacks diminishing over time (Kirwan and Mudd, 2012) (*medium confidence*).

In summary, climate change will significantly contribute to the continued decline in the extent of seagrass and kelps in the temperate zone (*medium confidence*) and the range of seagrass, mangroves and kelp in the northern hemisphere will expand poleward (*high confidence*). The limited positive impact of warming and increased CO_2 on some vegetated ecosystems will be insufficient to compensate the decline of their extent resulting from other human drivers such as land use change (*very high confidence*).

5.4.2.4. Coral Reefs

Coral reefs are shallow-water structures made of calcium carbonate mostly secreted by reef-building corals and encrusting macroalgae. They are among the most diverse ecosystems and are sources of many benefits through key services provided to humans.

Observed impacts

Coral reefs are susceptible to climate-related and non climated-related processes (see Box CC-CR). Mass coral bleaching has occurred in association with positive temperature anomalies over the past 30 years, sometimes followed by mass mortality (Hoegh-Guldberg, 1999; Kleypas *et al.*, 2008; Baker *et al.*, 2008). Bleaching events are variable in time and space: 7% of the grid cells comprising reefs exhibited at least one bleaching event in 1985-1994 compared to 38% in the subsequent decade due to intense El Niño events. Recovery from the 1998 global bleaching event was generally slow in the Indian Ocean (about 1% yr^{-1}), absent in the western Atlantic and variable elsewhere (Baker *et al.*, 2008).

Warming causes a poleward range expansion of some corals (*high confidence*; Greenstein and Pandolfi, 2008; Yamano *et al.*, 2011). The paleontological record suggests that the observed poleward range extension may soon be followed by equatorial range retractions (Kiessling *et al.*, 2012). Several reef crises of the last 500 Myr were at least partially governed by ocean acidification and warming (Kiessling and Simpson, 2011). Ocean acidification (5.3.3.5, Box CC-OA) has become a recent source of concern because persistence of coral reefs directly depends on the balance between the production and erosion of calcium carbonate (Andersson and Gledhill, 2013). It generally decreases calcification (Kroeker *et al.*, in press) and promotes dissolution of calcium carbonate and bioerosion (Tribollet *et al.*, 2009; Wisshak *et al.*, 2012), leading to a transition from net accretion to net erosion and to poorly cemented reefs (Manzello *et al.*, 2008).

Lower pH decreases calcification in many reef-building corals and coralline algae (Andersson *et al.*, 2011) and may have already decreased (e.g., Gattuso *et al.*, 1999; Silverman *et al.*, 2009) and most (e.g., De'ath *et al.*, 2009, Manzello, 2010) retrospective studies show decreased calcification in recent decades. Attribution has proven difficult but warming rather than acidification appears to be the primary driver (*medium confidence*; Cooper *et al.*, 2012).

Climate-related drivers other than ocean warming and acidification do not seem to have led to any obvious changes since the industrial revolution (*high confidence*). Coral reef growth is intimately linked to sea level but, within the uncertainties of past sea level rise and coral reef growth, most coral reefs seem to have kept pace with the recent sea-level rise (Buddemeier and Smith, 1988).

Projected impacts

The frequency and magnitude of coral bleaching and mortality will increase in the next few decades (*very high confidence*; Hoegh-Guldberg, 1999; Donner *et al.*, 2009; Chapter 30, 30.8.2). Under the A1B CO_2 emission scenario, 99% of the grid cells experience at least one severe bleaching event over 2090-2099 (Figure 5-3; Teneva *et al.*, 2011). Half of the coral reefs may avoid high frequency bleaching through 2100 assuming hypothetical acclimation and/or adaptation (*limited evidence, low agreement*; Logan *et al.*, sbm).

[INSERT FIGURE 5-3 HERE
Figure 5-3: Percent of reef locations (1°x1° grid cells which have coral reefs) that experience no bleaching, at least one mild bleaching event, or at least one severe bleaching event for each decade. Observed bleaching events are summarized from the ReefBase dataset (Kleypas *et al.* 2008). In the observations, some of the "no bleaching" cells may have experienced bleaching but it was either not observed or not reported. Modeled bleaching events are averages of data from four ensemble runs of the Community Climate System Model version 3 using the SRES A1B CO_2 scenario and the standard degree heating month formula (Teneva *et al.*, 2011). The labels of values ≤ 1% are not shown.]

Ocean acidification reduces biodiversity and favours seagrasses and fleshy algae against corals (Fabricius *et al.*, 2011). Since the effects of elevated temperature and acidity are synergistic in several reef-builders (Reynaud *et al.*, 2003; Anthony *et al.*, 2008), their combined impact may be larger than those observed near CO_2 vents today (*high confidence*). Ocean warming and acidification expected under RCP 8.5 will reduce calcification, elevate coral mortality and enhance sediment dissolution (*high confidence*; Manzello *et al.*, 2008). Coral reefs may stop growing and start dissolving when atmospheric CO_2 reaches 560 ppm due to the combined effects of both drivers (*medium evidence*; Silverman *et al.*, 2009).

The maximum rate of vertical accretion has been variable regionally during the last deglaciation (about 20 mm yr^{-1}; Dullo, 2005; Montaggioni *et al.*, 2005) and has not enabled all coral reefs to keep-up with sea level rise. Some reefs kept-up, even when the eustatic sea level rise exceeded 40 mm yr^{-1} (Camoin *et al.*, 2012). Therefore, a number of coral reefs could keep up with the maximum rate of sea level rise of 15.1 mm yr^{-1} projected at the end of the century (WGI, Table 13.5; *medium confidence*). A lower net accretion than during the Holocene, as reported for Caribbean

reefs (Perry *et al.*, 2013) weaken this capability. *high confidence*Reef submergence would increase turbidity leading to increased stress (Storlazzi *et al.*, 2011).

In summary, climate-related drivers are the primary cause of mass coral bleaching and mortality (*very high confidence*) and deteriorate the balance between coral reef construction and erosion (*high confidence*). The future magnitude of these effects will depend on the rates of warming and acidification (*very high confidence*), with a moderating role of biological acclimation and adaptation which appears limited (*medium confidence*).

5.4.2.5. Coastal Aquifers

A coastal aquifer is an underground layer of water-bearing permeable rock or unconsolidated materials from which groundwater can be extracted. Consequently, they are of strategic importance for the water supply of highly populated coastal areas, especially in small islands (Chap. 29, 29.3).

Observed impacts

Coastal aquifers are very sensitive to a range of climate and non climate-related drivers. Temperature and evaporation rise, changes in precipitation and extended droughts that affect aquifer recharge are some of the factors that can contribute to displacement of fresh groundwater by more saline water. Rising sea levels and partial or complete overwash from storm waves or storm surge are also relevant drivers, especially in low-lying areas and islands (Terry and Falkland, 2010, White and Falkland, 2010, Post and Abarca, 2010).

Combined with this, excessive groundwater extraction for coastal settlements and agriculture causes intrusion of saline water from the ocean or from deeper, more saline layers below the aquifer. For example, coastal aquifers on the east and west coasts of the US have experienced increased levels of salinity largely due to excessive anthropogenic water extraction (Barlow and Reichard, 2011). The combination of natural with anthropogenic drivers of over-extraction, pollution, mining for building and erosion due to shoreline works compound groundwater supply problems in small tropical islands in the Pacific, Indian and Atlantic Oceans (White *et al.*, 2007; White and Falkland, 2010). Detailed information on salinization observations in small islands can be found in Chapter 29.

Attribution of saline intrusion to incremental sea level rise is still not sufficiently supported (Rozell and Wong, 2010; White and Falkland 2010). In small islands, observed saltwater intrusion due to flooding and overwash under storm events cannot be attributed to climate change (Chap. 29). Furthermore, Werner (2010) noted that there are fundamental knowledge gaps that impede assessment of changes in seawater intrusion, which are mostly due to uncertainties in the predictive capabilities of the models, limitations in the assessment of small-scale processes and difficulties in characterizing the marine-groundwater interactions.

Projected impacts

The assessment of climate change impacts that may arise from changes in ground water recharge and sea level rise is still challenging, limiting the work currently available on climate change projected impacts on coastal aquifers. Rozell and Wong, 2010 assessed the impact of rising sea levels on fresh water resources on Shelter Island (USA) for two different combinations of precipitation change and sea level rise. Results show that projected impacts were highly dependent on local conditions. Based on a simplified analytical model Ferguson and Gleeson (2012) concluded that the direct impact of groundwater extraction has been and will be much more significant than the impact of sea level rise under a wide range of hydrogeolic conditions and population densities.

In summary, there is *very high confidence* that increased usage of groundwater resources for agriculture and coastal settlements globally has led to a reduction in groundwater quality, including increased salinization (*high agreement, robust evidence*). Human-induced pressure will continue to be the main driver for aquifer salinization (*high*

agreement). Climate change through changing patterns of precipitation, increased storminess and sea level rise will exacerbate these problems (*high agreement, limited evidence*).

5.4.2.6. Estuaries and Lagoons

Coastal lagoons are shallow water bodies separated from the ocean by a barrier and connected at least intermittently to the ocean, while estuaries are the primary conduit for water, nutrients and particulates from land to the sea.

Observed impacts

Sediment accumulation in estuaries is generally very high because of riverine particle delivery but heterogeneous and habitat-specific. Changes in sediment accumulation is directly affected by human drivers, such as dredging, and indirectly via habitat loss, changes in sea-level, storminess and sediment supply by rivers (Syvitski *et al.*, 2005). Coastal lagoons are also highly susceptible to alterations of sediment input and erosional processes driven by changes in sea level, precipitation, and storminess (Pickey and Young, 2009). Estuarine water with low tidal range are strongly affected by changes in run-off since the residence time depends on the relative strengths of runoff and tidal forcing and governs many ecosystem processes including nutrient processing, the metabolic balance, carbon dioxide exchange and hypoxia (Howarth *et al.*, 2009; Canuel *et al.*, 2012). River floods and other runoff events have been reported to impact estuarine communities and deliver large quantities of organic matter to coastal systems, controlling the cycling of organic matter and nutrients (Canuel *et al.*, 2012; Statham, 2012).

Enhanced nutrient delivery (5.3.4.3) has resulted in major changes in biogeochemical processes, community structure and ecosystem functions (Howarth *et al.* 2009), including enhanced primary production which has affected coastal fishery yield (Nixon, 1982; Savage *et al.*, 2012). Eutrophication has modified food-web structure (*high confidence*) and led to more intense and longer lasting hypoxia (5.3.4.4), more frequent occurrence of harmful algal blooms (*high confidence*; Breitburg *et al.*, 2009; Howarth *et al.*, 2009) and to enhanced emission of nitrous oxide (*high confidence*; Kroeze *et al.*, 2010; de Bie *et al.*, 2002).

Projected impacts

The increase of atmospheric carbon dioxide levels will reduce the efflux of CO_2 from estuaries (Borges, 2005; Chen and Borges, 2009; *high confidence*). Its impact on the pH of estuarine and lagoon waters will generally be limited because other drivers are generally more important (*high confidence;* 5.3.3.4 and Box CC-OA). For example, recent changes in the freshwater flow in the Scheldt estuary was the main factor controlling pH, either directly via a decreased supply of dissolved inorganic carbon and total alkalinity, and, indirectly, via the decreased input ammonia loadings and lower rates of nitrification (Hofmann *et al.*, 2009).

Sea-level rise will have likely impact sediment redistribution, the partitioning of habitats within estuaries and landward lagoon extension (*high confidence*; Anthony *et al.*, 2009) Lagoons may shrink because landward migration is restricted due to human occupation on the landward side (Pilkey and Young, 2009: Anthony *et al.*, 2010; Stutz and Pilkey, 2011).

Changes in hydrology could affect lagoons and estuaries in multiple ways. The water residence time could either increase or decrease, depending on direction and magnitude of changes in discharge and precipitation-evaporation balance (Anthony *et al.*, 2009) with diverging impacts on primary production, fisheries and aquaculture (Smith *et al.*, 2005b; Webster and Harris, 2004; Canu *et al.*, 2010). Altered riverine discharge may affect estuarine stratification with consequences for ecosystem metabolic balances, intensity and occurrence of biogeochemical processes, organism distribution patterns and frequency and duration of hypoxia (Hong and Shen, 2012; Rabalais *et al.*, 2009). However, stronger winds and droughts may reduce the extent, duration and frequency of estuarine stratification, counteracting the decrease in oxygen concentration (*medium confidence*; Rabalais *et al.*, 2009). Changes in precipitation extremes and freshwater supply may induce dramatic fluctuations in salinity with

associated dverse impacts on benthic macrofauna and ecosystem functions (Pollack *et al.*, 2011; Levinton *et al.*, 2011; Fujii and Raffaelli, 2008; Jeppesen *et al.*, 2007).

Warming will lead to enhanced stratification of estuaries and lagoons, increasing hypoxia (*medium confidence*; Diaz and Rosenberg, 2008; Rabalais *et al.*, 2009). It will also directly affect most biological processes and the trophic status of coastal ecosystem, and higher carbon dioxide emission (*limited evidence, medium agreement*; Canuel *et al.*, 2011). Warming will lengthen the duration of phytoplankton production season (Cloern and Jassby, 2008; *medium confidence*).

Changes in storm events would alter the extent and duration of estuarine stratification (Hong and Shen, 2012), the sediment deposition-erosion balance of lagoons and estuaries (Pilkey and Young, 2009), the structure and functioning of biological communities via the transport of communities and/or of their resources, and the underwater light climate (*medium confidence*; Wetz and Paerl, 2008; Canuel *et al.*, 2012).

Finally, any change in the primary production of lagoons will impact fisheries as there is an empirical correlation between primary production and fisheries yield (*limited evidence, medium agreement*; Nixon, 1982). For example, seawater warming and changes in seasonal patterns of precipitations projected in the Venice lagoon using the SRES A2 CO_2 emission scenario for the period 2071-2100, leads to a reduction in plankton production, a decline of habitat suitability for clam growth and aquaculture (Canu *et al.*, 2010).

In summary, the primary drivers of change in lagoons and estuaries are human drivers rather than climate change (*very high confidence*). Future changes in climate-related drivers such as warming, acidification, waves, storms, sea level and run-off will have consequences on the functions and services of ecosystems in lagoons and estuaries (*high confidence*) but the impacts cannot be assessed at the global scale as the key drivers operate at a local to regional scale.

5.4.2.7. Deltas

Deltas are low-lying coastal landforms formed by riverine sediments in the areas around river mouths, mostly during the last 6000–7000 years of relatively stable sea level. They are characterized by interplay between rivers, lands, and oceans and are influenced by a combination of river, tidal, and wave processes. Deltas are a coastal complex that combines natural systems in diverse habitats (e.g., tidal flats, salt marshes, mangroves, beaches, estuaries, low-lying wetlands) and human systems (e.g., houses, agriculture, aquaculture, industry, and transport). They have a population density more than 10 times the world average (Ericson *et al.*, 2006; Foufoula-Georgiou *et al.*, 2011). As low-lying plains, deltas are highly sensitive to changes in sea level. Deltas are subject to climatic impacts from rivers upstream (e.g., freshwater input) and oceans downstream (e.g., sea-level changes, waves) as well as within the deltas themselves. At the same time, they are affected by human activities such as land-use changes, dam construction, irrigation, mining, extraction of subsurface resources, and urbanization (Nicholls *et al.*, 2007).

Observed impacts

The combined impact of sediment reduction, relative sea-level rise, land-use changes in deltas, and river management on channels and banks has led to the widespread degradation of deltas (*very high confidence*). Decreased sediment discharge due to dam construction and irrigation creates an imbalance in sediment budget in coastal zones. Degradation of beaches, mangroves, tidal flats, and subaqueous delta front along deltaic coasts has been reported in many deltas (*very high confidence*)(e.g., Nile and Ebro, Sanchez-Arcilla *et al.*, 1998; Po, Simeoni and Corbau, 2009; Krishna-Godavari, Nageswara Rao *et al.*, 2010; Changjiang, Yang *et al.*, 2011; Huanghe, Chu *et al.*, 1996). Deltaic coasts naturally evolve by seaward migration of the shoreline, forming a delta plain; however, decreasing sediment discharge during the last 50 years has decreased the growth of deltaic land, even reversing it in some locations (e.g., Nile, Godavari, Huanghe). Artificial reinforcement of natural levees also has reduced the interdistributary basin sedimentation in most deltas, resulting in wetland loss.

The major impacts of sea-level rise are changes in coastal wetlands, increased coastal flooding, increased coastal erosion, and saltwater intrusion into estuaries and deltas (Mcleod *et al.*, 2010b), which are exacerbated by increased human-induced drivers (*very high confidence*). Ground subsidence amplifies these hazards in farms and cities on deltaic plains through relative sea-level rise (Day and Giosan, 2008; Mazzotti *et al.*, 2009). Relative sea-level rise due to subsidence has induced wetland loss and shoreline retreat (*high confidence*)(e.g., the Mississippi delta Morton *et al.*, 2005; Chao Phraya delta, Saito *et al.*, 2007). Episodic events superimpose their effects on these underlying impacts and accelerate land loss (*high confidence*) (e.g., Hurricanes Katrina and Rita in 2005, Barras *et al.*, 2008). To forestall submergence and frequent flooding, many delta cities now depend on a substantial infrastructure for flood defense and water management (Nicholls *et al.*, 2010).

Deltas are substantially impacted by river floods and oceanic storm surges and tsunamis (*very high confidence*). Tropical cyclones are noteworthy for their damages to deltas, e.g., the Mississippi delta by Hurricane Katrina in 2005 (Barras *et al.*, 2006), the Irrawaddy delta by Cyclone Nargis in 2008, and the Ganges-Brahmaputra delta by Cyclone Gorky in 1991 and Cyclone Sidr in 2007 (Murray *et al.*, 2012)(Box CC-TC). A detailed study of 33 deltas around the world found that 85% of the deltas had experienced severe flooding in the past decade, causing the temporary submergence of 260,000 km^2 (Syvitski *et al.*, 2009).

Projected impacts

The projected natural impacts on deltas under changing global climate are caused mainly by extreme- precipitation induced floods, sea-level rise, and accompanying changes of waves and storm surges. These will result in increased coastal flooding, decreased wetland areas, increased coastal erosion, and increased salinization of cultivated land and groundwater (*high confidence*) (McLeod *et al.*, 2010; Day *et al.*, 2011) (Box CC-TC). The surface area of flooding in 33 deltas around the world is projected to increase by 50% under the future sea-level rise projected for 2100 using the IPCC AR4 scenario (Syvitski *et al.*, 2009). Non-climatic drivers (e.g., reduction in sediment delivery, subsidence, and land-use changes) more than climatic drives have affected deltas for the last 50 years (*very high confidence*) (Syvitski, 2008). Densely populated deltas are particularly vulnerable due to further population growth together with the above-described impacts. The impacts of further sea-level rise beyond 2100 show a more complex and enhanced flood risk on deltas (e.g., Katsman *et al.*, 2011).

In summary, there is *very high confidence* that increased human drivers are the primary cause in changes of deltas (*high agreement, robust evidence*). There is *high agreement* that future climate changes through sea-level rise and increased storminess will exacerbate the problems in deltas with the increase of further human stress.

5.4.3. Human Systems

5.4.3.1. Human Settlements

The most important effects of climate change on coastal settlements include dry land loss due to erosion and submergence, damage of extreme events on built infrastructure (such as wind storms, storm surges, floods, heat extremes and droughts), effects on health, food and water-borne disease, effects on energy use, and effects on water availability and resources (Hunt and Watkiss, 2010). Assessments of climate impacts on settlements have almost exclusively focused on the impacts of sea level rise and coastal flood events. A large number of regional, national and sub-national scale studies have been conducted and Tables 5-4 and 5-5 highlight some of these studies. A comprehensive account of impacts, vulnerabilities and risks in specific regions is given in the Regional Chapters. At the global scale, studies have focused either on exposure to sea-level rise or extreme water levels or on the physical impacts of flooding, submergence and erosion.

[INSERT TABLE 5-5 HERE
Table 5-5: Summary of Coastal Vulnerability Assessments conducted at national or regional scale. Studies that either costed (Adapt$) or considered adaptation options (Adapt) are indicated. In studies that have considered

adaptation: WOA=without adaptation; WA=with adaptation. CVI=Coastal Vulnerability Index; GIS=Geographic Information System, DIVA=Dynamic Interactive Vulnerability Assessment model. RSLR=relative sea level rise.]

Exposure studies confirm the findings of AR4 that coastal vulnerability and risks are strongly influenced by non-climatic drivers. The population exposed to the 1 in 100 year coastal flood is projected to increase from 271 million in 2010 to 345 million in 2050 due to socio-economic development only (UN medium fertility projections) (Jongman *et al.*, 2012). For coastal cities there is *high confidence* that population growth, economic growth and urbanization are the most important drivers of increased exposure (Seto, 2011; Hanson *et al.*, 2011; Chapter 14). For 136 port cities above one million inhabitants the number of people exposed to a 1 in 100 year coastal flood event is expected to increase from 39 million in 2005 to 59 million by 2070 through 0.5 m global mean sea level rise alone and to 148 million if socio-economic development (UN medium population projections) is considered on top of this (Hanson *et al.*, 2011). Asia is expected to continue to have the largest exposed population, North America and Asia the largest economic exposure and North and Sub-Saharan Africa the largest increases in exposure (Dasgupta *et al.*, 2009; Vafeidis *et al.*, 2011; Jongman *et al.*, 2012). As urban population represents increasing proportion of world populations, urban floods will account for an increasing percentage of total flood impact as seen in Pakistan, Australia and Brazil (Jha *et al.*, 2011).

For deltas, another major driver of increases in exposure is relative sea-level rise due to subsidence. 85% of the world's largest deltas have experienced severe flooding in the last decade and the area exposed to flooding could increase by more than 50% by 2100 under current projections of sea-level rise (Syvitski *et al.*, 2009). Under medium UN population projections, human-induced subsidence alone is expected to increase the global economic exposure of 136 major port cities by around 14% although this driver only applies to 36 of the cities (Hanson *et al.*, 2011).

While some literature does not make a clear cut between exposure and impacts (e.g., Dasgupta *et al.*, 2007; Brecht *et al.*, 2012), it is important to distinguish these concepts, as exposure estimates do not consider existing or future adaptation measures that protect the exposed population and assets against coastal risk (Hinkel, 2012). Since AR4, a number of studies, listed in Table 5-5, have provided global assessments of coastal impacts on human settlements including the effects of adaptation. All of these studies also assess monetary costs of impacts and adaptation (5.5.3.). While there is *limited evidence* (few studies and models) three findings emerge.

First, while the global potential impacts of coastal flood damage and land loss on human settlements in the 21st century are substantial, impacts can be reduced substantially through coastal protection (*limited evidence, high agreement*). Nicholls *et al.* (2011) estimated that without protection 72-187 million people would be displaced due to land loss due to submergence and erosion by 2100 assuming sea level increases of 0.5-2.0 m by 2100. Upgrading coastal defenses and nourishing beaches would reduce these impacts roughly by three orders of magnitude. Hinkel *et al.* (2012) estimate the number of people flooded annually in 2100 to reach 170-260 million per year in 2100 without upgrading protection and two orders of magnitude smaller with dike (levee) upgrades, assuming global mean sea-level rises of 0.6-1.3 m by 2100.

Second, despite the delayed response of sea-level rise to global warming levels (WG1, Chapter 3) mitigation may limit 21st century impacts of increased coastal flood damage, dry land loss and wetland loss substantially (*limited evidence, medium agreement*) albeit there is *little agreement* on the exact numbers. Nicholls and Lowe (2004) estimated that stabilizing emission at 550 ppm reduces the annual number of people flooded a factor 50% in 2110 compared to a scenario of unmitigated emissions. Tol (2007) found that stabilizing emissions at 550 ppm reduces global impacts on wetlands and drylands by about 10% in 2100 compared to scenario of unmitigated emissions. Hinkel *et al.* (2012) reported that stabilizing emissions at 450 ppm-CO_2-eq reduces flood risks in 2100 by 23-29%. All three studies only consider the effects of mitigation during the 21st century and due to the thermal expansion component of sea level rise. Mitigation is expected to be more effective when considering impacts beyond 2100 and other components of sea leve rise (WG1 Chapter 13).

Third, studies confirm AR4 findings that there are substantial regional differences in coastal vulnerability and expected impacts (*limited evidence, high agreement*). Most countries in South, South East and East Asia are particularly vulnerable to sea-level rise due to rapid economic growth and coastward migration of people into urban coastal areas together with high rates of anthropogenic subsidence in deltas where many of the densely populated

areas are located (Nicholls and Cazenave, 2010). At the same time, economic growth also increases the capacity to adapt and the benefits of adaptation are also highest in these regions (Nicholls *et al.*, 2010). On the contrary, while many African countries experience a similar trend in rapid urban coastal growth, the level of economic development is generally lower and hence the capacity to adapt is smaller (Hinkel *et al.*, 2011; Kebede and Nicholls, 2012).

Many gaps remain. The available studies have only explored a small fraction of the underlying uncertainty. Only few assessments consider global mean sea-level rise scenarios beyond the range given in AR4, thus excluding the impacts of a possible large contribution of the ice sheets of Greenland and Antarctica to global mean sea-level rise (Sect. 5.3.2, and WG1 Ch. 13). Studies considering regional patterns of climate-induced sea-level rise as well as human-induced subsidence are few. Many studies rely on few or only a single socio-economic scenario. Few studies consider adaptation and those that do generally ignore the wider range of adaptation options beyond hard protection options. Integrated studies assessing multiple hazards, multiple impacts and trade-offs between adaptation options are rare.

_____ START BOX 5-1 HERE _____

Box 5-1. Coastal Megacities

Large coastal urban areas offer both concentrated risk and resources for living with and adapting to the impacts of climate change. When climate related disasters hit megacities costs can be very high: Storm Sandy is estimated to have resulted in more than US$100 billion of damages for New York and its hinterland. When impacts reach these levels, and when strategic infrastructure is damaged, losses in large cities are capable of impacting on regional and global economies through the disruption of globalized flows of goods, resources and capital. Large-scale coastal urbanization is most concentrated in south and southeast Asia. Asia is also a world region with high exposure to climate and weather related hazards and the potential for these to be compounded by geophysical hazards, and those more directly caused by human action such as subsidence.

Of 21 megacities worldwide defined by having populations in excess of 10 million, 14 are in the coastal zone – within 100km and 50m elevation from the coast (Figure 5-4) and it is anticipated that the number of coastal megacities will continue to grow, especially in Africa and Asia. Growth will be largely through planned development but may also feature of unplanned, spontaneous and often illegal development – with implications for the limits and scope of adaptive capacity and management. Growth in neighbouring urban regions offers the prospect of mega-cities or mega-urban-regions, currently the largest is the Hong Kong-Shenhzen-Guangzhou region in China, with a population of 120 million. Many other large coastal cities (e.g., Cairo, London and Sao Paulo) offer important lessons on planning and risk management at scales that indicate the importance of a flexible approach to the study of coastal mega-urbanization.

[INSERT FIGURE 5-4 HERE
Figure 5-4: Mega-urbanisation of on the coast. Source**:** Blackburn S and Marques da Silva C (2013) Mega-urbanisation on the coast: Global context and key trends in the twenty-first century, in Pelling M and Blackburn S (eds) Megacities and the Coast: Risk, Resilience and Transformation, Earthscan: London.]

Contemporary approaches to risk management acknowledge the need for soft risk reduction measures such as education, good governance, and risk communication, being applied in conjunction with hard engineering solutions such as sea walls, groynes and levees and green-engineered equivalents. However applying these principles in megacities is challenging, requiring collaboration between a multitude of stakeholders. These include actors operating at all scales from the international (in the case of large land-owning corporations and supranational donors) to the individual. Good governance is key to risk management, but there is much debate over precisely what this entails and its limitations.

The prospect of dangerous climate change bringing increasing rates of sea-level rise and coastal storminess by mid century asks serious questions of urban planners today. This is especially so in places where these hazard drivers are exacerbated by local conditions, for example of subsidence. Middle-income countries experiencing the most rapid mega-urban expansion also possess an opportunity to plan now for potential risk mid-century and beyond. It is more

difficult still to confront the challenge of retrofitting or redesigning cities where current land-use will configure future risk. The next decade is likely to be critical for realigning urban planning, reaching out to informal and regulating market-led developments. Responding to dangerous climate change requires joined-up risk management that can consider transformational adaptation with considerable local impacts on the way cities are imagined, governed and shaped, alongside contemporary, incremental adaptation options.

_____ END BOX 5-1 HERE _____

5.4.3.2. Industry, Infrastructure, Transport, and Network Industries

There is *high confidence* that coastal industries, their supporting infrastructure including transport (ports, roads, rail, airports), power and water supply, storm water and sewerage are sensitive to a range of extreme weather and climate events (Handmer *et al.* 2012) and many of these are projected to change over the coming decades (Seneviratne *et al.*, 2012). This is especially relevant considering the fact that most industrial facilities, infrastructure and networks are designed for life cycles extending over several decades, even extending well into the twenty-second horizon such as new nuclear power plants (Wilby *et al.* 2011).

Table 5-6 summarizes potential impacts of sea level rise, coastal floods and storms on critical coastal infrastructure in the communications, energy, transportation and water waste sectors.

[INSERT TABLE 5-6 HERE
Table 5-6: Impacts of sea level rise, coastal floods, and storms on critical coastal infrastructure by sector. Sources: Horton and Rosenzweig (2010), Zimmerman and Faris (2010).]

Severe storms with associated winds, waves, rain, lightning and storm surges are particularly disruptive to transport and power and water supplies. In such network configurations, flooding of even the smallest component of an intermodal system can result in a much larger system disruption. For instance, even though a transportation terminal may not be affected, the access roads to it could be, thus forcing the terminal to cease or reduce operation (CCSP, 2008). Sea transport accounts for more than 80% of global goods trade (by volume) and so disruption to port activities in one location can disrupt supply chains, which can have far reaching consequences (Handmer *et al.*, 2012).

Some low-lying railroads, tunnels, ports and roads are already vulnerable to flooding and rising sea levels (5.3.3.2) will exacerbate the situation by causing more frequent and more serious disruption of transportation services under extreme sea levels unless adaptation is enforced. Furthermore, sea-level rise will reduce the extreme flood return periods and will lower the design critical elevations of infrastructure such as airports, tunnels, coastal protections and ship terminals (Jacob *et al.*, 2007). Coastal infrastructural instability may result from natural hazards triggered by groundwater-level (GWL) variations resulting from rising sea level. For earthquake-prone coasts, this could be exacerbated by earthquake liquefaction if GWL increases with sea-level rise (Yasuhara *et al.*, 2007). Other impacts may arise in coastal industries in high latitudes affected by permafrost thaw causing ground stability and erosion thereby affecting transport safety and the industries that rely on such travel in these regions (e.g., Pearce *et al.*, 2010).

There is *high confidence* that climate impacts on coastal industries vary considerably depending on geographical location, associated weather and climate and specific composition of industries within particular coastal regions.

While there is *robust evidence* of the impacts and consequences of extreme events on coastal infrastructure and industrial facilities there are limited assessments on projected impacts. For example, it is estimated that a hypothetical 1 m rise in relative sea level projected for the Gulf Coast region between Alabama and Houston over the next 50-100 years would permanently flood a third of the region's roads as well as putting more than 70% of the regions ports at risk (CCSP, 2008).

Although not completely coastal, the estimated costs of climate change to Alaska's public infrastructure could add US$3.6-6.1 billion (+10% to 20% above normal wear and tear) from now to 2030 and US$5.6-7.6 billion (+10% to 12%) from now to 2080 (Larsen *et al.*, 2008). Higher costs of climate change for coastal infrastructure are expected due to its proximity to the marine environment. Other projected impacts are beneficial for the transportation system. For example, decline of Arctic sea-ice coverage could extend seasonal accessibility to high-latitude shipping routes such as the northwest shipping route that connects the Atlantic to the North Pacific (MCCIP, 2008).

Hanson *et al.* (2011) presents a first estimate of the exposure of the world's large port cities to coastal flooding due to sea-level rise and storm surge in the 2070s. The analysis suggests that the total value of assets exposed in 2005 across all cities considered is estimated to be US$3,000 billion; corresponding to around 5% of global GDP in 2005. By the 2070s, and assuming a homogeneous global sea level rise of 0.5 m, increased extreme water levels up to a 10% and a fixed subsidence rate in susceptible cities with respects today values, asset exposure is estomated to increase to approximately 9% of projected global GDP in this period.

5.4.3.3. Fisheries, Aquaculture, and Agriculture

The coastal zone supports significant fisheries, aquaculture and agricultural activities. Fisheries and aquaculture globally employ 43.5 million people (Daw *et al.*, 2009) and contribute for more than 20% to the dietary animal protein of nearly 1.5 billion people (FAO, 2010). Rice production, the world's number one food crop, is a major crop grown in the low-lying deltaic regions of Asia (Wassman *et al.*, 2009).

Observed impacts

Climate variability and change impact both fishermen livelihoods (Badjeck *et al.*, 2010) and fish production (Barange and Perry, 2009). In the North Sea, ocean warming over the period 1977-2002 led to 8 times more fish species (Hiddink and Hofstede, 2008). In southeastern Australia, Last *et al.* (2011) found an increasing abundance of 45 fish species of warm temperate origin (Ridgeway, 2007), a decline abundance for 9 species, and predicted the potential for longer term detrimental effects for cool temperate species endemic to the region. Impacts of climate change on aquaculture (*Mytilus edulis and Salmo salar*) in the UK and Ireland have been difficult to discern from natural environmental variability (Callaway *et al.*, 2009).

The impact of sea surface temperature changes on fisheries yields over the last 25 years is negative for the Northeast Atlantic large marine ecosystems, and positive for the Indian Ocean (Sherman *et al.*, 2009). In coastal Louisiana, saltwater intrusion was found to reduce the population size of the freshwater western mosquitofish (*Gambusia affinis*) (Purcell *et al.*, 2010). Eutrophication and hypoxia give rise to frequency and intensity of harmful algal blooms (MEA, 2005). A combination of factors renders the Pacific coast and coastal estuaries particularly vulnerable to acidified water (Newton *et al.*, 2010).

The combination of rice yield reduction induced by climate change and inundation of lands by seawater causes an important reduction in production (Chen *et al.*, 2012). Seawater inundation has become a major problem for traditional agriculture in Bangladesh (Rahman *et al.*, 2011), and in low-lying island nations (e.g. Lata and Nunn, 2012).

Projected impacts

Fisheries may be impacted either negatively or positively (Cinner *et al.*, 2012; Meynecke and Lee, 2011; Hare *et al.*, 2010) depending on the latitude, location and climatic factor. Using a partial-equilibrium analysis, Narita *et al.* (2012) estimated that the global economic costs of production loss of mollusks due to ocean acidification by the year 2100 could be over 100 billion USD. Warming ocean temperatures can lead to the migration of the sea urchin (*Centrostephanus rodgersii– Diadematidae*) in Australia (Ling *et al.*, 2009). For aquaculture, negative impacts of

rising ocean temperatures will be felt in the temperate regions whereas positive impacts will be felt in the tropical and subtropical regions (De Silva and Soto, 2009).

In summary, there is *medium confidence* that changes have occurred to the distribution of fish species with evidence of poleward expansion of temperate species (*high agreement, limited evidence*). There *is limited evidence* to suggest that tropical and subtropical aquaculture has not been adversely affected by rising ocean temperatures to date. There is also *medium confidence* that coastal agriculture has experienced negative impacts due mainly to increased frequency of submersion of agricultural land by saltwater inundation (*high agreement, limited evidence).*

5.4.3.4. Coastal Tourism and Recreation

Coastal tourism is the largest component of the global tourism industry. More than 60% of Europeans opt for beach holidays and beach tourism provides more than 80% of US tourism receipts (UNEP, 2009). More than 100 countries benefit from the recreational value provided by their coral reefs which contributed US$11.5 billion to global tourism (Burke *et al.*, 2011).

Observed impacts

Observed significant impacts on coastal tourism have occurred from changes in extreme events (e.g. flooding, tropical storms, storm surges, heat waves) and climate variability (e.g. drought and prevailing winds accelerating coastal erosion) which can cause damage to infrastructure and tourist attractions (Scott *et al.*, 2008; Bender *et al.*, 2010; Knutson *et al.*, 2010). Observed climate change impacts on the Great Barrier Reef include the coral bleaching episodes in 1998 and 2002 due to higher summer sea temperatures, more severe storms, rising sea levels and coastal erosion although tourists show a low level of climate change concern with respect to coral bleaching (Zeppel, 2012).

Projected impacts

In order to provide some idea of climate change impacts on coastal destinations, many studies have been made on projecting tourism demand, for example, in Europe (Perch-Nielson *et al.*, 2010), East Anglia, UK (Coombes *et al.*, 2009), the Baltic region (Haller *et al.*, 2011) and beach tourism in the Mediterranean (Moreno and Amelung, 2009a) and in 51 countries worldwide (Perch-Nielson, 2010). The studies provide varying details but it is difficult to draw overarching conclusions on tourism demand for coastal destinations. Less is known about the relationship between the impacts of climate change and specific tourist behaviour, activities or flows to coastal destinations (Moreno and Amelung, 2009b) (see Chapter 10). Usually tourists do not consider climate variability or climate change in their holidays *et al.* although there are a few studies to show on the contrary (Alvarez-Diaz *et al.*, 2010; Cambers, 2009).

As for future impacts on coastal tourism, there is *high confidence* in the impacts of extreme events and sea level rise aggravating coastal erosion. A scenario of 1 m sea level rise would be a potential risk to 906 major coastal resort properties in 19 countries in the Caribbean (Scott *et al.*, 2012). The presence of coastal tourism infrastructure will continue to exacerbate beach reduction and coastal ecosystems squeeze under rising sea levels, as exemplified in Martinique (Schleupner, 2008). Carbonate reef structures would degrade under a scenario of at least 2^{o}C by 2050 to 2100 with serious consequences for tourism destinations in Australia, Caribbean and other small island nations (Hoegh-Gulberg *et al.*, 2007). Ocean acidification would add its toll to coral reefs (Box CC-CR).

The costs of future climate change impacts on coastal tourism are enormous. For example, in the Caribbean region, a hypothetical 1-m sea-level rise would result in the loss or damage of 21 CARICOM airports, inundation of land surrounding 35 ports, and at least 149 multi-million dollar tourism resorts damaged or lost from erosion to the coastal beach areas.(Simpson *et al.*, 2011).

In summary, while coastal tourism can be related to climate change impacts, it is more difficult to relate tourism demand directly to climate change. Coastal tourism continues to be highly vulnerable to weather and climate

extremes and rising sea levels with the additional sensitivity to ocean temperature and acidity for the sectors that rely on reef tourism *(high confidence*). Developing countries and small island states within the tropics relying on coastal tourism, are most vulnerable to present and future weather and climate extremes, future sea level rise and the added impacts of coral bleaching and ocean acidification **(***very high confidence*).

5.4.3.5. Health

The relationship between health of coastal populations and climate change include direct linkages (e.g. floods, droughts, storm surges and extreme temperatures) and indirect linkages (e.g. changes in the transmission of vector, food and water borne infectious diseases and increased salinisation of coastal land that affects food production and freshwater supply). Coastal settlements, and in particular informal settlements, concentrate the risks of injury and death due to the risk of storm surges and flooding from rainfall and storm surge (Handmer et al, 2012). This section deals with human health in the context of the coastal zone, while Chapter 11 addresses general health issues and Chapter 6 deals with health issues associated with ocean changes. Understanding the relationship between climate and health is often confounded by socio-economic factors that influence coastal settlement patterns and the level and organisation of the response of authorities to health related issues (Baulcomb, 2011).

Mortality risk in coastal areas is related to exposure and vulnerability of coastal populations to climate hazards. Recent modeling of trends in these components highlights that mortality risk is highest in countries with low GDP and weak governance. A regional analysis of changes in exposure, vulnerability and risk indicates that although exposure to flood and cyclone hazards has increased since 1980, the risk of mortality has generally fallen. The reductions reflect strengthening of countries' capacity to respond to disasters (Box 5-1). However, mortality is still rising in the countries with the weakest risk governance capacities (UNISDR, 2011).

Coastal regions face a range of diseases that are sensitive to climate. Increased saline intrusion of coastal land through rising sea levels and changes to river flow is linked to increased incidence of hypertension disease (Vineas et al, 2011). For example, in Bangladesh, higher rates of maternal hypertension disorders have been identified in pregnant women living in coastal regions compared to further inland (Khan et al, 2008). Increasing temperature, humidity and rainfall can increase suitable mosquito habitats, shorten the breeding cycles and reduce the time to infection by vector-borne diseases such as malaria, dengue, leishmaniasis and chikungunya. (Stratten *et al.*, 2008; van Kleef *et al.*, 2010; Pialoux et al, 2007, Kolivras, 2010) and infectious diseases such as diarrhoea, infectious gastrointestinal disease, rotovirus and salmonella (e.g. Chou *et al.*, 2011, Hashizume *et al.*, 2007; 2008a Zhang *et al.*, 2007, 2010; Onozuka *et al.*, 2010). The parasitic disease, Schistosomiasis, is endemic in many tropical and small island coastal regions (Chapter 29) and infection rates have been found to increase linearly with temperature to 30°C but reduce beyond 35°C, because of increased mortality in the snail intermediate host. (Mangal *et al.* 2008).

Cholera outbreaks are also linked to rainfall, patterns and other seasonal climate patterns (e.g. Hashizume et al, 2008b, 2010) and variations in SST (e.g. Koelle et al, 2005). Outbreaks of toxins generated by Harmful Algal Blooms (HABs) such as ciguatera have been linked to SST variability (e.g. Jaykus *et al.*, 2008; Erdner *et al.*, 2011). However, in general there is *limited evidence* and *low confidence* in how global climate change will impact HABs (Chapter 6). The potential impacts of HABs in human health and different ecosystem services suggests increased monitoring of significant range extensions and associated increases in biotoxins is necessary (Hallegraeff, 2010). Nontoxic blooms that grow to high biomass also can have detrimental effects on biodiversity through oxygen depletion and physical shading of the benthos (Erdner *et al.*, 2011) with consequences for ecosystem health, human nutrition and health.

Under future climate conditions, expansion of brackish and saline water bodies in coastal areas under projected sea level rise may increase the incidence of associated vector-borne diseases (Ramasamy and Surendran, 2011) and salinity-related diseases such as diarrhea and hypertension (Vineas et al, 2011). Human responses to climate change also may also influence outcomes on health. However, sparsity of empirical climate-health data increases uncertainties around such projections (Kolstad and Johansson (2011).

Evidence continues to emerge of relationships between many diseases that affect human health in the coastal zone and climate including changes in air and water temperature, rainfall and humidity, coastal salinity and increased salinisation of coastal land. However, the relationships are often complex and vary between diseases and even regionally for the same disease. The interplay between climate and human systems with regards to health impacts is poorly understood and this continues to confound reliable projections of health impacts. (*high agreement, robust evidence*).

5.4.4. Summary: Detection and Attribution

Coastal systems, consisting of natural and human systems, have been heavily influenced by human activities including those associated with climate changes (*high agreement, robust evidence*).

Coastal ecosystems such as rocky shores and coral reefs show the most evidence of the impacts of climate change (5.4.2.2, 5.4.2.4), the most prominent effects being the range shifts of species in response to ocean warming (*high confidence*), changes in biodiversity (*high confidence*) in relation to ocean warming and acidification, and mass coral bleaching and mortality in response to ocean warming (*very high confidence*). Decreased calcification in many reef-building corals and coralline algae is reported widely (*high confidence*), however its attribution to either warming or acidification has proven difficult (*medium confidence*)(5.4.2.4). Ocean warming is also leading to range shifts in mangrove forests and seagrass meadows (*medium confidence*)(5.4.2.3). Seagrass meadows are already under stress due to ocean warming (*high confidence*), and in particular heat waves, which lead to widespread seagrass mortality (*high confidence*). Kelp forests have been reported to decline in temperate areas in both hemispheres, attributed to ocean warming (*high confidence*)(5.4.2.3). The spread of subtropical invasive macroalgal species is believed to be facilitated by climate change, adding to the stresses temperate seagrass meadows experience from ocean warming (*medium evidence, high agreement*)(5.4.2.3). The changes of the distribution of fish species with evidence of poleward expansion of temperate species have occurred (*medium confidence*)(5.4.3.3). There *is limited evidence* to suggest that tropical and subtropical aquaculture has been adversely affected by rising ocean temperatures to date (5.4.3.3).

Though the range shift of mangroves is recognized, mangrove forests and seagrass meadows are declining globally (*very high confidence*) mainly due to land-use changes and coastal erosion (5.4.2.3). Widespread erosion of beaches and dunes has been observed over the past century or more (*robust evidence*) (*very high confidence*). However attributing shoreline changes to climate change is difficult due to the multiple natural and anthropogenic drivers contributing to coastal erosion (*low confidence*) (5.4.2.1). There is *very high confidence* that increased usage of groundwater resources for agriculture and coastal settlements globally has led to a reduction in groundwater quality, including increased salinization (*high agreement, robust evidence*), however, attribution to climate change is *low* (5.4.2.5), human drivers being the primary cause in these changes and degradation of highly-populated deltas and lowlands around estuaries and lagoons (*high agreement, robust evidence*)(5.4.2.7).

Exposure studies confirm the findings of AR4 that coastal vulnerability and risks are strongly influenced by non-climatic drivers. Population of people living in coastal lowlands is increasing and more than 270 million people in 2010 are already exposed to flooding by the 1 in 100 year coastal flood (5.4.3.1)(*very high confidence*). Population growth and land subsidence in coastal lowlands are the major cause and there is *very low attribution* to climate changes. The interplay between climate and human systems with regards to health impacts is poorly understood (*high agreement, robust evidence*)(5.4.3.5).

The coastal systems are affected by both climate-related and human drivers, and complex interactions of both. Though there is *high* attribution to climate changes as coral bleaching and species shift, most of causes in other changes to the coastal system are attributed to mainly human activities (human drivers). Further analysis will be required to more clearly discriminate the relative contributions from human and climate-related drivers.

[INSERT FIGURE 5-5 HERE
Figure 5-5: Summary of detection and attribution in coastal areas.]

5.5. Adaptation and Managing Risks

This section assesses the literature on available on approaches for appraising and implementing coastal adaptation (5.5.1), adaptation options (5.5.2), costs and benefits of coastal adaptation (5.5.3), observed coastal adaptation practice (5.5.4), observed barriers to coastal adaptation (5.5.5), and finally linkages between coastal adaptation and mitigation (5.5.6).

5.5.1. Framing and Approaches

5.5.1.1. Overview of Approaches

Adaptation in general and coastal adaptation in particular are broad concepts referring to a wide range of human activities related to the process of framing the adaptation issue, assessing adaptation (i.e., identifying and analyzing adaptation options), implementing options and monitoring and evaluating these (e.g., UKCIP, 2003; PROVIA, 2013). As a result, a wide variety of approaches are applied (Chapters 2, 15, 16 and 17 for a comprehensive account).

For coastal adaptation, the literature on approaches falls into three categories: decision-analytical approaches, approaches of institutional and governance analysis and practical approaches that cover all stages of the adaptation process.

5.5.1.2. Decision Analysis

Decision-analytical (DA) approaches analyse a particular decision using formal methods in order to identify preferable actions from a set of alternative actions (also called options, alternatives or strategies) given some evaluation criteria. This section highlights some paradigmatic applications of DA methods to coastal adaptation; for a compressive treatment see Chapter 2 (Foundations for decision-making) and Chapter 17 (Economics of Adaptation).

Many standard methods for decision-making under uncertainty use the criterion of optimality (e.g., optimum utility, optimal cost-benefit ratio, etc). These methods cannot be applied for long-term adaptation decisions as they require the computation of expected utility or expected benefits, which is not possible in principle (Lempert and Schlesinger, 2001; Hinkel and Bisaro, 2013). As many coastal decisions involve options with investment time scales of 30 to over 100 years (e.g., land-use planning, flood defenses, construction of housing and transportation infrastructure; see 5.5.2), DA approaches beyond optimization are required (Hallegate, 2009).

Robust decision-making (RDM) refers to a range of alternative approaches that replace the evaluation criterion of optimality with the criterion of robustness. Uncertainty is not represented through a single probability distribution but through a range of alternative scenarios and robust strategies that work well over a wide range of these scenarios are preferred (Lempert and Schlesinger, 2000; Lempert and Collins, 2007). Application of RDM to Port of Los Angeles infrastructure is one of the few applications to coastal adaptation (Lempert *et al.* (2012).

Another set of approaches uses the criterion of flexibility to decide between alternative strategies. Flexible and reversible options are favored over non-flexible and non-reversible ones and decisions are delayed to keep future options open (Hallegate, 2009).

The adaptation pathways approach implements the criterion of flexibility by characterizing alternative strategies in terms of two attributes: i) adaptation tipping points (ATP), which are points beyond which strategies are no longer effective (Kwadijk *et al.*, 2010), and ii) what alternative strategies are available once a tipping point has been reached (Haasnoot *et al.*, 2012). Importantly, the exact time when an ATP is reached does not matter; it is rather the flexibility of having alternative strategies available that is driving the decision. Prominent applications of this

approach include the Thames Estuary 2100 Plan (Low *et al.*, 2009; Penning-Roswell *et al.* 2011; Box 5-2), the Dutch Delta Programme (Kabat *et al.*, 2009; Box 5-3) and the New York City Panel on Climate Change (Rosenzweig *et al.*, 2011).

These and other approaches may also be embedded into multi-criteria-analysis (MCA), which considers multiple criteria that may include robustness and flexibility. The application of MCA to coastal decisions is wide spread. Another response to the deep uncertainty characterizing future climate drives is adaptive management, which is the idea of practicing adaptation and evaluating outcomes *ext-post* instead of analyzing decisions *ex-ante*; (e.g. practical approaches in 5.5.2.4).

5.5.1.3. Institutional and Governance Analysis

Institutional and governance analysis (IA) comprise a variety of approaches that aim at describing and explaining the emergence and performance of institutions and governance structures (GS) (Hinkel and Bisaro, 2013). IA is particularly relevant to coastal adaptation, because deciding between options and implementing them is an ongoing process involving complex inter-linkages between public and private decisions at multiple levels of decision making and in the context of other issues, existing policies, conflicting interests and diverse GS (e.g, Few *et al.*, 2007; Urwin and Jordan, 2008; Hinkel *et al.*, 2009). The non-consideration of this context may hinder or mislead adaptation decisions and implementations (5.5.5). IA strives to understand this context and insights gained may be employed to craft effective institutions and policies for adaptation.

For coastal adaptation, there is *high confidence* that the effectiveness of existing GS is hindered due to a lack of horizontal and vertical integration of organizations and policies. Weak vertical administrative interplay in Sweden (Storbjörk and Hedren (2011)); poor integration in higher-level governance and limited effectiveness of institutional arrangements of Coastal Partnership in UK (Stojanovic and Barker, 2008); difficulty to translate national level recommendations into local level actions in the UK (Few *et al.*, 2007); coastal policies with ambigous or contradictory goals (Bagstadt *et al.*, 2007) and fragmented economic incentivices in the US (Seto, 2011) or coastal policies not taken into account longer-term climate change in a number of African cases (Bunce *et al.*, 2010) are a few examples.

There is *medium evidence* that governance issues are particularly challenging when considering planned retreat. While managed realignment is on the political agenda in Germany and the UK, the political costs of doing so are high as both the existing GS as well as public opinion are geared towards protection, so that short election cycles do not provide incentives for politicians to undertake actions that may produce benefits in the long term (Few *et al.*, 2007; Rupp-Armstrong and Nicholls, 2007). Along the coast of South East Queensland, Australia, the option of planned retreat is disappearing because of rapid coastal development favored by liability laws. To prevent this, risks and responsibilities would need to be redistributed from governments to beneficiaries of development (Abel *et al.*, 2011).

While there is *high confidence* that many institutional factors are decisive in enabling coastal adaptation, the role of coastal institutions in adaptation is generally under-researched. Contextually differentiated institutional analysis considering both biophysical and social system characteristics (Dietz *et al.*, 2003; Ostrom, 2009) as found in the fields of socio-ecological systems (Folke *et al.*, 2005; Ostrom 2007, 2009) and new institutional economics (Hagedorn *et al.*, 2002; Bougherara *et al.*, 2009; Ostrom, 2005, Geels, 2011) are practically non-existent. Most work focuses on Australia, US, Germany and the UK with little work on developing countries.

5.5.1.4. Approaches to Adaptation Practice

Generally, approaches to adaptation practice build on already existing policy and practice frameworks and cover the whole adaptation processes from framing the issue and analyzing options to implementing adaptation actions and monitoring and evaluation.

Integrated Coastal Zone Management (ICZM) is a long-term, institutionalized and iterative process that promotes the integration of coastal activities of relevant policy makers, practitioners and scientist across coastal sectors, space and organizations with a view to use coastal resources in a sustainable way (Hiledebrand and Norrena, 1992; Sorenses 1993; Sterr *et al.*, 2003; Sales, 2009; Christie *et al.*, 2005; WG2 Glossary). Considering climate change in this framework does not mean radical changes to ICZM, because ICZM already emphasizes the integration of coastal issues across sectors and policy domains as well as the long-term perspective (e.g., Hofstede, 2008; Falaleeva *et al.*, 2011), but there is need to extend decision making horizons (Tobey *et al.* 2010).

So far, however, there is *limited evidence* of the effectiveness of ICZM combined with climate change adaptation. ICZM itself has been applied throughout the world for over 40 years and while demonstrable befits are reported (e.g., Stojanovic and Ballinger, 2009) many obstacles to its successful implementation still remain (*high confidence*). A recent review of ICZM in Europe concluded that the complexity of coastal regulations, demographic deficits, lack of sustainable finance and a failure to involve communities, business and industry hinder its implementation (Shipman and Stojanovic, 2007). Developing countries also struggle to meet the goals of ICZM due to many factors (Box 5-4).

Another prominent framework used for coastal adaptation practice is adaptive management (AM), which has been developed as a response to the deep uncertainty characterizing ecosystem management, where it is often impossible to predict outcomes of management interventions (Holling, 1968; Walters, 1986). There are numerous applications of AM to coastal management (e.g., Walters, 1997; Marchand, 2011, Mulder *et al.*, 2011), but as the majority of these are very recent, there is *limited evidence* of its long-term effectiveness. Limitations of AM are also apparent such as the potential high cost of experimentation and and a range of institutional barriers hindering the delivery of flexible management approaches (e.g. Gunderson *et al.*, 1995, McLain and Lee, 1996; Johnson 1999).

Community-based adaptation (CBA) refers to the generation and implementation of locally-driven adaptation strategies that address both climate change impacts and development deficits for the climate vulnerable poor and strengthen the adaptive capacity of local people to climate and non-climate risk factors (Reid *et al.*, 2009; Nicholls *et al.*, 2007; Ayers and Dodman, 2010; Ayers and Huq, 2013; WG2 AR5 Chapter 14, 14.2.1; Chapter 15, 15.4.3.1; Chapter 24, 24.4.6.5). CBA approaches have been developed through active participatory processes with local stakeholders (Ayers and Forsyth, 2009), and operating on a learning-by-doing, bottom up, empowerment paradigm (Huq and Reid, 2007; Kates, 2000). CBA experiences emphasize that it is import to understand a community's unique perceptions of their adaptive capacities in order to identify useful solutions (Parvin *et al.*, 2008; Paul and Routray, 2010; Badjeck et al, 2009) and that scientific and technical information on anticipated coastal climate impacts needs to be translated into a suitable language and format that allows people to be able to participate in adaptation planning (Saroar and Routray, 2010). Further, effective CBA needs to consider measures that cut across sectors and technological, social and institutional processes; technology by itself is only one component of successful adaptation. (Sovacool *et al.*, 2011; Rawlani and Sovacool, 2011; Pelling, 2011; Gibbs, 2009).

Other important policy and practice frameworks in place in the coastal zone include poverty reduction, development and Disaster Risk Reduction (Romieu *et al.*, 2010; Mercer, 2010; Mitchell *et al.*, 2010; Polack, 2010; Gero *et al.*, 2011; Kirshen *et al.*, 2011; Halpern *et al.*, 2008b)

Across these and other approaches there is *high agreement* on the following three principles. One, information on efficient adaptation options alone (as assessed through DA approaches) may not fully serve managers need and requires to be supplemented by financial and technical assistance as well as boundary organizations which serve as an interface between science and practice (Tribbia and Moser, 2008). Two, the adaptation and decision making processes should be participatory and inclusive, integrating all relevant stakeholders (Dolan and Walker, 2004; O'Riordan and Ward, 1997; Milligan *et al.*, 2009). Three, the adaptation processes must be set up to foster mutual learning, experimentation and deliberation amongst stakeholder and researchers (Fazey *et al.*, 2010; Kenter *et al.*, 2011). Neither scientific climate knowledge alone nor indigenous knowledge alone is sufficient (Sales, 2009; Dodman and Mitland, 2011; Bormann et al, 2012). Coastal adaptation is increasingly acknowledged to be a "wicked problem" (Rittel and Webber, 1973), in the sense that there is often no clear agreement about what exactly the adaptation problem is and there is uncertainty and ambiguity as to how improvements might be made (Moser *et al.*

2012). As coastal systems are complex, diverse and dynamic, their governance needs experimentation and learning by doing (Jentoft, 2006).

While there is *high agreement* on these principles, there is little systematic review and hence *limited evidence* on why a given approach is effective in a given context (and not in another). The need for systematic evaluation and institutional research targeted at a differentiated understanding of these approaches is high. Furthermore, despite experimentation with these approaches, meeting the multiple goals, improving governance, accounting for the most vulnerable populations and sectors and fully integrating consideration of natural ecosystems is still largely aspirational. Meanwhile development in high risk areas grows, coastal ecosystems continue to degrade in many regions, coastal freshwater resources are being overdrawn in many highly populated areas, and vulnerability to coastal disasters grow (e.g., Jentoft, 2009; McFadden, 2008; Mercer, 2010; Shipman and Stojanovic, 2007).

5.5.2. Adaptation Options

Selecting appropriate adaptation options can be challenging considering the ample range of options available. A detailed discussion on general adaptation needs and options can be found in (chapter 16). As a first approximation, adaptation options were classified into: institutional and social options (14.3.2.1), technological and engineered options (14.3.2.2) and ecosystem-based adaptation options (14.3.2.3). In terms of coastal adaptation, most of the existing options can be included within this classification.

The IPCC classification of coastal adaptation strategies consisting of retreat, accommodation and protection (Nicholls *et al.*, 2007) is now widely used and applied in both developed and developing countries (Boateng, 2010; Linham and Nicholls, 2012). This trilogy of strategies has also been translated as retreat, defend or attack (Peel, 2010). Protection aims at advancing or holding existing defence lines by different options such as: land claim, beach and dune nourishment, the construction of artificial dunes, hard structures such as sea walls, sea dikes and storm surge barriers or removing invasive and restore native species. Accommodation is achieved, increasing flexibility, by flood proofing, flood agriculture, flood hazard mapping, the implementation of flood warning systems or replacing armoured by living shorelines. Retreat options include allowing wetlands to migrate inland, shoreline setbacks and managed realignment, for example, by breaching coastal defences allowing the creation of an intertidal habitat.

Since AR4 coastal adaptation options have been revised and summarized in several guidebooks (USAID, 2009; EPA, 2009; UNEP, 2010). Especially relevant has been the growth of Community Based Adaptation options. Table 5-7 compiles different examples, of options implemented to address climate change impacts in coastal areas.

[INSERT TABLE 5-7 HERE
Table 5-7: Community-based adaptation options.]

5.5.3. Global Adaptation Costs and Benefits

Since AR4, only a few studies have been published that provide comprehensive and internally consistent estimates of the costs of sea-level rise and adaptation at global scales. These relying either on the FUND (Anthoff *et al.*, 2010; Nicholls and Tol, 2009) or the DIVA model (Hinkel and Klein, 2009) and are listed in Table 5-5 and discussed here.

Generally, cost estimates are difficult to compare across studies due to differences in scenarios used, impacts and adaptation options considered, methodologies applied and baseline conditions assumed. No study covers all of the major sea-level rise impacts as reported in Table 5-4. All of these studies use the direct cost method, in which exogenous prices for adaptation options and damages are taken from data of the respective markets. For wetland loss, direct costs are used too but the “prices” are taken from monetary valuation studies for non-market goods and services (Woodward and Wui, 2001; Brander *et al.*, 2006; Barbier, 2012). Some studies use computable general equilibrium models and growth models to study the indirect and dynamic costs of climate change, including sea level rise. These studies are reviewed in Chapter 10.

There is *high agreement* that the cost of sea-level rise (sum of adaptation and residual damage cost) are smaller with coastal protection than without for the 21st century and the global scale, when considering the impacts of increased coastal flood damage and land loss due to erosion. (Nicholls and Tol, 2006; Anthoff *et al.*, 2010; Hinkel *et al.*, 2012). *Evidence is low*, however, as only a few studies are available. Considering dryland and wetland loss only, the FUND model shows that under a GMSLR of 20-40cm per century it would be economically justified to protect 80% of the exposed coast in all but 15 countries (Nicholls and Tol, 2006) and even under an extreme GMSLR of 6m per century 50% of today's coastline would still be worth protecting (Nicholls *et al.*, 2008). Considering flood damage only, an application of DIVA shows that for 21st century global mean SEA LEVEL RISE scenarios of 60-126cm, upgraded protection through dikes (levees) may reduce total costs by factors 3 to 5 as compared to no upgrades in protection (Hinkel *et al.*, 2012).

There is also *high agreement* that costs and benefits of sea-level rise impacts and adaptation vary strongly between regions and countries and that some developing countries and Small Island States may reach their limits of adaptive capacity or may not be able to bear the costs of impacts and adaptation without external support (Chapter 29, 29.6.2.1). Even with protection, the cost of land loss due to submergence are projected to be above 1% of national GDP for Micronesia, Palau, the Bahamas and Mozambique under 1m of sea level rise (Anthoff *et al.*, 2010). For coastal flooding, annual damage and protection cost are projected to lie between 5% and 9% of national GDP for Kiribati, the Solomon Islands, Vanuatu and Tuvalu in 2100 under 64 cm of global mean sea-level rise (Hinkel *et al.*, 2012). Further substantial costs arise particularly for developing countries due to their current adaptation deficit (i.e. coastal defenses are not adapted to the current climate variability), which is not well understood and requires further analysis (Parry *et al.*, 2009). For example, the adaption deficit of Africa with regards to coastal flooding is estimated to US $300 billion (1995 prices; Hinkel *et al.*, 2011) and that of Bangladesh with respect to cyclones to US$ 25 billion (2009 prices; World Bank, 2011).

Several methodological issues and gaps remain. As there are so few studies of the costs and befits of sea-leverl rise at a global level, *evidence is low*. Uncertainties are largely unknown and the need for further research is large. Impacts considered and damages and losses valued are incomplete. For example, costs of salinity intrusion, land loss due to increased coastal erosion, the backwater effect and the impact of sea-level rise in combination with other drivers on ecosystems have not been assessed at global scales (see Table 5-4). Generally for sea-level rise impacts, it is difficult to establish a “no adaptation” baseline and the choice of the baseline changes damage costs (Yohe *et al.*, 2011).

Furthermore, assessments have focused on protection via hard structures but many more adaptation options are available including, “soft” protection, retreat and accommodation options (Klein *et al.*, 2001; Sect. 5.1) and future work needs to consider these. While the costs of “soft” protection options are largely unknown (Linham and Nicholls 2010), these may provide additional benefits. For example, ecosystem-based adaptation options, also preserve and restore coastal ecosystems whilst protecting against impacts (Espinosa-Romero *et al.*, 2011; McGinnis and McGinnis, 2011; Pérez *et al.*, 2010; Anthony *et al.*, 2009; Alongi, 2008; Zeitlin *et al.*, 2012; Vignola *et al.*, 2009; IUCN, 2008). Finally, it must be noted that protection also further attracts people and development to the floodplain, which together with protection levels leads to ever increasing residual risks with potential catastrophic consequence in the case of defense failure. This is particularly true for many coastal cities such as London, Tokyo, Shanghai, Hamburg and Rotterdam that already rely heavily on coastal defenses (Nicholls *et al.*, 2007).

[INSERT TABLE 5-8 HERE
Table 5-8: Global assessments of costs of sea-level rise.]

5.5.4. Adaptation Practice

Observed adaptation practice generally refers to the body of commonly used actions and measures for climate change adaptation and differs from approaches (5.5.1) and options (5.5.2).

Much of the observed adaptation practice deals mainly with coastal hazards such as coastal erosion and coastal flooding, although imperfect at times (Hanak and Moreno 2012). In many parts of the world, small island indigenous communities address climate change consequences based on their own traditional knowledge (Percival, 2008; Langton *et al.*, 2012; Nakashima *et al.*, 2012).

Adaptation to sea level rise presents challenges on the ground as past adaptation to hazards may not be ecologically sustainable or economically affordable in light of some high-end sea level rise projections. Long-term adaptation to sea level rise has been confined to few major projects such as the Venice Lagoon project, the Thames Estuary 2100 project, London, and the Delta Works, Netherlands, (Norman, 2009) (Boxes 5-2 and 5-3). In addition, the complex nature of coasts as a socio-ecological system (5.2) makes adaptation practice challenging (Rosenzweig *et al.*, 2011).

_____ START BOX 5-2 HERE _____

Box 5-2. London's Themes Estuary 2100 Plan: Adaptive Management for the Long Term

The Environment Agency in Britain, which has the main responsibility for flood risk management in England and Wales, has recently undertaken the project Themes Estuary 2100 (TE2100) to investigate the future flood threat to London (Environment Agency, 2012). The motivation was a fear that due to accelerated climate change-induced sea-level rise time could already be too short for replacing the Thames Barrier (build in 1982) and other measures that protect London, because such major engineering schemes take 25 to 30 years to plan and implement.

The US$20 million TE2100 project was designed to assess combinations of non-structural and structural engineering measures. Over a period of five years, many disciplines were involved, including engineers, economists, ecologists, geomorphologists and sociologists. The TE2100 Plan was developed in stages, with substantial involvement of the Estuary's stakeholders, using multi-criteria analysis to choose between the many competing options.

The main findings were:

- Anticipated sea-level rise is expected not to outstrip the existing defences in the short term: so there is time to plan future flood risk reduction measures.
- The Thames Barrier has a very high design standard (1 to 5,000 years), higher than had been originally anticipated: such key assets need to be made to last as long as possible.
- The Estuary is geomorphologically stable: a sudden change in its character and hence the risk of flooding is unlikely.
- The area affected contains as high density of with immensely valuable London properties, and developing substantially: risk is rising rapidly.

As a result an adaptive plan that manages risk in an iterative way was adopted, with numerous and diverse kinds of measures spread over the next 50 to 100 years, "pulling down" risk to acceptable levels (Figure 5-6). This plan includes an adaptive approach to managing the existing flood defence 'assets' (walls, barriers, gates) in a carefully planned way over the next 100 years (Penning-Rowsell *et al.*, 2012). During this time they will all need replacing, and could at the same time be enhanced. The plan also includes a strategy to restrict development in the flood risk areas, so that the time available for implementing major new works is not eroded by rapidly increasing risk. Finally, in the longer term (beyond c. 2070) there will be the need to plan for more substantial measures if sea-level rise accelerates. This might include a replacement of the Thames Barrier, with higher protection standards, probably nearer to the sea. In the meantime the adaptive approach requires careful monitoring of the drivers of risk in the Estuary to ensure that flood management authorities are not taken by surprise and forced into emergency measures.

[INSERT FIGURE 5-6 HERE
Figure 5-6: Adaptation measures and pathways considered in the TE2100 project. The boxed show the measures and extend over the range of sea level rise they are effective. The blue arrows link to alternative measures that may be applied once a measure is no longer effective. The red lines show the various sea-level rise scenarios used in the analysis. The fat green line shows a possible future adaptation pathway in the unlikely event of extreme change (>4 m rise).]

_____ END BOX 5-2 HERE _____

To date, certain principles and good practices (methods that have shown consistently better results and could be used as benchmark) can be derived from many observed examples of coastal adaptation. In a broad-scale assessment of climate change threats to Australia's coastal ecosystems, seven principles in adaptation were suggested: clearly defined goals for location, thorough understanding of connectivity within and between ecosystems, consideration of non-climatic drivers, involvement of all relevant stakeholders, easily available and shared data, re-thinking of existing policy and planning constraints and adaptation at local/regional scales (Hawden *et al.,* 2011). Based on Oxfam's adaptation programmes in South Asia that include coastal communities, additional principles include a focus on the poor, vulnerable and marginalized, community or local ownership, flexible and responsive implementation, preparation for future and capacity building at multiple levels (Sterrett, *et al.,* 2011). An assessment of worldwide case studies indicates the importance of knowledge transfer of good practice methods for scaling up adaptation strategies in and between regions and beyond the national scale (Martinez *et al.,* 2011).

For European coastlines facing coastal erosion, flooding and landslide events, more specific practices are given in a good practice guide (McInnes, 2006). In the California adaptation study that includes coasts, the lessons learnt include using best available science, decision on goals and early actions, locating relevant partners, identification and elimination of regulatory barriers and encouragement of introduction of new state mandates and guidelines (Bedsworth and Hanak, 2010). Boateng (2010) presented 15 case studies from 12 countries of best practice in coastal adaptation for surveyors. Bangladesh provides good examples in areas of raising awareness, disaster warning and control, and protective building measures (Martinez *et al.,* 2011)**.** In general, documentation on good adaptation practices for coasts is improving.

The issues for coastal adaptation are not radically different from issues encountered with integrated coastal zone management (ICZM) which offers an enabling environment for adaptation practice (Celliers *et al.,* 2013) (Box 5-4). A guidebook by USAID (2009) indicates the transfer of successful experience in ICZM to coastal adaptation. Detailed descriptions of adaptation measures are available in a number of guides or manuals (Linham and Nicholls, 2010; NOAA, 2010; Engineers Australia, 2012). Eleven types of structural projects have been identified for coastal protection and restoration for Louisiana (CPRA, 2012). The major difference of coastal adaptation from ICZM is coping with the dynamic nature of coastal areas, greater uncertainty, longer time frames in planning (beyond 30 years), and long-term commitments inherent in climate change.

Adaptation practice *is likely* to move forward as climate change adaptation (CCA) converges with disaster risk reduction (DRR) (ISDR, 2009; Setiadi *et al.,* 2010; Tran and Nitivattananon, 2011; Hay, 2012). Adaptation practice *is likely* to expand with two emerging approaches to adaptation in recent years – community-based adaptation (CBA) and ecosystem-based adaptation (EBA). CBA involves all relevant stakeholders especially local communities and is a bottom-up approach instead of the usual top-down (Ayers and Huq, 2009; UNDP, 2010; Riadh *et al.,* 2012) (Table 5-7). EBA includes innovative measures (Clark and Jupiter 2010; Crooks *et al.,* 2011; Girot *et al.,* 2012; Jones *et al.,* 2012; Mercer *et al.,* 2012) especially using mangroves for both CCA and DRR (Lacambra *et al.,* 2008; Spalding *et al.,* 2012).

In summary, adaptation practice in the coastal zone continues to meet challenges of climate change and sea-level rise (*very high confidence*). While more traditional adaptation practices may be revealed there is a myriad of adaptation practices depending on technology, policy, financial and institutional support, supported by documentation on good practices. ICZM with its emphasis on integration *is likely* to remain a major process for coastal adaptation. With a better understanding of coasts as a complex socio-ecological system, the future *is likely* to see a wider net and application of adaptation practices (*very high confidence*).

_____ START BOX 5-3 HERE _____

Box 5-3. Paradigm Shift in Adaptation to Rising Sea Levels in The Netherlands

Inhabitants in the low-lying coastal area of the Netherlands have been facing coastal and river flooding for centuries. Extreme sea levels together with long-term delta subsidence have been responsible for major catastrophic events causing thousands of fatalities over the last ten centuries. The expansion of habitable land and the increase in the population exposed to catastrophic events have co-existed with technological improvements for coastal protection and large investments resulting in a dramatic decrease in mortality rate (Van Baars and Van Kempen, 2009). Most of the coastal protection has been implemented during the second half of the twentieth century, resulting in the construction of large and numerous structures altering the appearance of an important part of the Dutch coastal area (Kabat *et al.*, 2009).

At present, nine million residents live in coastal areas at an elevation below sea level, where roughly 65% of gross national product is generated (Stive *et al.*, 2011). The anticipation of a changing climate, including sea-level rise, during the twenty-first century, together with an audit carried out in 2007 giving evidence of an aging flood protection system and an increasing vulnerability has renewed the demand for new plans for water and coastal management.

In this context the Dutch Government has set out far-reaching recommendations on how to keep the country flood-proof over the 21st century by considering a paradigm shift, namely addressing coastal protection 'working with nature' and providing 'room for river' instead of only 'fighting' the forces of nature with engineered structures (Figure 5-7). This takes into account a sea-level rise of as high as 0.65-1.3 by 2100. Some of the recommendations include soft and environmentally friendly solutions such as preserving land from development to accommodate increased river inundation; raising the level of lakes to ensure a continuous supply of fresh water; removing existing protection structures to restore natural estuary and tidal regimes; improving the standards of flood protection by a factor of 10 until 2050; maintaining coastal protection by beach nourishment, expanding the coast seaward in the next century and putting in place the necessary political-administrative, legal and financial resources. The estimated total cost of implementing this ambitious plan is €2.5-3.1 billion a year to 2050, representing a 0.5% of the current Dutch annual gross national product (Stive *et al.*, 2011).

[INSERT FIGURE 5-7 HERE
Figure 5-7: Overview of the Delta Committee National Recommendations. Source: Stive et al., 2011.]

Aerts *et al.* (2008) estimated today's economic damage from flooding based on differentiation according to water depth of all 53 dyke rings as approximately €190 billion covering both direct and indirect damage. The estimated future potential damage would be €400-€800 billion in 2040 and €3700 billion in 2100 in the absence of any measures, given a sea-level rise of 24-60 cm in 2040 and 150 cm in 2100. The factors that govern calculations of estimated future potential damage are economic growth combined with indirect damage. The Delta Committee suggested that, under the umbrella of this paradigm shift in the approach to water and coastal management, climate change offers key challenges that can result in societal and economic growth and evolution, moving the Netherlands into a sustainable country (Kabat *et al.*, 2009).

_____ END BOX 5-3 HERE _____

_____ START BOX 5-4 HERE _____

Box 5-4. Climate Change Adaptation and Integrated Coastal Zone Management in Developing Countries

Integrated Coastal Zone Management (ICZM) promotes sectoral and spatial integration of various activities in the coastal zone by establishing coordination across various sectors and government institutions with a view to sustainably developing coastal resources and protecting the environment. This makes it feasible for combining climate change adaptation with ICZM as a part of an integrative effort in coastal management.

ICZM in developing countries fostered by international organizations, in particular, struggle to meet the goals of ICZM (Isager, 2008). The drawbacks in the implementation of their ICZM act as constraints in climate change

adaptation within ICZM. For example, when initial funding by the external organizations disappears national governments have to step up to finance the cost of ICZM (Ibrahim and Shaw, 2012). Ineffective coastal governance is more visible in cases where the capacity of actors is low, the operation of single agency is dysfunctional, and subsequently, the integration of multiple coastal agencies is beyond the reach of many developing countries (Ibrahim and Shaw, 2012; Martinez *et al.*, 2011). Politics are also a strong force because of the involvement of various stakeholders, the hierarchy of government agencies and ministries, and the power of the majority political party or political leaders (Tabet and Fanning, 2012; Isager, 2008). Furthermore, the nature of public participation in developing countries differs from that in developed countries, and different norms and cultures need to be taken into account to assess public participation central to ICZM (Barale and Özhan, 2010). In some cases, there is lack of knowledge regarding the coastal systems (González-Riancho *et al.*, 2010).

As legal and institutional capabilities critical to the implementation of ICZM are often not available in developing countries, governments generate climate change adaptation strategies that are part of shoreline management plan, regional development, disaster management, and coastal resource management. Cases of adaptation strategies specific to climate change in practice are few as most are at the planning stage equipped with scenarios. Existing strategies derive from responses to coastal disasters and economic and social change affecting coastal livelihoods, for example, readily accessible and trained volunteers respond well by disseminating cyclone warnings and evacuating and rescuing people (WRI, 2007) and this could be translated into a strategy for climate change adaptation. Other strategies in progress or at the trial stage include forested buffer zones such as wetlands and mangroves (Mustelin *et al.*, 2011) and incremental migration. The long-term results and their replicability need to be further assessed.

To anticipate climate change and adapt, a variety of strategies could be used in the future. No or low-regret options provide co-benefits to the goals of sustainable development, livelihood improvement, and human well-being (IPCC, 2012). Combining different strategies are also increasingly under consideration (Cheong, 2011; Cheong *et al.*, 2013; Cartwright, 2009) including the blend of ecology and engineering such as mangrove planting, buffer zones and land use, and insurance and structural coastal defence (Yohe *et al.*, 2011). Adaptation planning on different geographic scales ranging from international, national, and regional in addition to local is at work. Regional adaptation strategies (Martinez *et al.*, 2011) and community-based adaptation (Cutter *et al.*, 2012) are both on the rise. Although ICZM can be a valuable policy framework to integrate climate change adaptation and coastal management, no studies of the effectiveness of ICZM combined with climate change adaptation in developing countries exist yet to assess its utility. Furthermore, there is a need for more detailed understanding of the science of coastal change at the local level that can be coupled with existing adaptation strategies of coastal communities.

_____ END BOX 5-4 HERE _____

5.5.5. Adaptation Opportunities, Constraints, and Limits

During the last years the attention on adaptation opportunities, constraints and limits has grown considerably aiming at a better assessment of our knowledge on adaptation strategies. In order to avoid the existing confusion on the contents of these terms, definitions provided in Chapter 16, Box 16-1 are used here.

There is a growing recognition of the potential co-benefits and new opportunities that can be achieved by mainstreaming adaptation with existing local to national goals and priorities (Chapter 14). Disaster Risk Reduction (DRR) and adaptation share the common goals of reducing vulnerability against impacts of extreme events while creating strategies that limit risk from hazards (IPCC, 2012). This is especially true in coastal areas where extreme flooding events due to severe storm surges are one of the main sources of hazard (Box 5-5). Besides, integrating adaptation with national and local planning can also contribute to build resilience in coastal areas. There is a *very high agreement high confidence* that Integrated Coastal Zone Management (IZCM) can make it possible for coastal regions to achieve their diverse goals in their adaptation to climate change (*limited evidence*) (5.5.1.4).

Ecosystems-Based Adaptation (EBA) is considered to be an emerging adaptation opportunity for adaptation (Munroe *et al.* 2011). In coastal area the conservation or restoration of habitats (e.g. mangroves, wetlands and

deltas) can provide effective measure against storm surge, saline intrusion and coastal erosion by using biodiversity and the ecosystem services they provide as a mean for adaptation (Jones *et al.,* 2012; Duarte *et al.* 2013, van Wesenbeeck, B.K., 2013, Borsje, *et al.*, 2011).

Since AR4 a variety of studies have been published producing a better understanding of the nature of the constraints and limits to adaptation, both generally (Chapter 16) and more specifically in the coastal sector (e.g., Lata and Nunn, 2011; Mozumber *et al.*, 2011; Storbjörk and Hedrén, 2011; Bedsworth and Hannak, 2010; Frazier *et al.*, 2010; Saroar *et al.*, 2010; Moser *et al.*, 2008; Tribbia and Moser, 2008; Ledoux *et al.*, 2005).

Researchers have categorized constraints in different ways (Chapter 16). The common link among all constraints is that they make adaptation less effective or they can lead to missed opportunities, difficult trade-offs, or higher costs. Several examples of constraints for specific for coastal adaptation can be found in the literature. Among others: polarized views in the community regarding the risk of sea level rise and concerns about fairness about retreat schemes in Australia (Ryan *et al.*, 2011); lack of awareness of sea level rise risks and spiritual beliefs in Fiji (Lata and Nunn 2011); insufficient budget for the development of adaptation policies and other currently pressing issues in the US (Mozumber *et al.*, 2011; Tribia and Moser, 2007 and 2008); distinct preferences for retreat options depending on several social and exposure conditions in Bangladesh (Saroar and Routray, 2010); need to provide compensatory habitats under the Habitats Regulations and lack of local public support in the UK (Ledoux *et al.* 2005).

The wide range of constraints identified in this assessment reflects different coastal management contexts, different foci on levels of governance and actors/decision-makers, as well as different methods used in identifying them. The commonly heard claim that lack of information is the main constraint to coastal adaptation is refuted by the wide range of constraints identified, and many of them are empirically shown to be more important than lack of locally relevant, credible information. (*high agreement, robust evidence*). Different constraints typically do not act in isolation, but come in interacting bundles (*high agreement, robust evidence*). Therefore it is difficult to predict which constraints matter most in any specific context but instead multiple constraints need to be addressed if adaptation is to move successfully through the different stages of the management process (*high agreement, moderate evidence*) (Moser and Ekstrom, 2010; Storbjörk, 2010; Londsdale *et al.*, 2010). Besides, some factors can act as enablers and add capacity to adapt, while acting as constraints at others (*high agreement, moderate evidence*) (Burch, 2010; Storbjörk, 2010).

Finally, a common concern emerging from the literature reviews (Biesbroek *et al.*, 2011; Ekstrom *et al.*, 2011) is that some critical constraints arise from the interactions across policy domains, existing laws and regulations, and long-term impacts of past decisions and policies (*high agreement, low evidence*). A limit is reached when adaptation efforts are unable to provide an acceptable level of security from risks to existing objectives and values and prevent the loss of the key attributes, components or services of ecosystem (Chapter 16, Box 16-1; 16.2, 16.5) and may arise due to most of the constraints described above.

As with regards coastal areas, it is widely recognized that biophysical limitations arise, for example, in small developing island states where adaptation through retreat to increasing impact of sea level rise in conjunction with storm surges and flooding is not an option due to limited high land availability, creating a temporary and eventually permanent human displacement from low-lying areas (Green *et al.* 2009; Pelling and Uitto, 2001),(*high agreement, moderate evidence*). Nicholls *et al.* 2011, show that only a limited number of adaptation options are available for specific coastal areas if sea level exceeds a certain threshold (1 m) at the end of the century.

As with regards to natural (unassisted) adaptation, several researchers have examined particularly biophysical limits, e.g., of coastal marshes (Kirwan *et al.*, 2010a, b; Craft *et al.*, 2009; Langley *et al.*, 2009; Mudd *et al.*, 2009). Kirwan *et al.* (2010a) found that coastal marshes can adapt to conservative rates of sea-level rise (A1B), as long as there is sufficient sediment supply. By contrast, even coastal marshes with high sediment supplies, will *likely* submerge near the end of the 21st century under scenarios of more rapid sea-level rise (e.g., those that include ice sheet melting).

Box 5-5. Adaptation to Climate Change in the Framework of Coastal Disaster Management in Japan

Coastal disaster management in Japan is implemented through the Seacoast Law which was established in 1956 after the frequent severe natural disasters such as the Tonankai Earthquake Tsunami in 1944, Nankai Earthquake Tsunami in 1946 and Typhoon No. 13 in 1953. The aim of the law was to "protect the country's seacoast from damage due to sea or ground movement including, but not limited to, tsunami, storm surges and high waves". Later, in 1999, the law was amended to include "conservation of the coastal environment" and "promotion of proper use of the coast by public" in view of various functions of the coast. Under these laws the prefectural governors of each of 71 coastal zones covering the whole coastline in Japan shall established a master plan for coastal conservation. If deemed necessary to take management measures against damages the prefectural governor may designate seacoast conservation areas within the coastal zone. By 2010, about 14,200 km out of the total 35,300 km coastline have been designated and about 9,600 km was protected by coastal structures (River Bureau, 2011).

The crown height of coastal protection structures is determined from the height necessary of storm surges and tsunamis with an additional allowance. The sea-level rise at the time of design is taken into consideration by using the latest tide record. After the 2011 Tohoku Earthquake Tsunami, the Central Disaster Management Council (2011) decided to reconstruct protective coastal structures against the relatively frequent tsunamis (with a return period of several tens to one hundred and some years) and to save human lives by evacuation and all other means for the tsunami of the largest class based on scientific knowledge.

On this basis, the Committee on Adaptation Strategy for Global Warming in the Coastal Zone (2011) developed a manual for adaptation. According to the report, the land area below the mean sea level increases by about 50% in the three major bay areas (Tokyo, Nagoya and Osaka) if the sea level rises by 59 cm which is the highest projection in the IPCC (2007) Fourth Assessment Report. In the Tokyo Bay, the inundation area with a sea-level rise of 60 cm was predicted for Typhoon Muroto which landed on the western part of Japan in 1934 and is stronger than the present design typhoon by 40%. The results showed that 265 km^2 of the Tokyo metropolitan area would be inundated.

In order to develop an adaptation strategy, a case study on the criterion for priority was done. Two indicators were selected and calculated for each section of the land area. One indicator is evaluated from the age and earthquake resistance of the coastal structures in the section, reflecting the soundness of the structures and the urgency for improvement. The other reflects the effectiveness of the structural protection which is evaluated from the damage based on the assets in the predicted inundation area. Figure 5-8 shows the diagram for judging priority of adaptation to global warming. In Tokyo Bay, the allowance in the design crown height has absorbed the sea-level rise up to the present. However, adaptation to the future climate change needs to be implemented according to the diagram in parallel to improvement to aging coastal structures and earthquake resistance.

_____ END BOX 5-5 HERE _____

5.5.6. Synergies and Tradeoffs between Mitigation and Adaptation

Klein *et al.* (2007, p. 749) defined trade-offs between mitigation and adaptation as the "balancing of adaptation and mitigation when it is not possible to carry out both activities fully at the same time (e.g., due to financial or other constraints)". Successful adaptive coastal management of climate risks will involve assessing and minimizing potential trade-offs with other non-climate policy goals (e.g., economic development, enhancement of coastal tourism) and interactions between adaptation and mitigation (e.g. Bunce *et al.*, 2010b; Barbier *et al.*, 2008; Tol 2007; Brown *et al.*, 2002).

A range of studies suggest that adaptation will be the predominant approach to reducing climate risks to coastal communities, populations, resources and activities over the 21st because large increases in sea-level rise cannot be

ruled out (WG1, Chapter 13, 13.5.2.) and because of the time lag between emission reductions, temperature changes and impacts on global sea levels (Nicholls *et al.*, 2011; Nicholls *et al.*, 2007). Systematic assessment of potential synergies and trade-offs between mitigation, adaptation, and other, non-climatic policy goals and efforts to maintain or increase flexibility to enable policy adjustments in the future have been proposed as strategies to recognize, avoid and minimize the risk of negative policy interactions (e.g., Vermaat *et al.* 2005; Nicholls *et al.*, 2011; Chapter 20, 20.3.3.).

Positive synergies and complementarities between mitigation and adaptation in the coastal sector exist. Marine vegetated habitats (seagrasses, saltmarshes, macroalgae or mangroves) contribute to 50% of the total carbon burial in ocean sediments and provide additional functions including the buffering of impacts against storm surges and waves, soil preservation, raising the seafloor and shelter for fish nursery or habitat protection (Duarte *et al.* 2013, Alongi, 2002, Kennedy and Björk, 2009). Consequently, restoration or ecosystem engineering of marine vegetated areas can be considered as a good example of positive synergies between adaptation and mitigation in coastal areas (Duarte *et al.* 2013, Jones, *et al.* 2012, Borsje *et al.* 2011).

Many coastal zone-based activities and various coastal management activities involve emissions of greenhouse gases, the reduction or cessation of some of the may have positive implications for both mitigation and adaptation. The reduction/cessation of offshore oil production will imply a reduction in liquid fuel-related GHG emissions but would also imply a reduced risk of oil spills, a reduction of stresses on the marine/coastal eco-systems and variable socio-economic impacts on human communities and public health (O'Rourke and Connolly, 2003). This may result in reduced vulnerability or increased resilience and consequently a positive for adaptation.

However, some of the coastal adaptation options may have potential negative implications on mitigation. Relocation of infrastructure and development out of the coastal floodplains (retreat) will imply increase in one-time GHG emissions due to rebuilding of structures and possible increase in sprawl and ongoing transportation-related emissions (Biesbroek *et al.* 2009). The building or upgrading of coastal protection structures or ports will also imply an increased energy use and GHG emissions related to construction (cement production) (Boden *et al.* 2011).

Similarly, actions beneficial for mitigation in coastal areas may result in potential negative impacts for adaptation. A more compact coastal urban design, increasing development in floodplains (Giridharan *et al.* 2007) or the development of offshore renewable energy introducing additional drivers on near- and offshore coastal and marine ecosystems and species, are some examples.

5.5.7. Commitment to Adaptation

Recent results (Meehl *et al.* 2012) from global coupled climate model simulations with the new RCPs scenarios to 2300 confirm AR4 (Meehl *et al.* 2007) and indicate that there is a commitment to further sea level rise even if temperatures stabilize due to different levels of mitigation measures. This is mostly due to thermal expansion of seawater and the melting of ice-sheets and glaciers (WG1, Chapter 13).

Table 5-2 summarizes projections from (WG1, Chapter 13) for different extended RCPs for time horizons ranging to 2500 and considering GHG concentrations > 700 ppm. Results show that with aggressive mitigation measures in RCP2.6 limiting global warming, sea level continues to rise after 2100. With more moderate (RCP4.5.) and little (RCP8.5) mitigation, larger ongoing increases in sea level are expected lasting for several centuries.

It can be concluded that since AR4, there is *high agreement* that benefits from mitigation are most immediate for ocean acidification and least immediate for impacts related to sea level rise. A detailed discussion on adaptation efforts mitigation efforts and residual impacts can be found in Chapter 19.

A limited number of studies have estimated impacts due to sea level rise under low or high emission scenarios. Pardaens et al (2011), using projections from two coupled climate models considered the effects on 21st century sea-level rise of mitigation policies, under which the global-mean air temperature stabilizes close to a 2^{o}C increase, relative to a scenario of business-as-usual (a variant of the A1B scenario). The model-averaged projected sea level

rise for 2090–2099 relative to 1980–1999 is 0.29 m–0.51 m and a reduced range under mitigation of 0.17 m–0.34 m, primarily due to reduced thermal expansion. To estimate impacts on coastal populations of the sea level rise projections, the Dynamic Interactive Vulnerability Assessment (DIVA) model was used. Results suggest that by the end of the 21st century and without adaptation around 55% of the 84 million additional people flooded from sea level rise per year globally, under the business-as-usual scenario, could be avoided under such mitigation.

On the other end Nicholls *et al.* (2011) considering an estimate of sea-level rise by 2100, between 0.5 m and 2 m, for a temperature rise of 4°C or more over the same time frame and no mitigation, showed that a real risk of the forced displacement of up to 187 million people over the century (up to 2.4% of global population) exists. By introducing upgrade of protection structures as an adaptation option, it is estimated that the likelihood of protection being successfully implemented varies between regions, and is lowest in small islands, Africa and parts of Asia.

In summary, mitigation plays a role in reducing climate change risk in coastal areas. The intensity and time scale varies depending on the impact considered. Even with aggressive mitigation options future sea-level rise will continue for centuries, but model results show that it can be slowed down, providing more time for long-term strategic adaptation measures to be adopted.

5.6. Information Gaps, Data Gaps, and Research Needs

This chapter has updated knowledge about the impacts of climate change on the coastal systems not in isolation but also from the perspective of overexploitation and degradation that have been responsible for most of the historical changes. There is a better understanding of the varying impacts of weather and climate extremes and long-term sea-level rise on human systems.

That sea levels will rise is a confident projection of climate science but uncertainties around the magnitude of future sea lever rise remain large. It is very likely that GMSL rise during the 21sy century will exceed the observed rate for the period 1971-2100 (Chapter 13, WGI) and that sea level rise will continue to rise for several hundred years even if temperature is stabilized at 2-3^{o}C above pre-industrial values (Meehl *et al.*, 2012). However, many sea level rise assessments are not at spatial or temporal scales most relevant for decision makers who require information on baseline conditions and projections of change (Kettle, 2012) of relative sea level rise (i.e. including local subsidence) for vulnerability assessment and adaptation planning.

Quantitative predictions of future coastal change remain difficult despite the application of improvements in technology, e.g., aerial photographs, satellite imagery, LiDAR (Sesil *et al.*, 2009; Revell *et al.*, 2011; Pe'eri and Long, 2012) to investigate and characterize large-scale changes in shoreline. There is incomplete understanding of coastal changes over the decade and century timescales (Woodroffe and Murray-Wallace, 2012). Shoreline response is more complex than simple submergence because of factors such as sediment supply, offshore geology, engineering structures, and wave forcing (Ashton *et al.*, 2008).

The projection of the future impacts of climate change on natural systems is hampered by the lack of sufficiently detailed data at the required levels of space and time. Observed impacts on beaches, rocky coasts, wetlands, coastal aquifers or deltas area due to the joint effect of multi-drivers of climate and human-induced origin. There is still incomplete understanding of the relative role played by each of these drivers and, especially on their combined effect. Uncertainties are even higher when it comes to the evaluation of projected impacts. For coastal ecosystems virtually all data used to parametrize predictive models have been gathered during perturbation experiments involving only one driver, performed on isolated organisms in the laboratory, and on short periods of time (typically days to weeks). Reliable predictions require information on multifactorial experiments performed on communities (preferably in the field), and on time scale of months to years in order to take into consideration the processes of biological acclimation and adaptation.

Although sea level is projected to rise in future, there are significant gaps in vulnerability assessment of other specific coastal impacts. For example, climate modeling of diseases that could affect coastal areas is based mainly

on the mean values of climate. Also, despite tourism as one of most important industries in the coastal areas, not enough is known about tourists' behavioural reactions to projected climatic changes (Moreno and Amelung, 2009).

A wide range of coastal management framework and measures is available and used in coastal adaptation to climate change, and their scope for their integration has increased by combining scenarios of climate change and socio-economic conditions and risk assessment (Kirshen *et al.,* 2012). While various adaptation measures are available, at the local level, there remains insufficient information on assessment of adaptation options. Data and knowledge gaps exist or their reliability is insufficient. Despite the availability of potential useful climate information, a gap exists between what is useful information for scientists and for users in decision-making. The proposed actions to improve usability include varying levels of interaction, customization, value-adding, retailing and wholesaling (Lemos *et al.*, 2012) so that data and methods can be more openly-accessable to fellow scientists and public (Kleiner, 2011).

Coastal systems are affected by human and climate drivers and there are also complex interactions between the two. In general, where components of coastal systems are sensitive to temperature change, there is a greater degree of confidence that climate change has played a role. Data are available on the range shift in coastal plant and animal species and the role of higher temperatures on coral bleaching. However, in many cases in the human systems, the detected changes can be largely attributed to human drivers. Reducing our knowledge gaps on the understanding of the processes inducing changes would help to respond to them in an efficient way.

The economics of coastal adaptation is under researched. More comprehensive assessments of adaptation costs and benefits that simultaneously consider both the gradual impact of land loss due to sea level rise and the stochastic impacts of extreme water levels (storm surges, cyclones) are needed, as well as other impacts such as salt water intrusion, wetland loss and change and backwater effects. Assessments should also consider a more comprehensive range of adaptation options and strategies, including "soft" protection, accommodation and retreat options as well as the trade-offs between these.

Governance of coastal adaptation and the role of institutions in the transition towards sustainable coasts are under-researched. While institutional factors are recognized to be decisive in constraining and enabling coastal adaptation, there is little dedicated social science research aiming at understanding which institutional arrangement are effective in which socio-economic and biophysical contexts.

Developing a coastal adaptation knowledge network between scientists, policy makers, stakeholders and the general public could be considered as a priority area for coastal areas of large or regional areas affected by climate change and sea-level rise. This is well developed in the European Union, the Mediterranean and Australia but less so in the developing countries, except in certain regions, e.g. Caribbean islands, Pacific Islands.

Future research needs for coastal adaptation are identified by several developments in climate science. Based on Li *et al.* (2011) survey of the foci of climate research in the 21st century, the implications for coasts would be on biodiversity and flooding. Future technological advances may be significant, e.g., new forms of energy and food production, information and communication technology (ICT) for risk monitoring (Delta Commission, 2008) and these would be useful for flood risks and food production in deltas and coastal systems (aquaculture). With recent adverse climatic and environmental events on coasts, adaptation demands different decision regimes (Kiker *et al.*, 2010) but adaptation, mitigation and avoidance measures still require integrating research that includes natural and social sciences (CCSP, 2009). Although many gaps still remain, there is nevertheless a greater foundation of climate change research on coasts across a wide range of fields (Grieneisen and Zhang, 2011) upon which scientists, policymakers and public may find improved solutions for coastal adaptation.

Frequently Asked Questions

FAQ 5.1: How does climate change affect coastal ecosystems?

The major climate-related drivers affecting coastal ecosystems are sea-level rise, ocean warming and ocean acidification. The impact of sea level is mostly related to the capacity by animals (e.g. corals) and plants (e.g. mangroves) to keep up with the vertical rise of the sea. Ocean warming affects all organisms, increasing their

metabolism, causing mass mortality events of those living close their upper thermal limit, and/or affecting their geographical distribution. Ocean acidification negatively impacts many organisms that build shells and skeletons but its effects are poorly known at the ecosystem level.

FAQ 5.2: How is climate change influencing coastal erosion?

Coastal erosion can be caused by winds, waves and currents, especially during storms, as well as sea-level rise and for deltas, river sediment transport and deposition are important factors. Based on the simplest model, a rise in mean sea level usually results in a landward and upward displacement of the cross-shore seabed profile and a retreat of the shoreline. Increasing waves heights can cause the sand bars to move seawards and high storm surges (sea levels) also produce an offshore movement of sand due to non-equilibrium in the profile. Higher waves and surges may increase the probability of sand barrier and dune overwash or breaching. Changes in wave direction may result in increased sediment transport and subsequent erosion.

FAQ 5.3: How can coastal communities adapt to climate change impacts?

Various adaptation strategies are available which range from (managed) retreat, accommodation and protection. Adaptation through structural measures includes hard (e.g. sea walls) and soft (e.g. coastal revegetation) management options. Non-structural measures include land-use planning (e.g. rolling easements that require relocation of vulnerable infrastructure as critical risk thresholds are crossed) and climate-aware policies and plans, including EIA and building codes. Monitoring and compliance are required to ensure implementation of plans. Education is also important for building community resilience. Risk transfer mechanisms (e.g. insurance) address residual risk although where risks are too high, retreat from coastal areas may be the only viable response. A combination of strategies, tailored to suit the particular coastal community, may be required and will need to be reviewed and adjusted as circumstances change in the future.

FAQ 5.4: Does adequate planning for coastal uses contribute to a reduction in climate change risks?

Yes, adequate planning of coastal uses contributes to reduced climate change risks and lessens the chances of reactive responses to the impacts of extreme events. Such planning is normally supported by national legislation and considers both the problems of both climate change and coastal hazards, especially coastal flooding. Regional coastal strategies and plans are established with guidelines for local governments to implement. For measures to be taken, the focus is on precautionary measures irrespective of future climate change. An important paradigm change of planning land uses to reduce climate change is to use the buffer zone as a response to coastal inundation. The strategy is to work with nature rather than against nature, e.g. in the Netherlands. It should be noted that for many developing countries planning at the grass-root level either does not exist or is not yet workable requiring re-evaluation of how to make adaptation more sustainable..

FAQ 5.5: How does ocean acidification affect marine and coastal areas and islands?

PH, a measure of seawater acidity, has numerous implications on biological and geological systems. For example, in coastal systems, it plays a role in primary production which constitutes the base of the food chain, in the deposition of calcium carbonate in shells and skeletons, in the degradation of limestone, as well as in the abundance of certain forms of chemical elements and on their toxicity. Ocean acidification has therefore a lot of ramifications on the biology, ecology, biogeochemistry, and socio-economy of coastal systems. Some of these ramifications are well understood while others such as changes in coastal food-webs and fisheries are poorly known.

Cross-Chapter Boxes

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water structures made of calcium carbonate mostly secreted by reef-building (scleractinian) corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics. About 275 million people live within 30 km of a coral reef (Burke et al., 2011) and are likely to derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including those from provisioning (food, construction material, medicine), regulating (shoreline protection, water quality),

supporting services (oxygen supply) and cultural (religion, tourism). This is especially true in small islands (29.3.3.1).

Most human-induced disturbances to coral reefs were local (e.g., coastal development, pollution, nutrient enrichment and overfishing) until the early 1980s when global and climate-related disturbances (ocean warming and acidification) began to occur. Temperature and seawater acidity are two of the most important environmental variables determining the distribution of coral reefs (Kleypas et al., 2001). As corals are centrally important as ecosystem engineers (Wild et al., 2011), the impacts on corals have led to widespread degradation of coral reefs.

A wide range of climatic and non-climatic stressors affect corals and coral reefs and negative impacts are already observed (5.4.2.4, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae (genus *Symbiodinium*), which live in the coral tissues and play a key role in supplying the coral host with energy and nutrients (Baker et al., 2008) (see 6.2.5 for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies, is the most widespread and conspicuous impact (Fig. 5X; see Sections, 5.4.2.4, 6.2.5, 25.6.2, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Elevated temperature along with ocean acidification reduces the calcification rate of corals (*high confidence*; 5.4.2.4), and may tip the calcium carbonate balance of reef frameworks towards dissolution (*medium evidence and agreement*; 5.4.2.4). These changes will erode fish habitats with cascading effects reaching fish community structure and associated fisheries (*robust evidence, high agreement*, 30.5).

Around 50% of all coral reefs have experienced medium-high to very high impact of human activities (30-50% to 50-70% degraded; Halpern et al., 2008), which has been a significant stressor for over 50 years in many cases. As a result, the abundance of reef building corals is in rapid decline (1 to 2% per year, 1997-2003) in many Pacific and SE Asian regions (Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner et al., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and coral bleaching have led to a decline in coral cover on the Great Barrier Reef (about 51% between 1985 and 2012; De'ath et al., 2012).

One third of all coral species exhibit a high risk of extinction, based on recent patterns of decline and other factors such as reproductive strategy (Carpenter et al., 2008). Although less well documented, non-coral benthic invertebrates are also at risk (Przeslawski et al., 2008). Fish biodiversity is threatened by the permanent degradation coral reefs, including in a marine reserve (Jones et al., 2004). While many factors, such as overfishing and local pollution, are involved in the decline of coral reefs, climate change through its pervasive influence on sea temperature, ocean acidity, and storm strength plays a very significant role.

There is *robust evidence* and *high agreement* that coral reefs are one of the most vulnerable marine ecosystems (Chapters 5, 6, 25, and 30). Globally, more than half of the world's reefs are under medium or high risk of degradation (Burke et al., 2011) even in the absence of climatic factors. Future impacts of climate stressors (ocean warming, acidification and sea level rise) will exacerbate the impacts of non-climatic stressors (*high agreement, robust evidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9–60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation under the RCP3-PD scenario (Frieler et al., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30–88%, 68% uncertainty range). If present day corals have residual capacity to acclimatize and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*; Logan et al., sbm). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs produce 10-12% of the fish caught in tropical countries, and 20-25% of the fish caught by developing nations (Garcia & Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton et al. (2012) are already exploiting their coral reef fisheries in an unsustainable way (13.X.X).

- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke et al., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).
- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard et al., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4, 30.5).

Coral reefs make a modest contribution to the global domestic product but their economic importance can be high at the country and regional scales (Pratchett et al., 2008). For example, tourism and fisheries represent on average 5% of the GDP of South Pacific islands (Laurans et al., 2013). At the local scale, these two services provide at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans et al., 2013).

Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod et al., 2009). Although they are key conservation and management tools, they are less effective in reducing coral loss from thermal stress (Selig et al., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau et al., 2012). Controlling the input of nutrients and sediment from land is an important complementary management strategy because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann et al., 2012). There is also high confidence that, in the long term, limiting the amount of warming and acidity is central to ensuring the viability of coral reef systems and dependent communities (5.X.X and 30.5).

[INSERT FIGURE CR-1 HERE
Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Introduction

Anthropogenic ocean acidification and climate change share the same primary cause at the global level, the increase of atmospheric carbon dioxide (WGI, 2.2.1). Eutrophication and upwelling contribute to local ocean acidification (5.3.3.6, 30.5.4). Past and futures changes in chemistry are well known in the surface open ocean (WGI, 3.8.2 and 6.4.4) but are more difficult to project in the more complex coastal systems (5.3.3.6 and 30.5.2).

Chemistry and Projections

The fundamental chemistry of ocean acidification has long been understood: the uptake of CO_2 into mildly alkaline ocean results in an increase in dissolved CO_2 and reductions in pH, dissolved carbonate ion, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of surface seawater can be projected at the global scale with high accuracy from projections of atmospheric CO_2 levels. Time series observations of changing upper ocean CO_2 chemistry support this linkage (WGI Table 3.2 and Figure 3.17; WGII Figure 30.5). Projections of regional changes, especially in coastal waters (5.3.3.6), and at depth are more difficult;

observations and models show with high certainty that fossil fuel CO_2 has penetrated at depths of 1 km and more. Importantly, the natural buffering of increased CO_2 is less in deep than in surface water and thus a greater chemical impact is projected. Additional significant CO_2 increases and pH decreases at mid-depths are expected to result from increases in microbial respiration induced by warming. Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGII, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration).

Biological, Ecological, and Biogeochemical Impacts

The effects of ocean acidification on marine organisms and ecosystems have only recently been investigated. A wide range of sensitivities to projected rates of ocean acidification exists within and across organism groups and phyla with a trend for higher sensitivity in early life stages (*high confidence*; Kroeker et al., in press; 6.2.3-5, 6.3.4). A pattern of impacts, some positive, others negative, emerges for some processes and organisms (*high confidence*; Fig. X.C) but key uncertainties remain from organismal to ecosystem levels (Chap. 5, 6, 30). Responses to ocean acidification are exacerbated at high temperature extremes (*medium confidence*) and can be influenced by other drivers, such as oxygen concentration, nutrients, and light availability (*medium confidence*).

Experimental evidence shows that lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers such as reef-building corals (Box CC-CR, coralline algae (Raven, in press), bivalves and snails (Gazeau et al., in press) reducing their competitiveness compared to, e.g. seaweeds (Chap. 5, 6, 30). A reduced performance of these ecosystem builders would affect the other components of the ecosystem dependent on the habitats they create.

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*) and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may significantly stimulate nitrogen fixation in the oceans (*limited evidence, low agreement*; 6.2.3, 6.3.4). There are few known direct effects on early stages of fish and adult fish remain relatively undisturbed by elevated CO_2. Serious behavioral disturbances were reported, mostly on larval and juvenile coral reef fishes (6.2.4).

Projections of ocean acidification effects at the ecosystem level are limited by the diversity of species-level responses. Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities living on the sea-floor. Shifts in community structure have been documented in rocky shore environments (e.g., Wootton et al., 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012). Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.2-3), which could impact food webs and higher trophic levels (*limited evidence, high agreement*).

There is *limited evidence* and *medium agreement* that some phytoplankton and mollusks can adapt to ocean acidification, indicating that the long-term responses of these organisms to ocean acidification could be less than responses obtained in short-term experiments. However, mass extinctions during much slower rates of ocean acidification in Earth history (6.1.2) suggest that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of change (*high confidence*).

The effect of ocean acidification on global biogeochemical cycles is difficult to predict due to the species-specific responses to ocean acidification, lack of understanding of the effects on trophic interactions, and largely unexplored combined responses to ocean acidification and other climatic and non-climatic drivers, such as temperature, concentrations of oxygen and nutrients, and light availability.

Risks

Climate risk is defined as the probability that climate change will cause specific physical hazards and that those hazards will cause impacts (19.5.2). The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, includes both the probability that ocean acidification will affect key processes, and the magnitude of the resulting impacts. The changes in key processes mentioned above present significant ramifications on ecosystems and ecosystem services (Fig. 19.3). For example, ocean acidification will cause a decrease of calcification of corals, which will cause not only a reduction in the coral's ability to grow its skeleton, but also in its contribution to reef building (*high confidence*; 5.4.2.4). These changes will have consequences for the entire coral reef community and on the ecosystem services that coral reefs provide such as fisheries habitat (*medium confidence*; 19.5.2) and coastal protection (*medium confidence*; Box CC-CR). Ocean acidification poses many other

potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Socioeconomic Impacts and Costs

The biological, ecological and biogeochemical changes driven by ocean acidification will affect several key ecosystem services. The oceans will become less efficient at absorbing CO_2, hence less efficient at moderating climate change, as their CO_2 content will increase (*very high confidence*). The impacts of ocean acidification on coral reefs, together with those of bleaching and sea level rise, will in turn diminish their role of shoreline protection in atolls and small island nations as well as their direct and indirect benefits on the tourism industry (*limited evidence, high agreement*; Box CC-CR).

There is no global estimate of the observed or projected economic costs of ocean acidification. The production of commercially-exploited shelled mollusks may decrease (Barton et al., 2012) resulting in an up to 13% reduction of US production (limited evidence, low agreement; Cooley and Doney, 2009). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (Narita et al., 2012). The largest uncertainty is how the impacts on prey will propagate through the marine food webs and to top predators. Models suggest that ocean acidification will generally reduce fish biomass and catch (*limited evidence, high agreement*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (Branch et al., 2012; Griffith et al., 2012). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 500 billion USD, respectively for A1 and B2 SRES emission scenarios (Brander et al. 2012). Although this number is small compared to global GDP, it represents a large proportion of the GDP of some regions or small island states which rely economically on coral reefs.

Adaptation and Mitigation

The management of ocean acidification comes down to mitigation of the source of the problem and adaptation to the consequences (Rau et al., 2012; Billé et al., sbm). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts. Climate geoengineering techniques based on solar radiation management would have no direct effect on ocean acidification because atmospheric CO_2 would continue to rise (6.4.2). Techniques based on carbon dioxide removal could directly address the problem but their effectiveness at the scale required to ameliorate ocean acidification has yet to be demonstrated. Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep water oxygen levels (Williamson and Turley, 2012; 6.4.2; 30.3.2.3 and 30.5.7). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Specific activities, such as aquaculture, could adapt to ocean acidification within limits, for example by altering the production process, selecting less sensitive species or strains, or relocating elsewhere. A low-regret approach is to limit the number and the magnitude of drivers other than CO_2. There is evidence, for example, that reducing a locally determined driver (i.e. nutrient pollution) may substantially reduce its synergistic effects with a globally determined driver such as ocean acidification (Falkenberg et al., 2013).

[INSERT FIGURE OA-1 HERE

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.]

Box CC-TC. Case Study Building Long Term Resilience from Tropical Cyclone Disasters

[Yoshiki Saito (Japan), Kathleen McInnes (Australia)]

Tropical cyclones (also referred to as hurricanes and typhoons in some regions) cause powerful winds, torrential rains, high waves and storm surge, all of which can have major impacts on society and ecosystems. For example, Bangladesh and India account for 86% of mortality from tropical cyclones (Murray *et al.*, 2012), which is mainly due to the rarest and most severe storm categories (i.e. Categories 3, 4, and 5).

About 90 tropical cyclones occur globally each year (Seneviratne et al, 2012) although interannual variability is large. Changes in observing techniques particularly after the introduction of satellites in the late 1970s, confounds the assessment of trends in tropical cyclone frequencies and intensities. Therefore, SREX concluded that there is *low confidence* that any observed long-term (i.e. 40 years or more) increases in tropical cyclone activity are robust, after accounting for past changes in observing capability (Seneviratne, *et al.*, 2012; Chapter 2). There is also *low confidence* in the detection and attribution of century scale trends in tropical cyclones. Future changes to tropical cyclones arising from climate change are *likely* to vary by region. This is because there is *medium confidence* that for certain regions, shorter-term forcing by natural and anthropogenic aerosols has had a measurable effect on tropical cyclones. Tropical cyclone frequency is *likely* to decrease or remain unchanged over the 21st century, while intensity (i.e. maximum wind speed and rainfall rates) is *likely* to increase. Regionally specific projections have *lower confidencelower confidence* (see WG1 Box 14.2).

Longer term impacts from tropical cyclones includes salinisation of coastal soils and water supplies and subsequent food and water security issues from the associated storm surge and waves (Terry and Chui, 2012). However, preparation for extreme tropical cyclone events through improved governance and development to reduce their impacts provides an avenue for building resilience to longer term changes associated with climate change.

Densely populated Asian deltas are particularly vulnerable to tropical cyclones due to their large population density in expanding urban areas (Nicholls *et al.*, 2007). Extreme cyclones in Asia since 1970 caused over 0.5 million fatalities (Murray *et al.*, 2012) e.g., cyclones Bhola in 1970, Gorky in 1991, Thelma in 1998, Gujarat in 1998, Orissa in 1999, Sidr in 2007, and Nargis in 2008. Tropical cyclone Nargis hit Myanmar on 2 May 2008 and caused over 138,000 fatalities. Several-meter high storm surges widely flooded densely populated coastal areas of the Irrawaddy Delta and surrounding areas (Revenga *et al.*, 2003; Brakenridge *et al.*, 2012). The flooded areas were captured by a NASA MODIS image on 5 May 2008 (Figure TC-1).

[INSERT FIGURE TC-1 HERE
Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. (From Brakenridge *et al.*, 2012).]

Murray *et al.* (2012) compared the response to cyclone Sidr in Bangladesh in 2007 and Nargs in Myanmar in 2008 and demonstrated how disaster risk reduction methods could be successfully applied to climate change adaptation (Murray et al, 2012). Sidr, despite being of similar strength to Nargis, caused far fewer fatalities (3,400 compared to over 138000) and this was attributed to advancement in preparedness and response in Bangladesh through experience in previous cyclones such as Bhola and Gorky. The responses included the construction of multi-storied cyclone shelters, improvement of forecasting and warning capacity, establishing a coastal volunteer network, and coastal reforestation of mangroves. Birkmann and Teichman, (2010) caution that while the combination of risk reduction and climate change adaptation strategies may be desirable, different spatial and temporal scales, norm systems, and knowledge types and sources between the two goals can confound their effective combination.

Table 5-1: Projections of global mean sea level rise in metres relative to 1986–2005 based on ocean thermal expansion calculated from climate models, the contributions from glaciers, Greenland and Antarctica from surface mass balance calculations using climate model temperature projections, the range of the contribution from Greenland and Antarctica due to dynamical processes, and the terrestrial contribution to sea levels, estimated from available studies. For sea levels up to and including 2100, the central values and the 5-95% range is given whereas for projections from 2200 onwards, the range represents the model spread due to the small number of model projections available (source: WG1, Chapter 13).

	RCP	2080-2100	2100	2200	2300	2400	2500
Low	2.6	0.42 [0.29 to 0.55]	0.46 [0.32 to .61]	0.47–0.60	0.59–0.67	0.67–0.79	0.77–0.91
Medium	4.5	0.49 [0.36 to 0.63]	0.56 [0.41 to .71]	0.25–0.90	0.31–1.12	0.30–1.38	0.27–1.67
High	6.0	0.50 [0.37 to 0.64]	0.58 [0.42 to .74]	0.67–1.92	1.10–3.21	1.44–4.55	1.80–5.76
	8.5	0.64 [0.48 to 0.82]	0.76 [0.56 to .96]				

Table 5-2: Main climate-related drivers for coastal systems, their trends due to climate change, and their main physical and ecosystem effects (↑ increase; ↓ decrease; ⊄ no change; ? uncertain; ↔ regional variability).

Climate Driver	Physical effects	Trends	Projections	Progress since AR4
Sea Level	Submergence, flood damage, erosion; saltwater intrusion; rising water tables/impeded drainage; wetland loss (and change).	GMSL *very likely* (5.3.2.2, WG1 Ch. 13)	GMSL *very likely* (see Table 5.1, WG1 Ch. 13) « (5.3.2.2, WG1 Ch. 13)	Improved confidence in contributions to observed sea level. More information on regional and local SLR.
Storms (Tropical cyclones (TC's), extratropical cyclones (ETC's)	Storm surges and storm waves, coastal flooding, erosion; saltwater intrusion; rising water tables/impeded drainage; wetland loss (and change). Coastal infrastructure damage and flood defence failure.	TC's (Box 5.1, WG1 2.6.3) *Low confidence* in trends in frequency and intensity due to limitations in observations « ETC's (5.3.3.1 WG1 2.6.4) *Likely* poleward movement of circulation features but *low confidence* in intensity changes.	TC's (Box 5.1) *Likely* ¯ - Ë in frequency; *Likely* ↑ in the most intense TC's ETC's (5.3.3.1) *High confidence* that reduction of ETC's will be small globally. *Low confidence* in changes in intensity.	Lowering of confidence of observed trends in TC's and ETC's since AR4. More basin-specific information on storm track changes.
Winds	Wind waves, storm surges, coastal currents, coastal infrastructure damage.	*Low confidence* in trends in mean and extreme wind speeds (5.3.3.2, SREX, WG1 Ch 2).	*Low confidence* in projected mean wind speeds. *Likely* increase in TC extreme wind speeds (5.3.3.2, SREX).	Winds not specifically addressed in AR4.

Waves	Coastal erosion, overtopping and coastal flooding.	*Likely* positive trends in high latitudes (5.3.3.2, WG1, Ch 3).	*Low confidence* for projections overall but *medium confidence* for southern ocean increases (5.3.3.2).	Large increase in number of wave projection studies since AR4.
Extreme Sea Levels	Coastal flooding erosion, saltwater intrusion	*High confidence* of increase due to GSLR (5.3.3.3, WG1 Chapter 13).	*High confidence* of increase due to GSLR, *low confidence* of changes due to storm changes (5.3.3.3, WG1 Chapter 13) «	Local subsidence is an important contribution to RSLR in many locations.
Sea Surface Temperature	Changes to stratification and circulation; reduced incidence of sea ice at higher latitudes; increased coral bleaching and mortality, poleward species migration; increased algal blooms.	*High confidence* that coastal SST increase is higher than global SST increase « (5.3.3.4, WG1 Ch. 3).	*High confidence* that coastal SSTs will increase with projected temperature increase (5.3.3.4).	Emerging information on coastal changes in SSTs.
Freshwater Input	Altered flood risk in coastal lowlands; altered water quality/salinity; altered fluvial sediment supply; altered circulation and nutrient supply.	*Mmedium confidence (limited evidence)* in a net declining trend in freshwater input.	*Medium confidence* for general increase in high latitudes and wet tropics and decrease in other tropical regions «.	Emerging information on freshwater input.
Ocean Acidity	Increased CO2 fertilisation; decreased seawater pH and carbonate ion concentration (or 'ocean acidification') [this is not a "Physical effect"]	*High confidence* of overall increase, with high local and regional variability (5.3.3.5).	*High confidence* of increase at unprecedented rates but with local and regional variability (Box CC-OA).	OA not specifically addressed in AR4. Considerable progress made in chemical projections and biological impacts.

Table 5-3: Top ten nations with the largest populations and the highest proportions of population in low-lying coastal areas (Countries with fewer than 100,000 inhabitants are not included; 15 SIDs (Small Island Developing States) with total of 423,000 inhabitants are also excluded). Source: Bollman *et al.*, 2010.

Top ten nations classified by population in low-lying coastal regions			Top ten nations classified by proportion of population in low-lying coastal regions		
Nation	Population in low-lying coastal regions (10^3)	% of population in low-lying coastal regions	Nations	Population in low-lying coastal regions (10^3)	% of population in low-lying coastal regions
1. China	127,038	10 %	1. Maldives	291	100 %
2. India	63,341	6 %	2. Bahamas	267	88 %
3. Bangladesh	53,111	39 %	3. Bahrain	501	78 %
4. Indonesia	41,807	20 %	4. Suriname	325	78 %
5. Vietnam	41,439	53 %	5. Netherlands	9590	60 %
6. Japan	30,827	24 %	6. Macao	264	59 %
7. Egypt	24,411	36 %	7. Guyana	419	55 %
8. USA	23,279	8 %	8. Vietnam	41,439	53 %
9. Thailand	15,689	25 %	9. Djibouti	250	40 %
10. Philippines	15,122	20 %	10. Bangladesh	53,111	39 %

Table 5-4: Main impacts of relative sea-level rise. Adapted from Nicholls 2002 and Nicholls *et al.* 2010.

Biophysical impacts of relative sea-level rise	**Other climate drivers**	**Other human drivers**
Dryland loss due to submergence	Wave and storm climate, morphological change, sediment supply	Sediment supply, flood management, morphological change, land claim
Flood damage (due to surges, tropical cyclones)	Wave and storm climate, morphological change, sediment supply	Sediment supply, flood management, morphological change, land claim
Backwater effect (river)	Runoff	Catchment management and land use
Wetland loss (and change)	Sediment supply, CO_2 fertilization,	Sediment supply, migration space, direct destruction
Dryland loss due to erosion	Sediment supply, wave and storm climate	Sediment supply
Saltwater intrusion into surface waters	Runoff	Catchment management and land use
Saltwater intrusion into ground waters	Precipitation	Land use, aquifer use
Rising water tables/ impeded drainage	Precipitation	Land use, aquifer use

Table 5-5: Summary of Coastal Vulnerability Assessments conducted at national or regional scale. Studies that either costed (Adapt$) or considered adaptation options (Adapt) are indicated. In studies that have considered adaptation: WOA=without adaptation; WA=with adaptation. CVI=Coastal Vulnerability Index; GIS=Geographic Information System, DIVA=Dynamic Interactive Vulnerability Assessment model. RSLR=relative sea level rise.

Location	Physical impacts considered	SLR scenario	Socio-economic scenario	Physical and ecosystem vulnerability	Human system vulnerability	Method and tools	Reference
Africa							
Africa	Erosion, flooding	0.64-1.26 m SLR by 2100, plus local subsidence/ uplift	IMAGE model scenario		WOA: 16–27 million people flooded and US$5-9 billion annual damage costs WA: Adaptation cuts people flooded by two orders of magnitude and damage costs by half, adaptation deficit US$300 billion and annual costs US$2-6 billion	DIVA (Adapt$)	Hinkel *et al.*, 2011
Ghana (east coast)	Erosion, submergence	1-5m SLR		Possible erosion of existing coastal buffer zones that separate open coast from coastal lagoons and inundation of coastal plains		GIS	Boateng, 2012b
Tanzania (Dar-es-Salaam)	Flood exposure	0.13-0.66 m by 2070, plus local subsidence/ uplift, plus to 1-in-100 event	A1 with rapid urbanization		210,000 people and US$10 billion exposed to 100-year coastal flood by 2070	GIS	Kebede and Nicholls, 2012
Asia							
China				Sediment supply to major delta regions has reduced by 50% since early 1980's and is driving coastal erosion			Cai *et al.*, 2009
China	Flooding, erosion	Current rate of RSLR (average 6mm/yr)		Vulnerability to flooding and erosion of the 18,000 km coastline, is ranked very high-3%; high-29%; moderate- 58% and low-10%.		CVI	Yin *et al.*, 2012
East Timor	Flooding, erosion wetland loss, salt water intrusion	0.31-0.54 m by 2100, plus local subsidence / uplift	A2 and B1	Wetland area reduction under 0.54m SLR is greatest for the Solomon Islands (68%), the Philippines (51%) and East Timor (50%). Composition of wetland areas in 2100 change to include more mangroves and less unvegetated wetland areas in 2100 compared to 2010. Increased salinity intrusion up major rivers 14-27% under A2	Expected number of people flooded annually relative national population (pop): WOA 0.54% pop A2; WA 0.01% pop A2	DIVA (Adapt$)	McLeod *et al.*, 2010
Indonesia					WOA 1.19% pop A2; WA 0.00% pop A2		
Malaysia					WOA 0.46% pop A2; WA 0.00% pop A2		
Papua New Guinea					WOA 0.07% pop A2; WA 0.01% pop A2		
Philippines					WOA 0.80% pop A2; WA 0.00% pop A2		
Solomon Islands					WOA 0.27% pop A2; WA 0.00% pop A2		

				Increased salinity intrusion into land areas 7-12% under A2			
India (Udupi coast)	Erosion, submergence	1-10m SLR		Erosion risk: of the 95 km of coastline, 59% assessed as very high; 7%high, 4% moderate, 30% low erosion risk. 372-42 km^2 exposed to submergence from 1m SLR	Qualitative assessment of affected areas include residential and recreational areas, agricultural land and the natural ecosystem	CVI	Dwarakish *et al.*, 2009
Vietnam	Submergence exposure	1-5m			Exposure is largest in Red River and Mekong deltas. Options identified to prolong the use of these areas into the future	GIS	Boateng, 2012a
Australasia							
Australia	Flood exposure, Erosion	1.1 m, combined with either 1-in-100 year flood event or mean high tide level		Exposure to tropical cyclone related hazards across northern half of continent, health of Great Barrier Reef will affect coastal resilience in NE. Southern coastline with extensive cliffs, large bays, estuaries, gulfs and flats vulnerable to SLR inundation and cliff instability if wave climate changes. Greater erosion along populous eastern coast due to SLR and storm changes.	Potential inundation of, 157,000–247,600 of the 711,000 existing residential buildings close to water. Nearly 39,000 buildings at risk from erosion due to SLR. Indigenous communities, including island based deemed particularly vulnerable due to their remoteness and location on low elevation land.	GIS coastal geomorphology model and Bruun Rule GIS DEM infrastructure database	Department of Climate Change, 2009
Australia (Victoria)	Flood exposure	0.8-1.4 m SLR by 2100, plus 1-in-100 year flood event		Across 9 coastal settlements considered, area exposed to 1-in-100 flood ranges from 153 to 408 km^2 for 0-1.4 m SLR	Across 9 coastal settlements considered, land parcels exposed to 1-in-100 flood ranges from 2,362 to 47,102 for 0 to1.4 m SLR	Hydrodynamic modelling, GIS	McInnes *et al.*, 2011
Europe							
Croatia	Submergence exposure	0.2-0.86 m SLR		A long narrow steep coastline with one major reclaimed alluvial plain will become increasingly vulnerable to inundation particularly for larger SLR projections. Erosion of pocket beaches will increase.	Sewage systems, agriculture and maritime transport and tourism affected by greater flood frequency of low-lying land and berths and piers.	Qualitative assessment	Baric *et al.*, 2008
Denmark-Copenhagen	Flood exposure	0.0-1.25 m SLR			Copenhagen not highly vulnerable to coastal flooding due to existing flood protection. WOA: direct costs of 1-in-100 year event increase from €3-4.8 billion with 0.5m SLR	GIS (Adapt)	Hallegatte *et al.*, 2011
Estonia	Submergence exposure	1 m SLR adjusted for regional uplift (i.e.		Observed beach erosion has resulted from increased storminess in the eastern Baltic Sea, combined with decline in winter sea-ice cover. Future	Possible productivity benefit from longer growing season. Major towns are not threatened due to location inland and mitigating effects of uplift. Sandy beaches and emerging coastal	Qualitative assessmen	Kont *et al.*, 2008

		69–73 cm RSLR)		land loss will impact major bird breeding grounds	tourism at risk.	t	
France	Flood exposure, erosion	0.88 m SLR + 5.8m surge (Atlantic) and 2.7 m surge (Mediterranean)		Atlantic coast with extensive dune systems is assessed as more resilient to rising sea levels over the coming century compared with Mediterranean coast where narrow dune systems are highly urbanized		GIS	Vinchon *et al.*, 2009
Germany	Submergence exposure	1 m SLR		There is a high level of reliance on hard coastal protection against extreme sea level hazards which will increase ecological vulnerability over time	300,000 people exposed in the coastal cities and communities. Erosion and flooding risks US$300 billion (based on 1995 values) of assets	GIS DEM, land-use, socio economic data	Sterr, 2008
Great Britain	Erosion, submergence	0.8 – 1m SLR		Large parts of the coasts are presently sediment starved and eroding and this will continue	At the national scale, economic losses due to erosion are expected to remain considerably smaller than flood losses	Qualitative assessment	de la Vega-Leinert and Nicholls, 2008
Norway	Submergence	0.5 - 1m SLR		Nationally, low susceptibility to accelerated sea-level rise due to mainly steep and resistant coastlines	Extensive infrastructure on northern and western coastlines likely to be negatively affected by sea-level rise, and adaptation costs could be significant	Qualitative assessment	Aunan and Romstad, 2008
Poland	Submergence	0.3 – 1m SLR		Lagoons, river deltas and estuaries in the far east and west were considered most vulnerable		Qualitative assessment	Pruszak and Zawadzka, 2008
Portugal	Submergence	0.14-0.57 m by 2100 SLR		Estuaries and coastal lagoons are assessed as most vulnerable and already sediment starved coastal beaches will continue to erode		Qualitative assessment	Ferreira *et al.*, 2008
Turkey	Submergence	1 m SLR			Without adaptation, impacts could cost 6% of current GNP. Adaptation/protection could cost 10% of current GNP.	Qualitative (Adapt)	Karaca and Nicholls, 2008
European Union	Erosion, flooding, salinity intrusion	0.35-0.45 m by 2100 SLR	A2 and B1		WOA: 0.2-0.8 million people flooded and US$17 billion annual damage costs WA: adaptation cuts exposure by a factor of 100 and annual damage costs by a factor of 10.	DIVA (Adapt$)	Hinkel *et al.*, 2010
N. America							
US	Submergence exposure	Land below 6 m above			20 municipalities with populations greater than 300,000 and 160 municipalities	GIS	Weiss *et al.*, 2011

		MHHW			with populations between 50,000 and 300,000 have land area with elevations at or below 6 m and connectivity to the sea,		
US	Land loss due to submergence	0.19-1.26 m SLR by 2100	2% annual GDP growth		WA: Total cost (adaptation plus residual damage) of US$ 50-75 billion (discounted at 3%)	GIS, CBA of protection vs. retreat (Adapt$)	Neumann *et al.*, 2010
US South Florida	Land loss due to submergence	0.5, 1.0, 1.5 m SLR by 2100 combined with MHHW		Submergence affects areas of ~1300 km^2, ~1700km^2, ~ 3000 km^2 respectively for SLR scenarios considered	~68000, ~210000, ~750000 population exposed population to SLR scenarios respectively $8 billion, $47 billion, $144 billion exposed to SLR scenarios respectively	GIS	Zhang, 2011
US Florida Keys	Land loss due to submergence	0.3, 0.6, 0.9, 1.2, 1.5, 1.8m SLR by 2100 combined with MHHW		Submergence affects areas of ~82 km^2, ~95km^2, ~ 107 km^2, ~119 km^2, ~127km^2, ~ 133 km^2 respectively for SLR scenarios	2663, 6403, 11,026, 15933, 19802, 21768 population exposed population to SLR scenarios respectively ~$56 million, ~$367 million, ~$2 billion, ~$6 billion, ~$9 billion, ~$12 billion exposed to SLR scenarios respectively	GIS	Zhang et al, 2011
US	Land loss due to submergence	0.67 m by 2100			Under the mid-SLR scenario (), approximately 1,630,000 people are potentially affected by SLR. Of these, 332,000 (~20%) are among the most socially vulnerable.	GIS & Social Vulnerability Index (SoVI)	Martinich et al, 2012
NW territories (Canada)	Shoreline stability and population exposure	Temperature, wind patterns		Loss of sea ice and shorter winter season and more variable weather patterns lead to changes in coastal sea ice coverage. Effects on species health and numbers.	More hazardous travel conditions for traditional hunting practices. Loss of traditional knowledge, skills and values.	Qualitative (Adapt)	Pearce *et al.*, 2010

Table 5-6: Impacts of sea level rise, coastal floods, and storms on critical coastal infrastructure by sector. Sources: Horton and Rosenzweig (2010), Zimmerman and Faris (2010).

Communications	Energy	Transportation	Water and waste
Higher average sea level			
• Increased salt water encroachment and damage to low-lying communications infrastructure not built to withstand saltwater exposure • Increased rates of coastal erosion and/or permanent inundation of low-lying areas, causing increased maintenance cost and shortened replacement cycles • Tower destruction or loss of function	• Increased rates of coastal erosion and/or permanent inundation of low-lying areas, threatening coastal power plants and refineries • Increased equipment damage from corrosive effects of salt water encroachment resulting in higher maintenance costs and shorter replacement cycles	• Increased salt water encroachment and damage to infrastructure not built to withstand saltwater exposure • Increased rates of coastal erosion and/or permanent inundation of low-lying areas, resulting in increased maintenance cost and shorter replacement cycles • Decreased clearance levels under bridges	• Increased salt water encroachment and damage to water and waste infrastructure not built to withstand saltwater exposure • Increased release of pollution and contaminant runoff from sewer systems, treatment plants, brownfields and waste-storage facilities • Permanent inundation of low-lying areas, wetlands, piers, and marine transfer stations • Increased salt water infriltration into distribution systems transfer stations
More frequent and intense coastal flooding			
• Increased need for emergency management actions with high demand on communications infrastructure • Increase damage to communications equipment and infrastructure in low-lying areas	• Increased need for emergency management actions • Exacerbated flooding of low-lying power plants and equipment, as well as structural damage to infrastructure due to wave action • Increased use of energy to control floodwaters • Increased number and duration of local outages due to flooded and corroded equipment	• Increased need for emergency management actions • Exacerbated flooding of streets, subways, tunnel and bridge entrances, as well as structural damage to • Decreased levels of service from infrastructure due to wave action flooded roadways; increased hours of delay from congestion during street-flooding episodes • Increased energy use for pumping	• Increased need for emergency management actions • Exacerbated street, basemend and sewer flooding, leading to structural damage to infraesctructure • Episodic inundation of low-lying areas, wetlands, piers, and marine transfer stations

Table 5-7: Community-based adaptation options.

Impact	Type of option	Option	Brief description	References
Salinity	New and diversified livelihoods	Saline-tolerant crop cultivation	Farmer production of saline-tolerant multi-vegetable varieties and non-rice crops.	Rabbani *et al.* 2013; Ahmed 2010

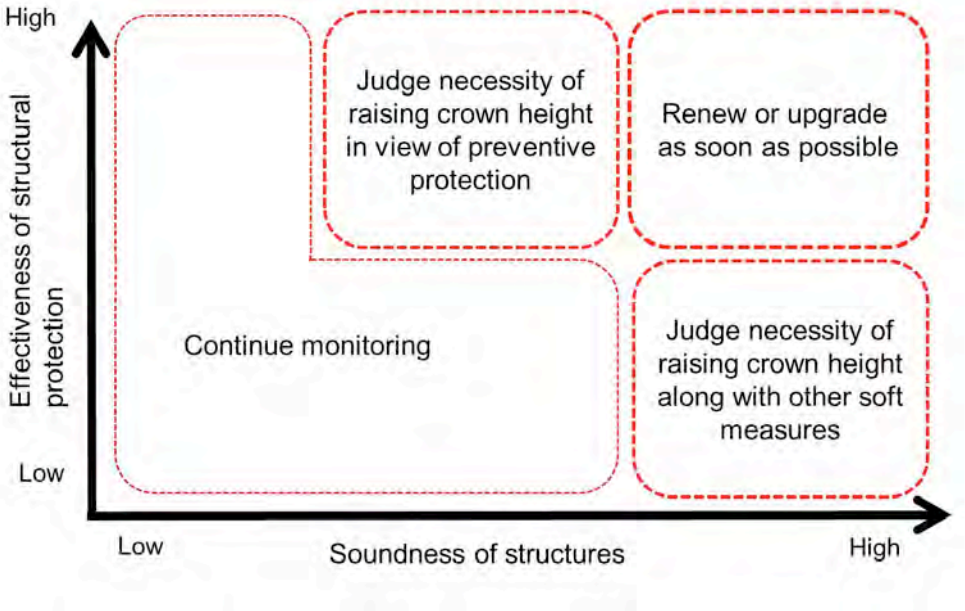

Figure 5-8: Priority in investment for adaptation to global warming.

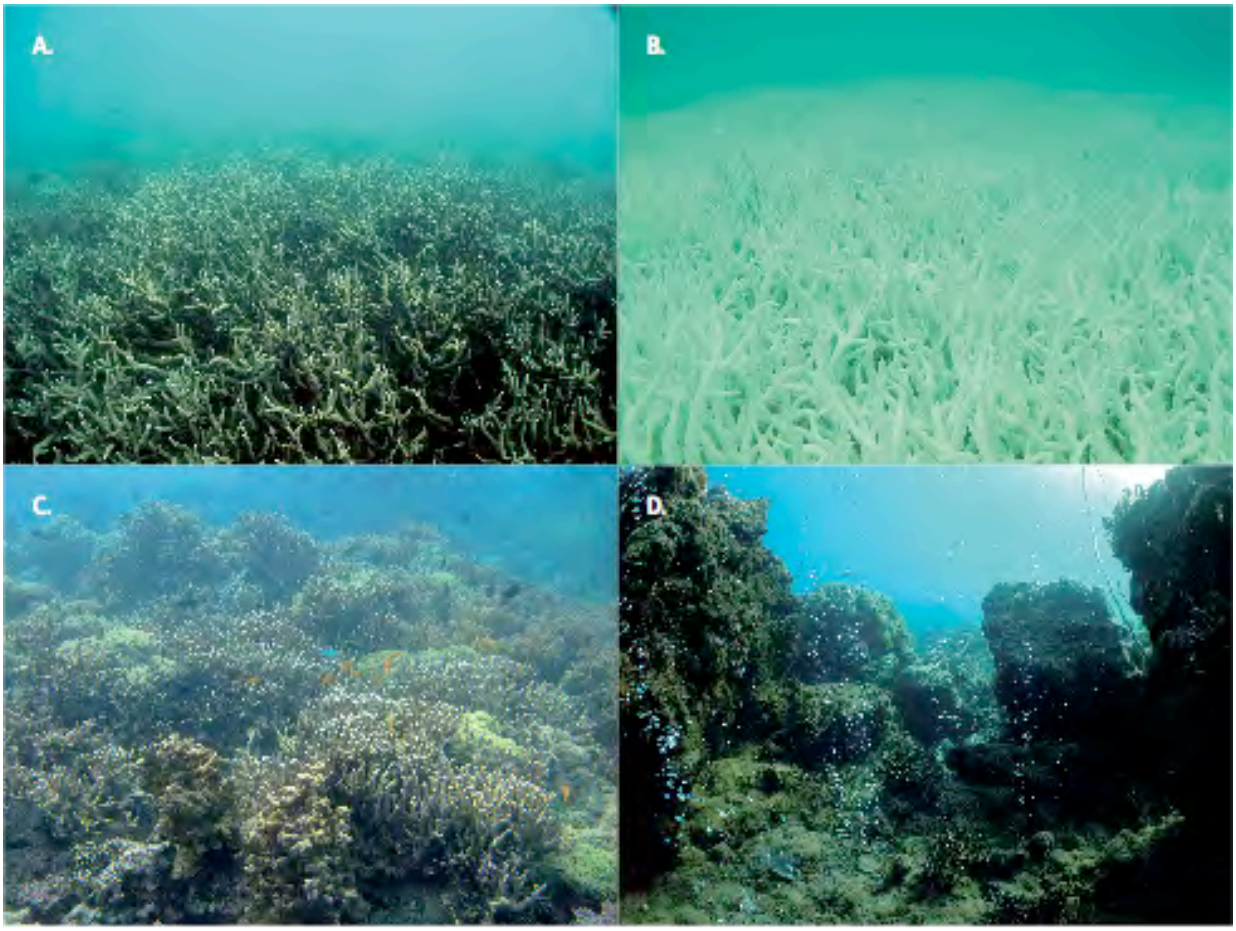

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

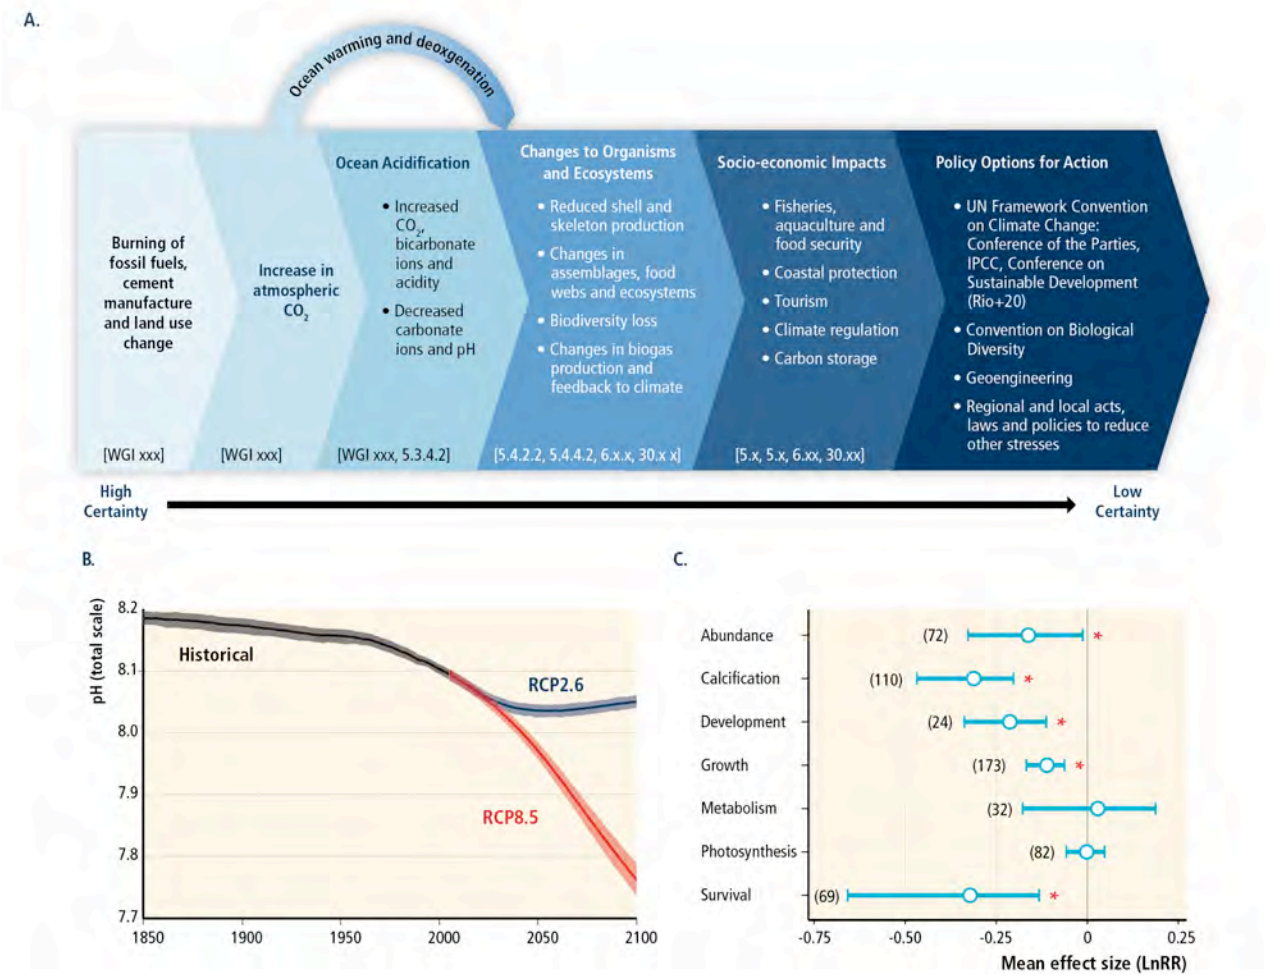

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.

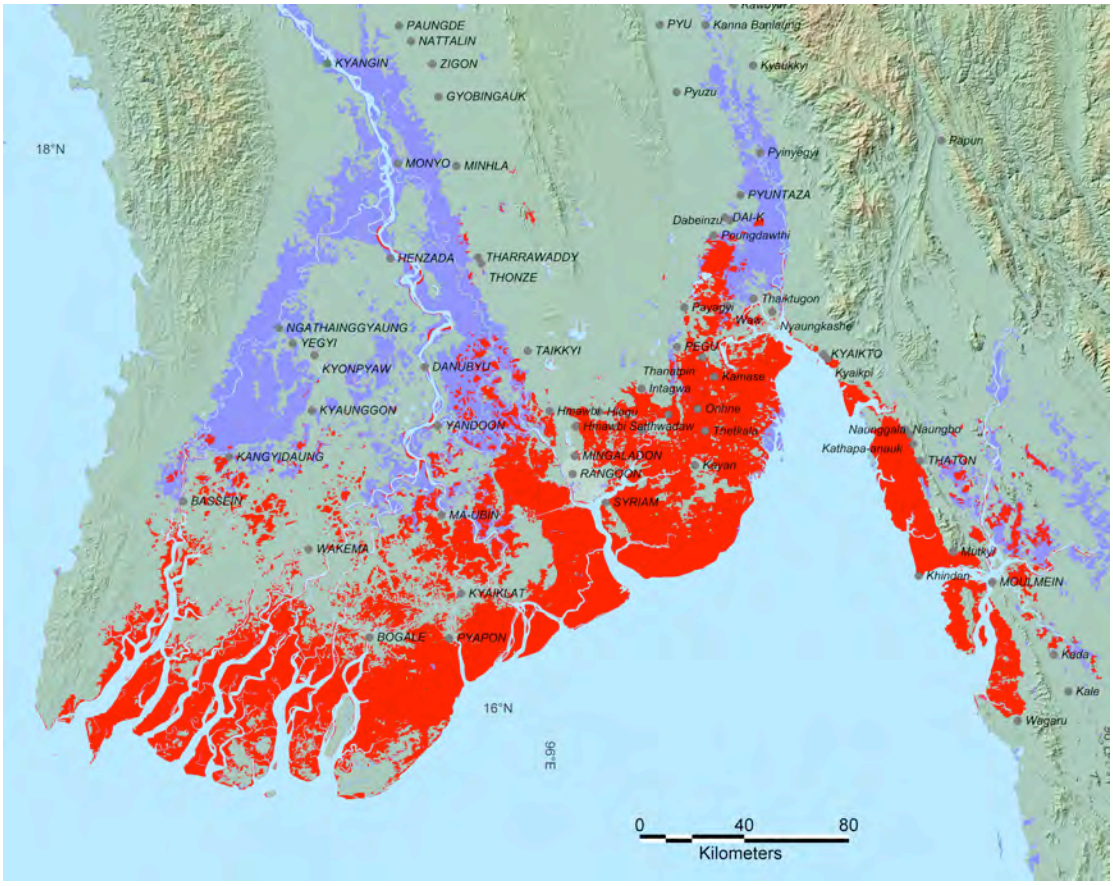

Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. (From Brakenridge *et al.*, 2012).

Executive Summary

Ocean ecosystems and their services will continue to respond to climate change (*high confidence*). Human societies benefit from and depend on ecosystem services, which are sensitive to climate change (*high confidence*), in particular the provisioning of food (fisheries and aquaculture) and other natural resources, nutrient recycling, climate regulation, protection from natural hazards, and aesthetic, cultural, and supporting services. [6.3.6, 6.4, 6.5]

Climate change is manifesting itself in the alteration of abiotic and biotic properties of the ocean (*high confidence*). Abiotic drivers changing in the ocean include circulation intensity, temperature, oxygen (O_2) and nutrient inventories, carbon dioxide (CO_2), ocean pH, salinity, and light regime. Biotic drivers range from the physiology of individual cells and organisms to ecosystem structure and function. [6.1.1, 6.2.2]

Marine ecosystems were and are being exposed to and affected by climate changes of different rates, magnitude and duration (*very high confidence*). In Earth history, natural climate change at rates slower than today's anthropogenic change has led to significant ecosystem shifts (*high confidence*). The fossil record and present field and laboratory observations confirm key environmental drivers and responses of ocean ecosystems to climate change (*high confidence*), including migration, altered ecosystem composition, changes in abundance, and extinctions (*high confidence*). [6.1.2, 6.3]

The combination and often amplification of climate change drivers acting globally and additional human-induced local drivers such as overfishing, pollution, and eutrophication exacerbating hypoxia, result in enhanced vulnerability of natural and human systems to climate-related forcings presently and into the future (*high confidence*). Key observations and vulnerabilities are reflected in the progressive redistribution of species, changes in species' abundance and the reduction in marine biodiversity in sensitive regions and habitats, putting the sustained provision of ecosystem services and fisheries productivity at risk (*high confidence*). Socio-economic vulnerability is high particularly in tropical developing countries, progressively increasing the risk of reduced food supply, income and employment (*high confidence*). Key uncertainties include the up-scaling of climate change effects from organism to ecosystem level, the adaptive capacity of marine organisms and human societies to these impacts, the interactions with other human drivers, the sustenance of biogeochemical functions and productivity in the global ocean, and the effectiveness of climate mitigation and adaptation measures.

Physical effects of climate change on marine ecosystems may act, under some circumstances, as an additional pressure that cannot be mitigated by local conservation measures or a reduction in human activities like fishing (*high confidence*). Effects of climate change will thus complicate management regimes, e.g. presenting direct challenges to the objectives of spatial management once species undergo large-scale distributional shifts. This increases the vulnerabilities of marine ecosystems and fisheries. [6.4]

Understanding of physiology combined with field observations demonstrates that vulnerability of most organisms is defined by their specialization on specific, limited temperature ranges and accordingly, by their thermal sensitivity (*high confidence*). Temperature defines the geographical distribution of species and their responses to climate change (*medium confidence*). Temperature extremes act through losses in abundance and (e.g. sea ice and coastal) habitat, local extinction and latitudinal shifts (*very high confidence*). Vulnerability is greatest in polar animals due to narrow temperature ranges (*medium confidence*) and in e.g. tropical species living close to their upper thermal limits (*medium confidence*). Some warm water corals and their reefs will continue to respond to warming with species replacement, bleaching from loss of associated algae and a decreased coral cover resulting in habitat loss (*high confidence*). In general, knowledge of the mechanisms of climate effects helps to understand changes in the past, present and future. Genetic adaptation may occur; the capacity to compensate for or keep up with the rate of ongoing thermal change is limited (*low confidence*). [6.2.2-5, 6.3.2, 6.5.2]

Warming is causing shifts in the geographical distribution, abundance, and migration patterns of species, paralleled by a reduction in their body size and a shift in the timing of seasonal activities. This results in altered interactions between species including changes in competition and predator-prey dynamics (*high confidence*). There are many observations of poleward shifts in the distribution and abundance of fishes and invertebrates and/or of their shifts to deeper and cooler waters (*high confidence*). Poleward shifts of plankton have occurred up to 250 km per decade, up to 30 times faster than terrestrial species (*high confidence*). While marine turtles also experience direct effects of warming, birds and mammals are mostly indirectly impacted through sensitivities of their prey to these altered conditions (*high confidence*) [6.2.2, 6.2.5, 6.3., 6.5].

Modeling projects that, through species gains and losses correlated with warming, the diversity of animals and plants will increase at mid and high latitudes (*high confidence*) and fall at tropical latitudes (*low confidence*) [6.3.2, 6.5.2] leading to a large-scale redistribution of global catch potential for fishes and invertebrates (*medium confidence*). If a decrease in global ocean net primary production or a shift downwards in the size spectrum of primary producers occur, the overall fisheries catch potential will decrease, in ways influenced by other human impacts on ecosystem structure. Animal displacements are projected to lead to a 30–70% increase in the fisheries yield of high-latitude regions but a drop of 40%- 60% in the tropics by 2055 relative to 2005 under the SRES A1B scenario (*medium confidence* for the general trend of shifting fisheries yields, *low confidence* for the magnitude of change). [6.2.5, 6.3.2, 6.4, 6.5]

The oceans currently provide about half of global net primary production (NPP). Environmental controls on NPP include temperature, CO_2, nutrient supply and irradiance all of which are projected to be altered (WGI). The direction, magnitude and regional differences of a change of NPP in the open ocean as well as in coastal waters have *limited evidence* and *low agreement* for a global decrease projected by 2100. At high (polar) latitude an increase in NPP is also projected with *low confidence*. [6.3.1, 6.5.1]

Microbes (Bacteria, Archaea, unicellular algae and protozoans) serve key roles in marine ecosystems and sustain large scale processes and climatic feedbacks which will be altered by climate change (*medium confidence*). Identifying which microbial species or groups and processes are being affected by climate change and how these will be altered is presently based on *limited evidence* and *low agreement* as these organisms and their responses to environmental change are extremely diverse and often modulated by non-linear biological interactions or uncertain changes in circulation and nutrient supply. A warming ocean may enhance the metabolic rates of microbes, but also cause species specific phenotypic and genotypic responses, e.g. challenge their thermal tolerance and thereby, their abundance, distribution and community structure. Warming, more nutrient-rich coastal oceans may enhance the development of harmful algal blooms (*low confidence*) or pathogen distribution like cholera (*low confidence*). [6.2, 6.3, 6.4.2, 6.5]

Rising atmospheric CO_2 not only causes ocean warming but also changes in carbonate chemistry termed ocean acidification. Laboratory, mesocosm and field data show that ocean acidification has ramifications for processes ranging from physiology and behavior to population dynamics (*medium* to *high confidence*). Across organisms, sensitivity decreases with increasing capacity to compensate for the elevated internal CO_2 concentration or falling pH (*medium confidence*). Most plants including algae, respond positively to elevated CO_2 levels by increasing photosynthesis and growth (*high confidence*). A wide range of sensitivities to projected acidification

exists within and across organism phyla (*high confidence*). Laboratory work demonstrated a capacity to undergo trans-generational or evolutionary adaptation in some species, thereby reducing the impact of the projected change (*low* to *medium confidence*). Limits to adaptational capacity remain unexplored (*low confidence*). [6.2.2-6, 6.3.4]

Field observations attributed to anthropogenic ocean acidification are few due to limited changes in water chemistry between pre-industrial times and today. Shell thinning in planktonic foraminifera from various regions and Southern Ocean pteropoda has been attributed fully or in part to acidification trends (*medium confidence*). Coastward shifts in upwelling regimes of the Northeast-Pacific and upwelled CO_2-rich waters presently causing larval oyster fatalities in aquacultures (*high confidence*) or shifts from mussels to fleshy algae and barnacles (*medium confidence*) provide an early perspective on future effects of ocean acidification. Ecosystems at risk of ocean acidification are warm and cold water coral reefs (*high* or *medium confidence*). However, sensitivity is species specific; e.g. cold water corals display significant capacity to compensate for exposure to acidified seawater (*medium confidence*) in long-term laboratory cultures. [6.1.2, 6.2.2, 6.2.5, 6.3.4]

Several environmental drivers act simultaneously on ocean biota, often leading to interactive effects and complex responses (*high confidence*). For example, physiological knowledge projects that ocean acidification and hypoxia narrow thermal ranges and enhance sensitivity to temperature extremes in organisms like corals, coralline algae, molluscs, crustaceans and fishes (*high confidence*). Combined warming and ocean acidification reduce calcification in warm water corals (*high confidence*). [6.2.5, 6.3.2, 6.3.5, 6.5.2]

The ongoing expansion of hypoxic regions termed Oxygen Minimum Zones (OMZs) or anoxic "dead" zones constrains the habitat of O_2-dependent animals, plants and microbes while it benefits anaerobic microbial life (*high confidence*). Warming-induced stratification, reduced intensity of ocean circulation and the decomposition of organic matter by heterotrophic organisms create an expansion of these specialized, microbially dominated ecosystems, the regional OMZs (*high confidence*). The removal of fixed nitrogen (denitrification) via the metabolism of selected bacteria and archaea can reduce nutrient inventories and alter the N:P balance. Hypoxia tolerance varies among species and is influenced by temperature, elevated CO_2, food consumption, and O_2-demand (*high confidence*). [6.2.2-6, 6.3.3, 6.3.5]

Intensified ocean upwelling in some eastern boundary systems produce cooler surface waters associated with enhanced productivity (*medium confidence*), but in addition to hypoxia effects consequences for higher trophic levels in those areas remain unknown. [6.1.1, 6.3.3, 6.3.4, 6.3.6]

Geoengineering approaches involving manipulation of the ocean to ameliorate climate change (e.g. purposeful nutrient fertilization, binding of CO_2 by enhanced alkalinity and direct CO_2 injection into the deep ocean) have very large associated environmental footprints (*high confidence*), with some actually requiring purposeful alteration of ocean ecosystems for implementation. Alternative methods focusing on solar radiation management (SRM) leave ocean acidification unabated. [6.4.2]

6.1. Introduction: Point of Departure, Observations, and Projections

The Oceans cover 71% of Earth's surface to an average depth of 3,800 m and represents more than 95% of the habitable environment (by volume) of our planet. Marine habitats exhibit natural variability on temporal scales from synoptic to interdecadal but the causes and ecological consequences are poorly understood as long-term series of direct observations from the open ocean are rare. The available information indicates that oceanic ecosystems are particularly sensitive to stresses mediated by climate change, partly because of direct effects on organisms and their interactions and partly because physical and chemical forcings control ocean temperatures, chemistry and the current regime, upper ocean stratification, nutrient supply and light regime and, hence, growth of phytoplankton, availability of food for heterotrophs (live organisms as prey, or their decomposing bodies, i.e. debris or dissolved organic matter) and the structure and function of the food webs. Physical and chemical attributes influence biogeochemical processes, including carbon cycle dynamics. They also shape the biological diversity the oceans support and the services they provide. Some of the knowledge on marine impacts has been assessed in the 4th IPCC assessment report, AR4 WGII Chs. 4-6, 15,16. For the first time in the series of IPCC reports, impacts on the oceans are a focus

in AR5, in the present sectoral chapter and a regional chapter (30). This allows for a more differentiated discussion of phenomena and impacts, as well as the associated uncertainties and the levels of confidence in observed and projected changes. For some of those, confidence has changed since AR4.

The present chapter focuses on the general principles and processes characterizing climate change impacts on the ocean system as a whole and its use by human society, so it focuses on global ocean processes rather than those in specific water columns or benthic provinces. It also addresses our understanding of functional mechanisms across all levels of biological organization, from molecular to organismal to ecosystem scale which is required for accurate projections of the ocean's responses to climate change. Division of the oceans into discrete functional units can help to elucidate variability and differences in ongoing and projected changes in key processes and carbon inventories across ocean regions (Figure 6-1). Oceanic ecosystems and the services that they provide must then be assessed on a region-specific basis (see WGII Chs 5, 28 and 30).

In order to assess the available evidence on the relationships between climate and ecosystem change, as well as to project future impacts, we rely on Representative Concentration Pathways (RCP) of climate change scenarios (Moss *et al*., 2010). We begin with a discussion of the variability of the principal physical and chemical parameters of the oceans and build on evidence available from paleo- and historical observations for identifying the forces causing change. Then, a conceptual framework of understanding climate change effects on organisms and ecosystems is developed and used to interpret empirical observations of ecosystem change, to assess the implications of such changes for ecosystem services and to identify plausible socioeconomic consequences.

[INSERT FIGURE 6-1 HERE
Figure 6-1: Productivity in 51 distinct global ocean biogeographical biomes as represented by a grid of thin black lines (after Longhurst, 1998), overlain with an average annual composite plot of chlorophyll *a* concentration, i.e., a proxy for phytoplankton stocks in the upper ocean, from the NASA/Orbimage SeaWiFs satellite (Bailey *et al*., 2006; McClain *et al*., 2004; McClain, 2009). The characteristics and boundaries of each biome are primarily set by the underlying regional physics and chemistry. Together, these provinces or biomes span several orders of magnitude in chlorophyll *a* from < 0.1 mg m^{-3} that characterize the low latitude oligotrophic regions (denoted by purple and blue) up to 10 mg m^{-3} in highly productive coastal upwelling regions in Eastern boundary currents (denoted by red).]

6.1.1. Recent Trends and Projections of Physical and Chemical Parameters

Trends in ocean conditions over the last 50 years reflect significant human impacts beyond natural variability on e.g. temperature or salinity or carbon content of the upper ocean (Pierce *et al*., 2012; WGI Ch.10).

6.1.1.1. Warming

Over the last 43 years average warming has occurred by >0.1 °C/decade in the upper 75 m and by 0.017 °C/decade at 700m depth (WGI Ch. 3), with trends strongest at high latitudes and regional differences between warming rates associated with prominent spatio-temporal structures (WGI Ch. 2) and scales of natural sea surface temperature variability (Figure 6-2), particularly strong at the typical ENSO high and low frequencies, and on multidecadal scales (>25 years). The interannual frequencies are dominant at most tropical oceans, while the multidecadal scale explains most of the high latitude variability. Changes in ENSO activity have been explored through global climate models, but trends in the spatial signature are highly uncertain. Moreover, global observation-based analyses of climate-induced changes in dominant variability frequencies are limited by data availability, especially for the low frequency scale at high latitudes, where the strongest warming is occurring. Temperature variations are accompanied by spatially variable changes in salinity. Both warming and freshening can cause enhanced stratification. Increases in salinity result from reduced precipitation relative to evaporation and have occurred in upper thermoclines of subtropical gyres at mid to low latitudes since 1970 (WGI Ch. 3). In contrast, freshening caused by enhanced precipitation relative to evaporation occurs at higher latitudes, exacerbated by increased sea ice melt. These trends are projected to continue into the 21st century (WGI Figure 12-34), leading to lower salinity intermediate waters sinking at high latitudes (Helm *et al*., 2010; WGI Ch. 3).

[INSERT FIGURE 6-2 HERE
Figure 6-2: Sea surface temperature variability in the last century (1911 to 2011). The top left map shows the sea surface temperature average for the period. The top right map illustrates the temperature range calculated as the difference between the maximum and minimum values for each grid component during the century. The spatial distribution of variability by time scales (left hand map series) was computed by accumulating the relative spectral densities of each 2°x2° grid box frequency-transformed series by frequency windows, corresponding to the multidecadal (period >25 years), bidecadal (15 to 25 years), decadal (8 to 15 years), low ENSO (El Niño Southern Oscillation) frequency (5 to 8 years), high ENSO frequency (3 to 5 years) and very high frequency (2 to 3 years) scales. The sum of the six maps at every single box corresponds to 100% of the interannual time series variability. The right hand histograms show the area of the World Ocean (%) at each weight interval, for each frequency window. All computations are based on the Extended Reynolds Sea Surface Temperature (NOAA, 2012).]

6.1.1.2. Acidification

Scenarios of future atmospheric carbon dioxide (CO_2) concentrations (given as partial pressures, pCO_2, in µatm) have been described by SRES and following several RCPs (Moss *et al.*, 2010; Meinshausen *et al.*, 2011). All RCPs lead to atmospheric pCO_2 levels somewhat less than 500 µatm by 2050. Then, under different RCPs, values between 420 µatm and 940 µatm can be expected by 2100.-On average, rising CO_2 concentrations in air cause significant increases in upper ocean CO_2 levels associated with oceanic drawdown of atmospheric CO_2 (Watson *et al.*, 2009). This leads to ocean acidification (OA), an increase in acidity measured as a decline in pH. OA also results in a progressive decrease of carbonate ion (CO_3^{2-}) concentration and thus of the saturation state (Ω) of calcium carbonates ($CaCO_3$; Zeebe and Westbroek, 2003; WGI Chs. 3, 6). Hence, the solubilities of calcite, Mg-calcite, or aragonite increase. These minerals are important components of shells or skeletons in many marine organisms (6.2.2). OA occurs on a background of natural variability of pH and Ω values over time and between sites from pH 8.2 in highly productive pelagic regions to 7.2 in mid-water layers where excess respiration causes low oxygen (O_2) and elevated CO_2 levels. While the physical and chemical basis of ocean acidification is well understood, few field data exist of sufficient duration, resolution and accuracy to document the acidification rate and its geographic and temporal variability (WGI Figure 3-17). Trends in anthropogenic OA clearly deviate from the envelope of natural variability (Friedrich *et al.*, 2012). OA presently ranges between -0.0015 and -0.0024 pH units per year (WGI Ch. 3, 6, 12; Dore *et al.*, 2009); average surface ocean pH has decreased by more than 0.1 units below the pre-industrial average of 8.17 and is expected to drop until 2100 by -0.13, -0.22, -0.28 to -0.42 pH units, at CO_2 levels of 421, 538, 670, and 936 ppm under the RCP 2.6, 4.5, 6.0 and 8.5 scenarios, respectively (WGI Figure 6-28). The rate of acidification varies regionally and is 50% higher in the Northern North Atlantic than in the subtropical Atlantic (Olafsson, 2009). Ice melt or excess precipitation cause salinity reductions (Jacobs and Giulivi, 2010; Vélez-Belchí *et al.*, 2010) and, thereby, an exacerbation of OA (Steinacher *et al.*, 2009; Denman *et al.*, 2011). In the absence of biota (6.2.2., 6.3.3), the changes in ocean chemistry due to OA will take thousands of years to be buffered through neutralization by calcium carbonate from sediments and tens to hundreds of thousands of years for the weathering of rocks on land to eventually restore ocean pH completely (Archer *et al.*, 2009).

6.1.1.3. Hypoxia

Oceanic O_2 concentrations range from over 500 µmoles kg^{-1} in productive, nutrient rich Antarctic waters (up to 140% saturation relative to equilibrium with the atmosphere; Carrillo *et al.*, 2004) to zero in coastal sediments rich in organic matter and in anoxic deep layers of isolated water bodies such as the Black Sea and the Cariaco Basin. The average value for the ocean is estimated as 178 µmol kg^{-1} (Sarmiento and Gruber, 2006). Large-scale fluctuations of O_2 concentrations have occurred over geological time (Wignall, 2001; Meyer and Kump, 2008), during glacial-interglacial cycles (Schmiedl and Mackensen, 2006; Robinson *et al.*, 2007), on multi-decadal (Yasuda *et al.*, 2006; Whitney *et al.*, 2007) inter-decadal (Arntz *et al.*, 2006), seasonal, synoptic and, in some high productivity regions, diurnal time scales (Grantham *et al.*, 2004; Connolly *et al.*, 2010). In ecological literature, the term hypoxia (see 6.3.3) is commonly used for O_2 concentrations below 60 µmoles kg^{-1}, according to the transition to communities with characteristic hypoxia adaptations. (It should be noted, however, that O_2 can become limiting to animal life once it falls from air saturation to levels well above this threshold (6.2.5) These hypoxic waters presently

occupy ~5% of the ocean volume ($7.6x10^{16}$ m^3) (Deutsch *et al*., 2011). Oxygen minimum zones (OMZs) associated with hypoxia at $O_2 < 22$ µmol kg^{-1} (< 0.5 ml L^{-1}) occupy nearly $30x10^6$ km^2 ($10.2x10^7$ km^3) in the open ocean (Paulmier and Ruiz-Pino, 2009) and cover about $1.15x10^6$ km^2 of the continental margin seabed (Helly and Levin, 2004; Diaz and Rosenberg, 2008). At the oxic-anoxic interface, suboxic waters with very low O_2 concentrations (< 4.5 µmoles kg^{-1}) occupy $4.6x10^{14}$ m^3 (less than 0.05 % of the ocean volume), mainly in the Northeast Pacific (Karstensen *et al*., 2008).

Hypoxia in midwater OMZs stretching over hundreds up to thousands of meters in the main ocean basis, and other O_2 deficient habitats is caused by respiration coinciding with CO_2 accumulation. Over the past 50 years, the mean rate of O_2 decrease was from 0.1 to over 0.3 µmoles kg^{-1} $year^{-1}$ (Stramma *et al.*, 2008; Stramma *et al.*, 2010), but in some OMZs it was much higher, due to warming, stratification and bacterial O_2 demand (WGI Box 6.5, Figure 1). Long-term declines in O_2 by about 7 µmoles kg^{-1} $decade^{-1}$ have been documented at mid water depths over much of the subarctic North Pacific (Keeling *et al.*, 2010). The number of extremely hypoxic coastal regions excluding metazoans, termed 'dead zones' and attributed to eutrophication induced deoxygenation, have increased from 120 in the 1980s to over 400 in 2008 (Diaz and Rosenberg, 2008). A rapid build-up of anoxic zones (void of O_2) has been found in stratified inland water bodies such as the brackish water Aral Sea (Zavialov, 2005; Zavialov *et al.*, 2009). With future warming, the spread of hypoxic zones will *very likely* accelerate, especially in temperate to subpolar regions where increases in ocean stratification due to warming or freshening of the surface layer can reduce the depth of winter mixing and create dense waters in association with ice formation. Most models project a decrease of global ocean oxygen content of 1 to 7 % by 2100 (Keeling *et al.*, 2010; WGI Figure 6-29 under RCP 8.5) implying feedbacks on the volumes of severely hypoxic and suboxic waters as well as key biogeochemical pathways (Deutsch *et al*., 2011). Fluvial runoff into the ocean causing eutrophication and associated hypoxia is projected to increase by 2100 due to climate-related intensification of the global water cycle (e.g. Milly *et al.*, 2008; Ch. 5.2.2.1.7). Figures vary for regions and catchment areas (Kundzewicz *et al.*, 2005). The evolution of low O_2 zones will also be linked to changes to the wind regime (e.g. Vecchi and Soden, 2007; Ren, 2010) and of the intensity, duration and seasonal timing of upwelling events (Snyder *et al*., 2003). The potential contribution of destabilized gas hydrates and bacterial methane oxidation to exacerbating hypoxia and acidification at high latitudes remains to be explored (Westbrook *et al*., 2009).

6.1.1.4. Other Physical and Chemical Drivers

Most modeling experiments indicate that the depth of the surface mixed layer will become shallower in the coming decades (e.g. Sarmiento *et al.*, 1998; Matear and Hirst, 1999) due to increased and seasonally extended (Holt *et al*., 2010) density stratification of the ocean especially in the tropics, the North Atlantic, the Northeast Pacific, and the Arctic (Capotondi *et al*., 2012). This may lead to decreased vertical transport of nutrients to surface waters (Polovina *et al.*, 2008; Doney, 2010). The resulting reduction in nutrient supply to phytoplankton growth may be partly compensated for by river plumes (Signorini *et al*., 1999), or by nutrient accumulation in the pycnocline as in the North Pacific (Whitney, 2011), or enhanced upwelling (Ch. 5.2.2.1.6) indicated by observations in the Peruvian (Gutiérrez *et al.*, 2011), Californian (Snyder *et al*., 2003; Rykaczewski and Dunne, 2010) and Canary systems (McGregor *et al*., 2007). However, upwelling rates projected by climate models largely diverge (Bakun *et al*., 2010).

6.1.1.5. Conclusions

It is *virtually certain* that with climate change, marine ecosystems are exposed to changing regimes of drivers, e.g. rising temperature, ocean acidification and the expansion of hypoxic zones. Warming of the surface layers *very likely* enhances and prolongs stratification, thereby limiting the nutrient inventory available to phytoplankton. Enhanced upwelling and human-induced eutrophication could partly compensate for the projected reduced nutrient supply in coastal oceans (*limited evidence, medium agreement*). Light availability to phytoplankton will *likely* increase due to shoaling of the surface mixed layer.

6.1.2. Paleo-Records

Paleontological records in marine sediments, from all ages and latitudes, provide information on spatial distributions of organisms and their abundance over time that can be readily related to the concurrent shifts in multiple environmental properties that are also recorded in these sediments. These records give us insights into extinctions, emergences, and changes in abundance and the environmental forcings that organisms are responding to. Temporal trends reveal influences of temperature, hypoxia and food availability on organisms and ecosystems, and changes in seasonal timing (phenology) of different components of the ecosystem (6.1.1, Figure 6-11). Spatial trends, from cores from different geographical locations, provide evidence of expansion of geographical ranges of plankton. These records are complemented by historical data sets of the last centuries of organisms which live for decades or centuries recording natural variability in the ocean system (WGI Ch. 3).

While the geological record often does not allow identification or direct attribution to a single driver of change or their relative importance, it supports by itself future projections on possible changes of a specific driver in extant ecosystems and their services only with *low* levels of *confidence* (6.4). Importantly though, increasing atmospheric CO_2 is causing warming in the surface ocean, altered/enhanced upper ocean stratification and consequently a decrease in dissolved O_2 concentration in the geological past and in the future. Thus, paleo and present day climatic shifts both share the same combination and sign of environmental changes (WGI). Therefore, a combination of data from the geological record and global circulation and carbon cycles models can use coupled warming and ocean acidification and deoxygenation events from the geological past to inform, with *medium confidence*, about future climate change impacts on ocean biota.

[INSERT FIGURE 6-3 HERE
Figure 6-3: Atmospheric CO_2 (bottom, grey) and temperature (middle, red/orange) changes with associated biotic changes (top) for the Paleocene Eocene Thermal Maximum (PETM) and the industrial era. Episodes of largest environmental change are indicated with yellow bars. CO_2 data are based on measurements at Mauna Loa (modern: Keeling *et al.*, 2005) and model output (PETM: Ridgwell and Schmidt, 2010; Zeebe *et al*., 2009). Temperature data are based on proxy data (modern: Wilson *et al.*, 2006; Lea *et al.*, 2003; PETM: Kennett and Stott, 1991) representing the regional temperature changes in the surface ocean. Modern biotic responses include changes in coralline algal growth (Halfar *et al.*, 2011), and coral calcification (De'ath *et al.*, 2009). Evolutionary changes are exemplified by the extinction of benthic foraminifera (Thomas, 2003). Abundance data (top row) of planktonic foraminifera and coccolithophores (modern: Field *et al.*, 2006; PETM: Bralower, 2002) indicate range expansion due to warming.]

The last glacial-interglacial transition is associated with an increase in atmospheric CO_2 of ~0.02 µatm/year on average over the transition (WGI Ch. 5) and hence fifty-fold slower than the current increase by 1 µatm/year on average over the last 100 years. Consequently, the resultant pH change of 0.002 pH units per 100 years during the glacial interglacial transition is small relative to the ongoing anthropogenic perturbation of >0.1 pH unit/century. Overall the glacial ocean was colder, with strong regional differences (WGI Ch. 5) and more O_2 rich than today's ocean. There is *high confidence* that foraminifera, coccolithophores, diatoms, dinoflagellates and radiolarians showed marked poleward range expansion during the last glacial-interglacial transition and abrupt short-lived events such as the Bølling-Allerød Warming (see WGI Ch. 5) (CLIMAP Project Members, 1976; MARGO Project Members, 2009). Lower CO_2 concentrations in the upper ocean during the glacial interval are associated with increased calcification in planktonic foraminifera (*limited evidence, medium agreement)*. In the Santa Barbara basin, changes in oxygenation did not cause extinctions in the benthic foraminifera (Cannariato *et al*., 1999) while in the Arabian Sea, a stronger monsoon and the associated increases in upwelling, productivity and local reduction in O_2 led to a loss in diversity in the benthic foraminiferal assemblages (Schmiedl and Leuschner, 2005).

The last time atmospheric CO_2 was close to today's was during the Pliocene warm period (3.3 to 3.0 Ma), with atmospheric CO_2 levels between 330-400 µatm (=ppm, Pagani *et al.*, 2010; Seki *et al.*, 2010) and temperatures ~+2 warmer than today (Haywood *et al.*, 2009, WGI Ch. 5) (*medium confidence*). Such a warming trend, occurring over several tens of thousands of years in contrast to 100 years projected for modern climate change, resulted in a poleward geographical expansion of tropical calcifying plankton species (Dowsett, 2007) (*high confidence*); however, no increases in species extinction or emergences compared to background rates has been associated with

Pliocene warming for coccolithophores (Bown *et al.*, 2004), corals (Jackson and Johnson, 2000) or molluscs (Vermeij and Petuch, 1986).

Perhaps the best analogue for the alteration of the future ocean is the Paleocene-Eocene Thermal Maximum (PETM), 55 million years ago (Ma), an event of rapid warming and ocean acidification, though model simulations for the future show 10 times higher rates of CO_2 input and hence ocean acidification in surface waters today than during the PETM (Ridgwell and Schmidt, 2010) (*medium confidence*). Depending on the assumed rate and magnitude of the CO_2 release during the PETM, models project a 0.25 to 0.45 pH unit decline in surface waters (Ridgwell and Schmidt, 2010) and a reduction in surface ocean aragonite saturation from Ω=3 to Ω=2 or even as low as 1.5. During the PETM, warming caused range expansion of warm-water taxa towards higher latitudes (*high confidence)*. While the composition of coccolithophore (Gibbs *et al.*, 2006, 2013) and dinoflagellate assemblages (Sluijs and Brinkhuis, 2009) changed, suggested to reflect the changes in nutrient availability and/or warming (6.2.2.-3), there was no bias in extinction towards more heavily calcifying species. In contrast, the benthic ecosystem recorded a 50% extinction among benthic foraminifera (Thomas, 2007) and a major change in the macrobenthic community (Rodríguez-Tovar *et al.*, 2011). In contrast to sediment dwellers, pelagic crustaceans (ostracods) did not show any significant change in species composition (Webb *et al.*, 2009). In shallow coastal waters, calcareous algae and corals were replaced by larger benthic foraminifera (Scheibner and Speijer, 2008) (*medium confidence*). Models for the PETM suggest that the increase in oceanic vertical temperature gradients and stratification led to decreased surface ocean productivity and O_2 depletion in the deep sea (Winguth *et al.*, 2012), particularly in the equatorial zone by weakening of the trade winds and hence reducing upwelling.

The very warm climates of the Mesozoic (251 to 65 Ma) led to a number of oceanic anoxic events (Jenkyns, 2010). For some of these events, anoxia was not restricted to the deep ocean but vertically expanded OMZs led to photic zone anoxia (Pancost *et al.*, 2004). Some of these Cretaceous oceanic anoxic events were associated with extinctions or increased turnover (normalized sum of originations and extinctions) of the marine plankton (an average of 30% for planktonic foraminifera and radiolarians) although the changes were very small for other groups of organisms, e.g. coccolithophores (maximum 7%, Leckie *et al.*, 2002). The causal link between O_2 reduction and the evolutionary change in these groups is tenuous as these events were also associated with warming, changes in nutrient supply and, possibly, ocean acidification (Hönisch *et al*., 2012).

For examples of marine ecosystem collapse at global scale, expansion into the deep record of the past 250 million years (Myr) is required. Some mass extinctions, and in particular the Permian Period extinction 251 Ma ago, have been associated with large scale inputs of carbon into ocean and atmosphere and the associated deep-sea O_2 decline and global warming (Knoll *et al.*, 2007; Kiessling and Simpson, 2011; Knoll and Fischer, 2011) with consequent warming, acidification and O_2 depletion, though the rate of change has not been accurately constrained to date for any of these events. The end Permian mass extinction preferentially affected reef organisms such as corals and sponges resulting in a 4 Myr period without reef builders (Kiessling and Simpson, 2011). The extinction rate of the end-Permian biological collapse was greater than any projection for coming centuries (Bambach, 2006), but it underscores the differing vulnerabilities of marine life to environmental perturbation among organisms of differing anatomy, physiology and ecology (Knoll and Fischer, 2011).

Of the last 100 Myr, only the last 2 Myr had CO_2 at levels lower than any projected for this decade and only the deep time older than 33 Ma record has CO_2 levels comparable to business as usual projections for the end of 2100 (WGI Ch. 5; Hönisch *et al*., 2012). That marine biota thrived throughout most of this era could imply that the organisms, which make up marine ecosystems, will not be impaired in a future warm, high CO_2 world. However, such comparisons are invalid because the key environmental issue of the 21st century is one of an unprecedented rate of change in CO_2 levels, not simply magnitude (Hönisch *et al*., 2012). The unparalleled rate and magnitude of modern ocean acidification in at least the last ~300 Myr of Earth history highlights the magnitude and scale of the current change in several environmental drivers. The slower events in the geological history provide *robust evidence and high agreement* of environmentally-mediated compositional changes in fauna and flora and, in some cases, of extinction and, to much lesser degree, emergences. Although similarities exist, no past natural climatic event perfectly parallels future projections, emphasizing how unprecedented future climate change is in the evolutionary history of most organisms. In light of the present rate of change the challenges involved may therefore be outside the adaptive capacity of many organisms living in today's ocean (*low to medium confidence*).

6.1.3. Long-Term Biological Observations

Ocean ecosystems are complex, time and space variable, and non-steady state (Figures 6-4, 6-5). While climate science has benefitted from paleo-observations of tree rings, sedimentary records and ice cores (6.1.2), data sets of oceanic phenomena are rare. Those existing (Table 6-1) provide evidence that spatial and temporal variability are inextricably linked (Stommel, 1963). Therefore, systematic, long-term interdisciplinary observations using repeated, highly calibrated measurements at a given field site are required to distinguish natural ecosystem variability from (long-term) anthropogenic trends. The undersampling of ocean phenomena in time (Henson *et al*., 2010) and space constrains meaningful assessments of current states and projections about future ones.

[INSERT TABLE 6-1 HERE
Table 6-1: Selected examples of long-term biological and ecological observations in the oceans (NPP denotes Net Primary Productivity).

[INSERT FIGURE 6-4 HERE
Figure 6-4: Multiple coupled temporal and spatial scales of variability in physical, physiological and ecological processes in marine systems. Observations over broad time and space scales are necessary to separate natural variability from human-induced impacts, and define appropriate observation tools. The shaded regions depict the approximate boundaries of major processes, and the boxes define the scales of selected measurement/ observation procedures. Langmuir cells are a series of wind-driven shallow, slow, counter-rotating circulations at the ocean's surface. From Karl (2010), as modified from Dickey (1991).]

Historical data sets of organisms with life histories of decades and centuries and high resolution sediment cores covering the last few centuries document the responses of biota to natural variability in the ocean system (such as the North Atlantic Oscillation Index [NAO], the Atlantic Multidecadal Oscillation [AMO], the Arctic Climate Regime Index [ACRI], Pacific Decadal Oscillation [PDO] or the El Niño-Southern Oscillation [ENSO]) but also to warming of the surface ocean since the 1970s (6.3.2). Many examples highlight the influences of temperature, hypoxia and abundance of food on organisms and ecosystems, causing, for example, changes in biodiversity, expansion of geographical ranges of plankton, changes in seasonal timing (phenology) of different components of the ecosystem and changes in macrobenthos calcification (6.2, 6.3; Figures 6-3, 6-5).

[INSERT FIGURE 6-5 HERE
Figure 6-5: Time-series of water column integrated primary production (PP) anomalies at: Northwestern Spain, La Coruña (43° 25.2 N, 8° 26.4 E); HOT (22° 45 N, 158°W); BATS (31° 50 N, 64° 10 W); Monterey Bay, Central California Current (37°N, 122°W); Cariaco Basin, Venezuela (10°30 N, 64°40 W), reproduced from Chavez *et al.* (2011). Anomalies were calculated by integrating over the water column, then interpolating to 14 d, smoothing with a moving average and differencing for each 14-d interval from the grand mean for that interval. All sites except Cariaco seem to show positive (pink) PP anomalies after 2000.]

The research questions presently addressed using long-term data sets range from changing species composition and phenology via investigations of physical and chemical drivers causing these changes to low-frequency events, e.g. regime shifts (abrupt, non-linear and persistent changes in the structure and function of a system, Table 6-1). National programs run by marine stations sampling regional seas provide detailed long-term data sets augmented by several international limited-term scientific programs such as the World Ocean Circulation Experiment (WOCE) and the Joint Global Ocean Flux Study (JGOFS). The ship-based time-series programs in the North Pacific Subtropical Gyre (HOT), the Sargasso Sea (BATS), Ligurian Sea (DYFAMED), Canaries (ESTOC), southwest of Kerguelen Island (KERFIX), northwest of Hokkaido Island (KNOT) and southwest of Taiwan (SEATS) have provided invaluable data on the physical and biogeochemical state of the oceans (Karl *et al*., 2003). Data from these sites have documented decadal scale ecosystem changes, including ocean acidification (Dore *et al*., 2009; WGI Ch. 3). Additional trends will emerge as the time-series programs continue and new sites are added.

Direct observations are complemented by satellite remotely-sensed datasets, with ocean color data (e.g. SeaWiFS) providing estimates of chlorophyll concentrations, used as a proxy for phytoplankton stocks. Because total chlorophyll cannot be measured from space, the near surface chlorophyll (approximately one optical depth) is extrapolated to whole water-column chlorophyll. Large uncertainties persist in the interpretation as chlorophyll estimates from satellite reflect both phytoplankton stocks and their physiological status (Dierssen, 2010; Behrenfeld, 2011). In conjunction with algorithms these chlorophyll estimates are converted to Net Primary Production (NPP) (6.1.3., Saba *et al*., 2011). Behrenfeld *et al.* (2006) using SeaWiFs data, report a prolonged and sustained global NPP decrease of 190 Tg C per year for the period 1999 to 2005 - an annual reduction of ~0.4 % of global NPP. In contrast, a time-series of directly measured NPP between 1988 to 2007 by Saba *et al.* (2010) (i.e. *in situ* incubations using the radiotracer ^{14}C-bicarbonate) revealed an increase (2 % yr^{-1}) in NPP for two low latitude open ocean sites. This indicates uncertainties in either methodology and/or the extent to which discrete sites are representative of oceanic provinces (Saba *et al*., 2010, 2011). Furthermore, modeling studies have argued that the <20 year archive of SeaWiFS is insufficient to distinguish climate-change mediated shifts in NPP from those driven by natural climate variability (Henson et al., 2010).

6.2. Diversity of Ocean Ecosystems and their Sensitivities to Climate Change

6.2.1. Overview: Ocean Characteristics and Climate Sensitivities

Global scale observation and modeling studies provide evidence, with *high confidence*, of present and future climate-mediated alterations of the ocean environment (6.1.1., WGI Chs. 3, 6; Bopp *et al*., subm) which in turn leads to impacts on ocean ecosystems (Boyd and Doney 2002; Brierley and Kingsford, 2009; Hoegh-Guldberg and Bruno, 2010; Drinkwater *et al*., 2010; Overland *et al*., 2010). An assessment of present findings and projections requires knowledge of the characteristics of ocean biota and ecosystems and the background of their climate sensitivity.

Life on Earth is phylogenetically and metabolically diverse as a result of nearly 4 billion years of evolutionary history. Marine microorganisms are the oldest forms of life, and the most diverse while the more complex organisms are constrained to limited functional types (Table 6-2). As anthropogenic climate change accelerates, a key issue is how quickly organisms can adapt. Evolutionary adaptation is typically thought to depend upon the genetic variation present within a population, and the environment is believed to select the fittest genotypes from within it (Rando and Verstrepen, 2007; Reusch and Wood, 2007). The inherent variability of marine environments (6.1.1) is suggested to ensure that genetic variation within populations is maintained at high levels. However, there is limited information about genetic variation within species, except for a few well-studied species of fishes and bacteria. The capacity of any species to adapt is highly variable, depending on mutation rates, generation time, and whether population size is large enough to harbour sufficient variation. Processes based on DNA point mutations may be too slow to permit adaptation to rapid climate change (Bowler *et al*., 2010). The fitness of marine organisms may, however, also be influenced by epigenetic regulation mechanisms, such as reversible histone modifications and DNA methylation (Richards, 2006), which are transmitted from generation to generation. Such processes are suggested to be remarkably rapid in terrestrial ecosystems (Bossdorf *et al*., 2008). There is currently *limited evidence, medium agreement* and *low confidence* in evolutionary adaptation induced by climate change in recent centuries.

[INSERT TABLE 6-2 HERE
Table 6-2:Variations in metabolism based on sources of energy, electrons and carbon according to Karl (2007a), complemented by the taxa which exploit these pathways. Mode of metabolism may relate to organizational complexity and tolerance to environmental extremes (Figure 6-8).

Metabolic pathways and their rate of use according to energy demand respond to changing temperatures in virtually all cases or to changing irradiance and CO_2 levels, specifically exploited by the respective modes of metabolism. These responses may be involved in direct or indirect effects of climate change and associated drivers (6.1.1) on marine organisms and contribute to set limits to their adaptability (6.2.2).]

6.2.1.1. Pelagic Biomes and Ecosystems

Organisms living in the pelagic biomes are key to biogeochemical processes in the ocean. The fixation of CO_2 via photosynthesis, a process also known as primary production, forms the base of the marine foodweb. Photosynthesis in the surface ocean is controlled by light, temperature, inorganic nutrients (CO_2, nitrate, phosphate, silicate, trace elements including iron, and the temperature dependent formation rate, stability and duration of the surface mixed-layer depth (MLD) (6.1.1., Sverdrup, 1953; Taboada and Anadón, 2012). Temperature and its variability (Figure 6-2) thus are key factors governing the occurrence, diversity, development, reproduction, behaviour and phenology of marine organisms (Edwards and Richardson, 2004; Beaugrand *et al.*, 2009; Brierley and Kingsford, 2009, Tables 6-3, 6-4). The delivery of nutrients from deep water below the euphotic zone is controlled by vertical eddy diffusivity and advection, caused by the combined effects of local winds and thermohaline (density)-driven processes such as ocean circulation (Rykaczewski and Dunne, 2010) which create net upwelling (temperate, subpolar) and net downwelling (subtropical) gyres (Table 6-3). Coastal oceans are nutrient enriched by tidal mixing, estuarine circulation and upwelling. All of these processes are subject to climate-related influences and associated shifts in physical forcing. Changes in environmental conditions and the displacement of organisms by convection cause variability in phytoplankton productivity, competitiveness and natural selection (Margalef, 1978; Margalef *et al.*, 1979) and result in changes in carbon sequestration (Figures 6-1, 6-6). Reduced nutrient availability causes primary production to fall, leading to a reduction in the amount of energy supplied through the web to higher trophic levels, including fish and invertebrates (*high confidence*, Ware and Thomson, 2005; Brander, 2007), and defining fishery yields (Cheung *et al*., 2008; Friedland *et al*., 2012). Species replacement might result in a redirection of carbon and energy flows. The wide range of trophic structures in marine foodwebs and the potentially non-linear changes in energy transfer under different primary production and temperature scenarios (Stock and Dunne 2010) make it difficult to accurately predict how changes in primary production will alter higher trophic levels.

[INSERT TABLE 6-3 HERE
Table 6-3: Environmental forcing on biological production by physical, chemical and biological characteristics of major pelagic ecosystems (Adapted from Barber, 2001, based on the original analysis by McGowan, 1974).]

[INSERT FIGURE 6-6 HERE
Figure 6-6: A schematic representation of the ocean's biological pump, which responds to climate change and is a relevant conduit for carbon sequestration. It is difficult to project how the pump might be altered (Table 6-4) and whether it would represent a positive or negative feedback to climate change which causes: A, shifts in NPP (Net Primary Production; Bopp *et al*., 2002); B, floristic and faunistic shifts in the pelagic realm (Beaugrand *et al.*, 2009) that may alter the relationship between OA and ballasting of settling particles (Klaas and Archer, 2002); C, changes in proportion of NPP released as DOM (Dissolved Organic Matter) due to the effects of ocean acidification (Engel *et al.*, 2004); E, warming and faster bacterial enzymatic rates of particle solubilization (Christian and Karl, 1995); and faunistic shifts at depth (Jackson and Burd, 2001). Modified from Buesseler *et al.* (2008) by J. Cook (WHOI).]

[INSERT TABLE 6-4 HERE
Table 6-4: A wide range of processes make up the ocean’s biological pump (Figure 6-6). In order to assess how a changing climate will alter the functioning of the pump, and the resulting biogeochemical feedbacks on global climate, the cumulative effects of climate-change mediated alteration of processes from cellular to ocean basin, and from pelagic to mesopelagic, must be quantified. This table illustrates, using published information, the complexity of the integrated knowledge platform needed to provide evidence of these biogeochemical ramifications and thus the present limits to clear conclusions about climate induced effects on the biological pump (C, Carbon; TEP, Transparent Exopolymer Particle; DOM, Dissolved Organic Matter; POM, Particulate Organic Matter).]

6.2.1.2. Benthic Habitats and Ecosystems

Benthic communities are defined as those that live in, on, or in association with the sea floor. Benthic organisms are classified by their size (mega-, macro-, meio-, microbenthos), their mode of energy supply (Table 6-2) or their mode of food uptake (suspension feeders, deposit feeders, herbivores, carnivores). Their habitats range from the intertidal to the deep sea and are characterized by climate regime, water depth, light penetration, distance from land,

topography, substrate (rocky, hard, soft, mixed), sediment grain size and chemistry or by the dominant plant or animal communities that they support. In general, benthic organisms living in shallow waters or the intertidal (where they experience temporary exposure to air) are prone to experience and tolerate the influence of widely fluctuating environmental parameters due to natural or anthropogenic influences, such as temperature extremes, hypoxia, elevated CO_2 or fluctuating sea level including sea level rise (WGI Chs. 3, 12). As benthic systems comprise sessile or slow moving plants and animals, they may be adapted to local conditions. Many of them are unable to escape from unfavorable changes except by means of fertilized eggs or planktonic larvae. In the deep sea, where environmental conditions remain unchanged on large geographical scales, some meiobenthic deep-sea organisms may show extremely wide distribution ranges (Menzel *et al*., 2011; Gooday and Jorissen, 2012).

Benthic ecosystems are coupled to the pelagic realm via the biological pump (Figure 6-6), the chemical exchange of nutrients, gases and by the existence of pelagic and benthic life history stages. Even in abyssal benthic habitats there is a continuous rain of organic detritus and this serves as the primary source of carbon and energy for benthic communities. This inextricable connection to primary marine productivity means that climate impacts on surface marine ecosystems (as oceans stratify, warm and become more acidic) will impact the most remote benthic communities, even if direct changes to the physical habitat do not occur (Smith *et al.*, 2009).

Benthic habitats are influenced by ecosystem engineers (sensu Jones *et al.*, 1994) which can be grouped into two categories. Autogenic engineering species (like corals) form habitat from the structures they produce (e.g. coral skeletons) while allogenic engineering species form habitat through their behaviour (e.g. by mechanical displacement of sediment, a process termed bioturbation). Both types of ecosystem engineers have the potential to influence the regeneration of nutrients and to affect benthic-pelagic coupling. If climate change negatively affects the engineering species, the entire ecosystem may be impacted.

6.2.2. Mechanisms and Principles of Climate Change Impacts across Organism Taxa

This section focuses on the principles of climate impacts known across organism taxa, 6.2.3. to 6.2.6. then report the taxon-specific aspects. A comprehensive understanding of mechanisms responding to climate related environmental factors at ecosystem, whole organism, tissue, cell and molecular levels of biological organization would provide a solid foundation for reliable interpretation and attribution of climate change effects on ocean biology. The genetic and physiological underpinning of climate sensitivity of organisms sets the boundaries for ecosystem response and provides crucial information on sensitivities, resilience and the direction and scope of future change. Empirical studies of marine organism and ecosystem sensitivities have made progress in identifying the mechanisms and processes linking climate to ecosystem changes (Drinkwater *et al.*, 2010; Ottersen *et al.*, 2010). Changes in community composition, species interactions and the food web often build on organismal effects elicited by environmental forcing (e.g. Pörtner and Farrell, 2008; Boyd *et al*., 2010; Ottersen *et al.*, 2010). Knowledge of the underlying mechanisms in a hierarchy of organismal to molecular effects (Pörtner, 2002a, Pörtner and Knust, 2007; Raven et al., 2012), appears as a major asset for attributing observations to climate and for projections of impacts (Pörtner *et al.*, 2012). Knowledge of overarching similarities across organism domains, archaea, bacteria, and eukarya (Woese *et al*., 1990) or kingdoms (Cavalier-Smith, 2004) would facilitate projections of climate impacts. Microbes, i.e. bacteria and microalgae support many fundamental biogeochemical cycles and may respond by exploiting their large diversity, e.g. undergoing species replacements (Karl *et al*., 2001), and thereby sustaining their biogeochemical roles. Species replacements also occur among macroorganisms (plants and animals), however, for most of them their resilience, well-being, abundance, survival and conservation have been the research foci.

After identifying the principle effects of individual drivers across organism taxa understanding their integrated action is required for comprehending climate change effects (6.3.5). Furthermore, such effects may be compensated for on long time-scales by acclimation and evolutionary adaptation to individual or multiple drivers, as seen in the coccolithophore *Emiliania huxleyi* under high pCO_2 (1100 and 2200 µatm) over 500 asexual generations (Lohbeck *et al*., 2012). In macroorganisms the rate of evolutionary adaptation is constrained by their long generation times but is enhanced by large phenotypic variability among larvae as a pool for selections, with high mortality rates (e.g. Sunday *et al*., 2011). In general, the mechanisms setting limits to acclimation or adaptation capacity are presently unknown for virtually all climate drivers. However, mass extinctions occurring during much slower rates of climate

change in earth history (6.1.2) suggest that evolutionary rates in macroorganisms may not be fast enough to cope with various drivers changing. Interactions of drivers like ocean warming, acidification, hypoxia, freshening with each other and with other human-induced drivers like eutrophication are addressed in 6.3.5.

6.2.2.1. Principles of Temperature Effects

Thermal reaction norms describe the temperature dependent changes in performances such as growth and have been used to evaluate sensitivity (Figure 6-7). They apply across organism phyla (Chevin *et al.*, 2010), viruses (Knies *et al*., 2006), bacteria (Ratkowsky *et al*., 1983), phytoplankton (Eppley, 1972; Thomas *et al*., 2012), higher algae and plants (Bolton and Lüning, 1982; Müller *et al.*, 2009, 2011; Vitasse *et al*., 2010) and animals (Huey and Kingsolver, 1989; Deutsch *et al*., 2008; Angiletta, 2009). The shape and width of the curves can shift within limits and mirror the large scale distribution boundaries of a species or population. Maximum temperatures tolerated differ largely between organisms, depending on organizational complexity (Figure 6-8). The knowledge of the mechanisms shaping such curves and associated thermal limits appears most advanced in animals (Pörtner *et al*., 2012; 6.2.5) but these have not been systematically explored in other organism groups (e.g. Green *et al*., 2008).

[INSERT FIGURE 6-7 HERE
Figure 6-7: Mechanisms linking organism to ecosystem response explain the why, how, when and where of climate sensitivity (based on knowledge for animals, after Pörtner, 2001, 2002a, 2012; Pörtner and Farrell, 2008, blue to red colour gradients illustrate transition from cold to warm temperatures). (A) As all biota, animals specialize on limited temperature ranges, within which they grow, behave, reproduce, defend themselves by immune responses. Optimum temperatures (T_{opt}) indicate performance maxima, pejus temperatures (T_p) the limits to long-term tolerance, critical temperatures (T_c) the transition to anaerobic metabolism, and denaturation temperatures (T_d) the onset of cell damage. These OCLTT thresholds (see text) can shift by acclimatization (horizontal arrows). Under elevated CO_2 levels and in hypoxic waters performance levels can decrease and windows of performance be narrowed (dashed green arrows pointing to dashed black curves). (B) Thermal range widths (horizontal arrows) change between individual life stages of a species. (C) The shift of performance curves between polar, temperate and tropical animal species reflect evolutionary adaptation to the respective climate zones. Via species-specific effects on performance and thermal limits (dashed curves, cf. A), additional stressors and species interactions cause shifts in higher-level processes (seasonal activities in response to light or temperature cues, shifts in predator-prey interactions or competition within changing coexistence ranges of interacting species). (D) Shifts in biogeography result during climate warming (modified after Beaugrand, 2009). The polygon delineates the range in space and time, the level of grey denotes abundance. Species display maximum productivity in southern spring, wide seasonal coverage in the centre and a later productivity maximum in the North. The impact of photoperiod increases with latitude (dashed arrow). During warming, the southern temperature and time window contracts while the northern one dilates (directions and shifts indicated by arrows). Control by water column characteristics or photoperiod may overrule temperature control in some organisms (e.g. diatoms), causing contraction of spatial distribution in the north.]

For animals breathing in water (invertebrates and fish exchange respiratory gases with water rather than air; FAQ 6.II), the dimensions of the thermal niche (Figure 6-7A) have been explained by the concept of oxygen and capacity limited thermal tolerance (OCLTT, Pörtner *et al.*, 2010) which integrates findings from ecosystem to molecular levels and explains thermal specialization and associated limitation. For other organisms the respective knowledge explaining thermal reaction norms is not available. Thermal specialization of animals results from economizing energy use, limiting the functional capacity of tissues. Beyond upper and lower thermal thresholds (T_p, Figure 6-7A) tolerance becomes time-limited. At large body size, O_2 supply limitations are exacerbated in the warmth, causing the organism to reach long-term heat limits at lower temperatures. The widths and positions of acute thermal windows on the temperature scale are changing dynamically over time, during short-term or seasonal acclimatization of the individual over days and weeks, during the life cycle of a species and with increasing body size (Figure 6-7A,B) as well as during long-term evolutionary adaptation, across generations, to a climate regime or local conditions (Pörtner, 2006; Pörtner *et al.*, 2008; Eliason *et al.*, 2011). Both acclimatization and adaptation involve adjustments in biochemical characters (membranes, enzymes), and their functional properties, however, the capacity to shift thermal boundaries (Figure 6-7A) is limited to within the thermal niche (Pörtner *et al.*, 2008, 2012). Such limits are effective in the field (Pörtner and Knust, 2007, Katsikatsou *et al*., 2012) and may contribute to the reduction of

abundances during warming (Pörtner and Knust, 2007), to coral losses (Donner *et al.*, 2005), to shifts in the seasonal timing of (zooplankton) biomass formation (Mackas *et al.*, 1998; Goldblatt *et al.*, 1999; Schlüter *et al.*, 2010) or to the reduction of animal body sizes in warming aquatic communities (Daufresne *et al.*, 2009; see examples in 6.3.2) and projected in the 21st century under climate change (Cheung *et al.*, 2012; 6.5). Modelling and paleo-studies have adopted the OCLTT concept to project climate effects (6.5) and explain climate-induced mass extinction events and evolutionary patterns in earth history (Pörtner *et al.*, 2005; Knoll *et al.*, 2007; Knoll and Fischer, 2011).

At community and ecosystem levels, differences in thermal sensitivities and shifts in the relative performance of animal species may underlie their changing competitive or trophic interactions and foodweb structure (Pörtner and Farrell, 2008; Figure 6-7 C), also via shifts in reproductive success, larval output, early juvenile survival and thus recruitment. Knowledge of such high-level functions shaping thermal reaction norms in other organism domains would be essential for a comprehensive view of shifting biogeographies, species interactions, abundances as well as community assemblages and foodwebs in space and time (Beaugrand *et al.*, 2003; Parmesan and Matthews, 2005). Mechanism-based insights link physiological impacts with changing species interactions (e.g. Pörtner, 2010, 2012; Harley, 2011), underpinning scenarios of community level responses to temperature change (Urban *et al.*, 2012), with respect to niche breadth, ecosystem mixing and the resulting extinction threats (6.3), informing modelling (6.5) as well as having implications for conservation and ocean management (6.3., 6.4).

[INSERT FIGURE 6-8 HERE
Figure 6-8: Ranges of temperatures and O_2 concentrations covered by various domains and groups of free living marine organisms (bacteria to animals, domains and groups modified after Woese *et al.*,1990) in various habitats (Storch *et al.*, subm). High organizational complexity enables an increase in body size, associated with decreasing tolerances to hypoxia and heat. In the domain Bacteria, the group Thermotogales comprises obligate anaerobes, displays less complex structures such as a single layer lipid membrane and is most tolerant to high temperatures. Highest temperatures of growth were found at 122°C in hydrothermal vent species under elevated hydrostatic pressure in laboratory experiments. Dashed white arrows denote wide O_2 tolerances in unicellular archeae, bacteria and protists, as compared to animals and plants (multicellular eukarya). Anoxic habitats are conquered by small multicellular and unicellular Eukarya, supported by less complex mitosomes or hydrogenosomes used in energy metabolism. Species richness of animals (upper right) increases with rising O_2 levels reflecting better hypoxia tolerance in small compared to large individuals and their taxa (6.3.3).]

6.2.2.2. Principles of CO_2 Effects in Ocean Acidification

Rising oceanic CO_2 concentrations causing ocean acidification (OA) will have multi-faceted effects on biota. By analogy with thermal stress phenomena, effects mediated by elevated CO_2 levels also range from molecular to systemic, including the neuronal level in animals. OA effects interact with those of other key drivers like temperature and hypoxia (Pörtner, 2010, 2012; Boyd, 2011; Gruber, 2011) and translate from organism into ecosystem level impacts. Meta-analyses of the biological effects of OA indicate that the rate of net calcification (i.e. calcification minus OA-mediated dissolution) is most responsive (Hendriks *et al.*, 2010), however, such meta-analyses cannot resolve for the diversity of species-specific responses, or diverse vulnerabilities of different processes or life stages (Hendriks and Duarte, 2010; Hendriks *et al.*, 2010; Kroeker *et al.*, 2010, 2013).

In marine organisms the diffusive uptake of CO_2 leads to elevated CO_2 partial pressures in all compartments (FAQ). CO_2 causes a (respiratory) acidosis in cells and body fluids which can affect various functions. The weak acid distribution characteristics of CO_2 (Pörtner, 2008, 2012) require a high capacity of ion and acid-base regulation (i.e. of the membrane transporters involved) to balance acidification and readjust setpoints in pH through net base accumulation (e.g. Heisler, 1986; Pörtner *et al.*, 2000; Claiborne *et al.*, 2002; Taylor *et al.*, 2011) (Figure 6-10A). In photolithoautotrophic microbes, accumulating CO_2 or bicarbonate may serve as substrates for metabolism, supporting primary production. The formation of carbonate from bicarbonate is essential in calcification, the formation of calcified structures built by the deposition of solid $CaCO_3$ and used across biota for defence and structural support. Calcification usually occurs in separate body compartments, where even in coccolithophores and corals, pH and thus, the concentration of CO_3^{2-} and Ω of $CaCO_3$ (aragonite, calcite, Mg calcite, 6.1.1) are maintained higher than in other body fluids or ambient water (Trotter *et al.*, 2011; Taylor *et al.*, 2011; McCullough *et al.*, 2012a,

Venn *et al*., 2013). CO_2 impedes the formation of carbonate at calcification sites such that calcification rate decreases or the effect is compensated for by ion transport, incurring elevated energetic costs. In addition, external carbonate shells rely on ambient seawater being supersaturated with regards to carbonates. Otherwise, shells would be dissolved unless protected from direct contact with sea water by organic coating (periostracum) as in molluscs or brachiopods. Falling calcite/aragonite saturation levelsΩ to below unity in the water, as evident in OMZs, favor the dissolution of carbonate shells (FAQ). Table 6-5 summarizes effects of OA in various organism taxa observed in laboratory studies, field experiments (mesocosms) and natural analogues which include submarine CO_2 venting areas in the vicinity of: Ischia, Italy (Hall-Spencer *et al*., 2008), Papua New Guinea (Fabricius *et al*., 2011) or Puerto Morelos, Mexico (Crook *et al*., 2012). With *medium confidence* some species will be tolerant to OA, however, the capacity of sensitive species to acclimatize or adapt remains largely unidentified.

[INSERT TABLE 6-5 HERE

Table 6-5: Assessment of tolerances to ocean acidification in marine taxa, considering the number of laboratory and field studies, and of parameters and species studied in the pCO_2 range from <650 to >10 000 µatm. (Parameters include growth, survival, calcification, metabolic rate, immune response, development, abundance, behaviour and others). Not all life stages, not all parameters and not the entire range of CO_2 concentrations were studied in all species. *Confidence* is based on the number of studies, the number of species studied and the agreement of results within one group. +: denotes that possibly more species or strains (genetically distinct populations of the same species) were studied, as only genus or family were specified; beneficial: most species were positively affected; vulnerable: most species were negatively affected; tolerant: most species were not affected. RCP 6.0: representative concentration pathway with projected atmospheric pCO_2 = 670 µatm, RCP 8.5: pCO_2 = 936 µatm in 2100 (Meinshausen *et al.*, 2011). *Confidence* is limited by the short to medium-term nature of various studies and the lack of sensitivity estimates on evolutionary timescales, across generations (see separate reference list). For an assessment of variability between species from the same phylum see Figure 6-10.]

6.2.2.3. Principles of Hypoxia Effects

The term hypoxia refers to a phenomenon, where ambient PO_2 falls below air saturation and constrains life (6.1.1). Hypoxia affects organisms relying on aerobic metabolism; tolerance thresholds determined as the critical O_2 tension (P_c) or concentration (O_2crit) vary across domains (Figure 6-8) and are high for larger organism. For animals, the P_c is traditionally defined at rest, as the O_2 partial pressure, below which energy turnover falls below regulated rates. At the P_c, a progressive transition from aerobic to anaerobic energy production begins (Pörtner and Grieshaber, 1993). In animals, the P_c is determined by the capacity of ventilatory and circulatory systems in relation to O_2 demand, developmental status, and body size. In active animals with a high O_2 demand or at the extremes of their thermal windows functional constraints set in early, under mildly hypoxic conditions. Most animals can only transiently sustain anaerobic metabolism, even if they are energy efficient and sustain long-term tolerance (Grieshaber *et al.*, 1994). Such time-limited tolerance is highest in large individuals, with a higher capacity of anaerobic metabolism than, for example in larvae, where such tolerance is low (Gray *et al.*, 2002; Jessen *et al*., 2009).

6.2.2.4. Principal Effects on Animals Breathing in Air: Marine Reptiles, Mammals, and Birds

Marine reptiles (sea turtles, marine snakes, crocodiles), mammals and seabirds breathe in air but live mostly in water. Therefore, ocean acidification and hypoxia would have minimal direct influences. There is evidence for increased sound propagation in a CO_2 enriched ocean but no evidence yet for any effect on biota (Ilyina et al., 2010). Hypoxic habitat compression for fishes may enhance the foraging opportunities for their air breathing predators (Hazen *et al*., 2009). Warming waters influence the ectothermic turtles, e.g. through range expansion (McMahon and Hays, 2006) and less so the homeothermic birds and mammals. Large body sizes enable some of these air breathers to travel across the widest aquatic temperature ranges possible and support some of the largest migration ranges on earth. Constraints on thermal tolerance are imposed by various degrees of insulation of the body core in mammals and birds which contributes to constrain their distribution to warmer (poor insulation) or colder waters (high insulation). Their larger independence from physical and chemical drivers in the oceans would make many of these air breathers more resistant to the direct influences of climatic change than fishes or invertebrates but would still expose them to

effects mediated via changes in habitat structure or the food web, related to changes in the availability of prey or other, including alternative food items (6.2.5., 6.3). If habitat structures offering retreat or ambush (e.g. sea ice for polar bears or walrusses) become less available, this will enhance the energetic costs of life. If food items are only found in thermally restricted areas or move to large depths, mammals and birds may be constrained to certain distribution ranges or exploitation of their physiological dive limits (McIntyre *et al*., 2011). Compared to oceanic migrators shifts in prey distributions and resultant oceanic habitat may have effects on the physiological costs of finding prey for foragers that are tied to land between trips (Hazen *et al*., 2012; Péron *et al*., 2012).

6.2.2.5. Principal Effects of Changes in Light, Nutrient, and Food Availability

In addition to temperature and CO_2, availability of light and nutrients to photoautotrophs may be altered directly or indirectly with a changing climate, partly through density-related stratification (Figure 6-9), the circulation regime at different spatial scales and the physical displacement of organisms. The supplies of major plant nutrients (macro-nutrients) such as nitrate, and of micronutrients such as iron (Pitchford and Brindley (1999) vary both seasonally (Boyd, 2002), regionally (Moore *et al.*, 2002) and with the current regime and may involve simultaneous limitation (co-limitation) by more than one resource (Saito *et al.*, 2008). Nutrients provide the elemental building blocks for macromolecules needed for cellular physiology. The net result of climatic change affecting all of these processes may be changes in primary productivity due to changing rates of photosynthesis and other physiological processes, as well as changes in community composition. For heterotrophs, from bacteria to fish, mammals and birds, the uptake of organic material as food, ultimately provided by primary production, is central not only to productivity but also for fueling energy consuming functions including the resistance of organisms to environmental change and pathogens (6.2.5., 6.3.6). Any direct influence of climate on the abundance and quality of feed organisms will thus translate to indirect effects on the productivity and well-being of foraging animals (Figure 6-7A,C).

6.2.2.6. Conclusions

Integrating findings across levels of biological organization, molecule to ecosystem, support a comprehensive cause and effect understanding of climate change effects on marine biota (*high confidence*). Some of the respective understanding is emerging but is fragmentary for many organism groups. Experimental observations therefore are largely empirical and cannot easily be scaled up to projecting species-specific responses. The principles of thermal reaction norms are not yet widely applied across organism domains (*medium evidence, limited agreement*) but the recent emergence of converging approaches from empirical, modeling and ecological studies enhances *confidence* to *high* as to their usefulness for developing coherent approaches in all organisms.

6.2.3. Microbes – Link to Biogeochemical Processes

The phylogenetic and metabolic diversity of the microbial world (6.2.1) sustains many unique cellular and key ecosystem processes such as CO_2 fixation and O_2 production, the conversion of nitrogen into ammonia (N_2 fixation), and the use of nitrate, sulphate, CO_2 and metals (Fe and Mn) as terminal electron acceptors in metabolism when O_2 is absent. Microorganisms also catalyze the horizontal transfer of genetic information between unrelated individuals, thereby enhancing biodiversity (McDaniel *et al*., 2010). Microorganisms also catalyze the horizontal transfer of genetic information between unrelated individuals, thereby enhancing biodiversity. The development of a better understanding of climate-induced alterations in the functioning of microorganisms builds on laboratory, mesocosm, and in situ studies as well as modeling. Together, these data will eventually inform us of what regions and which taxonomic groups are more susceptible to climate change and consequently where in the ocean to look for the biological imprint of a changing ocean (Boyd *et al.*, 2011).

6.2.3.1. Temperature – Related Processes

A warming ocean may initially enhance the metabolic rates of microbes (Banse, 1991) and stimulate their overall growth as in phytoplankton (Bissinger *et al*., 2008) but eventually challenge their thermal tolerance –as described by organismal performance curves (i.e. fitness versus environment) for different groups (Chevin *et al.*, 2010), leading to competitive advantages and species replacements. Ocean surveys of phytoplankton size structure revealed increasing fractions of small cells in warmer waters (Morán *et al.*, 2010). However, further experimental and field observations (Giovannoni and Vergin, 2012) are required to validate model projections (Taucher and Oschlies, 2011) of differential responses to warming by different microorganisms.

A coastal experimental microcosm study reports that resident heterotrophic bacteria are more responsive to warming than a laboratory-reared phytoplankter and hence this study illustrates the potential biogeochemical implications of a non-linear ecological response to warming, i.e. greater stimulation of bacterial rate processes relative to that for phytoplankton, within upper ocean foodwebs (Wohlers-Zöllner *et al*., 2011). Consistent with the finding of a warming induced shift to heterotrophy along a high to low latitude survey transect in both the North and South Atlantic (Hoppe *et al*., 2002), it has been hypothesized that heterotrophy might then play a bigger role in warmer oceans and hence microbially-mediated carbon flow to the atmosphere (i.e. CO_2 efflux,or outgassing) might increase (Sarmento *et al*., 2010). The underlying principles and wider applicability of these findings remain to be established (Kirchman *et al*., 2009) in further comparative studies (*limited evidence, low agreement*).

6.2.3.2. Irradiance

The range and mean level of underwater irradiances (light climate) encountered by phytoplankton will be altered by a changing climate (Doney, 2006), due to changing surface mixed layer depth, cloudiness and/or to alteration of sea-ice areal extent and thickness. The physiological response of phytoplankton to higher or lower irradiances caused by the predicted shallowing of the mixed-layer depth (6.1.1) and loss of ice cover, involves photophysiological acclimation via changes in cellular chlorophyll which is however constrained by unidentified limits to its plasticity (Falkowski and Raven, 1997). A longer growing season, due to more sea-ice free days, may have increased productivity (based on a time-series of satellite ocean color and a primary productivity algorithm) in Arctic waters (Arrigo and van Dijken, 2011). This study showed that the average annual NPP increased by an average of 8,1 Tg C yr^{-1} between 1998 and 2009, strongest between 2003 and 2007. In addition, massive under-ice blooms have been observed favored by light penetrating surface melt ponds and first-year ice (Arrigo *et al*., 2012). Little is known about expected shifts from sea-ice algae to free-drifting phytoplankton with a decrease in sea-ice cover and increased irradiance in polar waters in the coming decades. As some krill predominantly feed on sea ice algae, it is unclear (*low confidence*) whether they will be able to adapt to feeding on free drifting phytoplankton (Smetacek and Nichol, 2005).

6.2.3.3. Stratification – Nutrient and Irradiance Controls on Primary Production

A stronger vertical density gradient will reduce the communication between the sunlit upper ocean where photosynthesis takes place and the underlying nutrient-rich waters (Doney, 2006; Figure 6-9). Lower chlorophyll concentrations at warmer sea surface temperature in nutrient-poor low latitude waters, based on ocean color data, have in fact been interpreted as an effect of increased stratification on phytoplankton stocks (Boyce *et al.*, 2010). In contrast, higher chlorophyll concentrations at warmer sea surface temperature were found at high latitudes (Boyce *et al.*, 2010). It has thus been suggested based on *limited evidence* and *low agreement* due to methodological uncertainties (6.1.3) that expanding, permanently stratified, low chlorophyll, tropical regions (WGI Ch. 3), will result in declining phytoplankton stocks in the warming oligotrophic waters of the N and S Pacific and N and S Atlantic (Polovina *et al.*, 2008; Signorini and McClain, 2012; 6.3.1). Furthermore, increased frequency of, or a transition to, permanent El Niño favorable conditions in a warmer future world (Wara *et al.*, 2005) and further expansion of subtropical ocean gyres (Polovina *et al.*, 2008), may lead to lower global ocean NPP.

[INSERT FIGURE 6-9 HERE
Figure 6-9: Projected alteration of oceanic properties and atmospheric events due to a changing climate. Properties will be altered across the water column, from the mid-water stratum to the sunlit surface layer, and will influence the fitness of the residence biota. Changes in storm activity and dust deposition will influence ocean physics and chemistry, with consequent effects on ocean ecosystems (courtesy of Boyd and Law, 2011).]

However, projections of a global decrease in phytoplankton biomass have been refuted (McQuatters-Gollop *et al*., 2011; Mackas, 2011; Rykaczewski and Dunne, 2011). Time series with shorter than 20 years of observations do not resolve impacts of bidecadal variation such as the Pacific Decadal Oscillation or the lunar nodal cycle (e.g. Watanabe *et al*., 2008; Henson *et al*., 2010). Analysis of continental shelf ecosystems, including field data in the most productive upwelling areas covering the last 20 years (e.g. Chavez *et al*., 2011), revealed a large variety of trends at scales of several decades but a general increase of carbon fixation by phytoplankton on most shelves (Sherman and Hempel, 2009; Chavez *et al*., 2011; Bode *et al*., 2011), possibly caused by both climate change and by anthropogenic eutrophication. As satellite trends do not encompass the variability in subsurface chlorophyll (6.1.3) the putative enhancement of primary productivity at the nutricline (Whitney, 2011) remains undetected. Recent field studies point to a growing fraction of primary production derived from atmospheric N in large ocean basins (e.g. Mouriño-Carballido *et al*., 2011). In the presence of sufficient phosphate, fixation of atmospheric N may gain importance in warmer and stratified tropical and subtropical oceans (e.g. Sohm *et al*., 2011).

6.2.3.4. Ocean Acidification – Effects of Anthropogenic CO_2 Concentrations and Water pH

The physiological effects of ocean acidification (OA) appear to be species- and even population-specific. Elevated surface ocean CO_2 partial pressures (pCO_2) may lead to fertilization of phytoplankton but effects are species- or taxon-specific possibly depending on how they acquire carbon (i.e., the presence and in particular the type, capacity and energetic costs of carbon-concentrating mechanisms (CCM's, Giordano *et al.*, 2005; Kranz *et al.*, 2011; 6.2.2). Diatoms are considered to be relatively insensitive to elevated CO_2 with regard to growth and fixation rates (Rost *et al.*, 2003; Trimborn *et al.*, 2008), yet there are indications for CO_2-induced stimulation of primary production rates (Tortell *et al.*, 2008b). For dinoflagellates, relatively little is known with regard to their sensitivity to elevated CO_2 (Hansen *et al.*, 2007) although in one species carbon fixation rates were enhanced at 750 µatm CO_2 while growth remained unaffected (Fu *et al.*, 2008).

Changes in calcification under OA are species-specific. Overall, there is *medium evidence and low agreement* that CO_2 induced OA will result in exoskeletons that are insufficiently calcified for sustained structural support and protection. In coccolithophores, the response is highly variable, uncertainty is high as the function(s) of calcification are not known and consequences of lowered calcification are difficult to be estimated (e.g.Trimborn *et al*., 2007; Rost *et al*., 2008). Reductions, increases and unchanged shell architecture or calcification rate have been documented for RCP 8.5 CO_2 conditions projected around 2100 in different coccolithophore species (Riebesell *et al.*, 2000; Zondervan *et al.*, 2001; Langer *et al.*, 2006; Iglesias-Rodriguez *et al.*, 2008) with species-specificity (Langer *et al.*, 2006) and strain-specificity for calcification in *Emiliana huxleyi* (Langer *et al.*, 2009; Hoppe et al., 2011; Langer *et al.*, 2011) (see Table 6-6 for details). Low light (Zondervan *et al.*, 2002) or nitrogen limitation (Sciandra *et al.*, 2003) are suggested to limit the beneficial effect of OA on photosynthesis and to have a strong negative effect on calcification (Sciandra *et al.*, 2003; Rokitta and Rost, 2012). Nutrients and light cause functional adjustments through gene expression (Dyhrman *et al*., 2006; Richier *et al*., 2009).

[INSERT TABLE 6-6 HERE
Table 6-6: Selected ocean acidification effects on microbes and associated processes.]

Likewise, laboratory studies on planktonic N_2 fixing cyanobacteria (termed diazotrophs) indicate that some of these organisms respond to changing CO_2. In particular, strains (genetically distinct populations of the same species) of offshore cyanobacteria belonging to the genera *Trichodesmium* and *Crocosphaera* increased rates of carbon and N_2 fixation under elevated CO_2 (Lomas *et al*., 2012). However, the resulting responses in N_2 fixation have varied widely (Barcelos e Ramos *et al.*, 2007; Hutchins *et al.*, 2007; Levitan *et al*., 2007; Kranz *et al.*, 2010; Lomas *et al*., 2012) and not all marine N_2 fixing cyanobacteria increase rates of N_2 fixation under elevated pCO_2. Laboratory studies using the

bloom-forming cyanobacteria *Nodularia* (an organism largely found in stratified, eutrophic waters) revealed decreased growth and N_2 fixation under elevated CO_2 conditions (Czerny *et al.*, 2009). To date, the mechanisms underlying these observed physiological responses, especially those in open ocean nitrogen fixers, remain unknown. Cyanobacteria may reallocate energy from their costly CCMs toward N_2 fixation and acquisition of growth limiting nutrients (Kranz *et al.*, 2010; Levitan *et al*., 2010b). However, evidence for such diversion of energy from CCMs toward N_2 fixation is lacking. *Confidence* is thus *low* based on *limited in situ evidence* and *medium agreement* that there is an increase in nitrogen fixation with progressive ocean acidification.

6.2.3.5. Bacterial Life in Hypoxia and Anoxia – Oxygen Minimum Zones (OMZ)

Heterotrophic energy yield with O_2 is largest and is generally preferred over the use of alternate electron acceptors. It has only recently been shown that some bacteria can still grow aerobically and efficiently at even nanomolar O_2 concentrations (Stolper *et al.*, 2010). This has important implications for the formation of 'oxygen minimum (or even free) zones' (OMZs). R*obust evidence* indicates that bacteria both create and sustain OMZs by their diversity and plasticity of metabolism. Wherever the consumption of organic matter supporting bacterial metabolism exceeds the rate of O_2 re-supply, an OMZ will be formed, also characterized by elevated pCO_2 and enhanced acidification. With *high confidence*, OMZs are therefore a consequence of high organic loading or restricted water movement, or both (6.1.1; WGI Box 6.5, Figure 1). Most marine sediments also have OMZs due to limited penetration and exchange of dissolved O_2 with the bottom water. OMZs have also been detected in coastal waters downstream of regions of high inorganic nutrient or organic matter loading. Natural variation in thermocline depth can counter effects of OMZ expansion in the open sea (6.1.1., 6.3.3) by limiting oxidative demand in deepened, warmer, low O_2 thermocline waters (Deutsch *et al.*, 2011). Therefore, OMZ expansion may not be manifested as a monotonic change, but rather be complicated by decadal climate events.

6.2.3.6. Conclusions

While various physiological processes are known to respond to changes in irradiance, nutrient supply, temperature, CO_2 or hypoxia in microbes, the knowledge base on how these processes may be altered does not (yet) include a conceptual foundation suitable to support an integrated understanding of climate impacts on individual species and in turn on communities. The data available are patchy and the reported data trends are often in different directions, partly due to the application of different experimental protocols and/or the over-reliance on species or strains of microbes that are readily culturable and hence have been used for decades in laboratory research. *High confidence* is thus presently limited to the attribution of specific physiological responses of microorganism species, such as primary production, N_2 fixation, or calcification, to environmental drivers associated with climate change.

6.2.4. Macrophytes - Effects of Temperature and Ocean Acidification

Macrophytes (seaweeds and seagrasses) in the transition zone to coastal waters (WGII Ch. 5) cover only 0.6 % of the world's marine areas (Smith, 1981) but their production amounts to almost 10 % of total oceanic production (Charpy-Roubaud and Sournia, 1990). Their thermal growth-response curves (Figure 6-7) show a clear link between production and the local temperature regime. Temperate species with wide windows of thermal tolerance (Figure 6-2) acclimatize by shifting these windows following the seasonal temperature change (Kübler and Davison, 1995). Antarctic or tropical macroalgae are exposed to permanently low or high temperatures and have consequently specialized on limited temperature variability, paralleled by a low acclimatization potential (Pakker *et al.*, 1995; Eggert and Wiencke, 2000; Eggert *et al.*, 2006; Gómez *et al.*, 2011). In the tropics, observations indicate that seagrasses tolerate higher temperatures than seaweeds (Campbell *et al*., 2006). As in other organisms, the molecular basis of acclimatization and its limitation in relation to the climate regime require further study.

Primary production, shoot density, reproductive output and/or below-ground biomass of seagrasses generally respond positively to elevated pCO_2, indicating CO_2 limitation of their productivity. Such effects were identified in the laboratory and the field in the range above 720 to 1800 µatm (*high confidence*, e.g. Palacios and Zimmerman,

2007; Hall-Spencer *et al.*, 2008; Andersson *et al.*, 2011). Similarly, most non-calcifying seaweeds exhibit significantly increased production, growth and recruitment at CO_2 levels above 700 to 900 µatm (Kroeker *et al.*, 2010). In some macroalgae, such stimulation only occurs in combination with elevated temperature (Connell and Russell, 2010) or not at all (Porzio *et al.*, 2011). In experiments, calcifying algae show complex and species-specific responses of photosynthesis and/or carbon production to elevated CO_2, but calcification is highly impacted beyond species-specific thresholds of pCO_2 (*medium confidence*, Anthony *et al.*, 2008; Ries *et al.*, 2009, Ragazzola *et al.*, 2012). Calcification by temperate coralline red and calcareous green algae increased with rising CO_2 levels up to 900 µatm and only decreased at the highest concentration applied (2850 µatm) but did not fall below control rates (Ries *et al.*, 2009). During 3 months of CO_2 exposure, growth of cold water *Lithothamnion glaciale* decreased progressively with rising CO_2 levels. Structural integrity was weakened beyond 590 µatm (Ragazzola *et al*., 2012).

In conclusion, *confidence* is *high* that macrophytes specialize on limited temperature ranges, are sensitive to temperature extremes and that CO_2 stimulates primary production of some macroalgae and seagrass species. With *medium confidence*, calcifying species do not benefit and will be less competitive in a high CO_2 ocean.

6.2.5. Animal Performance and Sensitivities – Fitness and Interactions in Various Climate Zones

Climate change has the potential to affect all animal phyla, from ectotherms (like turtles, with a body temperature that fluctuates with ambient temperature) to endotherms (like mammals and seabirds which generate metabolic heat to sustain a constantly elevated body temperature) through effects on individual organisms, populations and communities or on species interactions and the food web. Existing knowledge of the principles of effect increases confidence in projections of future change (6.2.2).

6.2.5.1. Temperature-Dependent Biogeography and Species Interactions

The distribution, abundance and population dynamics of marine fishes and invertebrates correlate with climate change and climate variability monitored by hydro-climatic indices such as AMO or NAO (6.1.2). Ecosystem shifts attributed to climate change (Hoegh-Guldberg and Bruno, 2010) have mostly been related to temperature. Although temperature means are still most commonly used in marine attribution studies, temperature extremes rather than means are most often mediators of effects (Easterling *et al.*, 2000; Grebmeier *et al.*, 2006; Pörtner and Knust, 2007; Wethey *et al.*, 2011; Wernberg *et al*., 2013; Figure 6-7; 6.2.2). During heat exposure near biogeographical or equivalent limits (including the high intertidal or warming surface waters), reductions in growth, activity and abundance of fish and invertebrate populations set in with even small (<0.5°C) shifts in ambient temperature extremes (Takasuka and Aoki, 2006; Pörtner and Knust, 2007; Farrell, 2009; Nilsson *et al.*, 2009; Neuheimer *et al.*, 2011). Local extinction events follow due to mortality or behavioral avoidance of unfavorable thermal environments (Breau *et al.*, 2011). Shifted biogeographies follow clines from high to low temperature, along latitudes, an equivalent lateral gradient (Perry *et al*., 2005) or even a vertical gradient to deeper waters (Dulvy *et al*., 2008; Graham and Harrod, 2009, Figure 6-7).

In marine animals, the widths of thermal windows roughly match ambient temperature variability (Figure 6-2) according to climate regime and seasonality (Sunday *et al*., 2012). A comparison of fishes across latitudes suggests that high latitude polar species have narrow windows (stenotherms), species at temperate mid latitudes have the widest windows (eurytherms) and ranges are intermediate at tropical latitudes (Pörtner and Peck, 2010). Higher variability in atmospheric and ocean temperatures characterizes the Northern versus the Southern hemisphere (Jones *et al*., 1999, Figure 6-2), resulting in wider temperature ranges in Northern invertebrates and fishes and making them less vulnerable to warming than Southern ones, especially at sub-polar latitudes.

Wide thermal windows are often associated with higher energetic costs, reflected in high resting metabolic rates, as seen in sub-Arctic (Pörtner, 2006), small or highly mobile species (Pörtner, 2002b). Conversely, polar species with narrow thermal windows have low levels of energy demand. Variability in thermal windows between coexisting species is even found among Antarctic stenotherms (Peck *et al.*, 2009) and has implications for their relative climate sensitivity, their potential interactions (Milazzo *et al*., 2013) and community composition. Such principles (6.2.2)

may underlie "regime shifts" between coexisting species (Pörtner, 2012; Table 6-7). Critical mismatches between predator and prey organisms may cause abundance losses or local extinctions (Figure 6-7D; Beaugrand, 2009).

In the lifecycle of species, early life stages or adult spawners may be more sensitive to warming because of their narrower thermal windows, e.g..on the cold side for winter spawning Atlantic cod (Table 6-7). For bigeye, bluefin or skipjack tuna, effects during early life stages are less clear, their thermal window is also narrow, but at high temperatures. If adults spawning at high temperature need to prevent overheating, a compensatory shift in location to cooler (deeper) waters may occur (Lehodey *et al*., 2011). Indirect effects of warming, such as the changing composition and biomass of food, depend on ocean stratification and productivity, or expanding OMZs (6.3.2.-3).

[INSERT TABLE 6-7 HERE
Table 6-7: Examples illustrating species vulnerabilities and underlying mechanisms to changing temperature, hypoxia, ocean acidification (OA).]

Local adaptation may be strong in organisms living in heterogeneous environments like the intertidal (Kelly *et al*., 2012), causing functional differentiation. Functional and genetic differentiation into populations supports the wide biogeographical ranges of species like Atlantic cod and its ongoing invasion of Arctic waters (Pörtner *et al*., 2008). Acclimatization capacity is small in high polar, e.g. Antarctic species (Peck *et al*., 2010). In general, species at their warm or cold distribution limits have exploited their acclimatization capacity. Tropical reef fishes undergo rapid warm acclimation across generations (Donelson *et al.*, 2012); again, mechanisms and capacities are poorly known.

6.2.5.2. Hypoxia Effects

Animal life in low oxygen conditions (hypoxia) requires adaptations leading to a reduction in O_2 and energy demand, and the improved ability to efficiently extract O_2 from the water and transport it to tissues. This lowers the minimum oxygen content in the water that is needed to sustain life. This critical O_2 threshold (P_c, 6.2.2) varies with life stage, body size, temperature, consumed food, O_2 demand and is influenced by other environmental stressors (Pörtner, 2002b; Ekau *et al.*, 2010; Seibel, 2011). On average, large, more active animals have high O_2 demands, for example fishes, crustaceans and muscular squids, associated with high P_c thresholds and are, therefore, sensitive to permanent hypoxia. However, even in high activity animal groups some specialists such as Humboldt squid or bigeye tuna have adapted to live temporarily in hypoxic environments (Childress and Seibel, 1998; Richards *et al.*, 2009; Seibel, 2011). Time-limited tolerance is sustained by the depression of energy demand, for example during periods of metabolic arrest (e.g. developmental arrest or diapause of copepods; Auel *et al.*, 2005).

Hypoxia reduces tolerance to high temperature extremes, because oxygen demand and P_c rise with increasing temperature, reflecting increasing difficulty for animals to get enough oxygen and fuel their activities. This may occur fastest in warm oceans, where metabolic rates are higher and animals live closer to upper thermal limits (Pörtner, 2010). Conversely, high oxygen availability alleviates thermal stress (Mark *et al.*, 2002; Pörtner *et al.*, 2006) and acclimation to hypoxia increases thermal tolerance (Burleson and Silva, 2011), for example by enhancing blood pigment content or reducing energy demand.

Permanent life in the OMZ relies on energy demand being covered exclusively by aerobic metabolism. This is supported by cold temperature which causes energy demand to be low and, thereby, supports P_c thresholds to remain below ambient O_2 levels. Finally, low O_2 levels support a high abundance of meiofauna (very small fauna, <1mm), because their O_2 extraction from the water is facilitated by the combination of reduced energy demand and small body size (Yang *et al.*, 1992; Vetter *et al.*, 1994; Childress and Seibel, 1998; Pörtner, 2002b; Levin *et al.*, 2009). Moreover, food is abundant and predation by larger organisms reduced (Levin, 2003). Under extreme hypoxia (suboxia) only specialists can survive, resulting in a loss of biodiversity (Vaquer-Sunyer and Duarte, 2008). Once approaching anoxia, the centres of pelagic OMZs and benthic dead zones exclude animal life (Levin, 2003). Calcifiers, due to the lowering of metabolic rates at elevated pCO_2 are marginalized in OMZs (Levin, 2003).

6.2.5.3. Effects of CO_2-induced Ocean Acidification

The responses of invertebrates and fish to CO_2 imply sometimes positive but mostly negative effects on fitness with variable sensitivities between species and life stages within and across phyla. Present findings indicate a key role for extracellular pH in modulating the responses of various processes to elevated CO_2 (Figure 6-10A). The effects of a lowered pH (acidosis) on processes in organs like muscle or liver may explain when whole organism energy demand falls (Pörtner *et al*., 1998; Michaelidis *et al*., 2005; Langenbuch *et al.*, 2006; Pörtner, 2008; Liu and He, 2012), probably paralleled by reduced rates of ion exchange, protein synthesis, growth and feeding (Table 6-7).

The acidosis can be fully or partially compensated for and animal performance maintained by the stimulation of acid-base regulation and associated ion exchange (Figure 6-10A). Compensation, however, may cause increased energy demand and metabolic rates. Costs may increase for ion exchange or for calcification or growth. In fact, at mildly elevated CO_2-levels in rock oysters (Parker *et al.*, 2011) or in krill (Saba *et al*., 2012) energy turnover and ingestion rate (krill) increased, indicating significant capacity to resist the CO_2-induced depression of performance. Stimulation of growth induced by CO_2 has also been reported (cf. Gooding *et al*., 2009; Munday *et al.*, 2009b; Dupont *et al*., 2010) and might involve not only sufficient compensation but also enhanced energy efficiency under CO_2. Full exploitation of this ability depends on the availability and quality of food which in turn may support fitness and stress resistance (Gooding *et al.*, 2009, Melzner *et al*., 2011). A decrease in food quality of a diatom led to slower growth and reproduction of the copepod *Acartia tonsa* (Rossoll *et al*., 2012).

Sensitivity to CO_2 then relates to the capacity of acid-base regulation (Figure 6-10A). Such capacity can be upregulated during acclimatization, indicated by enhanced gene expression of ion exchange proteins as seen in echinoderm larvae (O'Donnell *et al*., 2010; Martin *et al.*, 2011), or in fishes (Deigweiher *et al.*, 2008; Tseng *et al*., 2013). In general, such capacity is higher in more active marine animals with high metabolic energy turnover, among fishes, cephalopods and also copepods, coastal crabs when compared to sessile, more inactive species (Table 6-7), Pörtner *et al*., 2005, 2011; Ishimatsu *et al.*, 2008; Melzner *et al.*, 2009; Ishimatsu and Dissanayake, 2010). The capacities of acclimatization and adaptation processes, as well as their limits in shifting tolerances remain to be explored.

[INSERT FIGURE 6-10 HERE
Figure 6-10: Top: Responses of a schematized marine animal (blue line) to ocean acidification (OA). Effects are mediated via diffusive entry of accumulating CO_2 (dark green, black arrows) into body compartments, resulting in a drop in compartmental pH (highlighted in red) and its effects (red dashed arrows) on various processes (light blue) as well as calcium carbonate saturation state (Ω) at calcification sites (after Pörtner, 2008). Variable sensitivity depends on the degree of pH decline and compensation, depending on the capacity of transmembrane ion transport. Bottom: % fraction of studied scleractinian coral, echinoderm, molluscan, crustacean and fish species affected negatively, positively or not at all by various levels of ambient CO_2. Effects considered include those on life stages and processes reflecting physiological performance (O_2 consumption, aerobic scope, behaviours, scope for behaviours, calcification, growth, immune response, acid-base balance, gene expression, fertilization, sperm motility, developmental time, production of viable offspring, morphology). As not all life stages, parameters and pCO_2 ranges were covered in all species two assumptions partially compensate for missing data: 1) Negative effects at low pCO_2 will remain negative at high pCO_2. 2) A positive or neutral outcome at both low and high pCO_2 will be the same at intermediate pCO_2. As responses reported for each species vary for each CO_2 range, variable species numbers result (on top of columns). The total number of species studied for a given group is represented as the number above the control column. Horizontal bars above columns represent frequency distributions significantly different from controls (from Wittmann and Pörtner, subm).]

In some cases, species might not be able to compensate despite a rise in whole organism metabolic cost. Possibly, extracellular acidosis persists and/or imbalances in energy budget result; e.g. some tissues like epithelia or calcification compartments may display enhanced costs, exceeding the downregulation of metabolism in others, e.g. muscle or liver. Enhanced calcification can then occur at the expense of somatic growth (Wood *et al.*, 2008; Beniash *et al.*, 2010; Thomsen and Melzner, 2010; Parker *et al.*, 2011). It was recently discovered that elevated CO_2 can cause behavioral disturbances in larval and juvenile coral reef fishes, while growth was reportedly undisturbed or even stimulated (Munday *et al.*, 2009b, 2011b). The behavioral disturbances would make fishes as sensitive as the

other animal phyla (Figure 6-10B; Munday *et al.*, 2010; Ferrari *et al*., 2011; Devine *et al*., 2012; Domenici *et al*., 2012). The neural sensitivity to moderate CO_2 increases seen in tropical reef fishes (Nilsson *et al*., 2012) warrants study of its long-term persistence and in species from other climate zones before general conclusions can be drawn.

Changes in calcification rates seen in experiments on animals vary largely but meta-analyses show a decrease to be the most uniform response (Box CC-OA). Reduced calcification and weakened calcified structures were seen in corals (see below, Box CC-CR), echinoderms, molluscs and, possibly, crustaceans (Kurihara and Shirayama, 2004; Arnold *et al.*, 2009; Comeau *et al.*, 2009; Lischka *et al.*, 2011). Some species enhanced calcification above control rates in the range of pCO_2 from 600 to 900 µatm (Ries *et al.*, 2009). Enhanced calcification in juvenile cuttlefish (cephalopods) and fishes (Gutowska *et al.*, 2008; Checkley Jr *et al.*, 2009; Munday *et al.*, 2011a) yielded stronger cuttlebones or otoliths. The role of enhanced calcification for fitness remains unclear.

Studies analyzing animal sensitivities to OA during their whole life cycle or during critical transition phases (e.g. fertilization, gastrulation, egg hatching, metamorphosis, moulting) are scarce (Table 6-7). In sensitive species from various phyla, early life stages appear most vulnerable. With delayed development, extended predator exposure of larvae may lead to enhanced mortalities. Effects on one life stage may carry over to the next one. Moulting success into the final larval stage was reduced in a crab (Walther *et al.*, 2010). In a sea urchin, negative impact was found to accumulate from larvae to juveniles and during 4 months acclimation from adults to larvae. This latter impact was, however, compensated for during extended acclimation of females for 16 months (Dupont *et al*., 2012), emphasizing the need for long-term acclimation studies to realistic scenarios. In an oyster species, however, enhanced resistance was carried over to offspring when parents were pre-exposed to elevated CO_2 levels (Parker *et al.*, 2012). It remains to be explored whether and to what extent animal species undergo evolutionary adaptation to progressive ocean acidification over generations. While this process is constrained by long generation times, it is facilitated by high phenotypic variability among larvae (Parker *et al*., 2011, 2012; Sunday *et al*., 2011). This may also explain the selective mortality seen in Atlantic cod larvae under elevated CO_2 (Frommel *et al*., 2012).

A meta-analysis of responses to CO_2 showed species- and taxon-specific sensitivity distributions in metazoa (Figure 6-10B), with various processes affected (Table 6-7; Box CC-OA). Echinoderms, the molluscan bivalves and gastropods as well as corals begin to respond negatively at lower CO_2 levels than crustaceans or cephalopods (Figure 6-10B). This sensitivity pattern resembles observations for the Permian mass extinction (Knoll *et al.*, 2007; Knoll and Fischer, 2011). The picture for fishes is less clear as the present findings of high sensitivity are not met by similar observations in the fossil record. Evolutionary adaptation may thus eliminate or minimize reported effects.

In general, effects of ocean warming, acidification and hypoxia may operate through interrelated physiological mechanisms (Pörtner, 2012). Such knowledge helps to reconcile apparently contrasting findings. For example, warming below the thermal optimum stimulates physiological processes beneficial for resistance to OA; compensation of CO_2 induced disturbances of growth and calcification has in fact been observed (Brennand *et al.*, 2010; Findlay *et al.*, 2010; Walther *et al.*, 2011). Warming to above optimum temperatures, however, exacerbates sensitivity to CO_2 and conversely, CO_2 enhances heat sensitivity in crustaceans (Walther *et al.*, 2009; Findlay *et al.*, 2010), coral reef fishes (Munday *et al.*, 2009a) and corals (via CO_2-enhanced bleaching; Anthony *et al.*, 2008; 6.2.2., Figure 6-7), causing a narrowing of the thermal niche (Walther *et al.*, 2009; Figure 6-7; 6.3.5).

The climate zone may thus shape CO_2 sensitivity due to differences in temperature, ocean chemistry and organism physiology. Elevated energy turnover in Northern hemisphere ectotherms (see above) may improve resistance, associated with a higher capacity in acid-base regulation. In contrast, low energy expenditure in Southern, deep sea and high polar, e.g. Antarctic species, may cause enhanced sensitivity (e.g. crustaceans, Pane and Barry, 2007). Reported patterns of acid-base regulation in Antarcic fishes under OA are unusual and their influences on sensitivity unclear (Strobel *et al*., 2012). Polar calcifiers are exposed to higher CO_2 solubility and lower carbonate saturation levels, possibly exacerbating sensitivity (Orr *et al.*, 2005). Tropical species may again be specialized and more sensitive than species from temperate regions (Pörtner *et al.*, 2011). This rough differentiation is complicated by local adaptation from within species genetic variability. At present, it is unclear if evolutionary adaptation to elevated CO_2 levels has occurred in polar waters, OMZs or marine sediments, possibly with reduced reliance on the strength of calcified structures (Clark *et al.*, 2009; Walther *et al.*, 2011; Maas *et al*., 2012).

6.2.5.4. Sensitivities of Warm and Cold Water Reef-building Corals

Tropical corals differ from most other animals by forming an endosymbiosis with dinoflagellates of the genus *Symbiodinium*, which enable their hosts to build and sustain carbonate reefs and their functions (Box CC-CR). *Symbiodinium* provides the host with organic carbon from photosynthesis (Trench, 1979; Pernice *et al*., 2012) and is provided with inorganic nutrients which are in short supply in clear tropical waters (Muscatine and Porter, 1977; Muscatine and D'elia, 1978). Unusual changes in light or salinity and small changes in temperature correlate with 'bleaching', the loss of symbionts and tissue color, possibly caused by Reactive O_2 Species (ROS). Damage to the symbionts involves disturbed excitation processing within the light harvesting centers of photosynthesis (Glynn and D'croz, 1990; Hoegh-Guldberg and Smith, 1989) and ROS release, also affecting CO_2 fixation by Rubisco (Ribulose Bisphosphate carboxylase, Jones *et al*., 1998) and/or photosystem II (PSII) functioning (Warner, 1999). Mass bleaching is correlated with small temperature anomalies (+1-2 °C of the long-term summer maximum, satellite observations), causing mortalities (Goreau and Hayes, 1994; Strong *et al*., 1997, 2011) and an observed average decrease in coral abundance by 1-2 % per year (Carpenter *et al*., 2008; Box CC-CR). It is debated whether corals adapt to warming (Box CC-CR), by considering shifting heat tolerances across coral genera (Hoegh- Guldberg and Salvat, 1995; Loya *et al*., 2001), the exchange of genetic clades of *Symbiodinium* with more tolerant varieties (Baker, 2001, 2004; Jones *et al*., 2008; Ulstrup and Van Oppen, 2003), as well as acclimatization phenomena (Howells *et al*., 2012). It remains unexplored whether such mechanisms can sustain reef formation.

OA causes genera-specific reductions in calcification (Kleypas et al., 1999, Hoegh-Guldberg *et al*., 2011; Kleypas and Langdon, 2006; Langdon and Atkinson, 2005; Leclercq *et al*., 2002). Coral communities around natural CO_2 seeps have lower growth, calcification and biodiversity (Manzello *et al*., 2008; Fabricius *et al*., 2011) and display a shift from net accretion to net erosion, depending on ambient CO_2 levels (Box CC-CR). Nutrient availability to symbionts may sustain calcification. Females may sacrifice calcification more than males due to energetic tradeoffs with reproduction (Holcomb *et al.*, 2010, 2012). Heterotrophic feeding supporting resilience (Edmunds, 2011) shows the energy dependence of coral calcification and acid-base regulation (Figure 6-10).

Temperature extremes acting synergistically with CO_2 reduce calcification and increase sensitivity to bleaching (Anthony *et al*., 2008; 6.3.5). Combined warming and OA following B2 and A1FI AR4 scenarios in mesocosms caused losses of symbionts and corals, and a nocturnal decalcification of the reef community in summer (Dove *et al.*, subm). Wide changes occur in gene expression including ones involved in carbonate deposition and skeleton formation (Kaniewska *et al*., 2012). Mechanisms of temperature and OA impacts clearly require further study.

Studies of the climate sensitivity of cold water corals are scarce. Findings that *Lophelia pertusa* respond strongly to 3°C warming, with a three-fold increase in metabolic rate (Dodds *et al.*, 2007) indicate that these have narrow thermal windows (cf. Pörtner, 2006). Three studies provided proof for resilience of *L. pertusa* to ocean acidification. In short-term ship-board incubations and with pH reductions of between 0.15 and 0.3 units, (Maier *et al.*, 2009) found calcification rates reduced by 30-56 %, especially in young, fast growing polyps. However, not only was net calcification maintained at water aragonite saturation <1, but acclimation to enhanced pCO_2 equivalent to pH reductions by 0.1 units led to calcification rates being maintained over six months (Form and Riebesell, 2012), likely due to upregulation of pH and carbonate saturation at calcification sites (McCulloch *et al*., 2012). The role of the aragonite saturation horizon in defining the distribution of cold water corals is thus not clear (Guinotte *et al*., 2006).

6.2.5.5. Sensitivities of Marine Reptiles, Mammals, and Birds to Climate Change

Long-term data sets indicate that some species of seabirds, marine mammals and sea turtles are responding to the anomalous ocean climate of the 20th century (Hughes, 2000). The reptiles, being ectotherms, are more responsive to temperature effects than seabirds and marine mammals (6.2.2). There is insufficient information to assess the risks for sea snakes or crocodiles. For turtles, poleward distribution shifts consistent with recent warming have been recorded in almost all marine groups. Decadal scale climate fluctuations affect their recruitment success and nesting abundance (Van Houtan and Halley, 2011), warming and abundance being inversely correlated in various species and regions (Chaloupka *et al.*, 2008; Mazaris *et al.*, 2009 b; Balazs and Chaloupka, 2004; Saba *et al*., 2007;

Broderick *et al*., 2001). Extreme weather causes nest flooding, considerably reducing hatching success (Van Houtan and Bass, 2007). Those capable of changing nesting sites (Fish and Drews, 2009; Hawkes *et al*., 2009) will be less impacted than those with high fidelity to nesting and foraging sites (Cuevas *et al*., 2008). During continued warming, modulated by changing rainfall (Santidrián Tomillo *et al*., 2012), turtle sex ratios may be skewed towards output of females, combined with higher egg and hatchling mortality (Fuentes *et al.,* 2009; Saba *et al*., 2012), earlier onset of nesting (Pike *et al*., 2006; Weishampel *et al*., 2004; Mazaris *et al.,* 2008), decreasing nesting populations (Chaloupka *et al.,* 2008) and shifts in dietary breadths (Hawkes *et al.,* 2009), leading to projected recruitment declines for, e.g. the leatherback turtles (Saba *et al*., 2012). Vulnerability due to shifting sex ratio alone remains unclear as nesting beaches have persisted with low production of male hatchlings over decades or longer (Broderick *et al*., 2000; Godfrey *et al*., 1999; Hays *et al*., 2003; Marcovaldi *et al*., 1997; Poloczanska *et al.,* 2009). The absence of sea turtles in certain regions may, however, be best explained by the temporal unavailability of food resources or strong thermoclines restricting their bottom foraging abilities (Braun-McNeill *et al.,* 2008; Gardner *et al.,* 2008).

Seabird range modifications probably caused by climate change were recorded in polar areas and the temperate zone of the North Atlantic (Grémillet and Boulinier, 2009). Northern-temperate species have shifted their ranges to higher latitudes (Robinson *et al.,* 2005; La Sorte and Jetz, 2010). Southward range expansion or population growth are reported in the southern hemisphere, (e.g. Dunlop 2001; Bunce *et al.,* 2002). Some species like the king penguin follow shifting foraging zones (Péron *et al*., 2012), others are affected by changing habitat structure like sea ice (e.g. the emperor penguin, Jenouvrier *et al*., 2012). Trans-hemispheric migratory seabirds such as the sooty shearwater *Puffinus griseus*, which spend the austral winter off the coast of California, probably shifted towards the central, equatorial Pacific waters, where increasing SSTs may have enhanced primary productivity and prey availability (Hyrenbach and Veit, 2003). Warming causes many bird species to breed earlier (Sydeman and Bograd, 2009). Extant high-latitude, cool-water species experience extended breeding seasons (Chambers *et al.,* 2005, 2011). Nevertheless, there is often no clear agreement (Heath *et al.,* 2009) whether those changes solely reflect ocean warming or a combination of human-induced climate change and natural variations or other synergistic factors like fishing pressure on seabirds' prey species, sea level rise and pollution (Heath *et al.,* 2009; Galbraith *et al.,* 2005; Votier *et al.,* 2005). Most of the changes in range shifts and seasonal activity involve shifts in trophic relationships. Seabirds with narrow geographic domains and limited phenotypic plasticity are expected to be more susceptible to climate change (Chambers *et al.,* 2005; Grémillet and Boulinier, 2009); even leading to the local extinction of populations (e.g. the Galápagos penguin *Spheniscus mendiculus*, Vargas *et al.,* 2007; and the marbled murrelet *Brachyramphus marmoratus*, Becker *et al*., 2007).

Predator-prey dynamics or impacts on specific habitats also shape the effects of climate change on the distribution, phenology and migration timing of marine mammals (Calambokidis *et al.,* 2009; Salvadeo *et al*., 2011). Some marine mammals shift their distribution poleward to follow the movement of their prey (Simmonds and Isaac, 2007). There is *medium evidence* and *agreement* suggesting that expected patterns may already be occurring, in case of dolphin, porpoise and whale species showing a northward shift in distribution (Salvadeo *et al.,* 2010; MacLeod *et al.,* 2005; Springer *et al*., 1999; Calambokidis *et al*., 2009; Moore and Barlow, 2011). As in birds, vulnerability is high for marine mammals with narrow geographic ranges and high habitat dependence. Examples are the critically endangered vaquita (*Phocoena sinus*) endemic to the Northern Gulf of California, which cannot move north because of the land barrier; or the polar bear (*Ursus maritimus*, Laidre *et al.,* 2008; Rode *et al.,* 2010, 2012) and the walrus (*Odobenus rosmarus*) that depend on sea ice as a platform for hunting, resting and giving birth. For polar bears, access to prey such as ringed seals has been disrupted by the later formation and earlier breakup of sea ice in the eastern Canadian Arctic. Seasonal migrants and ice-associated species in the Arctic (fin whale; minke whale, *Balaenoptera acutorostrata*; gray whale; killer whale, *Orcinus orca*, humpback whale, *Balaenoptera novaeangliae*; and bowhead whale, *Balaena mysticetus*) may benefit from the net loss of sea ice, due to better access to a pelagic-dominated ecosystem (Moore and Huntington, 2008).

6.2.5.6. Conclusions

Physiological knowledge indicates with *high confidence* that animals specialize on restricted temperature and predicts how the species-specific capacity for performance and associated energy turnover shape sensitivity to climate induced ocean warming, acidification and hypoxia, thereby supporting attribution of effects to climate

change. Increased food availability and sustained feeding capacity improve resilience (high confidence). Extreme temperatures surpassing the fringes of the thermal envelope cause local abundance losses, extinction and shifts in temperature dependent distribution ranges (*high confidence*). These trends are exacerbated by the growing influence of OA and hypoxia, leading to mechanism based projections of faster range contractions than with warming alone (*medium confidence*), however, quantitative conclusions have *low confidence*. The synergistic effects of stressors cause relative changes in the performance of interacting species and lead to shifts in species interactions and food webs (*limited evidence, medium agreement*). High sensitivities to OA are associated with low metabolic rates and functional capacities of marine animal species. Calcification rates in sensitive invertebrate groups including corals, echinoderms and molluscs decrease under OA, especially if combined with temperature extremes (*high confidence*). Polar species sensitive to warming will be marginalized, with no possibility for that fauna to escape to colder regions (*high confidence*), however, formal loss of a polar species has not been recorded yet. Some tropical species such as corals or ecosystems such as coral reefs exist close to their upper thermal limits. *Confidence* is *low* for direct attribution of changes in life history and population dynamics of marine mammals, birds and turtles to climate drivers. Conversely, *confidence* is *high* that climate effects on reptiles, birds, and mammals are mostly mediated through climate-dependent changes in habitat structure and food availability.

6.3. Trends in Biological Field Observations: Attribution to Climate Change?

Mechanistic knowledge (6.2) and long-term observations (6.1.2.-3) support attribution to climate change of impacts including: (i) changes in abundance and overall biomass, (ii) loss of habitat, (iii) changes in community composition and species richness, (iv) changes in species biogeographical ranges, (v) alterations to phenology and the frequency of events like exposures to extreme temperatures, (vi) changes in connectivity among populations and habitats (e.g. Carson *et al*., 2010) and (vii) propensity for change, including frequency and severity of waterborne diseases. For warming and hypoxia, effects are accelerated by exposures of organisms and ecosystems to shifting seasonal or even diurnal extremes and their frequency (*medium evidence* and *agreement*) (e.g. Pörtner and Knust, 2007; Diaz and Rosenberg, 2008). This may also apply to effects of anthropogenic OA (*low evidence* and *agreement*), as indicated by the detrimental effects of upwelling high CO_2 waters on oyster cultures in the Northeast-Pacific (Barton *et al*., 2012). This section analyzes how physical and chemical forces (6.1.1) shape biological responses in the field, as a result of their physiology (6.2). Modeling approaches and the resulting global projections are discussed under 6.5.

6.3.1. Contrasting Observations and Projections on Primary Production

Observations indicate significant alterations of net primary production (NPP) in the ocean when environmental controls are altered due to natural perturbations, shifts in ocean currents, volcanic eruptions and enhanced iron supply, as in high-nitrate low-chlorophyll (HNLC) waters of the NE Pacific (Hamme *et al.*, 2010). Climate variability can drive pronounced changes in primary productivity (Chavez *et al.*, 2011), such as during the El Niño to La Niña transition in Equatorial Pacific, when nutrient and trace element supply are enhanced (Chavez *et al.*, 1999). As outlined in 6.1.3. and 6.2.3., the limited temporal extent of the satellite datasets, and the contrasting evidence from satellite and field based time series data in low latitude waters lead to *medium confidence* that there has been a small but significant increase in global NPP over the last two decades, but this increase may be linked more closely to shifts in environmental variability than to climate change. At high latitudes, there is *medium confidence* based on *limited evidence* and *medium agreement* from satellite images and modeling studies of an observed trend of higher rates of NPP (6.2.3).

6.3.2. Temperature-Mediated System Changes

Temperature effects on ecosystems are built on organismal responses, direct or indirect via competing species or the foodweb (6.2.2) or via additional changes in the physical environment. Direct organismal responses include changes in distribution, abundance, phenology and body size, which are related to physiological responses that affect species' performances in growth and reproduction (6.2.2.-5). Marine ecosystems are also indirectly affected by temperature through changes in stratification, sea-ice extent and interactions with other drivers like OA and hypoxia

(6.3.3). Species responses to temperature depend on location, the respective climate regime and, potentially, local adaptation (6.2.2). Geographical shifts of marine species from similar locations vary (Genner *et al*., 2004; Perry *et al*., 2005; Simpson *et al*., 2011b) emphasizing that thermal window widths and associated thermal sensitivities are species- specific, related to mode of life, phylogeny and associated metabolic capacities (6.2.5). Differences between species-level changes affect community and ecosystem responses to temperature-mediated effects.

6.3.2.1. Species Abundance, Biogeography, and Diversity

There is *high confidence* that recent changes in abundance and distribution of marine species and the associated shifts in biomes and diversity patterns are resulting, at least partly, from temperature-mediated biological responses (Table 6-8). In pelagic systems (Box 6-1), plankton abundance is related to water temperature (6.3.1, Ch. 30). For example, data from the Continuous Plankton Recorder (6.1.3) in the Northeast Atlantic from 1960 to 1995 show that warmer temperature enhances phytoplankton growth (Edwards *et al*., 2001), and that plankton distribution in the North Atlantic shifted poleward at a mean rate of hundreds of km per decade since the 1950s (Beaugrand *et al.*, 2009; Beaugrand *et al.*, 2002; Bonnet *et al.*, 2005; Lindley and Daykin, 2005; Richardson *et al.*, 2006; Figure 6-11, Box 6-1). Coccolithophore blooms (*E. huxleyi*) were observed for the first time in the Bering Sea during the period 1997-2000, probably in response to a 4°C warming cue, combined with a shallower mixed layer depth, higher light levels and low zooplankton grazing (Merico *et al*., 2004). Warming may also have caused the southward movement of coccolithophores in the Southern Ocean in the 2000s (Cubillos *et al.*, 2007).

[INSERT TABLE 6-8 HERE
Table 6-8: Examples of observed biological responses resulting from temperature and temperature-mediated changes in the ocean.].

Similarly, the distribution of pelagic and demersal fishes and macroinvertebrates has shifted poleward at tens to hundreds of km per decade during warming since the 1970s, although the range shifts have not been uniform across taxa or ocean regions (Johns *et al.*, 2001; Johns *et al.*, 2003; Mackas and Beaugrand, 2010; McGinty *et al.*, 2011). In the Northeast Pacific, the center of distribution of forty fishes and invertebrates shifted north by an average of 34 ± 56 km since the early 1980s (Mueter and Litzow, 2008; WGII Ch. 28). A general increase in the frequency of southern species moving northward occurred with El Niño associated warming events in the late 50s, early 80s and late 90s and, with a general interdecadal climatic regime shift in the California Current, beginning in the late 70s (McGowan *et al.*, 1998). In the North Sea, marine species have been moving polewards by 22 km decade^{-1} and to deeper water by 3.6 m decade^{-1} in relation to warming from the 1970s to 2000s (Perry *et al*., 2005; Dulvy *et al*., 2008). A global meta-analysis including 311 marine species from non-single species studies estimated an average poleward shift of 8.9 km decade^{-1} (Przeslawski *et al*., 2012). These distribution changes are mostly attributed to temperature change, but may be influenced by other factors such as sea-ice extent, nutrient enrichment and overfishing. For comparison, average terrestrial species distribution shifts ranges from 6.1 km per decade (Parmesan and Yohe, 2003) to 16.9 km per decade (Chen *et al*., 2011), with a high diversity of range shifts among species. Shifts to cooler depths in marine environments are the equivalent of altitudinal shifts in terrestrial environments (Dulvy *et al*., 2008; Burrows *et al*., 2011). Poleward distribution shifts resulted in increased species richness in high latitude regions (Hiddink *et al*., 2008) and in changing community structure (Simpson *et al*., 2011), causing polar and temperate ecosystems to become more temperate and subtropical, respectively (Philippart *et al.*, 2011). In semi-enclosed seas such as the Mediterranean geographical barriers constrain range shifts and may cause a loss of endemic species (Ben Rais Lasram *et al*., 2010), with associated niches filled by alien species, either from nearby or artificially introduced (Philippart *et al*., 2011).

[INSERT FIGURE 6-11 HERE
Figure 6-11: **A**. Long-term changes in the ecosystem state based on 5 biological parameters (phytoplankton colour index, mean size of calanoids, mean calanoid diversity, an index of change in plankton composition and cod recruitment). The orange line denotes the mean ecosystem state for the period prior and after the abrupt ecosystem shift. **B**. Long-term changes in the multiscale temporal local variance of the ecosystem state (in red). High values indicate pronounced year-to-year changes in the ecosystem state. The light gray band shows the unstable period (1980-1989). **C**-**D**. Observed mean annual sea surface temperature in the North Sea during 1960-1981 (**C**) and 1988-

2005 (**D**). The location of the critical thermal boundary (9-10°C) is indicated by '+'. **E.** Long-term changes in the mean number of warm-temperate pseudo-oceanic species from 1958 to 2005. **F.** Long-term changes in the mean number of temperate pseudo-oceanic species from 1958 to 2005. The period 1958-1981 was a period of relative stability and the period 1982-1999 was a period of rapid northward shifts, indicating that the abrupt ecosystem shift observed in the North Sea was part of a large-scale response of the zooplankton biodiversity to warming temperatures (see **A**-**D**). Average values are below 1 because they are annual averages. Note that the colour bar is 10-fold inferior for warm-temperate pseudo-oceanic species because these species are less frequently observed than their temperate counterparts. From Beaugrand *et al*. (2008) and Beaugrand *et al*. (2009).]

Field observations show changes in abundance, distribution and diversity of ocean benthos in response to climate change, especially in intertidal organisms and coral reefs (WGII Ch. 5, *robust evidence, high agreement*) but also in other benthos (*medium confidence*), shaped by exposures to temperature extremes (WGII Ch. 5; cf. Figure 6-7). Phenomena in sedentary organisms and benthic macroalgae are complicated by the influence of local dynamics and topographic features (islands, channels, coastal lagoons, e.g. of the Mediterranean, Bianchi, 2007) on biogeographic boundaries (Poloczanska *et al.*, 2011). Considerable poleward shifts of warm water species including macroalgae (Table 6-8; van den Hoek, 1982; Müller *et al*., 2009, 2011; Fernández, 2011) or corals (Precht and Aronson, 2004; Yamano *et al*., 2011) have been observed over last decades (*high confidence*) and are projected to continue (Müller *et al*., 2009, 2011). In corals during the last interglacial this was paralleled by the equatorial deterioration and retreat of coral reef ecosystems (Kiessling *et al*., 2012), likely due to associated bleaching (6.2.5; Box CC-CR). This confirms that shallow-water reef-building corals and their low latitude ecosystems are among the most sensitive to warming (Veron *et al*., 2009). However, a large scale survey found diverse coral reef types along a climatic gradient, but no consistent latitudinal response to climatic drivers (Hughes *et al*., 2012). The distribution of sublittoral benthos may respond more slowly to warming than that of fishes, plankton and intertidal organisms, but immigration and proliferation of species from warmer waters has been observed in selected areas like the British channel (Hiscock *et al*., 2004; Hinz *et al.*, 2011) or the North Sea coastal area (Reise and van Beusekom, 2008). The diversity of these findings indicate various environmental influences and pathways of changing species composition.

6.3.2.2. Phenology

There is *robust evidence* from long-term observations that warming and other temperature-mediated changes have resulted in shifting phenologies of marine species (Table 6-8), ranging from phytoplankton and zooplankton blooms, to reproduction and migration of invertebrates, fishes and seabirds, with many biological events advanced in timing under warming. In the waters around the U.K., during a period of warming between 1976 and 2005, the seasonal timing of biological events of all major marine taxonomic groups (plant/phytoplankton, invertebrate and vertebrates) advanced on average, by 0.31 to 0.43 days year^{-1} (Thackeray *et al*., 2010). This rate of phenological shift is not statistically different from shifts observed for freshwater and terrestrial species. Overall, the average rate of shift across species in all biomes is estimated to be 0.39 d yr^{-1}. Patterns of phenology shifts are different between trophic groups, potentially causing trophic mismatch and disruption of interspecific interactions.

6.3.2.3. Body Size

There is *medium evidence* from long-term observations that warming and other temperature-mediated changes affect the body size of marine organisms (Table 6-8). Weight-at-age of some juvenile or younger fish populations were shown to increase with temperature, as warmer water increases growth rates (e.g. Brunel and Dickey-Collas, 2010; Neuheimer and Grønkjær, 2012). However, spatial and temporal comparisons of observed maximum body sizes of invertebrates and fish populations suggest a decrease in maximum body size as temperature increases (6.2.2., Box 6-1, e.g. Daufresne *et al*., 2009). Changes in body size observed in a local population under warming may be complicated by effects on energy budget through temperatures drifting outside of a species' optimum range, the availability and changing body size of prey, species interactions or effects of fishing (Cheung *et al*., 2012).

6.3.2.4. Trophic Interactions

There is *high confidence* that temperature affects marine trophic interactions through changes in the distribution and timing of peak abundances of prey and predator, their growth and consumption rates (grazing or predation; Table 6-8). A time series for four commercial fish species and their zooplankton prey in the Norwegian and Barents Seas showed that climate shapes population growth rates through complex influences early in life, including direct temperature effects on growth, further effects through prey and delayed feedback effects through predators (Stige *et al.*, 2010). In a study of temperature effects on five trophic levels, species interactions of primary producers (microalgae), primary, secondary and tertiary consumers (zooplankton, fishes and jellyfishes) and benthic detritivores (echinoderms and bivalves) were modified through trophic amplification due to differential species responses to temperature (Kirby and Beaugrand, 2009). There is *high confidence* that the responses of various plankton functional groups, diatoms, dinoflagellates or copepods to warming are not synchronous, resulting in predator – prey mismatches that carry over to higher trophic levels (Edwards and Richardson, 2004; Costello *et al.*, 2006; 6.3.5., 6.3.6). In the intertidal, the relative ranges of predator and prey change in response to warming lead to shifts in dominance through interactions and modifications in predator pressure (Harley, 2011).

6.3.2.5. Conclusions

Overall, there is *very high confidence* that temperature is directly affecting marine organisms, their biogeography and community structure in both pelagic and benthic systems. Effects are complemented by indirect effects, e.g. *via* stratification, sea ice melt and freshening (*high confidence*). In a warming world, ecosystems adapted to the coldest temperatures or existing at their upper thermal limits are more sensitive (6.2.5). Long-term field observations and experimental research have identified, with *high confidence* and building on *robust evidence* and *high agreement*, that shallow-water reef-building corals and their reefs are among the marine ecosystems most affected by climate change and especially associated warming. However, other factors change concomitantly, such that quantification of the fraction of ecosystem change attributable to temperature has not always been possible.

_____ START BOX 6-1 HERE _____

Box 6-1. The Atlantic Example: Long-Term Responses of Pelagic Organisms and Communities to Temperature

Long-term observations (6.1.3) encompassing the whole pelagic Northeast Atlantic over a 50 year period show changes in the seasonal abundance of phytoplankton and rapid northerly movements of temperate and subtropical species of zooplankton (e.g. calanoid copepods) and phytoplankton (e.g. dinoflagellates and diatoms) and changes in the ecosystem functioning and productivity (Edwards *et al.*, 2001; Beaugrand *et al.*, 2002; Edwards and Richardson, 2004). The range limit of warm water copepods shifted by 10° north since 1960 (Beaugrand *et al.*, 2009), with attendant mismatch in the seasonal timing of trophic levels and functional groups (Edwards and Richardson, 2004). Fluctuations in climate indices like the Northern Hemisphere Temperature (NHT) and the North Atlantic Oscillation (NAO) over multidecadal periods accompanied these changes. In cooler regions increased phytoplankton activity caused by warming probably favored growth and the observed increase in phytoplankton biomass, whereas a decrease in nutrient supply would have prevented growth in warmer regions and caused a decrease in biomass (6.2.3; Richardson and Schoeman, 2004). Hinder *et al*. (2012) attributed a recent decline in dinoflagellates in relation to diatoms to warming, increased summer windiness and thus, turbulence. In the Northwest Atlantic sub-polar region, shifts in plankton distribution may be limited by the prevailing flow from the north, in addition to sea-ice extent and temperature (Head and Pepin 2010).

In line with the increased understanding of physiology (6.2.2., 6.2.5) warming in the temperate to polar North Atlantic was paralleled by a reduction in the average body lengths of about 100 copepod species, from 3-4 mm to 2-3 mm. Warming also led to an increase in species richness among copepods and in the dinoflagellate genus *Ceratium* (Beaugrand *et al.*, 2010). For diatoms as major contributors to carbon export (Armbrust, 2009), warming and decreasing annual variability in SST were associated with lower diversity, smaller size and reduced abundance (Beaugrand *et al*., 2010). Morán *et al.* (2010) found that temperature alone explained 73% of the variance in the

contribution of small cells (picophytoplankton) to total phytoplankton biomass in the eastern and western temperate North Atlantic from -0.6 to 22°C. Global outbreak frequencies of jellyfish aggregations may follow rising SSTs (Mills, 2001; Purcell, 2005; Purcell and Decker, 2005), however, evidence is inconclusive. Some studies report an increasing trend (Brotz *et al*., 2012) and others do not support this view (Condon *et al*., 2013) (*low confidence).*

The ecosystem regime shift observed in North Sea plankton in the late 1980s involved an increase in phytoplankton and changes in species composition and abundance among holozooplankton (animals that are planktonic for their entire lifecycle) (Reid *et al.*, 2001; Kirby and Beaugrand, 2009; Kirby *et al.*, 2009; Lindley *et al.*, 2010). This North Sea regime shift was paralleled by the northward propagation of a critical thermal boundary (CTB) between the temperate and the polar biomes (Figure 6-1; Beaugrand *et al*., 2008). Surpassing the CTB led to pronounced and large-scale variations in phytoplankton productivity, an increase in calanoid copepod diversity (Beaugrand *et al*., 2008) and herring abundance (Schlüter *et al*., 2008), a reduction in the mean size of calanoids and a decrease in the abundance of Atlantic cod in the North Atlantic Ocean (Beaugrand *et al*., 2010). These patterns also extend to the Southern North Sea, where elevated salinities and average warming by 1.6°C both in summer and winter between 1962 and 2007 expanded the time window for growth of microalgae and possibly supported the invasion and increase in numbers of warm-adapted silicified diatoms (Wiltshire *et al*., 2010).

Regions of high vulnerability exist where mild warming can trigger rapid and substantial ecosystem shifts, offering a way to anticipate future shifts in all of the North Atlantic sector. Recent findings indicate a regime shift in the Bay of Biscay, the Celtic and the North Seas in the mid to end 1990s (Luczak *et al.*, 2011) when a shift in plankton composition and in the abundance of both sardine and anchovies and of the Balearic shearwater (*Puffinus mauretanicus*, an endangered seabird) paralleled stepwise warming. In contrast, changes in SST, plankton composition and productivity in the southern Bay of Biscay were less marked in areas influenced by seasonal upwelling (Valdés *et al*., 2007; Bode *et al*., 2009, 2011). In the North Sea, a further shift discovered at the end of the 1990s (Beaugrand *et al*., revised) impacted about 40% of the phytoplankton and zooplankton species and thus had the same magnitude as the North Sea regime shift in the 1980s.

Changes in local and regional species richness, abundance and community composition result from species-specific latitudinal range shifts, depth distribution and the associated change in the structure and functional properties of ecosystems, such as productivity, energy flows and invasion resistance (*high confidence*, Stachowicz *et al.*, 2002; Duffy, 2003; Simpson *et al*., 2011b). Similar to plankton, northward range extensions or redistributions in fishes were largest along the European Continental shelf and attributed to regional warming, e.g. by 1.05°C from 1977 to 2001 in the North Sea, with winter warming being effective for Atlantic cod (Perry *et al*., 2005; 6.2.5). In the Northwest Arctic winter and spring warming caused expansion of the thermal optimum area covering 4–8°C, associated with greater growth in Atlantic salmon (Friedland and Todd, 2012). Pelagic sardines and anchovies entered the North Sea in the early to mid 1990s, after about 40 years of absence, in response to intensified NAO and AMO (Alheit *et al.*, 2012). Red mullet and bass extend to western Norway, and Mediterranean and north-west African species extend to the south coast of Portugal (Brander *et al.*, 2003; Beare *et al.*, 2004; Genner *et al.*, 2004).

The cooling and freshening of the Northwest Atlantic during the late 1980-early 1990s had the opposite effect, causing capelin and their predator, Atlantic cod to shift farther south (Rose and O'Driscoll, 2002). Between the early 1990s and mid-2000s in the Northwest Atlantic sub-polar gyre, phytoplankton increased, due to warming induced stratification. At the same time Arctic copepod species became more abundant, due to increased influx of Arctic water (Head and Pepin, 2010). Although temperatures have risen on the Newfoundland Shelf (Colbourne *et al*., 2011), capelin and cod remain scarce throughout the region for reasons likely unrelated to climate (DFO 2011a,b). Further south, Arctic freshwater inflow caused freshening and associated stratification of the area around the Gulf of Maine, throughout the 1990s, resulting in enhanced phytoplankton abundance, a larger and later fall bloom, increased abundance of small copepods, and a decrease in the large copepod *Calanus finmarchicus* (de Young *et al*., 2004; Pershing *et al*., 2005, 2010). Various fish species showed poleward shifts in distribution (Table 6-8). This was associated with reduced survival of larval cod (Mountain and Kane, 2010), fewer right whale calves (Greene *et al*., 2003), but increased herring abundance (Greene and Pershing, 2007).

_____ END BOX 6-1 HERE _____

6.3.3. Effects of Hypoxic Events and Expansion of Oxygen Minimum Zones (OMZs)

Hypoxic or anoxic conditions in both water and sediments strongly impact marine biota (6.2.2). O_2 deficiency in expanding OMZs will shift pelagic communities from diverse midwater assemblages to diel migrant biota that return to oxygenated surface waters at night (Seibel, 2011). Expanding OMZs will cause habitat loss to groundfishes and pelagic predators, affect the distribution of key zooplankton and nekton species and influence their diurnal and ontogenetic vertical migrations (Auel *et al.*, 2005; Ekau *et al.*, 2010). Major effects of expanding OMZs thus are habitat compression or abundance losses for intolerant taxa such as billfishes and other pelagic fishes with a high O_2 demand (Prince and Goodyear, 2006; Prince *et al.*, 2010; Stramma *et al*., 2012; cf. 6.2.5), large benthic invertebrates like crabs (Chan *et al.*, 2008), mesopelagic fishes (Koslow *et al*., 2011) and groundfishes (McClatchie *et al.*, 2010). Hypoxia effects propagate along the food chain and thereby affect fish stocks and top predators (Stramma *et al.*, 2010). Conversely, hypoxia supports range expansions or population growth in tolerant taxa like anaerobic bacteria (Ulloa *et al*., 2012), gelatinous zooplankton (medusae, ctenophores) and selected fishes (gobies, hake), or possibly selected cephalopods (Gilly *et al.*, 2006; Zeidberg and Robinson, 2007; Bazzino *et al*., 2010), characterized by slow growth rates, low O_2 demand and high capacities to exploit available O_2. Overall, expanding hypoxia will result in a lower biodiversity (Levin, 2003; Levin *et al.*, 2009a; Ekau *et al.*, 2010; Gooday *et al.*, 2010).

Upwelling events can be associated with exposures to hypoxic high CO_2 deep water causing strong ecosystem responses (*high confidence*), such as hypoxia induced biomass reduction in fish and invertebrate fauna (Keller *et al.*, 2010) and increases in sulphide-oxidizing bacterial mats (Chan *et al.*, 2008). Shifts in upwelling activity with climate change coincide with an apparent increase in the frequency of submarine gas eruptions of methane and hydrogen sulphide, caused by enhanced formation and sinking of phytoplankton biomass to the hypoxic to anoxic sea floor (Bakun *et al.*, 2010). These eruptions and the combined factors acting have been blamed for extensive mortalities of coastal fishes and invertebrates (Bakun and Weeks, 2004) and reductions in fishing productivity, particularly of Cape hake (*Merluccius capensis)*, Namibia's most valuable fishery (Hamukuaya *et al.*, 1998).

Dissolved O_2, among other factors, plays an important role in shaping large alternating fluctuations of sardine and anchovy abundances, particularly off Peru. Anchovies are not strongly affected by a shallow oxycline (<10m), while sardines actively avoid such conditions (Bertrand *et al*., 2010). High susceptibility of early life stages to hypoxia in both pelagic and benthic ecosystems (Ekau *et al*., 2010), threatens population survival. In benthic ecosystems, the expansion of OMZs will, with *high confidence*, shift microbial and faunal composition, reduce diversity and alter the functional attributes of upper slope and shelf environments (Levin *et al.*, 2009a; Stramma *et al.*, 2010).

As CO_2 increases in parallel to O_2 depletion, marginalization of calcifiers is observed in OMZs (Levin, 2003), indicating interactions of hypoxia with acidification (6.2.2). Furthermore, significant correlations between H_2S concentrations and climate change indicators such as sea surface temperature and sea level pressure have been documented at interannual and interdecadal scales for the open part of the Black Sea (Daskalov, 2003; Faschuk, 2011). There is *medium confidence* that climate associated processes may change the parameters of anoxic and OMZs and of zones poisoned by hydrogen sulphide and thus influence corresponding pelagic and bottom faunal distributions, trophic relations, energy flows, and productivity (Figure 6-12).

[INSERT FIGURE 6-12 HERE
Figure 6-12: Schematic illustrating the principal mechanisms underlying the formation of hypoxic conditions and their biological background (modified from Levin *et al.*, 2009a; Levin and Sibuet, 2012). The buoyancy flux from fluvial discharges produces sharp density stratification at the base of the freshened layer (also valid for icemelt, high precipitation) near the surface and, hence, vertical mixing is greatly reduced. In consequence, the nutrient inputs from the river and the atmosphere accumulate in a narrow upper layer, leading to phytoplankton blooms. The enhancement of oxygen consumption due to respiratory catabolism of sinking organic matter results in hypoxic conditions of OMZs. Heating of the upper layer further increases stratification, while the wind-driven upwelling of hypoxic, nutrient-rich water from deeper layers adds to the formation of the oxygen minimum zone.]

With the expansion and enhanced variability of OMZs, both (dissimilatory) nitrate reduction and anaerobic ammonium oxidation (anammox) will cause enhanced loss of fixed nitrogen limiting oceanic primary productivity

(*medium confidence*). Water column denitrification and N_2 fixation are spatially and temporally variable (*limited evidence, low confidence*) suggesting that climate effects on these processes are *unlikely* to operate uniformly (Brandes *et al.*, 2007; Fernandez *et al*., 2011; Franz *et al*., 2012).

In conclusion, there is *medium confidence* that OMZ expansion is causing habitat loss to groundfishes and pelagic predators and affecting the distribution of key zooplankton and nekton species as well as influencing their diurnal and ontogenetic vertical migrations. There is *high confidence* that effects of OMZ expansion will propagate along the food chain. If O_2 levels decline and OMZs expand further, a community change toward hypoxia-tolerant fauna will occur in midwater (*high confidence*). The diversity of macroorganisms will decrease and, finally, higher marine organisms will disappear and heterotrophic microorganisms will dominate (*high confidence*).

6.3.4. Effects of Anthropogenic Ocean Acidification

The strongest evidence for effects of ocean acidification (OA) on ocean biology stems from short (h) to medium term (several months) perturbation experiments in the laboratory or, more recently, the field and the assessment of organism responses after exposures to elevated CO_2 levels (6.2.2.-5). The long-term progressive nature of anthropogenic OA over years, even centuries indicates that results obtained during such acute exposures may not be easily scaled up to effects on longer timescales. Depending on the organism studied and its generation time perturbation studies measure tolerance and acclimation, but rarely adaptation or natural selection.

At ecosystem level shell thinning in planktonic foraminifera was attributed to anthropogenic ocean acidification in Southern Ocean species (Moy *et al*., 2009) and to both anthropogenic OA and upwelling of CO_2 rich deep waters for planktonic foraminifera in the Arabian Sea (de Moel *et al.*, 2009) or for pteropods in the Southern ocean (Bednarsek *et al*., 2012; *limited evidence, medium agreement*). An eight year trend of (variable) pH decline in coastal waters and the observation of species replacements in communities associated with local pH dynamics support the projection of shifts from shelled species like mussels to fleshy algae and barnacles with acidification along the Northeast Pacific coast (*medium confidence*, Wootton *et al*., 2008). Otherwise, contributions of OA to climate-induced alterations in the field have not yet been clearly established, partly because OA is still early in the process and has a much smaller effect than other drivers like temperature. For example, declines in calcification reported in corals (De'ath *et al.*, 2009) were elicited by thermal extremes and associated declines in performance, but may include an as yet unclear contribution by OA. Species-specific declines in calcification were also correlated with average annual sea surface temperature but at different temperature ranges characterizing the respective reef (Carricart-Ganivet *et al*., 2012).

Field studies at the demographic/metapopulation level are presently limited to natural analogues (CO_2 vents; Kroeker *et al*., 2011; Fabricius *et al*., 2011), indicating losses in diversity, biomass and trophic complexity of benthic marine communities. These studies cannot fully project future changes.

6.3.4.1. Bacterial Communities and Nutrient Cycles

Existing studies on the effect of OA (either through reduced pH or increased CO_2) on autotrophic and heterotrophic bacterial production have provided inconsistent results emphasizing that these responses are still poorly known and complex. Microbes are characterized by large diversity and broad environmental adaptation and hence may respond to environmental challenges by exploiting such diversity via species replacements (Krause *et al*., 2012) which makes projections of their reaction to ocean acidification on an ecosystem level very difficult. Processes discussed are: (1) cellular elemental stoichiometry (C-N-P ratios, Riebesell, 2004; Fu *et al*., 2007), (2) rates of CO_2 and N_2 fixation (Riebesell, 2004; Riebesell *et al*., 2008; Hutchins *et al*., 2007; Hutchins *et al*., 2009), (3) rates of nitrification (Beman *et al*., 2011), and (4) changes in the proportion of dissolved to particulate photosynthate carbon production and the implied efficiency of the biological carbon pump (Kim *et al*., 2011; 6.4.1). Field experiments led to the projection that nitrification rates (ammonia oxidation to nitrite and nitrite oxidation to nitrate) of ammonium oxidizing bacteria and archaea will be reduced by 3–44% in response to pH decrements by 0.05–0.14 (Beman *et al.*, 2011). Such a decrease in pH corresponds to a rise in atmospheric CO_2 concentration by approximately 100 µatm as projected for the next 30 to 40 years (WG I AnnexII). The reported decrease in nitrification occurred regardless of

natural pH variability providing no evidence for acclimation of the nitrifiers to reduced pH, e.g. in upwelling areas. However, potential changes in cell abundance, for example, due to lower per cell nitrification rates could further decrease or restore, respectively, the total volumetric rate of nitrification. While effects have been observed in the laboratory and in coastal mesocosm studies (Weinbauer *et al*., 2011) or in field experiments (Beman *et al.*, 2011), there is no evidence as yet for a reduction in abundances or metabolic activities of microbial communities in the field at either extreme of extant pH variability (Joint *et al*., 2010). Krause *et al.* (2012) documented a change in composition, without loss in abundance for a coastal bacterial community at pH 0.4 and 0.5 below ambient for the North Sea. Liu *et al.* (2010) propose that the rates of several microbial processes will be affected by OA, some positively, others negatively. The potential of the microbial community to adapt to OA and maintain function, either by genetic change at the species level or through the replacement of sensitive species or groups at the community level, remains to be explored further such that projections of future changes are not yet possible.

6.3.4.2. Phyto- and Zooplankton Communities

While there is *high confidence* in systematic changes in plankton abundance and community structure over recent decades (6.1.2, 6.3.1), most of these changes were caused by both the direct and indirect effects of warming and are driven in many cases by climate variability (Chavez *et al.*, 2011). The specific effects of anthropogenic OA are much less clear. Physiological rates and growth of some groups benefit from "fertilization" by CO_2 and may gain predominance (Rost *et al.*, 2008; Hutchins *et al.*, 2009, Table 6-6). Such shifts may be influenced by light and nutrients (6.2.2). For natural phytoplankton assemblages there is *medium confidence* to date that NPP is stimulated by increased CO_2 concentrations (Riebesell *et al.*, 2008; Tortell *et al*., 2008b). As responses to elevated CO_2 may influence the competitive abilities of species, small differences in CO_2 sensitivity may lead to pronounced shifts in the dominance of species (Tortell *et al.*, 2008b, Beaufort *et al*., 2011).

Quantification of the calcite mass of the coccolithophore community in the present ocean and over the last 40 kyr revealed patterns of decreasing calcification with increasing pCO_2, which in large parts was attributed to shifts between differently calcified species and morphotypes according to carbonate chemistry (Beaufort *et al.*, 2011). The same study, however, also observed heavily calcified *E. huxleyi* morphotypes in upwelling systems characterised by low pH, a finding which highlights the complexity of assemblage-level responses. For example, a shift from 'overcalcified' to weakly 'calcified' coccolithophores *Emiliania huxleyi* at higher latitudes may not reflect effects on cellular calcification rates but a temperature-related shift in ecotype dominance (Cubillos *et al.*, 2007; 6.3.2). Due to the complexity in response patterns, an up-scaling of effects of calcification in coccolithophores from monospecific culture experiments cannot be achieved. Projections of OA impacts on phytoplankton become even more complicated by synergistic interactions with other drivers (Boyd, 2011; 6.3.5).

For zooplankton, field and laboratory studies lead to *medium confidence* that pteropods (planktonic molluscs with aragonite shells) at high latitudes will experience reduced calcification in response to OA until the end of the century (Orr *et al.*, 2005; Comeau *et al.*, 2009; Comeau *et al.*, 2010; Lischka *et al*., 2011; Bednarsek *et al*., 2012). This may have severe impact on Subarctic Pacific and Southern Ocean ecosystems as pteropods form an integral part of the foodweb as grazers and prey for fishes like pink salmon (Bathmann *et al.*, 1991; Armstrong *et al.*, 2005; Hunt *et al.*, 2008). The comparison of decreasing calcification and shell weight found in extant planktonic foraminifera exposed to elevated CO_2 (Bijma *et al.*, 1999; Russell *et al.*, 2004; Lombard *et al.*, 2010) with findings in historical specimens (Moy *et al*., 2009) and during glacial interglacial cycles (Barker and Elderfield, 2002) supports *high confidence* in projections of future reductions in net calcification in foraminifera.

6.3.4.3. Macrophytes and Macrofauna at Ecosystem Level

Laboratory studies (6.2.2., 6.2.4) suggest that most seagrasses and non-calcifying algae respond to OA by increasing growth and recruitment, while calcifying algae experience reduced productivity. In various animal phyla, sensitivity seems to be highest in early life stages or during critical transition phases in the life cycle (6.1.2., 6.2.2., 6.2.5.., Table 6-5). The wide range of responses among macrofaunal calcifiers in experiments (e.g. Ries *et al.*, 2009), in natural settings at volcanic CO_2 vents (e.g. at Ischia, Italy, Hall-Spencer *et al.*, 2008 and Papua New Guinea,

Fabricius *et al.*, 2011) and in mesocoms (Christen et al 2013) suggests a wide range of ecosystem level consequences. For example, diversity is lower and non-calcifiers increasingly outcompete calcifiers once pH falls to a mean of 7.8 to 7.7 with a loss of calcifiers around pH 7.2 (Christen *et al.,* 2013). Calcitic bryozoans replace coralline algae which have more soluble high calcite skeletons (Martin *et al.*, 2008), corals decrease calcification rates, seagrasses and non-calcifying algae gain competitive advantage (Fabricius *et al.*, 2011) and net calcification changes to dissolution. However, the high pH variability at natural sites with lower pH values than indicated by the average change (Hall-Spencer *et al.*, 2008; Porzio *et al.*, 2011) and recolonization of the seep areas by larvae from neighbouring areas with normal pH or during periods of high pH, limits the use of these sites for analogues of future OA. With *limited evidence* and, thus *medium agreement*, warming probably exacerbates CO_2 effects on communities at the warm edges of their biogeographical ranges and vice versa (6.2.2., 6.2.5). For cold-water corals experimental and observational findings suggest some resilience to OA (*low confidence*, 6.2.5). The reduction of salinity associated with freshwater input results in lower alkalinity, exacerbates OA and may thereby contribute to constrain the distribution of sensitive species further in estuaries or brackish oceans like the Baltic or in freshening polar oceans (6.1.1., *low confidence*, Miller *et al.*, 2009; Denman *et al.*, 2011). It remains to be explored whether organisms in ecosystems characterized by permanently elevated or fluctuating CO_2 levels (6.1.1), like upwelling areas and OMZs, have evolved a higher resistance to increased CO_2 levels than elsewhere.

6.3.4.4. Conclusions

Overall, *confidence* is *high* that ocean acidification will affect marine ecosystems for centuries. The severity of effects will depend on RCP emission scenarios followed and maximum CO_2 levels reached, but the severity of effects cannot be directly related to any scenario at present. Detection, attribution and projection of OA effects at ecosystem level, including large scale ecosystem functions and biodiversity, are limited by the nature and duration of existing laboratory, mesocosm and field studies. The diversity of responses observed in organisms (6.2.5) and communities remain qualitative at best and are fraught with *low confidence*. Thresholds beyond which effects will set in can be quantified only with *low confidence*. While lab and mesocosm experiments provide evidence for differential effects on interacting species, further studies need to explore how OA may change the composition of communities, impact food webs and affect higher trophic levels. Consequences for fitness, abundance, distribution and species interactions cannot be projected to date. Accordingly, *confidence* is *low* that OA will cause a stimulation of phytoplankton primary production overall in the oceans and is *low* to *medium* for the net stimulation of nitrogen fixation by phytoplankton. C*onfidence* is *medium* that CO_2 accumulation associated with OA will stimulate primary production in non-calcifying macrophytes and thus benefit their abundance, but discriminate against calcifying algae. *Confidence* is *low* to *medium* that differential sensitivities and associated shifts in performance and distribution will change the quality of predator prey relationships and competitive interactions.

6.3.5. Concurrent Community Responses to Multiple Drivers

Various environmental drivers will change concurrently, eliciting a variety of responses ranging from organismal physiology to the areal extent and boundaries of biogeographical regions. This complexity is often confounding the clear attribution of biological trends to individual or anthropogenic drivers (Parmesan *et al.*, 2011). Alterations in marine ecosystems worldwide (Pauly *et al.*, 1998; Oguz, 2007; Österblom *et al.*, 2007) have often been linked to human and especially fishing activities (Frank *et al.*, 2005; deYoung *et al.*, 2008; Jackson, 2008; Casini *et al.*, 2009), however, they may involve a contribution of climate variability and change. Table 6-9 provides an attempt to categorize these multiple influences on marine biota – including temperature, CO_2, dissolved O_2 and nutrient concentrations - (e.g. Sarmiento *et al.*, 1998; Matear and Hirst, 1999; Boyd and Doney, 2002; Ekau *et al.*, 2010) – or other human interventions, including the introduction of non-native species, overfishing, chemical pollution, or habitat destruction (Carlton, 2000). The drivers can act individually, or interactively with either synergistic (i.e. amplification of) or antagonistic (i.e. diminution of) effects. A recent metaanalysis of 171 experimental studies that exposed marine systems to two or more drivers identified cumulative effects that were either additive (26%), synergistic (36%), or antagonistic (38%) (Crain *et al*., 2008). Effects range from direct impacts of ocean warming on organismal physiology (Pörtner and Knust, 2007), to ocean acidification acting together with either warming,

hypoxia or salinity changes leading to complex large-scale synergistic influences such as on both coccolithophore calcite production and abundances under warming and elevated CO_2 (Feng *et al.*, 2009, Table 6-9).

Present day OA is developing more than 10 times faster than in comparable paleo-events (6.1.2; Ridgwell and Schmidt, 2010), when similar to today, OA coincided with warming and enhanced stratification of the oceans and, consequently, a stronger deoxygenation of deeper waters (Thomas, 2007; Gattuso *et al.*, 2011), making it again difficult to attribute changes to OA (6.3.5). Furthermore, ocean physicochemical conditions prior to each of those paleo-events were very different from the present situation. Nonetheless, the PETM (55 Ma) provides useful comparative information for plankton and benthic foraminifera (6.1.2). Insight into the fate of animals shows some of them are affected, however, causalities and patterns have not been clearly identified (*low confidence*). The Permian Triassic (251 Ma) displayed similar patterns of sensitivity across animal phyla as projected for marine animal phyla today (6.1.2., 6.2.5).

[INSERT TABLE 6-9 HERE
TABLE 6-9: Potential interactions between modes of anthropogenic forcing (environmental; harvesting; or complex; considering scales and velocity of change, frequency, intensity, and variability of events) on different levels of biological organisation. These interactions, from simple to complex, are illustrated with published illustrative examples, ranging from physiological studies (Pörtner and Knust, 2007) to modelling studies such as Griffith *et al.* (2011). E, O, and M denote studies using manipulation Experiments (lab or field), Observations, or Modelling approaches, respectively; note that there is an insufficient number of studies to assign a level of confidence to each of these findings "???" defines the bounds on our understanding of the relationship between forcing and its effect on organisational level.]

Many microbes in the surface ocean are simultaneously limited by, for example, nitrate and phosphate, cobalt and iron (Saito *et al.*, 2002; Bertrand *et al.*, 2007), or iron and irradiance (Boyd *et al.*, 2010; 6.2.2). Both synergistic and antagonistic effects of multiple drivers on upper ocean biota have been observed in shipboard and/or laboratory manipulation experiments (Boyd *et al.*, 2010), which may result from the interplay of such co-limitations with multiple factors changing (Folt *et al.*, 1999; Gruber, 2011). In phytoplankton warming under high CO_2, photo-physiological rates of the cyanobacterium *Synechococcus* were synergistically enhanced, whereas the cyanobacterial group *Prochlorococcus* showed no change (Fu *et al.*, 2007). Such differences may result in floristic phytoplankton shifts with the potential to restructure predator-prey interactions (Table 6-9). For example, the magnitude of CO_2 effects on growth, fixation rates or elemental ratios within single species is often strongly modulated by nutrient availability and light conditions (e.g. Zondervan *et al.*, 2002; Sciandra *et al.*, 2003; Fu *et al.*, 2007; Kranz *et al.*, 2010). As the co-limiting environmental factors vary between different groups, such as nitrogen fixers (e.g. Hutchins *et al.*, 2007; Kranz *et al.*, 2010), coccolithophores (e.g. Feng *et al.*, 2009, Rokitta and Rost, 2012) versus diatoms (Boyd *et al.*, 2010), the predictive capacity of climate change effects is currently limited (Boyd *et al.*, 2010). At ocean basin scale, modeling experiments of interactive environmental effects provide the most reliable projections to date. They mainly point to synergistic effects, such as those of reduced pH, hypoxia and/or warming. Projected OA effects involve altering the sinking particles (C:N ratio and/or reduced calcite content and slower sinking) and a knock-on effect on water column O_2 demand (Gruber, 2011).

For complex organisms like animals or higher plants, climate change also involves synergisms and antagonisms of both abiotic and biotic factors. As increasingly understood in animals, the main drivers mediating climate impacts on ocean ecosystems are intertwined in their impact on organisms and, conversely, are shaped by the responses of biota. Warming reduces O_2 solubility and enhances biotic O_2 demand. The critical oxygen threshold P_c rises in animals indicating reduced hypoxia tolerance (Nilsson *et al.*, 2010; Vaquer-Sunyer and Duarte, 2011). The consumption of O_2 generates hypoxia, introduces CO_2 and causes acidification (Millero, 1995; Brewer and Peltzer, 2009). O_2 deficiency, in turn narrows the thermal range of animals (Pörtner *et al.*, 2005). As a consequence, midwater mesopelagic and demersal fish stocks may decline with expanding hypoxia and loss of habitat in the North Pacific or California Current Ecosystem and throughout the Southern California Bight at rates much quicker than anticipated due to warming (Koslow *et al.*, 2011; McClatchie *et al.*, 2010)..Similarly, CO_2 constrains thermal windows, causing biogeographical range contractions, changing phenologies and changes in relative performance, affecting predator-prey relationships or competitive species interactions (Figure 6-7C). Knowledge largely builds on laboratory work (6.2.4.-5) leading to the projection that the narrowing of the thermal niche by CO_2 and hypoxia will

cause shrinking biogeographical ranges, (Figure 6-7). Conversely, CO_2 sensitivity is enhanced at thermal extremes. In OMZs, CO_2 has a protective effect and sustains time-limited hypoxia tolerance since it facilitates the reduction in energy demand (Reipschläger *et al*., 1997; Pörtner *et al.*, 1998, 2000). Regions influenced by river runoff and experiencing increased precipitation will see a shift from marine to more brackish and even freshwater species, with unclear consequences for the impacts of other drivers. Reductions in primary production reduce resilience at higher trophic levels causing changes in species interactions (Kirby and Beaugrand, 2009; Stock *et al.*, 2011; 6.3.5). The introduction of non-indigenous species, when supported by climate-induced shifts in competitive interactions, may provoke the displacement of ecotypes and shifts in ecosystem functioning, for example, in the Mediterranean Sea (Occhipinti-Ambrogi, 2007; Coll *et al.*, 2010; Costello *et al.*, 2010). A mechanistic framework, such as oxygen and capacity limited thermal tolerance (OCLTT) in animals (Pörtner, 2010, 2012), would support a comprehensive understanding of the integrated effects of multiple drivers on organisms and ecosystems.

At the level of animal communities synergistic or antagonistic effects of various drivers remain largely unexplored. Adaptation to climate zones and variability may co-define species sensitivities (6.2.2., 6.2.5). This includes the role of CO_2 and temperature in warm water coral reefs (6.2.2., 6.2.5). It also includes the role of light versus temperature in shaping seasonalities and species interactions, for example during latitudinal distribution shifts (Bradshaw and Holzapfel, 2010). In the Pacific, the complex interaction of climate variability (due to ENSO), warming ocean surface, shallowing mixed layer depth in relation to the positioning of the warm pool and its convergence with the Pacific Equatorial Divergence Province, linked to the associated aggregation of macrozooplankton and micronekton, may have contributed to the net eastward shift of skipjack tuna between 1985 and 2010 (Lehodey *et al*., 2011).

Complex interactions also characterize eastern boundary upwelling systems which cover 1% of the ocean surface area but account for about 11% of new production (Monteiro, 2010) and half of the world's commercial fish catches (Merrett and Haedrich, 1997). Understanding whether upwelling and climate change will impact resident biota in a synergistic or antagonistic manner is highly relevant for projections of climate impacts on these areas and their services to human society. Upwelling in a changing climate will have both beneficial and detrimental effects. Upwelling of hypoxic and acidified waters will combine with anthropogenic impact and negatively affect marine biota and ecosystem structure of the upper ocean. However, under projected scenarios of reduced upward supply of nutrients due to stratification (Steinacher *et al.*, 2010), upwelling of both nutrients and trace elements may become increasingly important in maintaining upper ocean nutrient and trace metal inventories. Upwelling areas may also increase nutrient content and productivity under enhanced stratification (Rykaczewski and Dunne, 2010). Upwelled and partially denitrified waters contain excess phosphate that may select for N_2 fixation (Deutsch *et al*., 2007; Deutsch and Weber, 2012), but field observations of N_2 fixation in these regions have not supported these predictions (Fernandez *et al*., 2011; Franz *et al*., 2012). The role of this process in global primary production thus needs to be validated (*low confidence*).

Observational (Schwing and Mendelssohn, 1997; Demarcq, 2009) and modeling evidence (Bograd and Lynn, 2003; Snyder *et al.*, 2003; Di Lorenzo *et al.*, 2005) indicates increased alongshore upwelling favored by winds over recent decades, as a putative consequence of warming (Bakun, 1990). Some spatial heterogeneity exists as in some areas like the Iberian peninsula, decreased upwelling occurs (Lemos and Sansó, 2006). The productivity of most wind driven upwelling systems has increased during the last decade (Demarcq, 2009). Habitat compression may initially even enhance fisheries catches in coastal regions or tropical OMZs. Upwelling regions sit closer to thresholds for hypoxia and acidification effects where ecosystem states may shift. For example, changes in sea surface temperature in the California Current System have been linked to latitudinal shifts in faunal composition and fisheries regimes and habitat expansion or contraction for the distribution of some species like sardine and anchovies or Humbold squid (Lluch-Belda *et al.*, 2001; Lluch-Belda *et al.*, 2003; Checkley *et al*., 2009b; Zwolinski and Demer, 2012; 6.3.3), or recruitment changes of near-shore invertebrates. Changing the duration, frequency and magnitude of the upwelling were relevant to explain the dynamic of benthos (Iles *et al*., 2012) and fisheries (Rykaczewski and Checkley, 2008). The effect of climate change on upwelling systems through stronger winds, altered current patterns or enhanced OA remains debated (Chavez and Messie, 2009).

6.3.6. Biotic Interactions

Impacts of climate change on marine populations (6.3.1.-5) underlie alterations of species interactions, ecosystems structure and functioning, including changes in trophodynamics and the physical and chemical characteristics of biogenic habitats. Changes in climate and NPP can affect the entire food web structure (Figure 6-13; Utne-Palm *et al.*, 2010) and the different components of the ecosystems, including fish resources (Parsons and Lear, 2001; Brown *et al.*, 2010; Cheung *et al*., 2010), by altering predation, competition, and food availability. Climate-driven shifts in dominant trophic pathways have been documented for a variety of marine ecosystems (Kirby and Beaugrand, 2009; Moloney *et al.*, 2011), in some cases, these are irreversible (Jarre and Shannon, 2010). As a consequence of warming, consumer control of food web structure may result because respiration of heterotrophic zooplankton and bacteria responds more strongly to changing temperature than photosynthesis of autotrophic phytoplankton (Connor *et al*., 2009; Gross, 2009). Community reassembly under climate change might involve the mixing of ecosystems with strongly altered trophodynamics (Cury *et al.*, 2003; Parmesan and Matthews, 2005; Luczak *et al.*, 2011). Trophic amplification may then drive an ecosystem towards a new dynamic regime.

[INSERT FIGURE 6-13 HERE
Figure 6-13: Schematic diagram of a marine foodweb and the expected responses to climate change including ocean acidification. A coupled pelagic and benthic foodweb is typically structured by the body size spectrum of species. Warming, hypoxia and ocean acidification lead to biogeographical shifts, changes in species abundance and in the dynamics of trophic interactions. The foodweb resulting from climate change includes reductions in the body size of organisms, changes in species composition and the resulting reconfiguration of trophic linkages. Fishing generally removes large-bodied and vulnerable species and truncates the body size spectrum of the community. As a result, the detection and attribution of foodweb responses to climate change are strongly confounded by fishing effects. The arrows represent species interactions (e.g. between predator and prey or competition for food or space). Broken lines (boxes and arrows) indicate the loss of populations and trophic linkages due to climate change.]

There is therefore *high confidence* that climate change will affect biodiversity, with specific differences between biomes and latitudes (Figure 6-1; 6.5., Sala and Knowlton, 2006; Cheung *et al.*, 2009) and cause community reassembly in time and space (Parmesan and Matthews, 2005; Parmesan *et al*., 2011). Species may gain predominance and abundance (Occhipinti-Ambrogi, 2007) from fitness benefits due to temperature change (6.2.2) while others become less competitive or easier prey. Shifted geographical distribution of marine species, e.g. to higher latitude or deeper water cause changes in community composition and interactions (Hawkins *et al*., 2009; Simpson *et al*., 2011b; Harley, 2011; Hazen et al., 2012). Reassembly of species might involve the mixing of ecosystems and strongly alter their food web functioning (Murphy, 1995; Anderson and Piatt, 1999; Moloney *et al.*, 2011) through trophic cascades (Cury *et al.*, 2003; Parmesan and Matthews, 2005; Luczak *et al.*, 2011).

Many impacts of climate change on food webs resemble those caused by other factors such as fishing, pollution, eutrophication, hypoxia (6.3.3) and habitat change (Brander, 2007), suggesting that unambiguous attribution to climate remains difficult (Parmesan *et al*., 2011). Conversely, the anthropogenic factors can affect ecosystem responses to climate change. Fishing truncates the age and size structure of populations making them more dependent on annual recruitment (Perry *et al.*, 2010; Genner *et al*., 2010; Botsford *et al.*, 2011) and reducing their ability to buffer environmental fluctuations (Planque *et al.*, 2010). Both adult and larval fishes show greater variability in abundance in exploited than unexploited populations (Hsieh *et al.*, 2006; Hsieh *et al.*, 2008). Both warming (e.g. Molinero *et al*., 2005) and acidification (Richardson and Gibbons, 2008), or removal of top or competing predators (e.g. Richardson *et al*., 2009; Condon *et al*., 2012) are discussed as reasons causing large fluctuations in gelatinous plankton (e.g. jellyfish) populations. Trans-Arctic interchange of species that repeatedly happened in warm periods (Dodson *et al*., 2007) may occur again, facilitated by enhanced trans-Arctic shipping.

Analyzing impacts on key species provides insight into how individual components of a food web will respond to perturbations. However, projections of future states must include the complex food webs interactions that influence the species and system level responses, which affect stability and resilience of the overall ecosystem to change (Martinez *et al.*, 2006; Neutel *et al.*, 2007; Dunne and Williams, 2009; Romanuk *et al.*, 2009). There is no single approach currently available for any oceanic system that includes the complex links within and among ecosystems, biogeochemistry and climate that are needed to do projections of future states of marine food webs with the certainty

needed for management and science (Fulton, 2011; Moloney *et al.*, 2011), and thus there is *low confidence* in the quantitative projections of such changes (for further discussion see 6.5).

Impacts of climate change on species providing structural habitat and support to high biodiversity (i.e. ecosystem engineers) can also result in profound ecosystem alterations. Tropical corals are known to respond to ocean warming and acidification with a variety of potentially deleterious effects on the structure of the biogenic habitat, from increased coral bleaching and impeded calcification rates to increased rates of coral disease (6.2.5; Veron *et al.*, 2009; Veron, 2011). For other benthic ecosystem engineers such as tropical calcified algae, bryozoans, sponges, and tube-forming serpulid worms (Wood, 1999), deep-water or cold-water corals or sponges, the knowledge on climate impacts is much less. However, they rely on productivity in surface waters, making them vulnerable to any alteration in local productivity patterns and food flux associated with climate change. In conclusion, there is *high confidence* that severe stress as projected from increased temperature, hypoxia and ocean acidification will cause reduced performance and increasing mortality in ecosystem engineers. As the number of available studies is scarce, projections of any more specific climate change effects come with *medium* to *low confidence*.

6.3.7. Summary and Conclusions

Except for the attribution of detected climate change effects to temperature, only a few cases allow clear attribution to another driver (6.6). *Robust evidence* from various ocean regions demonstrates with *high agreement and confidence* that temperature governs the geography, diversity, development, reproduction, behavior and phenology of marine organisms as well as the composition of communities and the seasonal timing of relevant processes (phenology). Accordingly, hydro-climatic variability, with a contributing role of the warming trend, causes large-scale changes in the biogeography, abundance and community composition and structure of marine species (*very high confidence*, 6.2.2.-5., 6.3.2). With *medium evidence* and *agreement*, changes in community composition are associated with reduced body body size (6.2.5) and increased diversity in some groups. Individual examples show, with *high confidence*, the specialization of animal species on regional climate regimes and, conversely, their sensitivity to change. Due to differential species responses to temperature, species interactions across trophic levels can be modified through trophic amplification (*medium* to *high confidence*).

Expansion of OMZs in response to climate leads to community shifts which are clearly attributable to exacerbating hypoxia (*high confidence*). Effects of a progressive decline in O_2 levels and gradual effects on communities have been insufficiently explored. In contrast to effects of temperature and extreme hypoxia, very few ecosystem level changes were attributed to anthropogenic or local ocean acidification trends (shell thinning in planktonic foraminifera, local pH dynamics causing species replacements, *medium confidence*). Otherwise, concomitant trends of warming, O_2 depletion, OA and other drivers prevent clear attribution. With *low evidence*, *medium agreement* and thus *medium confidence* community reassembly and ecosystem mixing may lead to new ecosystem states through trophic amplification (*low confidence*). With *limited evidence*, but *high agreement* and thus *medium confidence* climate change can strongly interact with top down human interferences like fisheries or other forms of harvesting which then accelerate such changes. Non-linearities that can operate within an ecosystem make the understanding and projection of marine ecosystem trajectories under climate warming more difficult.

6.4. Human Activities in Marine Ecosystems: Adaptation Benefits and Threats

6.4.1. Ecosystem Services

Human societies benefit from resources and processes supplied by natural ecosystems, collectively called ecosystem services (e.g. WGII Ch. 5). These are products such as food, fuel and biochemical resources, climate regulation and biogeochemical processes such as CO_2 uptake and carbon storage and water purification, cultural services like recreational and spiritual opportunities or aesthetic enjoyment, and functions supporting all other ecosystem services, such as nutrient cycling, photosynthesis and habitat creation. Most components of the marine environment contribute to more than one major category of ecosystem service: for example, ocean primary productivity is classified as a supporting service, but it affects provisioning services via fisheries and mineral extraction, regulating

services via the global carbon cycle and climate regulation, and cultural services via the enjoyment of a healthy ecosystem.

Attributing and forecasting possible climate-change-mediated changes in marine ecosystem services and assessing their effects on human communities is challenging. This is due to the lack of long-term time-series data, the confounding effects from human activities, the multiple and sometimes overlapping roles of marine ecosystem components in contributing to human well-being, and the difficulty of measuring and assessing the services themselves in ways that are comparable among ecosystem service categories. Some of the challenges are also related to the difficulty of projecting how human communities will adapt to changing marine ecosystem benefits.

6.4.1.1. Food from the Sea

Fisheries provide over 1.5 billion people with almost 20 % of their average per capita intake of animal protein. This value ranges up to over 90% in some regions (Bell *et al.*, 2009; Garcia and Rosenberg, 2010). Total World marine capture fisheries catches stabilized in the mid-1990s at between 75 and 85 million tonnes (FAO, 2010). Marine aquaculture contributes over 63 million tons per year to seafood production, mostly concentrated in coastal areas and comprising primarily molluscs and crustaceans. The growth of this industry has decelerated, but is still considered to be a development opportunity and a strong need in regions such as Africa and Latin America (WGII Ch. 7.4.2.2).

Experience based on other anthropogenic impacts on marine systems, indicates with *high confidence*, that shifts in ecosystems and fisheries production will create significant sustainability and management challenges, particularly amongst countries with fewer resources and adaptive capacity (Allison *et al.*, 2009; Worm *et al.*, 2009; Cooley *et al*., 2012). Fish stock migrations due to warming (6.3.2) have resulted in shifting composition of fisheries catches (Pinsky and Fogarty, 2012; Cheung *et al*., subm) and may result in shifting stock distribution (Sebatés *et al*., 2006) with consequent changes in accessibility and fishing operations costs, straddling economic zones, perturbing international fishery agreements and causing excessive exploitation (Hannesson, 2007; Sumaila *et al*., 2011). Warming may have beneficial effects on fisheries productivity in some regions, such as the North Atlantic because of the poleward distribution shift of exploited species and changes in primary productivity (Arnason, 2007; Stenevik and Sundby, 2007; Cheung *et al*., 2010), or for some Pacific Islands due to eastward redistribution of tuna stocks (Lehodey, 2000; Lehodey *et al.*, 2010, 2011). Invertebrate fisheries and aquaculture appear most vulnerable to the impacts of OA (Barton *et al*., 2012).

The potential interactions between warming, OA and other human impacts such as overfishing may exacerbate the impacts on a wide range of ocean processes and services, including marine fisheries (Table 6-9), For example, over-exploitation of fish stocks and the altered demography (Planque *et al.*, 2010; Petitgas *et al.*, 2006) may reduce the capacity of fish populations to buffer changes in climate variability (Fromentin and Fonteneau, 2001; Hilborn *et al.*, 2003; Ottersen *et al.*, 2006), leading to unpredictable non-linear outcomes (WGII Ch. 7.5.1.1.3).

Nations that depend strongly on fisheries and have limited adaptive capacities (Allison *et al.*, 2009), including many low-latitude and small island nations, are particularly vulnerable to climate change and OA impacts (Allison *et al.*, 2009). This will be exacerbated if increases in the frequency and severity of extreme events (e.g. floods or storms) effect citizens by damaging infrastructure, homes, health, livelihoods or non-marine food security (Kovats *et al.*, 2003; Rosegrant and Cline, 2003; Adger *et al.*, 2005; Haines *et al.*, 2006). Economic losses in landed catch value and the costs of adapting fisheries resulting from a 2°C global temperature increase by 2050 have been estimated at US$ 10-31 billion globally, with countries in East Asia and the Pacific being the most affected (Sumaila and Cheung, 2010; Sumaila *et al.*, 2011). Globally, the impacts will partially depend on the flexibility and response capacities of food production systems (Elmqvist *et al.*, 2003; Planque *et al.*, 2011a); however, the specific implications for the fishing industry are still poorly known, as *confidence* in future projections of shifts in primary production and knock-on effects through foodwebs and into fisheries is *low* (Brander, 2007; 2009; Planque *et al.*, 2011b; Stock *et al.*, 2011). Management and socioeconomic challenges may also result from increasing stock fluctuations, although modelling exercises illustrate that in general, management issues have a greater impact on biological and economic conditions than climate change is expected to have (Eide and Heen, 2002; Eide, 2007; 2008; Merino *et al.*, 2010).

6.4.1.2. Other Provisioning Services

Opportunities for marine industries may arise or disappear as systems change. For example, reductions in marine biodiversity due to climate change and other anthropogenic stressors (Tittensor *et al.,* 2010), like OA (CBD, 2009) and pollution, might have an overall negative effect on the discovery of genetic resources from marine species useful in the pharmaceutical, aquaculture, agriculture and other industries (Arrieta *et al*., 2010), leading to a loss of option value from marine ecosystems. Climate change increases the demand for marine renewable energy such as winds and wave power, although ecosystem impacts of the respective infrastructure need to be considered (6.4.2).

6.4.1.3. Climate Regulation

Climate regulation refers to the maintenance of the chemical composition of atmosphere and oceans by organisms and chemical as well as physical processes (Beaumont *et al.*, 2007). For 800,000 years prior to 1800, the interplay of biogeochemical processes on land and in the ocean (Sigman and Boyle, 2000) have resulted in relatively stable levels of atmospheric CO_2 level (between 170 and 276 µatm; Siegenthaler *et al.*, 2005; Lüthi *et al.*, 2008). Even over the last millions of years, proxy data suggest maximum CO_2 concentrations of 400 µatm (Pagani *et al.*, 2010; Seki *et al.*, 2010). There is *high confidence* that the effect of climate change on marine biota will alter the magnitude of many, if not all of the regulatory mechanisms in which organisms play a key role, such as the balance between photosynthesis and respiration (Johnson *et al.*, 2010), the biological pump (Volk and Hoffert, 1985; Feely *et al.*, 2008; Falkowski, 1997), the modulation of greenhouse gases with high warming potential such as nitrous oxide (N_2O; Jin and Gruber, 2003; Law, 2008) and other climatically reactive gases such as dimethylsulphide (DMS; Vogt *et al.*, 2008). In the geological past, during the PETM (6.1.2) warming of the global ocean and acidification led to changes in phytoplankton composition and in significant biologically mediated feedbacks. In coastal regions, increases in weathering and the hydrological cycle, and hence in runoff from land, led to eutrophication of shelf regions and increased freshwater runoff (Sluijs and Brinkhuis, 2009), while concomitantly open ocean productivity decreased (Gibbs *et al.*, 2006). At the onset of the PETM decreased carbon isotopic gradients between surface and deep waters are interpreted to be a result of increased stratification, reduced nutrient supply and a less efficient biological pump (Zachos *et al.*, 2003). The benthic foraminiferal fauna suggests that there was no reduction in export production reaching the deep ocean, suggesting better organic carbon preservation due to lower O_2 conditions (Thomas, 2007). There is no evidence for decreased biological carbonate production despite higher atmospheric CO_2 levels during the PETM (Gibbs *et al.*, 2010; 6.1.2). Simulations from coupled ocean-atmospheric carbon cycle and climate models suggest that climate change may decrease global ocean NPP (*low confidence*, 6.5.1). Such changes in NPP are projected to lead to a decrease in the export of biogenic carbon to the deep ocean (Bopp *et al*., 2002; Boyd and Doney, 2002; Hashioka and Yamanaka, 2007), which can have a positive feedback on climate change (WGI Ch. 6). However, the effect of a changing climate on some potentially important feedbacks such as the ocean's biological pump cannot be reliably modelled, as many of the factors controlling the functioning of this pump are poorly understood (Figure 6-6).

6.4.1.4. Natural Hazard Regulation

Natural hazards are generally increasing alongside global warming, with floods and storm surges accounting for over two-thirds of the natural disasters affecting people (SREX). The role of natural ocean structures and organisms in reducing the effects of natural hazards has been undervalued. For example, empirical and modeling studies show that coral reefs contribute to buffering the impact of tsunamis (Fernando *et al.*, 2005; Kunkel *et al.*, 2006; WGII Chs. 5, 30). Field and laboratory experiments and climate models indicate that climate change and OA may slow coral growth by nearly 50% by 2050 (Hoegh-Guldberg *et al.*, 2007; WGII Ch. 5). With *high confidence* anthropogenic climate change including OA that threaten coral reefs will make some islands and coastal areas more vulnerable with respect to tsunamis, as well as storm surges. Similar to coral reefs, wetlands and mangroves provide biologically diverse buffer zones that protect coastal regions from storm surges and wave activity (WGII Ch. 5), The impacts of OA and other climate related changes as well as pollution, deoxygenation and other overlapping stressors

on mangroves or wetlands have not been determined (Cooley *et al*., 2009; Cooley, 2012), and some of these stressors enhance each other's effects (Cai *et al*., 2011; Howarth *et al*., 2011; Feely *et al*. 2010).

6.4.1.5. Cultural Services

Recreation and support of tourism can be economically assessed using indirect valuation methods, but other cultural services relating to spiritual and heritage issues are extremely difficult to assess. Nevertheless, cultural services are often cited by coastal users as primary reasons for preservation. Marine biodiversity is an important component of ecosystem services, including cultural services. In many tropical countries, coral reefs and their enormous biodiversity sustain substantial tourist industries that attract millions of SCUBA divers every year. Annual net benefits from global reef tourism amount to about US$ 9.6 billion (Cesar *et al.*, 2003; Box CC-CR). If degradation of cultural ecosystem services occurs because of climate change, coastal visitors could choose to spend their recreational budgets on terrestrial attractions (UNWTO, 2008). New tourism opportunities could arise as people travel to see disappearing ecosystem types (e.g. Antarctic tourism, Liggett *et al.*, 2011) or newly open previously inhospitable areas as peak seasons shift (e.g. Amelung *et al.*, 2007; Moore, 2010) or as the locations of key attractors shift (e.g. cetaceans, Lambert *et al.*, 2010), but these opportunities seem short-lived and unsustainable.

Many cultures depend on spiritual and aesthetic benefits from marine ecosystems. While environmental change endangers harvests of culturally important species, cultural forces are putting simultaneous pressure on indigenous traditions, raising ethical questions about cultural preservation (e.g. Nuttall, 1998). In less remote coastal communities, aesthetic benefits from marine ecosystems influence economically measurable factors, such as the relationship of better water quality and lower instances of harmful algal blooms with higher real estate prices and shellfish landings (Jin *et al.*, 2008). Impacts of climate change on coastal habitats (Ch. 5) affect the aesthetic benefits of wetlands, sandy beaches and, in general, natural coastlines.

Heritage benefits of preserving marine ecosystems are extremely difficult to assess. Not only is the challenge because some heritage benefits will be enjoyed by future generations who derive economic benefits from a healthy, diverse ecosystem, but it is also because losses are presently being avoided by maintaining a bank of resources that could be tapped if needed. For example, the research and conservation value of coral reef biodiversity and its non-use value are estimated together at US$ 5.5 billion annually (Cesar *et al.*, 2003). Any biodiversity loss or pollution of marine ecosystems would decrease the benefits associated with the "insurance policy" of having untapped resources and those associated with the legacy of offering healthy systems to future generations. As with spiritual and aesthetic benefits, maintaining heritage benefits poses challenges for managers who have to consider present-day issues of equity and ethics as well as multigenerational (and possibly multi-cultural) ethical questions.

6.4.1.6. Supporting Services

These services form the foundation of all other ecosystem services. Identifying all supporting services in the marine environment is virtually impossible, as they are so diverse in nature and scales. However, potential changes in marine ecosystems due to climate change and OA can highlight the role of organisms and processes that are especially important in providing supporting services. For example, damage to calcifying algae and corals will reduce habitat for other marine species (6.3.5) and the biodiversity they sustain, the cultural and leisure values of these landscapes and their climate regulation capacity. The provision of open waterways for shipping is a specific supporting service that is expected to change in measurable ways in the next several decades (WGII Ch. 30.6.3.3). Reductions in sea ice in the Arctic may allow new trade passages such as the North West Passage to be established (Wilson *et al.*, 2004; Granier *et al.*, 2006), thereby raising the possibility of economically viable trans-Arctic shipping, as well as increasing access to regional resources supporting natural resource extraction and tourism. Accompanying the positive aspects of this development are negative consequences as well, such as increasing emission of greenhouse gases and other pollutants (Lauer *et al.*, 2009; Corbett *et al.*, 2010), and more potential for invasion of non-indigenous species due to hulls and ballast waters (Lewis *et al.*, 2004).

6.4.1.7. Conclusions

Human societies benefit from and depend on ecosystem services, including the provisioning of food and other goods, climate and natural hazards regulation, cultural and supporting services (*high confidence*). Attributing and projecting their climate-change-mediated shifts remains a challenge, partly because of the intrinsic difficulties of assessing these services, lack of long time-series data and confounding human impacts. However, available evidence from empirical and modeling studies provides *high confidence* that climate change impacts marine ecosystems, leading to changes in provision, regulation and supportive services, while there is *limited evidence* and *medium agreement* that climate change affect cultural services. Food production from the sea is already facing diverse stressors, such as overfishing and habitat degradation, which are expected, with *high confidence*, to interact with climate change phenomena, including temperature rise (6.3.2), ocean deoxygenation (6.3.3), and ocean acidification (6.3.4), causing significantly negative effects in particular to developing nations in tropical regions. The more northerly (and developed) nations may benefit from climate change, at least initially. There is *medium evidence* and *agreement* that climate change is affecting capture fisheries, although projections of such impacts into the future have *low confidence* partly because of the *low confidence* in marine primary production (6.5). Based on evidence from the geological past (*robust evidence*) and the present data (*limited evidence*), there is *high agreement* and *confidence* that marine ecosystems regulate climate through mechanisms such as the biological pump, the balance between photosynthesis and respiration and modulation of greenhouse gases. There is *high confidence* that the effect of climate change on biota will alter the magnitude of many, if not all of these processes. Projections on the direction and magnitude of specific biotic feedbacks to climate change are presently at an early stage of development and have l*ow confidence*.

6.4.2 Management-Related Adaptations and Risks

6.4.2.1. Ecosystem Management

Biophysical and socio-economic effects of climate change will pose new questions and elicit new strategies in the already highly demanding enterprise of managing ocean resources (Eide and Heen, 2002; Eide, 2007). There is *high confidence* that a changing climate will have both positive and negative socio-economic and geopolitical consequences affecting the future management of ocean resources (6.4.1). Ecosystem-based management (EBM), or the ecosystem approach (EA), is already being increasingly adopted globally (FAO, 2003) to deal with the multitude of human pressures on marine ecosystems (Sherman *et al.*, 2005; Hoel, 2009). Extended EBM would include climate-driven changes, as well as new human activities, as the many different drivers will interact and confound each other (Planque *et al.*, 2010; Eero *et al.*, 2011). Such an extension and integration (Miller *et al.*, 2010) is based on *high confidence* that the effects of different human activities will undermine resilience to other, including climate impacts or the effectiveness of mitigation and adaptation measures, by increasing variability (and reducing predictability), and limiting scope for adaptation (e.g. Hughes, 2004; Eero *et al.*, 2011; Sissener and Bjorndal, 2005). Thus, managing ecosystems under climate change requires increasing the resilience of the ecosystems and adaptive capacity of management systems through reducing other human perturbations (e.g. overfishing) (Brander, 2008).

Climate change effects cannot be completely mitigated by reducing the impacts from other non-climate drivers, highlighting the need for adaptive management accompanied by the detection and attribution of climate change impacts. Increased variability of ecosystems and the low predictability of some biological responses under climate change undermine the effectiveness of existing ocean management and conservation measures. Particularly, climate change may contribute to large-scale ecosystem regime shifts. Although there is potential for the early detection of ecosystem shifts through analysis of time-series of environmental and biological data (Carpenter and Brock, 2006; deYoung *et al*., 2008), long-term forecast of a regime shift is limited by an insufficient number of observations and limited quantitative understanding of regime shifts. In addition, biogeographical shifts under climate change (*high confidence*, 6.5) present direct challenges to the objectives of spatial management, which has become a fundamental part of EBM (Douvere, 2008). This does not invalidate the use of spatial management, but it does mean that “fixed in law forever” site attached zoning to protect specific species may need to become more flexible to ensure that the original objectives are maintained as species move or community structure shifts (Soto, 2001; Hawkins, 2012).

6.4.2.2. Geoengineering Approaches

Recent comparative assessments suggest that the main geoengineering approaches involving the oceans may have large associated environmental footprints (Boyd, 2009; Russell *et al.*, 2012). These geoengineering approaches include, Carbon Dioxide Reduction (CDR), Solar radiation management (SRM) and other similar approaches (see Table 6-10; IPCC, 2012). CDR removes atmospheric CO_2 by directly sequestrating it into the ocean (Boyd, 2008; Shepherd *et al*., 2009). SRM relies on causing increased albedo, for example via stratospheric sulphur injection (Crutzen, 2006). SRM may reduce warming and cause changes in precipitation and their impacts on ecosystems. The use of SRM is fraught with the shortcoming that CO_2 release and OA are left unabated unless SRM is combined with CO_2 emission reductions or CO_2 removal. Also, the sudden cessation of SRM after its implementation would exacerbate the climate effects on ecosystems (Russell *et al*., 2012).

[INSERT TABLE 6-10 HERE.
Table 6-10: Challenges for the oceans that will arise from the employment of a range of geoengineering methods (SRM, solar radiation management, CDR, carbon dioxide removal).]

CDR techniques involving the ocean include fertilization by nutrient addition, binding of CO_2 and build-up of DIC by the addition of alkalinity and direct CO_2 injection into the deep ocean (Table 6-10; Williamson *et al*., 2012), all of which have potentially negative consequences for marine ecosystems. Ocean fertilization through the addition of iron to high-nutrient low-chlorophyll (HNLC) oceanic waters would increase the net export of organic material to the deep ocean and its coupled decomposition, thereby causing deep water CO_2 accumulation. A further issue with fertilization is that it would affect all major biogeochemical cycles of the ocean with as yet unclear side effects, including the formation of methane (CH_4) and N_2O (Law, 2008) or the stimulation of harmful algal blooms (Trick *et al*., 2010; Silver *et al*., 2010). Enhanced NPP by ocean fertilization would add more carbon to the base of food webs (de Baar *et al.*, 2005) and stimulate growth of, e.g. deep-sea benthos (Wolff *et al*., 2011). The increase in organic material in an ocean region (through fertilization or storage of biomass) may cause enhanced O_2 demand and deep-water O_2 depletion (Sarmiento *et al.*, 2010; Table 6-10), which can add to the increase in level and extent of hypoxia and, consequently, their impacts on marine ecosystems (6.2.2., 6.2.5., 6.3.3., 6.3.5). The synergistic effects of hypoxia and hypercapnia will further exacerbate the biological impacts (*high confidence*). The addition of alkalinity e.g. calcium oxide, to neutralize the increased acidifying water would involve large-scale mining and their consequences on land. The biological effects of enhancing Ca^{2+} ions and dissolved inorganic carbon during alkalization remain insufficiently explored. Direct injection of CO_2 into the ocean and, especially, its localized disposal (deep-sea lake option) causes local effects of CO_2 and associated acidification on deep-sea organisms (6.2.2., 6.2.5., 6.3.4., *high confidence*, Caldeira *et al.*, 2005) but appear less harmful on larger scales than the combined impacts of hypoxia and acidification caused by ocean fertilization (Pörtner *et al.*, 2005; 6.3.3).

6.4.2.3. Health Issues

Human health may be directly impacted by harmful algal blooms (HABs) or the spreading or redistribution of disease vectors. HABs are mostly a natural phenomenon (Dale *et al.*, 2006), although biogeographical range extensions caused by regional climate change may have increased the regional presence of HABs (Edwards *et al.*, 2006), posing a major threat to the functioning of near-shore ecosystems. Range expansion of HABs can be related to warming, nutrient fluctuations in upwelling areas, eutrophication in coastal areas and enhanced surface stratification, which all have species-specific responses e.g. causing shifts in seasonal cycles and blooms (Johns *et al.*, 2001) or increased HABs as in the North Sea (Smyth *et al.*, 2004; Edwards *et al.*, 2006). For nearshore waters, analysis of both planktonic time-series archives and sediment cores, which record HAB cysts, have revealed few examples of strong linkages between altered HABS and climate change (Dale *et al.*, 2006). OA may exacerbate the toxicity of species contributing to HABs in coastal oceans under nutrient limited conditions (Tatters *et al*., 2012; Sun *et al*., 2011). Overall, there is *limited evidence, low agreement* and *low confidence* in how global climate change will impact HABs. However, because of the potential impacts of HABs on human health and different ecosystem services, adaptation measures of human societies have been suggested to include appropriate monitoring of increases and range extensions of biotoxin problems (Hallegraeff, 2010).

Climate change may drive changes in the abundance or distribution of pathogen species (Hoegh-Guldberg and Bruno, 2010), although attribution to climate change is confounded by climate variability and non-climate drivers (Lafferty 2009; Dobson, 2009). Specifically, the distribution of the waterborne bacterium, *Vibrio cholera*, the causative agent of cholera, may be supported by climate change. *V. cholera* is a marine bacterium that associates with marine organisms, especially chitinized zooplankton (Vezzulli *et al.*, 2010). Climate variability can affect the marine host species, and consequently the levels of the pathogen in coastal marine environments. In regions where cholera is endemic (e.g, India, Bangladesh, Latin America), cholera outbreak is correlated with elevated sea water temperature and zooplankton blooms (Lobitz *et al.*, 2000; Lipp *et al.*, 2002). Based on an 18-year climate record for Bangladesh, Pascual *et al.* (2000) reported an interannual component of cholera outbreaks at the dominant frequency of El Niño-Southern Oscillation (ENSO), and the recent reappearance of cholera in Peru has also been linked to the intense 1991-1992 El Niño event (Lipp *et al.*, 2002). There is evidence that an increase in sustained maximum surface temperatures of the temperate Baltic Sea is related to an increase in reported *Vibrio* infections (Baker-Austin *et al*., 2013). Continued warming of coastal habitats, excessive nutrient loading leading to phytoplankton and zooplankton blooms, sea water inundation due to sea level rise and ocean warming in temperate zones are all projected to exacerbate the expansion and threat of cholera (*limited evidence, low confidence*).

The risk of ciguatera-poisoning from seafood consumption is also related to ocean warming. Ciguatera-poisoning may occur when people consume fish, mainly from tropical reefs, that has bioaccumulated ciguatoxins due to exposure to the epiphytic dinoflagellate *Gambier discus* sp. Based on historical records, significant correlations have been reported between fish poisoning and sea surface temperature in South Pacific nations (Hales *et al*., 1999); however, such relationship is non-linear and dependent on the specific thermal window of the specific dinoflagellate (Llewellyn, 2010). Thus any scenario of an increase in ciguatera-poisoning under ocean warming based on linear extrapolations of observed phenomena has *low confidence*.

6.4.2.4. Conclusions

There is *high confidence* that the already challenging task of managing the oceans, their resources and linkages to human societies, will face new questions and difficulties due to the impacts of climate change on marine ecosystems. Fisheries and ecosystem management in the future might have to deal not only with the traditional sustainability goals, but might also have to increase ecosystems resilience to climate variability and change. Active ocean manipulation strategies to amend climate change may prove detrimental for different aspects of the ecosystems, which highlights the need for further research. There is strong interest in elucidating the potential changes of different human health issues related to direct exposure to toxic organisms and pathogens or to the ingestion of marine organisms that have bioaccumulated toxins. However, there is *limited evidence* and *low confidence* on how harmful algal blooms and the prevalence of pathogens will respond to climate change.

6.5. Future Projections of Climate Change Impacts through Modeling Approaches

A range of models are applied to explore climate change effects on marine biota, from primary productivity through to higher trophic levels, and to test hypotheses about responses of marine species, food webs and ecosystems (Rose *et al.*, 2010; Stock *et al*., 2011; Fulton *et al.*, 2011). Models range from empirical approaches to mechanistic models describing population/species responses and/or trophic interactions in marine ecosystems over a range of temporal and spatial scales (Barange *et al*., 2010; Stock *et al*., 2011). Earth System Models that couple atmosphere and ocean as well as climate and carbon cycles project changes in ocean biogeochemistry under a range of CO_2 emission scenarios (WGI Ch. 6). Models that focus on population and species level responses to environmental changes include population dynamic models, species distribution models and models which explicitly link climate change effects from changes in ocean physical and chemical conditions to the interactions between species at different trophic levels and human activities such as resource extraction and aquaculture (Rose *et al*., 2010). Uncertainty in model projections of changes in marine ecosystems is partly contingent on the level of confidence in climatic and oceanographic projections (6.1.1; WGI). Models are currently useful for developing scenarios of directional changes in net primary productivity, species distributions, community structure and trophic dynamics of marine ecosystems,

and their implications for ecosystem goods and services under climate change. However, quantitative projections from these models have *low confidence* (Rose *et al.,* 2010; Hannah *et al.,* 2010; Stock *et al*., 2011).

6.5.1. Ocean Primary Production

The long-term average of global ocean net primary productivity (i.e., NPP) is projected to change with climate, with large variations in the magnitude, direction and pattern of projected changes because of differences in model structure and parameterization (Figure 6-14). Four global coupled climate-ocean biogeochemical Earth System Models (WGI Ch. 6) projected an increase in NPP at high latitudes as a result of alleviated light and temperature limitations particularly in Northern and Southern Hemisphere 'subpolar gyre' biomes (Steinacher *et al*., 2010). However, the increase is more than offset by decreases in primary productivity in the North Atlantic, the tropics and the permanently stratified oceans at mid-latitude due to the reduced input of macro-nutrients into the euphotic zone. Reduced mixed layer depth and slowed circulation cause a decrease in macronutrient flux (Polovina *et al*., 2011; Figure 6-14). These result in a reduction in global mean NPP by 2 to 13% in 2100 relative to 1860 under a high emission scenario (SRES A2, between RCP6.0 and RCP8.5). This is consistent with projections from a more recent analysis that is based on 10 Earth System Models (Bopp *et al.*, subm). The study shows consistent decreases in global NPP that amount to -8.6 (±7.9), -3.9 (±5.7), -3.6 (±5.7), -2.0 (±4.1)% in the 2090s relative to the 1990s, under the scenarios RCP8.5, RCP6.0, RCP4.5 and RCP2.6, respectively. However, the magnitude of projected changes in global NPP varies widely between models (e.g. from 0 to 20% decrease in NPP globally under RCP 8.5). Main reasons for such variations include differences in parameterizations and assumptions between models. In contrast, earlier model projections show changes in global NPP from a decrease of > 10% (Field *et al.*, 1998; Boyd and Doney, 2002) to a slight increase by up to 8.1% under an intermediate scenario (SRES A1B, similar to RCP6.0) (Sarmiento *et al*., 2004; Schmittner *et al*., 2008). These projections do not consider the potential contribution of primary production derived from atmospheric N_2-fixation in tropical and subtropical regions, favored by increasing stratification and reduced nutrient inputs from mixing, although this burst in N_2-fixation is not sustainable without phosphate (e.g. Moore *et al*., 2009; Boyd *et al*., 2010). This may lead to an underestimation of primary production (Mohr *et al*., 2010; Mulholland *et al*., 2012; Wilson *et al*., 2012), however, the extent of such underestimation is unknown (Luo *et al*., 2012). Also, uncertainties in the accuracy of NPP observations further increase the uncertainty of projections, particularly from empirical models (e.g. Sarmiento *et al*., 2004; see 6.1.3). Furthermore, the potentially incomplete understanding of the effects of multiple drivers such as ocean warming, deoxygenation and acidification on NPP renders future projections uncertain. Changes in NPP have direct and indirect implications for higher tropic level organisms and fisheries (6.2., 6.4., 6.5.2., 6.5.3).

[INSERT FIGURE 6-14 HERE
Figure 6-14: Multi-model mean changes of projected vertically-integrated net primary production (small and large phytoplankton). To indicate consistency in the sign of change, regions are stippled where all four models agree on the sign of change. Changes are annual means under the SRES A2 scenario (between RCP6.0 - 8.5) for the period 2080 to 2099 relative to 1870 to 1889, after Steinacher *et al*. (2010).]

6.5.2. Higher Trophic Levels

Projected future changes in physical and biogeochemical conditions of the ocean are expected to affect the distribution and abundance of marine fishes and invertebrates (Figure 6-15). In the global ocean, driven by projected changes in temperature and other physical and chemical oceanographic factors, latitudinal distributions of 1066 species of exploited marine fishes and invertebrates are projected to shift by a median of around 50 km per decade (range limits) to higher latitudes by 2050 relative to 2000 under the SRES A1B (RCP6.0) scenario (Cheung *et al.,* 2009), Some species are projected to shift towards the equator following a regional temperature gradient (Burrows *et al*., 2011; Cheung *et al.*, 2012a). The rate of range shifts is projected to be three times higher for pelagic than for demersal fishes (Cheung *et al*., 2009), with demersal fishes shifting at a rate of around 25 – 36 km per decade (Cheung *et al.*, 2012a). The expansion of hypoxic waters may, however, have a greater impact on demersal fishes than warming (Koslow et al 2011). As a result of distribution shifts, high latitude regions (the Arctic, Southern Ocean) are projected to have high rates of species invasions. Intermediate latitudes are expected to experience both

invasions and local extinctions. High rates of local extinction are projected for the tropics and semi-enclosed seas (e.g. Mediterranean Sea, Persian Gulf). The global pattern of distribution shifts is generally consistent with regional-scale projections and past observations (e.g. Lenoir *et al*., 2011; Cheung *et al*., 2012b). However, detailed quantitative projections are sensitive to model structure and assumptions (Hare *et al*., 2012; Jones *et al*., 2013). Also, responses of specific populations may differ from average responses at species level (Hazen *et al*., 2012).

[INSERT FIGURE 6-15 HERE
Figure 6-15: Scenarios of climate change effects on the biogeography, biology and fisheries catch potential of marine fishes and invertebrates. (A) Hypothesis of changes in distribution, biology and fisheries catch potential of fish stocks under climate change. (B) Example of a projected rate of shift in distribution range along latitude and depth for 610 exploited demersal fish species from 1991-2010 to 2041 – 2060 under the SRES A2 scenario (Cheung *et al*., 2011; Cheung *et al*., 2012a). (C) Projected change in the maximum body size of 610 species of marine fishes from 2000 to 2050 under the SRES A2 (between RCP6.0 - 8.5) scenario (Cheung *et al.*, 2012a). The white area is not occupied by the sampled species. (D) Example of projections of maximum fisheries catch potential of 1000 species of exploited fishes and invertebrates from 2000 to 2050 under the SRES A1B scenario (redrawn from Cheung *et al*., 2010).]

Available projections suggest high impacts of ocean warming on coral reefs through coral bleaching, although some of the main assumptions in these approaches need to be verified (CC-CR). Coral reefs are projected to undergo long-term degradation by 2020 to 2100 relative to the 2000s under RCP 3, 4.5 and 8.5 or their equivalent. The degree of impact will depend on their adaptability to thermal stress and the interaction of multiple stressors (Hoegh-Guldberg, 1999; Sheppard, 2003; Donner *et al*., 2005; Meissner *et al*., 2012; Teneva *et al*., 2012; CC-CR). Reefs that are projected to be most threatened by bleaching by 2100 under the SRES A1B scenario, based on different indicators, include the Central and Western Equatorial Pacific, Coral Triangle and parts of Micronesia and Melanesia (Teneva *et al*., 2012). Degradation of coral reefs will impact key ecosystem services (Hoegh-Guldberg, 2011; 6.4; Box CC-CR).

Some groups of marine megafauna are projected to shift in distribution and abundance (6.2.5). Cetacean richness is projected to increase above 40° latitude in both hemispheres and both pinniped and cetacean richness to decrease at lower latitudes by 2040-2049 relative to 1990-1999 under the SRES A1B scenario (Kaschner *et al*., 2011). Using SST as a predictor, the distribution of loggerhead turtles is projected to expand poleward in the Atlantic Ocean and to increase in available habitat in the Mediterranean Sea by 2070-2089 relative to 1970-1989 (Witt *et al*., 2010). Leatherback turtle may decrease in abundance at a rate of 7% per decade because of reduced hatching success with warming following the SRES A2 scenario (Saba *et al*., 2012). Abundance of some seabirds such as Cassin's auklet in the California Current ecosystem or Emperor penguin in Antarctica is projected to decline because of climate induced changes in oceanographic conditions, such as temperature and upwelling intensity (Wolf *et al*., 2010) or summer sea ice conditions (Jenouvrier *et al*., 2012).

6.5.3. Ecosystems and Fisheries

Projected responses of marine ecosystems at different levels of organization are expected to result in large changes in fisheries resources, with increased vulnerability particularly in tropical regions. One of the most direct impacts of climate change on marine ecosystem services is through fisheries (6.4; WGII Ch. 7). Existing projections of impacts on fisheries under climate change are based on changes in ocean net primary production, as well as recruitment, growth, mortality, abundance and distribution of fish stocks. Assuming that the potential fish catch is proportional to net primary production, the fish catch in the North Pacific Ocean subtropical biome is projected to increase by 26% while that in the temperate and equatorial biomes may decrease by 38 and 15%, respectively, by 2100 relative to 2000 under the SRES A2 (RCP6.0 to 8.5) scenario (Polovina *et al*., 2011). Changes in phytoplankton size structure are also projected to affect fisheries catch potential (Cheung *et al*., 2011), resulting in a decrease in the potential catch of large fishes (0 – 75.8%) in the central North Pacific and increases of up to 43% in the California Current region over the 21st century under the SRES A2 scenario (Woodworth-Jefcoats *et al*., 2013). Globally, climate change is projected to result in a large-scale redistribution of global catch potential, with an average 30–70 % increase in yield in high-latitude regions, but a 40 – 60% drop in the tropics by the 2050s relative to the 2000s under

the SRES A1B (RCP6.0) scenario (Figure 6-15) (Cheung *et al.*, 2010; Blanchard *et al*., 2012). This highlights the high vulnerability of national economies of tropical coastal countries through impacts of climate change on fisheries (Allison *et al*., 2009; 6.4). Fisheries targeting specific species may show more complex responses to climate change. For example, driven by changes in temperature and primary production, catches of skipjack and bigeye tuna in the south Pacific were projected to increase by 2035 relative to 1980-2000 under the SRES B1 and A2 scenario, but for 2100, skipjack tuna catch is projected to decrease under the A2 scenario, while bigyeye tuna catch decreases under both A2 and B1 scenarios (Lehodey *et al*., 2011). Regionally, catches in the western Pacific are projected to decrease while those in the eastern Pacific will increase (Lehodey *et al*., 2011). Moreover, driven by changes in growth and distribution under warming and changes in O_2 content, maximum body weight of exploited demersal marine fishes is projected to decrease globally by 10-24% under the SRES A2 (RCP6.0 to 8.5) scenario (Cheung *et al*., 2012a, Figure 6-15). The decrease in maximum body size may affect natural mortality rates, trophic interactions, and reduce yield-per-recruit and, thus, potential catch. Projected changes in the distribution and production potential of fisheries resources are expected to affect economics, human livelihood and food security (Allison *et al*., 2009; Sumaila and Cheung, 2010), although the magnitude and direction of the projected socio-economic impacts are poorly quantified.

Identifying responses to climate change is complicated by species interactions and multiple stressors. OA and hypoxia are expected to reduce maximum catch potential by 2050 relative to 2000 in both the North Atlantic and Northeast Atlantic (Ainsworth *et al*., 2011; Cheung *et al*., 2011). Fishery of molluscs is projected to be particularly vulnerable to OA (Cooley and Doney, 2009), with a substantial decline in the global production of molluscs potentially occurring between 2020 and 2060 (Cooley *et al*., 2012). However, these projections admittedly are sensitive to the assumed vulnerability of the modeled organisms to OA (6.2.5., 6.3.4). Responses of exploited marine species and their fisheries may interact with other human stressors such as overfishing, exacerbating the impacts on fisheries catches (e.g. Lindegren *et al*., 2010; Ainsworth *et al*., 2011). Moreover, differences in vulnerability and adaptive capacity of species to changing environmental and ecosystem conditions will affect the responses of fisheries to climate change (e.g. Fulton, 2011; Griffith *et al.*, 2011; Le Borgne *et al*., 2011). The complex and non-linear interactions and responses of both biophysical and socio-economic systems to climate change and ocean acidification may lead to changes that have a low probability of occurrence based on empirical data (Doak *et al*., 2008). The risk of such low probability but potentially high impact events may be under-estimated in existing model projections (Williams and Jackson, 2007; Lindenmayer *et al*., 2010).

6.5.4. Conclusions

Current understanding is rudimentary of how different modes of forcing like warming, ocean acidification, de-oxygenation and other human impacts, either individually or together, will interact and affect levels of biological organization, from physiology to biomes (i.e., *limited evidence, medium agreement*). Models that integrate climate and ocean changes with biological responses and interactions, and with human activities, at present, have led to some agreement on species and food web responses to climate change. However, these models do not include biological processes such as trophic interactions and evolutionary adaptation that affect responses of biota to physical and chemical changes. Further insights into understanding the relative roles of bottom up and top down effects and their interplay require consideration of scale-dependency, regional and interspecific differences, and improved acquisition and management of biological data. Such insights would improve model projections.

Most projections on ocean biogeochemistry represent open-ocean systems rather well, but coastal and shelf seas regions only poorly. There is a large variation in estimates of the present-day magnitudes and distribution of primary production in models and observation-based estimates (6.1.3., 6.3.1). Accordingly, there is *low confidence* that primary production will decrease by 2100 under low (SRES B1 or RCP4.5) and high emission scenarios (A2 or RCP6.0 - 8.5), also, there is *limited evidence* and *low agreement* and *confidence* on projecting an increase in global NPP or an increase at high latitudes and a decrease in the tropics, although model results are similar.

Confidence is *high* that the distribution of fishes, invertebrates, cetaceans and some marine megafauna will shift further under most emission scenarios, with the projected rates and directions of range shifts being consistent with observations in the last century. More specifically, *confidence* is *high* that the average shift in distribution is

generally poleward at large spatial scales and *confidence* is *medium* in projected shifts of fishes and invertebrates to deeper water, except in areas where hypoxia prohibits deeper movement. Species richness and abundance of warmer-water species will increase at high latitudes (*high confidence*) and decrease in the tropics (*low confidence*). Projections of shifts in abundance and distribution of individual populations and species are more variable and sensitive to model structure and parameters.

Despite some agreement between model results, there is *medium confidence* in the projected direction of fisheries production and *low confidence* in the projected magnitude of changes. Maximum fisheries catch potential is projected to increase at high latitudes and decrease in the tropics by 2050 under SRES B1 (RCP4.5) and A1B (RCP6.0) scenarios (*medium confidence*). *Confidence* in quantifying such projections is *low* due to *low confidence* in projected primary production rates, biological responses such as species interactions, and in projected effects of multiple climate drivers and human activities.

Overall, the projected responses of marine organisms and ecosystems to climate change include changes in primary productivity (*low confidence*), species' life history (*medium confidence*), distribution, abundance and diversity across marine foodwebs (*high confidence*) in a time frame of 20 to 80 years from 2010. These changes increase the vulnerability of human societies, particularly those that are dependent on coastal resources (*limited evidence, medium agreement*) by affecting income, employment and food security through their effects on fisheries, tourism, and regulatory services such as coastal protection (6.4, Box CC-CR, *medium confidence*).

6.6. Chapter Conclusions and Key Uncertainties

This section provides an overview of chapter results on confidence in the detection and projection of climate change effects on ocean systems, as well as in the attribution of effects to the respective forcings (Figure 6-16). Case studies, processes, and concepts relevant in assessing the effects of climate change are represented by their acronyms in text and figure. While the anthropogenic signal is clearly seen in the oceans (6.1.1) clear attribution to anthropogenic influences on climate is not always possible in individual case studies, due to the inherent variability of system characteristics (6.1.3).

[INSERT FIGURE 6-16 HERE
Figure 6-16: Overview of the levels of confidence in detection (left), as well as in projection (right) of climate change effects on ocean systems, in relation to the levels of confidence in attributing these effects to the respective climate forcings. While confidence is often high that there are effects, the direct attribution to one driver in field experiments is difficult as several processes are highly correlated with each other such as warming and changes in stratification and hence nutrient depletion. Some climate change impacts have been condensed into rather broad categories in order not to overpopulate the figures (e.g. **BG**, **B**io-**G**eochemical processes). Note that the term attribution is not only used in the context of detections but also for projections. Projections include both qualitative and quantitative extrapolations and simulations from fundamental principles and models. Experiments (field, laboratory and modeling) simulating future conditions may enhance the respective confidence levels above those for detection which refers to present day observations in the field. The empirical observations resulting from those experiments are directly attributable to the respective drivers. Confidence rises further if these experiments identify the affected mechanisms and their response to future conditions. See text for further discussion of the depicted depicted examples and categories. Confidence assignments focus on the nature and size of effects, not on the capacity of models to reliably quantify their magnitude.]

6.6.1. Drivers of Change and their Effects

Present day observations and those from the **G**eological **R**ecord (**GR**, Figure 6-16) show similar signs in respect to environmental changes, e.g. warm times at high CO_2 levels, and similar ecological consequences in the ocean (*robust evidence, medium agreement* and *confidence*). However, the ongoing rate of anthropogenic CO_2 release and hence ocean acidification is unprecedented in the last 300 Ma (*robust evidence, high agreement and confidence,* 6.1.2).

Long-term observations show **T**emperature **E**ffects (**TE**) through warming-induced species displacements and largely poleward shifts in biogeographical distribution (20 to 200 km per decade) of zooplankton and fishes, paralleled by shifts in seasonal activity, species abundance, migration, and body size (6.3.2., *very high confidence*), and leading to shifts in **C**ommunity **C**omposition (**CC,** *high confidence*). Thermal effects reflect the differential specialization of all life forms on limited ambient temperature ranges. Long-term variability in oceanographic conditions paralleled by observed changes in ecosystem structure and fish stocks also provide *robust evidence* (*high agreement*) for a key role of temperature and changing current regimes in causing these effects. **TE**s are *likely* to continue in the 21st century, causing further changes in **CC** (*high confidence*) and, due to species shifts, decreasing **F**isheries **C**atch **P**otentials (**FCP**) at low to mid and increasing **FCP**s at high latitudes (*high confidence*, 5a in figure). These trends will possibly be strengthened by decreased primary production at low and increased PP at high latitudes but changes in **FCP** due to changes in NPP have *low confidence* (6.5.2., 6.5.3., 6.6.2., 5b in figure). **P**olar **O**rganisms (**PO**) which live at very high latitudes and are unable to migrate, acclimate or adapt to warming (*high confidence*), are becoming marginalized contributing to the projected high species turnover in polar areas (*high confidence*, 6.2.5., 6.5.2).

Hypoxic **Z**ones (**HypZ**), in marine sedimentary habitats and pelagic OMZs presently expand due to restricted water movement (enhanced stratification), warming, elevated microbial respiration, high loading with organic matter and nutrients (*high confidence*). They will continue to expand in the future, due to climate induced warming trends (*high confidence*, 6.1.1., 6.2.3). Vertical expansion of OMZs has led to the compression of habitat for organisms, e.g. pelagic billfishes, with a high O_2 demand (*high confidence*). Overall, there is *medium confidence* that local and regional **H**ypoxia **E**ffects (**HE**) during OMZ expansion are causing habitat loss to groundfishes and pelagic predators and affecting the distribution of key zooplankton and nekton species. Progressive hypoxia is causing shifts in **CC** to hypoxia tolerant species, excluding the calcifiers due to elevated pCO_2 (*high confidence*), benefiting the microbes, and leading to reduced biodiversity and the loss of higher life forms (*robust evidence, high agreement* and *confidence*) (6.2.5., 6.3.3). **HypZ** expansion will cause **HE**s to be exacerbated in the future (*very high confidence*).

Few field observations have detected **O**cean **A**cidification **E**ffects (**OAE**), e.g. through decreases in shell weight of foraminifera (*medium confidence*). Attribution of effects to CO_2 is supported by experimental studies simulating future conditions (*medium confidence*) and showing species-specific sensitivities across phyla (*high confidence*). An acidified surface ocean (due to shifted upwelling and anthropogenic OA) is causing clear negative effects on the oyster aquaculture along the North American west coast (*high confidence* in detection, *low confidence* in attribution to anthropogenic causes), which provides a *high confidence* glimpse into the future of anthropogenic OA and associated **O**yster **E**ffects (**OE**). Projected effects are most harmful in some warm water corals, echinoderms, bivalves, gastropods or crustose algae, and less so in some crustaceans and tropical fishes. Projections from experimental studies and observations at natural analogues indicate shifts in **C**ommunity **C**omposition (**CC**) to more active animals and from calcifiers to non-calcifiers in all organism groups (*high confidence* in both projection and attribution, 6.3.4., 6.2.5).

Climate change involves combinations and synergisms of temperature effects with those of other climate related drivers (ocean acidification, hypoxia, freshening, organism shifts resulting in changing interactions between species, changes in habitat structure, e.g. loss of sea ice). Strong interactions with other human impacts like eutrophication, fishing or other forms of harvesting accelerate and amplify climate induced changes (*high confidence*, 6.2.2., 6.3.5). **S**ynergistic **E**ffects (**SE**) will be exacerbated in the future (*medium confidence*), but have not yet been clearly identified (detected) in the field (*low confidence*). Attribution to such synergisms is supported by experimental evidence, especially in animals or plants (*medium confidence*).

Available evidence from empirical and modeling studies provides *high confidenc*e that climate change impacts marine ecosystems, leading to present changes in provisioning, regulating and supportive **E**cosystem **S**ervices (**ES,** *medium confidence***)**, while there is *limited evidence* and *medium agreement* that climate change affects cultural services. However, attributing their shifts to climate change remains a challenge (*low confidence*), partly because of the intrinsic difficulties of assessing these services, lack of long time-series data and confounding human impacts. However, in light of *high confidence* in projected climate change impacts and available cause and effect

understanding, some services will be affected by future climate change (*high confidence* in projection, *medium confidence* in attribution).

6.6.2. Microbial Responses and Biogeochemical Consequences

Various microbial processes (6.2.3., microbes are archaea, bacteria and protists including phytoplankton) respond to changes in irradiance, nutrient supply, temperature, CO_2 or hypoxia (*high confidence*). Experimental evidence from laboratory and mesocosm studies has identified processes potentially responsive to climate change including impacts of ocean acidification on the N cycle (6.2.3), carbon sequestration and export production, calcification, and respiration with the result of water O_2 depletion and acidification (see **HypZ**). However, the knowledge base is insufficient to build projections on a whole organism understanding of climate impacts on species, strains or communities in the field. A functional **M**icrobial **C**oncept (**MC**) supporting the attribution to climate of detected **M**icrobial **E**ffects (**ME**), from gene to ecosystem to large scale changes in biogeochemistry and also for projections into the future is not available at the current level of understanding (6.3.1., *low confidence*). Overall, *confidence* is *low* in that shifts in **B**io-**G**eochemical processes (**BG**) such as O_2 production, carbon sequestration and export production, nitrogen fixation, climate-feedback by DMS production, nutrient recycling, or calcification are presently happening at detectable scales or will do so in the future, paired with *low confidence* in attribution to climate change (6.3.3., 6.3.4., 6.3.5).

The trends in net primary production (NPP) recently reported for much of the low latitude ocean using satellite observations differ considerably from those few long-term direct estimates of offshore NPP (6.1.3., 6.3.1). The latter indicate a small but significant increase in **g**lobal **NPP** (**gNPP**) over the last two decades (*medium confidence* in detection, *low confidence* in attribution). Higher rates of **NPP** at **h**igh latitudes (**hNPP**, attributable to climate change with *high confidence*, 6.3.1) are indicated by satellite images (*medium confidence*) and may be due to a reduction and thinning of sea-ice. Trends in NPP may be strengthened with further warming. Modeling projects that **gNPP** may decrease by 2100 under SRES A1 and A2 scenarios, however, such global trends cannot presently be quantified with sufficient accuracy and projections are fraught with *low confidence* (6.5.1); for **hNPP**, *confidence* in projections of an increase is equally *low*.

6.6.3. Responses of Animals and Plants and their Implications

Temperature Effects (**TE**) include strong **MA**croorganism **E**ffects (**MAE)**, i.e. effects on animals and plants. Causes and effects are understood for fishes and most invertebrates via their **O**xygen and **C**apacity **L**imited **T**hermal **T**olerance (**OCLTT,** 6.2.2., *robust evidence, medium agreement* and *high confidence*). Such knowledge also supports projections into the future (6.5., *medium confidence*), limited by the unknown potential of organisms to adapt. Alterations in **AB**undance (**AB**) of e.g. corals, fishes or intertidal species result when organisms are exposed to increasing extreme temperatures (*high confidence* in detection and attribution). Such trends will be exacerbated during future warming (*high confidence*, 6.5.2). Multiple drivers (warming, ocean acidification, hypoxia) have **S**ynergistic **E**ffects (**SE**) which can also be understood by analyzing the oxygen and capacity limited thermal tolerance of animals (6.2.6., 6.3.5). The following examples reflect the present predominance of **TE**s. Warming causes shifts in the geographical distribution of North **A**tlantic **C**od (**AC**, 6.3.2., *high confidence* in detection, *medium confidence* in attribution), falling abundance of **E**elpout in the **W**adden **S**ea (**EWS**, 6.2.2., 6.3.2., 6.3.7., *medium confidence* in detection, *high confidence* in attribution), collapsing spawning migrations of **P**acific **S**almon (**PS**, 6.3.2., *high confidence* in detection, *high confidence* in attribution) in the Fraser River, Canada, growth patterns in relation to distribution around New Zealand of **B**anded **M**orwong (**BM**, *high confidence* in detection, *medium confidence* in attribution), and shifts from **S**ardines to **A**nchovies in the Sea of **J**apan (**SAJ**, 6.2.5., 6.3.2., *medium confidence* in detection, *medium confidence* in attribution). Loss of deep habitat and biomass of **M**id-**W**ater **F**ishes (**MWF**, 6.3.3., *medium confidence* in detection) off California is attributed to hypoxia (*high confidence*). At temperate and high latitudes communities display increasing fish **S**pecies **R**ichness (**SR**) resulting from latitudinal shifts of species and loss of sea ice (6.3.7., 6.5.2., *high confidence* in detection, *medium confidence* in attribution). These observed changes have been attributed to warming, although the relative contributions of regional climate variation and long-term global trends have not been quantified. Latitudinal shifts due to **TE**s are projected to

continue in the 21st century under all IPCC emission scenarios (*very high confidence* in detection and in attribution, 6.2.5., 6.3.2., 6.3.5., 6.3.7., 6.4.1., 6.5.2).

Regime shifts and regional changes in **P**lankton **P**henology (**PP**, *medium confidence*) cause changes in food composition and availability to animals, in concert with shifts in their own distribution such as of fishes like **A**tlantic **C**od (**AC**, *medium confidence* in attribution to climate change, 6.3.2). As a consequence, changes in **F**ish **C**atch **P**otential (**FCP**, *high confidence*) due to species shifts and changing species composition (5a in figure) are partly attributable to climate change (*high confidence*) and to maintained fishing pressure (6.5.3).

Among **M**arine **A**ir **B**reathers (**MAB**, i.e. mammals, seabirds and sea turtles), detected effects include changing abundance and phenology, species distribution shifts, and turtle sex ratios (*high confidence*), all of which are attributed to climate change (*high confidence*). These effects are rarely directly linked to climate drivers (e.g. temperature driven turtle sex ratio) but mostly to shifting habitat structure (e.g. loss of sea ice), availability of prey organisms, or foraging efficiency, in both mammals (polar bear, walrusses) and birds (penguins, albatrosses), resulting in differential sensitivities of species. Such trends will be exacerbated by future warming (*high confidence*, 6.2.5).

Increased bleaching and decreased calcification displayed by several **R**eef-building **W**arm water **C**orals (**RWC**, *very high confidence*) over the last three decades are, with *very high confidence*, attributed to the ongoing warming trend and the associated rise in extreme temperature events and amplitudes (6.2.5, Box CC-CR). With *very high confidence*, such trends will be exacerbated during future warming, with some amelioration by latitudinal shifts and evolutionary adaptation (6.3.2., *medium evidence*, *low confidence*). The patterns seen may involve an increasing influence of ocean acidification, confirmed by similar phenomena during mass extinctions in earth history.

6.6.4. Key Uncertainties

Key uncertainties on how the global ocean will respond to climate change, result from the limited number and duration of observational time series in the oceans and thus from insufficient sampling and limited capacity and infrastructure in countries around the world to study ocean response to climate change. Research foci differ between research areas (studies of pelagic versus benthic ecosystems, biogeochemical processes, sensitivities of species, families, phyla or organism kingdoms and domains, and studies of special mechanisms of functioning or adaptation). Processes investigated by various biological disciplines also differ largely between studied organisms, plants, animals, phytoplankton, and bacteria. Each of the listed foci is important but they are usually not well integrated and reductionist with respect to the level of organization in focus, i.e. ecosystem, whole organism, tissue, cell or molecular. Furthermore, scaling from physiological studies on individual species to shifts in species interactions or foodwebs has not been successful to date. A unifying approach addressing principles across organism domains is lacking such that an integrated framework of climate sensitivity at ecosystem level presently does not exist. For all climate drivers, especially ocean warming, acidification and hypoxia, studies integrating mechanistic knowledge and evolution over generations, as well as in various climate zones and biomes are needed. Laboratory and modeling experiments need to be inspired by long-term field observations and observations at natural or paleo-analogues. Modeling activities need to better integrate observations and mechanism-based understanding, last not least in order to better project the future interactions between human and natural systems in a changing climate. As a corollary, the coordination of research concepts and approaches is deficient and a coherent picture of climate change effects is thus not available, leaving a strong coordinating role for international (both inter- and non-governmental) organizations.

Frequently Asked Questions

FAQ 6.1: Why is ocean life fundamental to the planet's sensitivity to climate change?

Oceans cover 70 % of the planet and provide important services to humankind. The life they contain creates about half of the oxygen (O_2) we breathe and also consume by the burning of fossil fuels. Oceans currently absorb ~25 % of the carbon dioxide (CO_2) emitted from the burning of fossil fuels, convert it into organic matter and export parts of it to the deep ocean. Oceans take up 93% of the heat accumulating during global warming and thereby play a key

role in climate regulation. Fisheries and aquaculture provide on average 20 % of the animal protein to more than 1.5 billion people. The oceans provide habitats for charismatic species and sustain ecosystems valued in tourism and for recreation. The rich biodiversity of the oceans offers resources for innovative approaches like medical drug design or biomechanics. Ocean ecosystems contribute to offsetting the effects of natural hazards - for example, coral reefs are known to protect shoreline and efficiently buffer tsunamis and storm surges.

Climate change in the oceans involves rising temperatures, acidification elicited by accumulating CO_2, changed nutrient supply and the expansion of low O_2 areas. These drivers pose risks for ocean life and may impair the ability of marine biota to perform their vitally important functions. Such effects occur on a background of natural variability of these drivers. Additionally, oceans experience other anthropogenic pressures such as overfishing, pollution, nutrient runoff via rivers and the associated eutrophication. In light of the key role of the oceans in global climate change it is crucial but difficult to clearly identify the combined effects of these multiple drivers. Effects of the various drivers may not only be additive but often synergistic, i.e. the effect of each driver is amplified by the concomitant change of the other drivers, causing important but difficult to predict non-linear effects on a wide range of ecosystem processes.

Some insights into future scenarios can be obtained from analysing past events of climate change and from extrapolating the existing long time series (i.e. decades) of data into the future. State-of-the-art ecosystem models built on empirical observations enable us to obtain estimates for responses of marine biota to climate change. Examples are the projected large scale shift in the distribution of commercially relevant fishes to high latitudes and the loss of their catch potential at their original sites. However, formulating well founded or detailed projections is a challenging task because of the large number of interactive feedbacks that must be taken into account. Furthermore, the current rate of environmental change is unprecedented compared to climate changes in the past and, therefore, demands adaptation in only a small number of generations compared to long-term changes in nearly all of the geological record. Changes may thus be too rapid for adaptation to occur. The resilience of marine ecosystems to climate-change mediated impacts is likely to be reduced by the individual and interactive effects of multiple drivers.

FAQ 6.2: What is special about climate change effects on the oceans and can we predict the consequences?

Although there are many similarities in how climate change will alter the land and ocean ecosystems, for example through warming trends, there are also fundamental differences, primarily due to the aquatic environment and associated physicochemical properties of the ocean, including ocean circulation and sea water chemistry. The anthropogenic CO_2 accumulating in the atmosphere enters the ocean and is acidifying the water (making it less alkaline). CO_2 content will thus increase in both the atmosphere and the warming ocean, and be taken up by the organisms. Animals living and breathing in water (for example, fishes, squids, mussels) have naturally 5 to 20 times lower CO_2 levels in their blood and therefore experience stronger changes and are more sensitive than animals on land including aquatic turtles, mammals, seabirds which also live in water but breathe air at the ocean surface.

The warming of the ocean has significant indirect effects on oceanic properties - for example by forming stable ocean layers separated by density differences, which alter the degree of communication between cold nutrient-rich waters at depth and warm nutrient-poor waters near surface. Increasing respiration by organisms in the mid-water layers of stratified oceans will lead to expanding oxygen-poor waters, so-called oxygen minimum zones (OMZs). Respiration also produces CO_2, enriches it further in the water and causes more acidification in expanding OMZs. Low oxygen waters exclude large, more active fishes from living permanently in these areas. Specialized animals with a low O_2 demand will remain such that the communities living in hypoxic areas are very different from those found in well oxygenated waters. Thus, ocean biota (except for sea birds, turtles, mammals) will have to adjust to a fundamentally different environment and one that may be even more altered than that of the land.

At the moment, the uncertainties in modeling prevent any quantification of how much of the change is caused by climate change and how much of it is caused by other human activities. For improved and more reliable projections of future changes, mechanisms and unifying principles shaping the impacts of climate change on various organism groups or on biogeochemical processes must be better understood and included into mechanism based modeling approaches.

FAQ 6.3: How will marine ecosystems look like under climate change?

There is general consensus among scientists that climate change significantly affects marine ecosystems and may have profound impacts on future ocean biodiversity. Recent changes in species distributions, species richness and community structure have been attributed to ocean warming. Projected changes in physical and biogeochemical drivers, such as warming, acidification, hypoxia, nutrient supply and sea ice cover, will continue to affect marine

biota. Under most climate change scenarios, a shift or expansion of habitat range limits towards higher latitudes by tens of kilometres per decade can be foreseen for many species of plankton, fishes and invertebrates, resulting in shifts of species richness and altered community composition. Organisms that are more tolerant to direct effects of climate change may be affected indirectly through climate change restructuring existing food webs. In polar areas cold-adapted species among invertebrates and fishes may be lost by local extinctions and be marginalized due to warming. Similarly, species in semi-enclosed seas such as the Wadden Sea and the Mediterranean Sea face higher risk of local extinction because distributional shifts in response to warming and other environmental changes are limited by the land-boundary.

Overall, climate change will lead to large-scale shifts in the patterns of marine productivity, biodiversity, community composition and ecosystem structure. Extinction of species that are sensitive to climate change, including ocean acidification, will lead to a decrease in species richness. In particular, the impacts of climate change on vulnerable organisms such as warm water corals are expected to affect the associated ecosystems, such as coral reefs. Alteration of the seasonal activity (phenology) of marine organisms, their biology and distribution will disturb food web interactions such as the grazing of copepods (small crustaceans) on planktonic algae. Ocean primary production is also expected to change but the global patterns are more difficult to project. Existing model projections suggest an increase in primary production at high latitudes such as in the Southern Ocean (higher mean light levels for photosynthesis at lower ice cover) and decreases in the tropics and at mid-latitudes (reduced nutrient supply). Human stressors such as overfishing, eutrophication and pollution are expected to exacerbate the impacts of climate change. Increasing temperature, nutrient fluctuations, and eutrophication may favor harmful algal blooms in coastal including upwelling areas. Climate change may also cause shifts in the distribution and abundance of pathogens such as for cholera.

FAQ 6.4: Why do marine organisms rely on a sufficiently alkaline ocean?

Many marine species, ranging from microscopic plankton to shellfish and coral reef builders are generically referred to as calcifiers, as they depend on using solid calcium carbonate ($CaCO_3$) to construct their skeletons or shells. Solid calcium carbonate comes in different forms called calcite and aragonite; aragonite is more soluble in water than calcite. Sea water contains ample calcium in solution but this needs to be transported to the sites where calcification occurs. In contrast, the carbonate is not transported from the water to calcification sites but newly formed where it is needed. To form carbonate ions in high concentrations and to thereby calcify more easily, the calcification site is made alkaline, meaning that pH is increased by the organism to values higher than in other parts of the body or in ambient sea water. This process demands energy which the organism has to be able to supply. If high CO_2 levels from outside penetrate the organisms this process is becoming even more challenging and costly. If a lot of energy is needed for calcification, energy for other biological processes like growth might become limiting, making these organisms less competitive, reducing their weight or reproduction, all of which is needed for sustaining ecosystem diversity, and services.

CO_2 accumulating in the seawater can also affect the stability of shells and skeletons (Box CC-OA). At low CO_2 levels, the sea water has high carbonate levels and keeps $CaCO_3$ in solid form. As the oceans acidify, by the anthropogenic accumulation of CO_2, the concentration of carbonate falls making $CaCO_3$ more soluble and this water may start dissolving carbonate shells. Some of these shells are shielded from direct contact with sea water by a special coating (as is the case in mussels). Combined with the increased energy needed for calcification, organisms might struggle to repair their shells which are dissolving in corrosive seawater. Presently, corrosive waters upwelling closer to the Northwest coast of the United States impact the oyster aquacultures and illustrate the principles of such effects.

Ocean acidification not only affects species producing calcified exoskeletons. Ocean acidification affects organisms either directly or indirectly. For most organisms investigated, sensitivity is highest at extreme temperatures and thus, at the edges of their thermal ranges highlighting the potential for combined effects with temperature. Indirect effects might be changes in their prey organisms due to their specific sensitivities to climate change. Ocean acidification therefore has the potential to disturb food webs and fisheries.

Cross-Chapter Boxes

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water structures made of calcium carbonate mostly secreted by reef-building (scleractinian) corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics. About 275 million people live within 30 km of a coral reef (Burke et al., 2011) and are likely to derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including those from provisioning (food, construction material, medicine), regulating (shoreline protection, water quality), supporting services (oxygen supply) and cultural (religion, tourism). This is especially true in small islands (29.3.3.1).

Most human-induced disturbances to coral reefs were local (e.g., coastal development, pollution, nutrient enrichment and overfishing) until the early 1980s when global and climate-related disturbances (ocean warming and acidification) began to occur. Temperature and seawater acidity are two of the most important environmental variables determining the distribution of coral reefs (Kleypas et al., 2001). As corals are centrally important as ecosystem engineers (Wild et al., 2011), the impacts on corals have led to widespread degradation of coral reefs.

A wide range of climatic and non-climatic stressors affect corals and coral reefs and negative impacts are already observed (5.4.2.4, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae (genus *Symbiodinium*), which live in the coral tissues and play a key role in supplying the coral host with energy and nutrients (Baker et al., 2008) (see 6.2.5 for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies, is the most widespread and conspicuous impact (Fig. 5X; see Sections, 5.4.2.4, 6.2.5, 25.6.2, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Elevated temperature along with ocean acidification reduces the calcification rate of corals (*high confidence*; 5.4.2.4), and may tip the calcium carbonate balance of reef frameworks towards dissolution (*medium evidence and agreement*; 5.4.2.4). These changes will erode fish habitats with cascading effects reaching fish community structure and associated fisheries (*robust evidence, high agreement*, 30.5).

Around 50% of all coral reefs have experienced medium-high to very high impact of human activities (30-50% to 50-70% degraded; Halpern et al., 2008), which has been a significant stressor for over 50 years in many cases. As a result, the abundance of reef building corals is in rapid decline (1 to 2% per year, 1997-2003) in many Pacific and SE Asian regions (Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner et al., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and coral bleaching have led to a decline in coral cover on the Great Barrier Reef (about 51% between 1985 and 2012; De'ath et al., 2012).

One third of all coral species exhibit a high risk of extinction, based on recent patterns of decline and other factors such as reproductive strategy (Carpenter et al., 2008). Although less well documented, non-coral benthic invertebrates are also at risk (Przeslawski et al., 2008). Fish biodiversity is threatened by the permanent degradation coral reefs, including in a marine reserve (Jones et al., 2004). While many factors, such as overfishing and local pollution, are involved in the decline of coral reefs, climate change through its pervasive influence on sea temperature, ocean acidity, and storm strength plays a very significant role.

There is *robust evidence* and *high agreement* that coral reefs are one of the most vulnerable marine ecosystems (Chapters 5, 6, 25, and 30). Globally, more than half of the world's reefs are under medium or high risk of degradation (Burke et al., 2011) even in the absence of climatic factors. Future impacts of climate stressors (ocean warming, acidification and sea level rise) will exacerbate the impacts of non-climatic stressors (*high agreement, robust evidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9–60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation under the RCP3-PD scenario (Frieler et al., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30–88%, 68% uncertainty range). If present day corals have residual capacity to acclimatize and/or

adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*; Logan et al., sbm). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs produce 10-12% of the fish caught in tropical countries, and 20-25% of the fish caught by developing nations (Garcia & Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton et al. (2012) are already exploiting their coral reef fisheries in an unsustainable way (13.X.X).
- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke et al., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).
- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard et al., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4, 30.5).

Coral reefs make a modest contribution to the global domestic product but their economic importance can be high at the country and regional scales (Pratchett et al., 2008). For example, tourism and fisheries represent on average 5% of the GDP of South Pacific islands (Laurans et al., 2013). At the local scale, these two services provide at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans et al., 2013).

Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod et al., 2009). Although they are key conservation and management tools, they are less effective in reducing coral loss from thermal stress (Selig et al., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau et al., 2012). Controlling the input of nutrients and sediment from land is an important complementary management strategy because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann et al., 2012). There is also high confidence that, in the long term, limiting the amount of warming and acidity is central to ensuring the viability of coral reef systems and dependent communities (5.X.X and 30.5).

[INSERT FIGURE CR-1 HERE
Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Introduction

Anthropogenic ocean acidification and climate change share the same primary cause at the global level, the increase of atmospheric carbon dioxide (WGI, 2.2.1). Eutrophication and upwelling contribute to local ocean acidification (5.3.3.6, 30.5.4). Past and futures changes in chemistry are well known in the surface open ocean (WGI, 3.8.2 and 6.4.4) but are more difficult to project in the more complex coastal systems (5.3.3.6 and 30.5.2).

Chemistry and Projections

The fundamental chemistry of ocean acidification has long been understood: the uptake of CO_2 into mildly alkaline ocean results in an increase in dissolved CO_2 and reductions in pH, dissolved carbonate ion, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of surface seawater can be projected at the global scale with high accuracy from projections of atmospheric CO_2 levels. Time series observations of changing upper ocean CO_2 chemistry support this linkage (WGI Table 3.2 and Figure 3.17; WGII Figure 30.5). Projections of regional changes, especially in coastal waters (5.3.3.6), and at depth are more difficult; observations and models show with high certainty that fossil fuel CO_2 has penetrated at depths of 1 km and more. Importantly, the natural buffering of increased CO_2 is less in deep than in surface water and thus a greater chemical impact is projected. Additional significant CO_2 increases and pH decreases at mid-depths are expected to result from increases in microbial respiration induced by warming. Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGII, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration).

Biological, Ecological, and Biogeochemical Impacts

The effects of ocean acidification on marine organisms and ecosystems have only recently been investigated. A wide range of sensitivities to projected rates of ocean acidification exists within and across organism groups and phyla with a trend for higher sensitivity in early life stages (*high confidence*; Kroeker et al., in press; 6.2.3-5, 6.3.4). A pattern of impacts, some positive, others negative, emerges for some processes and organisms (*high confidence*; Fig. X.C) but key uncertainties remain from organismal to ecosystem levels (Chap. 5, 6, 30). Responses to ocean acidification are exacerbated at high temperature extremes (*medium confidence*) and can be influenced by other drivers, such as oxygen concentration, nutrients, and light availability (*medium confidence*).

Experimental evidence shows that lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers such as reef-building corals (Box CC-CR, coralline algae (Raven, in press), bivalves and snails (Gazeau et al., in press) reducing their competitiveness compared to, e.g. seaweeds (Chap. 5, 6, 30). A reduced performance of these ecosystem builders would affect the other components of the ecosystem dependent on the habitats they create.

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*) and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may significantly stimulate nitrogen fixation in the oceans (*limited evidence, low agreement*; 6.2.3, 6.3.4). There are few known direct effects on early stages of fish and adult fish remain relatively undisturbed by elevated CO_2. Serious behavioral disturbances were reported, mostly on larval and juvenile coral reef fishes (6.2.4).

Projections of ocean acidification effects at the ecosystem level are limited by the diversity of species-level responses. Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities living on the sea-floor. Shifts in community structure have been documented in rocky shore environments (e.g., Wootton et al., 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012). Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.2-3), which could impact food webs and higher trophic levels (*limited evidence, high agreement*).

There is *limited evidence* and *medium agreement* that some phytoplankton and mollusks can adapt to ocean acidification, indicating that the long-term responses of these organisms to ocean acidification could be less than responses obtained in short-term experiments. However, mass extinctions during much slower rates of ocean acidification in Earth history (6.1.2) suggest that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of change (*high confidence*).

The effect of ocean acidification on global biogeochemical cycles is difficult to predict due to the species-specific responses to ocean acidification, lack of understanding of the effects on trophic interactions, and largely unexplored combined responses to ocean acidification and other climatic and non-climatic drivers, such as temperature, concentrations of oxygen and nutrients, and light availability.

Risks

Climate risk is defined as the probability that climate change will cause specific physical hazards and that those hazards will cause impacts (19.5.2). The risks of ocean acidification to marine organisms, ecosystems, and

ultimately to human societies, includes both the probability that ocean acidification will affect key processes, and the magnitude of the resulting impacts. The changes in key processes mentioned above present significant ramifications on ecosystems and ecosystem services (Fig. 19.3). For example, ocean acidification will cause a decrease of calcification of corals, which will cause not only a reduction in the coral's ability to grow its skeleton, but also in its contribution to reef building (*high confidence*; 5.4.2.4). These changes will have consequences for the entire coral reef community and on the ecosystem services that coral reefs provide such as fisheries habitat (*medium confidence*; 19.5.2) and coastal protection (*medium confidence*; Box CC-CR). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Socioeconomic Impacts and Costs

The biological, ecological and biogeochemical changes driven by ocean acidification will affect several key ecosystem services. The oceans will become less efficient at absorbing CO_2, hence less efficient at moderating climate change, as their CO_2 content will increase (*very high confidence*). The impacts of ocean acidification on coral reefs, together with those of bleaching and sea level rise, will in turn diminish their role of shoreline protection in atolls and small island nations as well as their direct and indirect benefits on the tourism industry (*limited evidence, high agreement*; Box CC-CR).

There is no global estimate of the observed or projected economic costs of ocean acidification. The production of commercially-exploited shelled mollusks may decrease (Barton et al., 2012) resulting in an up to 13% reduction of US production (limited evidence, low agreement; Cooley and Doney, 2009). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (Narita et al., 2012). The largest uncertainty is how the impacts on prey will propagate through the marine food webs and to top predators. Models suggest that ocean acidification will generally reduce fish biomass and catch (*limited evidence, high agreement*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (Branch et al., 2012; Griffith et al., 2012). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 500 billion USD, respectively for A1 and B2 SRES emission scenarios (Brander et al. 2012). Although this number is small compared to global GDP, it represents a large proportion of the GDP of some regions or small island states which rely economically on coral reefs.

Adaptation and Mitigation

The management of ocean acidification comes down to mitigation of the source of the problem and adaptation to the consequences (Rau et al., 2012; Billé et al., sbm). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts. Climate geoengineering techniques based on solar radiation management would have no direct effect on ocean acidification because atmospheric CO_2 would continue to rise (6.4.2). Techniques based on carbon dioxide removal could directly address the problem but their effectiveness at the scale required to ameliorate ocean acidification has yet to be demonstrated. Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep water oxygen levels (Williamson and Turley, 2012; 6.4.2; 30.3.2.3 and 30.5.7). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Specific activities, such as aquaculture, could adapt to ocean acidification within limits, for example by altering the production process, selecting less sensitive species or strains, or relocating elsewhere. A low-regret approach is to limit the number and the magnitude of drivers other than CO_2. There is evidence, for example, that reducing a locally determined driver (i.e. nutrient pollution) may substantially reduce its synergistic effects with a globally determined driver such as ocean acidification (Falkenberg et al., 2013).

[INSERT FIGURE OA-1 HERE

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to

calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.]

Table 6-1: Selected examples of long-term biological and ecological observations in the oceans (NPP denotes Net Primary Productivity).

Region	Name of time series	Duration covered	Type of information	Interpretation
Global	SeaWiFS (Sea-viewing Wide Field-of-view Sensor)	1997-2011	Near surface chlorophyll	Direct and indirect effects of warmer oceanic conditions, associated with climate variability, result in lower chlorophyll concentrations and decreased rates of NPP (Behrenfeld *et al.* 2006a). Satellite time-series is insufficient to make robsut projections on the effect of climate change on chlorophyll concentrations or rates of NPP (Henson *et al*., 2010)
English Channel and later into the open sea	CPR (Continuous Plankton Recorder)	1920s - ongoing	Zoo- and phytoplankton abundance/ presence absence	• changes in the seasonal abundance of phytoplankton (Edwards *et al.*, 2001) • rapid northerly movements of temperate and subtropical species of zooplankton and phytoplankton (Beaugrand *et al.*, 2009) • climate induced trophic mismatch between phytoplankton and zooplankton and its impact on fisheries (6.3.2.; Edwards and Richardson, 2004)
North Sea	Helgoland Roads (Alfred Wegener Institute)	1962 - ongoing	salinity, secchi disk depth, macronutrients, phytoplankton, zooplankton, intertidal macroalgae, zoobenthos and bacterioplankton	• Increase in green algae, decrease in brown algae, increased number of invaders on macrofauna, changing foodweb and bloom dynamics (Wiltshire *et al.*, 2010)
California	CalCOFI (California Cooperative Oceanic Fisheries Investiga-tions)	1949 - ongoing (quarterly, 1969-1984 triennial) on variable grid	Ecological assessment	• El Niño impacts marine invertebrates and fishes (Chelton *et al*., 1982; Butler, 1989; Rebstock, 2001) • decline in zooplankton biomass during periods of warming (Roemmich, 1992; Roemmich and McGowan, 1995a; Roemmich and McGowan, 1995b) • multidecadal shifts in the pelagic ecosystems (sardines and anchovies) (Brinton and Townsend, 2003; Lavaniegos and Ohman, 2003; Chavez *et al*., 2003).
North Pacific Subtropical gyre	Climax HOT (Hawaii Ocean Time-series)	1968 - 1985 and 18 expeditions, mostly in summer months 1988 - ongoing monthly	ecosystem structure and variability	• Doubling of ship-measured chlorophyll a concentrations during period 1968-1985 (Venrick *et al*., 1987). • Change from large eukaryotic to small photosynthetic prokaryotes (Karl *et al*., 2001) • Decrease in dissolved phosphate concentrations due to proliferation of nitrogen fixing microorganisms (Karl 2007b)

Fisheries data series	Various	Various, see to the right	Fish stock assessments	• from 1950, fisheries landings and aquaculture production statistics, FAO: http://www.fao.org/fishery/statistics/en • from 1950, Sea Around Us project: www.seaaroundus.org, • from 1950, Global fishing effort database, Anticamara *et al*., 2011; • from 1970, ICES Trawl Surveys – DATRAS, ICES: http://datras.ices.dk/Home; • from 1950, RAM Legacy Stock Assessment Database (Ricard *et al*., 2012) • from 1903, British landings and effort data for major exploited fish stocks (Engelhard, 2005, ICES, 2010, 2011)

Table 6-2: Variations in metabolism based on sources of energy, electrons and carbon according to Karl (2007a), complemented by the taxa which exploit these pathways. Mode of metabolism may relate to organizational complexity and tolerance to environmental extremes (Figure 6-8).

Source of Energy[1]	**Source of Electrons**	**Source of Carbon**	**Domain / Taxon**
Sunlight *photo-*	Inorganic *-litho-*	CO_2 *-autotroph*	Bacteria, Archaea, Eukarya (algae and higher plants)
	Organic *-organo-*	Organic *-heterotroph*	Bacteria
Chemical *chemo-*	Inorganic *-litho-*	CO_2 *-autotroph*	Bacteria Archaea
	Organic *-organo-*	Organic *-heterotroph*	Bacteria Archaea Eukarya (Protozoa, Metazoa)

[1]A "mixotroph" is an organism that has the ability to use more than one source of energy, electrons or carbon

Table 6-3: Environmental forcing on biological production by physical, chemical and biological characteristics of major pelagic ecosystems (Adapted from Barber, 2001, based on the original analysis by McGowan, 1974).

	Size		**Stratification**			**Nutrient**[1]	
System	**Area (km^2x10^6)**	**%**	**Degree of**	**Duration**	**Productivity and Pattern**	**Level**	**Source**
Low-latitude gyre	164	52	Strong	Permanent	Low to to medium (debated)	Low	Eddy diffusion
Southern Ocean	77	25	Very weak, except strong when ice melts in summer	Seasonal	Moderate to high in summer only, Strongly seasonal	High	Mixing and upwelling
Equatorial upwelling	22	7	Aperiodic, upward vertical transport (temporally variable ranging from active upwelling to permanent stratification)	Permanent	High, Continuous	High	Upwelling and horizontal mixing
Subarctic gyre	22	7	Moderate stratification following winter mixing	Seasonal convective mixing	Low in winter, Strongly seasonal	High	Convective mixing and eddies
Eastern Boundary Current	21	7	Medium	Permanent	Moderate, Seasonal	Medium	Upwelling and lateral advection
Coastal upwelling	6	2	Strong stratification following vertical transport	Continuous	High, Weakly seasonal	High	Upwelling

[1]Nitrate and phosphate

Table 6-4: A wide range of processes make up the ocean's biological pump (Figure 6-6). In order to assess how a changing climate will alter the functioning of the pump, and the resulting biogeochemical feedbacks on global climate, the cumulative effects of climate-change mediated alteration of processes from cellular to ocean basin, and from pelagic to mesopelagic, must be quantified. This table illustrates, using published information, the complexity of the integrated knowledge platform needed to provide evidence of these biogeochemical ramifications and thus the limits to clear conclusions about climate induced effects on the biological pump (C, Carbon; TEP, Transparent Exopolymer Particle; DOM, Dissolved Organic Matter; POM, Particulate Organic Matter).

Alteration of physiological rates	Biogeographical changes	Altered foodweb structure - Trophodynamics	Changes to particle dynamics	Biogeochemical changes / climatic feedbacks
NPP (Bopp *et al*., 2002)	Microbial community structure (Giovannoni and Vergin, 2012)	Altered prey-predator linkages (Lewandowska,and Sommer, 2010)	Faecal pellet geometry (Wilson *et al*., 2008)	Particle flux/C sequestration (Bopp *et al*., 2002)
Bacterial ectoenzymes (Christian and Karl, 1995)	Phytoplankton community structure – biomes (Boyd and Doney, 2002)		C partitioning between DOM vs. POM – TEP (Riebesell *et al*., 2007)	Shifts in elemental stoichiometry of planktonic communities (Karl *et al*., 2003)
TEP production (Engel *et al*., 2004)	Alteration of zooplankton biomes (Beaugrand *et al.*, 2009)		Sinking rates/seawater viscosity (Lam and Bishop, 2008)	Remineralization rate – [O_2]; hypoxia; nutrient resupply (Gruber, 2011)
Microzooplankton grazing rates (Rose *et al*., 2009)			Ballasting - calcite versus opal (Klaas and Archer, 2002)	Activity of the microbial loop; vertical carbon export (Grossart *et al.*, 2006; Piontek *et al*., 2010)

Table 6-5: Assessment of effects of ocean acidification on marine taxa with the number of laboratory and field studies, processes, parameters and total number of species studied in the range from pCO_2 <650 to >10000 µatm. Processes and parameters investigated in multiple life stages include growth, survival, calcification, metabolic rate, immune response, development, abundance, behaviour and others. Not all life stages, not all parameters and not the entire range of CO_2 concentrations were studied in all species. *Confidence* is based on the number of studies, the number of species studied and the agreement of results within one group. E.g. most species of calcifying macroalgae were negatively affected when exposed to a pCO_2 of 670 µatm (RCP 6.0 in 2100), considering e.g. calcification or growth, which renders the group as vulnerable with *medium confidence*. +: denotes that possibly more species or strains were studied, as only genus or family were specified; beneficial: most species were positively affected; vulnerable: most species were negatively affected; tolerant: most species were not affected. RCP 6.0: representative concentration pathway with projected atmospheric pCO_2 = 670 µatm in 2100; RCP 8.5: representative concentration pathway with projected atmospheric pCO_2 = 936 µatm in 2100 (Meinshausen *et al.*, 2011). *Confidence* is limited by the short to medium-term nature of various studies and the lack of sensitivity estimates on evolutionary timescales, across generations (see separate reference list). For an assessment of variability between species from the same phylum see Figure 6-10.

Taxon	No. of studies	No. of para-meters studied	Total no. of species studied	pCO_2 where the most vulnerable species is negatively affected or investigated pCO_2 range* (µatm)	Assessment of tolerance to RCP 6.0 (*confidence*)	Assessment of tolerance to RCP 8.5 (*confidence*)
Cyanobacteria	8	5	5+	370-1000*	Beneficial (*low*)	Beneficial (*low*)
Coccolithophores	20	6	4+	800	Tolerant (*low*)	Vulnerable (*low*)
Diatoms	9	5	7+	400-820*	Tolerant (*low*)	Tolerant (*low*)
Dinoflagellates	5	4	3+	350-750*	Beneficial (*low*)	Beneficial (*low*)
Foraminifers	7	4	5	800	Tolerant (*low*)	Vulnerable (*low*)
Seagrasses	3	6	4	300-21000*	Beneficial (*medium*)	Beneficial (*medium*)
Macroalgae (non-calcifying)	5	5	3+	350-20812*	Beneficial (*medium)*	Beneficial (*low*)
Macroalgae (calcifying)	15	10	19+	550	Vulnerable (*medium*)	Vulnerable (*medium*)
Corals	25	17	22+	560	Tolerant (*low*)	Tolerant (*medium*)
Annelids	4	6	4+	2800	Tolerant (*medium*)	Tolerant (*medium*)
Echinoderms	33	29	29+	600	Tolerant (*medium*)	Vulnerable (*high*)
Molluscs	54	33	40+	600	Vulnerable (*low*)	Vulnerable (*high*)
Bryozoans	2	3	5+	2900	Tolerant (*medium*)	Tolerant (*medium*)
Crustaceans	33	27	37	700	Tolerant (*low*)	Tolerant (*medium*)
Fish	30	24	25	700	Vulnerable (*low*)	Vulnerable (*low*)

Table 6-6: Selected ocean acidification effects on microbes and associated processes. The experiments were conducted throughout more than a decade which large changes in experimental setup and data reporting (Riebesell *et al*., 2010) though information is still underreported in more recent papers, e.g. Krause *et al*, 2012, report pH values but not CO_2 or other carbonate system parameters. Therefore, pH as a common variable is reported in this table and not CO_2. The CO_2 values range from 150ppm (in this example pH 8.52) to 1500 ppm (pH 7.69) but changes in dissolved inorganic carbon (DIC) and total alkalinity (TA) do not allow a direct conversion from CO_2 to pH. Also note that the pH scale used was not always reported which can lead to errors up to 0.15 pH units between the NBS and free scale.

Organism	pH	Effect	Synergistic effects	reference
Archaea and ammonium oxidizing **bacteria**	pH reductions by 0.05–0.14 in water samples from various field sites	Decreased nitrification rates		Beman *et al.*, 2011
Batch bacterial community	8.22-8.15, 7.82, 7.67	Community shift No change in abundance		Krause *et al*., 2012
Cyanobacteria	8.4, 7.8	Prochlorococcus/ Synechococcus – no clear change in C-fixation Trichodesmisum – enhanced rates of N_2 and C fixation	With excess Fe, P	Lomas *et al*., 2012
Trichodesmium	8.52 to 7.69	Enhanced rates of photosynthesis, higher cell division rates, altered nutrient utilization (C:N and C:P ratios) and enhanced rates of N_2 fixation	Under P limitation	Barcelos e Ramos *et al.*, 2007; Hutchins *et al.*, 2007; Kranz *et al.*, 2010
Trichodesmium	8.35-7.80	Decreased N_2 fixation rates and growth	under iron limitation	Shi *et al.*, 2012
Trichodesmium erythraeum	8.28-8.01	No increase in N_2 fixation No increase in CO2 fixation	High light Low light	Garcia *et al.*, 2011
Synechococcus	8.05, 7.80	Increased cell division higher photosynthetic rate	Ambient temperature versus 4°C warming	Fu *et al.*, 2007
Prochlorococcus	8.05, 7.80	No change	Ambient temperature versus 4°C warming	Fu *et al.*, 2007
Diatom				
Pseudo-nitzschia fraudulenta	8.4, 8.2, 7.9	Increased toxicity Higher growth rate	Si limitation	Tatters *et al.*, 2012
Pseudo-nitzschia multiseries	8.38, 7.94	Increased toxicity		Sun *et al.*, 2011
Diatom-dominated assemblages		Increased primary production		Tortell *et al.*, 2008
Thalassiosira weissflogii	8.10, 7.8			Shi *et al.*, 2009

Coccolithophores				
Emiliania huxleyi	Various levels	Increased growth		Riebesell *et al.*, 2000; Rost *et al.*, 2003; Leonardos and Geider, 2005
Dinoflagellates				
Prorocentrum minimum	8.28 to 8.01 (based on T, DIC, CO_2)	Higher carbon fixation rates growth unaffected		Fu *et al.*, 2008

		CALCIFICATION	
Species	pH	Effect	Reference
Emiliania huxleyi	8.2-7.75 ~8.5-~7.9	Reduced calcite production Increased POC production reduced PIC/POC	Riebesell *et al.*, 2000; Zondervan *et al.*, 2001; For list see Ridgwell *et al.*, 2009 and Hoppe *et al.*, 2011
Emiliania huxleyi Strain NZEH	8.15, 8.13, 7.96, 7.85, 7.77	Increased PIC production by 80% Increased POC by 150% No change in PIC/POC	Iglesias-Rodriguez *et al.*, 2008
Emiliania huxleyi Strain RCC1256 Strain NZEH	Numerous experiments 8.44 - 7.2	No change in POC production 10% Reduced calcification between 288 to 1206 µatm, lower growth No change in growth, slightly reduced calcification and POC	Hoppe *et al.*, 2011;
Emiliania huxleyi Strain NZEH	8.10, 7.8	36% increase in PIC 69% increase in POC	Shi *et al.*, 2009
Emiliania huxleyi	Various experiments from 8.45 to 7.77	35% reduction in calcification between 200 and 900 µatm No change in POC Optimum response in POC	Langer *et al.*, 2009
Emiliania huxleyi		Independent of light limitation reduction in PIC/POC, POC independent of light PIC decrease with increasing CO2 at high light, Unaffected at low light	Zondervan *et al.*, 2002
Emiliania huxleyi	8.02, 7.82	Under nitrogen limitation: reduced calcite production and reduced POC, smaller cell volume	Sciandra *et al.*, 2003
Emiliania huxleyi mescosm		40% decrease in net community calcification from 175 to 600 ppmV CO_2 no change in NPP Calcite formation decreased with CO_2 concentration, reduction of weight of liths, Increased TEP formation from 190, 410 to 710 ppmV CO_2	Delille *et al.*, 2005; Engel *et al.*, 2005
Calcidiscus leptoporus	8.74, 8.44, 8.27, 8.13, 7.93, 7.86 8.33, 8.34, 7.72, 7.6, 7.49, 7.86	Optimum calcification at 400ppm Optimum calcification between 400-900 ppm various methods in altering carbonate chemistry	Langer *et al.*, 2006 Langer *et al.*, 2011
Coccolithus pelagicus	8.56, 8.22, 7.81	No significant change	Langer *et al.*, 2006
Gephyrocapsa oceanica	8.2-7.75	Reduced calcite production, reduced PIC/POC	Riebesell *et al.*, 2000; Zondervan *et al.*, 2001

Table 6-7: Examples illustrating species vulnerabilities and underlying mechanisms to changing temperature, hypoxia, ocean acidification (OA).

General pattern	Phenomenon	Driver	Mechanism / Sensitivity	References
Species displacement, regime shifts abundance losses	Northward shift in the distribution of North Sea cod (*Gadus morhua*) stocks	Winter/spring warming (*high confidence*)	Bottlenecks of high sensitivity during early life stages as well as adult spawning stage in winter/early spring	Perry *et al.*, 2005; Pörtner *et al.*, 2008
	Decreased abundance of northern temperate species, increased abundance of southern species in the Bay of Biscay (France)	Increasing annual mean temperatures at 100 m depth.	Bottlenecks of high sensitivity during recruitment	Hermant *et al.*, 2010
	Shift from sardines (*Sardinops melanostictus*) to anchovies (*Engraulis japonicus*) in the Sea of Japan observed between 1993 and 2003	Warming (*high confidence*) at the interdecadal scale	Thermal windows of growth and reproductive output are found at higher temperatures for anchovies than sardines, food preferences of the competing species being similar.	Li *et al.*, 1992; Takasuka *et al.*, 2007, 2008
	Bigeye (*Thunnus obesus*), skipjack (*Katsuwonus pelamis*), albacore (*T. alalunga*), yellowfin (*Thunnus albacares*) or bluefin tuna (*T. maccoyli*), mildly affected by warming trends, shifting core habitat, abundances, and heat stress of spawners projected.	Wide specific thermal ranges (Bigeye 11-29, skipjack 17-30, yellowfin 18-31 or bluefin tuna 10.5-21, albacore 13-25°C; optimal thermal window narrowest and warmest during spawning, effects of reduced primary productivity.	– Eurythermal tissue characteristics, large body size, wide roaming ranges. – Larvae most sensitive to water temperature, widening their thermal habitat as they grow. – Adults at spawning stage need to prevent overheating, a shift in location to cooler waters may occur to maintain spawning success, e.g. in surface-dwelling skipjack tuna.	Katz, 2002; Pörtner, 2004; Lehodey *et al.*, 2011; Hazen *et al.*, 2012
	Variable sensitivity of Pacific tuna species to the availability of dissolved O_2. Bigeye tuna routinely reach depths where ambient O_2 content is below 1.5 ml L^{-1} (≈ 60 µmoles kg^{-1}).	Species specific exposures and tolerances to hypoxia, related to feeding activity in hypoxic zones.	Oxygen transport via hemoglobin is adapted to be highly efficient supporting high metabolic rates as needed during feeding in the OMZ.	Lehodey *et al.*, 2011; Seibel, 2011
	Variable sensitivities to OA within and across animal phyla (Figure 6-9 B)	Anthropogenic OA, Sea water acidification by elevated pCO_2 in OMZs, upwelling areas, involving	– Lowered extracellular (blood plasma) pH causing a lowering of the rates of ion exchange and metabolism in muscle	Reipschläger and Pörtner, 1996; Pörtner *et al.*, 2000; Vezzoli *et al.*, 2004; Langenbuch and Pörtner, 2003;

		anthropogenic ocean acidification.	or liver (hepatocytes) of vertebrates and invertebrates. – High sensitivity at reduced energy turnover in tissues and/or whole organism by – reduced ion exchange, – use of more energy efficient transport mechanisms, – reduced protein synthesis, enhanced nitrogen release from amino acid catabolism and protein degradation, – slower growth	Fernández-Reiriz *et al.*, 2011; Langenbuch and Pörtner, 2002; Langenbuch *et al.*, 2006; Michaelidis *et al.*, 2005; Pörtner *et al.*, 1998; Stumpp *et al.*, 2012
			Further affected fitness-relevant processes: – gonad maturation, – egg fertilization, – egg haching, – brooding success, – larval development, – critical transition phases in development (onset of feeding, moulting), – larval and adult calcification and growth, – neuronal metabolism and functioning, behaviors (feeding, disorientation and distortions in olfactory and acoustic perceptions) – immune response, – exercise performance	Bibby *et al.*, 2008; Boyd and Burnett, 1999; Chan *et al.*, 2011; Dupont *et al.*, 2008; Kurihara and Shirayama, 2004; Kurihara, 2008; Havenhand *et al.*, 2008; Hernroth *et al.*, 2011; Kawaguchi *et al.*, 2011; Michaelidis *et al.*, 2005; Munday *et al.*, 2009c, 2010; Nilsson *et al.*, 2012; Pörtner, 2002b; Reuter *et al.*, 2011; Reipschläger *et al.*, 1997; Sewell and Hofmann, 2011; Shirayama and Thornton, 2005; Simpson *et al.*, 2011; Walther *et al.*, 2010.

Table 6-8: Examples of observed biological responses resulting from temperature and temperature-mediated changes in the ocean.

Responses and attribution	References
Species abundance, biogeography and diversity	
Observations by the European Large Marine Ecosystems study report the northward movement of species and the conversion of polar into more temperate and temperate into more subtropical system characteristics. Effects are attributed to climate change but may be influenced by nutrient enrichment and overfishing. Due to the lack of geographical barriers and to advective processes, the mean poleward movement of plankton reached up to 200–250 km per decade between 1958–2005.	Beaugrand *et al.*, 2009; Philippart *et al.*, 2011
Retreat of colder water plankton to the north in the Northeast Atlantic between the 1950s and 2000s.	Beaugrand *et al.*, 2002
Between 1960 and 2000 the Newfoundland Shelf in the Northwest Atlantic saw an increase in the abundance of arctic boreal plankton species, notably the copepods *Calanus hyperboreus* (Kroyer), *Calanus glacialis* (Jaschnov) and the dinoflagellate *Ceratium arcticum* due to an increased contribution of Arctic water via the shelf branch of the Labrador Current. In 1996, a dramatic drop in the NAO allowed a flood of cool Labrador slope water to round the tail of the Grand Bank, carrying *C. hyperboreus* along the Scotian shelf-break, to reach Georges Bank two years later.	Johns *et al.*, 2001; Greene and Pershing, 2003
In the Southwest Atlantic sector and the Bellingshausen Sea a historical analysis of the distribution of Antarctic macrozooplankton between 1925 and 1951 demonstrated the key role of temperature and differential thermal windows in setting distribution ranges. Food (chlorophyll *a*) availability codefined the distribution of krill (*Euphausia superba*).	Mackey *et al.*, 2012
NAO-driven variability in growth rate has been documented for the Atlantic quahog, *Arctica islandica* from Iceland, the coralline alga *Clathromorphum compactum* off Newfoundland and the bivalve *Clinocardium ciliatum* in the Barents Sea (combined NAO and ACRI). A role for temperature has yet to be unequivocally demonstrated.	Schöne *et al.*, 2005; Carroll *et al*., 2011; Halfar *et al.* 2011
A benthic fish species, the eelpout (*Zoarces viviparus*) at its southern distribution limit, the German Wadden Sea, displayed abundance losses during warming periods and rising summer extreme temperatures, with early disappearance of the largest individuals.	Pörtner and Knust, 2007
Studies of tropical coral reefs document large scale bleaching (6.2.2.4.4.), growth reductions and decreased calcification in *Porites* and other corals over the last two decades, a change unprecedented in the last centuries largely induced by warming.	Lough, 2008; De'ath *et al.*, 2009; Cooper *et al*., 2012
The giant kelp *Macrocystis pyrifera* off the eastern north Pacific has shown changes in both distribution and abundance during major El Niño events (Tegner and Dayton, 1987; Tegner et al., 1996), with particularly strong consequences and widespread mortality at its southernmost distribution limit off Baja California.	Ladah *et al*., 1999; Valdez *et al*., 2003
In the Northwest Atlantic the majority of fish caught in trawl surveys show a northward movement in response to warming since the 1960s, with some of the shifts being correlated with the AMO.	Nye *et al*., 2009; Lucey and Nye, 2010; Nye *et al*., 2011

Responses and attribution	References
Phenology	
In the waters around the U.K., during a period of warming between 1976 and 2005, the seasonal timing of biological events of all major marine taxonomic groups (plant/phytoplankton, invertebrate and vertebrates) advanced on average, by 0.31 to 0.43 days year^{-1}	Thackeray *et al*., 2010.
Migration time of pink salmon (*Oncorhynchus gorbuscha*) in Alaska is almost two weeks earlier now relative to 40 years ago which is related to warming. This is related to the rapid microevolution for earlier migration timing.	Kovach *et al*., 2012
Body size	
Asymptotic size of different populations of Atlantic cod (*Gadus morhua*) and Atlantic Herring (*Clupea harengus*) are negatively related to temperature.	Taylor, 1958, Brunel and Dickey-Collas, 2010
Decrease in asymptotic size of haddock (*Melanogrammus aeglefinus*) in the North Sea from the 1970s to the 2000s is significantly related to changes in sea surface temperature.	Baudron *et al*., 2011
Trophic and competitive interactions	
Both warming and the decreasing spatial extension of krill habitat benefits the salp (Pakhomov, 2004) and may also govern the on-going reductions in Adelie and chinstrap penguin populations via reductions in prey availability.	Trivelpiece *et al.*, 2011.
Direct effects of warming on both, the Atlantic cod and the putative copepod prey species of juvenile cod are involved in climate effects on Atlantic cod (*Gadus morhua*) populations in the Eastern North Atlantic. The regime shift in the North Sea, from the larger copepod *Calanus finmarchicus* to ones forming lower biomass including *C. helgolandicus* represent an unfavorable shift to less energy dense food particles for juvenile cod and to a later timing for reproduction, such that *Calanus* eggs and nauplii are less abundant as food for newly hatched cod larvae. This shift was thereafter shown to be largely caused by temperature.	Beaugrand *et al*., 2003; Helaouët and Beaugrand, 2007
Significant community-wide changes in abundance and composition among 150 intertidal and subtidal algae and invertebrates resulted from direct effects of temperature on key taxa as well as indirect effects through ecological interactions after long-term warming by 3.5 °C from 1985 to 1995 at a power station in temperate California. In the Californian intertidal after warming by 0.79-1.26 °C within 60 years (1931-1933 vs. 1993 -1996) southern species increased and northern decreased in abundance, in line with range-related community shifts.	Sagarin *et al.*, 1999
The relative ranges of predator (sea stars) and prey (mussels and barnacles) change in response to climatic differences reflecting and leading to associated changes in interactions and modifications in predator pressure.	Harley, 2011
In tropical seas, turf algae can rapidly colonize thermally damaged corals depending on the extent to which coralline red algae, which are the most important substrate for coral recruitment, suffer from ocean acidification.	Doropoulos and Diaz-Pulido, 2013; Fricke *et al*., 2011; Hoegh-Guldberg *et al*., 2007

Table 6-9: Potential interactions between modes of anthropogenic forcing (environmental; harvesting; or complex; considering scales and velocity of change, frequency and variability of events, intensity) on different levels of biological organisation. These interactions, from simple to complex, are illustrated with published illustrative examples ranging from physiological studies (Pörtner and Knust, 2007) to modelling studies such as Griffith *et al.*, (2011). E, O, and M denote studies using manipulation Experiments (lab or field), Observations, or Modelling approaches, respectively; note there are an insufficient number of studies to assign a level of confidence to each of these findings "???" defines the bounds on our understanding of the relationship between forcing and its effect on organisational level.]

Anthropogenic Forcing

Biological Organisation studied at ecosystem level	*Single Environmental Driver*	*Multiple Environmental Drivers*	*Fishing / Foodwebs*	*Fishing / Climate change*
Individual species	Lab experiments and field observations show that warming alters organismal physiology and thereby, in situ abundance (Pörtner and Knust, 2007) E & O	Shipboard manipulation experiment addressing interactive effects of temperature and CO_2 on coccolithophore calcification (Feng *et al.*, 2009) E	Interactive effects of multiple drivers on larval fish (Perry *et al.*, 2010; Runge *et al.*, 2010) O & M	???
Population	Lab cultures show how altered pH elicits different responses of coccolithophore species (Langer *et al.*, 2006) E	Lab cultures show differential responses of cyanobacterial groups to temperature and CO_2 (Fu *et al.*, 2007) E	Altered maturation age and growth rate of populations due to fishing (Fairweather *et al.*, 2006; Hseih *et al.*, 2006) O	???
Ecosystem	Mesocosm experiments simulating the effect of individual drivers (e.g. ocean acidification, benthic: Christen *et al.* 2013; pelagic: Riebesell *et al.*, 2013) E, O or M	Mesocosm experiments studying differential effects of light and temperature, on copepods versus diatoms (Lewandowska and Sommer, 2010) E	Effects of fishing on ecosystem structure – trophic cascades (Frank *et al.*, 2005) O	Interplay of fishing and climate pressures on ecosystems promotes lower trophic levels (Kirby *et al.*, 2009) O; enhances diversity loss in benthic communities (Griffith *et al.*, 2011) M
Biome	Time-series observations on warming and the alteration of zooplankton biomes (Beaugrand *et al.*, 2009) O	???	???	???

Table 6-10: Challenges for the oceans that will arise from the employment of a range of geoengineering methods (SRM, solar radiation management, CDR, carbon dioxide removal).

Topic	Brief Description	Challenge and Impact	References
Solar radiation management techniques	Deflection of approximately 1.8 per cent of sunlight, by various techniques, is able to offset the global mean temperature effects of a doubling of atmospheric carbon dioxide content from preindustrial values	Will leave ocean acidification unabated (*high confidence*). Response of primary production to light reduction unclear.	Crutzen, 2006; Caldeira and Wood, 2008
Ocean storage by direct injection	Capture of CO_2 post-combustion from mainly coastal power plants, followed by injection of liquid CO_2 by pipeline or from a ship into the deep ocean.	Will add to ocean acidification and create localized harm to marine life (*high confidence*). Quantities will be small relative to the atmospheric invasion signal. CO_2 injected will dissolve and be transported by ocean circulation with eventual surface exposure.	Caldeira *et al.*, 2005
Sub-sea geologic storage	Capture of CO_2 from extracted gas or from post-combustion followed by well injection into a porous submarine aquifer beneath impermeable geologic strata.	Extensive experience in place from the Norwegian Sleipner field activity in the North Sea. No evidence of ocean impact from leakage to date.	Benson *et al.*, 2005
Ocean Fertilization	Spreading of trace amounts of reduced iron, over very large areas of the surface ocean where excess nutrients occur. Overcoming the local iron deficiency creates extensive phytoplankton blooms drawing down sea surface pCO_2. Fertilization can also be carried out by using direct or indirect (ocean pipes) addition of macronutrients to oceanic regions where they are depleted.	Much of the exported organic matter is remineralized at shallow depths creating local oxygen stress and shallow CO_2 enrichment, methane and N_2O production. These effects are temporary and the effective retention time is short. If sustained, reduced surface-ocean and increased deep-ocean acidification. O_2 loss in ocean interior (*medium confidence*).	de Baar *et al.*, 1995; de Baar *et al.*, 2005; Pörtner *et al.*, 2005; Boyd *et al.*, 2007; Buesseler *et al.*, 2008; Law, 2008; Cao and Caldeira, 2010
Artifical upwelling or downwelling	Ocean fertilization by bringing nutrient rich deep water (from 200 - 1000 m) to the surface. Downwelling occurs in parallel, transporting physically dissolved CO_2 into the deep ocean.	Deep water contains high levels of CO_2, which if released counteracts the binding of CO_2 by fertilization. No evidence available.	Lovelock and Rapley, 2007 Oschlies *et al.*, 2010
Sequestration of organic carbon	Storage of terrestrial biomass in the coastal or deep ocean	Physical impact, regional loss of oxygen, CO_2 accumulation and acidification during degradation, increases in methane, N_2O and H_2S. No evidence available.	Metzger and Benford, 2001; Strand and Benford, 2009
Carbonate neutralization	Dissolution of power plant flue gas into sea water yielding an acidic solution which is neutralized by addition of crushed limestone. The resulting bicarbonate rich fluid is discharged to the ocean.	Involves the transport and crushing to fine scale of large quantities of limestone and the processing of very large quantities of sea water. Environmental impact issues not yet explored.	Rau, 2011
Accelerated olivine weathering	Uses wind powered electrochemical processes to remove HCl from the ocean and neutralizes the acid with silicate minerals such as olivine for disposal. The net result is to add alkalinity to the ocean akin to natural silicate weathering processes.	Complex system as yet untested in pilot processes. Involves mining and crushing large quantities of silicate minerals. Very long time scale consequences uncertain.	House *et al.*, 2007; Köhler *et al.*, 2010

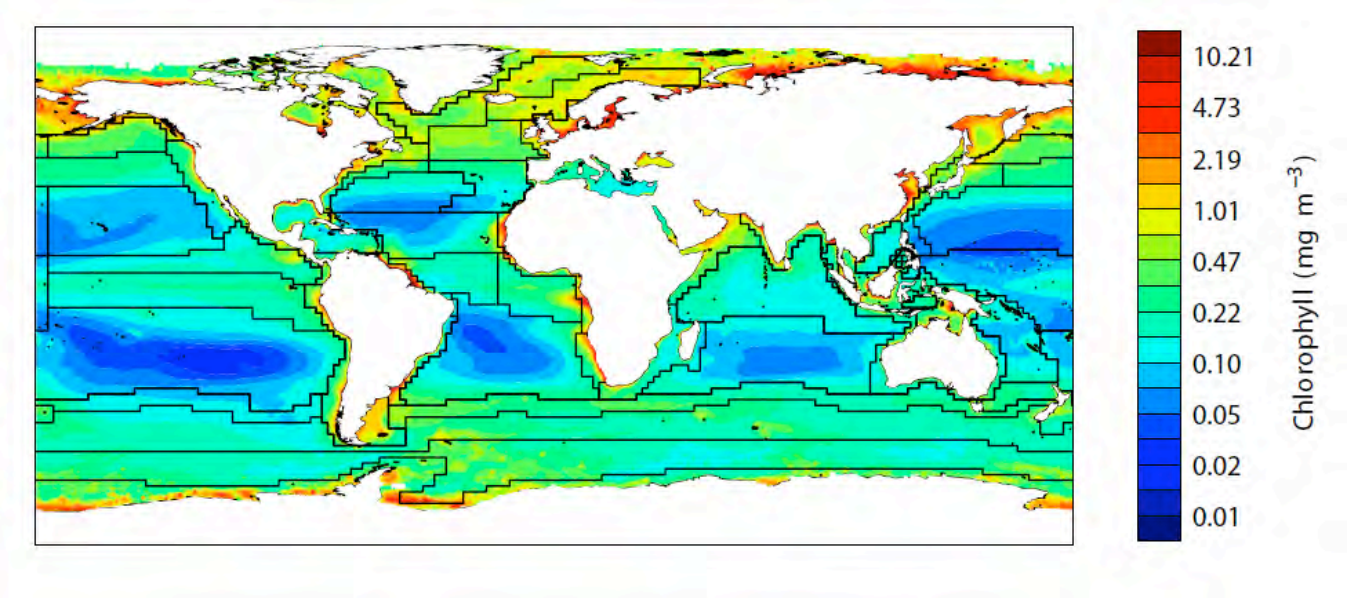

Figure 6-1: Productivity in 51 distinct global ocean biogeographical biomes as represented by a grid of thin black lines (after Longhurst, 1998), overlain with an average annual composite plot of chlorophyll *a* concentration, i.e., a proxy for phytoplankton stocks in the upper ocean, from the NASA/Orbimage SeaWiFs satellite (Bailey *et al*., 2006; McClain *et al*., 2004; McClain, 2009). The characteristics and boundaries of each biome are primarily set by the underlying regional ocean physics and chemistry. Together, these provinces or biomes span several orders of magnitude in chlorophyll *a* from < 0.1 mg m^{-3} that characterize the low latitude oligotrophic regions (denoted by purple and blue) up to 10 mg m^{-3} in highly productive coastal upwelling regions in Eastern boundary currents (denoted by red).

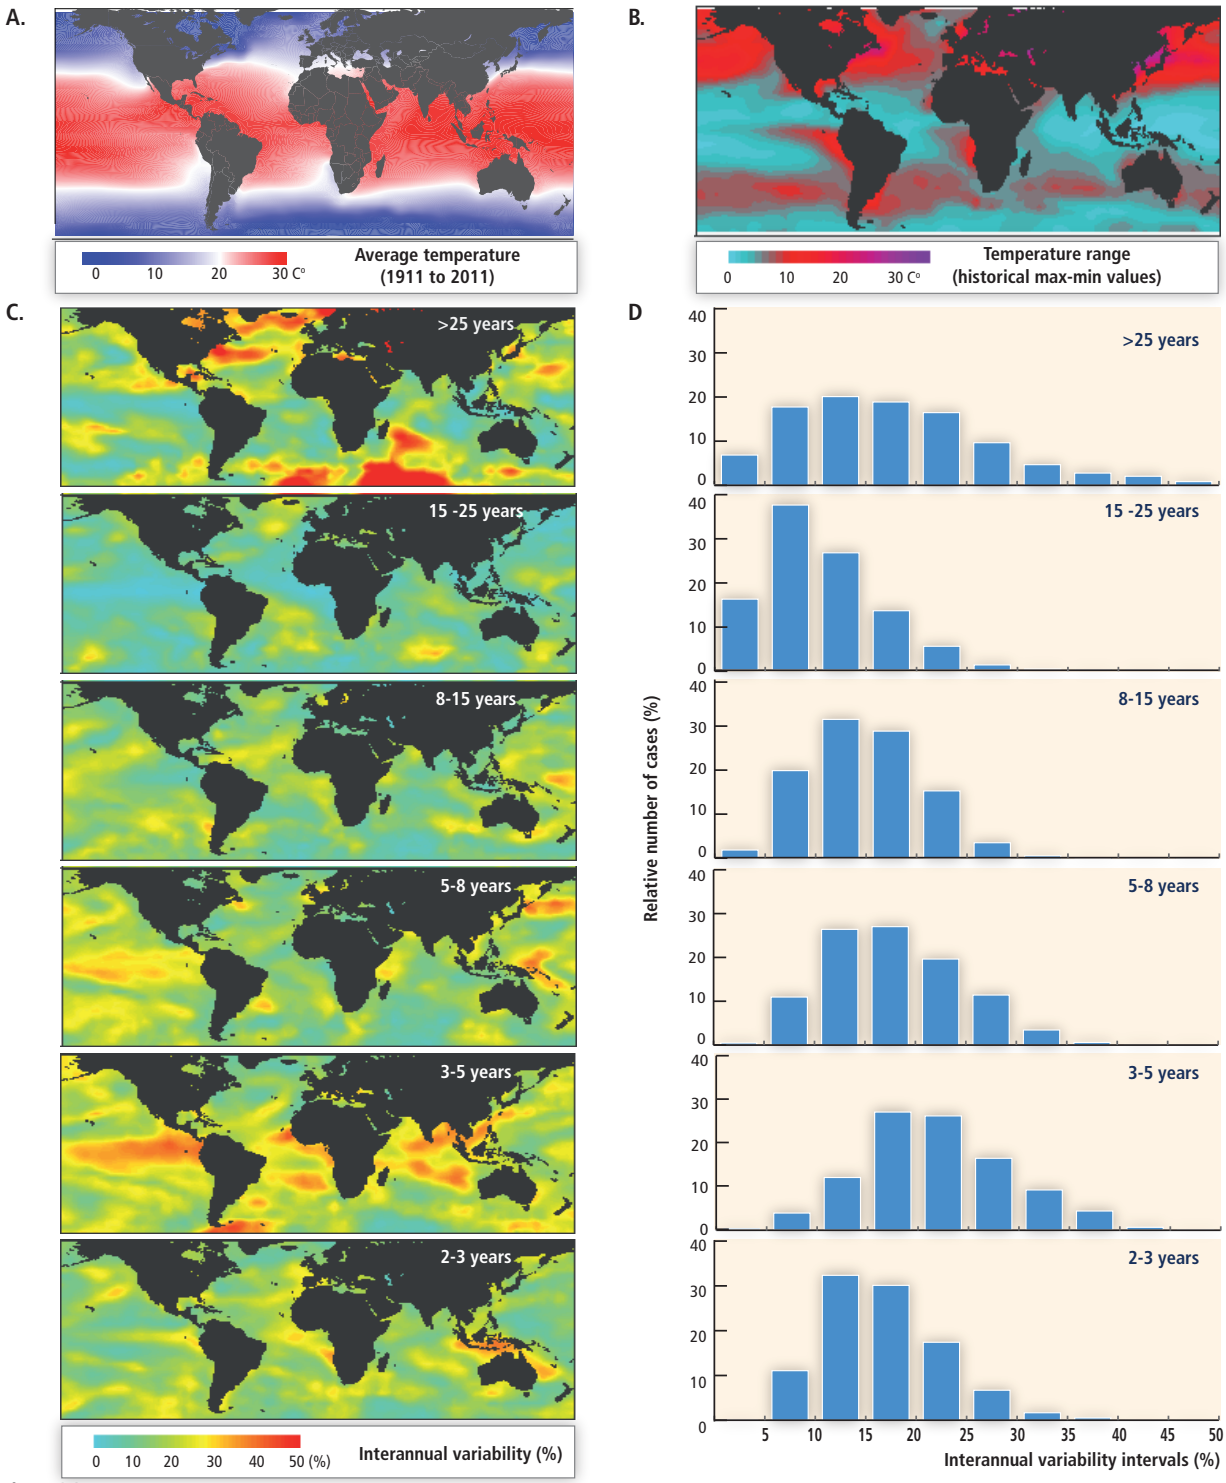

Figure 6-2 | Last Century sea surface temperature variability. A) The long term (1911 to 2011) sea surface temperature average. B) The temperature range calculated as the difference between the historical maximum and minimum values for each grid component. C) The spatial distribution of variability by time scales was computed by accumulating the relative spectral densities of each 2°x2° grid box frequency-transformed series by frequency windows, corresponding to the multidecadal (period >25 years), bidecadal (15 to 25 years), decadal (8 to 15 years), low ENSO frequency (5 to 8 years), high ENSO frequency (3 to 5 years) and very high frequency (2 to 3 years) scales. The sum of the six maps at every single box corresponds to 100% of the interannual time series variability. D) The relative number of cases (grid boxes) at each temperature class intervals. The class intervals represent fractions of the temperature range at each variability scale. The sum of all cases for each histogram accounts of the 100% of the area, and the sum of all the temperature fractions from all histograms accounts for the total temperature ranges shown in the upper right map. All computations are based on the Extended Reynolds Sea Surface Temperature (NOAA, 2012).

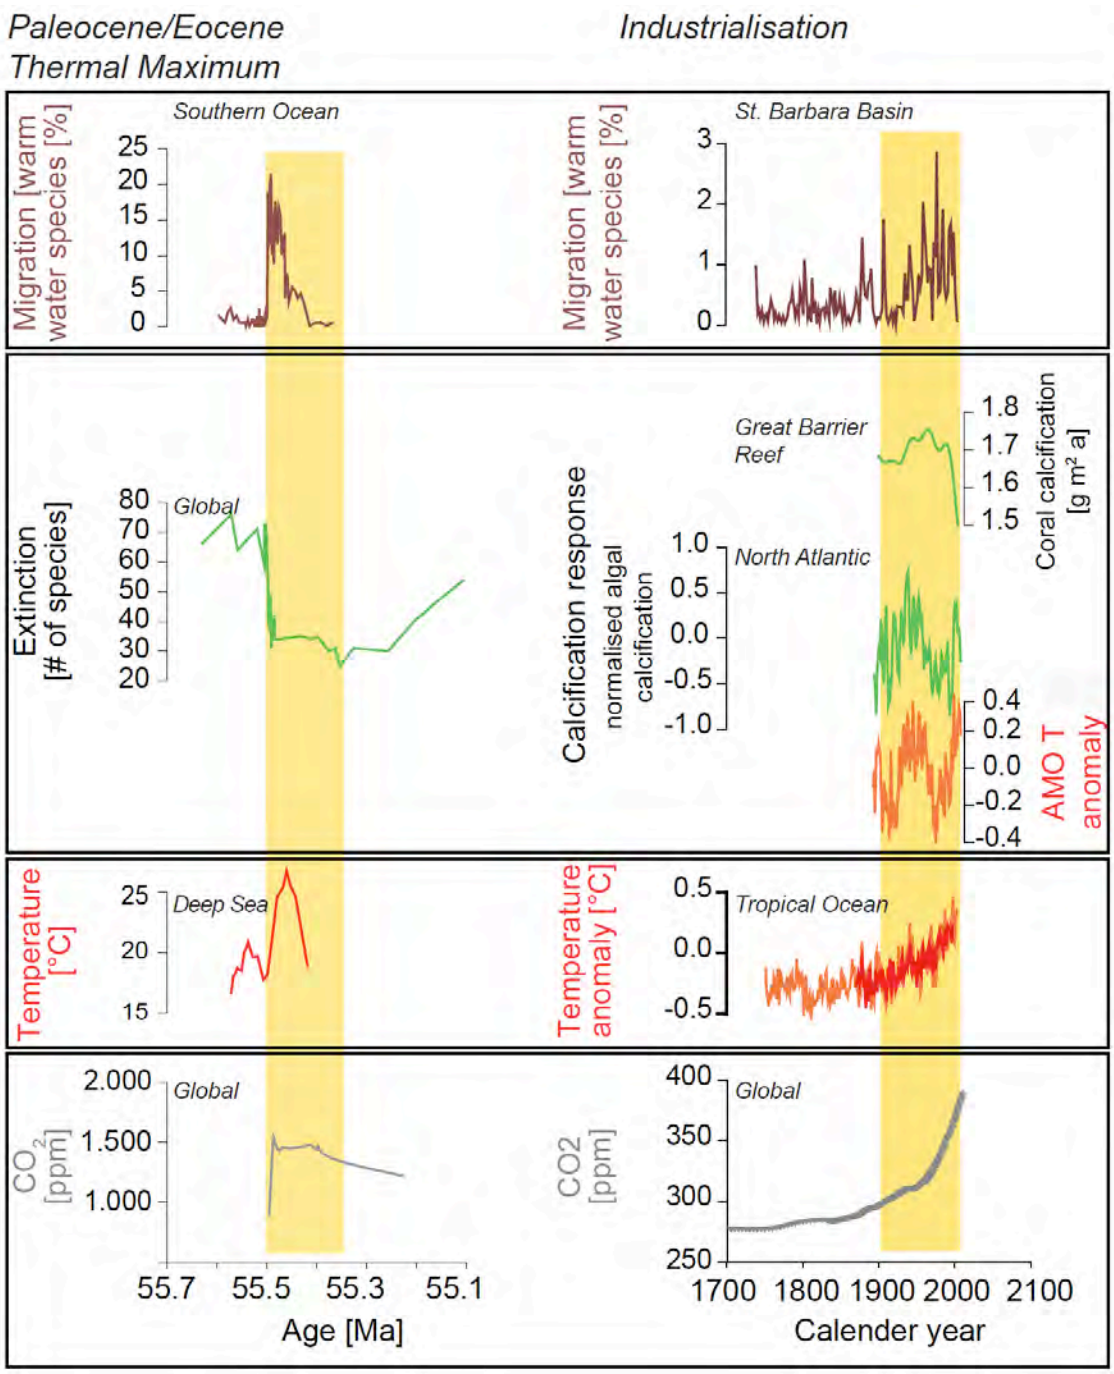

Figure 6-3: Atmospheric CO_2 (bottom, grey) and temperature (middle, red/orange) changes with associated biotic changes (top) for the Paleocene Eocene Thermal Maximum (PETM) and the industrial era. Episodes of largest environmental change are indicated with yellow bars. CO_2 data are based on measurements at Mauna Loa (modern: Keeling *et al.*, 2005) and model output (PETM: Ridgwell and Schmidt, 2010; Zeebe *et al.*, 2009). Temperature data are based on proxy data (modern: Wilson *et al.*, 2006; Lea *et al.*, 2003; PETM: Kennett and Stott, 1991) representing the regional temperature changes in the surface ocean. Modern biotic responses include changes in coralline algal growth (Halfar *et al.*, 2011), and coral calcification (De'ath *et al.*, 2009). Evolutionary changes are exemplified by the extinction of benthic foraminifera (Thomas, 2003). Abundance data (top row) of planktonic foraminifera and coccolithophores (modern: Field *et al.*, 2006; PETM: Bralower, 2002) indicate range expansion due to warming.

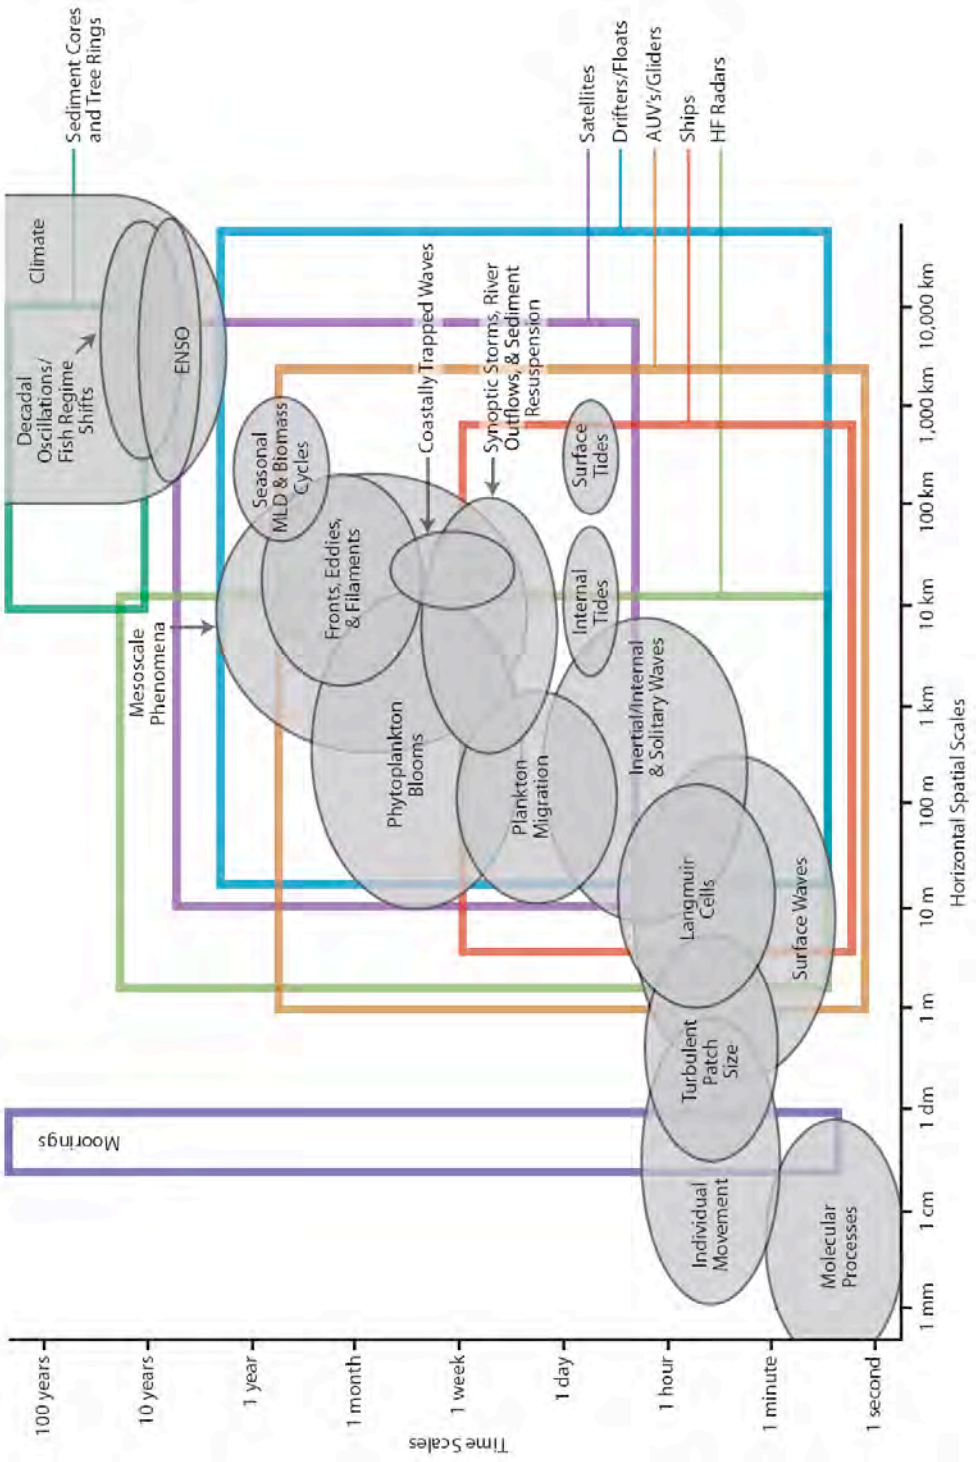

Figure 6-4: Multiple coupled temporal and spatial scales of variability in physical, physiological and ecological processes of interest in contemporary marine system research. Observations over broad time and space scales are necessary to separate natural variability from impacts due to human-induced effects, and define the observation tools that are necessary to obtain relevant data. The shaded regions depict the approximate boundaries of major processes of interest, and the boxes define the scales of selected measurement/observation procedures. Langmuir cells are a series of wind-driven shallow, slow, counter-rotating circulations at the ocean's surface. From Karl (2010), as modified from Dickey (1991).

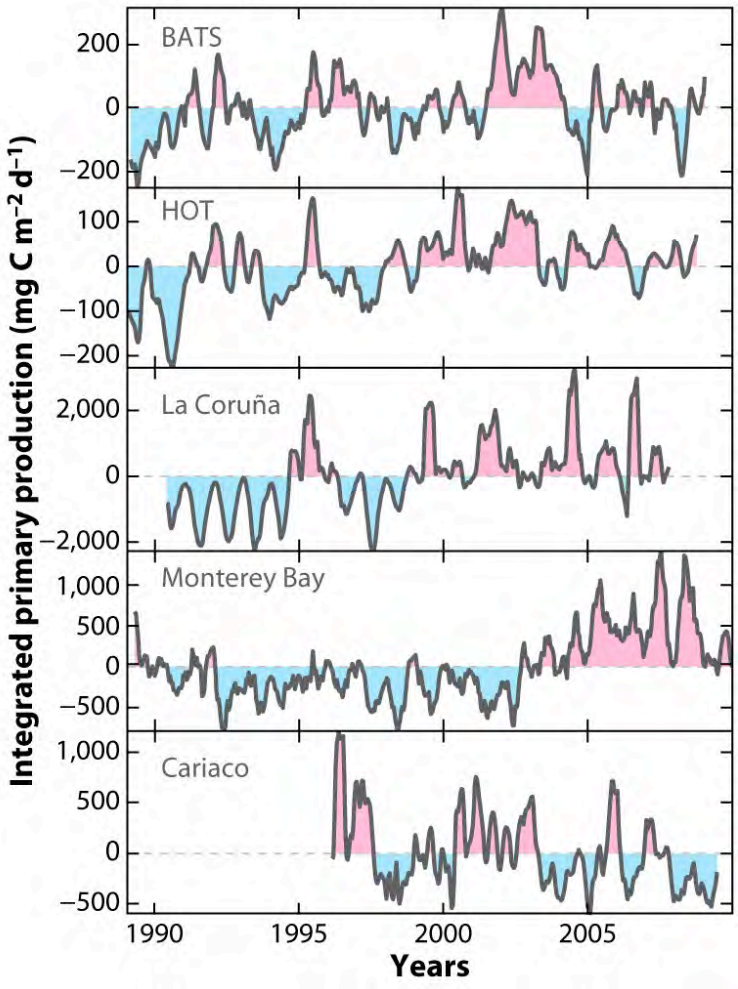

Figure 6-5: Time-series of water column integrated primary production (PP) anomalies at: Northwestern Spain, La Coruña (43° 25.2 N, 8° 26.4 E); HOT (22° 45 N, 158°W); BATS (31° 50 N, 64° 10 W); Monterey Bay, Central California Current (37°N, 122°W); Cariaco Basin, Venezuela (10°30 N, 64°40 W), reproduced from Chavez *et al.* (2011). Anomalies were calculated by integrating over the water column, then interpolating to 14 d, smoothing with a moving average and differencing for each 14-d interval from the grand mean for that interval. All sites except Cariaco seem to show positive (pink) PP anomalies after 2000.]

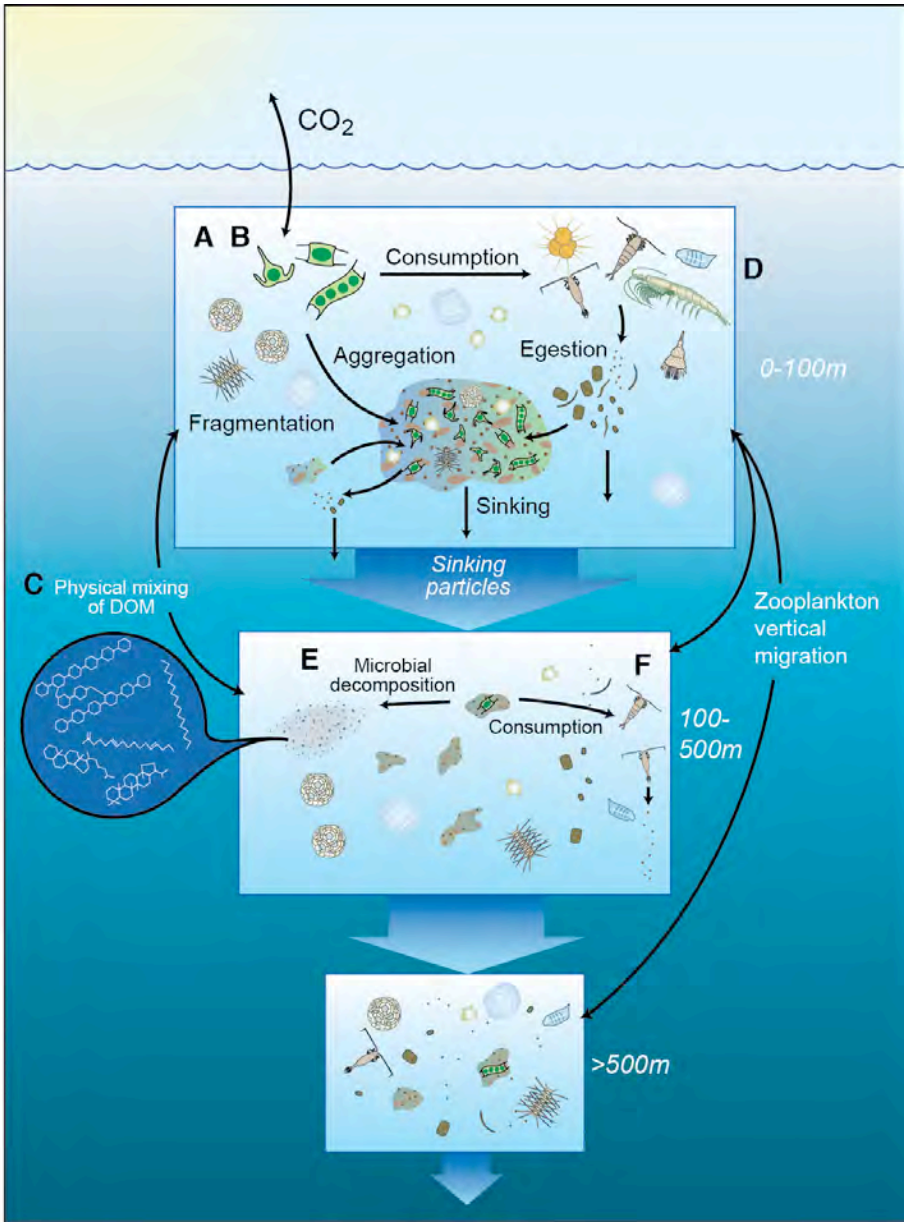

Figure 6-6: A schematic representation of the ocean's biological pump, which responds to climate change and is a relevant conduit for carbon sequestration. It is difficult to project how the pump might be altered (Table 6-4) and whether it would represent a positive or negative feedback to climate change which causes: A, shifts in NPP (Net Primary Production; Bopp *et al.*, 2002); B, floristic and faunistic shifts in the pelagic (Beaugrand *et al.*, 2009) that may alter the relationship between OA and ballasting of settling particles (Klaas and Archer, 2002); C, changes in proportion of NPP released as DOM (Dissolved Organic Matter) due to the effects of ocean acidification (Engel *et al.*, 2004); E, warming and faster bacterial enzymatic rates of particle solubilization (Christian and Karl, 1995); and faunistic shifts at depth (Jackson and Burd, 2001). Modified from Buesseler *et al.* (2008) by J. Cook (WHOI).

Figure 6-7: Mechanisms linking organism to ecosystem response explain the why, how, when and where of climate sensitivity (based on knowledge for animals, after Pörtner, 2001, 2002a, 2012; Pörtner and Farrell, 2008, blue to red colour gradients illustrate transition from cold to warm temperatures). (A) As all biota, animals specialize on limited temperature ranges, within which they grow, behave, reproduce, defend themselves by immune responses. Optimum temperatures (T_{opt}) indicate performance maxima, pejus temperatures (T_p) the limits to long-term tolerance, critical temperatures (T_c) the transition to anaerobic metabolism, and denaturation temperatures (T_d) the onset of cell damage. These OCLTT thresholds (see text) can shift by acclimatization (horizontal arrows). Under elevated CO_2 levels and in hypoxic waters performance levels can decrease and windows of performance be narrowed (dashed green arrows pointing to dashed black curves). (B) Thermal range widths (horizontal arrows) change between individual life stages of a species. (C) The shift of performance curves between polar, temperate and tropical animal species reflect evolutionary adaptation to the respective climate zones. Via species-specific effects on performance (dashed curves, cf. A), additional stressors and species interactions cause shifts in higher-level processes (seasonal activities in response to light or temperature cues, shifts in predator-prey interactions and competition within changing coexistence ranges of interacting species). (D) Shifts in biogeography result during climate warming (modified after Beaugrand, 2009). The polygon delineates the range in space and time, the level of grey denotes abundance. Species display maximum productivity in southern spring, wide seasonal coverage in the centre and a later productivity maximum in the North. The impact of photoperiod increases with latitude (dashed arrow). During warming, the southern temperature and time window contracts while the northern one dilates (directions and shifts indicated by arrows). Control by water column characteristics or photoperiod may overrule temperature control in some organisms (e.g. diatoms), causing contraction of spatial distribution in the north.

Figure 6-8

Figure 6-8: Ranges of temperatures and O_2 concentrations covered by various domains and groups of free living marine organisms (bacteria to animals, domains and groups modified after Woese *et al*.,1990) in various habitats (Storch *et al*., subm.). High organizational complexity enables an increase in body size, associated with decreasing tolerances to hypoxia and heat. In the domain Bacteria, the group Thermotogales comprises obligate anaerobes, displays less complex structures such as a single layer lipid membrane and is most tolerant to high temperatures. Highest temperatures of growth were found at 122°C in hydrothermal vent species under elevated hydrostatic pressure in laboratory experiments. Dashed white arrows denote wide O_2 tolerances in unicellular archeae, bacteria and protists, as compared to animals and plants (multicellular eukarya). Anoxic habitats are conquered by small multicellular and unicellular Eukarya, supported by less complex mitosomes or hydrogenosomes used in energy metabolism. Species richness of animals (upper right) increases with rising O_2 levels reflecting better hypoxia tolerance in small compared to large individuals and their taxa (6.3.3.).

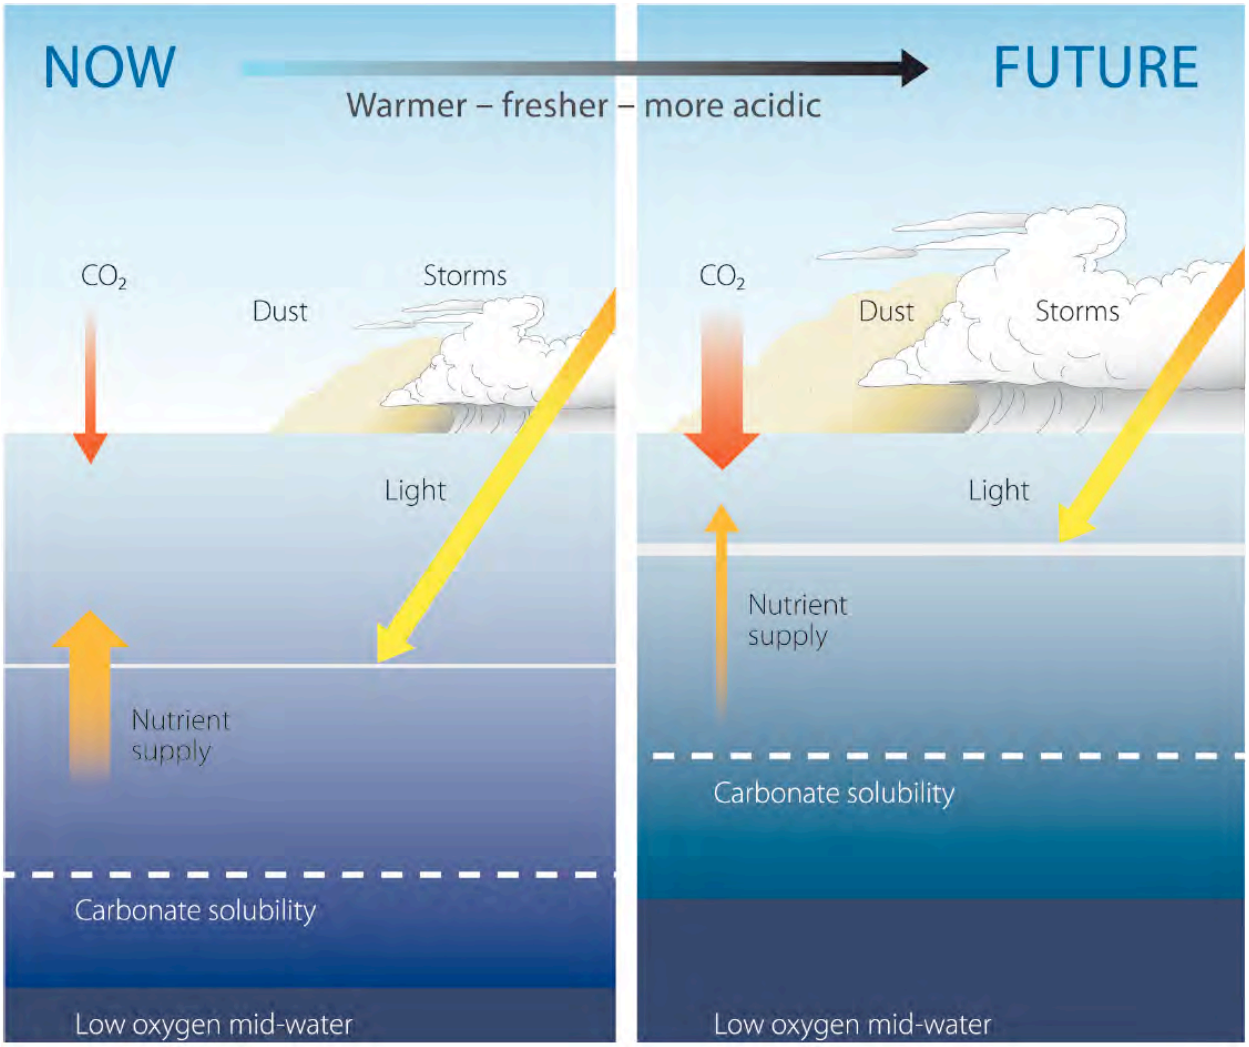

Figure 6-9: Projected alteration of oceanic properties and atmospheric events due to a changing climate. Properties will be altered across the water column, from the mid-water stratum to the sunlit surface layer, and will influence the fitness of the residence biota. Changes in storm activity and dust deposition will influence ocean physics and chemistry, with consequent effects on ocean ecosystems (courtesy of Boyd and Law, 2011).

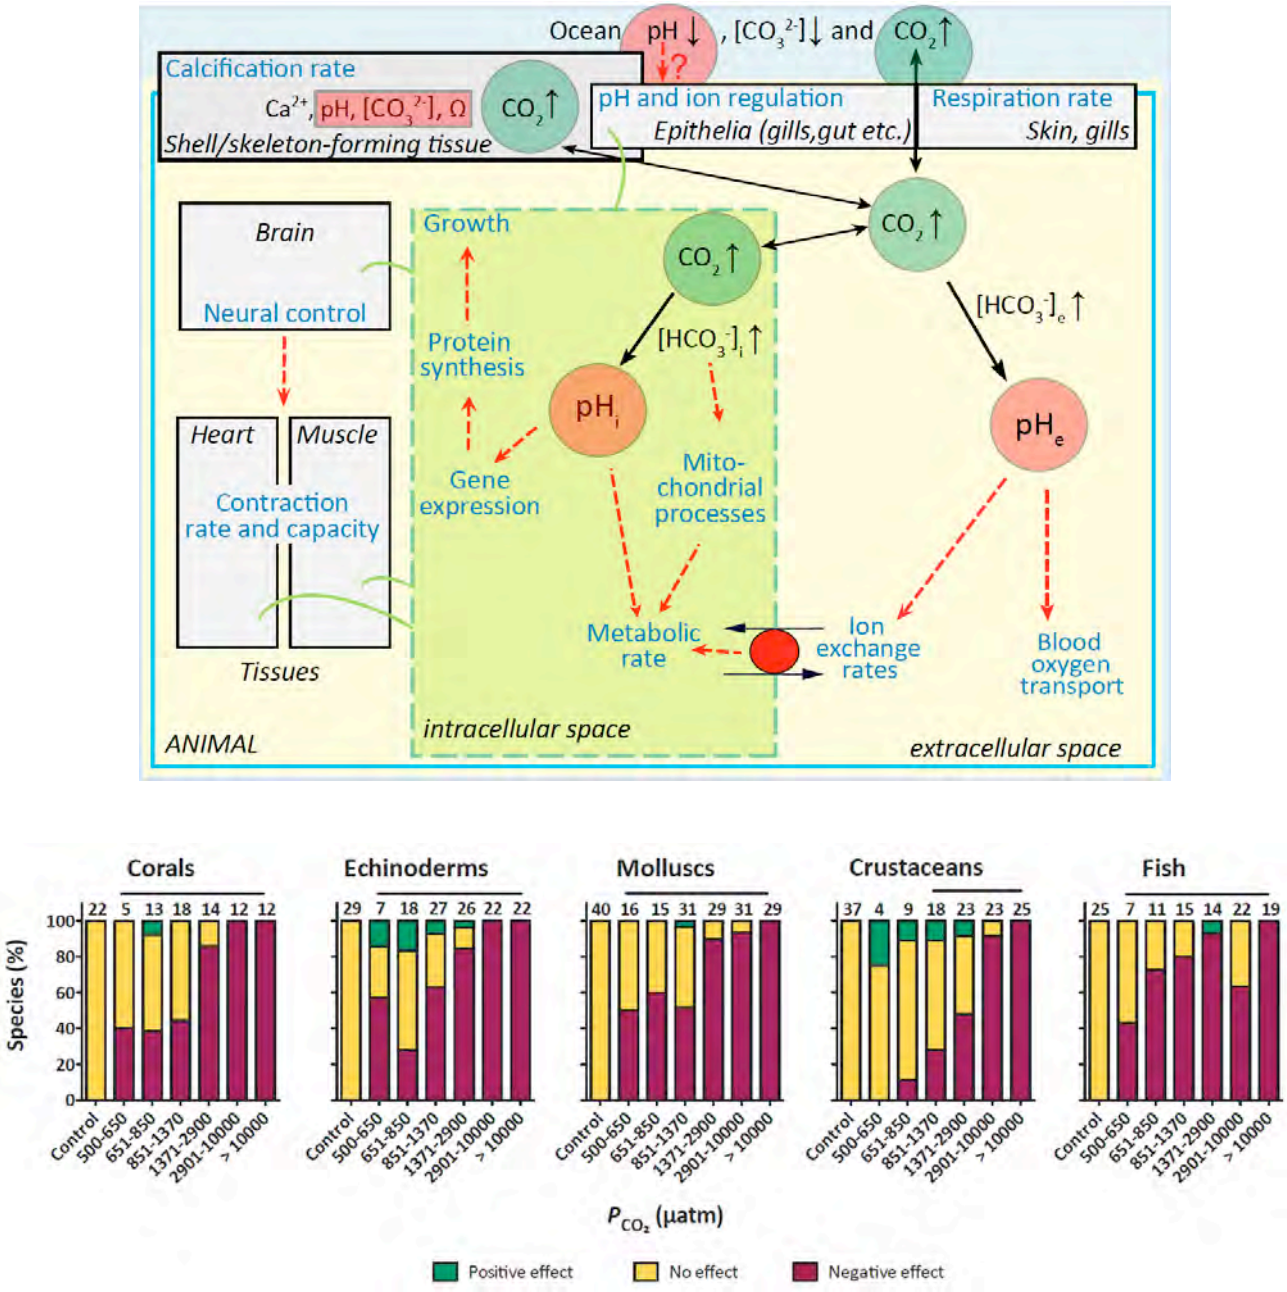

Figure 6-10: Top: Responses of a schematized marine animal (blue line) to ocean acidification (OA). Effects are mediated via diffusive entry of accumulating CO_2 (dark green, black arrows) into body compartments, resulting in a drop in compartmental pH (highlighted in red) and its effects (red dashed arrows) on various processes (light blue) as well as calcium carbonate saturation state (Ω) at calcification sites (after Pörtner, 2008). Variable sensitivity depends on the degree of pH decline and compensation, depending on the capacity of transmembrane ion transport. Bottom: % fraction of studied scleractinian coral, echinoderm, molluscan, crustacean and fish species affected negatively, positively or not at all by various levels of ambient CO_2. Effects considered include those on life stages and processes reflecting physiological performance (O_2 consumption, aerobic scope, behaviours, scope for behaviours, calcification,

growth, immune response, acid-base balance, gene expression, fertilization, sperm motility, developmental time, production of viable offspring, morphology). As not all life stages, parameters and pCO_2 ranges were covered in all species two assumptions partially compensate for missing data: 1) Negative effects at low pCO_2 will remain negative at high pCO_2. 2) A positive or neutral outcome at both low and high pCO_2 will be the same at intermediate pCO_2. As responses reported for each species vary for each CO_2 range, variable species numbers result (on top of columns). The total number of species studied for a given group is represented as the number above the control column. Horizontal bars above columns represent frequency distributions significantly different from controls (from Wittmann and Pörtner, subm.).

Figure 6-11

Figure 6-11: **A**. Long-term changes in the ecosystem state based on 5 biological parameters (phytoplankton colour index, mean size of calanoids, mean calanoid diversity, an index of change in plankton composition and cod recruitment). The orange line denotes the mean ecosystem state for the period prior and after the abrupt ecosystem shift. **B**. Long-term changes in the multiscale temporal local variance of the ecosystem state (in red). High values indicate pronounced year-to-year changes in the ecosystem state. The light gray band shows the unstable period (1980-1989). **C**-**D**. Observed mean annual sea surface temperature in the North Sea during 1960-1981 (**C**) and 1988-2005 (**D**). The location of the critical thermal boundary (9-10°C) is indicated by '+'. **E.** Long-term changes in the mean number of warm-temperate pseudo-oceanic species from 1958 to 2005. **F.** Long-term changes in the mean number of temperate pseudo-oceanic species from 1958 to 2005. The period 1958-1981 was a period of relative stability and the period 1982-1999 was a period of rapid northward shifts, indicating that the abrupt ecosystem shift observed in the North Sea was part of a large-scale response of the zooplankton biodiversity to warming temperatures (see **A**-**D**). Average values are below 1 because they are annual averages. Note that the color bar is 10-fold smaller for warm-temperate pseudo-oceanic species because these species are less frequently observed than their temperate counterparts. From Beaugrand *et al*. (2008) and Beaugrand *et al*. (2009).

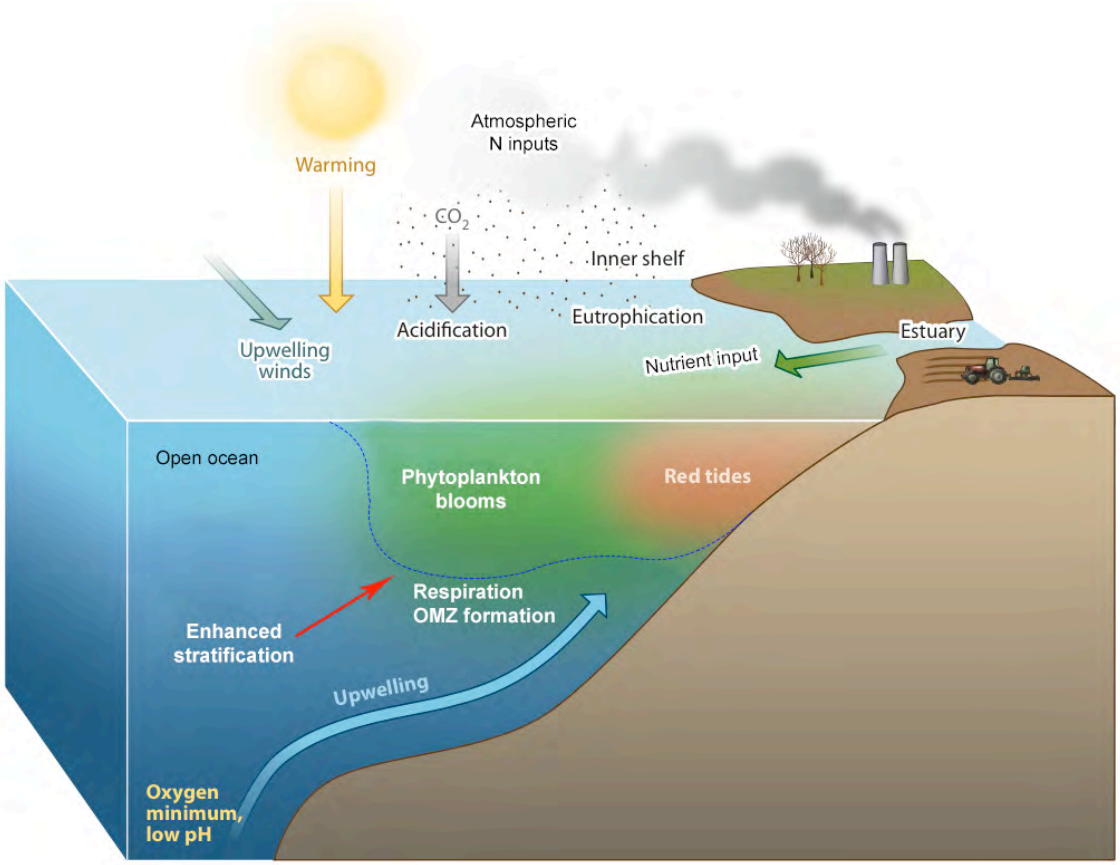

Figure 6-12: Schematic illustrating the principal mechanisms underlying the formation of hypoxic conditions and their biological background (modified from Levin *et al.* 2009; Levin and Sibuet, 2012). The buoyancy flux from fluvial discharges produces sharp density stratification at the base of the freshened layer (also valid for icemelt, high precipitation) near the surface and, hence, vertical mixing is greatly reduced. In consequence, the nutrient inputs from the river and the atmosphere accumulate in a narrow upper layer, leading to phytoplankton blooms. The enhancement of oxygen consumption due to respiratory catabolism of sinking organic matter results in hypoxic conditions of OMZs. Heating of the upper layer further increases stratification, while the wind-driven upwelling of hypoxic, nutrient-rich water from deeper layers adds to the formation of the oxygen minimum zone.

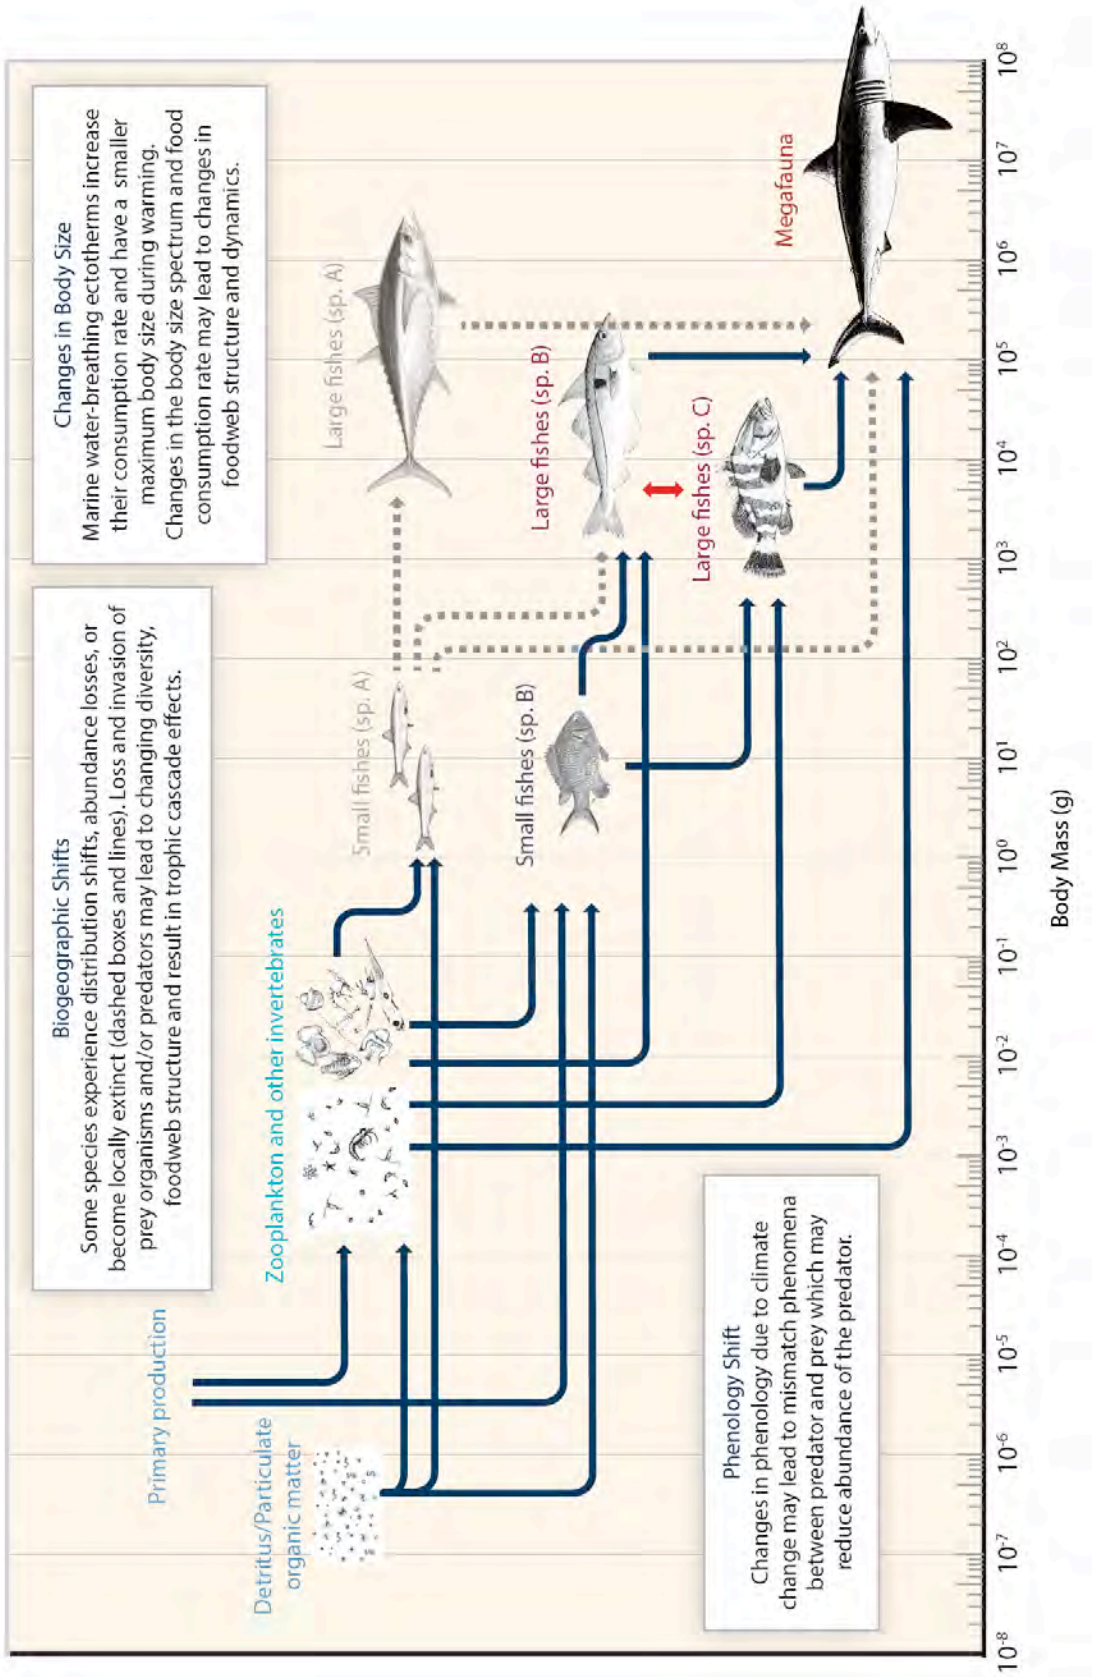

Changes in Body Size
Marine water-breathing ectotherms increase their consumption rate and have a smaller maximum body size during warming. Changes in the body size spectrum and food consumption rate may lead to changes in foodweb structure and dynamics.
Biogeographic Shifts
Some species experience distribution shifts, abundance losses, or become locally extinct (dashed boxes and lines). Loss and invasion of prey organisms and/or predators may lead to changing diversity, foodweb structure and result in trophic cascade effects.
Phenology Shift
Changes in phenology due to climate change may lead to mismatch phenomena between predator and prey which may reduce abundance of the predator.

Figure 6-13

Figure 6-13: Schematic diagram of a marine foodweb and the expected responses to climate change including ocean acidification. A coupled pelagic and benthic foodweb is typically structured by the body size spectrum of species. Warming, hypoxia and ocean acidification lead to biogeographical shifts, changes in species abundance and in the dynamics of trophic interactions. The foodweb resulting from climate change includes reductions in the body size of organisms, changes in species composition and the resulting reconfiguration of trophic linkages. Fishing generally removes large-bodied and vulnerable species and truncates the body size spectrum of the community. As a result, the detection and attribution of foodweb responses to climate change are strongly confounded by fishing effects. The arrows represent species interactions (e.g., between predator and prey or competition for food or space). Broken lines (boxes and arrows) indicate the loss of populations and trophic linkages due to climate change.

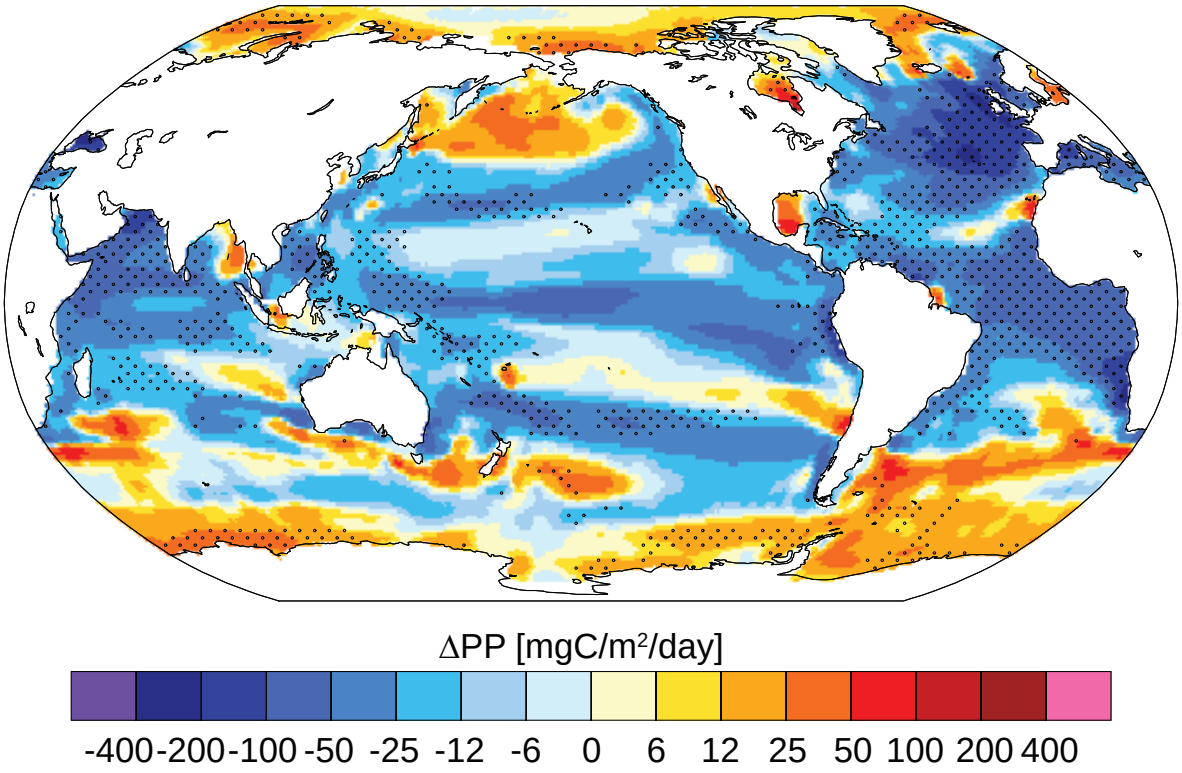

Figure 6-14: Multi-model mean changes of projected vertically-integrated net primary production (small and large phytoplankton). To indicate consistency in the sign of change, regions are stippled where all four models agree on the sign of change. Changes are annual means under the SRES A2 scenario (between RCP6.0 - 8.5) for the period 2080 to 2099 relative to 1870 to 1889, after Steinacher *et al.* (2010).

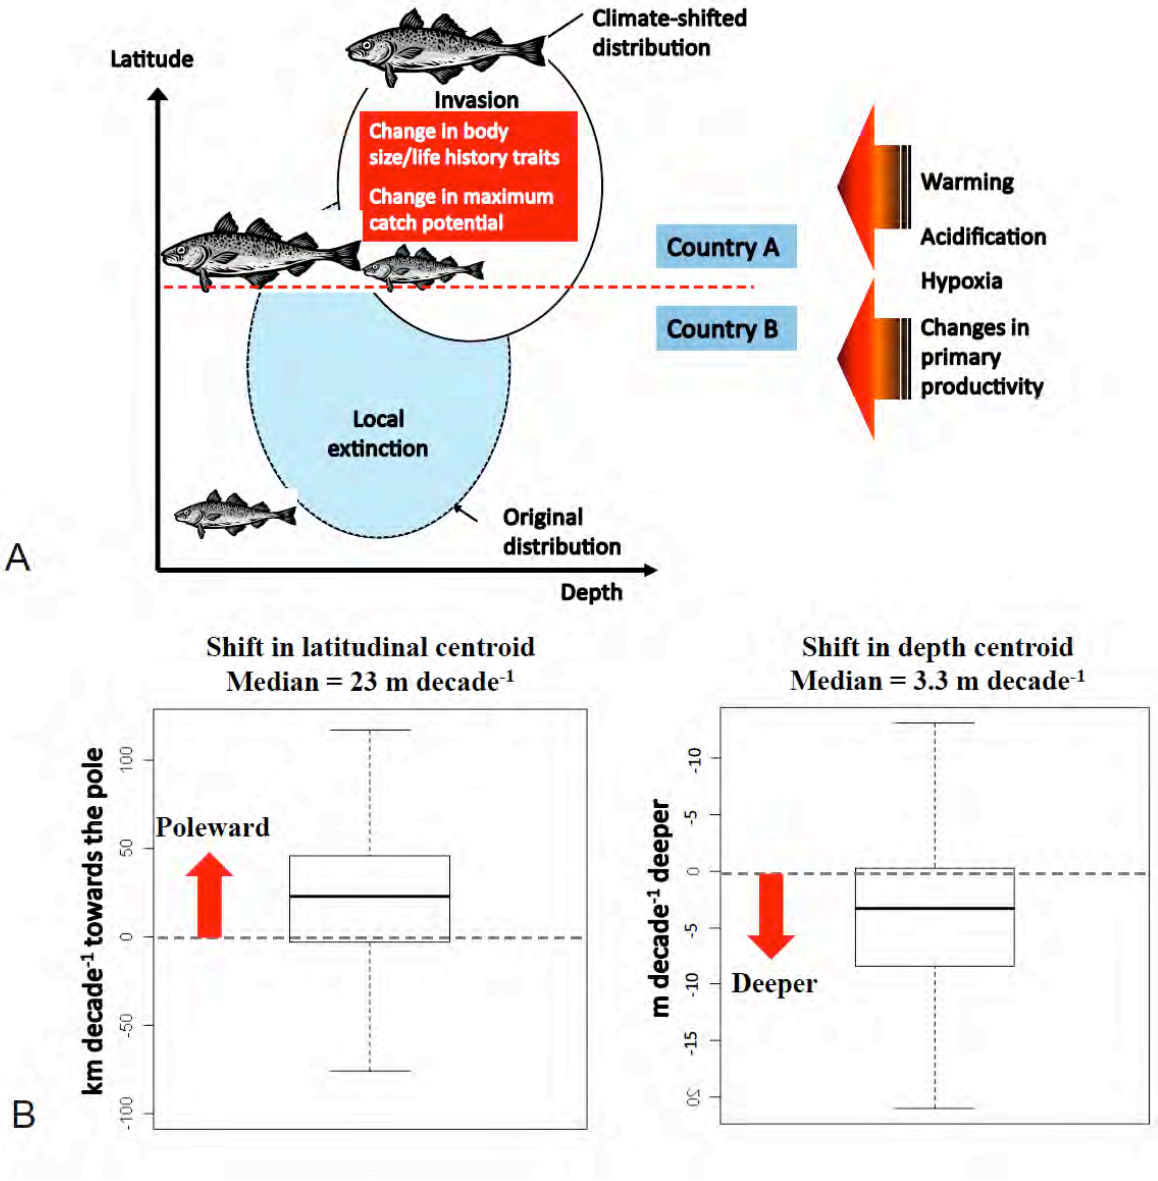

Figure 6-15 A, B

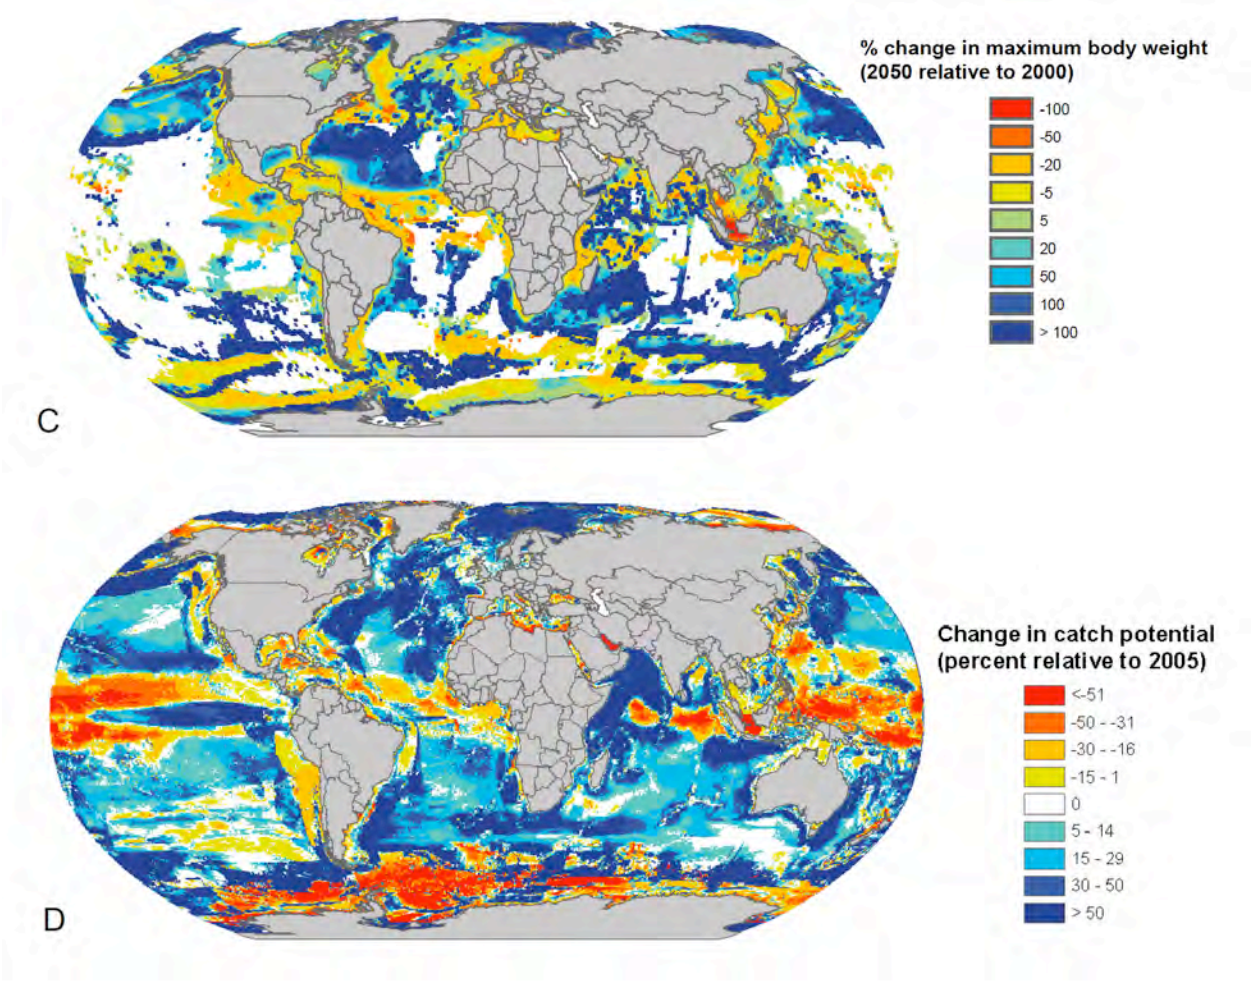

Figure 6-15: Scenarios of climate change effects on the biogeography, biology and fisheries catch potential of marine fishes and invertebrates. (A) Hypothesis of changes in distribution, biology and fisheries catch potential of fish stocks under climate change. (B) Example of a projected rate of shift in distribution range along latitude and depth for 610 exploited demersal fish species from 1991-2010 to 2041 – 2060 under the SRES A2 scenario (Cheung et al., 2011; Cheung et al., 2012a). (C) Projected change in the maximum body size of 610 species of marine fishes from 2000 to 2050 under the SRES A2 (between RCP6.0 - 8.5) scenario (Cheung et al. 2012a). The white area is not occupied by the sampled species. (D) Example of projections of maximum fisheries catch potential of 1000 species of exploited fishes and invertebrates from 2000 to 2050 under the SRES A1B scenario (redrawn from Cheung et al., 2010)

Figure 6-16

Figure 6-16: Overview of the levels of confidence in detection (left), as well as in projection (right) of climate change effects on ocean systems, in relation to the levels of confidence in attributing these effects to the respective climate forcings. Some climate change impacts have been condensed into rather broad categories in order not to overpopulate the figure (e.g. **BG**, **B**io-**G**eochemical Processes). Note that the term attribution is not only used in the context of detections but also for projections. Projections include both qualitative and quantitative extrapolations and simulations from fundamental principles and models. Experiments (field, laboratory and modeling) simulating future conditions may enhance the respective confidence levels above those for detection which refers to present day observations in the field. The empirical observations resulting from those experiments are then attributable to the respective drivers. Confidence rises further if these experiments identify the affected mechanisms and their response to future conditions. See text for further discussion of the depicted examples and categories. Confidence assignments focus on the nature and size of effects, not on the capacity of models to reliably quantify their magnitude.

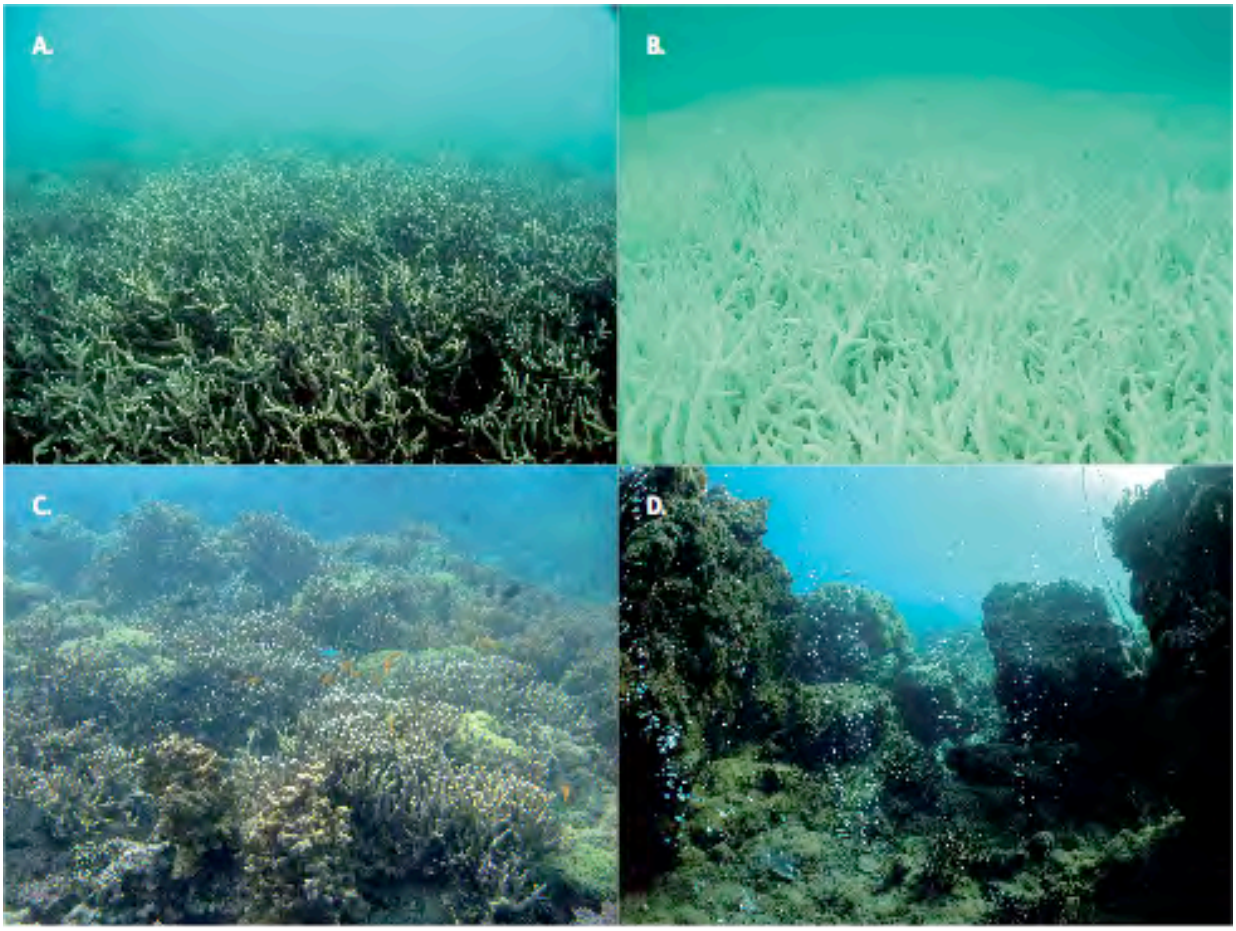

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge et al., 2004). Mortality was comparatively low due in part because these communities were able shuffle symbiont types to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones et al., 2008). C and D: three CO2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO2 is related to fundamental changes in coral reef structures (Fabricius et al., 2011). Coral communities at three high CO2 (Fig. XB; median pHT 7.7, 7.7 and 8.0), compared with three control sites (Fig. XA; median pHT 8.02), are characterized by significantly reduced coral diversity (-39%), severely reduced structural complexity (-67%), low densities of young corals (-66%) and few crustose coralline algae (-85%). Reef development ceases at pHT values below 7.7. Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

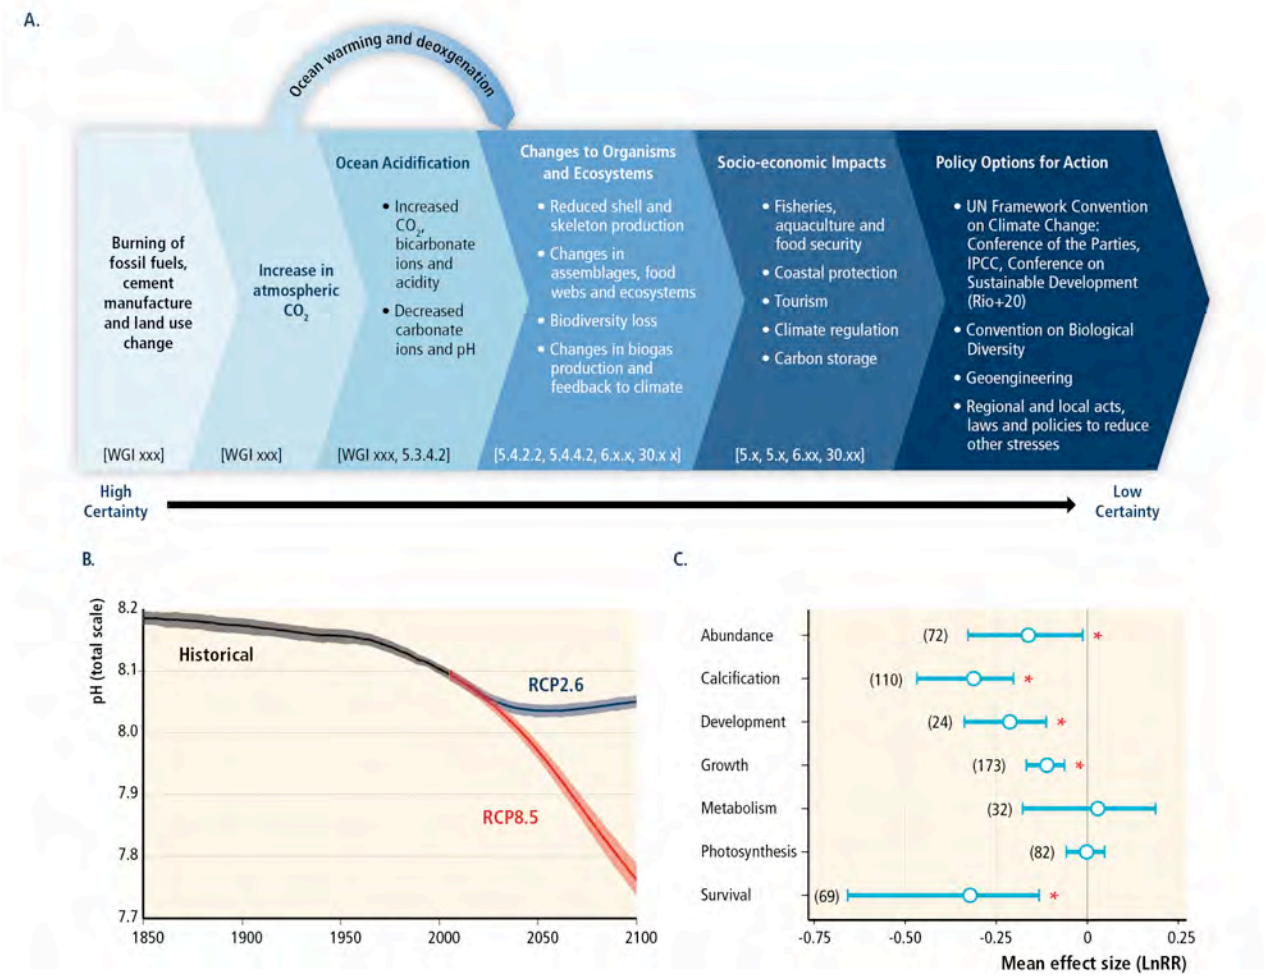

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.

Executive Summary

The effects of climate change on food production are already evident in several regions of the world (*medium evidence, high agreement*). Negative impacts of climate trends have been more common than positive ones, although the latter predominate at high latitudes (*high confidence*). Since AR4, there have been several periods of rapid food price increases, demonstrating the partial sensitivity of current markets to climate variability. The role of climate change in these recent price changes is poorly understood, but *likely* small relative to other factors (*medium evidence, high agreement*). Social and economic issues such as energy policy and changes in household income will remain the main drivers of changes in food security in the near-term, regionally and locally. [7.2, Figures 7-2/3/4, Table 7-1]

By mid-century, when the global population will reach about nine billion people, many elements of the food system will be adversely affected by changes in climate (*high confidence*). Thereafter, and with *robust evidence and high agreement,* the human food system at scales from the local to global and particularly in low-latitude lands will be seriously and negatively affected by projected climate change from the mid-21st century onwards. [7.1, 7.2, 7.4] Global arable area is likely to increase from 2007 to 2050 (*medium evidence, high agreement*), with projected increases over this period of between 9% and 25% (*medium evidence, medium agreement*). When the effects of global warming are included, estimates range from a 20% increase in cropping area to a decline of 9% but with large regional differences (*limited evidence, low agreement*). [7.4.1]

Under scenarios of high levels of warming, leading to global mean temperatures of 4-6 ºC or higher above pre-industrial levels, extrapolation from current models suggests that the global risk to food production and security becomes very severe (*medium evidence, high agreement*). Such risks could affect ca. 90% of the global population based on the human population at that time and its demographic distribution (*medium evidence, low agreement*). These effects will be additively compounded by other factors such as the rise in tropospheric ozone

levels (*medium evidence, medium agreement*) and competition for water resources as between agriculture, food systems and other sectors of the economy. [7-4, Figure 7-5]

Long term climate changes are impacting the abundance and distribution of harvested aquatic species, both freshwater and marine, and aquaculture production systems in different parts of the world. [7.2.1.2, 7.3.2.6, 7.4.2] These are expected to continue with negative impacts on nutrition and food security for especially vulnerable people in some regions but with benefits in other regions which become more favourable for aquatic food production (*medium evidence, high agreement*). [7.5.1.1.3]

There is new understanding since AR4 of the sensitivity of crops to extreme heat, which reinforces the importance of temperature changes for determining impacts of climate change on crop yield at regional scales (*medium evidence, medium agreement*). At scales of individual countries or smaller, differences in precipitation projections continue to be an important source of uncertainty in future impacts (*medium evidence, high agreement*). [7.3]

Extreme heat also a negative effect on food quality in terms of nutrition and processing (*robust evidence, high agreement*). Impacts of increased heat stress and more frequent extreme events will be negative in all regions for livestock (*robust evidence, high agreement*); changes in animal diseases and vectors are less certain (*medium evidence, medium agreement*). Extreme climatic events, defined as extremely high and low temperatures and droughts and floods, are important for all food and fodder production, but particularly for annual determinate crops in which yield is harvested as seeds *(medium evidence, medium agreement)*. [7.3.2]

Evidence since AR4 confirms the positive effects of CO_2 and negative effects of elevated tropospheric ozone on crop yields (*high confidence*). There is emerging experimental and modelling evidence (*medium evidence, high agreement*) that interactions between production factors such as CO_2 and ozone, mean temperature, extremes, water and nitrogen can alter primary food production in complex ways. In concert with experimental results, the chapter results take more account of model and other uncertainties than has been the case previously. The large number of studies on mean crop yield impacts of changes in climate and CO_2 allow more robust statements than previously possible, but less confidence is given to simulated increases in yield variability (*medium evidence, medium agreement*). [7.3, Figures 7-5/7]

Changes in climate and CO_2 levels will enhance the distribution and increase the competiveness of agronomically important and invasive weeds (*robust evidence, high agreement*). Rising CO_2 reduces the effectiveness of herbicides (*medium evidence, high agreement*). The effects of climate change on disease pressure on food crops is uncertain, with evidence pointing to changed geographical ranges of diseases but less certain changes in disease intensity (*medium evidence, low agreement*). [7.3.2.1.2]

Without adaptation, moderate warming of up to 2ºC local temperatures are expected to reduce yields on average for the major cereals (wheat, rice and maize) in temperate regions, although many individual locations may benefit (*medium confidence*). There is confirmation that even modest warming up to 2ºC will decrease yields in low-latitude tropical regions (*robust evidence*, *medium agreement*). Reductions of more than 5% are *more likely than not* beyond 2050 and *likely* by the end of the century. From the 2070s onwards, all of the positive yield changes are in temperate regions, suggesting that yield reduction in the tropics are very likely by this time and substantial, particularly for wheat (*robust evidence, high agreement*). [7-4, Figures 7-5/6/7]

Adaptation possibilities of food systems to climate change show a very wide range in effectiveness, with *medium confidence* that adaptation will increase in effectiveness with increasing local mean temperature up to ca. 3ºC local warming above pre-industrial, after which the net benefits no longer increase (*medium evidence, medium agreement*). Most studies however, have focussed on food production rather than on adapting food systems. Generally (*medium evidence, high agreement,*) adaptation leads to lower reductions in food production than in its absence with an overall crop yield difference in adaptation cases of about 15-20% over non-adaption cases, with more effective adaption at higher latitudes (*limited evidence, medium agreement,)* but with some adaptation options more effective than others. Thus, benefits of adaptation are greater for wheat, rice and maize in temperate rather than tropical regions. Key adaptations for fisheries are for policy and management to maintain ecosystems in

a state that is resilient to change, enabling occupational flexibility, and developing early warning systems for extreme events (*medium evidence, high agreement*). [7.5.1.1.3] Livestock systems' adaptations centre around adjusting management to the available resources, using breeds better adapted to the prevailing climate and removing barriers to adaptation such as improving credit access (*medium evidence, medium agreement*). A range of potential adaptation options exist across all food system activities, not just in the food production, but benefits from potential innovations in food processing, packaging, transport, storage and trade are insufficiently researched. [7.1, 7.5, 7.6, Figures 7-5/9]

In summary, the key messages from the synthesis and evaluation of the current evidence of the impacts of climate change on food security and food production systems and their adaptation are that:

- **The effects of climate change on food production systems and security are starting to be evident. [7.2]**
- **The combination of an extra two billion people who will require upwards of 50% more food by the mid-21st century in combination with predicted decreases in yields of the major cereals for global warming of more than *ca.* 2-3ºC, will put ever increasing pressure on the food system as a whole, even after taking account of calculated uncertainties. [7.1, 7.4]**
- **Adaptation is predicted to be partially effective in ameliorating the negative effects of warming. [7.5]**
- **Extremely high levels of warming (i.e., above 4°C increase in global mean temperature) will place immense pressure on global food security. [7.4]**
- **Climate changes impacts on the abundance and distribution of harvested aquatic species will affect the nutrition and food security for especially vulnerable peoples. [7.3, 7.4]**

7.1. Introduction and Context

Many definitions of food security exist. Maxwell and Slater (2003) noted over 200 as early as 1992 (Spring, 2009) and more have been formulated (Defra, 2006). While many of the earlier definitions centred on food production, the majority of more recent definitions promote the notion of access to food. The 1996 World Food Summit definition (FAO, 1996), which states that food security is met when "*all people, at all times, have physical and economic access to sufficient, safe, and nutritious food to meet their dietary needs and food preferences for an active and healthy life*", is still widely adopted. This definition puts the notion of access to food centre stage, also integrating dimensions of food availability, food utilisation and stability over time. The definition has a focus on the under-consumption of food whereas overconsumption and obesity are also relevant as factors in global public health.

While food security has been on the development agenda for decades, world-wide attention was given considerable impetus by the food 'price spike' in 2007-08, triggered by a complex set of long-term and short-term factors (von Braun and Torero, 2009). According to some estimates, the 'price spike' increased the number of hungry people by some 40 million (FAO, 2008) but other studies report a lower number (Headey and Fan, 2010). This link between food prices and numbers of food insecure people underscores the importance of the affordability of food in relation to food security. There is strong agreement that more than enough food is currently produced *per capita* to adequately feed the global population, yet about 870 million people remained hungry in 2012 (FAO, 2012), and millions more with insufficient nutrient (Pinstrup-Andersen, 2009). The two overriding questions for this chapter are how far climate change adds to current issues in food production systems and food security and the extent that it will do so in the future.

7.1.1. Summary from AR4

Food systems as integrated activities dealing with the impacts of climate change on the supply and demand for food did not feature strongly in AR4, where the strong emphasis was on food, fibre and forest production. Summary points from AR4 were that, with *medium confidence*, in mid- to high-latitude regions moderate warming will raise crop and pasture yields. However, even slight warming will decrease yields in low-latitude regions. Extreme climate and weather events will, with *high confidence*, reduce food production with or without changes in mean conditions. The benefits of adaptation in crops such as changing varieties and/or planting times and other managements enable

avoidance of a 10-15% reduction in yield corresponding to 1-2°C local temperature increase. Adaptive capacity will be exceeded in low-latitude areas with temperature increases of more than 3°C. Local extinctions of particular fish species are expected with *high confidence* at the edges of their ranges and any slowing in the meridional overturning circulation will have serious negative impacts on fisheries with a *medium confidence* level.

7.1.2. Food Systems

A food system includes all processes and infrastructure involved in satisfying a population's food security. It relates to the *Activities* of gathering/catching, growing, harvesting, storing, processing, packaging, transporting, marketing, consuming food, and disposing of food waste and food-related items (the 'food chain'). It also includes the food security *Outcomes* of these *Activities* related to availability and utilization of, and access to, food as well as those related to other socioeconomic and environmental factors. Drawing together the extensive (yet relatively distinct) literatures built up by the food chain and food security communities, respectively, a revised 'food systems' model has been formalised (Ericksen, 2008; Ericksen *et al*., 2010; Ingram, 2011). This model recognises that food systems operate within, are influenced by, and feed back to social, political, economic and environmental contexts (Figure 7-1).

[INSERT FIGURE 7-1 HERE
Figure 7-1: Main global environmental change (GEC) and socioeconomic drivers of food systems, the main food system activities, and the outcomes of these activities. The figure also shows the three main components of food security (circles), all of which need to be stable over time: Availability (with elements of production, distribution and trade); Access (affordability, allocation and preference); and Utilisation (nutritional value, cultural value and safety).]

There is good agreement that the impacts of climate change on food systems are expected to be widespread, complex, geographically and temporally variable, and profoundly influenced by socio-economic conditions (Vermeulen *et al*., 2012). Changes in food system activities give rise to changes in food security outcomes, *(medium evidence, high agreement)* but often researchers only consider the impacts on the food production element of food security. Food security needs consideration of how any intervention (i.e. a change in the food system activities) will also affect all other components of the food security outcomes; in principle, any intervention, even if only targeted at only one component (e.g. availability) will affect all three components due to the dynamic interactions between them, either directly or mediated via the feedback loops in Figure 7-1. Efforts to increase food production are nevertheless increasingly important as 50% more food will be needed by 2030 given current food consumption trends and assuming no significant reduction in food waste (FAO, 2010a).

7.1.3. The Current State of Food Security

There were an estimated 870 million people undernourished during the period 2010-2012, approximately 12.5% of the global population (FAO *et al*., 2012); thus, the vast majority of people currently have sufficient food. The vast majority of the undernourished (852 million) live in developing countries *(medium evidence, medium agreement).* Typically this is estimated based on aggregate national calorie availability and assumptions about food distribution and nutritional requirements. More precise estimates are possible with detailed household surveys, which often show higher incidence of food insecurity than estimated by FAO. Smith *et al*., (2006) estimated average food insecurity rates of 59% for 12 African countries, compared to 39% estimate from FAO for the same period.

While there is *medium evidence, medium agreement* on absolute numbers, there is *robust evidence*, *high agreement* that Sub-Saharan Africa has the highest proportion of food insecure people; with up to 60% of people consuming insufficient calories for an active life. The largest numbers of food insecure are found in South Asia, which has roughly 300 million undernourished (FAO *et al*., 2012). In addition to common measures of calorie availability, food security can be broadened to include nutritional aspects based on the diversity of diet including not only staple foods but also vegetables, fruits, meat, milk, eggs, and fortified foods (FAO, 2011). There is *robust evidence* and

high agreement that lack of essential micronutrients such as zinc and vitamin A affect hundreds of millions of additional (Lopez *et al*., 2006; Pinstrup-Andersen, 2009).

Food insecurity is closely tied to poverty, and more detailed surveys on poverty provide insight into where the food insecure live. Globally, about 25 to 30 percent of poor people – measured using either a $1 or $2 per day standard - live in urban areas (Ravallion *et al*., 2007; IFAD 2010). This is partly because most poor countries have a greater fraction of people living in rural areas, but also because poverty rates tend to be higher in rural settings (by slight margins in South Asia and Africa, and by large margins in China). In Latin America, poverty is more skewed to urban areas, with roughly two-thirds of the poor found in urban areas, a number that has been growing in the past decade *(medium evidence, medium agreement)*. The urban share of poverty has also been rising in other regions, although more slowly. It is expected that rural areas will continue to have the majority of poor people for at least the next few decades, even as population growth is higher in urban areas *(medium evidence, medium agreement)* (Ravallion *et al*., 2007; IFAD 2010).

For urban poor, who produce relatively small amounts of food, increases in food prices generally reduce food security. Since most rural poor produce some portion of the food they consume, the picture is more complicated. Much of the poor's income is from agricultural activities, which stands to benefit if prices rise. As mentioned, however, the rural poor still tend to be net consumers or marginal net producers. That is, they consume nearly all of what they grow and still need to buy additional food. If prices are rising more quickly for crops they grow, they can sell those and buy cheaper calories, resulting in a net increase in well-being. Rural wage rates may also increase in response to higher prices (for example, if workers are paid with a set amount of grain), with benefits for the many who earn part of their income from working other lands. Thus, the long-term welfare effects of price rises on rural poor are complex, and can vary depending on local factors.

The effects of price volatility are distinct from the effects of gradual price rises, for two main reasons. First, rapid shifts make it difficult for the poor to adjust their activities to favour producing higher value items. Second, increased volatility leads to greater uncertainty about the future, and can dampen willingness to invest scarce resources into productivity enhancing assets, such as fertilizer purchases in the case of farmers or rural infrastructure in the case of governments. Several factors have been found to contribute to increased price volatility: poorly articulated local markets, increased incidence of adverse weather events and greater reliance on production areas with high exposure to such risks, biofuel mandates, and increased links between energy and agricultural markets (World Bank, 2012). In some cases, trade interventions intended to reduce domestic food price volatility (e.g. export bans) had adverse effects both in local and global markets (HLPE, 2011; World Bank, 2012). Vulnerability to food price volatility depends on the degree to which households and countries are net food purchasers, the level of integration into global, regional and local markets and their relative degree of volatility, which in turn is conditional upon their respective governance (HLPE, 2011; World Bank, 2012) with *robust evidence* and *medium agreement*.

7.2. Observed Impacts, with Detection and Attribution

7.2.1. Food Production Systems

Food production systems have changed substantially over the past few decades. These changes were primarily the result of factors other than atmospheric CO_2 or climate, such as cultivar improvement and increased use of synthetic fertilizers, herbicides and irrigation. In many contexts the effects of past changes in weather or CO_2 level are viewed as noise that obscures the effects of agronomic or genetic changes. Yet understanding the effect of past CO_2 and climate shifts are a useful precursor to assessing future impacts and adaptation needs.

The number and strength of non-climate drivers of food systems and food security make formal detection and attribution of impacts extremely difficult. Most of these confounding factors, such as fertilizer use or adoption of modern hybrids in the case of crops, are not very well characterized in terms of spatial and temporal distributions, and the relationships between these factors and specific outcomes of interest (e.g., crop production) are often difficult to quantify. Attribution in other food production sectors is equally difficult. No studies to our knowledge simulate historical trends in food-related outcomes with and without changes in anthropogenic emissions of

greenhouse gases. A possible exception (Auffhammer *et al*., 2006) compared rice yield predictions in India using climate model simulations of temperature in the late 20th century with yields using observed temperatures for 1930-1960, the latter period used as a surrogate for climate without changes in greenhouse gases after 1960. In their study, they find rice yields would have been significantly higher without greenhouse gas emissions, thus attributing negative impacts to emissions but with *limited evidence*.

Attributions of crop changes are further complicated by the fact that models linking climate and agriculture must, implicitly or explicitly, make assumptions about farmer behaviour. In most cases, models implicitly assume that farming practices or technologies did not adjust in response to climate over the period of interest. This assumption can be defended in some cases based on ancillary data on practices, or based on small differences between using models with and without adaptation (Schlenker and Roberts, 2009). However, in some instances the relationship between climate conditions and crop production has been shown to change over time because of management changes (Zhang *et al*., 2008; Liu *et al*., 2009; Sakurai *et al*., 2012).

7.2.1.1. Crop Production

Many studies of cropping systems have estimated impacts of observed changes in climate over the past few decades. Based on these studies, there is *medium confidence* (*medium evidence, high agreement*) that climate trends have negatively affected wheat and maize production for many regions, as well as *medium confidence* (*medium evidence, high agreement,*) for negative impacts on global aggregate production of these crops (Figure 7-2). There is also medium confidence (*medium evidence, high agreement*) that effects on rice and soybean yields have been small in major production regions and globally (Figure 7-2). There is also *high confidence* (*robust evidence*, *high agreement)* that warming has benefitted crop production in some cold regions, such as Northeast China or the United Kingdom (Jaggard *et al*., 2007; Supit et al., 2010; Chen *et al*., 2011; Gregory and Marshall, 2012).

[INSERT FIGURE 7-2 HERE
Figure 7-2: Summary of estimates of the impact of recent climate trends on yields for four major crops. Studies were taken from the peer-reviewed literature and used different methods (i.e., physiological process-based crop models or statistical models), spatial scales (e.g., stations, provinces, countries, or global), and time periods (median length of 29 years). Some included effects of positive CO_2 trends (see 7.3.2.1.2) but most did not. (a) shows number of studies with different level of impact (% yield per decade), (b) shows boxplot of studies separated by temperate vs. tropical regions, modelling approach (process-based vs. statistical), whether CO2 effects were included, and crop. Studies were for China (Tao *et al*., 2006; Tao *et al*., 2008; Wang *et al*., 2008; You *et al*., 2009; Chen *et al*., 2010; Tao *et al*., 2012), India (Pathak *et al*., 2003; Auffhammer *et al*., 2012), United States (Kucharik and Serbin, 2008), Mexico (Lobell *et al*., 2005), France (Brisson *et al*., 2010), Scotland (Gregory and Marshall, 2012) Australia (Ludwig *et al*., 2009), and some studies for multiple countries or global aggregates (Lobell and Field, 2007; Welch *et al*., 2010; Lobell *et al*., 2011). Values from all studies were converted to percentage yield change per decade.]

A sizable fraction of crop modelling studies were concerned with production for individual sites or provinces, scales below which the changes in climate conditions are attributable to anthropogenic activity (IPCC 2013, WG1, Chapter 10). Similarly, most crop studies have focused on the past few decades, a time scale shorter than most attribution studies for climate. However, some focused on continental or global scales (Lobell and Field, 2007; You *et al*., 2009; Lobell *et al*., 2011), at which trends in several climatic variables, including average summer temperatures, have been attributed to anthropogenic activity (IPCC 2013, WG1, Chapter 10). In particular, global temperature trends over the past few decades are attributable to human activity (IPCC, 2013, WG1, Chapter 10), and the studies discussed above indicate that this warming has had significant impacts on global yield trends of some crops.

Figure 7-3 presents a summary of the detectability of changes in growing season conditions (as measured by total degree-days during summer) and crop yield changes, as well as the ability to attribute changes to climate and CO_2 trends (in the case of yield changes) or anthropogenic emissions (in the case of growing season climate changes). As discussed above, attribution of yield impacts relies on multi-step attribution based on process understanding and observed climate trends. Also illustrated in Figure 7-3 is the fact that not all major cropping regions have

experienced significant climate trends in the past few decades, with the United States (in the lower, left-hand corner) the most notable example.

[INSERT FIGURE 7-3 HERE
Figure 7-3: Confidence in detection and attribution of observed impacts on crop yields and growing season degree days. Yield impacts include both direct climate effects and effects of elevated CO_2, but do not consider farmer adaptation. Confidence Levels were derived based on expert judgement of the available literature, following the IPCC uncertainty guidance (Mastrandrea *et al.*, 2010). Negative yield impacts: 1= Global maize , 2= Global wheat, 3= South Asia wheat; 4 = China maize and wheat; Positive yield impacts: 5 = UK wheat, sugarbeet, and potato. Increase in growing degree days: 6 = South Asia, main crops; 7 = China, main crops; 8 = Europe, main crops; 9 = Latin America, main crops; 10 = North America, maize and soybean. Yield impact confidence based on studies listed in Figure 7-2. Growing degree day confidence based on detection and attribution of trends in growing season temperatures (IPCC 2013, WG1, Chapter 10).]

In general, little work in food production or food security research has focused on formally attributing observed changes to anthropogenic influence on the climate system. However, as the field of climate detection and attribution proceeds to finer spatial and temporal scales, and as agricultural modelling studies expand to broader scales, there should be many opportunities to link climate and crop studies in the next few years. Importantly, climate attribution is increasingly documented not only for measures of average conditions over growing seasons, but also for extremes. For instance, (Min *et al.*, 2011) attribute changes in rainfall extremes to anthropogenic activity, and these are widely acknowledged as important to cropping systems (Rosenzweig *et al.*, 2002). Frost damage is an important constraint on crop growth in many crops, including for various high-value crops, and significant reductions in frost occurrence have been observed and attributed to greenhouse gas emissions in nearly every region of the world (Alexander *et al.*, 2006; Zwiers *et al.*, 2011; IPCC, 2012). Positive trends in the occurrence of unusually hot nights are also attributable to human activity in most regions (Perring *et al.*, 2010, IPCC 2013, WG1, Chapter 10). These events are damaging to most crops, an effect that has been observed most commonly for rice yields (Peng *et al.*, 2004; Wassmann *et al.*, 2009; Welch *et al.*, 2010) as well as rice quality (Okada et al. 2011). Extremely high daytime temperatures are also damaging and occasionally lethal to crops (Porter and Gawith, 1999; Schlenker and Roberts, 2009), and trends at the global scale in annual maximum daytime temperatures have been attributed to greenhouse gas emissions (Zwiers *et al.*, 2011). At regional and local scales, however, trends in daytime maximum are harder to attribute to greenhouse gas emissions because of the prominent role of soil moisture and clouds in driving these trends (Christidis *et al.*, 2005; Lobell *et al.*, 2007; Zwiers *et al.*, 2011).

In addition to effects of changes in climatic conditions, there are clear effects of changes in atmospheric composition on crops. It is *virtually certain* that the increase of atmospheric CO_2 by over 100 ppm since pre-industrial times has enhanced water use efficiency and yields, especially for C_3 crops, although these benefits played a minor role in driving overall yield trends (Amthor, 2001; Long *et al.*, 2006; McGrath and Lobell, 2011). As described earlier, increases in carbon dioxide are expected to have had negative impacts on carbon accretion in coral reefs with potential consequences for associated ecosystems and dependent social and economic activities (Hoegh-Guldberg *et al.*, 2007).

Emissions of CO_2 have also been associated with ozone (O_3) precursors that have driven a rise in tropospheric O_3 that harms crop yields (Morgan *et al.*, 2006; Mills *et al.*, 2007; *Section 7.3.2.1.2*). It is *very likely* that elevated O_3 since pre-industrial times has suppressed global production of major crops compared to what they would have been without O_3 increases, with estimated losses of roughly 10% for wheat and soybean and 3-5% for maize and rice (van Dingenen *et al.*, 2009). Impacts are most severe over India and China, but are also evident for soybean and maize in the United States (Fishman *et al.*, 2010; Boone et al. 2013).

7.2.1.2. Fisheries Production

The detection and attribution of impacts are as confounded in inland and marine fisheries as in terrestrial food production systems. Overfishing, habitat modification, pollution and inter-annual to decadal climate variability can all have impacts that are difficult to separate from those directly attributable to climate change. One of the best

studied areas is the North East Atlantic, where the temperature has increased rapidly in recent decades, associated with a poleward shift in distribution of fish (Perry *et al*., 2005; Brander, 2007; Cheung *et al*., 2010; *robust evidence, high agreement*). In the North Sea, within the NE Atlantic, the average species richness in the region, as indicated by the number of species recorded per year increased by approximately 33% between 1985 and 2006, a period during which North Sea bottom temperatures also rose significantly (Hiddink and Hofstede, 2008); inferring that the increase in richness has been related to the rising water temperature. These trends will have mixed implications for fisheries and aquaculture with some commercial species negatively and others positively affected (Cook and Heath, 2005). There is a similar well-documented example in the oceans off SE Australia with large warming trends associated with more southwards incursion of the Eastern Australian Current. This has resulted in southward migration of marine species into the oceans around eastern Tasmania with consequent impacts on ecosystem dynamics (Last *et al*., 2011; *robust evidence, high agreement*).

Coral reef ecosystems are important sources of fish for food for local inhabitants. More than 60% of coral reefs are considered to be under immediate threat of damage from a range of local threats, of which overfishing is the most serious followed by coastal development and pollution. The percentage under threat rises to 75% when the effect of rising ocean temperatures is added to these local impacts (Burke *et al*., 2011). There have been ongoing incidences of coral bleaching from rising sea temperatures since the 1970s which have already caused a global decline in coral reef cover and the trend is expected to continue as temperatures continue to rise (Munday *et al*., 2008; Chapter 30.6.1.1.2). Ocean acidification presents an additional threat by reducing carbon accretion (see Box 5-3 for further information). Wilson et al. (Wilson *et al*., 2006) demonstrated that declines in coral reef cover typically led to declines in abundance of the majority of fish species associated with coral reefs, with species that depended on live coral for food and shelter most impacted while some species that fed on invertebrates, algae or detritus increased.

There is considerably less information available on climate change impacts on fisheries and fishery resources in freshwater systems. (Xenopoulus *et al*., 2005) investigated the effect of climate change and water withdrawal on freshwater fish extinctions under the assumptions of two scenarios which they reported were consistent with IPCC SRES scenarios A2 and B2. They forecast that discharge would increase in between 65 and 70% of river basins in the world but it would decrease by as much as 80% in 133 rivers for which fish species data were available. In the rivers experiencing reduced discharge, by 2070 up to 75% of the local fish biodiversity would be 'headed toward extinction' because of changes in climate and water consumption. The areas where the highest rates of fish extinctions were forecast tended to be in tropical and subtropical areas. The authors concluded that climate change, through increased evapotranspiration and reduced precipitation, would be the most important cause of this loss under the two SRES scenarios with water consumption making a considerably smaller contribution. Rates of extinction in fish species cannot be directly related to changes in fishery production but their results indicate that there will be changes in riverine fish communities and productivity which will impact on fisheries, with negative impacts more probable in tropical and sub-tropical systems (*limited evidence; low agreement*).

Considerable attention has been given to the impacts of climate change in some African lakes but with mixed interpretations (see also Chapter 22.3.3.1.4.). For inland fisheries, there is evidence that increasing temperature has reduced the primary productivity of Lake Tanganyika in East Africa by increasing the stability of the water column and thereby reducing upwelling of nutrients into surface waters. The study by O'Reilly et al. (2003) estimated that this would have led to a decrease of approximately 30% in fish yields. However, Sarvala et al. (2006) disagreed and concluded that observed decreases in the fish catches could be explained by changed fishery practices. There has been a similar difference of opinion for Lake Kariba where Ndebele-Murisa et al., (2011) argued that a reduction in fisheries productivity had been caused by climate change while Marshall (Marshall, 2012) argues that the declines in fish catches experienced there can only have been caused by fishing. The Sahel region in northern Africa has historically demonstrated high variability. It experienced good rainfall in the 1960s, followed by severe drought over the next 7 years and below average precipitation from then until 2007. This dry period resulted in the area of Lake Chad decreasing from 26,000 km^2 in the 1960s to 1,425 km^2 in 2003. The decreasing area was associated with a decline in reported fish catches in Chad from over 100,000t in the late 1960s to under 70,000t in the early 1990s although there is considerable doubt about the accuracy of the reported catch figures, including up to the present (Welcomme, 2011; *medium evidence, low agreement*).

7.2.1.3. Livestock Production

In comparison to crop production, considerably less work has been published on observed impacts for non-crop food production systems, such as livestock and fisheries, and to our knowledge nothing has been published for hunting or collection of wild foods. A study of blue-tongue virus, an important ruminant disease, evaluated the effects of past and future climate trends on transmission risk, and concluded that climate changes have facilitated the recent and rapid spread of the virus into Europe (Guis et al. 2012).

7.2.2. Food Security

Food production is an important aspect of food security (Section 7.1), and the evidence that climate change has affected food production implies some effect on food security. Yet quantifying this effect is an extremely difficult task, requiring assumptions about the many non-climate factors that interact with climate to determine food security. There is thus limited direct evidence that unambiguously links climate change to impacts on food security.

One important aspect of food security is global food prices (Section 7.1.3). Although food prices gradually declined for most of the 20th century, since AR4 there have been several periods of rapid increases in international food prices (Figure 7-4). A major factor in recent price changes has been increased crop demand, notably via increased use in biofuel production related both to energy policy mandates and oil price fluctuations (Roberts and Schlenker, 2010; Wright, 2011; Mueller et al. 2011; Abbot et al. 2011). Yet fluctuations and trends in food production are also widely believed to have played a role in he recent price changes, as illustrated in Figure 7-4. Spikes in prices do not always follow weather induced shortfalls in supply, as illustrated by the lack of response to several events in the 1990's. However, price effects are especially likely in years with low stocks, which can result from sustained periods of low supply growth relative to demand. Domestic policy reactions can also amplify international price responses to weather events, as was the case with export bans announced by several countries since 2007 (FAO, 2008). In a study of global production responses to climate trends, (Lobell *et al*., 2011) estimated a price increase of 19% due to the impacts of temperature and precipitation trends on supply, or an increase of 6% once the beneficial yield effects of increased CO_2 over the study period were considered. Since the price models were developed for a period ending in 2003, these estimates do not account for the policy responses witnessed in recent years which have amplified the price responses to weather.

[INSERT FIGURE 7-4 HERE
Figure 7-4: Since the AR4 report, food prices have reversed historical downward trend. Plot shows history of FAO food and cereal price index, along with events when a top 5 producer of a crop had yields 25% below trend line (indicative of a big weather effect). Australia is included despite not being a top five producer, because it is an important exporter and the drops were 40% or more below trend line. Prices may have become more sensitive to weather-related supply shortfalls in recent years, perhaps reflecting the importance of interactions with global storage levels and rapid growth in crop demand. At the same time, because of increased biofuel demand, food prices are also increasingly linked to the price of crude oil, shown in the blue line (data available at http://www.eia.gov). Therefore, there is clear evidence since AR4 that prices can rise rapidly, but the role of weather in these increases remains unclear. All indices are expressed as percentage of 2002-2004 averages.]

7.3. Assessing Impacts, Vulnerabilities, and Risks

7.3.1. Methods and Associated Uncertainties

7.3.1.1. Assessing Impacts

Methods developed or extended since AR4 have resulted in more robust statements on climate impacts through:

- Improved quantification and presentation of uncertainty. Descriptions of processes and trade-offs, and expression of uncertainty in the temporal dimension, are two methods that have been shown to be more effective that presentation of uncertainty in the outcome variable (e.g. yield).

- Greater use of historical empirical evidence of the relationship between climate and food production.

The methods used for field and controlled environment experiments remain similar to those at the time of AR4. There has been a greater interest in the use of Remote Sensing (RS)/Geographic information System (GIS) techniques for assessing temporal and spatial changes in land use particularly in agricultural land use for assessment of food security status (Fishman *et al.*, 2010). There has also been an increase in the number of Free Air Concentration Enrichment (FACE) studies that examine ozone instead of, or in addition to, carbon dioxide. A number of meta-analyses of experimental studies, in particular (FACE) studies have been made since AR4. However, debate continues on the disparities between results from FACE experiments and non-FACE experiments, such as in open-top chambers or greenhouses. As reported in AR4, FACE studies tend to show lower elevated CO_2 responses than non-FACE studies. Although some authors have claimed that the results of the two are statistically indistinct, others have argued that the results are only similar when the FACE experiments are grown under considerably more water stress than non-FACE experiments (Ainsworth *et al.*, 2008). Hence comparisons between different methodologies must take care to control for differences in water levels. Another reason for differences between experiments may be differences in the temporal variance of CO_2 – i.e. whether concentrations are fluctuating or constant (Bunce, 2012). Unfortunately, the number of FACE studies are still quite low, which limits statistical power when evaluating the average yield effects of elevated CO_2 or interactions with temperature and moisture (*Section 7.3.2*).

Numerical simulation models can be used to investigate a larger number of possible environmental and management conditions than physical experiments. This, in turn, enables a broader range of statements regarding the response of food production systems to climate variability and change. Previous assessment reports have documented new knowledge resulting from numerical simulation of the response of food production to climate change. AR4 noted the increasing number of regional studies, which is a trend that has continued to date (Challinor *et al.*, 2009). Since AR4, crop models have been used to examine a large number of management and environmental conditions, such as interactions among various components of food production systems (Lenz-Wiedemann *et al.*, 2010), determination of optimum crop management practices (Soltani and Hoogenboom, 2007), vulnerability and adaptability assessments (Humaira *et al.*, 2009), evaluation of water consumption and water use efficiency (Mo *et al.*, 2009; Kang *et al.*, 2009), estimation of changes and uncertainties (Bellocchi *et al.*, 2010) and fostering communication between scientists, managers, policymakers and planners (*robust evidence; medium agreement*).

Novel developments since AR4 in the methodologies used for modelling since include more work that quantifies uncertainty in both climate and its impacts, particularly for crops, and models that include crop growth as part of broader land surface and earth systems models (e.g. (Bondeau *et al.*, 2007; Osborne *et al.*, 2007). Ensemble techniques for climate impacts, which were in their infancy at AR4, now include the use of Baysian methods to constrain crop model parameters (Iizumi *et al.*, 2009; Tao *et al.*, 2009a). It is also increasingly common to assess both bio-physical and socio-economic drivers of crop productivity within the same study (Fraser *et al.*, 2008; Reidsma *et al.*, 2009; Tao *et al.*, 2009b; Challinor *et al.*, 2010). Finally, an important recent development is the systematic comparison of results from different modelling and experimental approaches for providing insights into model uncertainties as well as to develop risk management (Challinor and Wheeler, 2008; Kang *et al.*, 2009; Schlenker and David, 2010; Rosenzweig *et al.*, 2013).

Increased quantification of uncertainty can lead to clear statements regarding climate impacts. Studies with different methods have been shown to produce convergent results for some crops and locations (Challinor *et al.*, 2009; *medium evidence, medium agreement*). The methods used to describe uncertainty have also improved since AR4. The projected range of global and local temperature changes can be described by quantifying uncertainty in the temporal dimension, rather than that in temperature itself (Joshi *et al.*, 2011), and a similar approach can be used for crop yield (Figure 7-5). Descriptions of uncertainty that present key processes and trade-offs, rather than ranges of outcome variables, have also proved to be useful tools for understanding future impacts (Thornton *et al.*, 2009; Hawkins *et al.*, 2012; Ruane *et al.*, 2013).

A considerable body of work since AR4 has used extensive datasets of country- , regional- and farm- level crop yield together with observed and/or simulated weather time series in order to assess the sensitivity of food production to weather and climate. These statistical models offer a complement to more process-based model

approaches, some of which require many assumptions about soil and management practices. The regional-scale statistical models that have been developed in recent years can thus produce more widely applicable results than field and controlled environment experiments, whilst avoiding the need for assumptions regarding management and planting dates. Although statistical models forfeit some of the process knowledge embedded in other approaches, they can often reproduce the behavior of other models (Iglesias *et al*., 2000; Lobell and Burke, 2010) and can leverage within one study a growing availability of crop and weather data (Welch *et al*., 2010; Lobell *et al*., 2011). Statistical models usually exclude the direct impact of elevated CO_2, making multi-decadal prediction problematic. Similarly, technological progress and its interaction with climatic variability are not simulated by statistical models. Regional-scale process-based models tend to include at least some of these processes. In determining future trends, crop models of all types can only extrapolate based on historically-determined relationships. Process-based models extrapolate based on measured interactions and mechanisms, whilst statistical models extrapolate based on empirically determined relationships. Agro-climatic indices provide another alternative to process-based crop models that avoid various assumptions by focusing on farmer-relevant metrics, rather than providing yield predictions *per se* (Trnka *et al*., 2011). However, correlations between climate, or associated indices, and yield are not always statistically significant.

The robustness of crop model results depends on data quality, model skill prediction and model complexity (Bellocchi *et al*., 2010). Modelling and experiments are each subject to their own uncertainties. Measurement uncertainty is a feature of field and controlled environment experiments. For example, interactions between CO_2 fertilisation, temperature, soil nutrients, ozone, pests and weeds is not well understood (Soussana *et al*., 2010) and therefore most crop models do not include all these effects, nor broader issues of water availability, such as competition for water between industry and households (Piao *et al*., 2010). There are also uncertainties associated with generalizing the results of field experiments, since each one has been conducted relatively few times under a relatively small range of environmental and management conditions, and for a limited number of genotypes. This limits breadth of applicability both through limited sample size and limited representation of the diversity of genotypic responses to environment (Craufurd *et al*., 2013). For example, yield increases normalised by increase in CO_2 have been found to vary between zero and over 30% among crop varieties (Tausz *et al*., 2011).

Models have the advantage of exploring a larger number of situations, but with less certainty in the determination of the response variable than in field studies. The uncertainty in climate simulation is generally larger than, or sometimes comparable to, the uncertainty in crop simulation using a single model (Iizumi *et al*., 2011).There is significant uncertainty in agricultural simulation arising from climate model error, and since AR4 the choice of method for GCM bias correction has been identified as a source of uncertainty, even in the absence of downscaling, which is comparable in some cases to that from scenarios and choice of GCM (Hawkins *et al*., 2012). There is also a contribution to uncertainty in crop model output from yield measurement error, through the calibration procedure. Yield measurements rarely have associated error bars to give an indication of accuracy. Greater access to accurate regional-scale crop yield data can lead to decreased uncertainty in projected yields

The use of multiple crop models in impacts studies is relatively rare. Field-scale historical model intercomparisons have shown variations in yield and biomass of more than 100% (Palosuo et al., 2011).Early results from impacts studies with multiple crop models suggest that the crop model uncertainty can be larger than that caused by GCMs, due in particular to high temperature and temperature-by-CO_2 interactions (Asseng *et al*., 2013). Given these different strengths and weaknesses, and associated dependencies, it is critical that both experimental and modeling lines of evidence, and their uncertainties, are examined carefully when drawing conclusions regarding impacts, vulnerabilities and risks. This approach to assessment is applied to each of the topics described in the rest of the chapter.

7.3.1.2. Treatment of Adaptation in Impacts Studies

Adaptation occurs on a range of timescales and by a range of actors. Incremental adaptation, such as a change in crop management, can occur relatively autonomously within farming systems. It is the type of adaptation most commonly assessed in the impacts literature, and it is the only form of adaptation discussed in sections 7.3 and 7.4. Systemic and transformational adaptations are discussed in section 7.5.

7.3.2. Sensitivity of Food Production to Weather and Climate

Since AR4, understanding of the impacts of a range of biophysical processes and associated outcomes has been improved:

- Heat stress effects have been better quantified at regional and local scales. There is no evidence that the response is uniform across spatial scale.
- AR4 states that water stressed crops may benefit more than well-watered crops from elevated CO2. Work since then suggests this may not consistently be the case.
- Evidence shows the greater importance of temperature over precipitation in determining regional-scale crop yields in some regions
- Impacts on crop yield as a function of local temperature change: AR4 confirmation that even slight warming will decrease yields in low-latitude regions (*medium confidence*) and that temperate wheat yield decreases are *about as likely as not* for moderate warming.

The majority of research into the sensitivity of food production to weather and climate remains focussed on crops. The majority of that work is focussed on impacts on the major annual crops such as maize, wheat and rice, a focus that is commensurate with the area harvested of these crops (White *et al*., 2011). Whilst there are many other crops of importance to food systems, the crops discussed here reflect both the availability of research and the global remit of this chapter.

7.3.2.1. Cereals, Oilseeds, and Legumes

7.3.2.1.1. Mean and extremes of temperature and precipitation

Both statistical and process-based models have widely been used since AR4 to assess the response of crop yield to temperature. Model results confirm the importance of known physiological processes, such as the shortening of the time to maturity of a crop with increasing mean temperature (Iqbal *et al*., 2009), decline in grain set when high temperatures occur during flowering (Moriondo *et al*., 2011), and increased water stress at high temperatures throughout the growing cycle (Lobell *et al*., 2013b). Temperatures responses are generally well-understood for temperatures up to the optimum temperature for development. The impacts of prolonged periods of temperatures beyond the optimum for development are not as well understood (Craufurd and Wheeler, 2009). For example, temperatures above 34 °C after flowering appear to rapidly speed senescence in wheat (Lobell *et al*., 2013b; Asseng *et al*., 2013), but many crop models do not represent this process.

The overall relationship between weather and yields is often crop and region specific, depending on differences in baseline climate, management and soil, and the duration and timing of crop exposure to various conditions. For example, rice yields in China have been found to be positively correlated with temperature in some regions and negatively correlated in others (Zhang *et al*., 2010). This difference may be due to positive correlation between temperature and solar radiation in the former case, and negative correlation between temperature and water stress in the latter case. Similarly, although studies consistently show spikelet sterility in rice for daytime temperatures exceeding 33 °C (Jadadish et al., 2007; Wassmann *et al*., 2009), some statistical studies find a positive effect of daytime warming on yields because these extremes are not reached frequently enough to affect yields (Welch *et al*., 2010). Responses to temperature may vary according whether yields are limited by low or high temperatures. However, there is evidence that high temperatures will limit future yields even in cooler environments (Semenov et al., 2012; Teixeira *et al*., 2013).

In cool season legumes, the threshold for heat stress during the reproductive phase is above 25ºC (daily maximum temperature) and experimental results with field-pea in North India show that temperatures higher than 25ºC at the onset of the reproductive phase led to reductions in pod setting (30%), seeds per pod (41%) and seed weight (36%) and consequently total productivity decreased by 48% (Ali and Gupta, 2012). Also in North India chickpea yields during the last years decreased between 0.53 and 3 q. ha^{-1} per 1ºC increase in seasonal temperature (Kalra *et al*.,

2008).Even if chickpea is more heat tolerant than other cool season legumes, high temperatures (above 30ºC) during the reproductive phase can affect seed yield (Devasirvatham *et al*., 2012). Simulation results for short duration pigeon pea in Kenya projected decreases in yields between 7% and 28.7% with 1ºC and 5ºC increase in temperature respectively (Cooper *et al*., 2009).

The relative importance of temperature and water stress for crop productivity can be assessed using models, and can vary according to the criteria used for assessment (Challinor *et al*., 2010). There are also some cases where the sign of a correlation depends on the direction of the change. For example, (Thornton *et al*., 2009) found that the response crop yields to climate change in the drylands of East Africa is insensitive to rainfall, since wetter climates are associated with warmer temperatures that act to reduce yields. Variation in crop-climate relationships can also result from the analytical methods used and/or the spatial scale of the analysis e.g. (Challinor and Wheeler, 2008). For example, increases in daily maximum temperature have been found to increase the yield of rice at a number of sites across Asia (Welch *et al*., 2010), whilst negative responses due to spikelet sterility are a well-known phenomenon in controlled environment experiments. Crop models can be used to quantify abiotic stresses such as these (Challinor *et al*., 2009), although only by hypothesizing that the functional responses to weather derived from experiments are valid at regional scales. Thus, whilst many fundamental bio-physical processes are understood at the plant or field scale, it remains difficult to quantify the extent to which these mechanisms are responsible for the observed regional-scale relationships between crop yield and weather.

Since precipitation exhibits more spatial variability than temperature, temporal variations in the spatial average of precipitation tend to diminish as the spatial domain widens. As a result, precipitation becomes less important as a predictor of crop yields at broad scales (Lobell and Field, 2007; Li *et al*., 2010). Similarly, projected changes in precipitation from climate models tend to be more spatially variable than temperature, leading to the greater importance of projected temperatures as the spatial scale of analysis grows wider (Lobell and Burke, 2008). There is also evidence that where irrigation increases over time the influence of temperature on yields starts to dominate over that of precipitation (Hawkins *et al*., 2012)

A meta-analysis of yield impact studies for major cereals (Challinor *et al*., 2013), including both pre- and post- AR4 contributions, gave broadly similar results to AR4 and to a more recent meta-analysis using multiple impacts models (Frieler *et al*., 2013). Challinor *et al*. (2013) reported tropical and temperate regions separately: yields of maize, wheat and rice begin to decline with 1-2ºC of local warming in the tropics, with temperate maize yields being less clearly affected at these temperatures and moderately affected for greater warming (Figure 7-5). The new analysis confirms AR4 findings that even slight warming will decrease yields in low-latitude regions (*medium evidence, high agreement*). However, whilst AR4 had few indications of yield reductions at less than 2ºC of local warming, the new analysis has, in the absence of incremental adaptation, more yield decreases than increases at all temperatures. Hence, whilst AR4 concluded with *medium confidence* that in mid- to high-latitude regions moderate warming will raise crop yields, new knowledge suggests that temperate wheat yield decreases are *about as likely as not* for moderate warming. Quantitative assessments of yield changes can be found in section 7.4. Within both tropical and temperate regions regional variability, which cannot be summarised in meta-analyses, will be important in determining how climate change affects particular agricultural systems.

[INSERT FIGURE 7-5 HERE
Figure 7-5: Percentage simulated yield change as a function of local temperature change temperature for the three major crops and for temperate and tropical regions. Shaded bands indicate the 95% confidence interval of regressions consistent with the data based on 500 bootstrap samples, which are separated according to the presence (blue) or absence (red) of adaptation. Note that 10 of the 1125 datapoints across all six panels are outside the yield change range shown. These were omitted for clarity.]

7.3.2.1.2. Impact of carbon dioxide and ozone

There is further observational evidence since AR4 that response to a change in CO_2 depends on plant type; C_3 or C_4 (DaMatta *et al*., 2010). The effect of increase in CO_2 concentration tends to be higher in C_3 plants (e.g. wheat, rice, cotton, soybean, sugar beets, and potatoes) than in C_4 plants (e.g. corn, sorghum, sugarcane), because photosynthesis

rates in C_4 crops are less responsive to increases in ambient CO_2 (Leakey, 2009). The highest fertilization responses have been observed in tuber crops, which have large capacity to store extra carbohydrates in belowground organs (Fleisher *et al.*, 2008; Högy and Fangmeier, 2009).

FACE studies have shown that the impact of elevated CO_2 varies according to temperature and availability of water and nutrients; yet there is a strong geographical bias of FACE studies towards temperate zone (Leakey et al., 2013). Water-stressed crops are expected to respond more strongly to elevated CO_2 than well-watered crops, because of CO_2 induced increases in stomatal resistance. This suggests that rain-fed cropping systems will benefit more from elevated CO_2 than irrigated systems, and that rain-fed systems in drier regions or years will benefit more than in wetter conditions. This expectation has been cited in TAR and AR4, and new evidence based on historical observations supports this notion by demonstrating that the rate of yield gains in rain-fed systems is higher for dry years than for wet years (McGrath and Lobell, 2011). However, this response is not seen consistently across models and FACE meta-analyses and there is some suggestion that the relationship between water stress and assimilation may vary with spatial scale, with canopy analyses showing a reversal of the expected leaf-level dry vs wet signal (Challinor and Wheeler, 2008).

Ozone in the stratosphere provides protection from lethal short-wave solar ultraviolet radiation, but in the troposphere it is a phytotoxic air pollutant. Global background concentration of ozone has increased since pre-industrial era due to anthropogenic emission of its precursor, by vehicles, power plants, biomass burning and other sources of combustion. Like CO_2, O_3 is taken up by green leaves through stomata during photosynthesis but unlike CO_2, its concentration is significantly variable depending on geographic location, elevation and extent of anthropogenic sources. Being a powerful oxidant, ozone and its secondary by-products damage vegetation by reducing photosynthesis and other important physiological functions (Mills *et al.*, 2009; Ainsworth and McGrath, 2010). This results in stunted crop plants, inferior crop quality and decreased yields (Booker *et al.*, 2009; Fuhrer, 2009; Vandermeiren *et al.*, 2009; Pleijel and Uddling, 2012) and posing a growing threat to global food security (*robust evidence, high agreement*).

The literature published since AR4 further corroborates the negative impacts of increasing concentrations of surface ozone on yield losses on global (Van Dingenen *et al.*, 2009; Teixeira *et al.*, 2011; Avnery *et al.*, 2011a; Avnery *et al.*, 2011b) and regional level (Northern Hemisphere: Hollaway et al, (2011); USA: (Emberson *et al.*, 2009; Fuhrer, 2009; Fishman *et al.*, 2010); India (Roy *et al.*, 2009; Rai *et al.*, 2010; Sarkar and Agrawal, 2010); China: (Wang *et al.*, 2007; Piao *et al.*, 2010); Bangladesh: (Akhtar *et al.*, 2010); Europe: (Hayes *et al.*, 2007; Vandermeiren *et al.*, 2009; Fuhrer, 2009). The global yield losses of soybean, wheat and maize in 2000 ranged from 8-15% amounting to production losses of $11-18 billion (Avnery *et al.*, 2011a). The projected yield losses for the near future (year 2030) would be substantial but less severe under IPCC B2 scenario than A2; yield reduction under A2 would be 9-25% with production losses of $17-35 billion and under B1 scenario 9-17% with production losses of $12-21 billion (Avnery *et al.*, 2011b). In separate meta-analyses, some researchers reported even higher losses in wheat yield (Feng *et al.*, 2008) and high losses in rice yield (Ainsworth, 2008) at elevated ozone concentrations. These studies also pointed out the regional hotspots of East and South-east Asia and Eastern US, strong seasonality of O_3 formation (with peaks in pre- and post-monsoon months in India) depending on precursor emission and climate factors and role of crop management practices, such as cropping system, crop species (Teixeira *et al.*, 2013) and crop genotype (Feng *et al.*, 2011), (Biswas *et al.*, 2008; Zhu *et al.*, 2011). The sensitivity of crops to O_3 damage was in the order: soybean ≥ wheat > rice > maize. The irrigated crops suffered highest production losses. Ozone may have direct effect on reproductive process, leading to reduced seed and fruit development and abortion of developing fruit (Royal Society, 2008; *robust evidence, high agreement*).

The interactive effects of ozone with other environmental factors such as CO_2, temperature, moisture, light, are important but not well understood. Generally, the ambient and increasing concentrations of O_3 and CO_2 individually exert counteractive effects on C_3 plants (Tianhong *et al.*, 2005; Ainsworth, 2008; Gillespie *et al.*, 2012); but their interactive effect may compensate for each other (Ainsworth, 2008; Taub *et al.*, 2008; Gillespie *et al.*, 2012). In some studies, crops grown in both elevated CO_2 and O_3 concentrations showed yield losses which were less than with O_3 alone (Taub *et al.*, 2008; Fuhrer, 2009). The losses might also be greater when elevated O_3 combines with high temperature (Long, 2012) particularly during grain filling of wheat, when elevated ozone causes premature leaf senescence (Feng *et al.*, 2008; Feng *et al.*, 2011). Such interactions may be important for understanding ozone

tolerance in C_3 food crops and for exploiting rising CO_2 concentrations for yield enhancement (Ainsworth *et al.*, 2008; Mittler and Blumwald, 2010; Ziska *et al*., 2012). Periods of abundant radiation, high temperature and adequate water supply most favourable for agricultural production are also favourable for the formation of surface ozone; thus the effects of ozone on crops are often not visible in contrast to other yield reducing factors such as insect pests and diseases (Long, 2012).

7.3.2.2. Other Crops

Increases in temperature are already affecting phenology in perennial crops since the accumulation of winter chill hours is decreasing. Observed trends in winter chill range between -50 and -260 chill hours per decade in California and predicted rates of reduced winter chill, for the period between 1950 and 2100, are on the order of -40 h per decade (Baldocchi and Wong, 2008). Averaging over three GCMs annual winter chill loss by 2050 compared to 1970 would amount 17.7 % to 22.6 % in Egypt (Farag *et al*., 2010). The analysis made by (Wolfe *et al*., 2008) using HadCM3 projections under A1F1 and B1 scenarios indicate that some 400 h could be assured along the century, benefiting species with low chill requirement in the north-eastern USA.

Earlier flowering and maturity have been observed *(robust evidence, high agreement*) worldwide in grapes (García-Mozo *et al*., 2010; Duchêne *et al*., 2010; Jorquera-Fontena and Orrego-Verdugo, 2010; Sadras and Petrie, 2011; Webb *et al*., 2011), apples (Fujisawa and Koyabashi, 2010; Grab and Craparo, 2011) and other perennial horticultural crops (Sugiura *et al*., 2012; Glenn *et al*., 2013). Assessing climate change impacts on fruit production in California towards 2050, (Lobell and Field, 2011) found a slightly positive yield trend (*ca*. 5%) for almonds and negative trends for table grapes (5%), berries (10%) and cherries (20%) as compared to 2000. Also in eastern Washington in US under A1F1 and B1 scenarios without the effect of elevated CO2, future climate change is projected to decrease apple production by 1%, 3%, and 4% for 2020, 2040, and 2080 respectively, but when the effect of CO_2 is added, yields are projected to increase by 6% (2020s), 9% (2040s), and 16% (2080s) (Stöckle *et al*., 2010). Reductions in suitability for grapevine are expected in most of the wine producing regions (Hall and Jones, 2009; White *et al*., 2009; Jones *et al*., 2010). Grapes/wine production and quality will be affected in Europe, US, Australia
(Jones *et al*., 2005; Wolfe *et al*., 2008; Cozzolino *et al*., 2010), Chapter 25 WG2), although it could be a benefit in Portugal (Santos *et al*., 2011) and British Columbia in Canada (Rayne *et al*., 2009).

Important crops in Brazil like sugarcane and coffee are expected to migrate towards more favorable zones in the South (Pinto, 2007; Marin *et al*., 2009; Pinto et al., 2008; Chapter 27 WG2). Sugarcane fresh stalk mass is generally expected to gain from both warming and elevated CO2 in Brazil (Marin *et al*., 2013). The suitability for coffee crops in Costa Rica, Nicaragua and El Salvador will be reduced by 40% (Glenn *et al*., 2013) while the loss of climatic niches in Colombia will force the migration of coffee crops towards higher altitudes by mid-century (Ramirez-Villegas *et al*., 2012). In the same way, increases in temperature will affect tea production, in particular at low altitudes (Wijeratne, et al., 2007).

Cassava is an important source of food for many people in Africa and Latin America and recent studies suggest that future climate could not significantly affect its productivity as this crop is characterized by elevated optimum temperature for photosynthesis and growth, and a positive response to CO_2 increases (Jarvis *et al*., 2012; Rosenthal and Ort, 2012; El-Sharkawy, 2012).

The suitability for potato crops is expected to increase in very high latitudes and high tropical altitudes towards 2100 (Schaefleitner *et al*., 2011). Projections for Europe indicate that by 2030 and 2050 the impacts on potato yields will be mostly positive but towards the end of the century negative impacts are expected in the overall continent except in some northern countries (Supit *et al*., 2012). In Eastern China yields are expected to increase in the North and to decrease in the South by 2100 (Chavas *et al*., 2009), also in the Peruvian Altiplano negative impacts are expected under A2 and B2 scenarios by 2100 (Sanabria and Lhomme, 2012) while in eastern Washington in US, potato yields could slightly decrease (-2/-3%) under A1F1 and B1 scenarios (Stöckle *et al*., 2010).

7.3.2.3. Pests, Weeds, Diseases

7.3.2.3.1. Sensitivity of pests, weeds, and diseases to weather and climate

As a world-wide average, current yield loss in major crop species due to animal pests and (non-virus) pathogens, in the absence of any physical, biological or chemical crop protection, is estimated at 18% and 16%, respectively (Oerke, 2006). Although physical changes associated with climate uncertainty are recognized and assessed, (e.g. drought, water, temperature) in the context of agricultural productivity, less attention has focused on biological interactions and climate, even though it is universally recognized that weeds, insects and diseases have limited crop yield potential. A fair question then is to ask whether such limitations will increase or decrease in response to future changes in CO_2/climate?

The effects of weather on important diseases and pests, including optimal temperature and moisture conditions, have been studied in detail for decades (De Wolf and Isard, 2007). This research forms a base for understanding that climate change will change potential losses to many pests and diseases. Changes in temperature can support range expansions through changes in winter and summer extremes, and thus the potential for overwintering or summer survival. CO2 and ozone can either increase or decrease plant disease, and can exhibit important interactions in effects, suggesting incorporation of these risk factors in analyses may need to be system specific (Chakraborty *et al*., 2008; Eastburn *et al*., 2011). It is challenging to estimate the extent to which observed changes in effects may be due to climate change because of the many factors that interact to result in pest and disease risk and management decisions (Chakraborty and Newton, 2011; Garrett *et al*., 2011). Interactions with landscape effects may be particularly important in such perennial agricultural systems as forests and grasslands (Pautasso *et al*., 2010).

The rarity of long-term studies of plant diseases and pests is a problem for the evaluation of climate change effects, but there are some examples of the potential for such analyses available. Studies of a wheat experiment at Rothamsted Research Station UK, maintained for over 160 years, have revealed shifts in foliar wheat pathogens linked to rainfall, temperature, and SO_2 emissions (Bearchell *et al*., 2005; Shaw *et al*., 2008). Wheat rust risk has been observed to respond to ENSO (Scherm and Yang, 1995). Over almost seven decades, earlier and more frequent epidemics of potato late blight, and more frequent pesticide use, were observed in Finland, associated with changing climate conditions and lack of crop rotation (Hannukkala *et al*., 2007). Up to a point, adaptation to climate change will be similar to adaptation to other new scenarios as agricultural systems have moved around the world (Coakley *et al*., 1999; Juroszek and von Tiedemann, 2011). As an example of the effect of climate on management efficacy, higher diversity potato systems designed for management of potato late blight had lower utility in climatic zones where potato growing seasons were longer and presumably there were higher regional pathogen loads (Garrett et al., 2009).

Changes in climate are expected to affect the range of specific species of insects and diseases for a given crop growing region. For example, Cannon (1998) has suggested that migratory insects could colonize crops over a larger range in response to temperature increases, with subsequent reductions in yield. Guitierrez (2000) has suggested that predator and insect herbivores are will respond differently to increasing temperature, with possible reductions in insect predation (i.e. greater insect numbers). While plant-pathogen interactions are recognised as a factor affecting crop yields, our ability to predict CO_2/climate change impacts on pathogen biology and subsequent changes on yield of rice, soybean, wheat inter alia is tenuous at best, because with few exceptions (Savary *et al*., 2011), experimental data are not available and analyses focus on individual diseases rather than the complete set of important diseases (*medium evidence, medium agreement*).

Ostensibly, since many agricultural weeds are C_4, and soybean, wheat and rice, C_3, increasing CO_2 should reduce crop losses due to weedy competition since the C_3 pathway, in general, shows a stronger response to rising carbon dioxide levels. However, the argument that rising CO_2 will reduce weedy competition because the C_4 photosynthetic pathway is over-represented among weed species (Holm, 1977) does not consider the range of available C_3 and C_4 weed species present within the agronomic seed bank. For example, in the United States, every crop, on average, competes with an assemblage of 8-10 weed species (Bridges, 1992). In addition, CO_2, and/or climate, can also affect weed demographics. For example, with field grown soybean, elevated CO_2 per se appeared to be a factor in increasing the relative proportion of C_3 to C_4 weedy species with subsequent reductions in soybean yields (Ziska and

Goins, 2006). For rice and barnyard grass (C_4), increasing CO_2 favored rice, but if both temperature and CO_2 increased simultaneously, the C_4 weed was favored, primarily because higher temperatures resulted in increased seed yield loss for rice (Alberto et al, 1996). Overall, rising atmospheric CO_2 can increase the extent of crop losses due to a greater response of the weed relative to the crop (Ziska, 2000; Ziska, 2003). If weeds are not managed such losses may exceed any observed stimulation in crop yield associated with elevated CO_2 (Ziska, 2000; Ziska, 2003). For weeds that share physiological, morphological, or phenological traits with the crop, including those weeds that are wild relatives of the domesticated crop species, (often among the "worst" weeds in agronomic situations, e.g. rice and red rice) the decrease in seed yield from weeds may, in fact, be greater in response to increasing atmospheric CO_2 (Ziska, 2010). Climate change may be a factor in extending the northward migration of agronomic and invasive weeds (e.g. (Ziska *et al.*, 2011). The projected warming may be exceeding maximum rates of plant migration observed in post-glacial time periods (Malcolm *et al.*, 2002), resulting in preferential selection for the most mobile plant species. A number of characteristics associated with long-distance dispersal are commonly found among weeds (Rejmánek, 1996) suggesting that they will be among the fastest to migrate with increasing temperatures (Dukes and Mooney, 1999). In addition, climate (e.g. precipitation) and/or temperature may change the demographics of C_3 and C_4 weed species in crop production (e.g. (Ziska and Goins, 2006; McDonald *et al.*, 2009).

Initial studies indicate a potential decline in herbicide efficacy with rising CO_2 and/or temperature for some weeds (Ziska and Goins, 2006; Archambault, 2007; Manea *et al.*, 2011). For Canada thistle, increasing CO_2 appears to have induced greater below-ground growth of roots, diluting the active ingredient of the herbicide and making chemical control less effective (Ziska *et al.*, 2004). To date, studies on physical, cultural or biological weed control are lacking.

7.3.2.3.2. Effects of climate change on pests, weeds, and diseases

Climate change scenario analyses are available for some pests and diseases. For example, range expansion has been predicted for the destructive *Phytophthora cinnamomi* in Europe (Bergot *et al.*, 2004) and for phoma stem canker on oilseed rape in the UK (Evans *et al.*, 2008). Increased generations under climate change for the coffee nematode have been predicted for the coffee nematode in Brazil (Ghini *et al.*, 2008). Walnut pests in California are predicted to experience increased numbers of generations under climate change scenarios (Luedeling *et al.*, 2011). Potato late blight risk increases in some areas of the world, and decreases in others, under climate change scenarios (Sparks *et al.*, 2013). Luck (2011) summarized the mixed results for the qualitative effects of climate change on pathogens that cause disease of four major food crops - wheat, rice, soybean and potato - where some diseases increased in risk while others decreased under climate change scenarios. In syntheses, there is a tendency for risk of insect damage to plants to increase (Deutsch *et al.*, 2008; Paulson *et al.*, 2009). Typical scenario analyses are limited by simplistic assumptions, and work remains to evaluate how conclusions will change as more complete scenarios, such as those including migration and invasion patterns and other types of global change, are considered (Savary *et al.*, 2005; Garrett *et al.*, 2011). Effects on soil communities represent an area that needs more attention (Pritchard, 2011). Mycotoxins and pesticide residues in food are an important concern for food safety in many parts of the world, and identified as an important issue for climate change effects in Europe (Miraglia *et al.*, 2009).

7.3.2.4. Pastures and Livestock

Pastures response to climate change is complex because, in addition to the major climatic drivers (CO_2 concentration, temperature, and precipitation), other plant and management factors affect this response (e.g., plant competition, perennial growth habits, seasonal productivity, and plant-animal interactions). Projected increases in temperature and the lengthening of the growing season should extend forage production into late fall and early spring, thereby decreasing the need for accumulation of forage reserves during the winter season in USA. In addition, water availability may play a major role in the response of pasturelands to climate change although there are differences in species response (Izaurralde *et al.*, 2011). There is general consensus that increases in CO_2 will benefit C_3 species; however, warmer temperatures and drier conditions will tend to favour C_4 species (Izaurralde *et al.*, 2011; Hatfield *et al.*, 2011, WG2 Chapter 4).

Projected scenarios for Europe indicate that increased temperatures and CO_2 concentrations have the potential to increase herbage growth and to favour legumes more than grasses, but changes in seasonal precipitation would reduce these benefits particularly in areas with low summer rainfall (Hopkins and Del Prado, 2007). Similarly, legume content of grasslands in most of southern Australia is projected to increase to the 2070s, with larger increases in wetter locations (Moore and Ghahramani, 2013). Further implications for grasslands may arise from increased frequency of droughts, storms and other extreme events (Hopkins and Del Prado, 2007).

Impacts of climate change on feed crops and grazing systems include changes in herbage growth brought about by changes in atmospheric CO_2 concentrations and rainfall and temperature regimes, and changes in the composition of pastures and in herbage quality. The interactions among climate, plants, livestock grazing and land management practices are complex, and evaluating the impacts of climate change on these elements is difficult (Craine *et al.*, 2010). In North American cattle production systems, future increases in precipitation will probably not compensate for the declines in forage quality that accompany projected temperature increases, and cattle will experience greater nutritional stress in the future (Craine *et al.*, 2010) Also in French grasslands (Graux *et al.*, 2013) and in sown pastures in Tasmania (Perring *et al.*, 2010), results from simulations indicate that forage quality will decrease in the future.

Pastureland species in the USA may experience accelerated metabolism and advanced development with rising temperature, often resulting in changes in length of the growing season, although soil resources will often constrain temperature effects (Izaurralde *et al.*, 2011). Similar effects are projected for European grasslands, many of which may be mediated via management - sometimes with impacts on mitigation too: ruminants fed tropical legumes produced 20% less methane than those fed C_4 grasses (Archimède *et al.*, 2011).

While elevated atmospheric CO_2 concentrations reduce sensitivity to lower precipitation in grassland ecosystems and can reduce mortality and increase recovery during severe water stress events, it is still unclear how general this result is (Soussana *et al.*, 2010). Evaluating the differential responses of plant species to elevated CO_2 will require models to include mechanisms of resource capture and use among plant functional types (Lazzarotto *et al.*, 2009; Soussana *et al.*, 2010). Studies on climate change impacts on pastureland that include assessment of the mediating effects of management as well as changes in water, carbon, and nutrient cycling have been undertaken (e.g. (Rütting *et al.*, 2010; Moore and Ghahramani, 2013), but more comprehensive studies are needed (McKeon *et al.*, 2009; Izaurralde *et al.*, 2011).

Moreover, IPCC emission scenarios for many cropland regions project elevated ozone concentrations in the atmosphere to the 2050s and beyond. At the same time, crop sensitivity may decline in areas where warming is accompanied by drying, such as in central Europe (Soussana *et al.*, 2010). Parameters in models for ozone risk assessment are uncertain and model improvements will be needed to identify regions most at risk from ozone in future climates (Fuhrer, 2009). At this stage, more experiments using free-air ozone enrichment will be needed across different habitats, climates and productivity levels before generalisations about the sensitivity of pastures to ozone can be made (Fuhrer, 2009).

As livestock productivity increases, be it increasing milk yield in dairy cattle or higher growth rates and leanness in pigs or poultry, so metabolic heat production increases and the capacity to tolerate elevated temperatures declines (Zumbach *et al.*, 2008; Dikmen and Hansen, 2009). Over the long term, single-trait selection for productivity will tend to result in animals with lower heat tolerance (Hoffmann, 2010). Recent work adds to previous understanding (AR4 Chapter 5) and indicates that heat stress in dairy cows can be responsible for the increase in mortality and economic losses (Vitali *et al.*, 2009); it affects a wide range of parameters in broilers (Feng et al, 2008); it impairs embryonic development and reproductive efficiency in pigs (Barati *et al.*, 2008); and affects ovarian follicle development and ovulation in horses (Mortensen *et al.*, 2009). The impacts of a changing UK climate on dairy cow production were analysed by (Wall *et al.*, 2010), who showed that in some regions, milk yields will be reduced and mortality increased because of heat stress throughout the current century, under a medium-high greenhouse gas emissions scenario, annual production and mortality losses amounting to some £40 million by the 2080s. Given that there is a genotype-by-environment interaction on the impacts of heat stress (Bohmanova *et al.*, 2008), breeding goals that focus on production traits tend to reduce heat tolerance. Breeding goals that aim to reduce greenhouse gas emissions need to take possible future climatic conditions into account (Hoffmann, 2010). Tools to do this in

developed country situations are becoming available (e.g. (Hayes *et al.*, 2009). Developing countries may be more reliant on local breeds, most of which are not well characterized, although such breeds may be not only heat tolerant but also tolerant of poor seasonal nutrition and parasites and diseases (Hoffmann, 2010).

Host and pathogen systems will change their ranges because of climate change. Species diversity of some pathogens may decrease in lowland tropical areas as temperatures increase (Mills *et al.*, 2010). The temperate regions may become more suitable for tropical vector-borne diseases such as Rift Valley fever and malaria, which are highly sensitive to climatic conditions (Rocque *et al.*, 2008). An overall increase in suitable conditions for pathogens and vectors is expected, rather than just a shift in distribution, because minimum temperatures are increasing more than maximum temperatures (Ostfeld, 2009). Vector-borne diseases of livestock such as African horse sickness and bluetongue may expand their range northwards because rising temperatures increase the development rate and winter survival of vectors and pathogens (Cutler *et al.*, 2010). Diseases such as West Nile virus and schistosomiasis are projected to expand into new areas (Rosenthal, 2009). The distribution, composition and migration of wild bird populations that harbour the genetic pool of Avian Influenza viruses will all be affected by climate change, although in ways that are somewhat unpredictable (Gilbert *et al.*, 2008). The changing frequency of extreme weather events, particularly flooding, will affect diseases too. For example, outbreaks of Rift Valley fever in East Africa are associated with increased rainfall and flooding due to El Niño-Southern Oscillation events (Gummow, 2010; Pfeffer and Dobler, 2010). In general, the impacts of climate change on livestock diseases remain difficult to predict and highly uncertain (Mills *et al.*, 2010; Tabachnick, 2010).

Current trends in consumption, production and environmental patterns will lead to water crises in many parts of the world (de Fraiture *et al.*, 2010). Every populated river basin in the world will experience changes in river discharge, and large human and livestock populations will experience water stress such that proactive or reactive management interventions will almost certainly be required (Palmer *et al.*, 2008). Climate change will affect the water resources available for livestock production and keeping via impacts on runoff and groundwater. In Kgatleng District, Botswana, climate change could lead to an annual increase of more than 20% in cattle water demand by 2050 because of increased temperatures under A1 SRES emission scenarios. At the same time, a decline is to be expected in the contribution of surface pan water to cattle water supply, leading to substantial increases in the abstraction of groundwater for cattle (Masike and Urich, 2008). Such problems of water supply for increasing livestock populations will be exacerbated by climate change in many places in sub-Saharan Africa and South Asia. Nevertheless, there are sufficient water resources available to satisfy global food demands during the next 50 years, but only if water is managed more effectively (de Fraiture and Wichelns, 2010). There is ample scope to improve livestock water productivity considerably (Molden *et al.*, 2010); for example, in mixed crop-livestock systems of sub-Saharan Africa via feed, water and animal management (Descheemaeker *et al.*, 2010).

7.3.2.5. Food and Fodder Quality and Human Health

Climate change is will have some adverse impacts food quality through both biotic and abiotic stresses (Ceccarelli *et al.*, 2010). These changes may affect crop quality by altering carbon and nutrient uptake and biochemical processes that produce secondary compounds or redistribute and store compounds during grain development and maturation which in turn could impact human and livestock health by altering nutritional intake. They also affect economic value by altering traits valuable to processers or the consumers. Food quality is any characteristic other than yield that is valuable to the producer or consumer, and includes properties such as protein and starch concentrations, which affect dough quality, dough strength, and loaf volume of wheat flour; chalkiness, amylose content and gelatinization temperature in rice, which affect taste; and mineral concentrations, which affect nutrient intake of consumers.

Change in N concentration, a proxy for protein concentration, is the most examined quality trait, and since AR4, studies have been extended to almost all the major food crops. Meta-analysis of 228 experimental observations finds decreases between 10 to 14 % in edible portions of wheat, rice, barley and potato, but only 1.5 % in soybeans, a nitrogen-fixing legume, when grown in elevated (540 - 958 ppm CO_2) compared to current (315 - 400 ppm CO_2) concentrations (Taub et al, 2008). The decrease in protein content of cereals grown in elevated CO_2 concentrations

was reported by many other workers (Piikki *et al.*, 2007; Hogy *et al.*, 2009; Erbs *et al.*, 2010; Ainsworth and McGrath, 2010; DaMatta *et al.*, 2010; Erda et al., 2010; Fernando *et al.*, 2012).

Mineral concentration of edible plant tissues are affected by growth in elevated CO_2 in a similar manner as N. Although there are numerous studies measuring mineral concentration, there are many minerals relevant to human health. Therefore, there are relatively few measurements for any given mineral. Although there were several studies published before the release of AR4, this topic was not covered in any depth in AR4. Meta-analysis of studies prior to 2002 finds that P, Ca, S, Mg, Fe, Zn, Mn and Cu decline by 2.5 - 20 % in wheat grain and leaves of numerous species in elevated CO_2, but K increases insignificantly in wheat grain (Loladze, 2002; Hogy *et al.*, 2009; Fernando *et al.*, 2012). Since 2002, studies generally find decreases in Zn, S, P, Mg and Fe in wheat and barley grain, but results are mixed for Ca and K, whereas limited evidence shows an increase in Cu, Mo and Pb (Hogy *et al.*, 2009; Erbs *et al.*, 2010; Fernando *et al.*, 2012). The magnitude of such decreases is likely to be affected by several factors including crop species, soil type, tissue (e.g. tuber, leaves or grain) and water status. In addition to effects of climate on plants directly, climate change-mediated soil degradation may affect nutrient composition by altering mineral availability (Lal, 2009).

The primary reason for the decline in protein concentration, and by extension mineral concentrations, is that enhanced production of carbohydrates in elevated CO_2 decreases the concentrations of all non-carbonaceous compounds because the increase in canopy carbon uptake increases without a concomitant increase in nutrient uptake. Thus, the increased amount of carbon dilutes the concentrations of other nutrients (Poorter *et al.*, 1997). The declines in nitrogen concentration are usually larger than expected from carbon dilution alone though (Taub *et al.*, 2008; Pleijel and Uddling, 2012) which indicates that nutrient uptake per unit biomass is lower under elevated CO_2 concentration. The reasons for this are unclear but altered root architecture, reduced root uptake activity and reduced flow of nutrients to the roots (Taub and Wang, 2008). Understanding the basis for these declines is imperative as it would allow for prediction of nutrient decline in various environments, and give some insight into nutrient change in relation to change in other environmental factors in the future climate.

Elevated O_3 concentrations appear to have the opposite effect as elevated CO_2. Meta-analysis of about 50 wheat experiments found that elevated O_3 increased grain protein concentration by decreasing yield (Pleijel and Uddling, 2012). For other species, studies find both increases and decreases of N and several minerals (Taub *et al.*, 2008), and as such no firm conclusions can be drawn, but they likely response similarly. Similarly, experiments examining the effect of drought on mineral concentrations find both decreases and increases in mineral concentrations (Ghorbanian *et al.*, 2011; Sun *et al.*, 2011).

Elevated CO_2 can lower the nutritional quality of flour produced from grain cereals (Hogy *et al.*, 2009; Erbs *et al.*, 2010) and of cassava (Gleadow *et al.*, 2009). When coupled with increased crop and pathogen biomass, elevated CO2 can result in increased severity of the *Fusarium pseudograminearum* pathogen, leading to shriveled grains with low market value (Melloy *et al.*, 2010). High and low temperature even for a short time during reproductive growth can cause pollen sterility and shriveling of grain in wheat with consequent reduction in yield and market value. Extreme temperatures and elevated CO_2 concentrations reduce milling quality of rice by increasing chalkiness, which causes breakage during milling, leading to reduced head yield (the percentage of unbroken kernels) but increased consumer -valued traits, such as reduced amylase concentration , increased mass viscosity and increased breakdown, all of which correlate with taste, are increased (Yang *et al.*, 2007) . The cultivars, however, vary in their susceptibility (Ambardekar *et al.*, 2011; Lanning *et al.*, 2011). Rice is sensitive to daytime extreme temperature and humidity during flowering and also to high night-time temperature causing a decrease in rice eating quality and assimilates accumulation, and yield (Okada *et al.*, 2009; Wassmann *et al.*, 2009).

There is robust evidence and high agreement that elevated CO_2 on its own likely results in decreased N concentrations. Combining knowledge of N and mineral studies, there is *medium evidence* and *medium agreement* that mineral concentrations will decline. The majority of these data are from wheat, with comparatively little information from key crops such as maize, rice, potato and cassava; thus magnitudes are uncertain for the species. Increases in CO_2 concentration are global and uniform, thus this effect will have global impacts, but confidence in this effect does not imply confidence in changes regarding human health for several reasons. First, elevated CO_2 can increase yield of minerals (g mineral per m^2 land area) even though concentrations are decreased (Duval *et al.*,

2011). Therefore, for any group for which increased crop yields allows for greater consumption (e.g., because they produce and consume the food directly, or through effects of prices) intake of calories and minerals could increases, despite lower mineral concentrations. Furthermore, since calorie intake is the primary concern in many food insecure populations, even if intake of minerals is decreased, those negative effects could be outweighed by increased calorie intake. Second, altered temperature, precipitation and ozone concentrations affect nutrient concentrations and their effects are globally variable. Third, changes in mineral concentrations do not directly relate to changes in consumption since many foods are processed in ways that affect nutrient concentrations, e.g., the nutrient-rich outer layers of rice are removed, leaving the starch dense endosperm. Lastly, impacts on health must take into account current diets. Decreased mineral intake will matter for those who currently do not meet, or just barley meet, requirements, but will not affect those who already exceed requirements. Little is known about combined effects of climate change factors on food quality or the economic and behavioral changes that will occur. Thus, there is little to no confidence regarding effects of climate change on human health through changes in nutrient composition. Hence, a complete understanding of how climate-induced changes in food quality will impact human health in different environments and how this information will be used to make predictions about impacts on health is needed.

7.3.2.6. Fisheries and Aquaculture

The fisheries and aquaculture sector differs from mainstream agriculture and is characterized by distinct interactions and needs in relation to climate change. Capture fisheries in particular, comprising the largest remaining example of harvesting natural, wild resources, are strongly influenced by global ecosystem processes. The social, economic and nutritional requirements of the growing human population are already driving heavy exploitation of capture fisheries and rapid development of aquaculture. This demand will increase over the next 20 to 30 years at least: (Merino *et al.*, 2012) forecast that in addition to a predicted small increase in marine fisheries production, between 71 and 117 MT of fish will need to be produced by aquaculture to maintain current average *per capita* consumption of fish. Climate change is an additional threat to the sustainability of capture fisheries and aquaculture development, adding to the threats of over-fishing and other environmental impacts (FAO, 2009). Expected changes in the intensity, frequency and seasonality of climate patterns and extreme events, sea level rise, glacier melting, ocean acidification and changes in precipitation with associated changes in groundwater and river flows are expected to result in significant changes across a wide range of aquatic ecosystem types and regions. There is no conclusive evidence at this stage, but the potential risks of climate change enabling the spread of pathogenic species has been raised and there are some concerns that, for example, poleward increases in temperature could lead to the spread of pathogens with impacts on wild and cultured aquatic resources (De Silva and Soto, 2009).

7.3.2.6.1. Mean and extremes of temperature and precipitation

There is widespread agreement that, under most emission scenarios, increasing mean temperatures will lead to changes in the distribution of marine fish and invertebrate species. In general, the distribution of species will shift towards the poles as has already been observed in, for example, the North Sea (Brander, 2007)) and Australia (Hobday, 2010) JP: I have highlighted the following in red for you to decide if it needs to be deleted,Chapter 6 of this volume). These shifts will result in positive and negative impacts on fisheries production with the direction of change varying from locality to locality and species to species. Overall, increased temperatures are expected to reduce ecosystem productivity in most tropical and subtropical oceans, seas and lakes and to increase productivity in high latitudes. Projections based on a dynamic bioclimate envelope model under the SRES A1B scenario suggested that climate change could lead to an average 30–70% increase in fisheries yield from high-latitude regions (>50^{o} N in the northern hemisphere), but a decrease of up to 40% in the tropics by 2055 compared to yields obtained in 2005 (Cheung *et al.*, 2010). A recent study using a suite of models linking physical, ecological, fisheries, and bioeconomic processes projected that, under the A1B scenario, the global yield from ‘large’ fish could increase by 6% and that of the ‘small fish’ used in fishmeal production by 3.5%. This forecast was predicated on the assumption that marine fisheries and fish resources would be managed sustainably (Merino *et al.*, 2012). A study on the effects of climate warming on marine fish along the Portuguese coast forecast, under the A2 and B2 emission scenarios, that fish species richness would increase, potentially creating opportunities for the development of new commercial

fisheries (Vinagre *et al.*, 2011). Fulton (2011) used available end-to-end models to forecast the impacts of climate change under the A2 scenario across approximately two-thirds of Australia's EEZ. The results indicated that by 2060 the large-scale commercial fisheries in all of the regions that were covered by the models would experience an overall increase of 90% in their economic returns, although differing across sectors. The change in returns for the small-scale sector varied between the regions from a decrease of 30-51% in some regions to an increase of 9-14% in another. The difference between the sectors was because the large-scale fisheries had greater flexibility to adapt to changes in distribution, composition and abundance of their target species (Fulton, 2011). These and other available forecasts demonstrate substantial differences in the direction and magnitude of impacts of climate change on fisheries production around the world, driven by different physical and biological attributes and the ability of fisheries operations and management to adapt to the changes that do occur.

The changes in marine yields projected by (Cheung *et al.*, 2010) result from changes in distribution of important fish stocks. In the case of freshwater fisheries, natural boundaries will frequently restrict the ability of species to change distribution. Endemic species, those in fragmented habitats and those in aquatic systems with a predominantly east–west orientation will be particularly restricted (Ficke *et al.*, 2007), as will food production systems dependent on them.

Many aquatic species are routinely subjected to large daily and seasonal fluctuations in temperature and are able to cope with them. For example, temperatures in shallow coastal habitats in the tropical Pacific can vary by more than 14ºC diurnally (Pratchett *et al.*, 2011). Nevertheless, changes in temperature extremes are expected to have impacts in some cases. For example, a study on salmon populations in Washington State, USA by (Mantua *et al.*, 2010) demonstrated the important impacts of seasonal variations and extremes, as opposed to means, on population responses to climate change. The study concluded that warming in winter and spring would have some positive impacts while increased summertime stream temperatures, seasonal low flows and changes in the peak and base flows would have negative impacts. Coral reefs are particularly susceptible to extremes in temperature: temperatures 1 or 2ºC in excess of normal maximums for 3 to 4 weeks are sufficient to disrupt the essential relationship between endosymbiotic dino-flagellates and their coral hosts leading to coral bleaching. Large scale bleaching of coral reefs has increased in recent decades both in intensity and frequency (Hoegh-Guldberg *et al.*, 2007); Box 5-3).

Reliable fine scale projections are not available at present because of the ecological complexity of the responses as well as the potential role of human adaptation in minimising risks and taking advantage of new opportunities.

7.3.2.6.2. Impact of ocean acidification

The impact of increasing CO2 concentrations on coral reefs as a result of higher concentrations of carbonic acid in the ocean reducing the availability of carbonate to the reef building organisms is addressed in the Cross-chapter ocean acidification box (IPCC 2014, WG2). It is reported there, citing the original references, that the annual economic cost of ocean-acidification-induced coral reef loss by 2100 has been estimated to be 870 and 500 billion USD respectively for A1 and B2 SRES emission scenarios and that the global cost of loss of production of molluscs could be over 100 billion USD by 2100.

7.3.2.6.3. Combined impacts on fish and seafood production

Climate change is modifying the distribution of marine and freshwater species with a general displacement towards the poles and is leading to changes in the size and productivity of suitable aquatic habitats. This will have a mixture of negative and potentially positive impacts which will vary from locality to locality. The ability to take advantage of new opportunities brought about by these changes will depend on the adaptive capacity of countries and local communities.

Where these ecological changes are significant, countries and communities will need to adapt through, for example, changes in fishing and aquaculture practices and operations. Given the proximity of fishing and aquaculture sites to oceans, seas and riparian environments, extreme events can be expected to have impacts on the associated

infrastructure and to affect safety at sea and for communities, with those living in low-lying areas at particular risk. In areas that experience water stress and competition for water resources, aquaculture operations and inland fisheries production will be at risk. The impacts of climate change on the fisheries and aquaculture sector will have implications for the four dimensions of food security i.e. availability of aquatic foods, stability of supply, access to aquatic foods, and utilization of aquatic products (FAO, 2009).

7.3.3. Sensitivity of Food Security to Weather and Climate

7.3.3.1. Non-Production Food Security Elements

As indicated in the discussion in 7.1.1 and Figure 7-1, food security is dependent on access and consumption patterns, food utilization and nutrition, and overall stability of the system as much as food production and availability. The overall impact of climate change on food security is considerably more complex and potentially greater than projected impacts on agricultural productivity alone. Figure 7-1 indicates the main components of food security and their key elements. All of these will be affected by climate change to some extent. For example, climate change effects on water, sanitation and energy availability have major implications for food access and utilization as well as availability. Likewise, changes in the frequency and severity of climate extremes can affect stability of food availability and prices, with consequent impacts on access to food.

7.3.3.2. Accessibility, Utilization, and Stability

7.3.2.2.1. Climate change impacts on access

As noted in the discussion in section 7.1.3, change in the levels and volatility of food prices is a key determinant of food access. Given the hypothesis that climate change will be a contributing factor to food price increases, and hence its affordability, the vulnerability of households to reduced food access depends on their channel of food access (*medium evidence; medium agreement).* Table 7-1 divides households into five main categories of food access, indicating their relative impacts of food price increases.

[INSERT TABLE 7-1 HERE
Table 7-1: Households divided into five categories of food access, indicating the impacts for them of food price increases.]

Concern about the impact of increased food prices on poverty and food security arises due to the high share of income that poor consumers spend on food, thus generating a disproportionately negative effect of price increases on this group (FAO, 2011). A recent study by the World Bank estimated a net increase of 44 million people in extreme poverty in low and middle income countries as a result of food price increases since June 2010 (Ivanic *et al.*, 2011).

Recent studies have indicated that the distribution of net food buyers and net food sellers varies considerably across countries and can be expected to change with the process of economic development (Zezza *et al.*, 2008; Aksoy *et al.*, 2010; FAO, 2011) . Changing consumption patterns associated with dietary transitions that accompany income growth, urbanization, market development, and trade liberalization determines the rate and nature of food demand growth and nutritional levels, and thus is a key determinant of global and local food security (Kearney, 2010). However the evidence base on potential climate change impacts on consumption patterns, or on other non-production elements of food security is thin (*limited evidence, low agreement*), particularly when compared with the literature on climate change impacts on food production and availability.

The variation in the distribution and vulnerability to loss of food access across household types indicates the complexity of assessing the potential effects of climate change on food access at future time periods where these factors may be expected to change. Nonetheless, there are reasons for concern about climate change impacts on food access due to the high rates of food insecurity and significant share of population in many low income countries of one of the most vulnerable groups to loss of access: e.g. agricultural producers who are net food buyers. Similarly,

low income agricultural dependent economies that are net food importers, which are those that already have high rates of food insecurity, could experience significant losses in food access through a double negative effect on reduced domestic agricultural production and increased food prices on global markets.

7.3.2.2.2. Climate change impacts on stability

There is increasing evidence and confidence in the effect of climate change on increasing the incidence and frequency of some types of climate extreme events (IPCC, 2012), and this will have significant impacts on food security (*medium evidence; medium agreement*) Recent experience with global climate pattern impacts on food security indicate the potential nature and magnitude of increased climate extremes. An impact assessment of the 2010 Pakistan floods surveyed 1800 households 6 months after the floods and found that 88% of the households reported income losses of up to 50%, with significantly higher rates in rural than urban areas (Kirsch *et al*., 2012). The same study indicated that loss of key services such as electricity, sanitation and clean water resulted in lower standards of living even in the wake of significant relief attempts, again with significantly heavier effects on rural populations (Kirsch et al., 2012). The Russian heat wave of 2010 and subsequent export ban contributed to the more than doubling of global wheat prices by the end of the year. The degree to which these price increases affected domestic consumers and poverty depended on national responses in importing countries, although a significant net negative effect on poverty was found (Ivanic *et al*., 2011).

Increased incidence of climate extremes increases uncertainty, which mitigates incentives to invest in agricultural production, potentially offsetting positive impacts from increasing food price trends. This is particularly true for poor smallholders with limited or no access to credit and insurance. Greater exposure to climate risk, in the absence of well-functioning insurance markets, leads to: 1) greater emphasis on low-return but low-risk subsistence crops (Roe and Graham-Tomasi, 1986; Fafchamps, 1992; Heltberg and Tarp, 2002), 2) a lower likelihood of applying purchased inputs such as fertilizer (Kassie et al., 2008; Dercon and Christiansen, 2011), 3) a lower likelihood of adopting new technologies (Feder *et al*., 1985; Antle and Crissman., 1990), and 4) lower investments (Skees *et al*., 1999). All of these responses generally lead to both lower current and future farm profits *(robust evidence, high agreement*) (Rosenzweig and Binswanger, 1993; Hurley, 2010).

It is also well documented that in many rural areas, smallholders in particular do not have the capacity to smooth consumption in the face of climate shocks, particularly generalized shocks that affect a majority of households in the same location (Dercon, 2004; Skoufias and Quisumbing, 2005; Dercon et al., 2006; Fafchamps, 2009; Prakash, 2011). Any increases in climate extremes will exacerbate the vulnerability of all food insecure people, including smallholders (*robust evidence, high agreement*). Currently, smallholders rely to a large extent on increasing labor off-farm where possible (Fafchamps, 1999; McPeak, 2004; Kazianga and Udry, 2006), but also by decreasing both food consumption and non-food expenditures, such as those on education and healthcare (Frankenberg, 1999; Skoufias and Quisumbing, 2005) (*medium evidence, high agreement*). Furthermore, some evidence also suggests that poorer households are more likely to reduce consumption, while wealthier households liquidate assets to cover current deficits (*limited evidence, medium agreement*) (Kazianga and Udry, 2006; Carter and Lybbert, 2012). Reductions in food consumption, sales of productive assets, education and healthcare can lead to long-term losses in terms of income-generation and thus to future food security (*limited evidence, medium agreement*) (Hoddinot and Maluccio, 2002; Skoufias and Quisumbing, 2005). Increased uncertainty of future climate conditions and increases in climate extremes will increase food insecurity unless these significant barriers to consumption and asset smoothing can be addressed (*medium evidence, medium agreement*).

7.3.2.2.3. Climate change impacts on utilization

Climate change impacts on utilization may come about through changes in consumption patterns in response to shocks, as well as changes in nutrient content of food as well as food safety (*medium evidence; medium agreement*). Rationing consumption to prioritize calorie-rich, but nutrient poor foods is another common response (Bloem *et al*., 2010). The effects are a decrease in dietary quality as well as quantity, which are magnified by pre-existing vulnerabilities – and lead to long term loss of health, productivity capacity and low incomes (*medium evidence;*

medium agreement) (Bloem *et al*., 2010; Alderman, 2010; Brinkman *et al*., 2010; Campbell *et al*., 2010; Sari *et al*., 2010). The biological effects of climate change on nutrient content of foods is one of main pathways for effects on utilization. A summary of recent literature on the impacts of climate change on the composition of nutrients in food items is given in HLPE (2012). Research on grains generally shows lowering of protein content with elevated temperature and CO_2 levels (Ainsworth and McGrath, 2010; Erda et al., 2005; Hatfield *et al*., 2011). There is good agreement that for plant-derived foods, mycotoxins are considered the key issue for food safety under climate change (Miraglia *et al*., 2009). The impacts of climate change on mycotoxins in the longer term are complex and region-specific; temperatures may increase sufficiently to eliminate certain mycotoxin-producing species from parts of the tropics, but in colder tropical regions and temperate zones, infections may increase (Cotty and Jaime-Garcia, 2007).

7.3.4. Land Use Change and Autonomous Adaptation

As noted in the AR4, changes in land use, for example adjusting the location of crop production, are a potential adaptation response to climate change. Studies since the AR4 have confirmed that high latitude locations are likely to become more suitable as the total time regions (Iqbal *et al*., 2009). Trnka et al. (2011), for example, examined projections of eleven agro-climatic indices across Europe, and found that declines in frost occurrence will lead to longer growing seasons, although temperature and moisture stress will likely lead to greater inter-annual variability in crop suitability. The potential influence of pests and diseases is commonly beyond the scope of such studies (Gregory et al., 2009).

For tropical systems where moisture availability or extreme heat rather than frost limits the length of the growing season, there is a likelihood that the length of the growing season and overall suitability for crops will decline (*medium evidence, medium agreement*) (Jones and Thornton, 2009; Zhang and Cai, 2011). For example, half of the wheat-growing area of the Indo-Gangetic Plains could become significantly heat stressed by the 2050s, whilst temperate wheat environments are likely to expand northwards as climate changes (Ortiz *et al*., 2008). Similarly, by 2050, the majority of African countries will experience climates over at least half of their current crop area that lie outside the range currently experienced within the country (Burke *et al*., 2009). The majority of these novel climates have analogues in other African countries. In mountainous regions, where temperature varies significantly across topography, changes in crop suitability can be inferred from the variation of temperature across topography. The resulting vertical zones of increasing, decreasing and unchanging suitability can be relatively robust in the face of uncertainty in future climate (Schroth *et al*., 2009).

The interaction between water resources and agriculture is likely to be increasingly important as climate changes. For example, whilst projected changes in crop productivity in China are uncertain, even within a single emissions scenario, irrigation has significant adaptation potential (Piao *et al*., 2010). However, limitations to availability of water will affect this potential (Frieler *et al*., 2013). Changes in water use, including increased water diversion and development to meet increasing water demand, and increased dam building will also have implications for inland fisheries and aquaculture, and therefore for the people dependent on them (Ficke *et al*., 2007; FAO, 2009). In the case of the Mekong River basin, a large proportion of the 60 million inhabitants are dependent in some way on fisheries and aquaculture which will be seriously impacted by human population growth, flood mitigation, increased offtake of water, changes in land use and overfishing, as well as by climate change (Brander, 2007). Ficke et al. (2007) reported that at that time there were 46 large dams planned or already under construction in the Yangtze River basin, the completion of which would have detrimental effects on those dependent on fish for subsistence and recreation.

The models used in projections of land suitability and cropland expansion discussed above rely on assumptions about non-climatic constraints on crop productivity, such as soil quality and access to markets. These assumptions are increasingly amenable to testing as the climate system shifts, by comparing observed changes in cropland area with model predictions. The location of the margin between cropping land and extensive grazing in southern Australia has varied with decadal climate conditions and is projected to shift towards the coast with hotter and drier conditions, notwithstanding the positive impacts of elevated CO_2 (Nidumolu et al., 2011). Recent trends in climate have seen reductions in cropping activity consistent with these projections (Nidumolu et al., 2011).

The application of first-generation biofuel conversion technologies have expanded the uses for traditional commodities such as maize, oil seeds, and sugarcane, enabling farmers to market their crops beyond the traditional food, feed or industrial food-processing uses. Such changes in land use have potentially adverse consequences for food security. There are a number of developing countries that are relatively food secure, and have a higher demand for fossil-based fuels – Brazil, Malaysia, Peru, Argentina, and Thailand–. A number of these countries which are export-oriented and have relatively large areas of land available are currently expanding biofuel production in order to meet both domestic and international demand (Ewing and Msangi, 2009). However, the expansion of biofuel production has created new linkages, trade-offs, and competition between the agricultural and energy sectors. It has also introduced new food-security risks and new challenges for the poor, particularly when natural-resource constraints have led to trade-offs between food and biofuel production and also to rising food prices (FAO, 2008; von Braun and Torero, 2009; Chum et al., 2011). The current food crop based biofuels are of concern as their development will also exacerbate food insecurity particularly in many of developing countries. Biofuels targets imply that an additional 140 and 150 million people may be at risk of hunger by 2020. Africa and South Asia will account for over two-thirds of those people most affected (Fischer *et al*., 2009).

7.4. Projected Integrated Climate Change Impacts

7.4.1. Projected Impacts on Cropping Systems

Crop productivity remains the most well studied aspect of food security impacts from climate change, with many projections published since AR4. These newer studies confirm many of the patterns identified in AR4, namely that tropical areas fare worse than temperate areas for small amounts of warming, and all areas are projected to have negative yield impacts past 3°C of local warming without adaptation, even with benefits of higher CO_2 and rainfall (Challinor *et al*., 2013). One exception is that more recent studies often show negative impacts for temperate wheat for 1-3 °C local warming, whereas AR4 showed primarily positive responses at these temperatures.

Figure 7-6 shows the changes in mean crop yield in twenty-year bins, from a meta-analysis of over 1800 projections (Challinor *et al*., 2013), including cases with no adaptation and a range of incremental adaptations. Taking the data as an indication of risk of crop yield reduction shows that reductions in mean yield become *more likely than not* from the 2030s. Reductions of more than 5% are *more likely than not* beyond 2050 and *likely* by the end of the century. Some important regional differences are masked in the figure. From the 2070s onwards, all of the positive yield changes are in temperate regions, suggesting that yield reduction in the tropics are *very likely* by this time. This is consistent with the analysis of Knox *et al*. (2012). A recent model intercomparison of global gridded crop models (Rosenzweig *et al*., 2013) presents a similar pattern for projections from site-based crop models.

[INSERT FIGURE 7-6 HERE
Figure 7-6: Projected changes in crop yield as a function of time. The y-axis indicates degree of consensus and the colours denote percentage change in crop yield. Data are plotted according to the 20-year period in which the centre point of the projection period falls. Taken from (Challinor *et al*., 2013).]

Fewer studies have explicitly compared projections for different regions or crops to identify areas at most risk. (Lobell *et al*., 2008) used a statistical crop model with 20 GCMs and identified South Asia and Southern Africa as two regions that, in the absence of adaptation, would likely suffer negative impacts on several important crops. Yields changes have also been assessed by regional meta-analyses: Knox *et al*. (2012) found yield reductions of up to 50% in the second half of the century for Sub-Saharan Africa and South Asia, with wheat, maize, sorghum, and millets more affected than rice, cassava, and sugarcane.

Changes in the interannual variability of yields are likely to be important in determining future stability of food availability and access. Figure 7-7 shows projected changes in the coefficient of variation of yield from some of the few studies that publish this information. The data shown are consistent with reports of CV elsewhere: Müller *et al*. (2013) conducted gridded simulations across the globe and reported an increase of more than 5% in CV in 64% grid cells, and a decrease of more than 5% in 29% of cases. Increases in CV can be due to reductions in mean yields

and/or increases in standard deviation of yields, and often simulated changes are a combination of the two. However, many studies reported increases in standard deviation, for example (Challinor *et al*., 2010) projected increasing occurrence of extremely low crop yields due to heat and water stress. Teixeira *et al*. (2013) report that under SRES A1B for 2070-2100 high temperature stress is likely to affect many parts of the globe, including temperate regions. Semenov and Shewry (2011) also find evidence from models that temperate heat stress will be an important determinant of yield from the 2050s. Thus temperature extremes due to changes in the distribution of climate are likely to increase yield variability. Overall, there is *medium confidence* that climate change will increase variability in crop yield in many regions (*medium evidence, medium agreement*).

[INSERT FIGURE 7-7 HERE
Figure 7-7: Projected percentage change in coefficient of variation (CV) for wheat (gold), maize (green), rice (blue) and C4 crops (red) taken from C2010 (Challinor *et al*., 2010), B2012 (Berg et al., 2012), T2009 (Tao et al., 2009), TZ2013 (Tao and Zhang, 2010), TZ2012 (Tao and Zhang, 2011) and U2012 (Urban et al., 2012). U2012 and C2012 plot multiple data points: U2012 shows the range (mean plus and minus one standard deviation) of percentage changes in CV. For C2012 paired CV changes were not available, so the box shows changes in the mean CV, the mean CV plus one standard deviation, and the mean CV minus one standard deviation. The studies used a range of scenarios (SRES A1B, A2, A1F1 and B1). B2012 is a global study, U2012 is for the US, and the remaining studies are for China.]

Given an increasing likelihood that mean global warming will be in excess of 2ºC (New et al. 2011) and perhaps up to 4ºC by 2100, studies have examined the effects of such warming on two very different regions; sub-Saharan Africa and northern Europe (Finland). With *medium evidence* and *high agreement*, the studies (Rötter et al., 2011; Thornton et al, 2011) conclude that positive effects of modest warming and increased CO_2 levels on crop yields are likely to be reversed at minimum temperatures increases of 4ºC, leading to grain yield decreases in excess of 20% in relation to current conditions (Rötter et al. 2011). An analysis for sub-Saharan Africa predicted overall decreases of 19% for maize yields, 68% decrease for bean yields and a small increase for fodder grass (*Brachiaria descumbens*) given 5ºC global average warming (Thornton *et al*., 2011).

Weed populations and demographics are expected to change, with an overall poleward migration in response to warming (Ziska *et al*., 2011). An overview of crop and weed competitive studies indicate that weeds could limit crop yields to a greater extent with rising levels of carbon dioxide per se (Ziska, 2010). This may be related to the greater degree of phenotypic and genotypic plasticity associated with weedy species relative to the uniformity inherent in large cropping systems (Treharne, 1989); such plasticity, in turn, would be advantageous in a rapidly changing climate. Finally, chemical control of weeds, which is the preferred management method for large-scale farms, may become less effective (*medium evidence, medium agreement*), with increasing economic and environmental costs.

Climate change effects on productivity of food systems will alter land use patterns, both in terms of total area sown to crops and the geographic distribution of that area. Given expected trends in population, incomes, bioenergy demand, and agricultural technology, global arable area is likely to increase from 2007 to 2050 (medium evidence, high agreement), with projected increases over this period of +9% (Bruinsma, 2009), +8% (Fischer *et al*., 2009), +10-20% (Smith *et al*., 2010), and +5-25% (Schmitz *et al*., 2013) (medium evidence, medium agreement). Not all such studies included the effects of global warming. Where this is the case, estimates range from a 20% increase in cropping area (Schmitz *et al*., 2013) to a decline of 9% (Zhang and Cai, 2011), but with large regional differences (limited evidence, low agreement). Countries at northern latitudes and under the current constraint of low temperature may increase cultivated area (limited evidence, low agreement). The generally lower nutrient quality of soils and the lack of available and necessary infrastructure required to convert virgin land into productive arable land, make estimates of any actual increase in harvested cropping areas highly uncertain, with this uncertainty increasing even more after 2050.

7.4.2. Projected Impacts on Fisheries and Aquaculture

7.4.2.1. Capture Fisheries

There have been a number of studies on the probable impacts of climate change on capture fisheries (see also Chapters 6 and 30). These take the form of studies on single-species (e.g. tuna species: (Loukos *et al.*, 2003; Lehodey *et al.*, 2010); and cod: (Drinkwater, 2005), ecologically significant taxonomic groups (e.g. coral reefs: (Hoegh-Guldberg *et al.*, 2007; Munday *et al.*, 2008), geographical regions (e.g. Australia: (Brown *et al.*, 2010) North Sea: (Cook and Heath, 2005; Hiddink and Hofstede, 2008); and the Pacific island countries and territories: (Bell *et al.*, 2011) and global (e.g. (Brander, 2007; Cheung *et al.*, 2010). All of them make considerable effort to minimise uncertainties but inevitably rely on underlying assumptions and retain considerable residual uncertainty.

Simulation studies on skipjack and bigeye tuna in the Pacific under the B1 and A2 scenarios suggest that the vulnerability of skipjack tuna to climate impacts in 2035 is low under both scenarios but moderate under B1 and high under A2 by 2100. Projections under the A2 scenario suggest a 32% decrease in biomass of skipjack in the western and 50% increase in the eastern Pacific Ocean by 2100 compared to biomasses in 2000, but the authors express lower confidence (evaluated by them at 5-33% confidence) in these results than for the B1 scenario where confidence is evaluated at 33-66% confidence (Lehodey, 2011). For bigeye tuna, the results are broadly similar. These shifts in distribution would tend to favour some of the smaller Pacific Island Countries and Territories (PICTs) in the central Pacific which are particularly dependent on revenues from sale of tuna fishing rights (Bell *et al.*, 2011). Tropical tuna fisheries are also discussed in Chapter 30.6.1.1.1.

Coastal fisheries make significant contributions to food security and livelihoods of rural and urban populations in the PICTs where, for the majority of them, average fish consumption is more than 50 $kg.person^{-1}.year^{-1}$. The food requirements of the human population of this area are predicted to increase by between 20 and 60% over the next 20 years (Bell *et al.*, 2011). Climate change is expected to impact directly on the productivity of coastal fisheries in the PICTs through increased sea surface temperature and ocean acidification and indirectly through climate-driven damage to coral reefs, mangroves, sea-grasses and intertidal flats (Pratchett *et al.*, 2011). Extreme events such as increased severity of tropical cyclones could also impact on some species. Under both B1 and A2 emissions scenarios, the vulnerability in 2035 (as estimated through the framework described in Bell et al. (2011b) of coastal fisheries as a whole is considered to be low. Under the B1 emissions scenario, the overall vulnerability of coastal fisheries is considered to be moderate in the PICTs in the west of the region and low for those in the East. The high emissions A2 scenario is expected to lead to major changes in the tropical Pacific, for example through deterioration of coral reef habitats and weakening of the South Equatorial Current and Counter Current. The net result is forecast to be a reduction in coastal fisheries production by 2100, under the A2 scenario, of by 20-35% in the west and 10-30% in the east, leading to an estimated vulnerability of moderate to high in the west and moderate in the east (Pratchett *et al.*, 2011).

In a broad-based modelling study (Brown *et al.*, 2010) forecast that, under the A2 emissions scenario, primary production in the ocean around Australia will increase over the 50-year period from 2000-2050 as a result of small increases in nutrient availability from changes in ocean stratification and temperature, although the authors acknowledge considerable model uncertainty. This increase is forecast, in general, to benefit fisheries catch and value. As another example, described in Section 2.1, impacts on fish and fisheries in the North Sea are widely expected to vary from area to area and species to species.

7.4.2.2. Aquaculture

Complementing the study by Mantua et al. (2010) on the impacts of climate change on salmon populations in Washington State, USA, (Huppert *et al.*, 2009) considered the impacts on the coast of that state. They concluded that there would be a number of physical and chemical consequences including inundation of low-lying coastal areas from sea level rise, coastal flooding from major storm events and increased ocean temperatures and acidification. These physical and chemical drivers are forecast to create a number of problems for the important shellfish aquaculture industry in the state arising from reduced growth and reproductive rates as a result of increased

temperatures, inundation of existing shellfish habitats from sea level rise, increased incidence of harmful algal blooms and higher rates of mortality as a result of greater acidity of sea water and resulting decreased calcification rates in skelton and shell formation. The authors report that the socio-economic impacts cannot be quantified at this stage but are considered to be substantial.

Aquaculture is considered to be under-developed in the island states and territories of the tropical Pacific. At present just over 20 000 people are estimated to be employed in aquaculture enterprises throughout the region, including the culture of black pearls in French Caledonia. Starting from this low base, pond aquaculture is seen as an important contributor to meeting the shortage of fish required for food security in the region. Using a structured vulnerability framework which uses the B1 and A2 emission scenarios to make forecasts to 2035 and 2100 (Bell *et al*., 2011b), it was concluded that production of freshwater species such as tilapia, carp and milkfish will probably benefit from the expected climate changes, while coastal enterprises are expected to encounter problems in the same time horizons, varying according to species. The drivers of these trends include changes to temperature, rainfall and sea-level rise (Pickering *et al*., 2011).

7.4.2.3. National and Regional Vulnerability

The consequences of the many and diverse impacts on capture fisheries and aquaculture, both positive and negative, on food security are more difficult to estimate than the biological and ecological consequences. A preliminary but informative study by (Allison *et al*., 2009) attempted to estimate the vulnerability of the economies of 132 countries to climate change impacts on fisheries in 2050 under the A1FI and B2 scenarios (also discussed in Chapter 6.4.1.1.2). They estimated vulnerability as a composite of three components: exposure to the physical effects of climate change, the sensitivity of the country to impacts on fisheries (measured by total fisheries production, contribution of fisheries to national employment, export income and dietary protein) and adaptive capacity within the country (a composite index derived from life expectancy, indicators of education levels, various indicators of governance effectiveness and size of economy). This analysis suggested that under both scenarios several of the least developed countries were also amongst the most vulnerable. They included countries in central and western Africa, Peru and Columbia in South America and four tropical Asian countries. Food security will be a major consideration in these vulnerable countries.

7.4.3. Projected Impacts on Food Prices and Food Security

AR4 presented a summary of food price projections based on five studies that used projected yield impacts as inputs to general or partial equilibrium models of commodity trade. Many additional projections of this type have been made since AR4, expanding the number of trade models used, the diversity of yield projections considered, and the disaggregation of prices by commodity (Hertel *et al*., 2010; Baldos and Hertel, 2013; Lobell *et al*., 2013; Nelson *et al*., 2013). Many of the studies did not include CO_2 effects, which is sometimes justified on the grounds that studies are concerned with "worst-case" scenarios, or that the bias from omitting positive CO_2 effects balances the known bias from omitting negative effects of elevated O_3 and increased weed and pest damage.

Based on these studies, it is *very likely* that changes in temperature and precipitation, without considering effects of CO_2, will lead to increased food prices by 2050, with estimated increases ranging from 3-84%. The combined effect of climate and CO_2 change (but ignoring O_3 and pest and disease impacts) appears *about as likely as not* to increase prices, with a range of projected impacts from -30% to +45% by 2050. One lesson from recent model intercomparison experiments (Nelson *et al*., 2013) is that the choice of economic model matters at least as much as the climate or crop model for determining price response to climate change, indicating the critical role of economic uncertainties for projecting the magnitude of price impacts.

The AR4 concluded that climate change was likely to result in higher real prices for food past 2050. This conclusion remains intact with *medium confidence*, albeit with a relative lack of new studies exploring price changes to 2100 or beyond. The pathways by which price changes can affect food security are outlined in section 7.3. A limited number of studies have estimated the effects of price changes on food security and related health outcomes. Nelson *et al*.

(2009) project that, without accelerated investment in planned adaptations, climate change by 2050 would increase the number of undernourished children under the age of 5 by 20-25 million (or 17-22%), with the range including projections with and without CO_2 fertilization. Lloyd et al. (2011) used the projected changes in undernourishment from Nelson (2009) to project the impact of climate change on human nutrition, estimating a relative increase in moderate stunting of 1–29% in 2050 compared with a future without climate change. Severe stunting was projected to increase by 23% (central SSA) to 62% (South Asia). Baldos and Hertel (2013) estimate that climate change results in an increase in global malnourished population by 49 million (11%) in 2050, but that the combined effects of climate change and CO_2, which results in yield increases in their study, reduces the number by 66 million (15%).

In summary, there is *medium confidence* (*limited evidence, high agreement*) that if global yields are negatively impacted by climate change, there would be a resulting increase in both food prices and the global headcount of food insecure people. However, it is only *about as likely as not* that such global yield effects will be experienced by 2050 as the net effect of climate and CO_2 changes, but *likely* that such changes will occur later in the 21st century. At the same time, it is *likely* that overall growth and development will remain a relatively stronger driver of food security over the next few decades, particularly when accompanied by changes in institutions and policies (Goklany, 2007; Parry *et al*., 2009). Importantly, all of the studies that project price impacts assume some level of on-farm agronomic adaptation, often by optimizing agronomic practices within the model. Most, but not all, also prescribe income growth rates as exogenous factors, despite the fact that incomes are heavily dependent on agriculture in many poor countries. One study that accounted for income effects found that, in countries such as Indonesia that had both a large share of poverty in agriculturally dependent households and yield impacts that were small relative to other regions, poverty was reduced by the effects of climate change (Hertel *et al*., 2010). However, in most countries the positive income effects of higher prices could not outweigh the costs of reduced productivity and higher food prices.

Recent work has also highlighted that productivity in many sectors besides agriculture are significantly influenced by warming, with generally negative effects of warming on economic output in tropical countries (Hsiang, 2010; Dell *et al*., 2012). Given the importance of incomes to food access, incorporating these effects into future estimates of food security impacts will be important. Conflict is also known to be an important factor in food security (FAO, 2010a), and evidence of climate variability effects on conflict risk (Hsiang *et al*., 2011) indicates a need to also consider this dimension in future work.

The impacts of climate change on food production and food security will depend on interactions between the multiple drivers outlined above. The timing of extreme events, which are expected to become more frequent (IPCC, 2012), is one such driver. Extremes contribute to variability in productivity (Figure 7-7) and can form part of compound events that are driven by common external forcing (e.g. El Niño), climate system feedbacks, or causally unrelated events (IPCC, 2012). Such compound events, where extremes have simultaneous impacts in different regions, may have negative impacts on food security, particularly against the backdrop of high food price volatility (Figure 7-4). There are very few projections of compound extreme events (IPCC, 2012), and interactions between multiple drivers are difficult to predict. Thus nonlinear interactions in food systems may mean that thresholds are reached through non-predicted mechanisms. Effective monitoring and prediction, and building resilience into food systems, are likely to be two key tools in avoiding the negative impacts resulting from these interactions (Misselhorn *et al*., 2010).

The impacts of climate change on food production and food security will depend on interactions between the multiple drivers outlined above. The timing of extreme events, which are expected to become more frequent (IPCC, 2012), is one such driver. Extremes contribute to variability in productivity (Figure 7-6) and can form part of compound events that are driven by common external forcing (e.g. El Niño), climate system feedbacks, or causally unrelated events (IPCC, 2012). Such compound events, where extremes have simultaneous impacts in different regions, may have negative impacts on food security, particularly against the backdrop of high food price volatility. There are very few projections of compound extreme events (IPCC, 2012), and interactions between multiple drivers are difficult to predict. Thus nonlinear interactions in food systems may mean that thresholds are reached through non-predicted mechanisms. Effective monitoring and prediction, and building resilience into food systems, are likely to be two key tools in avoiding the negative impacts resulting from these interactions (Misselhorn *et al*., 2010).

7.5. Adaptation and Managing Risks in Agriculture and Other Food System Activities

7.5.1. Adaptation Needs and Gaps based on Assessed Impacts and Vulnerabilities

7.5.1.1. Methods of Treating Impacts in Adaptation Studies – Incremental to Transformational

The pervasiveness of climate impacts on food security and production (Section 7.2), the commitment to future climate change from past greenhouse gas emissions (cross reference to WGI) and the very high likelihood of additional climate changes from future greenhouse gas emissions (cross reference to WGI) means that some level of adaptation of food systems to climate change will be necessary. Here we take adaptation to mean reductions in risk and vulnerability through the actions of adjusting practices, processes and capital in response to the actuality or threat of climate change. This often involves changes in the decision environment, such as social and institutional structures, and altered technical options that can affect the potential or capacity for these actions to be realized. Adaptation can also enhance opportunities from climate change (IPCC AR4 Chapters 5 and 17). These adaptations will need to be taken in the context of a range of other pressures on food security such as increasing demand as a result of population growth and increasing per capita consumption (Section 7.1).

In the period since the AR4 the literature on adaptation and food production has increased substantially, although there has been less focus on adaptations to food systems and on value chains: the linked sets of activities that progressively add value as inputs are converted into products the market demands. Many adaptation frameworks or approaches have been published, informing the approach in the AR4 which addressed both autonomous and planned adaptations. Autonomous adaptations are incremental changes in the existing system including through the ongoing implementation of extant knowledge and technology in response to the changes in climate experienced (Glossary). They include coping responses and are reactive in nature. Planned adaptations are proactive and can either adjust the broader system or transform it (Howden *et al.*, 2010). Adaptations can occur at a range of scales from field to policy. There is an increasing recognition in the literature that whilst many adaptation actions are local and build on past climate risk management experience, effective adaptation will often require changes in institutional arrangements and policies to strengthen the conditions favourable for effective adaptation including investment in new technologies and infrastructure. Building adaptive capacity by decision-makers at all scales (e.g. Nelson et al. 2008) is an increasingly important part of the adaptation discourse which has also further addressed costs, benefits, barriers and limits of adaptation (e.g. Adger et al. 2009).

The sector-specific nature of many adaptations means that sectors will initially be addressed separately below.

7.5.1.1.1. Cropping

Effective adaptation of cropping could be critical in enhancing food security and sustainable livelihoods, especially in developing countries (Chapter 5 AR4). There is increasing evidence that farmers in some regions are already adapting to observed climate changes in particular altering cultivation and sowing times and crop cultivars and species (e.g. Olesen et al. (2011) and marketing arrangements (WG II Box 9-4, Fujisawa and Koyabashi 2011) although this response is not ubiquitous (Bryan et al. 2009). There are a large number of potential adaptations for cropping systems and for the food systems of which they are part, many of them enhancements of existing climate risk management and all of which need to be embedded in the wider farm systems and community contexts.

The possibility of extended growing seasons because of higher temperatures increasing growth in cooler months means that changing planting dates is a frequently identified option for cereals and oilseeds (Krishnan et al, 2007; Magrin et al., 2009; Travasso et al., 2009; Laux et al., 2010; Stockle et al., 2010; Shimono et al., 2010, Deressa et al. 2009. Van de Giesen et al. 2008, Mary and Majule 2009, Meza and Silva 2009, Olesen et al. 2011, Tao and Zhang 2010, Tingem and Rivington 2010, Cho et al. 2012). Aggregated across studies, changing planting dates may increase yields by a mean of 13% but with substantial variation (Figure 7-8). Early sowing is being facilitated by improvements in machinery and by the use of techniques such as dry sowing (Passioura 2010), seedling transplanting and seed priming and these adaptations can be integrated with varieties with greater thermal time

requirements so as to maximize production benefits and to avoid late season frosts (e.g. Tingem and Rivington 2010, Crimp et al. 2012, Cho et al. 2012). In some situations early sowing may allow double cropping where currently only a single crop is feasible. For example, this could occur for irrigated maize in central Chile (Meza et al., 2008) and the double crop wheat/soybean in the southern pampas of Argentina (Monzon et al, 2007), increasing productivity per unit land although increasing nitrogen and water demand at the same time. However, in Mediterranean climates, early sowing of cereals is dependent on adequate planting rains in autumn and climate projections indicate that this may decrease in many regions (WG 1 cross-reference), limiting the effectiveness of this adaptation (Figure 7-8) and possibly resulting in later sowings than are currently practiced. In such circumstances, use of short duration cultivars could be desirable so as to reduce exposure to end of season droughts and high temperature events (Orlandini et al. 2008; Walter et al. 2010). There is *medium confidence* (*high agreement, medium evidence*) that optimisation of crop varieties appears to be an effective adaptation, increasing yields by around 50% compared with the use of current varieties and planting schedules when aggregated across studies (Figure 7-8). Flexibility in planting dates and varieties according to seasonal conditions could be increasingly important with ongoing climate change (Meza and Silva 2009, Deressa et al. 2009). Approaches that integrate climate forecasts at a range of scales in some cases are able to better inform crop risk (e.g. Cooper et al. 2008; Challinor *et al*., 2009; Baethgen 2010, Li et al. 2010) although care is needed to ensure that the provision of forecasts does not increase existing inequities in farming or fishing communities.

[INSERT FIGURE 7-8 HERE
Figure 7-8: The benefit (% difference from baseline) for different crop management adaptations (CA – cultivar adjustment; IO – irrigation optimisation; PDA – planting date adjustment; PDA early – adjusting planting date earlier; yes – other treatments). The bars indicate $\pm$ SE.]

Warmer conditions may also allow range expansion of cropping activities polewards in regions where low temperature has been a past limitation (*low confidence*: *medium agreement, limited evidence*) provided varieties with suitable daylength response are available. This may particularly occur in Russia, Canada and the Scandinavian nations although the potential may be less than earlier analyses indicated due to increased climate extremes, water limitations and various institutional barriers (Alcamo *et al*., 2007; Dronin and Kirilenko, 2011; Kulshreshtha, 2011; Kvalvik *et al*., 2011; Tchebakova *et al*., 2011; Bindi and Olesen 2011). In many of these cases, the northerly range expansion may only offset the reduction in southerly cropping areas and yields due to lower rainfall, water shortages and high temperatures (*medium confidence: high agreement, limited evidence*).

Improving cultivar tolerance to high temperature is a frequently identified adaptation for almost all crops and environments worldwide as high temperatures are known to reduce grain number, fill and quality (Challinor *et al*., 2009; Wassmann *et al*., 2009; Krishnan et al. 2007; Luo et al. 2009; Shimono et al. 2010; Stockle et al. 2010; Wassman et al. 2008) noting that a new cultivar usually takes between 8 and 20 years to deliver. Improving gene conservation and access to gene banks could facilitate the development of cultivars with appropriate thermal time and thermal tolerance characteristics (e.g. Mercer et al. 2008, Wassman et al. 2008) as well as to take advantage of increasing atmospheric CO_2 concentrations (Ziska *et al*., 2012) and respond to changing pest, disease and weed threats with these developments needing **t**o be integrated with *in situ* conservation of local varieties (IAASTD 2009).

Similarly, the prospect of increasing drought conditions in many cropping regions of the world (e.g. Olesen et al. 2011) raises the need for breeding additional drought-tolerant crop varieties (Tao and Zhang, 2011; Mutekwa 2009, Naylor et al. 2007), for enhanced storage and access to irrigation water, more efficient delivery systems, improved irrigation technologies such as deficit irrigation, more effective water harvesting, agronomy that increases soil water retention through practices such as minimum tillage and canopy management, increase in soil carbon and more effective decision support (Olesen et al 2011, Thomas, 2008, Falloon and Betts 2010, Luo et al. 2009, Lioubimtseva et al. 2009; Piao *et al*., 2010) amongst many other possible adaptations (e.g. WG II 22.4.3.7.1). Increasing soil organic carbon levels plays an important role for improved water retention and absorption capacity of soils (El-Hage et al. 2010; Smith and Olesen 2010). Several agricultural practices support increased soil carbon levels, such as use of organic fertilizers (compost, farm yard manure), crop rotations with deep rooting forage legumes or mulching of crop residues (e.g. Diacono and Montemurro 2010; Smith and Olesen 2010). Increasing soil carbon levels can also contribute to climate change mitigation (AR5 WG III). There is *medium confidence* (*high agreement, limited*

evidence) that crop adaptations can lead to moderate yield benefits under persistently drier conditions (about 10% from aggregation of studies (Challinor et al. 2013) and that irrigation optimisation for changed climate can increase yields by about 4% (Figure 7-8).

Diversification of activities is another climate adaptation option for cropping systems (Thornton *et al*., 2010; Lioubimtseva et al 2009). For example, Reidsma and Ewert (2009) found that regional farm diversity reduces the risk that is currently associated with unfavourable climate conditions in Europe. Diversification of activities often seeks to incorporate higher value activities or those that increase efficiency of a limited resource such as through increased water use efficiency (Thomas, 2008). For future conditions, Seo (2010) assessed that under climate predictions for 2060, integrated crop-livestock farms could increase in number in Africa at the expense of specialized crop or livestock systems. The analysis indicated that the net revenue of the specialized farms could decrease by up to 75% compared with only 10% for the mixed farm but the nature and degree of change will in part depend on the specific climate changes. In some cases, increased diversification outside of agriculture may be favoured (e.g. Coulthard 2008, Mary and Majule 2009; Mertz *et al*., 2009a).

The above adaptations, either singly or in combination, could significantly reduce negative impacts of climate change and increase the benefit of positive changes as found in AR4 (*high confidence: high agreement, medium evidence*). To quantify the benefits of adaptation, a meta-analysis of recent crop adaptation studies has been undertaken for wheat, rice and maize (see Section 7.5.2). This meta-analysis adds more recent studies to that undertaken in the AR4 (Chapter 5). It indicates that the average benefit (the yield difference between the adapted and non-adapted cases) of adapting crop management increases approximately linearly with increasing temperature change being equivalent to about 15% of current yields for a temperature increase of 5ºC (Figure 7-9). This response is, however, extremely variable, ranging from negligible benefit from adaptation (even potential dis-benefit) to very substantial. The responses are dissimilar between wheat, maize and rice (Figure 7-5) and differ markedly between adaptation management options (Figure 7-8). For example, cultivar adaptation is assessed by several studies as providing substantially more benefit (mean of over 50%) than changing planting dates (13%) or optimizing irrigation to the new climatic conditions (4%).

[INSERT FIGURE 7-9 HERE
Figure 7-9: Yield change (% difference from baseline) as affected by temperature aggregated across all crops for paired non-adapted and adapted cases. Only studies that examine both a 'no adaptation' and an 'adaptation' scenario are used.]

Potential increased variability of crop production means there is *high confidence* (*high agreement, medium evidence*) that other aspects of food systems such as food reserve, storage and distribution policies and systems may need to be enhanced (IAASTD 2009) along with a range of broader issues such as provision of effective insurance markets, clarity in property rights, building adaptive capacity and developing effective participatory research cultures that apply to more than just farming systems (Chapter 9, AR4 Chapter 5).

It is notable that most of the above adaptations raised above and used in this analysis are essentially either incremental changes to existing agricultural systems or are systemic changes which integrate new aspects into current systems. Few could be considered to be transformative changes. Consequently, the potential adaptation benefits could be understated and a considerable opportunity cost may emerge (*low confidence: medium agreement, limited evidence*) (Challinor et al. 2013).

7.5.1.1.2. Livestock

Extensive livestock systems occur over a huge range of biophysical and socio-ecological systems, with a consequent large range of potential adaptations. In many cases, these livestock systems are highly adapted to past climate risk, and there is *high confidence* that this provides a sound starting point for climate change adaptation (*high agreement, medium evidence*). These adaptations include matching stocking rates with pasture production, adjusting herd and water point management to altered seasonal and spatial patterns of forage production, managing diet quality (using diet supplements, legumes, choice of introduced pasture species and pasture fertility management), more effective

use of silage, pasture spelling and rotation, fire management to control woody thickening, using more suitable livestock breeds or species, migratory pastoralist activities and a wide range of biosecurity activities to monitor and manage the spread of pests, weeds and diseases (Fitzgerald et al. 2008, Howden et al. 2008, Nardone et al. 2010, Ghahramani and Moore 2013, Moore and Ghahramani 2013). Combining adaptations can result in substantial increases in benefits in terms of production and profit when compared with single adaptations (Ghahramani and Moore 2013, Moore and Ghahramani 2013). In some regions, these activities can in part be informed by climate forecasts at differing time-scales to enhance opportunities and reduce risks including soil degradation (e.g. McKeon et al. 2009). Many livestock systems are integrated with or compete for land with cropping systems and one climate adaptation may be to change these relationships. For example, with increased precipitation, farmers in Africa may need to reduce their livestock holdings in favour of crops, but with rising temperatures, they may need to substitute small ruminants in place of cattle with small temperature increases or reduce stocking rates with larger temperature rises (Kabubo-Mariara 2009, Seo 2010, Thornton et al. 2010). As with other food systems there is a range of barriers to adaptation which could be addressed on-farm and off-farm by changes in infrastructure, establishment of functioning markets, improved access to credit, improved access to water and water management technologies, enhanced animal health services and enhanced knowledge adoption and information systems (Howden et al. 2008, Kabubo-Mariara 2009, Mertz et al. 2009).

Heat stress is an existing issue for livestock in some regions (*high confidence: high agreement, robust evidence*), especially in higher productivity systems (7.3.2.6). For example, some graziers in Africa are already making changes to stock holdings in response to shorter term variations in temperatures (Seo et al. 2008). Breeding livestock with increased heat stress resistance is an adaptation often identified but there are usually trade-offs with productivity (Nardone et al. 2010) and so this option needs careful evaluation. Increased shade provision through trees or cost-effective structures can substantially reduce the incidence of high heat stress days (Nidumolu et al. 2011). In cooler climates, with warming there might be lesser need for winter housing and feed stocks.

7.5.1.1.3. Fisheries

The resources for capture fisheries are largely already fully or overexploited with an estimated 32 percent of stocks being overexploited and 53% being fully exploited (FAO 2010). Comparable global statistics are not available for inland fisheries but the status of those stocks may not be any better. Overfishing is widely regarded as the primary pressure on marine fishery resources but other human activities including coastal and offshore mining, oil and gas extraction, coastal zone development, land-based pollution and other activities are also negatively impacting status and production (WG II 30.6.7, Rosenberg and MacLeod 2005, Cochrane et al. 2009). For inland fisheries, overfishing is also widespread but the majority of impacts on the integrity of freshwater ecosystems and their resources originate from outside the sector (Welcomme et al. 2010). Climate change adds another compounding influence in both cases.

The vulnerability of fisheries and fishing communities to climate change will depend on their exposure to its physical and ecological effects, their dependence on the fishery and their sensitivity to physical effects, and their adaptive capacity (Allison et al. 2009). Adaptive responses to climate change in fisheries could include: management approaches and policies that strengthen the livelihood asset base, improved understanding of the existing response mechanisms to climate variability to assist in planning adaptation, recognising and responding to new opportunities brought about by climate change, monitoring biophysical, social and economic indicators linked to management and policy responses and adoption of multi-sector adaptive strategies to minimise negative impacts (WG II 6.4.2.1, Allison et al. 2009, Badjeck et al. 2010, MacNeil et al. 2010). A wide range of management tools and strategies have been developed to manage fisheries. However, Grafton (2010) points out that this array of tools is necessary but not sufficient for adaptation to climate change in fisheries. He argues that the standard tools for fisheries management were developed to control fishing mortality and to maintain adequate levels of recruitment to fishery stocks but without necessarily addressing the needs for resilience to change or to be able to function under changing climates. He therefore proposes that these conventional management tools must be used within processes that i) have a core objective to encourage ecosystems that are resilient to change and ii) that explicitly take into account uncertainties about future conditions and the effect of adaptation, and make use of models to explore the implications of these (Grafton 2010). There are also opportunities for fisheries to contribute to mitigation efforts

(Grafton 2010). Complementary adaptive responses include occupational flexibility, changing target species and fishing operations, protecting key functional groups, developing early warning systems for extreme events and the establishment of insurance schemes (Coulthard 2008, FAO 2009a, Daw et al. 2009, MacNeil et al. 2010, Koehn et al., 2011). Governance and management of fisheries will need to follow an ecosystem approach to maximise resilience of the ecosystem, and to be adaptive and flexible to allow for rapid responses to climate induced change (FAO 2009a, Daw et al. 2009). Some adaptation options for tropical industrial tuna fisheries and coral reef fisheries are presented in Chapter 30, Section 30.6.1.1.

In contrast to capture fisheries, aquaculture is estimated to be the fastest-growing animal-food-producing sector and is outpacing human population growth. Per capita supply from aquaculture increased at an average annual growth rate of 6.6 percent from 1970 to 2008 (FAO, 2010). Adaptive responses in aquaculture include use of improved feeds and selective breeding for higher temperature tolerance strains to cope with increasing temperatures (De Silva and Soto 2009) and shifting to more tolerant strains of molluscs to cope with increased acidification (Huppert et al. 2009). Better planning and improved site selection to take into account expected changes in water availability and quality; integrated water use planning that recognises and takes into account the water requirements and social and economic importance of fisheries and aquaculture in addition to other sectors; and improving the efficiency of water use in aquaculture operations are other adaptation options (De Silva and Soto 2009). Integrated water use planning will require making trade-offs between different land and water uses in the watershed (e.g. Mantua et al. 2010). De Silva and Soto (2009) also describe the need for insurance schemes accessible to small-scale producers so as to increase their resilience. In some near-shore locations there may be a need to shift property lines as the mean high water mark is displaced landwards by rising sea level (Huppert et al. 2009).

There are no simple, generic recipes for fisheries adaptation. Bell et al. (2011) suggest a list of 24 separate, but inter-related, actions that could be taken to adapt fisheries and aquaculture in the tropical Pacific to climate change. They break these management steps into three categories according to the primary objective: economic development and government revenue; maintaining the contribution of fish to food security; and maximising sustainable livelihoods. These authors also point out that actions and policies for adaptation in fisheries and aquaculture must complement those for other sectors. They suggest that the greater the number of different production systems to which communities have access, the greater the chance that some systems available to them will not be negatively impacted and that some may even benefit from climate change. Similar case-by-case, integrated planning will be required in all other regions and at scales from community to regional to achieve clearly defined adaptation goals.

7.5.1.1.4. Indigenous knowledge

Indigenous Knowledge (IK) has developed to cope with climate hazards contributing to food security in many parts of the world. Examples in the Americas include Alaska, where the Inuit knowledge of climate variability assured the source of food to hunters and reduced various risks (Ford 2009, Alessa 2008, Weatherhead et al. 2010), down to the southern Andes where the Inca traditions of crop diversification, genetic diversity, raised bed cultivation, agroforestry, weather forecasting and water harvesting are still used in agriculture (Goodman-Elgar 2008, Renard et al., 2011; McDowell and Hess 2012). In Africa, weather forecasting, diversity of crops and agropastoralism strategies have been useful in the Sahel (Nyong et al. 2007). Rainwater harvesting has been a common practice in Sub-Saharan Africa (Biazin et al. 2011) to cope with dry spells and improve crop productivity, while strategies from agropastoralists in Kenya are related to drought forecasting based on the fauna, flora, moon, winds and other factors (Speranza et al. 2010). In South Africa, farmer's early warming indicators of wet or dry periods in Namibia based on animals, plants and climate observations contributed to deal with climatic variability (Newsham and Thomas 2011). In the same way, in Asia and Australia IK plays an important role to assure food security of certain groups (Marin, 2010, Speranza et al. 2010; Biazin et al. 2012, Salick and Ross 2009, Kalanda et al. 2011; Green et al. 2010; Pareek and Trivedi 2011), although IK and the opportunities to implement it can differ according to gender and age in some communities (WG II 9.3.5.2.9, Rengalakshmi 2007; Turner and Clifton 2009, Kalanda et al. 2011) leading to distinct adaptive capacities and options.

However, because of changes already occurring in climate (seasonal changes, changes in extreme events: IPCC Extremes SR IPCC 2012) there is medium confidence that the reliance on IK could be reduced (Kalanda et al. 2011;

Speranza et al. 2009, McDowell & Hess 2012) affecting the adaptive capacity of a number of peoples globally (*medium agreement, medium evidence*). Moreover, there is *medium confidence* that some policies and regulations leading to limit the access to territories, promoting sedentarization, the substitution of traditional livelihoods, reduced genetic diversity and harvesting opportunities as well as loss of transmission of IK, may contribute to limit the adaptation to climate change in many regions (Nakashima et al. 2012) (*medium agreement, medium evidence*).

7.5.1.2. Practical Regional Experiences of Adaptation, including Lessons Learned

Given the early stages of climate change, there are relatively few unequivocal examples of adaptation (see Section 7.5.2) additional to existing climate risk management. Where there have been management changes these have often been in response to several driving variables of which climate is only one (Smit and Wandel 2006, Mertz et al. 2009, Chen et al. 2011, Odgaard et al. 2011). More farmers express an intention to change rather than having implemented adaptive actions (Battaglini et al. 2009) although in some regions there appears to be adaptation to climate change that is happening now (Olesen et al. 2011, Fujisawa and Kobayashi 2010, Bohensky et al. 2012). Activities to build adaptive capacity to better manage climate change are more widespread (Twomlow et al. 2008) but there remain questions as to how this capacity will evolve and be maintained (Nelson et al. 2009). Crucial in this will be devolution of the decision-making process so as to integrate local, contextual information into adaptation decision-making (Nelson et al. 2008).

7.5.1.2.1. Observed and expected barriers and limits to adaptation

Adaptation is strongly influenced by factors including institutional, technological, informational and economic (WG II 14, WG II 15) and there can be barriers (restrictions that can be addressed) and limits in all these factors (WG II 16: *very high confidence: high agreement, robust evidence*). Several barriers to adaptation of food systems have been raised including inadequate information on the climate, climate impacts and on the risks and benefits of the adaptation options, lack of adaptive capacity, inadequate extension, institutional inertia, cultural acceptability, financial constraints including access to credit, insufficient fertile land, infrastructure, lack of functioning markets and insurance systems (WG II 16, Bryan et al. 2009, de Bruin and de Link 2011, Deressa et al. 2009, Kabubo-Mariara 2009). Limits to adaptation can occur for example where crop yields drop below the level required to sustain critical infrastructure such as sugar or rice mills (Park et al. 2012). In some cases, these can be effectively irreversible. Some studies have shown that access to climate information is not the principal limitation to improving decision making and it can result in perverse outcomes, increasing inequities and widening gender gaps (Coles and Scott 2009). Incomplete adoption of adaptations may also occur.

Lack of technical options can also be a barrier to adaptation. New varieties of crops or breeds of livestock are assessed with *high confidence* as providing possible core adaptations of production systems (*high agreement, medium evidence*) (Mercer et al. 2008, Tingem and Rivington 2010) however, there is substantial investment needed to develop these along with delays before they are available, both of which can act as adaptation barriers. This may be addressed in part by investments to improve local crop varieties or livestock breeds that are easily adopted (IAASTD, 2009). There also can be physiological limits to performance such as upper temperature limits for heat tolerance (AR4 WGII 5.2.1).

7.5.1.2.2. Facilitating adaptation and avoiding maladaptation

Adaptation actions would usually be expected to provide benefits to farmers, the food industry along the value chain or perhaps to a broader community. However, there are possible maladaptations that arise from adapting too early or too late, by changing the incorrect elements of the food system or changing them by the incorrect amount. A key maladaptation would be one which increased emissions of greenhouse gases, this making the underlying problem worse (Smith and Olesen 2010; AR5 WGIII Chapter 11, *high agreement, robust evidence*). A recent review of agricultural adaptations however, has found that most categories of climate change adaptation options tend to reduce greenhouse gas emissions (Smith and Olesen 2010, Falloon and Betts 2010) (*medium confidence: medium*

agreement, medium evidence). These adaptations include measures that reduce soil erosion or reduce leaching of nitrogen and phosphorus, for increasing soil carbon, measures for conserving soil moisture and reducing temperature extremes by increasing vegetative cover.

There is a strong focus on incremental adaptation of existing food systems in the literature since AR4 (see above) however, and there is *medium confidence* that this may result in large opportunity costs that could arise from not considering more systemic adaptation or more transformative change (Kates et al. 2012; Howden et al. 2010) (*high agreement, limited evidence*). For example, in the USA, changes in farming systems (i.e. the combination of crops) have been assessed as providing significant adaptation benefit in terms of net farm income (Prato et al. 2010). There is a need to also engage farmers, policymakers and other stakeholders in evaluating transformative, pro-active, planned adaptations such as structural changes (Mäder, 2006; McCrum et al. 2009, Olesen et al. 2011). This could involve changes in land allocation and farming systems, breeding of functionally-different crop varieties, new land management techniques and new classes of service from lands such as ecosystem services (Howden et al. 2010). In Australia, industries including the wine, rice and peanut industries are already adopting transformative changes such as change in location so as to be early adopters of what are perceived as opportunities arising from change (Park et al. 2012).

There is substantial commonality in adaptation actions within different agricultural systems. For example, changing varieties and planting times are incremental adaptations found in studies of many different cropping systems as evidenced by the sample size in the meta-analysis. Collating information on the array of adaptation options available for farmers, their relative cost and benefit and their broad applicability could be a way of initiating engagement with decision-makers. In the climate mitigation domain, this has been attempted using marginal abatement cost curves which identify mitigation options, their relative cost and the potential size of emission-reductions (IPCC WG3). These curves can be used in setting investment priorities and informing policy discussions. The local nature of many adaptation decisions, their interactions with other highly contextual driving factors and the time and climate change-sensitive nature of adaptation decisions means however, that global, time-independent curves are not feasible. The studies in Figure 7-8 indicate that there some options which may be more relevant and useful to consider than others. These results however, illustrate the potential scope and benefit of developing effective crop adaptation options if implemented in an adaptive management approach.

7.5.2. Food System Case Studies – Examples of Successful and Unsuccessful Adaptation

Incremental, systemic and transformational adaptation to climate change is beginning to be documented, though the peer-reviewed literature largely covers vulnerability assessments and intentions to act, not adaptation actions (Berang-Ford et al. 2010).

Case 1: Incremental adaptation in the Sahel

Much of the literature covers incremental, reactive adaptation, but given actors are constantly adapting to changing social and economic conditions, incremental adaptation to climate change is difficult to distinguish from other actions (Berrang-Ford et al. 2010, Speranza 2010), and in fact is usually a response to a complex of factors. This case, of the zaï soil management practice in the Sahel region, is an example where a complex of factors drives local actions, and factors such as growing land scarcity and new market opportunities, rather than climate, may be the primary factors (Barbier et al. 2009, Mertz et al. 2010). Inherent poor soil quality and human activities have resulted in soil degradation – crusting, sealing, erosion by water and wind, and hardpan formation (Zougmoré et al. 2010, Fatondji et al. 2009). Zaï, a traditional integrated soil and water management practice, can combat land degradation and improve yield and decrease yield variability by concentrating runoff water and organic matter in small pits (20-40 cm in diameter and 10-15 cm deep) dug manually during the dry season and combined with contour stone bunds to slow runoff. A handful of animal manure or compost is placed in each pit. . By breaking the soil crust, the pits facilitate greater water infiltration, while the applied organic matter improves soil nutrient status and attracts termites, which have a positive effect on soil structure. The zaï technique is very labour intensive requiring some 60 days of labour per hectare. Innovations to the system, involving animal-drawn implements, can reduce labour substantially.

Case 2: Mixed farming systems in Tanzania

In Morogoro, Tanzania, farming households have adapted in many ways to climatic and other stresses (Paavola 2008). They have extended cultivation through forest clearance or reducing the length of the fallow period. Intensification is under way, through change in crop choices, increased fertiliser use and irrigation, and especially greater labour inputs. Livelihood diversification has been the main adaptation strategy – this has involved more non-farm income-generating activities, tapping into natural resources for subsistence and cash income (e.g. charcoal production), and has included artisanal gold and gemstone mining. Households have also altered their cropping systems, for example, by changing planting times. Migration is another frequently used strategy – with farmers moving to gain land, access markets or get employment. Parents also send children to cities to work for upkeep and cash income to reduce the household numbers that need to be supported by uncertain agricultural income. While many of these strategies help in terms of the short-term needs, in the longer term they may be reducing the capacity of households to cope. For instance, land cover change has negative impacts on future water supplies for irrigation, and deforestation and forest degradation means faltering forest-based income sources. This will be particularly problematic to the more vulnerable groups in the community, including women and children.

Case 3: Planning for adaptation in a CARE project

Anticipatory and planned adaptation has been initiated in many places, but it has been poorly documented in the peer-reviewed literature. In many cases these adaptation actions are the basis of externally-funded projects. For example, the humanitarian organization CARE is piloting an approach to increase the capacity of vulnerable communities to adapt to adverse climate change (Patt et al. 2009). In their project in Bangladesh they work directly with households to implement practical strategies to support adaptation to climate risk, as well as with local organisations to build their capacity to support communities to adapt. The initial stage in their work involves participatory assessments of vulnerability and adaptive capacity and perceived climate risk. In Bangladesh flooding, salinity, waterlogging and cyclones were the key challenges to be addressed. Given that vulnerability and adaptive capacity is gendered, the assessments were undertaken separately with men's and women's groups. The results of the assessments were then used to identify strategies to increase capacity to cope with the challenges, both present and those predicted under climate change. At the household level an example of an adaptation strategy that was taken up by households was the shift from raising chickens to raising ducks in light of increased flood risks. The work highlighted the difference in family responsibilities between men and women and differing vulnerability, and how this translates to differing priorities when planning for adaptation. Lack of mobility of women means that women have less access to information regarding potential hazards and possible adaptation strategies.

Case 4 Transformational change in the primary industries of Australia

Many of the cases identified in chapter 7 are examples of incremental adaptation; in many circumstances climate change may call for transformational changes in the agricultural sector, as incremental change will be insufficient (Howden et al. 2010). The primary industries in Australia are highly sensitive to the impacts of climate change and transformational adaptation is being considered and planned for (Park et al. 2012; Rickards and Howden 2012). Examples of transformational adaptations being implemented now include 1) relocation of parts of the rice and peanut industries to regions where future rainfall and irrigation water availability are anticipated to be more favourable causing major change in transport chains, inputs and management and, 2) the relocation of parts of the wine industry to cooler regions to offset risks of warming and forcing changes in supply chains through changes in grower contracts to increase the proportion of grape supplies from cooler regions with lower risk from high temperatures (Park et al. 2012). Researchers are working with those transforming to understand the processes needed so as to generalize and communicate them.

7.5.3. Key Findings from Adaptations – Confidence Limits, Agreement, and Level of Evidence

There have been many studies of crop adaptation since the AR4. In aggregate these show that adaptations to changed temperature and precipitation will bring substantial benefit,(*high confidence: high agreement, robust evidence*) with some adaptations (e.g. cultivar adaptation) being more effective than others (e.g. irrigation optimisation) (7.5.1.1.1). Most studies have assessed key farm-level adaptations such as changing planting dates and associated decisions to match evolving growing seasons and improving cultivar tolerance to high temperature, drought conditions and elevated CO_2 levels. There is *medium confidence* (*medium agreement, limited evidence*) that

limits to adaptation will increasing emerge for such incremental adaptations beyond temperature changes of around 2ºC raising the need for more systemic or transformational changes (7.5.1, 7.5.1.2.2), An example of transformational change is latitudinal expansion of cold-climate cropping zones polewards but this may be largely offset by reductions in cropping production in the mid-latitudes due to rainfall reduction and temperature increase (*medium confidence: high agreement, limited evidence) (7.5.1.1.1).* Adaptations to food systems additional to the production phase have been identified and sometimes implemented but the benefits of these have largely not been quantified.

Livestock and fisheries systems also have available a large range of possible adaptations often tailored to local conditions but there is not adequate information to aggregate the possible value of these adaptations although there is *high confidence* (*high agreement, medium evidence*) that they will bring substantial benefit, particularly if implemented in combination (7.5.1.1.2, 7.5.1.1.3). Key livestock adaptations include matching stocking rates with pasture availability, water management, monitoring and managing the spread of pests, weeds and diseases, livestock breeding and adjusting to changed frequencies of heat stress and cold conditions (7.5.1.1.2). Fishery adaptations include management approaches and policies that strengthen the livelihood asset base, take an ecosystem approach to managing the resource and adoption of multi-sector adaptive strategies to minimise negative impacts. Importantly, there is an emerging recognition that existing fishery management tools and strategies are necessary but not sufficient for adaptation to climate (7.5.1.1.3).

Indigenous knowledge is an important resource in climate risk management and is important for food security in many parts of the world. There is *medium confidence* (*medium agreement, medium evidence*) that climate changes are reducing reliance on indigenous knowledge in some locations but also that some policies and regulation are limiting the contribution that indigenous knowledge can make to effective climate adaptation (7.5.1.1.4).

The focus on incremental adaptations and few studies on more systemic and transformational adaptation or adaptation across the food system mean that there is *medium confidence* (*high agreement, limited evidence*) that there may be underestimation of adaptation opportunities and benefits (7.5.1.2.2). In addition to this, there is a range of limits and barriers to adaptation and many of these could be addressed by devolution of the decision-making process so as to integrate local, contextual information into adaptation decision-making (7.5.1.2.2).

7.6. Research and Data Gaps – Food Security as a Cross-Sectoral Activity

Research and data gaps are seen mainly in the fact that most work since AR4 has concentrated on food production and not included other aspects of the food system that connects climate change to food security. Features such as food processing, distribution, access and consumption have recently become areas of research interest in their own right but only tangentially attached to climate change.

Other areas of neglect include food quality and nutritional aspects of climate change, the need to update and revise food production impact models, the need to create reliable, integrated food systems models at the regional and global scales geared to including climate change effects on the global food system.

In terms of crop production, important research questions are the extent to which CO_2 acts as a stimulant to crop growth, particularly in combination with other trace gases such as ozone. More attention needs to be given to the interaction between crop physiological thresholds in terms of high and low temperatures and drought and flooding. To date crop-climate models have not adequately included such thresholds and need to include them and examine their effects on crop yields and their quality under low and high levels of global warming. Excluding such features from models means that currently they may underestimate the impacts of global warming.

One of our conclusions from attempts to synthesise information on yield variation is that many studies either do not examine yield variability or do not report it. We recommend that closer attention is paid to yield variability, both for quantity and quality of food production, especially given observed price fluctuations associated with climate events. Within the context of yield variability, we expect environmental thresholds and tipping points, such as high temperatures, droughts and floods, to become more important in the future. Specific recommendations are food

production experiments in which changes in variability reflect predicted changes for given warming scenarios. Including such thresholds in models for high levels of global warming (i.e. 4-5 °C above pre-industrial) will very likely lead to reduced predictions of yield given changes in climate variability and increasing mean temperature. Research has also demonstrated that accurate crop productivity data would significantly improve future projections of yield. Important gaps in knowledge continue to be studies of weeds, pests, and diseases, including animal diseases, in response to climate change and how related adaptation activities can be robustly incorporated into food security assessments.

Current forecasts of changes in distribution and productivity of marine fish species and communities are typically at a global or regional scale only and include adaptations to a limited extent. Increasing the resolution to forecast impacts and changes at the national and local ecosystem scale would provide valuable information to governments and stakeholders and enable them to prepare more effectively for expected impacts on food production and security.

The real contribution of inland fisheries and small-scale aquaculture to food security and nutrition is still poorly understood in many developing countries and regions and is probably frequently under-estimated. Research is required to determine the true contributions from these sectors and their vulnerability to climate variability and change to ensure that planning and implementation of adaptation gives due consideration to them and does not result in undesirable negative impacts on food security.

Currently, approximate estimates of the vulnerability of countries to climate change impacts on fisheries are available. Building on this start, further research is required to improve the accuracy of these estimates and to increase the resolution of the study to identify the most vulnerable zones and communities within countries for priority action in adaptation. There is considerable general information available on what adaptive strategies will be required where fisheries and aquaculture are expected to be impacted by climate change but there are very few case studies of actual adaptation or preparation for adaptation in practice. Implementation of case studies in a range of different social and ecological contexts would enable the existing theories to be tested and revised according to lessons learned.

Possibilities for agronomic and breeding adaptations of food production to global warming are possible up to *ca*. 5ºC above pre-industrial but that the relative effectiveness of these often plateaus after about 3ºC. However, food security studies are urgently required to estimate the actual range of adaptations open to farmers and other actors in the food system especially when possible changes in climate variability are included .
From this chapter it is evident that since AR4, the production aspects of food production have continued to be studied much more comprehensively than the non-production elements of food security. Further studies require impacts and adaptation of global food security and systems in relation to global warming to be studied under a full range of radiative forcing scenarios and that these studies should be quantitative as possible. Such research should include climate impacts and adaptations of crops, livestock, fisheries, fruits and vegetables as production elements and processing, distribution and retailing and consumption patterns as the non-production but equally important elements of food security.

Frequently Asked Questions

FAQ 7.1: What factors determine food security and does low food production necessarily lead to food insecurity?
Observed data and many studies indicate that a warming climate has a negative effect to crop production, generally reduce yields of staple cereals such as wheat, rice and maize, which, however, differs between regions and latitudes. Elevated CO_2 could benefit crops yields in short term by increasing photosynthesis rates, however, there is big uncertainty in the magnitude of the CO_2 effect and that interactions with other factors. Climate change will affect fisheries and aquaculture through gradual warming, ocean acidification and through changes in the frequency, intensity and location of extreme events. Other aspects of the food chain are also sensitive to climate but such impacts are much less well known. Climate-related disasters are among the main drivers of food insecurity, both in the aftermath of a disaster and in the long run. Drought is a major driver of food insecurity, and contributes to a negative impact on nutrition. Floods and tropical storms also affect food security by destroying livelihood assets. The relationship between climate change and food production depends to a large degree on when and which

adaptation actions are taken. Other links in the food chain from production to consumption are sensitive to climate but such impacts are much less well known.

FAQ 7.2: How could adaptation actions enhance food security and nutrition?

Over 70 per cent of agriculture is rain-fed. This suggests that agriculture, food security and nutrition are all highly sensitive to changes in rainfall associated with climate change. Adaptation outcomes focusing on ensuring food security under a changing climate could have the most direct benefits on livelihoods, which have multiple benefits for food security, including: enhancing food production, access to markets and resources, and reduced disaster risk. Effective adaptation of cropping can help ensure food production and thereby contributing to food security and sustainable livelihoods in developing countries, by enhancing current climate risk management. There is increasing evidence that farmers in some regions are already adapting to observed climate changes in particular altering cultivation and sowing times and crop cultivars and species. Adaptive responses to climate change in fisheries should include: management approaches and policies that maximize resilience of the exploited ecosystems, ensuring fishing and aquaculture communities have the opportunity and capacity to respond to new opportunities brought about by climate change, and the use of multi-sector adaptive strategies to reduce the consequence of negative impacts in any particular sector. However, these adaptations will not necessarily reduce all of the negative impacts of climate change, and the effectiveness of adaptations could diminish at the higher end of warming projections.

FAQ 7.3: How could climate change interact with change in fish stocks, ocean acidification?

Millions of people rely on fish and aquatic invertebrates for their food security and as an important source of protein and some micronutrients. However, climate change will affect fish stocks and other aquatic species: increasing temperatures will lead to increased production of important fishery resources in some areas but decreased production in others while increases in acidification will have negative impacts on important invertebrate species, including species responsible for building coral reefs which provide essential habitat for many fished species in these areas. The poorest fishers and others dependent on fisheries and subsistence aquaculture will be the most vulnerable to these changes, including those in small-island developing States, central and western African countries, Peru and Columbia in South America and some tropical Asian countries.

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Introduction

Anthropogenic ocean acidification and climate change share the same primary cause at the global level, the increase of atmospheric carbon dioxide (WGI, 2.2.1). Eutrophication and upwelling contribute to local ocean acidification (5.3.3.6, 30.5.4). Past and futures changes in chemistry are well known in the surface open ocean (WGI, 3.8.2 and 6.4.4) but are more difficult to project in the more complex coastal systems (5.3.3.6 and 30.5.2).

Chemistry and Projections

The fundamental chemistry of ocean acidification has long been understood: the uptake of CO_2 into mildly alkaline ocean results in an increase in dissolved CO_2 and reductions in pH, dissolved carbonate ion, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of surface seawater can be projected at the global scale with high accuracy from projections of atmospheric CO_2 levels. Time series observations of changing upper ocean CO_2 chemistry support this linkage (WGI Table 3.2 and Figure 3.17; WGII Figure 30.5). Projections of regional changes, especially in coastal waters (5.3.3.6), and at depth are more difficult; observations and models show with high certainty that fossil fuel CO_2 has penetrated at depths of 1 km and more. Importantly, the natural buffering of increased CO_2 is less in deep than in surface water and thus a greater chemical impact is projected. Additional significant CO_2 increases and pH decreases at mid-depths are expected to result from increases in microbial respiration induced by warming. Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGII, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion

concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration).

Biological, Ecological, and Biogeochemical Impacts

The effects of ocean acidification on marine organisms and ecosystems have only recently been investigated. A wide range of sensitivities to projected rates of ocean acidification exists within and across organism groups and phyla with a trend for higher sensitivity in early life stages (*high confidence*; Kroeker et al., in press; 6.2.3-5, 6.3.4). A pattern of impacts, some positive, others negative, emerges for some processes and organisms (*high confidence*; Fig. X.C) but key uncertainties remain from organismal to ecosystem levels (Chap. 5, 6, 30). Responses to ocean acidification are exacerbated at high temperature extremes (*medium confidence*) and can be influenced by other drivers, such as oxygen concentration, nutrients, and light availability (*medium confidence*).

Experimental evidence shows that lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers such as reef-building corals (Box CC-CR, coralline algae (Raven, in press), bivalves and snails (Gazeau et al., in press) reducing their competitiveness compared to, e.g. seaweeds (Chap. 5, 6, 30). A reduced performance of these ecosystem builders would affect the other components of the ecosystem dependent on the habitats they create.

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*) and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may significantly stimulate nitrogen fixation in the oceans (*limited evidence, low agreement*; 6.2.3, 6.3.4). There are few known direct effects on early stages of fish and adult fish remain relatively undisturbed by elevated CO_2. Serious behavioral disturbances were reported, mostly on larval and juvenile coral reef fishes (6.2.4).

Projections of ocean acidification effects at the ecosystem level are limited by the diversity of species-level responses. Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities living on the sea-floor. Shifts in community structure have been documented in rocky shore environments (e.g., Wootton et al., 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012). Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.2-3), which could impact food webs and higher trophic levels (*limited evidence, high agreement*).

There is *limited evidence* and *medium agreement* that some phytoplankton and mollusks can adapt to ocean acidification, indicating that the long-term responses of these organisms to ocean acidification could be less than responses obtained in short-term experiments. However, mass extinctions during much slower rates of ocean acidification in Earth history (6.1.2) suggest that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of change (*high confidence*).

The effect of ocean acidification on global biogeochemical cycles is difficult to predict due to the species-specific responses to ocean acidification, lack of understanding of the effects on trophic interactions, and largely unexplored combined responses to ocean acidification and other climatic and non-climatic drivers, such as temperature, concentrations of oxygen and nutrients, and light availability.

Risks

Climate risk is defined as the probability that climate change will cause specific physical hazards and that those hazards will cause impacts (19.5.2). The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, includes both the probability that ocean acidification will affect key processes, and the magnitude of the resulting impacts. The changes in key processes mentioned above present significant ramifications on ecosystems and ecosystem services (Fig. 19.3). For example, ocean acidification will cause a decrease of calcification of corals, which will cause not only a reduction in the coral's ability to grow its skeleton, but also in its contribution to reef building (*high confidence*; 5.4.2.4). These changes will have consequences for the entire coral reef community and on the ecosystem services that coral reefs provide such as fisheries habitat (*medium confidence*; 19.5.2) and coastal protection (*medium confidence*; Box CC-CR). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Socioeconomic Impacts and Costs

The biological, ecological and biogeochemical changes driven by ocean acidification will affect several key ecosystem services. The oceans will become less efficient at absorbing CO_2, hence less efficient at moderating climate change, as their CO_2 content will increase (*very high confidence*). The impacts of ocean acidification on

coral reefs, together with those of bleaching and sea level rise, will in turn diminish their role of shoreline protection in atolls and small island nations as well as their direct and indirect benefits on the tourism industry (*limited evidence, high agreement*; Box CC-CR).

There is no global estimate of the observed or projected economic costs of ocean acidification. The production of commercially-exploited shelled mollusks may decrease (Barton et al., 2012) resulting in an up to 13% reduction of US production (limited evidence, low agreement; Cooley and Doney, 2009). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (Narita et al., 2012). The largest uncertainty is how the impacts on prey will propagate through the marine food webs and to top predators. Models suggest that ocean acidification will generally reduce fish biomass and catch (*limited evidence, high agreement*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (Branch et al., 2012; Griffith et al., 2012). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 500 billion USD, respectively for A1 and B2 SRES emission scenarios (Brander et al. 2012). Although this number is small compared to global GDP, it represents a large proportion of the GDP of some regions or small island states which rely economically on coral reefs.

Adaptation and Mitigation

The management of ocean acidification comes down to mitigation of the source of the problem and adaptation to the consequences (Rau et al., 2012; Billé et al., sbm). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts. Climate geoengineering techniques based on solar radiation management would have no direct effect on ocean acidification because atmospheric CO_2 would continue to rise (6.4.2). Techniques based on carbon dioxide removal could directly address the problem but their effectiveness at the scale required to ameliorate ocean acidification has yet to be demonstrated. Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep water oxygen levels (Williamson and Turley, 2012; 6.4.2; 30.3.2.3 and 30.5.7). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Specific activities, such as aquaculture, could adapt to ocean acidification within limits, for example by altering the production process, selecting less sensitive species or strains, or relocating elsewhere. A low-regret approach is to limit the number and the magnitude of drivers other than CO_2. There is evidence, for example, that reducing a locally determined driver (i.e. nutrient pollution) may substantially reduce its synergistic effects with a globally determined driver such as ocean acidification (Falkenberg et al., 2013).

[INSERT FIGURE OA-1 HERE

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.]

Box CC-WE. The Water-Energy-Food Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Ken Strzepek (UNU/USA), FerencToth (IAEA/Hungary), Blanca Elena Jimenez Cisneros (Mexico), Taikan Oki (Japan)]

Water, energy, and food are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure CC-WE-1. The depth and intensity of those linkages vary enormously between regions and production systems. Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Chapter 3.7.2, 7.3.2, 10.2,10.3.4, McMahon and Price, 2011, Macknick et al, 2012a, Cary and Weber 2008). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Kahn and Hajra 2009, Gertenet al. 2011). While food production and transport require large amounts of energy (Pelletier et al 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (7.3.2, Diffenbaugh et al 2012, Skaggs et al, 2012).

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change.]

Most energy production methods require significant amounts of water, either directly (e.g. crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Chapter 10.2.2 and 10.3.4, and Davies et al 2013, van Vliet et al 2012). Water is also required for mining, processing, and residue disposal of fossil fuels. Water for biofuels, for example, has been reported by Gerbens-Leenes et al. 2012 who computed a scenario of water use for biofuels for transport in 2030 based on the Alternative Policy Scenario of the IEA. Under this scenario, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water for energy currently ranges from a few percent to more than 50% of freshwater withdrawals, depending on the region and future water requirements will depend on electric demand growth, the portfolio of generation technologies and water

management options employed (WEC 2010, Sattler et al., 2012). Future water availability for energy production will change due to climate change (Chapter 3.5.2.2).

Water may require significant amounts of energy for lifting, transport and distribution, treatment or desalination. Non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced or reclaimed wastewater vs. desalinated seawater (Plappally and Lienhard 2012, Macknick et al, 2012b). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user, Döll et al. 2012) is generally more energy intensive than surface water – in some countries, 40% of total energy use is for pumping groundwater. Pumping from greater depth (following falling groundwater tables) increases energy demand significantly– electricity use ($kWhr/m^3$) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard 2012). A lack of water security can lead to increasing energy demand and vice versa, e.g. over-irrigation in response to electricity or water supply gaps.

Other linkages through land use and management, e.g. afforestation, can affect water as well as other ecosystem services, climate and water cycles (4.4.4, Box 25-10). Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security (3.7.2, 4.4.4). Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water (McCornick *et al.,* 2008, Bazilian *et al.,* 2011, Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy demand, bioproductivity and other factors (see Figure WE-1 and Wise et al, 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this Assessment Report.

Table 7-1: Households divided into five categories of food access, indicating the impacts for them of food price increases.

Food Access Category	Characteristics	Impacts of food price increase on food access
Primarily subsistence (autarkic)	Subsistence farmers, herders, fishers and forest dependent populations; generally low share of population	Limited impact.
Food producers: net sellers	Generally lower share of population compared with net buyers (Aksoy and Sid-Dimelik, 2008; Zezza *et al.*, 2008; FAO, 2011)	Positive impact through increased income effect. Major beneficiaries are those with greatest surplus (e.g. larger, more commercialized farms).
Food producers: net buyers	Majority of poor rural households (IFAD, 2010; FAO, 2011)	Ambiguous: depends on relative size of income and price effects, but generally expected to be negative due to high share of income spent on food (Ivanic and Martin, 2008; FAO, 2011; Ivanic *et al.*, 2011)
Rural non-farming households	Rural landless: characterized by high rates of food insecurity; average share of population for 15 low income countries was 22% (Aksoy *et al.*, 2010).	Negative impact due to high share of income spent on food; however some limited evidence that wage increases may accompany price increases in which case overall effects are ambiguous (Aksoy and Sid-Dimelik, 2008; FAO, 2011)
Urban consumers	Growing share of population in most countries	Negative impact by reducing food affordability. Especially vulnerable to changes in global food prices, as they are more likely to consume staple foods derived from tradable commodities, whereas rural populations are more (FAO, 2008; Ivanic *et al.*, 2011).

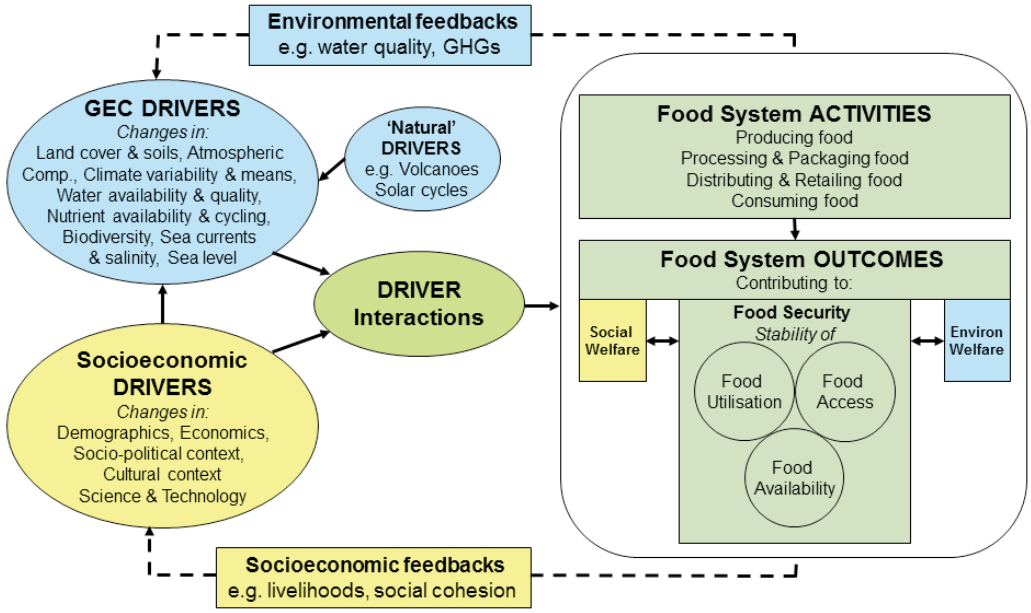

Figure 7-1: Main global environmental change (GEC) and socioeconomic drivers of food systems, the main food system activities, and the outcomes of these activities. The figure also shows the three main components of food security (circles), all of which need to be stable over time: Availability (with elements of production, distribution and trade); Access (affordability, allocation and preference); and Utilisation (nutritional value, cultural value and safety).

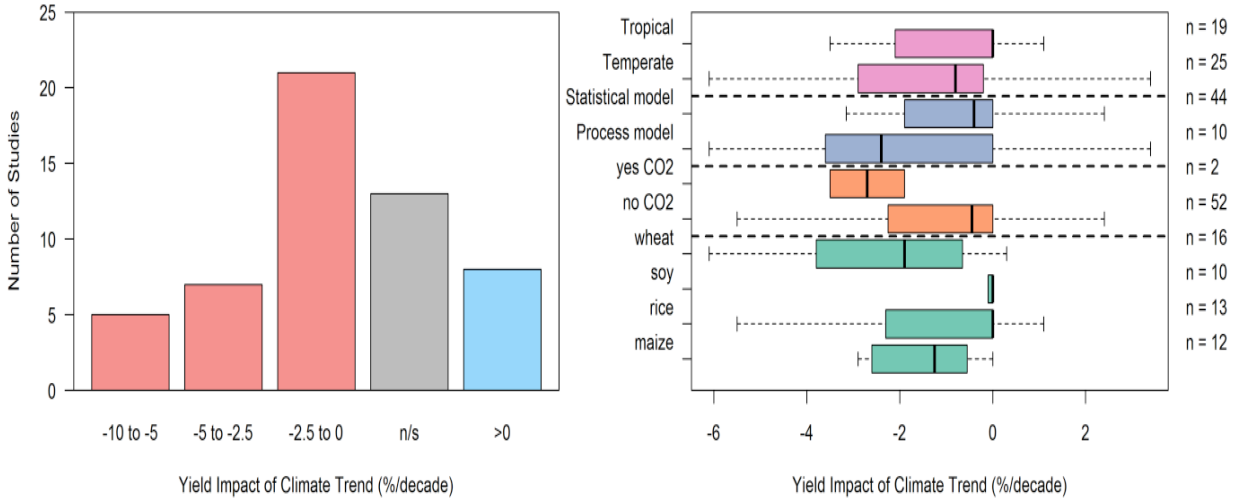

Figure 7-2: Summary of estimates of the impact of recent climate trends on yields for four major crops. Studies were taken from the peer-reviewed literature and used different methods (i.e., physiological process-based crop models or statistical models), spatial scales (e.g., stations, provinces, countries, or global), and time periods (median length of 29 years). Some included effects of positive CO_2 trends (see 7.3.2.1.2) but most did not. (a) shows number of studies with different level of impact (% yield per decade), (b) shows boxplot of studies separated by temperate vs. tropical regions, modelling approach (process-based vs. statistical), whether CO2 effects were included, and crop. Studies were for China (Tao *et al.*, 2006; Tao *et al.*, 2008; Wang *et al.*, 2008; You *et al.*, 2009; Chen *et al.*, 2010; Tao *et al.*, 2012), India (Pathak *et al.*, 2003; Auffhammer *et al.*, 2012), United States (Kucharik and Serbin, 2008), Mexico (Lobell *et al.*, 2005), France (Brisson *et al.*, 2010), Scotland (Gregory and Marshall, 2012) Australia (Ludwig *et al.*, 2009), and some studies for multiple countries or global aggregates (Lobell and Field, 2007; Welch *et al.*, 2010; Lobell *et al.*, 2011). Values from all studies were converted to percentage yield change per decade.

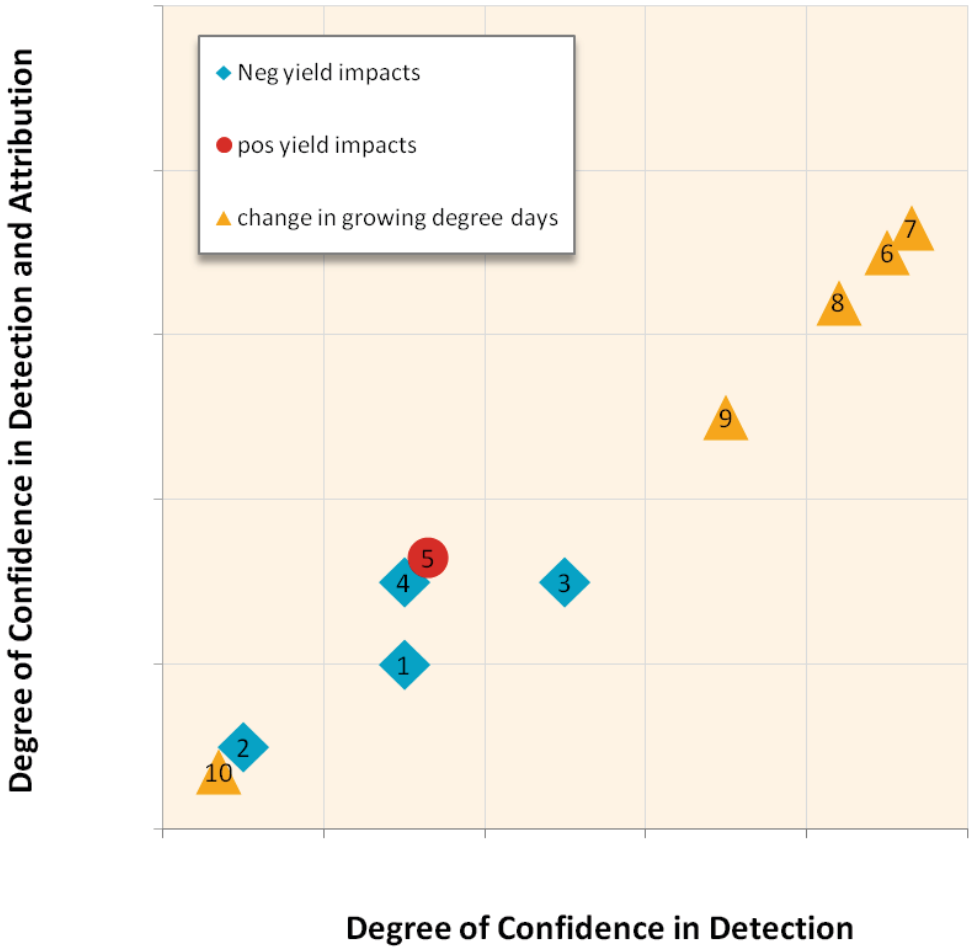

Figure 7-3: Confidence in detection and attribution of observed impacts on crop yields and growing season degree days. Yield impacts include both direct climate effects and effects of elevated CO_2, but do not consider farmer adaptation. Confidence Levels were derived based on expert judgement of the available literature, following the IPCC uncertainty guidance (Mastrandrea *et al.*, 2010). Negative yield impacts: 1= Global maize , 2= Global wheat, 3= South Asia wheat; 4 = China maize and wheat; Positive yield impacts: 5 = UK wheat, sugarbeet, and potato. Increase in growing degree days: 6 = South Asia, main crops; 7 = China, main crops; 8 = Europe, main crops; 9 = Latin America, main crops; 10 = North America, maize and soybean. Yield impact confidence based on studies listed in Figure 7-2. Growing degree day confidence based on detection and attribution of trends in growing season temperatures (IPCC 2013, WG1, Chapter 10).

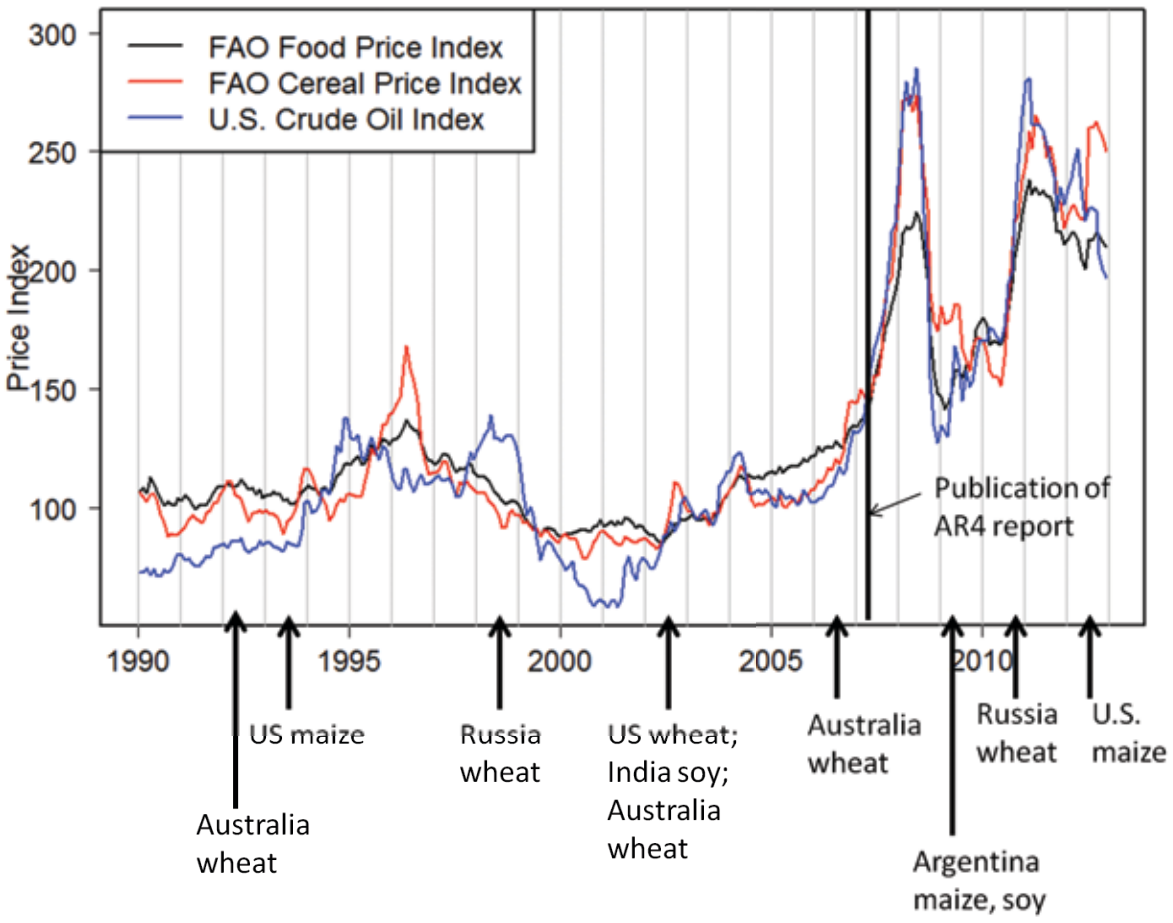

Figure 7-4: Since the AR4 report, food prices have reversed historical downward trend. Plot shows history of FAO food and cereal price index, along with events when a top 5 producer of a crop had yields 25% below trend line (indicative of a big weather effect). Australia is included despite not being a top five producer, because it is an important exporter and the drops were 40% or more below trend line. Prices may have become more sensitive to weather-related supply shortfalls in recent years, perhaps reflecting the importance of interactions with global storage levels and rapid growth in crop demand. At the same time, because of increased biofuel demand, food prices are also increasingly linked to the price of crude oil, shown in the blue line (data available at http://www.eia.gov). Therefore, there is clear evidence since AR4 that prices can rise rapidly, but the role of weather in these increases remains unclear. All indices are expressed as percentage of 2002-2004 averages.

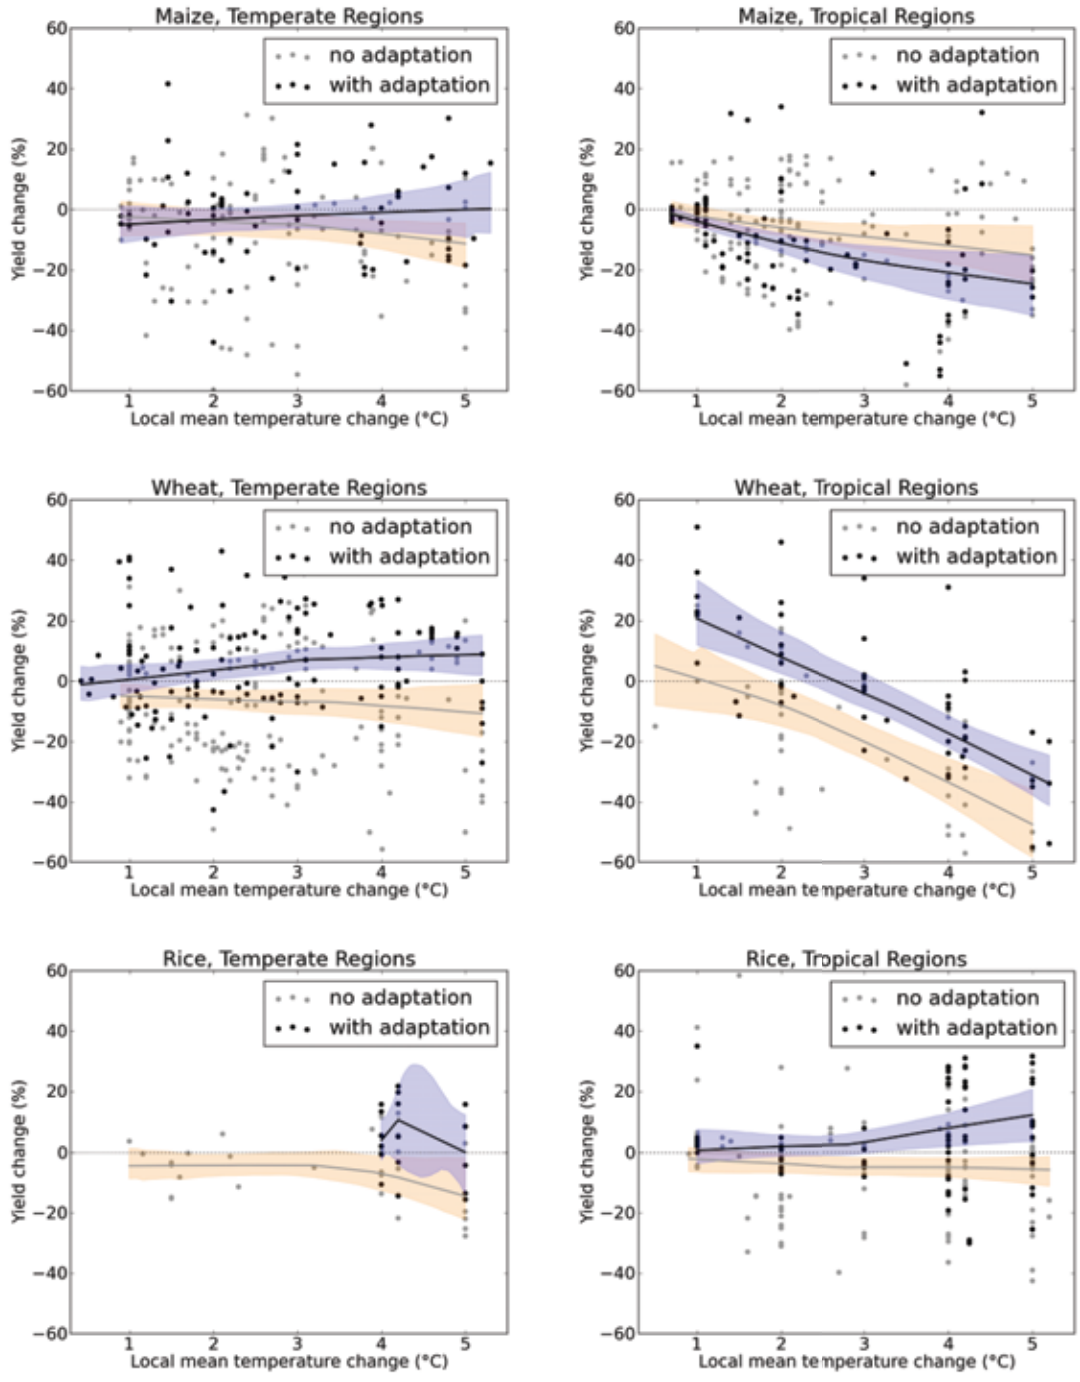

Figure 7-5: Percentage simulated yield change as a function of local temperature change temperature for the three major crops and for temperate and tropical regions. Shaded bands indicate the 95% confidence interval of regressions consistent with the data based on 500 bootstrap samples, which are separated according to the presence (blue) or absence (red) of adaptation. Note that 10 of the 1125 datapoints across all six panels are outside the yield change range shown. These were omitted for clarity.

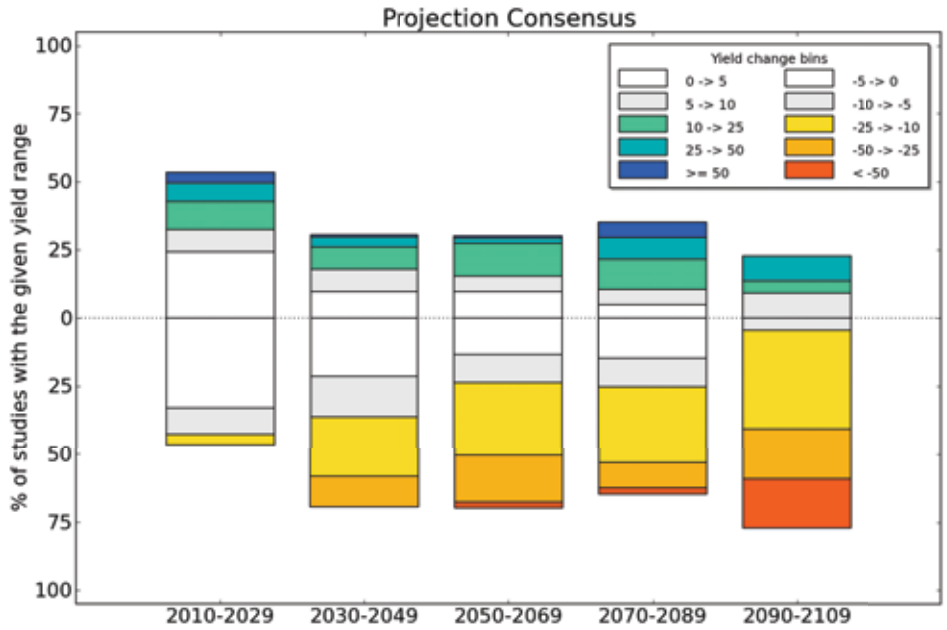

Figure 7-6: Projected changes in crop yield as a function of time. The y-axis indicates degree of consensus and the colours denote percentage change in crop yield. Data are plotted according to the 20-year period in which the centre point of the projection period falls. Taken from (Challinor *et al.*, 2013).

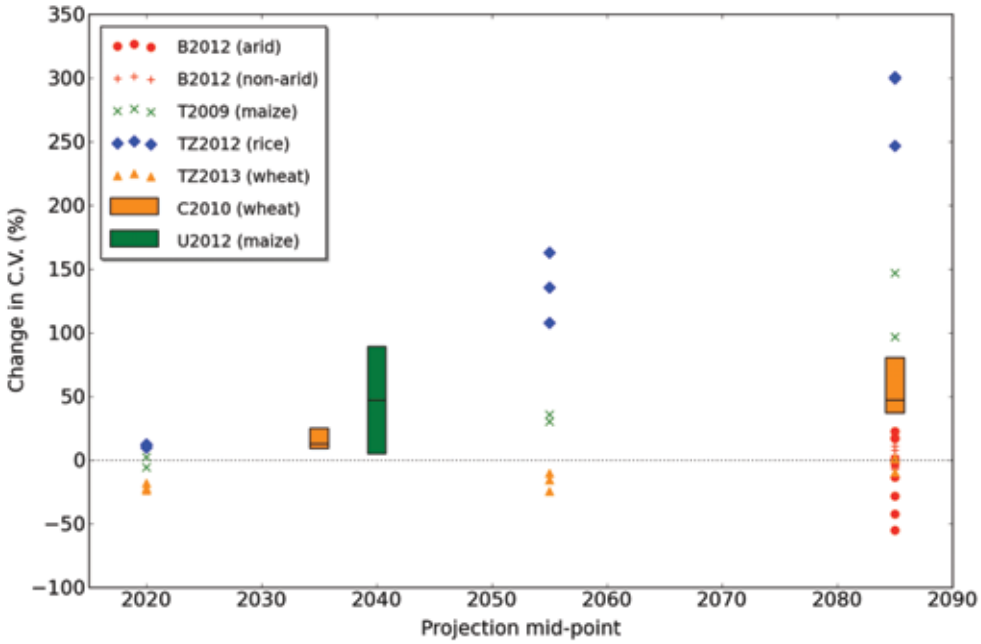

Figure 7-7: Projected percentage change in coefficient of variation (CV) for wheat (gold), maize (green), rice (blue) and C4 crops (red) taken from C2010 (Challinor *et al.*, 2010), B2012 (Berg et al., 2012), T2009 (Tao et al., 2009), TZ2013 (Tao and Zhang, 2010), TZ2012 (Tao and Zhang, 2011) and U2012 (Urban et al., 2012). U2012 and C2012 plot multiple data points: U2012 shows the range (mean plus and minus one standard deviation) of percentage changes in CV. For C2012 paired CV changes were not available, so the box shows changes in the mean CV, the mean CV plus one standard deviation, and the mean CV minus one standard deviation. The studies used a range of scenarios (SRES A1B, A2, A1F1 and B1). B2012 is a global study, U2012 is for the US, and the remaining studies are for China.

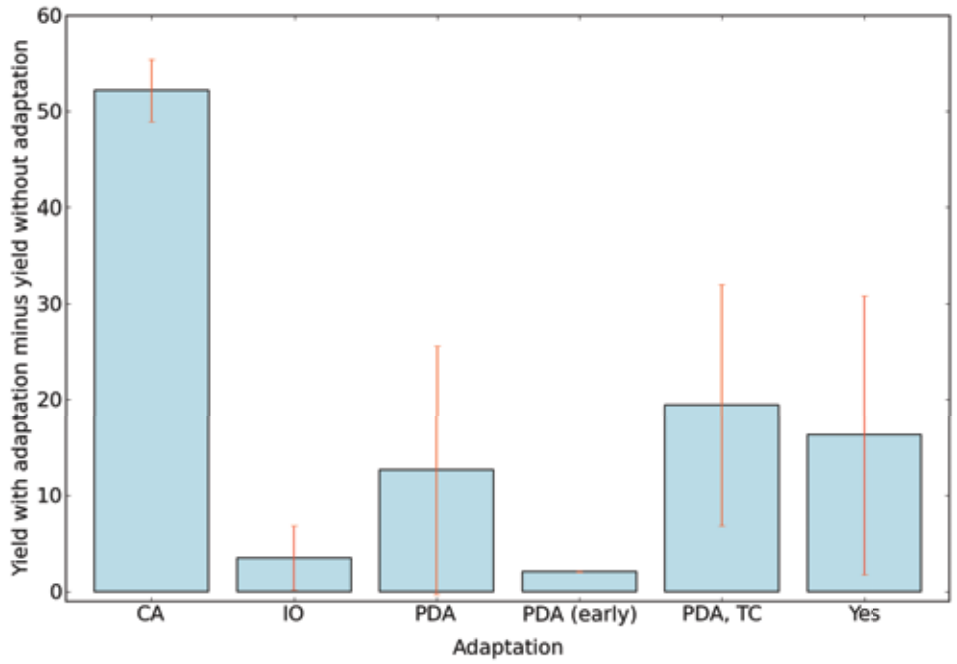

Figure 7-8: The benefit (% difference from baseline) for different crop management adaptations (CA – cultivar adjustment; IO – irrigation optimisation; PDA – planting date adjustment; PDA early – adjusting planting date earlier; yes – other treatments). The bars indicate ± SE.

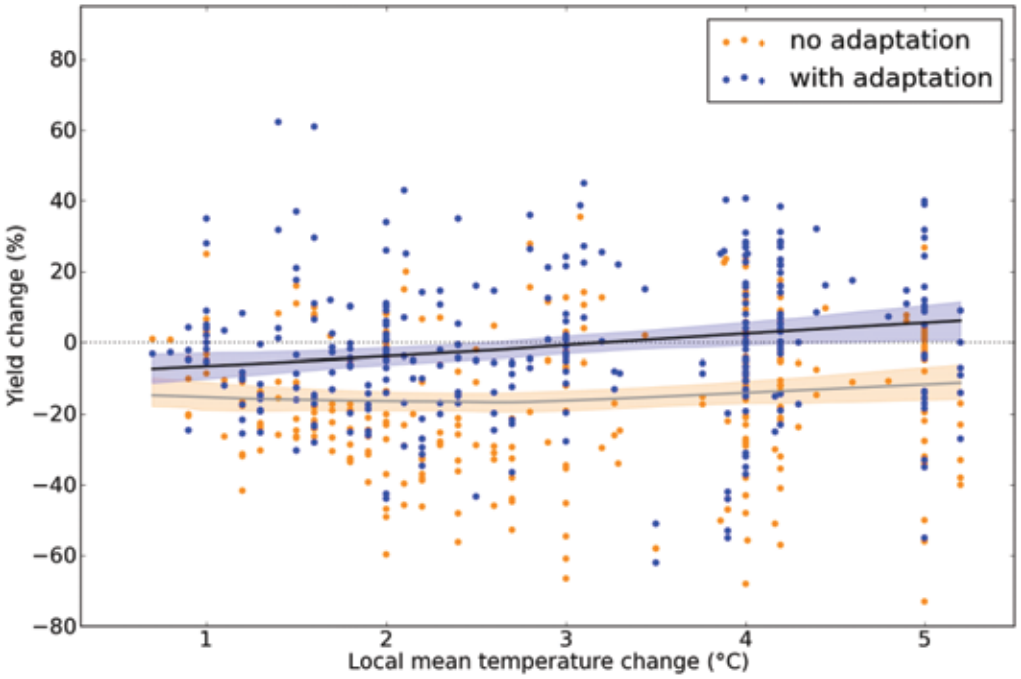

Figure 7-9: Yield change (% difference from baseline) as affected by temperature aggregated across all crops for paired non-adapted and adapted cases. Only studies that examine both a 'no adaptation' and an 'adaptation' scenario are used.

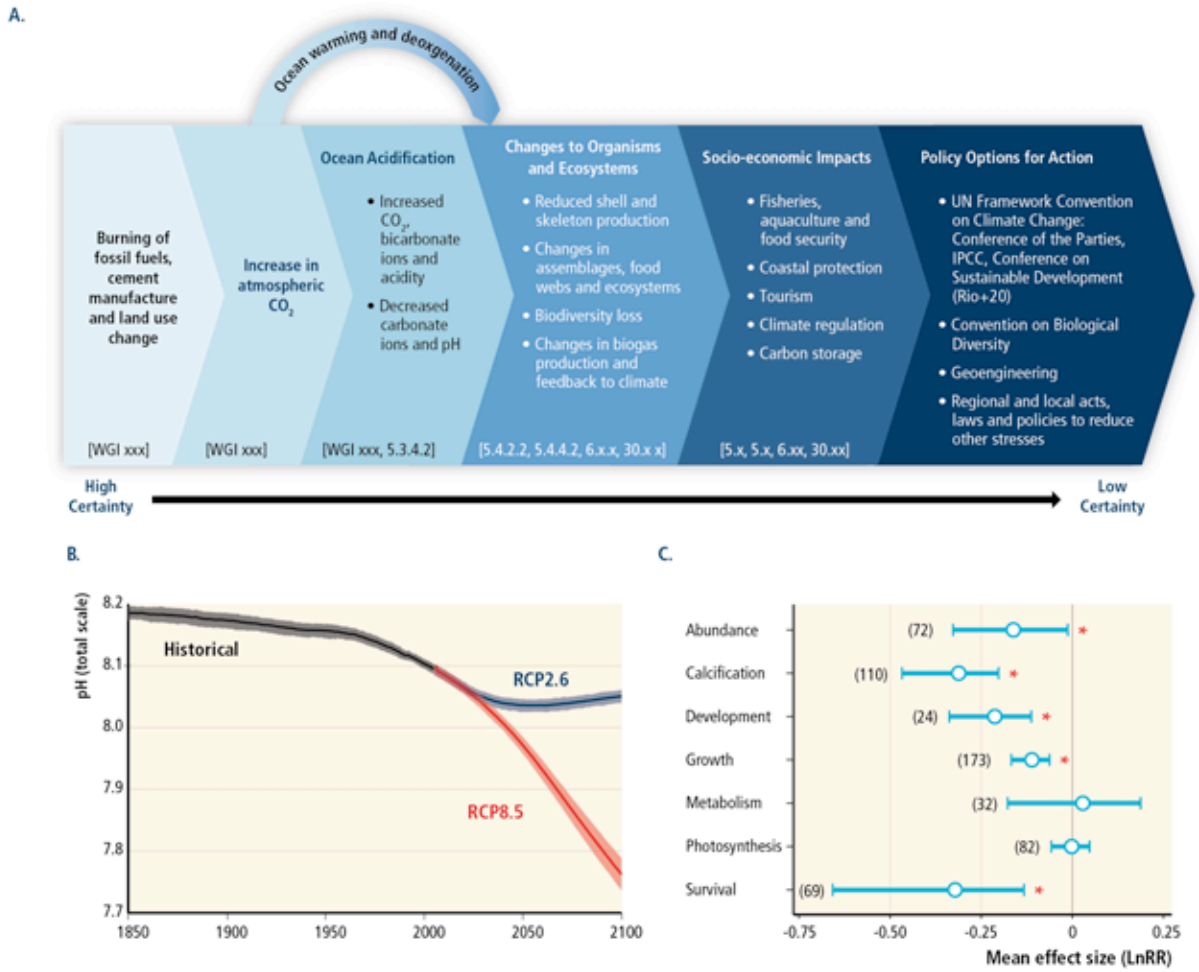

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley & Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (IPCC AR5 WG1 report, Figure 6.28). C: Effect of near future acidification on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., in press). The effect size indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a significant effect.

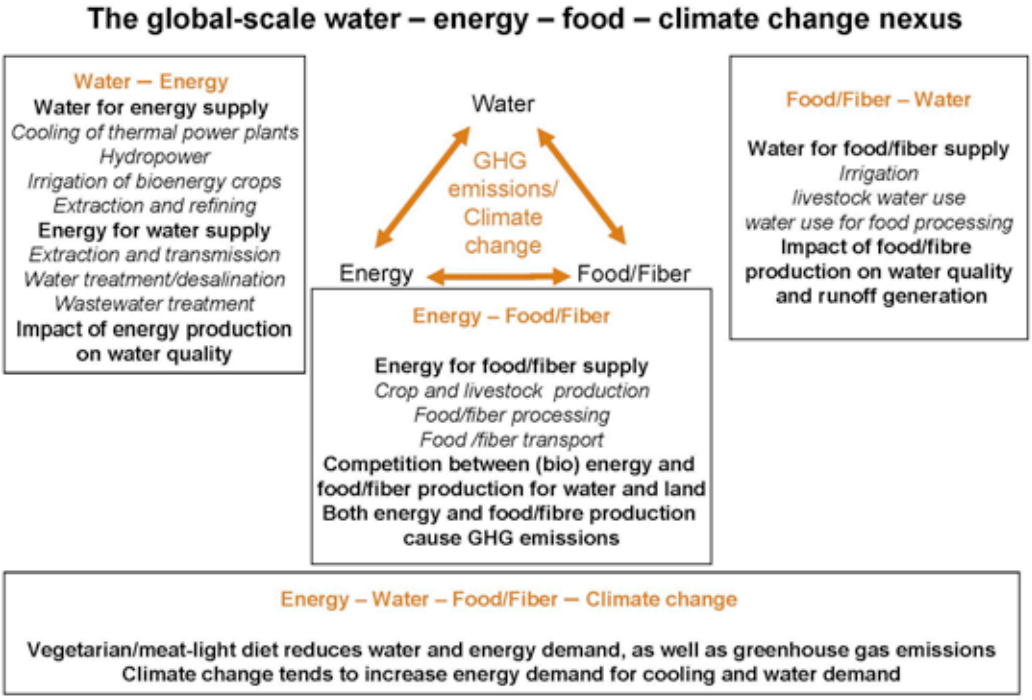

Figure WE-1: The water-energy-food nexus as related to climate change.

Chapter 8. Urban Areas

Coordinating Lead Authors
Aromar Revi (India), David Satterthwaite (UK)

Lead Authors
Fernando Aragón (Mexico), Jan Corfee-Morlot (USA / OECD), Robert B.R. Kiunsi (United Republic of Tanzania), Mark Pelling (UK), Debra Roberts (South Africa), William Solecki (USA)

Contributing Authors
Jo da Silva (UK), David Dodman (Jamaica), Andrew Maskrey (UK), Sumetee Pahwa Gajjar (India)

Review Editors
John Balbus (USA), Omar-Dario Cardona (Colombia)

Volunteer Chapter Scientist
Alice Sverdlik (USA)

Contents

Executive Summary

8.1. Introduction
- 8.1.1. Key Issues
- 8.1.2. Scope of the Chapter
- 8.1.3. Context – An Urbanizing World
- 8.1.4. Vulnerability and Resilience
  - 8.1.4.1. Differentials in Risk and Vulnerability within Urban Centres
  - 8.1.4.2. Understanding Resilience for Urban Centres in Relation to Climate Change
- 8.1.5. Conclusions from the Fourth Assessment (AR4) and New Issues Raised by this Chapter
  - 8.1.5.1. Key Uncertainties and Research Priorities
  - 8.1.5.2. What has Changed since AR4

8.2. Urbanization Processes, Climate Change Risks, and Impacts
- 8.2.1. Introduction
- 8.2.2. Urbanization – Conditions, Processes, and Systems within Cities
  - 8.2.2.1. Magnitude and Connections to Climate Change
  - 8.2.2.2. Spatiality, Physical Planning, and Climate Change
  - 8.2.2.3. Temporal Dimensions: Rapid Onset, Slow Onset, Production Cycles
  - 8.2.2.4. Urbanisation and Ecological Sustainability
  - 8.2.2.5. Regional Differences and Context-Specific Risks
- 8.2.3. Urbanization and Climate Change and Variability – Primary (Direct) and Secondary (Indirect) Impacts
  - 8.2.3.1. Urban Temperature Variation: Means and Extremes
  - 8.2.3.2. Urban Heat Islands
  - 8.2.3.3. Drought and Water Scarcity: Means and Extremes
  - 8.2.3.4. Coastal Flooding, Sea Level Rise, and Storm Surge
  - 8.2.3.5. Inland Flooding and Hydrological and Geo-Hydrological Hazards at Urban Scale
  - 8.2.3.6. Air Pollution: Means and Extremes
  - 8.2.3.7. Emerging Human Health, Disease, and Epidemiology Issues in Cities
- 8.2.4. Urban Sectors: Exposure and Sensitivity
  - 8.2.4.1. Water Supply, Wastewater, and Sanitation
  - 8.2.4.2. Energy Supply

8.2.4.3. Transportation and Telecommunications
8.2.4.4. Built Environment, and Recreation and Heritage Sites
8.2.4.5. Green Infrastructure and Ecosystem-based Adaptation
8.2.4.6. Health and Social Services
8.2.5. Urban Transition to Resilience and Sustainability
8.2.5.1. Uncertainty and Surprise
8.2.5.2. Extreme Event Probability
8.2.5.3. Transitions
8.2.5.4. Social Dynamics, Economic Tensions, and Multiple Stressors
8.2.5.5. Historical Analogues

8.3. Adapting Urban Areas
8.3.1. Introduction
8.3.2. Development Plans and Pathways
8.3.2.1. Adaptation and Development Planning
8.3.2.2. Disaster Risk Reduction and its Contribution to Climate Change Adapation
8.3.3. Adapting Key Sectors
8.3.3.1. Adapting the Economic Base of Urban Centres
8.3.3.2. Adapting Food and Biomass for Urban Populations
8.3.3.3. Adapting Housing and Urban Settlements
8.3.3.4. Adapting Urban Water, Storm, and Waste Systems
8.3.3.5. Adapting Electric Power and Energy Systems
8.3.3.6. Adapting Transport and Telecommunications Systems
8.3.3.7. Green Infrastructure and Ecosystem Services within Urban Adaptation
8.3.3.8. Adapting Public Services and Other Public Responses

8.4. Putting Urban Adaptation in Place: Governance, Planning, and Management
8.4.1. Urban Governance and Enabling Frameworks, Conditions, and Tools for Learning
8.4.1.1. Multi-Level Governance and the Unique Role of Urban Governments
8.4.1.2. Mainstreaming Adaptation into Municipal Planning
8.4.1.3. Delivering Co-Benefits
8.4.1.4. Urban Vulnerability and Risk Assessment Practices: Understanding Science, Socio-Economics, and Policy Interactions
8.4.1.5. Assessment Tools: Risk Screening, Vulnerability Mapping, and Urban Integrated Assessment
8.4.2. Engaging Citizens, Civil Society, the Private Sector, and Other Actors and Partners
8.4.2.1. Engaging Stakeholders in Urban Planning and Building Decision Processes for Learning
8.4.2.2. Supporting Household and Community-Based Adaptation
8.4.2.3. Private Sector Engagement and the Insurance Sector
8.4.2.4. Civil Society Partnerships and Philanthropic Engagement
8.4.2.5. University Partnerships and Research Initiatives
8.4.2.6. City Networks and Urban Adaptation Learning Partnerships
8.4.3. Resources for Urban Adaptation and their Management
8.4.3.1. Domestic Financing: Tapping into National or Sub-national Regional Sources of Funding and Support
8.4.3.2. Multilateral Humanitarian and Disaster Management Assistance
8.4.3.3. International Financing and Donor Assistance for Urban Adaptation
8.4.3.4. Institutional Capacity and Leadership, Staffing, and Skill Development
8.4.3.5. Monitoring and Evaluation to Assess Progress

8.5. Conclusions
8.5.1. Introduction
8.5.2. What Hinders Adaptation Progress in Urban Areas?
8.5.3. What Contributes to the Development of Effective Transformative Adaptation Plans?

Frequently Asked Questions

8.1: How does disaster risk reduction relate to climate change adaptation?
8.2: Doesn't good development produce urban adaptation?
8.3: Wouldn't urban problems be lessened by rural development?
8.4: Shouldn't urban adaptation plans wait until there is more certainty about local climate change impacts?

References

Executive Summary

Successful global climate change adaptation depends centrally on what is done in urban areas (*high agreement, medium evidence*). Urban areas house more than half the world's population and concentrate most of its assets and economic activities. They also concentrate a high proportion of the population, and economic activities most at risk from climate change. In addition, a high proportion of global greenhouse gas emissions are generated by urban-based activities. Furthermore, projections for the next few decades suggest that it is in and around urban areas that almost all the increase in the world's population and much of the increment in capital formation, economic activity, infrastructure development, ecosystem degradation and emissions will take place. [8.1] Adaptation action in urban areas that delivers mitigation co-benefits is one of the most powerful and resource-efficient means of addressing climate change, as outlined in the AR5 Working Group III report.

There has been a very large expansion in the literature of relevance to climate change adaptation in urban areas since AR4 (*very high confidence*). [8.1] This includes documents prepared by many city governments and some international agencies on their initial responses to adaptation. There is also evidence of a greater interest in climate change adaptation from certain professions (including architects, engineers and urban planners and those working on disaster risk management). There is also a new literature underlining the importance of a shift in emphasis from urban adaptation to building resilience at city and regional scale. This will support the capacity to withstand unexpected impacts, flexibility, redundancy and planning for 'safe failure' in response to increasingly extreme climate adaptation as outlined in the AR5 SREX report. [8.1] Beyond this, an emerging literature is exploring urban transformations - adaptation that helps address the key drivers of anthropogenic climate change through combined processes of sound development, disaster risk reduction, increased resilience and ecosystem adaptation. [8.5] There is also some discussion of the adaptation limits that urban centres face and difficult decisions over what can be done that might include resettlement or abandonment of previously developed land. [8.3]

Cities are complex inter-dependent systems with potential synergies that could be leveraged to support climate change adaptation (*high agreement, low evidence*). In many cities, adaptation effectiveness is constrained by complex inter-dependencies – for instance the impact of power failures or fuel shortages on water supplies, drainage, transportation, telecommunications and health care services. There is also the dependence of emergency services on all-weather roads, functioning communications systems and robust health care centres and the dependence of urban populations and economies on food and resources from beyond their boundaries. [8.2] A few cities have adaptation initiatives underway for energy systems or are considering what steps are needed to do so; energy policy discussions in the past have been dominated by mitigation concerns. [8.3] Urban enterprises developed within globalized systems of production depend on reliable supply chains which may face particular difficulties. [8.3] Conventional infrastructure investment decision-making may be interventionist or reactive and overlook more open-ended and flexible concepts such as adapting well, climate smart, sustainable adaptation and resilience. [8.5] Thus raising urban adaptive capacity in the context of climate change requires effective multi-level governance (so all levels of government work together) with institutions that facilitate coordination across multiple, nested and poly-centric authorities and have the capacity to mainstream adaptation measures. There are synergies to be encouraged in peri-urban or nearby rural areas where land-use management around a city supports rural livelihoods and protects ecosystem services. [8.3] This is yet to be built in most parts of the world. [8.4, 8.5]

The scale and concentration of urban climate risk and hence the imperative for adaption are better acknowledged now but poorly understood and rarely acted upon (*medium confidence*, characterized by *high agreement* and *medium evidence*). Increasing concentrations of population, assets and economic activities in the urban areas of almost all countries, irrespective of income-level will increase the concentration of climate-related risks for a large and growing proportion of the world's population. [8.1] This could threaten economic and development processes, poverty reduction and ecological sustainability. Awareness of these emergent risks is growing, but responses are weak except for a handful of cities largely in high-income countries. [8.3, 8.4] Three identifiable strategies to enable urban adaptation are: awareness building, evidence-based analysis and action at the appropriate level. [8.4] Most current adaptation action focuses on low-cost interventions such as infrastructure and asset-creation as a co-benefit of existing development interventions. The weak emphasis on human, institutional and ecological adaptation with long-term resilience building potential is a matter of concern. [8.5, 8.3]

Rising sea levels, associated coastal and riverbank erosion and flooding in conjunction with storm surges could all lead to widespread impacts on populations, property and coastal vegetation and ecosystems, and threats to commerce, business, and livelihoods (*very high confidence*). Sea-level rise represents one of the primary shifts in urban climate change risks, given the large and often increasing concentration of urban populations in coastal locations. [8.2] Coastal cities with extensive port facilities and large scale industries in low-elevation coastal zones including petro-chemical and energy related industries are vulnerable to climate change related increased flood exposure. [8.2] Many cities in Asian high growth economies are located on low-lying coastal areas, which are undergoing rapid urbanand economic transformation. Without adaptive measures and with rising concentrations of population, infrastructure, and industries along these coasts, there could be a non-linear increase in coastal vulnerability over the next two decades. [8.3] Many cities and smaller urban centres already experience large floods regularly and will be at greater risk of flooding if rainfall intensities increase. This in turn could lead to the destruction of properties and public infrastructure, contamination of water sources, water logging, loss of business and livelihood options and increase in water related diseases as noted in wide range of studies. [8.2]

Climate change can influence the dynamics of city microclimates while cities can alter a localized region's climate (*high confidence,* based on *high agreement* and *high evidence*). The dense nature of many large cities, high energy consumption, and regional climate conditions produces pronounced influences on anthropogenic heat emissions. [8.2] Reviews of megacity impact on air flow indicate that megacities, especially coastal cities, influence both internal city environmental and regional weather and air quality. [8.2] Additional environmental impacts have also been observed, such as increased levels of surface run-off. Other coupled processes includethe effect of microscale to mesoscalechanges in the built environment on Urban Heat Islands (UHI) thereby impacting mesoscale processes such as land-sea breeze effect and katabatic winds, inturnmodifyingthe spatial extent and magnitude of local urban climate change impacts resulting from radiative forcing. [8.2]

Increasing city resilience to climate change, building adaptive capacity and adequate resourcing could enable cities to 'bounce forward' (*medium confidence*, supported by *high agreement* and *low evidence*). Effective multi-level urban risk governance, alignment of multiple (potentially conflicting) policies and incentives, early and appropriate adaptation choices and implementation action could increase city resilience to climate change and build needed local and regional adaptive capacity. This would strengthen development processes, limit maladaptation, support more effective adaptation and build positive synergy with climate mitigation measures. This combined with strengthening of local ecological and built infrastructure and services, better integrated urban and adaptation planning, strengthened local government and community adaptation capacity, synergy with the private sector and appropriate financing and institutional development could enable cities (especially in low- and middle-income countries) to use their limited resources to 'bounce forward' rather than respond in a fractured, ad-hoc and poorly-resourced manner to existing or impending climate risks. [8.4, 8.5] "Bouncing forward" is enabled by building transformatory adaptive capacity and climate resilience through a mix of sound development, disaster risk reduction, and ecosystem-based adaptation rather than 'end-of-the-pipe' or incremental adaptation interventions.

Sound development is a necessary, but not sufficient condition to enable urban climate resilience (*medium confidence*, supported by *high agreement* and *medium evidence*). There is a widespread assumption that sound urban development, especially universal provision of basic infrastructure and services (piped water, provision for sanitation and drainage, solid waste collection, health care, schools, emergency services, policing) are sufficient to

enable urban resilience to climate change, based on the perceived experience of some high-income nations. [8.2] These provide an important base from which to build resilience. The importance of harmonization and synergy of climate adaptation and mitigation with poverty reduction, livelihood development, food security, universal access to adequate housing and basic services and disaster risk reduction is slowly being understood. But this is a complex terrain that needs more evidence and experimentation to gauge the effectiveness and limitations of current models of infrastructure and service provision – including 'social capital'-based and community-led climate adaptation and acceptance of this among national governments and mainstream development agencies. [8.3, 8.5]

City-based disaster risk reduction is a strong foundation around which to build urban climate resilience (*high confidence*, based on *high agreement* and supported by *medium evidence*). Many urban areas have long been exposed to a range of hazards and disaster risks that could be exacerbated by climate change: water shortages and droughts in urban regions, geo-hydrological hazards, inland and coastal flooding, windstorms and storm surges, high levels of air pollution, extremes in urban heat and cold and urban heat islands and novel compound and slow onset hazards that impact ecosystem resilience. [8.2] Experience in effective city-level disaster risk reduction to address these challenges largely by vulnerability reduction and exposure modification, has been built in many cities across over the last few decades via local hazard, risks and vulnerability studies and interventions. Some national governments have set up frameworks and financing mechanisms to support local government and civil society implement disaster risk reduction. This is a valuable foundation for climate change adaptation but it will need to also take account of how hazards, risks, slow onset impacts and vulnerabilities change over time and thereby seek to converge development and disaster risk reduction policies, institutional development and investmentmobilisation to meet short- to medium-run risk reduction and longer-term urban adaptation goals. [8.3]

Urban concentration and agglomeration economies can be a strategic asset in climate adaptation action (*medium confidence*, based on *medium agreement* and *low evidence*). Many of the challenges and opportunities for urban adaptation come from the concentration of people and enterprises in locations of high risk. There are agglomeration economies for much of the infrastructure and services for climate change adaptation but they need to be acted on. There is *high agreement*, supported by *high evidence*, that many urban centres are on sites that face high levels of risk with risks exacerbated by built and ecological infrastructure deficits. Many cities in low- and middle-income nations have a high proportion of their population in informal settlements that lack risk-reducing infrastructure and services and that are located on floodplains, alongside rivers, in areas prone to slips and rockfalls or on steep unstable slopes. These sites are settled because their residents cannot afford housing on safer sites. Where local governments are unable or unwilling to act on these, population concentration brings disadvantages. [8.2, 8.3] This has been seen as an argument to incentivize adaptation-led relocation but that can cause very large disruptions to both residents and economic activity. [8.2] Urban agglomeration economies are often discussed in regard to enterprises. Cities may represent a particular centre of interest for private sector engagement around climate change partly because they concentrate large infrastructure investments and related business. [8.4] There are potential urban agglomeration economies around cost-effective adaptation and resilience building via improved built and ecological infrastructure and services and bringing together people, communities and institutions to respond collectively to climate change risks. [8.3] There is also the need to take recognize potential conflicts between the adaptation and mitigation agendas, as well as the establishment of locally specific limits to adaptive interventions. [8.5] The "density conundrum" where increased urban densities could enhance climate mitigation potential can limit the possibilities of ecosystem based adaptation, cross thresholds of acceptable biodiversity change and may exacerbate urban heat island risk. [8.3]

Building climate resilience in cities can be well-served by ecosystem-based adaptation with water and food systems as foci (*medium confidence*, based on *high agreement* among practitioners and *medium evidence*). Ecosystem-based adaptation is regarded as one of the morecost-effective and sustainable approaches to urban adaptation, although the costs of needed land acquisition can be high. [8.5] This is even though climate change will impact ecosystem services by altering ecosystem functions such as temperature and precipitation regimes, evaporation, humidity and soil moisture levels. Ecosystem-based adaptation is closely linked to sustainable water management ensuring sufficient supplies, increased capacities to manage reduced freshwater availability, flood risk reduction, managing waste water flows and ensuring water quality. [8.3, 8.5] There are considerable knowledge gaps in determining the limits or thresholds to adaptation of various ecosystems and where and how ecosystem based adaptation is best integrated with other adaptation measures. [8.5] There is *high confidence* that urban food-

adaptation is linked to progressive public policy on food security and livelihood development; addressing constraints in agricultural production and food supply chains and limiting food price shock impacts caused by extreme eventson the food and nutrition security of low-income groups. [8.3]

Good quality, affordable and well-located housing provides one of the bases for city-wide adaptation to climate change (*high confidence*, supported by *high agreement* and *high evidence*). Climate change adaptation in urban centres will be built on the bedrock of good quality and affordable housing that conforms to appropriate health and safety and climate-resilient building standards and has sufficient residual structural integrity over its service life to protect its occupants against extreme weather, especially heat waves and storms. Good quality housing should provide its occupants with a comfortable, healthy and secure living environment and protect them from injuries, losses and damage. This requires effectiveland-use planning and regulation to control development in flood-prone and other high risk areas. It is particularly important for vulnerable groups especially children and older residents with chronic health conditions. This can be enabled via a range of structural interventions, interventions that reduce risks to housing and support access to quality housing for low-income groups, non-structural interventions (like insurance) and disaster risk reduction measures. Well-coordinated strategies are required to address a multiplicity of agencies working at various levels, overlapping regulation and lack of committed resources. [8.3]

Reducing basic service deficits and building resilient infrastructure systems could significantly reduce global climate risk (*very high confidence*, supported by *high agreement* and *high evidence*). Around one billion people live in informal settlements in urban areas with inadequate or no provision for infrastructure and services that provides a foundation for adaptation. Here, poverty and social inequality may be aggravated by climate change and the lack of adaptive capacity. The adaptive capacity of an urban centre is much influenced by the quality and coverage of infrastructure (piped water supplies, sewers or other forms of provision for sanitation, drains, all weather roads and electricity provision) and services that include solid waste collection (vital for keeping drains functioning), policing, health care, emergency services and measures to reduce disaster risk. The extent to which urban and higher levels of governments are able to mobilize resources, choose the most appropriate technical and institutional systems for service delivery influences adaptive capacity and deepens climate resilience. [8.3] The rate and magnitude of urban development in some low- and middle-income countries also brings great challenges that many high-income nations do not have to deal with.

Urban governments are the fulcrum of successful urban climate adaptation (*high confidence*). Local governments are responsible for many of the needed measures for climate change adaptation in urban areas. This makes sense since most risks and vulnerabilities are rooted in local contexts and much of the risk reducing infrastructure and services are within their jurisdictions. [8.3] The incorporation of climate change adaptation into each urban centre's development planning and investments is well served by an iterative process of learning about changing risks and opportunities and drawing in different stakeholders, to inform a balanced assessment of policy options and decisions. Engagement with local stakeholders, built upon openness and transparency about climate change information and its risks, can ensure the needs and priorities of low-income and vulnerable groups get attention and that the private sector is brought into discussions. The role of urban governments in climate adaptation is now more widely recognized, but in many nations, local governments need a stronger financial and institutional base to be able to act on this, including land use management and infrastructure investment. [8.4] Operationalisation will also need a redirection of current priorities, investment and capacity building plans including those that strengthen the investment capacity of urban, city and metropolitan governments. [8.2, 8.3]

City governments are slowly learning from climate change adaptation implementation experience (*medium confidence*, based on *high agreement* and *medium evidence*). The last five years have brought many examples of city governments assessing urban adaptation needs and responding. [8.3] These have often included the designation of a unit within city government with responsibility for adaptation, measures to involve key sectors so they understand why they need to engage with adaptation, the importance of local champions to initiate measures and ensure continuity and the importance of dialogue and discussion with all key stakeholders. [8.4, 8.5] There is also recognition of the need to review building codes, the climate data on which the codes are founded, infrastructure standards and land-use management thereby developing scalable approaches to local adaptation planning. [8.3] City governments that have taken adaptation seriously have drawn in other institutions for support, including local universities and research centres and representative organizations of those living in informal settlements. [8.4]

Effective ways to engage local government attention have been the demonstration of climate change adaptation's importance for a city's continuing economic success, improved service delivery, job creation and risk management. [8.5]

The process of city-based climate adaptation learning is slow, complex and fraught with multiple interlinked challenges (*very high confidence*). Although some city governments have developed innovative adaptation plans, the scale and scope of what is needed is still poorly appreciated. Multiple changes across legal and regulatory frameworks, jurisdictions, policies and intergovernmental flows are needed to mainstream urban climate adaptation. These can be slow to be accepted and slower to implement. The capacity to integrate climate risk, disaster risk reduction, urban infrastructure and planning are being slowly built in some parts of the world. Sector policies need to take account of climate change. Many such policies will require changes to prevent increases in the vulnerabilities of urban populations, infrastructure and natural systems. In most urban centres, these include policies on water, wastewater, solid waste, natural resource management, building regulations, land-use management, transport planning, and disaster management. [8.4] Other challenges that need addressing include: reducing the lack of clarity of multi-level governance mandates; addressing the tension between local and higher-level and sometimes international agency driven priorities; the competition that long-term climate adaptation horizons will face from short-cycle electoral processes, a focus only on growth and competitiveness and local short-run priorities; overcoming the lack of human and financial resources and compartmentalisation and fragmentation of urban government. An openness to emergent and uncertain climate risks via awareness and institutional development can bridge the gap between the need for phased adaptation interventions and the many years it would take for their benefits to become visible. [8.3, 8.4, 8.5] The practice of effective monitoring of development and of the implementation of adaptation plans is still evolving, given the localized nature of most urban adaptation action. [8.5]

Locally-relevant adaptation plans, data and feedback mechanisms are important for building urban climate resilience (*high agreement* and *medium evidence*). Governments, households and the private sector need relevant, reliable local information, including climate projections, to encourage them to act and inform their actions. Despite growing attention, much-needed information and assessment of climate change at urban spatial scales is generally still lacking. Unlike mitigation planning, adaptation programmes are less open to a standard set of requirements, given that actions are oftenrooted in local circumstances, involve multiple stakeholders, are cross-sectoral, multi-scalar and multi-synchronous, and include a high level of uncertainty. [8.5] Only a small number of cities, largely in high-income countries, have quantified risks in local contexts and even fewer have quantified possible costs of climate change risks under different climate and/or socio-economic scenarios. First and second order impacts such as sea level rise and coastal and riverine flood risk and health and water resources are among the most studied sectors, while third order impacts on energy, transport and built infrastructure receive far less attention, and yet these sectors are often targeted for mitigation-focused interventions. While science and climate change information is increasingly available, socio-economic drivers of vulnerability and impacts, such as an increasing health risk and disease burdens are less well understood. [8.2, 8.4] Tools for risk screening and management, which draw on detailed data and projectionsboth from physical science and the socio-economic domains, can help engage the interest of local governments, businesses and civil society organizations. They can also help the translation into information useful for decision-making. City experience is slowly developing around multi-stakeholder adaptation engagement and awareness generation to build broad based support; mainstreaming climate adaptation processes into municipal planning, land use management and building and infrastructure codes. Improved feedback, monitoring and reporting capacity supported by new generation risk screening, vulnerability mapping and integrated urban climate assessment tools are helping catalyse social-learning to help mainstream climate adaptation into urban policies and planning. [8.4] Assessment tools such as scenario-planning that go beyond spatial and multi-criteria assessment to consider the urban environment as a system to better understand the inter-connections, cascading impacts and vulnerabilities are also recommended [8.4, 8.5)]

Enabling the agency of low-income households and vulnerable communities is a powerful adaptation strategy (*high confidence*). Informal settlements in low- and middle-income nations are among the largest existing and emerging concentrations of climate vulnerable urban populations, assets, infrastructure and ecosystem services. [8.1, 8.2, 8.3] Many urban governments are unable to extend a full range of entitlements, services and the institutional support necessary for effective adaptation to these settlements. For most cities and smaller urban centres in low- and middle-income nations, poverty reduction needs more attention because of the strong association between poverty

and environmental health, disaster and climate change risks. [8.5] In many high climate risk locations, community and household-led adaptation have intervened with their limited resources to fill this gap. In informal settlements, engagement with community learning provides a means for participatory community risk assessment, where local capacity to adapt is built in part through accessing their knowledge. The scale and range of what this can achieve is increased with local governments' support; simply shifting the burden of adaptation to the community level is unlikely to bring success. [8.4] It is now more common for local and national governments to work with the inhabitants of informal settlements to install or upgrade infrastructure and services and address insecure tenure; this can strengthen social capital creation processes and build their resilience to climate change impacts. [8.4] Enabling community-led adaptation can be challenging and depends on a number of factors including representativeness of leadership, supportive local governance, community organizations' ability to pressure government and other stakeholders to respond to their concerns, as well as a recognition of the limits of community-based intervention. [8.4, 8.5]

Effective local action requires coordinated support from higher levels of governments and other stakeholders (*medium agreement* supported by *medium evidence*). To be effective adaptors, urban governments need a mandate around climate change adaptation via supportive policy and enabling legislative frameworks from higher levels of governments (including national, supra-national and state/provincial levels). Universities and research institutions, multilateral and bilateral agencies, financial and insurance and other private sector agencies have successfully assisted urban governments and households to mobilize around climate adaptation. Since effective adaptation for urban centres needs local responses and includes major roles for local governments and civil society (especially those representing those most at risk), consideration needs to be given to mechanisms by which international support for adaptation can work at scale while supporting local processes [8.4, 8.5] Large metropolitan areas and their rapid growth raise the level of complexity of managing adaptation, requiring action to be coordinated across multiple urban jurisdictions. The role of local government champions has often proved critical in providing initial leadership towards promoting and sustaining an adaptation agenda. [8.5] Although there is some evidence of innovative responses at the sub-national levels to plan for extreme weather events and climate change, limited local government capacity and experience suggests a need for support from higher levels of government. [8.4] A phased approach, whereby the most urgent matters, such as rapid-onset disasters, are prioritized first, leaving a longer time period to plan for slow-onset impactswhich may be associated with greater uncertainty, is most likely to attract local government attention. [8.5]

Building human and institutional capacity for urban climate resilience will accelerate implementation and improveoutcomes (*high confidence*). A binding constraint to effective and timely urban adaptation and building resilience is effective institutions and leadership across government, communities, civil society, knowledge institutions and the media. This can be addressed by a number of structural interventions to enable city-wide alliances and frameworks to be built, institutionalization of processes, building a culture of exchange between learning organizations and a strong emphasis on capacity building. [8.4] The locus of the climate change focal point in government has a strong bearing on its success. There is evidence of expanding urban adaptation leadership, but building a wide support base for adaptation across many sectors, in and outside of government to de-risk the impact of slow institutional development and leadership change is an important priority. Local or regional boundary organisations such as nearby academic or research communities have been shown to have influence and support policy decisions. Networking and sharing experiences among adaptation practitioners and between cities is also an important vehicle to improve city-level outcomes. [8.4, 8.5]

Adapting urban centres' economic base can enhance comparative advantage, deepen climate resilience and limit disadvantage (*high agreement*, supported by *medium evidence*). Climate change will shift the comparative advantages of cities and regions and differentially threaten or enhance the resource, asset and economic base and so lead to significant structural changes and impacts on local, national and potentially the global economy. Effective adaptation can protect a city's economic base via a mix of strategies. These include extreme weather exposure reduction via effective land-use planning, selective relocation and structural measures; reduction in the vulnerability of lifeline infrastructure and services (water, energy, waste management, food, biomass, mobility, local ecosystems and telecommunications) and measures to assist vulnerable sectors and households; mitigation of business interruption and capital stock losses and support to the 'waste economy' and the 'green economy'. These may be easier and cheaper to implement in new and peri-urban developments. [8.3]

There is limited commitment to and development of urban climate adaptation finance (*high agreement* and *low evidence*). Available finance for urban adaptation span domestic and external public and private sources. Domestic public funding can be raised through a variety of measures ranging from urban fiscal policies (where there is capacity to do this) to revenue transfers from national (and often provincial or state) government. External public funding can come from traditional development finance sources (i.e. multilateral development banks and bilateral development co-operation partners). The need for urban adaptation investments will far exceed available public funding. Smaller cities and other urban centres with weak and fragmented governance structures may be least equipped to access available climate change funding, even as they house some of the most vulnerable populations. Domestic private investment by individuals, households and businesses is expected to be the most sustainable and significant source of funding for adaptation. Its effectiveness depends on what local and higher-level governments do to encourage and support this, as well as helping deliver infrastructure and services. Hence, a range of innovative fiscal instruments, measures to attract 'climate-smart 'public and private investment and micro-insurance coverage of lower-income households, risk transfer mechanisms and innovative market-based insurance coverage, will be needed to address climate adaptation finance needs. This will need a supportive public policy environment to enable efficient market resource allocation to promote adaptation and overcome persistent market barriers. It also needs frameworks for land-use management to ensure appropriate economic and livelihood development incentives, avoid high-risk zones and implement appropriate building and infrastructure standards. A growing share of current development finance is being committed (in principle) to adaptation, especially towards technological investment and capital projects. However, mechanisms are not yet in place to ensure that it supports locally-driven adaptation practice in urban centres. There is a need to reconcile top-down and bottom-up planning, enabling structured planning, programming and outcome monitoring. A key to improving effectiveness of international public finance will be building the capacity for country-led planning processes that include urban adaptation and are backed by adaptation monitoring and data collection, designed specifically for the complexity of urban projects. The systematic programming of adaptation into international humanitarian and disaster response funding is still to develop. In addition, most national Action Plans under the UNFCCC have little emphasis on urban adaptation. Thus, urban climate adaptation financing and structuring remains an area where innovation and improvement are much needed to deliver demand-driven and responsive solutions, while catering to local contexts and possibilities. [8.4, 8.5]

8.1. Introduction

8.1.1. Key Issues

Successful adaptation to climate change depends centrally on what is done in urban centres – that now house more than half the world's population and concentrate most of its assets and economic activities. As 8.4 emphasizes, this needs to include responses by multiple levels of government, individuals and communities, the private sector and civil society. The serious impactsof extreme weather on many urban centres each year show risks and vulnerabilities that need to be addressed and climate change will usually add to these. What is done in urban centres also has major implications for mitigation, especiallyfuture levels of greenhouse gas emissions and for delivering co-benefits, as discussed in WGIII. This chapter focuses on the connections between urban centres and climate change and on the possibilities for governments, enterprises and populations to adapt to and develop resilience to its direct and indirect impacts.

As discussed in 8.4, most of the investment required for sound adaptation will come from a multitude of small-scale private decisions spanning individuals, households, communities and firms. Furthermore, the level of funding needed for urban adaptation exceeds the capacities of local and national governments and international agencies. This might suggest little role for governments – and especially local governments. But whether or not the 'multitude' of small scale private decisions do contribute to adaptation (and resilience to climate change's impacts) depend on what local governments do, encourage, support and prevent – as well as their contribution to providing needed infrastructure and services. An important part of this is providing an appropriate regulatory framework that supports adaptation (and prevents maladaptation) in the choices made by individuals, households and firms – for instance in the management of land use (with new sites available for development, dangerous sites avoided and key ecological services protected) and the application of building standards within their jurisdiction.

In reviewing adaptation needs and options for urban areas, the documentation points to two key conclusions. The first is how much the adaptive capacity of a city depends on: past plans and investments in infrastructure and services; existing capacities for such investments and land-use management; and for ensuring buildings meet health and safety standards. This provides the foundation for city resilience on which adaptation can be built. For almost all urban centres in low-income and many in middle-income nations; there is little of this foundation of resilience. The second is the importance of city and municipal governments acting now to incorporate climate change adaptation into their development plans and policies. But to do so requires not only building the foundation of resilience (and its institutional and financial underpinnings) but also to mobilize new resources and continuously develop local capacities to respond. This is not to diminish the key roles of other actors including the private sector, the demands and priorities of residents, civil society and higher levels of government. But it will fall to city and municipal government to provide the scaffolding and regulatory framework within which all other stakeholders contribute and collaborate. Thus, adaptation in urban areas depends heavily upon the competence and capacity of local governments and a locally rooted iterative process of learning about changing risks and opportunities, identifying and evaluating options, making decisions, and revising strategies in collaboration with a range of actors (see Chapter 2 for more discussion of this).

8.1.2. Scope of the Chapter

This chapter focuses on what we know about how climate change will impact on urban centres and their populations and enterprises, what measures can be taken to adapt to these changes (and protect vulnerable groups) and the institutional and governance changes needed to underpin this.Both this chapter and Chapter 9 on rural areas highlight the multiple linkages between rural and urban areas. This chapter also has overlaps with Chapter 10, especially in regard to infrastructure, although this chapter focuses on urban infrastructure and in particular the infrastructure that comes within the responsibilities or jurisdiction of urban governments.

This chapter draws its urban statistics from the United Nations Population Division (see United Nations 2012). Urban centres vary from metropolitan areas with more than 20 million inhabitants to those with few thousand (or in some nations a few hundred) inhabitants. There is no international agreement as to how urban centres or populations should be defined or distinguished from rural populations and there is considerable variation in how governments choose to define urban areas (see United Nations 2012). This influences the proportion of the population said to live in urban areas for any nation. Many nations define as urban centres all settlements with populations above a threshold - for instance 1,000 or 2,500 or 5,000 inhabitants. So a nation's urban population and level of urbanization can vary substantially, depending on which threshold is used (or other criteria chosen and applied). Virtually all nations classify settlements with 20,000 plus inhabitants as urban; it is around the proportion of the population that live in settlements between a few hundred and 20,000 inhabitants that national differences emerge. There is also the ambiguity as to the dividing line between rural and urban. In some instances, urban boundaries include large rural areas while in others, urban centres have grown beyond official boundaries and into areas that are within neighbouring jurisdictions and may be defined as rural. Most large cities have more than one boundary – for instance one based on the local government jurisdiction or linked to the built up area, another based on the metropolitan area and another on the metropolitan region or planning region. Boundaries for metropolitan areas or extended metropolitan regions often include substantial rural populations. Most suburban areas are within urban boundaries. In addition, just as urban centres depend on rural resources and eco-system services, it is common for a proportion of the workforce in larger urban centres to live outside the urban centre and commute – and this may include many that live in settlements designated as rural. There is also no agreed definition for what constitutes a city – although the term city implies an urban centre with some economic, political or cultural importance so it would not be applied to most small urban centres.

8.1.3. Context – An Urbanizing World

In 2008, for the first time, more than half the world's population was livingin urban centres and the proportion living in urban centres continues to grow (United Nations 2012). Three quarters of the world'surban population and most

of its largest cities are now in low- and middle-income nations. UN projections suggest that almost all the increase in the world's population up to 2050 will be in urban centres in what are currently low- and middle-income nations (see Table 8-1). It is within urban centres within most nations and globally that most GDP is generated and most new investment has concentrated (World Bank 2008, Satterthwaite et al. 2010).Clearly, in terms only of the population, economic activities and climate risk they concentrate and the progressive increase in such concentration, adapting urban areas to climate change needs serious attention.

[INSERT TABLE 8-1 HERE
Table 8-1:The distribution of the world's urban population by region, 1950–2010 with projections to 2030 and 2050.]

There is an economic logic underpinning most urbanization as all wealthy nations are predominantly urbanized and as rapid urbanization in low- and middle-income nations is usually associated with rapid economic growth (ibid). Most of the world's largest cities are in its largest economies (ibid). If rapid urbanization and rapid city population growth is associated with economic success, it suggests that more resources can be drawn on to support adaptation. But in most urban centres in low- and middle-income nations, including many successful cities, local governments have been unable to keep up with the economic and physical expansion and there are large deficits in provision for infrastructure and services that have relevance for climate change adaptation. Around one in seven of the world's population live in poor quality, overcrowded accommodation in urban areas with inadequate or no provision for basic infrastructure and services and mostly in informal settlements (UN-Habitat 2003, Mitlin and Satterthwaite 2013). Within the world's urban population, it is in these settlements that much of the risk and vulnerability to climate change is concentrated. And a substantial proportion of these settlements are in economically successful cities (Mitlin and Satterthwaite 2013). So this chapter is concerned not only with an adaptation deficit for urban centres but also with a development deficit that has relevance for risk and vulnerability to climate change.

Many aspects of urban change in recent decades have been so rapid that they have overwhelmed government capacity to manage it. Of the world's cities with 750,000 plus inhabitants in 2010, 52 had populations growing more than twenty fold since 1960 and 116 had populations growing more than tenfold (statistics in this paragraph drawn from data in United Nations 2012). The increasing concentration of the world's urban population and its largest cities outside the nations with the highest incomes that Table 8-1 shows represents an important change. Over the 19th and 20th centuries, most of the world's urban population and most of its largest cities were in its most prosperous nations. Urban areas in low- and middle-income nations now have close to two-fifths of the world's total population and close to three-quarters of its urban population. They also have most of the world's large cities. Of the 23 'mega-cities' (cities whose population was reported to exceed 10 million) by 2011, only 5 were in high-income nations (two in Japan, two in USA, one in France). Of the remaining 18, four were in China; three were in India and two in Brazil. However, over three fifths of the world's urban population is in urban centres with less than 1 million inhabitants and it is in these that much of the growth in urban population is occurring.

Underlying these population statistics are large and often complex economic, social, political and demographic changes including the multiplication in the size of the world's economy and the shift in economic activities and employment structures from agriculture to industry and services (and within services to information production and exchange).One of the most significant changes has been the growth in the size and importance of cities whose economies increased and changed as a result of globalization (Sassen 2006). Another is the many large cities that are now centres of large extended metropolitan regions.

One difficulty that this chapter faces is in providing a summary of trends for settlements that have more than half the world's population when there is such diversity among these in terms of their current vulnerability to extreme weather, the scale and nature of risks that climate change is bringing or will bring (and who is most at risk), the extent to which their population lives in good quality homes served with conventional infrastructure and services that provides the basis for adaptation (what this chapter terms accumulated resilience) and the extent to which their governments are acting or able to act on adaptation and being supported to do so by higher levels of government and where needed international agencies. Table 8-2 illustrates this diversity and how each urban centre falls within a spectrum in at least four key factors that influence adaptation: local government capacity, the proportion of the population served with risk-reducing infrastructure and services; the proportion of the population living in housing

built to appropriate health and safety standards; and the levels of risk from climate change's direct and indirect impacts. This chapter also draws on detailed case studies of three cities to illustrate this diversity – New York (Solecki 2012a), Durban (Roberts and O'Donoghue, 2013) and Dar es Salaam (Kiunsi, 2013).

[INSERT TABLE 8-2 HERE
Table 8-2: The large spectrum in the capacity of urban centres to adapt to climate change. One of the challenges for this chapter is to convey the very large differences in adaptive capacity between urban centres. There are tens of thousands of urban centres worldwide with very large and measureable differences between them in population, area, economic output, human development, ecological footprint and greenhouse gas emissions. The differences in adaptive capacity are far less easy to quantify. This Table seeks to illustrate differences in adaptive capacity and factors that influence it.]

Many attributes of urban centres can be measured and compared. Populations vary from a few thousand inhabitants (or a few hundred in some nations) to the largest cities with 20-36 million inhabitants. Areas vary from less than one to thousands of square kilometres. Average life expectancy at birth for urban centres varies from over 80 years to under 40 years – and under-five mortality rates vary by a factor of 20 or more (Mitlin and Satterthwaite 2013). Average per capita incomes vary by a factor of at least 300; so too do the investment capacities of urban governments (UCLG 2011). Greenhouse gas emissions per person vary by more than 100 (Dodman 2009, Hoornweg et al. 2011). There are large differences between urban centres in the extent to which their economies are dependent on climate-sensitive resources (including commercial agriculture, water and tourism).There are also large variations in the scale and nature of impacts from extreme weather. As Table 8-2 suggests, there are urban indicators that are relevant for accumulated resilience to climate change impacts (the proportion of the population with water piped to their homes, sewers, drains, health care and emergency services) but less so for the scale and nature of climate change related risks and for the quality and capacity of government.

Recent analyses of disaster impacts show that urban centres concentrate a high proportion of theworld's population most affected by extreme weather events (United Nations 2009, 2011, IFRC 2010). As shown in Table 8-2, a high proportion of such urban centres have local governments that lack the capacity to reduce such disaster risk and very large deficits in the infrastructure and institutions needed to do so. Their low-income households may require particular assistance due to greater exposure to hazards, lower adaptive capacity, more limited access to infrastructure or insurance, and fewer possibilities to relocate to safer accommodation as compared to wealthier residents. There are also many cities that have high resilience to extreme weather and have the infrastructure and institutions that can provide resilience to the exacerbation of extreme weather events and change in resource availabilities associated with climate change.

All successful urban centres have had to adapt to environmental conditions and resource availabilities, although local resource constraints have often been overcome by drawing resources and using sinks from 'distant elsewheres' (Rees 1992, McGranahan 2007); this includes importing goods that are resource intensive and whose fabrication involves high greenhouse gas emissions. The growth of urban population over the last century has also caused a very large anthropogenic transformation of terrestrial biomes. Urban centres cover only a small proportion of the world's land surface; Schneider et al 2009 suggested that they cover only 0.51 per cent of the total land area and among the world's regions only in Western Europe did they cover more than 1 per cent. However, their physical and ecological footprints are much larger, as urban based enterprises and consumers draw on a much larger land area. The net ecological impact includes the decline in the share of wild and semi natural areas from about 70 per cent to under 50 per cent of the land area. This was largely to accommodate the demand for crop and pastoral land to support human consumption, leading not only to a decrease in biodiversity but a threat to ecological services that support both rural and urban areas. Future projections (Seto et al 2012) suggest that if current trends continue, that urban land cover will increase by 1.2 million square kilometres by 2030. This would represent nearly tripling the global urban land from around 2000 and would result in a "considerable loss of habitats in key biodiversity hotspots" destroying the green infrastructure that will be key in helping areas adapt to the impacts of climate change (ibid page 16083)

Many of the challenges and opportunities for urban adaptation are derived from the central features of city life – the concentration of people, buildings, economic activities and social and cultural institutions (Romero-Lankao and Dodman 2011). A key part of urban centres' adaptive capacity is related to agglomeration economies. These are

usually discussed in relation to the advantages for enterprises locating there. But the concentrations of people, enterprises and institutions in urban areas also provides potential agglomeration economies in lower unit costs for providing each building with piped water, sewers, drains and a range of services (solid waste collection, schools, health care, emergency services, policing) and bringing together people, communities and institutions to respond collectively (Hardoy et al. 2001). But these need to be acted on and to have local governments capable of acting on them. In most urban centres in low- and middle-income nations, these are not acted upon and the result is very large deficiencies in infrastructure and services. Although urban centres in high-income nations are much better served, there may also be particular challenges – for instance in addressing aging infrastructure and in adapting energy systems, the building stock and infrastructure and services to the altered risk set that climate change's direct and indirect impacts will bring (see Zimmerman and Faris 2010 and Solecki 2012a for discussions of this for New York).

Effective urban governments will also need to work with range of government and civil society institutions at local and supra-local levels and to get support and enabling frameworks from higher levels of government. In addition, as this chapter discusses, the concentration of people and economic activities also presents particular challenges for climate change adaptation – including the management of storm and surface run-off and measures to reduce heat islands. Large cities also concentrate demand and need for ecological services and natural resources (water, food and biomass), energy and electricity and these may rely on supply chains that climate change will disrupt. Thus, the increasing concentration of the world's population in urban centres will bring increased risk concentration ofa range of climate-related hazards for a large and growing proportion of the world's population – while also having the potential to support more effective adaptation.

8.1.4. Vulnerability and Resilience

For each of the direct and indirect impacts of climate change, there are groups of urban dwellers that face higher health and other risks (illness, injury, mortality, damage to or loss of homes and assets). This can be on the basis of age (for instance infants or elderly people's greater susceptibility to particular hazards such as heat waves) or health status (for instance those with particular diseases, injuries or disabilities that make them more susceptible to these impacts). Or it may be because they live in locations that face greater risks – for instance on coasts or by rivers where flood risks have increased or will increase. These are often termed vulnerable groups – although to state the obvious, these are only vulnerable to climate change impacts if the hazard poses a risk. Remove the vulnerable population's exposure to the hazard (e.g. drains preventing flooding) and there is no impact. Infants may face serious health risks when water supplies are contaminated by flooding but rapid and effective treatment for diarrhoea and quickly re-establishing availability of drinking quality water greatly reduces impacts (Bartlett 2008). There are also adaptations by individuals, households, communities, private enterprises or government service providers that may reduce risks or reduce exposure.

Although there are many definitions of vulnerability (see for instance Füssel 2007), these agree that it centres on an inability to avoid harm when exposed to a hazard – including an inability to avoid the hazard, anticipate it (and take measures to avoid it or limit its impact), cope with it and recover from it (bounce back) (see also the report Glossary). So vulnerable groups may be identified on the basis of any of these four factors. Adaptation can also include 'bouncing forward' as resilience is increased and so built to protect against future hazards and uncertainty about such hazards.

The term vulnerability is also applied to sectors that may includefood processing, tourism, water, energy and mobility infrastructure and their cross-linkages e.g. perishable commodities dependent on efficient transport. Much tourismissensitive to climate change as it may damage key tourist assets e.g. coral reefs and beaches or make particular locations less attractive to tourists because of changes in temperatures or increases in extreme weather. Oil price changes will affect travel costs.

Certain types of infrastructure on which urban centres rely are more at risk: e.g. most transport, drainage and electricity transmission systems and many water supply abstraction and treatment works. Infrastructure plans and investments generally include some scope for coping with climate variability but in many locations these will need

to increase reserve margins, back up capacity and other structural adaptation measures. Conventional infrastructure investment decision-making may overlook or fail to value needed redundancy. Cities as complex, inter-connected systems are vulnerable to intersectoral connections – for instance the dependence of water supplies, drainage, traffic management, telecommunications, health care services and some trains on electricity supply and the dependence of emergency services on all-weather roads and functioning bridges (da Silva et al 2012, Solecki 2012a).

8.1.4.1. Differentials in Risk and Vulnerability within Urban Centres

In urban centres where virtually all buildings meet health and safety standards, where land-use planning keeps developments from sites at risk and there is universal provision for infrastructure and basic services, the exposure differentials between high- and low-income groups to climate-related risk is much reduced. Although low-income groups are often termed vulnerable, having a low-income and few assets in many of these cities does not necessarily imply greater vulnerability to climate change. In low- and middle-income countries, typically the larger the deficit in infrastructure and service provision, the larger the differentials in exposure to most climate change impacts by income group. This means a disproportionate climate impact on low-income groups in low- and middle-income nations, who are often made more vulnerable because of poor quality and insecure housing, inadequate infrastructure and lack of provision for health care, emergency services and measures for disaster risk reduction.

Where provision for adequate housing, infrastructure and services is most lacking, the capacity of individuals, households and community organizations to anticipate, cope and recover from the direct and indirect losses and impact of disasters (of which climate-related events are a sub-set) becomes increasingly important (see 8.4).Here, the speed of response and effectiveness of post-disaster response is especially important to those who are more susceptible and have less coping capacity. Their effectiveness depends on understanding the specific vulnerabilities, needs and priorities of different income-groups, age groups and groups that face discrimination, including that faced by women and by particular social or ethnic groups.

Additionally, a growing literature on successful urban adaptation interventions shows that they recognize the interrelations and interdependence between multiple sectors, levels and risks in a dynamic physical, economic, institutional and socio-political environment (Gasper et al., 2011, Kirshen et al., 2008). Therefore, climate policies may need to be embedded in responses to multiple risks and stresses (Reid and Vogel 2006).

8.1.4.2. Understanding Resilience for Urban Centres in Relation to Climate Change

A literature discussing resilience to climate change for urban centres and what contributes to this has emerged in recent years - and this section draws on this literature (Miller 2007, Pelling 2011a, Leichenko 2011, da Silva et al. 2012, Tyler and Moench 2012, Brown et al. 2012). Although resilience is usually considered to be the opposite of vulnerability, vulnerability is often discussed in relation to particular groups within the population whereas resilience is more often discussed in relation to what helps protect them such as infrastructure or climate-risk sensitive land-use management. Addressing resilience for cities is also more than identifying and acting on specific climate change impacts as it looks to the performance of each city's complex and interconnected infrastructure and institutional systems and includes a capacity to withstand unexpected or unpredicted changes. When considered for cities, it is common for certain characteristics of resilience to be identified – for instance flexibility, redundancy, responsiveness, capacity to learn and safe failure (Moench et al., 2012, Tyler et al. 2012, da Silva et al. 2012, Brown et al. 2012). There is also recognition of the complexities of urban systems and the multiple inter-dependencies between different sectors that were noted above.

But when considering a specific city, the level and forms of resilience are often related to specific local factors, services and institutions – for instance for each district in a city, will the storm and surface drains cope with the next storm (a particularly pressing issue for cities that have heavy rainfall in particular seasons).During heat waves, will measures to help those most at risk from high temperatures work and reach all high-risk groups? Here, resilience is not only the ability to recover from the impact (bouncing back) but the ability to avoid or minimize the need to recover (United Nations 2011). Thus, a considerable part of resilience is the functioning of institutions to provide the

above and the knowledge base needed to do so (da Silva et al. 2012).The emerging literature on the resilience of cities to climate change also highlights the need to focus on resource availabilities and sinks beyond the urban boundaries and it may also require coordinated actions by institutions from other jurisdictions or higher levels of government (for instance watershed management upstream of a city to reduce flood risks see Brown et al. 2012, Ramachandraiah 2011). There are also the slow onset impacts that pose particular challenges and that may also be outside the jurisdiction of urban governments – for instance the impact of drought on agriculture that can raise food prices and reduce rural demand for urban services.

Cities in high-income nations and many in middle-income nations have become more resilient to extreme weather (and most other potential catalysts for disasters) through a range of measures that have responded to risks and to the political processes that demanded such responses (Satterthwaite 2011). This resilience has been built over many decades and often required intense political negotiation. The resilience accumulated through this in what was built and in the capacity of institutions provides resilience to some climate change impacts, even though the measures that built resilience were not in response to climate change impacts (see for instance Hardoy and Ruete 2013 on Rosario, Argentina).What strongly influences resilience to extreme weather for urban dwellers is the quality of buildings (homes and workplaces), the effectiveness of land-use planning and regulation to control development in flood-prone and other high risk areas, the quality and coverage for key infrastructure and services, early warning systems for extreme weather and adequate public response measures, whether their incomes are sufficient to invest part in resilience (living in healthy homes, life insurance, insurance for possessions and home, savings, pensions, asset ownership…), what safety nets are available if income is insufficient and the regulatory framework for ensuring the application of the above. Urban governments have importance for most or all of these, although their provision usually depended on changes at national level – for instance in legislation and in financial support (although political change at national level was also in part driven by political pressure from urban dwellers and innovation by city governments). Private companies or non-profit institutions may provide some of the key services and private companies have key roles in provision and often maintenance of infrastructure -but the framework for provision and quality control is provided by local government or local offices or national or provincial government.

A city's accumulated resilience can be assessed by the extent to which it has reduced hazards, reduced risk and reduced exposure, with particular attention to how this serves or protects vulnerable groups and at-risk areas. Also by the measures in place to enhance capacity to cope and adapt. Such an assessment can also consider how well this 'accumulated resilience' will serve climate change adaptation. Of course, there are hazards that city governments cannot reduce (for instance earthquakes) or that need global action (eg reducing greenhouse gas emissions).

Although the components of accumulated resilience were not in response to risks from climate change, the web of institutions and finances that produced and maintain them provide a base for climate change adaptation (and more broadly for resilience). Building and infrastructure standards can be adjusted if needed (there is infrastructure in place that can be adjusted - for instance increasing capacity for storm and surface water drainage systems), existing service provision can be adjusted for new risks or risk levels (measures to reach populations vulnerable to heat stress during heat waves and within heat islands) and city planning and land-use management can be adjusted to any new or heightened risk (keeping building and city expansion away from areas facing new risk levels).This can be supported by changes in private sector investments (over time shifting away from high-risk areas) and changes in insurance premiums and coverage. So the web of institutions and the buildings, infrastructure and services that have developed in response to non-climate change risks provide a foundation for developing resilience to climate change.They provide the basis on which to build adaptive capacity to withstand climate-change related direct and indirect disturbances. They can also go beyond this and "bounce forward" by building climate resilience through a mix of sound development, disaster risk reduction and ecosystem-based adaptation, rather than incremental adaptation interventions..

Whether they will do so depends on whether urban governments take this on – and whether the demands of their inhabitants and these inhabitants' capacity to organize and get change promote this; also whether the institutions and their complex inter-relationships have the capacity to learn. Obviously, the extent to which these provide or can provide resilience in the future also depends on global agreements that slow and stop the increases in risk from GHG emissions and other drivers of climate change.

Many cities that have accumulated resilience may not act on the changes in hazards and risks that climate change is bringing or will bring. So here, the issue is whether the institutions and political pressures that built the accumulated resilience shift now to resilience as a process – responding dynamically and effectively to evolving and changing climate-related risks (and evolving and changing knowledge bases for this).For cities with accumulated resilience, there may be climate change impacts that such accumulated resilience does not serve - for instance potential disruption to resource flows. Or the actions needed for resilience are outside city boundaries.

For urban centres with little accumulated resilience, *resilience as a process* has importance, both to help reduce over time the (often very large) deficiencies in most or all the infrastructure, services and regulatory frameworks that provide resilience in high-income nations and to build resilience to climate change impacts. For around a third of the world's urban population, this has to be done in a context of limited incomes and assets and poor living conditions and little resilience to any stress or shock. Just an increase in prices of food staples or a drop in income (an income earner being ill or injured) or a new cost (medicines needed for a sick family member) can quickly mean inadequate food and thus hunger and reduced capacity to work and to resist infections.

The above also implies a different perspective on how climate change adaptation needs to be supported. It emphasizes how resilience to climate change impacts is intimately tied to the quality of governance (in which local governance has particular importance) and in the government capacity and willingness to listen to, work with, support and serve those who lack resilience. Here too, the idea of resilience as 'bouncing forward' has importance – as shown by the many successful partnerships between local government and grassroots organizations formed by residents of informal settlements that have built or improved homes and neighbourhoods. This would also be part of the shift from resilience to transformation (see Pelling 2011a, Shaw and Theobald, 2011, Manyena et al 2011).

Thus, resilience can be considered in relation to individuals/households, communities and urban centres. In each, it includes the capacity to take action that avoids a climate change impact (live in safe location, have a safe house, have risk reducing infrastructure), to take action before climate impact takes place to reduce its impact (especially relevant for extreme weather events), to cope with the impact and to bounce back (to the previous state) and to 'bounce forward' to a more resilient state that would lay the ground for transformative adaptation.For urban centres, bounce back includes a government capacity to rapidly restore key services and repair infrastructure and 'bounce forward' is building the socio-institutional processes and capacities that enable the accumulation of resilience.

8.1.5. Conclusions from the Fourth Assessment (AR4) and New Issues Raised by this Chapter

AR4's chapter on Industries, Settlements and Human Society noted that these are accustomed to variability in environmental conditions but more at risk if change is more extreme (e.g. beyond what had been experienced in the past), persistent or rapid, especially if not foreseen and where capacities for adaptation are limited.

Except for abrupt extreme events, climate change impacts are not dominant issues for urban centres but their importance is in their interaction with other stressors that may include rapid population growth, political instability, poverty and inequality, ineffective local governments, jurisdictional fragmentation and aging or inadequate infrastructure. Key challenges to getting attention to adaptation include the difficulties of estimating and projecting the magnitudes of climate risk in particular places and sectors with precision and a weak knowledge base on the costs of adaptation.

AR4 described how the interactions between climate change and global urbanization has led to concentrations of urban populations in low-income nations with weak adaptive capacity. It also described the interactions between climate change and a globalized economy that include long supply chains and impacts spreading from directly impacted areas and sectors to other areas and sectors through complex linkages. Many impacts will be unanticipated and total impacts are also poorly estimated by considering only direct impacts. Key global vulnerabilities include interregional trade and migration patterns.AR4's Chapter 7 also described how climate change impacts and most key vulnerabilities are influenced by local contexts including geographic location, the sensitivity to climate of enterprises located there, development pathways and population groups unable to avoid dangerous sites and homes.

Key risks are most often related to climate phenomena that exceed thresholds for adaptation (eg extreme weather or abrupt changes) and limited resources or institutional capacities to reduce risk and cope (development context). Climate change will increase demands on water and energy supplies and often on health care and emergency response systems.

Individual adaptation may not produce systemic adaptation. In addition, adaptation of systems may not benefit all because of differential vulnerability of particular groups and places. Adaptation will require a greater awareness of threats and alternatives beyond historical experience and current access to finance.

Technological innovation for climate adaptation comes largely from industry and services motivated by market signals and these may not be well matched with adaptation needs and residual uncertainties. Many are incremental adjustments to current business activities. Planning guidance and risk management by insurers will have roles in locational choice for industry.

Certain types of infrastructure are more at risk – including most transport, drainage and electricity transmission systems and many water supply abstraction and treatment works. There is a need to increase reserve margins and develop back up capacity. Adaptation of infrastructure and building stock is often dependent on changes in the institutions and governance framework e.g. in planning regulations and building codes. Climate change has become one of many changes to be understood and planned for by local managers and decision makers.

8.1.5.1. Key Uncertainties and Research Priorities

A range of key uncertainties and research priorities emerge from recent literature:

- The limits to understanding and predicting impacts of climate change at a fine grained geographic and sectoral scale
- Inadequate knowledge on the vulnerabilities of urban citizens, enterprises and centres to the direct impacts of climate change, to second and third order impacts and to the interdependence between systems
- Inadequate knowledge on the adaptation potentials for each urban centre (and its government) and their costs and on the limits on what adaptation can achieve (informed by a new literature on loss and damage)
- Serious limitations on geophysical, biological and socio-economic data needed for adaptation including data on nature-society links and local (fine-scale) contexts (see for instance WMO 2008)
- Uncertainties about trends in societal, economic and technological change with or without climate change including the social and political underpinnings of effective adaptation
- Understanding the different impacts and adaptation responses required to rapid and slow onset disasters

8.1.5.2. What has Changed since AR4

There is now a much larger and more diverse literature on current and potential climate change risks for urban populations and centres and the vulnerabilities of different urban centres and their structure and functioning. There has also been a very large expansion in the literature on urban 'adaptation,' and on building resilience at city and regional scales. This includes a large increase in the number of city governments that have published documents on adaptation. There is more engagement with urban adaptation by some professions (including architects, engineers, urban planners and disaster risk reduction specialists). There are also books that focus specifically in climate change and cities with a strong focus on adaptation (see Bicknell et al 2009, Rosenzweig et al 2011a and UN-Habitat 2011a, Cartwright et al 2012). This makes a concise and comprehensive summary more difficult. But this has also produced more clarity in what contributes to resilience in urban centres and systems. Specifically:

- A more detailed understanding of key urban climate processes and improved analytical and down-scaled integrated assessment models at regional and city scale
- A more detailed understanding on the governance of adaptation in urban centres and the adaptation responses being considered or taken (including a large and important grey literature produced by or for city governments and some international agencies) and in many high-income and some middle-income nations, support for this from higher levels of government

- More nuanced understanding of the many ways by which poverty and discrimination exacerbates vulnerability to climate impacts (see also Chapter 13)
- More detailed studies for particular issues of built environment responses to promote adaptation (see for instance the growth in the literature on green and white roofs)
- More case studies of community-based adaptation in its potential contributions and in its limitations
- More consideration of the role of ecosystem services and of green and blue infrastructure in adaptation
- More considerations on the financing, enabling and supporting of adaptation for households and enterprises
- More on learning from innovation in disaster risk reduction
- A greater appreciation of the inter-dependencies between different infrastructure networks and of the need for adaptation both in 'hard' infrastructure and in the 'soft' institutions that plan and manage it.
- More examples of city governments and their networks contributing to national and global discussions of climate change adaptation (and mitigation) including establishing voluntary commitments (see for instance the Durban Adaptation Charter for local governments) and engaging with the Conference of Parties

8.2. Urbanization Processes, Climate Change Risks, and Impacts

8.2.1. Introduction

This section assesses the connections between ongoing urbanization and climate change in relation to patterns and conditions of climate risk, impact, and vulnerability. The focus is on urbanization and its local, regional and global environmental consequences and the processes that maylead to increased risk exposure, constrain people in high-risk livelihoods and residences, and generate vulnerabilities in critical infrastructure. Understanding urbanization and associated risk and vulnerability distributions is critical for an effective response to climate change threats and their impacts (Romero Lankao and Qin, 2011; Bulkeley, 2010;Solnit, 2008; Satterthwaite, et al., 2009; Vale and Campanella, 2005), promotion of sustainable urban habitats and the transition to increased urban resilience. There is a particular interest in the ability of cities to respond to environmental crises, and the resilience and sustainability of cities (Solecki et al., 2011, Solecki, 2012).

The section assesses the direct impacts of climate change on urban populations and urban systems. Together, direct climate impacts and shifts in urbanization change the profile of societal risk and vulnerability. Both can alter transition pathways that lead towards greater resilience and sustainable practices and the basis of how such practices are managed within a community. Understanding and acting on the connections between climate change and urbanization is crucial since changes in one can affect the other. We investigate a range of direct impacts including those on physical and ecological systems, social and economic systems, and coupled human-natural systems. Where relevant and fundamental to the understanding, cascading impacts (where systems are tightly coupled) and secondary (indirect) impacts also are noted.

8.2.2. Urbanization – Conditions, Processes, and Systems within Cities

8.2.2.1. Magnitude and Connections to Climate Change

Section 8.1 emphasizes how much conditions in urban centres vary, how they are influenced by the proportion of the population with incomes too low to allow them to afford food and non-food needs, the extent to which the whole population (and vulnerable groups within this population) are served by the basic infrastructure and network of services that should serve as the main reducers of risk, the extent to which their site is at risk from climate change impacts, and the competence, capacity and accountability of their government (Pelling,2003; Moser and Satterthwaite, 2008; Hardoy and Pandiella, 2009). Variations in these factors have important consequences for the process of climate change, for how climate change contributes to global environmental change, shaping impacts in urban areas, and for how cities might be able to respond (Stone, 2012; Rosenzweig et al., 2011a; Seto and Satterthwaite, 2010; Seto and Shepherd, 2009; US NAS, 2012; Güneralp and Seto, 2008).

Urbanization can be considered in relation to key qualities and parameters (spatial, temporal, and sustainability) to capture the shifting, complex interactions between climate change and urban growth within a global toregional context. Giventhe significant and usually rising levels of urbanization (see 8.1.3), more people will be exposed to impacts of climate change in urban areas, with a growing proportion being exposed in large centres and megacities (de Sherbinin et. al., 2007; Revi, 2007). Additionally, many smaller urban centres in Africa, Latin America and Asia are growing rapidly but are "often institutionally weak and unable to promote effective mitigation and adaptation actions" (Romero Lankao and Dodman, 2011: 14). It is in the urban centres in these regions with less than a million inhabitants where most population growth is expected (United Nations 2012). It is largely these that have limited institutional and financial capacity to address development challenges and incorporate adaptation and mitigation as elements of urban development.

Urbanization alters local environments via a series of physical phenomena that can result in problems such as heat islands and local flooding that can be exacerbated by climate change. It is critical to understand the interplay between the urbanization process, current local environmental change and accelerating climate change. For example, the past long-term trend in surface air temperature in urban centres has been found to be associated with the intensity of urbanization (Kalnay et al 2006; Ren et al., 2007; Fujibe, 2009; Kolokotroni et al., 2010; Chen et al., 2011; Iqbal and Quamar 2011; Fujibe, 2011; Rim, 2009; Santos and Leite 2009; Tayanc et al., 2009; Sajjad et al., 2009; Jung, 2008; He et al., 2007; Stone, 2007). Climate change can influence the dynamics of the microclimate associated with a given city and a city may likewise alter a localized region's climate. Some coupled processes that may be influenced by the interaction of urbanization and climate change include: changing the effect of urbanization (microscale to mesoscale) by strengthening and/or increasing the range of a UHI, altering small scale processes, such as a land-sea breeze effect, katabatic winds, etc.,modifyingsynoptic scale meteorology (e.g. changes in the position of high pressure systems in relation to UHI events), and the spatial extent and magnitude of climate change (on a city) resulting from global radiative forcing from GHGs.

The dense nature of many large cities (including megacities) produces pronounced urban influences on anthropogenic heat emissions and surface roughness. The level of this impact is linked to the level of wealth, energy consumption and micro and regional climate conditions. Anthropogenic heat fluxes for large cities can be very high: up to 50-500 W m^{-2} has been observed in a global analysis (Flanner, 2009; Allen et al., 2011) in London (Iamarino et al., 2011) and Singapore (Quah and Roth, 2012), with values locally reaching 1500 W m^{-2} in Tokyo (Ichinose et al., 1999). Under clear skies and light wind conditions, large cities can be more than 10°C warmer than surrounding rural environments (Oke, 1982). There is strong seasonal, diurnal, and meteorological variability in temperature which influences the level of significance that these urbanization related changes have on a specific city.

In a review of relationships between coastal megacities and environmental change, Grimmond (2011) found increasing evidence that cities can influence weather (e.g. rainfall, lightning) through complex urban land use–weather–climate feedbacks (see also Ohashi and Kida, 2002). Megacity impact on air flows, especially for coastal cities has been modelled, for New York and Tokyo (Holt et al., 2009; Holt and Pullen, 2007; Thompson et al., 2007). Megacities influence both internal city environmental and regional weather and air quality. Megacity-coastal interactions may also impact the hydrological cycle and pollutant removal processes through the development of fog, clouds, and precipitation in and around megacities and coastal areas (Landsberg, 1970; Ohashi and Kida, 2002; Shepherd et al., 2002). Other modelling efforts define building density and design and the scale of urban development are important local determinants of the influence of urbanization on local temperature shifts (Oleson et al., 2012; Trusilova et al., 2008).

The results of climate modelling exercises indicate an 'urban effect' that leads locally to higher temperatures and reduced humidity while additional warming also marginally increases rainfall over large cities. The replacement of vegetation with urban surface outweighs this positive impact to reduce the overall land carbon sink (Grimmond, 2011). With respect to temperature specifically, Jackson et al. (2010 and 2012) confirm that building material properties are influential in creating different urban climate temperature regimes, which have the potential to alter energy demand for climate control systems in buildings. These results suggest that climate impacts of large cities, including the megacities, are open to change should they be redesigned and use of energy-efficient building materials, passive design technologies and appropriate land-use are scaled up. Urbanization and climate change also will lead to other environmental impacts such as increased levels of surface runoff(Hamdi et al., 2011).

8.2.2.2. Spatiality, Physical Planning, and Climate Change

The pattern of urban spatial development is a critical factor in the interactions between urbanization, climate-related risks, and vulnerability. Urban form densities range from concentrated to dispersed, while most planned urban settlements exhibit declining population density outward from the urban core (Seto et al., 2010; Leichenko and Solecki, 2008). In cities with large fringe and unplanned settlements, this pattern can be reversed. In both cases urban growth is experienced through horizontal expansion and sprawl (United Nations2012; Hasse and Lathrop, 2003). Rapid urban population growth in the last decade has been increasingly marked by growth in vertical density (high-rise living, and working) in many nations, especially in Asia. Higher density living can offer opportunities for resource conservation but also challenges for planning and urban management (see 8.3.3.7).

Many large cities have developed into extended metropolitan regions across a wide range of settlement conditions from low, middle and high-income nations (Seto et al., 2010; Leichenko and Solecki, 2005). In such regions, this can force a multiplication of loci for economic activity, industry, educational excellence, and concentrations of poverty. It is often problematic for these multiple centres to interact in planned ways that can benefit from traditional scale economies, creating pressures for geographical, social, administrative and political fragmentation – leading to a transition from a city with a single centre to city metropolitan region with multiple centres and uni-polarity to multi-polarity which is typically observed in most large city development (Laquian, 2011).

Urban expansion has fostered extensive networks of critical infrastructure, which are frequently vulnerable to climate change (Solecki et al., 2011; Rosenzweig et al., 2011a). For instance, New York City's dispersed communications network faces several climate-related risks. Electrical support facilities can be flooded, while cellphone towers can topple due to strong winds or become corroded as sea levels rise (Zimmerman and Faris, 2010). In Alaska, telecommunications towers are already settling due to warming permafrost (Larsen et al.,2008). During the extreme rainfall event in 2005, Mumbai's telecommunications networks ceased to function due to a mix of overload, shut down of the power system and lack diesel supplies for generators (Revi, 2006). Waterallocation for cities that are rapidly growing and in water-scarce regions, like Delhi and Beijing, are increasingly being strained which can generate increased vulnerability to changes in precipitation patterns associated with climate change.

Settlement patterns strongly shape conditions for climate change adaptation and mitigation (Stone et al., 2010; Biesbroek et al., 2009). For instance, within Toronto, per capita greenhouse gas emissions from housing and transport varied from 1.3 to 13 tCO_2 equivalent when comparing a dense inner-city neighbourhood with good access to public transport with a sprawling outer suburb (VandeWeghe et al., 2007, Hoornweg et al.,2011). Cities generate challenges for adaptation by concentrating people and assets in ways that increase climate-related risks and vulnerabilities. By the same token, urban areas create advantages to support resilience through the "economies of scale and proximity that they present for key protective infrastructure and services for risk-reducing governance innovations..." (Satterthwaite, 2009: 560). Higher-density development with adequate transport links can promote social integration and equity, particularly in cities where low-income households live in peripheral settlements (Dulal et al., 2011). Physical planning interventions can be combined with command-and-control measures (e.g. zoning), land use taxes, price mechanisms, and public education campaigns to promote sustainable transport and settlement patterns (Grazi and van den Bergh, 2008).

8.2.2.3. Temporal Dimensions: Rapid Onset, Slow Onset, Production Cycles

For any city or region, it is important to understand the connections between climate risk and vulnerability and the rate of change in aspects of urbanization including populations and households, urban spatial expansion, and redevelopment of existing urbanized areas. Urbanization is associated with changing dimensions of migration and materials flows both into and out of cities and within them (Grimm et al., 2008). The level of increase or in some cases decrease of these conditions, create a dynamic quality in cities. Urban risks are not static and will continue to change in the future. Rapidly changing cities have the challenge of managing this growth via housing and infrastructure development while also attempting to simultaneously understand the relative impact of climate

change. For example in sub-Saharan Africa, the combination of relatively high population growth rates and increasing levels of urbanization (projected to reach 46 percent by 2030) will bring a corresponding rise in exposure to climate change impacts. The conflation of local environmental change resulting from urbanization with climate change shifts make the identification and implementation of effective adaptation strategies more difficult. For example, water shortages are already a chronic concern for many cities in low and middle income nations and this typically worsensas the population and demand continue to grow (Muller, 2007).Overlaying climate change-related reductions in supply or heightened uncertainties facing water managers with this existing instability creates the conditions for greater management and governance crises (Gober, 2010, Milly et al., 2008*)*.

8.2.2.4. Urbanisation and Ecological Sustainability

The urbanization-climate change connection has important implications for ecological sustainability. Urbanization is one of the key drivers of global environmental change and is directly connected to the question of ecological sustainability, and to the ecological underpinning of urban life (Huang, Yeh, and Chang, 2010). An "important aspect of achieving urban sustainability is strengthening our ability to respond to the changing relation between urbanization and climate" (Grimm et al., 2008:758). As cities grow and change, the demand for resources expands and transforms, increasing cities' ecological footprint (Rees, 1992; Wackenagal et al., 2006)and long distance resource linkages to 'distant elsewheres' (Rees 1992). In many cases, city-resource supply connections have become more distant and more at risk of interruption (e.g., Seto et al., 2012; Jenerette and Larsen, 2006).

Climate change can accelerate ecological pressures in cities, as well as interact with existing urban environmental, economic, and political stresses (Leichenko, 2011; Wilbanks and Kates, 2010). For example, New Orleans' geophysical vulnerability is shaped by its low-lying location, accelerating subsidence, rising sea levels, and heightened intensity or frequency of hurricanes due to climate change—a combination of natural phenomena exacerbated by "settlement decisions, canal development, loss of barrier wetlands, extraction of oil and natural gas, and the design, construction, and failure of protective structures and rainfall storage" (Wilbanks and Kates, 2010:726) ; Ernston et al.,2010). Cities in arid regions already struggle with water shortages often in the context of rising demand, but for many such cities, climate change will further reduce water availability because of shifts in precipitation and/or evaporation (Gober, 2010).

8.2.2.5. Regional Differences and Context-Specific Risks

Case studies and regional reviews assessing urban vulnerabilities to climate change have revealed diverse challenges and large differences in levels of adaptive capacity (Rosenzweig et al., 2011a; Hunt and Watkiss, 2011). For instance, discussions in African cities (Castan Broto et al., 2013; Simon, 2010; Kithiia, 2011) have highlighted the lack of capacity and awareness of climate change, as well as often extremely high levels of vulnerability among the continent's large and rapidly growing urban poor populations. Other reviews have considered cities in Latin America (Luque et al., 2013; Hardoy and Romero-Lankao, 2011), North America (Zimmerman and Faris, 2011), Europe (Carter, 2011), and China (Liu and Deng, 2011). Studies have analyzed Asian cities' health risks due to climate change (Kovats and Akhtar, 2008) and other urban vulnerabilities in South and Southeast Asia (Birkmann et al.,2010; Alam and Rabbani, 2009; Revi, 2009).

The global distribution of urban risks is highly context-specific, dynamic, and uneven between and within regions. Absolute exposure to extreme events over the next few decades will be concentrated in large cities and countries with urban populations in low-lying coastal areas, as in many Asian nations (McGranahan, Balk, and Anderson, 2007). Settlements located in river flood plains also are prone to flooding during extreme or persistent precipitation / severe storm conditions. Urban populations' exposure to climate change related risks is influenced by the scale of the population concentration in cities and the proportion of the population in urban areas. However, recent improvements in urban governance and rising wealth in Latin America (one of the world's most urbanized regions) have helped to strengthen adaptive capacity (Hardoy and Romero-Lankao, 2011).

Studies from different cities confirm how much the scale and nature of climate change risks will differ; Section 8.1 and Table 8-2 also emphasized the very large differences between cities in their current resilience to such risks, in the capacity to adapt and in the proportion of their population in informal settlements, most of which lack risk-reducing infrastructure. Many are on dangerous sites including steep slopes and low lands adjacent to unprotected river banks, ocean shorelines and have structures that do not meet building codes (Hardoy et al., 2001; Pelling, 2003). However, those who are generally most vulnerable to climate change impacts are women, children, health compromised and the elderly among this population in informal settlements due to the fact that either they are less mobile (e.g., women with child care responsibilities), have less resources, or are physically weak. Hence, the combination of a lack of infrastructure access, low incomes and limited assets puts them at high risk from disasters (Moser and Satterthwaite, 2008).

8.2.3. Urbanization and Climate Change and Variability – Primary (Direct) and Secondary (Indirect) Impacts

Climate change will lead to increased occurrences and intensity of extreme weather events such as heavy rainfall, warm spells and heat events, drought, intense storm surges and associated sea-level rise (see SREX IPCC 2012; Hunt and Watkiss, 2011; Romero-Lankao and Dodman, 2011; Rosenzweig et al., 2011a). Physical factors such as topography and geo-hydrological conditions typically differentiate variations in the distribution of impacts within an urban area. Social (e.g. equity and justice issues), geographic (e.g. high density locations, suburban, exurban locations) and temporal (e.g. short, medium, and long term shifts) contexts should also be considered.

8.2.3.1. Urban Temperature Variation: Means and Extremes

Heat waves and warm spells will connect with urban heat island effects resulting in increased air pollution (Blake et al., 2011; Campbell-Lendrum and Corvalán, 2007) and may cause heat-related health problems (Hajat et al., 2010; see also 8.2.3.7). Conversely, widespread reduction in cold waves will induce shifts in heating demands (Mideksa and Kallbekken, 2010) and potential reduction in mortality from cold waves. Increased warming is predicted in a wide variety of cities including sub-tropical, semi-arid, and temperate sites with respect to human thermal comfort level (Thorsson et. al., 2011). For more discussion on cities and impacts of increased warming in specific regions refer to the regional chapters of this report. It is still unclear whether or not climate change will exacerbate the UHI phenomenon in cities (Oleson et al., 2012).

8.2.3.2. Urban Heat Islands

Urban heat islands are difficult to quantify and there is debate within the literature on how to define them (Stewart, 2011). Many studies indicate that the UHI will decrease or at least stay constant in the future (Oleson et al., 2012). In London, urban heat islands were observed with recorded night-time temperatures up to 7ºC higher in central London than in Wisley, a rural location 32 km to the southwest (Wilby, 2007). Although small urban centres may also experience the UHI, the extent of urban-rural temperature different are not linearally related to urban population size (Smith and Levermore, 2008). Studies have also linked the extent and expansion of urbanization with past UHI trends, urban heating, current variability, and projected climate change. Recent studies with physically based models such as Oleson (2012) and McCarthy et al. (2010) show mixed signals with reductions in UHI in many areas of the world and increases in some areas in response to climate change simulations. McCarthy et al. (2011) looks specifically at London and Manchester and does not find an increase in UHI in the 2050s.

Future projections of UHI under global warming conditions were conducted for Tokyo. The air temperature of Tokyo in August is projected to increase about 2ºC by the 2070s according to an average of 5 GCMs under the SRES A1b scenario (the range of uncertainty in GCMs is about 2ºC). Another warming of about 0.5ºC is projected due to the maximum possible land-use change. As a result, total UHI intensity is projected to increase from 1.5ºC to 2.0ºC through the 2070s (Adachi et al., 2012).

London's annual number of nights with heat islands stronger than 4ºC has increased by 4 days/decade since the late 1950s; meanwhile, the average nocturnal heat island intensity rose by just ~0.1ºC/decade over the same period (Wilby, 2007). Projections suggest that by 2050, London's nocturnal UHI in August could rise another 0.5°C, representing a 40 percent increase in the number of nights with intense UHI episodes (*ibid*). For New York City, climate change is expected to exacerbate the existing UHI conditions via increase of extended heat waves (Rosenzweig et al., 2009).

For cities in India, connections between urbanization and the development of UHI, and the implications with future climate have been defined (Mohan et al., 2011a; 2011b; 2012). Overall, there is evidence that a current trend of increasingly frequent extreme events will increase with climate change (Manton, 2010). The inter-comparison of the annual mean minimum temperatures of two stations within Delhi (Safdarjung and Palam) post 1970's onwards show that night time temperature trends are synchronized with the city's pace of urban expansion (Mohan et al., 2011b).

8.2.3.3. Drought and Water Scarcity: Means and Extremes

Drought can cause many impacts in urban areas, including increases in food prices and food insecurity because of reduced supply, water shortages, electricity power shortages for urban areas that depend mostly on hydropower and an increase in water related diseases; these may also lead to a wide set of economic impacts as well as increased rural to urban migration (Farley et al., 2011; Herrfahrdt-Pahle, 2010; Vairavamoorthy et al., 2008). Averaging across all climate changescenarios, recent findings suggest that nearly 100 million more city-dwellers "will live under perennial water shortage under climate change conditions than under current climate" (McDonald et al., 2011:2). The study also notes the role of demographic growth: The model results show that currently 150 million people live in cities with perennial water shortage, defined as having less than 100 L per person per day of sustainable surface and groundwater flow within their urban extent" and by 2050, this figure could increase to almost 1 billion (ibid.). Drought and water scarcity also affect cities in high-income countries. A detailed economy-wide, 70-industry analysis of the economic impacts of climate change on water availability in the USA for 2010 through 2050 highlighted the interacting industry-level effects, employment impacts, consequences to personal income, and ramifications for the U.S. Gross Domestic Product (GDP). When compared to a baseline economic forecast, the calculations produced an average risk of damage of $1 trillion to the U.S. economy from climate change over the 40 years, with losses in employment equivalent to nearly 7 million full-time jobs (Backus et al., 2012).

8.2.3.4. Coastal Flooding, Sea Level Rise, and Storm Surge

Sea-level rise represents one of the primary shifts in urban climate change risks, given the increasing concentration of urban populations in coastal locations and within low-elevation zones (McGranahan et al., 2007). Rising sea levels, the associated coastal and riverbank erosion, or flooding in conjunction with storm surge could all lead to widespread impacts on populations, property and coastal vegetation and ecosystems, and threats to commerce, business, and livelihoods (Nicholls 2004, Hanson et al., 2011; Carbognin et al., 2010; Pavri et al., 2010; El Banna and Frihy, 2009; Zanchetting, 2007; Dossou and Glehouenou-Dossou, 2009). It is the lowland areas in coastal cities such as Lagos, Mombasa, or Mumbai that are usually more at risk of flooding, especially if a city also has less provisions for drainage (Adelekan, 2010; Awuor et al., 2008; Revi, 2009). Structures constructed on infilled soils in the lowlands of Lagos, Mumbai and Shanghai are more exposed to risks of flood hazards than similar structures built on consolidated materials (*ibid.*). Many coastal cities have sites at risk from both riverine and coastal storm surge (Mehrotra et al., 2011a).

Cities with extensive port facilities and large scale petro-chemical and energy related industries are vulnerable to climate change's increased flooding potential. Hanson et al. (2011) estimate the change in flooding, by the 2070s in the exposure of large port cities to coastal flooding with scenarios of socio-economic growth, sea level rise and heightened storm surge, and subsidence. They find that population at risk could more than triple while asset exposure is expected to increase more than ten-fold with a 0.5 meter rise in sea-level. The study identifies the "top-20" cities for both population and asset exposure to coastal flooding. The high risk cities in both the current and 2070 rankings are spread across low, middle, and high-income nations, but are concentrated in Asian deltaic cities.

The cities include: Mumbai, Guangzhou, Shanghai, Miami, Ho Chi Minh City, Kolkata, New York, Osaka-Kobe, Alexandria, Tokyo, Tianjin, Bangkok, Dhaka, and Hai Phong. Using asset exposure as the metric, cities in high-income nations and in China figure prominently - Miami, New York City, Tokyo and New Orleans as well as Guangzhou, Shanghai and Tianjin. These analyses which highlight the large number of assets and population which will be exposed and vulnerable underscores the need for long-term urban risk reduction measures.

8.2.3.5. Inland Flooding and Hydrological and Geo-Hydrological Hazards at Urban Scale

The exposure to climate related hazards will vary due to differences in the geomorphologic characteristics of the city (Luino and Castaldini, 2010). Heavy rainfall and storms surges would impact urban areas through flooding which in turn could lead to the destruction of properties and public infrastructure, contamination of water sources, water logging, loss of business and livelihood options and increase in water borne and water-related diseases as noted in wide range of studies (Revi, 2007; Dossou and Glehouenou-Dossou, 2007; Kovats and Akhtar, 2008; Sharma and Tomar, 2010; Adelekan, 2010; Hardoy and Pandiella, 2009; de Sherbinin et. al., 2007; Douglas et al., 2008; Roberts, 2008; Nie et al., 2009; Shepherd et al., 2011). Case studies of inland cities have considered the elevated risk of flooding due to climate change, such as in Kampala (Lwasa, 2010; Lwasa, 2013) and travel disruptions in Portland (Chang et al.,2010). Significant research focus has been on attempts to improve modeling of the frequency and condition of extreme precipitation events and resulting flooding (Ranger et al., 2011; Onof and Arnbjerg-Nielsen, 2009; Nelson et al., 2009; Olsson et al., 2009; Sen, 2009).

8.2.3.6. Air Pollution: Means and Extremes

Climate change is associated withimplications for urban air quality (Athassiadou et al., 2010), air pollution, and health policy (see Chapter 11 of WGI AR5 for more discussion). Urban air quality in most cities already is compromised by localized air pollution from industry andtransportation, and often commercial and residential sources. Air quality can be adversely affected by limited ventilation within and aroundstructures. Emerging literature on climate change and air quality shows that there is strong evidence that climate change would generally increase ozone in the US and Europe, but that the pattern of that change is not clear, with some areas increasing and some decreasing. The effects on particulate matter (PM) are also unclear, as are the effects on ozone and PM outside of the US and Europe. Effects on particular urban areas are highly uncertain and may include increases and decreases of certain pollutants (Weaver, 2009; Jacob and Winner, 2009).

8.2.3.7. Emerging Human Health, Disease, and Epidemiology Issues in Cities

Good evidence exists that temperature extremes (heat and cold) affect health, particularly mortality (see 11.2.2). The impacts vary by setting, but populations in urban areas appear more sensitive to heat effects than rural areas in temperate zone countries. Since AR4, there have been more studies on urban populations in low and middle income countries (see for instance Burkart et al 2011 for urban populations in Bangladesh and Egondi et al 2012 for children and non-communicable disease deaths in Nairobi's informal settlements). Heat waves are known to have significant impacts on health that can be exacerbated by drought conditions or high humidity. Studies in high-income countries suggest a greater vulnerability among the elderly to heat-related mortality (see Åström et al 2011 for a review of this). In urban settings where child mortality is high, high and low temperatures have been shown to have an impact on mortality (e.g. Egondi et al. 2012). Furthermore, some occupations are more at risk as they are exposed to higher temperatures for long durations and low-income households are more at risk when heat waves disrupt or limit income-earning opportunities (Kovats and Akhtar 2008) (see also 11.2.7 for more detailed discussion of occupational heat stress).

WHO (2012) notes that climate change may affect the future social and environmental determinants of health, including clean air, safe drinking water, sufficient food and secure shelter. All these are relevant to urban areas. Increased risks from water scarcity, heat waves and flooding were discussed ready. The incidence of asthma exacerbation may be affected by any climate-change related increases in ground level ozone exposures (Barata et al.,

2011; O'Neill and Ebi, 2009; Reid et al., 2009; Gamble, 2009b; Kinney, 2008); other pollutants may also be affected particularly in those cities with PM10 and ozone levels far above WHO guidelines (WHO 2011b). Climate change may affect the distribution, quantity, and quality of pollen in urban areas, as well as altering the timing and duration of pollen seasons. WHO (2012) also noted that diarrhoeal diseases, malnutrition, malaria and dengue are climate-sensitive and in the absence of appropriate adaptation responses, could be adversely affected by climate change (see chapter 11).

8.2.4. Urban Sectors: Exposure and Sensitivity

This section assesses how the observed and forecasted direct impacts of climate change influence the exposure of city residents, infrastructure, and systems to risk by considering key affected sectors and populations and possible interrelations. Direct impacts include all costs and losses attributed to the impact of hazard events, but exclude systemic impacts for example on urban economies through price fluctuations following disaster or the impact of disaster losses on production chains (see UN-ECLAC 1991). Both the temporal and spatial scale of the shifts in climate risk across cities and urbanizing sites in the next few decades are considered. In addition, we analyze how the scale and character of risks change and grow in cities as shifts in climate extremes, means and long-term trends (e.g. sea-level rise) take place.

Climate change will have profound impacts on a broad spectrum of city functions, infrastructure, and services and will interact with and potentially exacerbate many existing stresses. These impacts can occur both *in situ* and through long-distance connections with other cities and with rural locations, such as sites of resource production and extraction (Seto et al., 2012; Satterthwaite et al., 2010). The interaction between climate change and existing environmental stresses can lead to a range of synergies, challenges, and opportunities for adaptation with complex interlinkages and often highly uncertain or non-linear processes (Ernston et al., 2010). For example, the 2007 floods in the city of Villahermosa covered two thirds of Tabasco State in Mexico with serious consequences for the city's economic base. Regional damages and asset and infrastructure losses amounted to US$ 3.1 billion, equivalent to 30 percent of the state annual GDP (CEPAL, 2008). The flood that struck the Chao Phraya River in 2011 not only caused a high loss of life and damages to many companies and several industrial estates in Bangkok but also had a wider economic impact because of the disruption to industrial supply chains (Komori et al 2012).Urban centres serving prosperous agricultural regions are particularly sensitive to climate change if water supply or particular crops may be at risk. In Naivasha, Kenya, drought threatens high-value export oriented horticulture (Simon, 2010). Urban centres that serve as major tourism destinations may suffer when the weather becomes stormy or excessively hot and lead to a loss of revenue.

Similarly, infrastructure will be impacted by systemic and cascading climate risks (Hunt and Watkiss, 2011). Climate stresses, particularly extreme events, will have effects across interconnected urban systems – both within and across multiple sectors (Gasper et al. 2011). The cascading effects of climate change are especially evident in the water, sanitation, energy and transportsectors, due to the often tightly-coupled character of urban infrastructure systems (see Rosenzweig and Solecki 2010 for a discussion of this for New York City). The U.S. National Climate Assessment effort has looked at the impacts of climate change on infrastructure considering the water, land, and energy nexus, as well as on a large number of industries (Skaggs et al., 2011; Wilbanks et al., 2012). These systemic cascades can have both direct and indirect economic impacts (Hallegatte et al., 2011; Ranger et al., 2011) which can extend from the built environment to urban public health (Frumkin et al., 2008; Keim, 2008).

A critical element of climate impacts is that they will affect infrastructure investments that have long operational lives, in some cases up to 100 years or more (Hallegatte and Dumas, 2009). In low and most middle-income cities very large additional investment is needed to address deficits in infrastructure and services since without this, making the short to long-term trade-off to improve resilience is difficult (Dodman and Satterthwaite, 2009). This deficit provides an opportunity for 'climate smart' infrastructure planning that considers the combined needs of pro-poor development and climate change adaptation and mitigation. This is a more difficult task for cities such as New York with dense aging infrastructure, materials that "may not be able to withstand the projectedstrains and stresses from a changing climate" (Zimmerman and Faris, 2010).

Recent assessments have projected the rising population and asset exposure in large port cities (see 8.2.3.4; also Hanson et al.,2011; Munich Re, 2004), alongside case studies in Copenhagen (Hallegatte et al.,2011) and Mumbai (Ranger et al.,2011). By 2070, the exposed assets in cities such as Ningbo (China), Dhaka (Bangladesh) and Kolkata (India) may increase by more than 60-fold (Hanson et al., 2011).

8.2.4.1. Water Supply, Wastewater, and Sanitation

Water and sanitation systems strongly shape household well-being and health, while exerting a wider influence upon urban economic activities, energy demands and the rural-urban water balance(Gober, 2010). Climate change will impact residential water demand and supply and its management (O'Hara and Georgakakos, 2008).Among the projected impacts of climate change on water are: altered precipitation and runoff patterns in cities, sea level rise and resulting saline ingress, constraints in water availability and quality, and heightened uncertainty in the assumptions that underpin long-term planning and investment in water and waste water systems (Muller, 2007; Fane and Turner, 2010; Major et al., 2011).Local government departments and water utilities responsible for water supply and waste water management must confront these new climatic patterns and major uncertainties in availabilities and learn to respond to a dynamics and evolving sets of constraints (Milly et al.,2008).

Climate change will increase the risk and vulnerability of urban populations to groundwater and aquifer quality reduction (e.g. Praskievicz and Chang, 2009; Taylor and Stefan, 2009) and subsidence and increased salinity intrusion. High levels of groundwater extraction have led to serious problems of subsidence in cities such as Bangkok (Babel et al 2006) and Mexico City (Romero-Lankao 2010) that damages buildings and fractures pipes and can increase flood risks (see also Jha et al., 2012). This problem can be compounded in coastal cities when saline intrusion reduces ground water quality and erodes structures.

In many rapidlydeveloping cities, climate change's impacts on water supplies will interact with growing population, growing demand and economic pressures. This will potentially heighten water stress and increase negative impacts on the natural resource base with impacts on water quality and quantity. Caribbean nations are urbanising with an expanding middle class. This is sharply raising the demand for water and increasing the associated challenges of managing runoff, storm water, and solid wastes (Cashmanet al., 2010). Aggravating such water stresses, climate change could significantly reduce rainfall levels especially during the Caribbean's crucial rainy season (*ibid.*).

In Shanghai, climate change is expected to bring decreased water availability, as well as flooding, groundwater salinization and coastal subsidence. The city's population of 17 million is projected to continue expanding, often within areas that are "likely increasingly flood-prone" (de Sherbinin et al. 2007: 60). Groundwater depletion has contributed to land subsidence in these already vulnerable areas, reinforcing the water stresses and risks of erosion, but Shanghai's wealth and correspondingly greater adaptive capacity may help to manage these complex risks *(ibid.)*. In several large Andean cities, declining volumes of glacial melt water and expected further declines have been observed for several cities (Chevallier et al. 2011; Buytaert et al. 2010).

Several studies estimate how climate change will alter the relationship among water users and the implied tensions over the supply and the demand for water (Tidwell et al., 2011; Roy et al., 2012). Large-scale critical infrastructure such as sanitation systems for cities (e.g. Cape Town – Ziervogel et al., 2010) may also be affected. In small and mid-sized African cities, threats from floods on drinking water quality taken fromwells, is a growing concern (Cisse et al., 2010).

Water shortages will exacerbate existing tensions and conflicts between the various end-uses (residential, commercial, industrial, agricultural, and infrastructural) (Tidwell et al., 2011; Roy et al., 2012).Floods, droughts and heavy rainfall have also impacted agriculture and urban food sources, and climate change can exacerbate food and water scarcity in urban areas (Gasper et al., 2011). Some water systems, under some scenarios and short-term time frames, are not projected to experience negative impacts. For instance, Chicago's Metropolitan Water Reclamation District (MWRD) found that reduced precipitation due to climate change would decrease pumping and general operations costs, since sewers will contain less rainwater in drier seasons (Hayhoe et al.,2010).

Wastewater and sanitation systems will be increasingly overburdened during extreme precipitation events if attention is not paid to maintenance, the limited capacity of drainage systems in old cities, or the lack of any provision for drainage in most unplanned settlements and in many urban centres (Howard et al., 2010; Wong and Brown, 2009, Mitlin and Satterthwaite 2013). In the city of La Ceiba in Honduras, stakeholders concluded that addressing urban drainage and improved management of the Rio Cangrejal watershed were top priority for protecting the population against projected climate change impacts; the city lacks a stormwater drainage system but experiences regular flooding from heavy rainfall and storm surges (Smith et al., 2011). Flooding is often made worse by uncontrolled city development that cause natural drainage channels and flood plains to be built over and a failure to maintain drainage channels (and their blockage by solid wastes where there is no waste collection service). These problems are most evident in urban centres in low- and middle-income nations and where there are no drains or sewers that can help cope with heavy precipitation (see Douglas et al 2008) and no service to collect solid wastes (many cities in low-income nations have less than half their population with a regular solid waste collections service – see Hoornweg and Bhada-Tata 2012). Many cities in high-income nations also face challenges. An analysis of three cities in Washington State sought to assess future streamflows and the magnitudes of peak discharges, concluding that "concern over present (drainage) design standards is warranted" (Rosenberg et al., 2010: 347). Climate change was identified as one of the key drivers affecting Britain's future sewer systems (Tait et al., 2008). According to a model of urbanisation and climate change impacts in an urban catchment, the volume of sewage released to the environment by combined sewage overflow spills and flooding was projected to increase by 40% (ibid).

8.2.4.2. Energy Supply

Since energy exerts a major influence on economic development, health, and quality of life, any disruption or unreliability in power or fuel supplies due to climate change can have far-reaching consequences. Most urban businesses (from the largest to many home-based enterprises), infrastructure, services (including healthcare and emergency services) and residents rely heavily on power supplies (Findland Safety Investigations Authority, 2011; Halsnaes and Garg, 2011; Hammer et al., 2011). This is also true for water treatment and supply, rail-based public transport, road traffic management and often flood-protection measures (Jollands et al.,2007). Power interruptions in communication networks can pose problems for rescue and emergency services that rely on telecommunications for their operations (Safety Investigations Authority of Finland, 2011).

Past experiences with power outages indicate some of the knock-on effects (Chang et al., 2007). New York City's blackout of 2003 lasted 28 hours and halted electricity, mass transport, surface vehicles due to signalling outages, "and water supply for a much longer period" (Rosenzweig and Solecki, 2010). Low-income households in Chittagong utilize candles or kerosene lamps during the city's frequent power outages, which were found to disturb children's studies, increase expenses, and overheat homes (Rahman et al., 2010). A review of climate change impacts on the electricity sector (Mideksa and Kallbekken, 2010) projects reductions in the efficiency of cooling for thermal power, changes in hydropower and wind power potential, and changing demand for heating or cooling in the US and Europe.

Less is known regarding the demand side energy impacts of climate change outside high-income nations. In most urban centres in low-income and some middle-income nations, a significant proportion of the population does not have access to electricity, and energy use in low-income households is still dominated by charcoal, firewood, or biomass based fuels (Satterthwaite and Sverdlik, 2012). Most of these nations are also expected to experience large increases in mean temperatures or rising frequency of heat-waves due to climate change (IPCC 4AR).

Climate change will alter the patterns of urban energy consumption, particularly with respect to electricity demand and/or energy needed for cooling or heating (for a review see Mideksa and Kallbekken, 2010). In settings with extensive air conditioning use, climate change will bring increases in air conditioning demand and in turn heightened electricity demand (Radhi,2009; see also Hayhoe et al.,2010 for a discussion of this in relation to Chicago). In temperate and more northern regions, winter temperature increases will bring decreases in energy demand for heating (Mideksa and Kallbekken, 2010). In most cases within individual cities, potential increases in

summertime electricity demand from climate change will exceed reductions in winter energy demand reductions (Hammer et al., 2011).

Many cities' economies will be impacted if climate change induces water scarcity and variability that interrupt hydropower supplies. If climate changereduces Brazil's hydroelectric generation, this will have negative impacts on the economies of the many urban centres supplied in Brazil as well as across national to neighboring counties(Lucena et al., 2009; Lucena 2010; Schaeffer et al., 2009). Cities in sub-Saharan Africa often rely on hydropower for their electricity, and failures in hydropower supplies "can lead to a more general 'urban failure' " (Muller, 2007). Discussing supply side concerns, Laube et al. (2006) identify water shortages in Ghana following low precipitation periods and competition with hydropower between energy and water provision including to downstream urban centres as a possible impact. Declining water levels in the Hoover Dam have raised the possibility that Los Angeles will lose "a major power source as hydroelectric turbines shut down," and that Las Vegas will experience a severe decline in drinking water availability (Gober, 2010).

Summer heat waves are associated with spikes in demand with extensive use of air conditioning,resulting in brownouts or blackouts (Mideksa and Kallbekken, 2010; Mirasgedis et al., 2007).Cities in the temperate regions of Australia are already experiencing regular blackouts on hot summer days, largely due to increased residential air-conditioner use (Maller and Strengers, 2011). Research in Boston (Kirshen et al., 2008) suggested that rising energy demands in Boston's hotter summers have a "disproportional impact on (the) elderly and poor,increased energy expenditures; loss of productivity and quality of life" (*ibid:*241). Any increase in the frequency or intensity of storms may disrupt electricity distribution systems because of the collapse of power lines and other infrastructure (see for instance Rosenzweig et al., 2011a; 2011b; 2011c; see also Chapter 10).

8.2.4.3. Transportation and Telecommunications

Climate change related extreme events will affect transportation and telecommunication infrastructure including a variety of capital stock in urban areas such as bridges, roads, railways, pipelines, and port facilities, data sensors, and wire and wireless networks (Major et al., 2011; Jacob et al., 2011; Hallegatte et al., 2011; Koetse and Rietveld, 2009). Assessing possible disruptions of transport networks within cities and urban systems is critical. Loss of telecommunication access during extreme weather events can inhibit disaster response and recovery efforts because of its critical role in providing logistical support for such activity (Jacob et al., 2011).

The literature on transport and climate change focuses more on mitigation, with limited attention within the urban literature to adaptation (Hunt and Watkiss, 2011). Existing studies on climate change impacts are often limited to the short term demand side, particularly in passenger transport (Koetse and Rietveld, 2009). However climate change creates several challenges for transport systems. The daily functioning of most transport systems is already sensitive to weather fluctuations including extreme precipitation, temperature, winds, visibility, and for coastal cities, rising sea levels with the associated risks of flooding and damages (Mehrotra et al., 2011b; Love et al., 2010). Transport is thus highly vulnerable to climate variability and change, and the economic importance of transport systems has increased with the rise of just-in-time delivery methods, heightening the risk of losses due to extreme weather (Gasper et al., 2010). In addition to adapting road transport, it will be necessary to ensure bridges, railway cuttings, and other hard infrastructure are resilient to climate change over their service lifespan (Jaroszweski et al., 2010). For railways, few studies have examined the effects of climate change but weatherrelated rail system failures may be caused by high temperatures, icing, and storms (Koetse and Rietveld, 2009; see also Dobney et al 2010 for future heat related delays in UK railways). Very few studies have examined the vulnerability of air and seaborne transport and infrastructure. The impacts of climate change could translate into a greater number and longevity of weather-related delays with extreme weather possibly occurring more frequently and more severely. This would bring further disruptions for aviation (Eurocontrol, 2008) and maritime transport (Becker et al., 2012).

Most cities in low and middle-income nations are still developing their transport systems (Dimitriou and Gakenheimer, 2011), especially in their largerand more rapidly growing cities.For example, Asian cities and the transportation networks located within and around them are often at risk from extreme weather events (Regmi and Hanaoka, 2011). India's transportation and telecommunications networks are still being built, and adaptation as well

as mitigation measures "will need to be integrated within the design of these systems" (Revi, 2009: 329) to maximise co-benefits and synergies and minimise trade-offs (Biesbroek et al., 2009; Hamin and Gurran, 2008).

Loss of sea ice can benefit some cities as it increases opportunities for developing road networks or ports, although it may be costly to adapt the road, air and water transport networks in addition to the known environmental risks associated with such redevelopment (Larsen et al., 2008). For industries and communities in Northern Canada, reduced freshwater-ice levels creates economic benefits such as longer shipping seasons (Prowse et al.,2009). Lost sea ice could also promote new seaports in marine environments, but inland towns require sizable investments in land-based roads to replace winter ice roads that formerly utilised small lakes and stream networks (ibid.). Thawing of permafrost can result in instability and major damage to roads, infrastructure, and buildings in and around northern cities and towns (ibid.).

The direct impacts of extreme weather on transportare often more easily assessed than the indirect impacts or possible knock-on effects between systems. Studies have often examined the direct impacts of flooding upon transport infrastructure, but the indirect costs of delays, detours, and trip cancellation "may also be substantial" (Koetse and Rietveld, 2009). During Mumbai's 2005 floods, there were serious direct impacts in terms of injuries, deaths and property damage but also serious indirect impacts as most city services were shut down for 5 days without contact via rail, road or air (Revi, 2005). Transport and other urban infrastructure networks are often interdependent and located in close physical proximity to one another (Kirshen et al., 2008). Yet only a few assessments have jointly considered the impacts upon transport and other associated sectors (Hayhoe et al.,2010 for Chicago, Kirshen et al.,2008 for Boston).Implementing adaptation strategies in the transport sector requires "coordination at national, regional, and local levels", since climate change impacts are widespread and extend across scales (Regmi and Hanaoka, 2011).

Transportation systems are critical for effective disasters response – for example, where there is an urgent need for evacuating populations prior to an approaching storm or where disaster response requires an urgent need to ensure provision for food, water and emergency services to affected populations.

8.2.4.4. Built Environment, and Recreation and Heritage Sites

Good quality housing should provide its occupants with a comfortable, healthy and secure living environment and protect them from injuries, losses and damage (Haines et al. 2013). For many low-income households, home-based enterprises are also important components of livelihoods. As such, housing has a key role in protecting urban populations and their assets – and has particular importance for protecting vulnerable groups including infants and young children (Bartlett 2008), older residents or those with disabilities or chronic health conditions. This also means protection against displacement since low-income urban dwellers are particularly at risk from disruptions to household income.

Urban housing is "often the major part of the infrastructure affected (by disasters)..." (Jacobs and Williams, 2011:176). Extreme events like cyclones and floods inflict a heavy toll on housing, particularly those structures built with informal building materials and built outside of safety standards (United Nations, 2011). Dhaka's 1998 floods damaged 30% of the city's units and of these, 32% were permanent/semi-permanent homes belonging to wealthier households, but 36% were lower-quality owned by the lower-middle classes and 32% by the poorest (Alam and Rabbani, 2007). Adelekan (2012) shows how a relatively modest increase in wind speeds during storms caused widespread damage and high costs of rebuilding or repairs in central Ibadan. In addition, increased climate variability, warmer temperatures, precipitation shifts, and increased humidity will accelerate the deterioration and weathering of many stone and metal structures in cities (Stewart et al., 2011; Bonazza et al., 2009; Smith et al., 2008; Thornbush and Viles, 2007; Grossi et al., 2007).

Recreational sites such as parks and playgrounds will also be affected. In New York City, recreational sites are defined as critical infrastructure and often located in low elevation areas subject to storm surge flooding (Rosenzweig and Solecki, 2010). Although climate change may have significant impacts on traditional tourist destinations, little research has examined the effects upon urban tourism in particular (Gasper et al., 2011).

The increased risks that climate change is bringing to the built environment (Wilby, 2007;Spennemann and Look, 1998) also means risks to the built heritage. This has led to the Venice Declaration on Building Resilience at the Local Level Towards Protected Cultural Heritage and Climate Change Adaptation Strategies which brings together UNESCO, UN-HABITAT, EC and individual city mayors. One example of this is Saint-Louis in Senegal, a coastal city that is also on the mouth of the Senegal river that has frequent floods and large areas at risk from river and coastal flooding. It is a World Heritage Site and there are initiatives to reduce flooding risks and to relocate families from locations most at risk but the local authority has very limited investment capacity (Diagne 2007, Silver et al., 2013).

8.2.4.5. Green Infrastructure and Ecosystem-based Adaptation

A wide variety of ecosystem services and green infrastructure will be impacted by climate change. Climate change will alter ecosystem functions such as temperature and precipitation regimes, evaporation, humidity, soil moisture levels, vegetation growth rates (and allergen levels), water tables and aquifer levels, and air quality. These can influence the effectiveness of pervious surfaces used in storm water management, green/white/blue roofs, coastal marshes utilized for flood protection, food and urban agriculture and overall biomass production. Mombasa will experience more variable rainfall as a result of climate change, making initiating and expanding green infrastructure more difficult (Kithiia and Lyth, 2011). Trees in British cities will be increasingly prone to heat stress and to attacks by pests, including non-native pathogens and pests that could survive for the first time under warmer or wetter conditions (Tubby and Webber, 2010). Urban coastal wetlands will be inundated with sea level rise. In New York City, remnant coastal wetlands will be lost to sea-level rise because the wetlands will not be able to migrate inland due to bulk heading and intensive coastal development (Rosenzweig et al., 2012).

8.2.4.6. Health and Social Services

The effects of climate change will also be evident across several urban social and public services such as health and social care provision, education, police and emergency services including firefighting and ambulances (see Health, Chapter 11 in this volume for more discussion). Many low and middle-income cities lack adequate social and public service provision (Bartlett, 2008; Satterthwaite et al,2007) while higher-income cities are only beginning to consider climate change in their health or disaster management plans (Brody et al.,2010).Although there are few studies on adapting education, police, or other key services, a growing public health literature has discussed multi-sectoral adaptation strategies (Huang et al., 2011). Cities' existing public health measures provide a foundation for adapting to climate change, such as heat warning systems or disease surveillance (Bedsworth, 2009; McMichael et al., 2008). Negative climate impacts on some of the most vulnerable in society– the very young and children (Sheffield and Landrigan, 2011; Watt and Chamberlain, 2011; Ebi and Paulson, 2010) the elderly (Oven, 2012; White-Newsome et al., 2011) and the severely disadvantaged (Kenny et al., 2010; Ramin and Svoboda, 2009) have been highlighted (see Chapter 11)

8.2.5. Urban Transition to Resilience and Sustainability

The question of how to promote increased resilience and enhanced sustainability in urban areas (as illustrated in Table 8-2) has become a central research topic and policy consideration. What information is needed and what steps should be taken to promote this type of transition are central to this discussion. It is well recognized that climate change risks affect this process byheightening uncertainties and altering longstanding patterns of environmental risks in cities, many of which continue to face other significant stressors such as rapid population growth, increased pollution, resource demands, and concentrated poverty (Mehrotra et al., 2011a; Wilbanks and Kates, 2010). This section discusses how climate change increasingly affects municipal decision-making frames and alters local conceptions of cities as vehicles for economic growth, for political change, for meeting livelihoods and basic needs as well as larger-scale goals of resilience and sustainability.

8.2.5.1. Uncertainty and Surprise

Climate change will contribute to more uncertain and dynamic urban conditions, making past environmental responses and baselines less valuable for predicting cities' future environments (Solecki et al., 2010). It has been suggested that "the complexities and uncertainties associated with climate change pose by far the greatest challenges that planners have ever been asked to handle" (Susskind, 2010:219). Municipal and higher-level adaptation plans will need to take into account uncertainty about future climates and extremes. These will need to consider direct and indirect economic costs, including the trade-off of inaction and locking into ill-adapted infrastructure versus investment in adaptation when climate change is less than anticipated (Hallegatte et al., 2007). Several U.S. studies have considered the cost on inaction for specific states (Wilbanks et al., 2012, Niemi et al., 2009a, 2009b, 2009c, Repetto 2011a, 2011b, 2012a, 2012b, 2012c, 2012d, Backus et al., 2012). An obvious transitional management issue is related to the many urban wastes´ repositoriesaround current city boundaries.

Several decision-making settings in urban areas are influenced by shifts in the likelihood of extreme weather events and the need to respond to climate-related surprises. Water resource managers (Fane and Turner, 2010; Dessai and Hulme, 2007), insurance companies (Crichton, 2007; Botzen et al., 2010), public health, disaster, and emergency responders (Keim, 2008; Huang et al.,2011; Hess et al.,2009) will need to grapple with heightened climate-related uncertainties and the demands of climate proofing. Infrastructure planners need to adopt various strategies to incorporate uncertainty, such as selecting no-regret strategies, favoring reversible and flexible options, buying 'safety margins' in new investments, promoting soft adaptation strategies, and/or reducing decision time horizons (Hallegatte and Dumas, 2009). Other strategies include scenario planning, sensitivity analyses, and examining risk tolerances. New challenges also will arise. For example, the need to expand the agriculture frontier, for increasing food production, will bring agricultural activities closer to the urban boundaries. This means that the fumigation effects will add a new health hazard to urban inhabitants as well as adversely affect water supply.

8.2.5.2. Extreme Event Probability

Shifts in extreme weather and climate event probability have affected how cities are understood by stakeholders and decision-makers - cities are seen as potentially more prone to experience environmental hazards and disasters. It is important to assess how these changes are integrated back into local decision-making. In New York City, the prospect of increased climate variability has spurred an integration of climate resiliency efforts into extreme event planning and actions including increased storm water management during intense precipitation events to forestall or prevent inland and street-level flooding (Rosenzweig and Solecki, 2010). ConverselyJakarta has several early-warning disaster systems in place but no adaptation plans have been developed; Jakarta's Spatial Plan does not incorporate climate change and the local government's focus is on disaster management rather than preparing for climate change (Firmana et al., 2011).

Urban decision-makers have widely divergent motivations and strategies for incorporating extreme events into local adaptation plans. Cities have implemented adaptation measures in response to "specific local or regional natural disasters, which may or may not be climate-related", such as enhancing preparedness measures in the Greater Mumbai Disaster Management Plan after the City's 2005 floods (Revi, 2006; Bulkeley 2010,). Findings in the UK (Tompkins et al.,2010) and other European cities (Carter, 2011) suggest that the primary motives for adaptation measures are rarely climate-related; policymakers instead prioritise biodiversity conservation, energy reduction, or responding to current climate extremes. However, some authors argue that adaptation strategies can be more meaningfully implemented when coupled and integrated within other agendas, such as improving health or enhancing urban competitiveness (Nath and Behera, 2011; Carter, 2011). Further research is needed to evaluate the merits of stand-alone adaptation plans, as opposed to approaches that seek to mainstream climate change into urban planning (Romero-Lankao and Dodman, 2011).

8.2.5.3. Transitions

In recent years, different models of urban environmental transition (e.g. shifts from a sanitary city to sustainable city presented by McGranahan 2007) have been introduced to illustrate how the connections between health hazards and environmental impacts as cities and neighbourhoods develop. This includes the use of global and local sinks for wastes that are outside their boundaries (ibid, Wilson, 2012). Within these models, key variables have been identified that make cities vulnerable to climate change (e.g. extensive infrastructure networks, high density population in exposed or other sensitive sites). Established sustainability approaches e.g. compact cities, eco-regions, polycentric new-town planning systems, urban agriculture, development as a strategy for moderating urbanization (Williams et al., 2012) are among the most common transition strategies. These strategies often are associated with high, often limiting, redevelopment costs.

Climate change has encouraged stakeholders and decision-makers to re-evaluate the environment of their cities as dynamic and connected to several transition contexts, especially with respect to movement toward low-carbon economies (Buckeley et al., 2010; Mdluli and Vogel, 2010). Other transition contexts are associated with an understanding of the urban systems and functions that are increasingly under stress so that past approaches are no longer adequate (Pelling and Dill, 2010).

Transitions in the contextof climate change emerge in two situations. The first is a systems-level perspective where urban systems could reach a tipping point in which a failure or collapse could occur. The second is a broader scale societal transition to enhanced resilience and adaptive capacity (and attention to mitigation) in the face of accelerated climate change (Solecki and Murphy, 2013; Ernstson et al., 2010; Mdluli and Vogel, 2010; Tompkins et al., 2010; Gusdorf et al., 2008; Pelling, 2011a). The latter can often occur without resulting in a broader scale transition (Pelling and Navarrete, 2011) with incremental changes also potentially precipitating regime level shifts. Although such shifts can also happen as a result of discrete regime failure (Pelling, 2011a) this is less common. Such transformational changes have been observed in a variety of urban disaster contexts. Most often they follow urban earthquake events (e.g. in Nicaragua, Guatemala, Turkey) but are also associated with flooding in Bangladesh (Pelling, 2011a). Disasters can enable regime level change at moments in history where competing approaches to development have political voice, an organizational base that articulates competing analysis of the causes of the disaster and weak systemic counter response.

8.2.5.4. Social Dynamics, Economic Tensions, and Multiple Stressors

Climate change may exacerbate existing social and economic stressors in cities with the potential to affect urban livelihoods, engender political or social upheaval, or generate other negative impacts upon humansecurity(Siddiqi, 2011; Simon and Leck, 2010; Bunce et al., 2010 – see regional chapters for this report for more details). Climate change could potentially contribute to violent conflicts and spur migration (de Sherbinin et al, 2011;Adamo, 2010; Reuveny, 2007), yet there is considerable uncertainty regarding projections. Migration may represent an important household strategy to adapt by diversifying income-sources and livelihoods (Tacoli, 2009). Although climate change could significantly disrupt livelihoods, outcomes will depend upon particular social structures, state institutions, and other broader determinants of human security (Barnett and Adger, 2007). In sum, “dwindling resources in an uncertain political, economic and social context are capable of generating conflict and instability, and the causal mechanisms are often indirect” between climate and conflict (Beniston, 2010:567).

Specific tensions emerging from climate change impacts have been derived from studies connecting climate impacts with disaster recovery (Solecki et al., 2011). These tensions include temporary or permanent poverty; food insecurity; lack of access to freshwater; and shifts in the informal economy. Shifts in social dynamics include the possibility and aspiration that reconstruction and recovery can improve people’s livelihoods, changing the structure of the urban economy through the disaster cycle; changes in city administration; private and public property ownership; lifestyle (Coombes and Jones, 2010) and in more dramatic cases change in the urban centre’s economic base. To help understand climate-related tensions in cities, a stronger research focus upon cities, human security, and climate change has been advocated (Simon and Leck, 2010). The links between humanitarian work and climate change are increasingly recognized, but further collaborations between climate scientists, researchers, aid workers,

and international funding agencies is needed (Braman et al., 2010). Holistic strategies help to link development goals with adaptation, so that "multi-dimensional and multi-scale approaches (can) better guide the construction of adaptation responses to climate change and integrate them to development strategies" (Sánchez-Rodriguez, 2009).

Climate change also creates implications for equity from different management solutions (Pelling et al, 2012). For example, the privatization of urban water supply and sanitation systems advantages specific groups over others. Conversely, community-based solutions that also build social capital can be a component in generating generic urban resilience. However, these may exacerbate inequality at the city level with those local areas with strong levels of social capital being able to benefit most from local community led action or support for local initiatives from international and national partners (UN Habitat 2007; Pelling et al, 2012).

8.2.5.5. Historical Analogues

The experience of cities in coping with environmental/resource crises in the past provides a useful analog to understand climate change impacts and shifts in urbanization process (Solecki, 2012; Ranger et al., 2011; Ford et al., 2010; McLeman and Hunter, 2010; Hallegate et al., 2007; Gibbons et al., 2006). Cities often have been able to respond to localized risks and vulnerabilities such as resource shortages and environmental quality issues by externalizing the problems either through expansion of the resource catchment or by externalising the environmental quality threats (e.g. sewerage, rubbish) to more remote and distant locations (McGranahan, 2007; Tarr, 1997). This is more complex in the case of climate change in that the source of the risk and vulnerability is external to individual cities and outside their span of control. City governments have dealt with many environmental health problems by reducing or removing the hazard, but this is beyond their capacities to accomplish with respect to climate change.

Urban development and urbanization has been dramatically impacted by past changes associated with large scale exogenous factors which have either been pervasive (e.g. globalization) and/or profound e.g. wartime devastation, civil war and natural hazards such as earthquakes, cyclones, as well as the application of new technologies (e.g., automobiles, electricity, the internet). Identity is particularly important in this context because the physical fabric can be rebuilt, but in so-doing the identity of a city may be changed. In these situations,, it is evident that well-governed cities demonstrate a capacity to adapt and to learn from crises (Solecki, 2012). As described in 8.3, there is increasing evidence of policy, practice and scientific interest in urban adaptation as a core strategy to address climate change risks.

8.3. Adapting Urban Areas

8.3.1. Introduction

The literature on urban climate change adaptation has increased very significantly since the Fourth Assessment (AR 4). The growing interest in urban adaptation is mainly evident in three aspects. The first is a literature examining risks and vulnerabilities for particular cities. The second, overlapping with this, are papers discussing what might constitute resilience. The third is documentation produced by or for particular city governments on adaptation. There is less documentation of local government decisions to include climate change adaptation in plans and investment programmes, although some city governments report on this (see Solecki 2012, Roberts 2008a and 2010).

Planning urban climate change adaptation faces uncertainties about the magnitude and location of present and future hazard risk and vulnerability at the urban scale as most climate models function at a lower resolution than most cities. The availability of relevant risk data continues to be challenging as it is often not collected. Or if it is, it is rarely quantitative or at the appropriate scale and often fragmented across city departments (Hardoy and Pandiella 2009). Many suggested adaptation measures are in response to specific local or regional hazard risks, which may not be directly climate-related (Bulkeley 2010). Climate data needs to be integrated geographically, across time-scales, and consider the range of regional benefits and costs of climate policy if it is to be useful to and spark local dialogue in adaptation (Ruth 2010).

There is a growing body of literature on opportunities to strengthen urban climate resilience in household, community and city development plans, infrastructure development investment and the management of ecosystems and of cities' physical expansion. City governments that have developed adaptation policies recognize that their strategies, investments and actions plans have to be part of an iterative process that can change with the availability of new information, analyses or frameworks - as presented in the "Iterative Risk Management Approach to Climate Change" (National Research Council 2011). What is important is the recognition by local governments of the need for a unit that has responsibilities for this – drawing together relevant data, often drawn from different departments, keeping key politicians and civil servants informed, encouraging engagement in this by different sectors and departments and consulting with key stakeholders (Roberts 2010, Brown et al. 2012).

8.3.2. Development Plans and Pathways

As AR4 emphasized, many of the forces shaping greenhouse gas emissions are those underlying development pathways – including the scale, nature and location of private and public investment in infrastructure (Wilbanks, Romero Lankao et al. 2007). These also influence the form and geography of urban development and the scale and location of climate-related risks to urban buildings, enterprises and populations. Responsibility for encouraging new investments and migration flows away from high risk sites is often shared between local, provincial and national government through a combination of climate sensitive disaster risk management and urban planning and zoning. But the priority given by national and urban governments to economic growth usually means that this is rarely implemented with vigour (Douglass 2002, Reid et al, 2013).

8.3.2.1. Adaptation and Development Planning

Urban adaptation is becoming important for some national, regional and city governments although the first steps may have come from stakeholders outside the state sector. In high-income countries, interactions between national climate policies and local level and the division of responsibilities have been examined (see, for instance, Massetti et al 2007 for Italy). There is also attention to local adaptationimplementation through subsidies and flexible schemes in different city contexts and the transfer of authority and resources to city level (for the Netherlands see Gupta et al. 2007). The design of new decision making strategies for local governments considers the complexity and dynamics of evolving social-ecological systems (Kennedy et al. 2010). Examples include adaptation plans and local responses in Sydney to cope with sea level rise and storms (Hebert and Taplin 2006) and adaptation planning in California (Bedsworth and Hanak 2010). In China, adaptation programmes are being developed and implemented at national and local level. The debate emphasizes the policy space and the division of responsibility between national and local levels (Teng and Gu. 2007).

Since AR4, there has been a growing literature on urban adaptation in low and middle-income nations. A review of the literature on climate change impacts and adaptation in cities (Hunt and Watkiss 2011) could draw on eight case studies in Asia, five in Africa and four in South America – as well as from case studies from Europe, Northern America and Australasia. Among the papers and books considering climate change adaptation in urban areas since 2007 are those on Cape Town (Mukheibir and Ziervogel 2007, Ziervogel et al 2010 and Cartwright et al 2012), Durban (Roberts 2008a, 2010, Roberts et al 2012, Cartwright et al 2013 and Roberts and O'Donoghue 2013) and other urban centres in Africa (Douglas et al., 2008, Wanget al 2009, Lwasa 2010,World Bank 2011, Kithiia and Lyth 2011, Adelekan 2012, Kiunsi 2013, Castán Broto et al 2013, Silver et al 2013), urban centres in Bangladesh (Alam and Rabbani 2007, Jabeen et al 2010, Banks et al 2011, Haque et al 2012, Roy et al 2013), India (Revi 2008,Sharma and Tomar 2010, Saroch et al 2011), Latin America (Hardoy and Pandiella 2007, Romero Lankao 2007, 2010, Hardoy and Romero Lankao 2011, Luque et al 2012, Hardoy 2013, Hardoy and Ruete 2013). Other papers or books with discussions of urban adaptation in low- and middle nations include Blanco 2007, Carolini 2007, Martine et al. 2007, McGranahan et al. 2007, de Sherbinin et al. 2007, UN-Habitat 2007, United Nations Population Fund 2007, Agrawala and van Aalst 2008, Bartlett 2008, Ayers 2009, Bicknell et al. 2009, Kovats and Akhtar 2008, Tanner et al., 2009, Hardoy and Pandiella 2009,Wong 2009, World Bank 2010b, 2010c, 2011, Manuel-Navarrete et al. 2011, UN-Habitat 2011a, Rosenzweig et al 2011a, Moench et al 2011and Bulkeley and Tuts 2013. Four relevant issues can be highlighted: the fact that these nations have most of the world's current and future

urban population; the need to consider key development issues of poverty and social inequality as multidimensional problems that may be aggravated by climate change; the need to consider human agency among low-income inhabitants and their organizations as an important resource in building local responses to climate change; and the relevance of well-funtioning multilevel governance in developing adaptation strategies (Sánchez-Rodríguez 2009).

Although few publications suggest specific operational strategies, they stress the importance of the linkage between climate adaptation and development. We noted already how development deficits in urban areas can contribute to adaptation deficits. Manuel-Navarrete et al. (2011) explores the interplay between visions of development, governance structures and strategies to cope with hurricanes in the Mexican Caribbean where exposure and vulnerability are influenced by political decisions and contingent development paths. Similarly there are few reports on multidimensional approaches to guide operational adapation. There is growing attention to integrating adaptation with development interventions and addressing structural drivers of social and urban vulnerability – see for instance Climate Action Plans of Mexico City, Cartagena and San Andrés de Tumaco (Sánchez-Rodríguez 2009).

Two factors help explain the lack of detailed attention to urban climate change adaptation in low- and middle-income nations. The first is the lack of attention to urban adaptation within national policies on climate change in comparison with sectors like agriculture. Responsibility for climate change policies is often with ministries or agencies that have little in their work that is urban and little influence on others whose cooperation is essential e.g. for social policies, public works and local government (Ojima 2009, Roberts 2010, Hardoy and Pandiella 2007). Governments' social policies and priorities influence the social and spatial distribution of climate related risk and vulnerability – for instance provisions for health care, emergency services and safety nets - yet few agencies recognize their potential role in reducing risk and vulnerability. Adaptation in informal settlements and the incorporation of individual and group agency in bottom-up adaptation strategies is of particular relevance in low-income and most middle-income nations (Sánchez-Rodríguez 2009, Bicknell et al 2009). Recent experiences of Central American cities like Tegucigalpa and in some cities in the Philippines show that the involvement of low-income communities in risk reduction may be the first steps towards climate change adaptation (Aragón-Durand 2011, Carcellar et al. 2011).

The second factor explaining the lack of attention to urban adaptation is that the initial focus for many cities was on mitigation, in part because international support was available for this (although this is changing). Local decision-makers frequently view climate change as a marginal issue, with adaptation usually ranked lower than mitigation on the urban policy agenda (Bulkeley 2010, Simon 2010). For instance, Mexico City's climate change agenda focuses on mitigation with adaptation still a vague concept that is not incorporated into concrete actions and decisions (GDF 2006, 2008). Adaptation is seen as a capacity to withstand weather-related impacts such as floods through early warning systems rather than comprehensive, long-term measures such as watershed management to reduce the speed and volume of flood waters. There is little academic and policy literature on climate change adaptation for Brazilian cities (Ojima 2009, Soares Moura da Costa 2009). In Sao Paulo, more attention has been given to mitigation with adaptation action limited to broad declarations about needed actions in different sectors even as the city often gets impacted by floods, landslides and water scarcity (Puppin de Oliveira 2009, Nobre et al 2010, Martins and Ferreira 2011). The pressure on national and local governments to act is lessened by the absence of public awareness of the importance of addressing climate change adaptation (see Nagy et al. 2007). There is also a "knowledge gap" between policymakers and scientists regarding knowledge needed to enhance adaptation as in the case of Tijuana (see Sanchez-Rodríguez, 2011).

8.3.2.2. Disaster Risk Reduction and its Contribution to Climate Change Adapation

The growing concentration of people and economic activities in urban centres and the increasing number and scale of cities can generate new patterns of disaster hazard, exposure and vulnerability. This trend is visible in the large and rising number of localized disasters in urban areas in many low- and middle-income nations, mainly associated with extreme weather (storms, flooding, fires and landslides) (United Nations 2009, 2011). This has particular relevance for climate change adaptation, given the increase in the frequency and intensity of potentially hazardous weather events that climate change is bringing or may bring. Extreme weather events have also helped raise the awareness of citizens and local governments of local risks and vulnerabilities.

Exposure to disaster risk from weather events in expanding urban areas increases when local governments fail to implement their responsibilities, including needed expansion or upgrade in infrastructure and services and risk reduction through implementing building standards and appropriate land-use management (ibid). This is typically in countries with low per capita GDPs and weak local governance (i.e., in the first two categories of Table 8-2). It may be exacerbated by rapid urban population growth.

The most urbanized nations generally have the lowest mortality to extreme weather events (United Nations 2009). Urbanization accompanied by more capable and accountable local governments can reduce disaster risk as is evident in the declines in mortality from extreme weather (and other) disasters in many middle and all high-income nations (United Nations 2011).

While local government investment usually represents a small proportion of total investment in and around an urban centre, it has particular importance in risk reduction through investments in risk-reducing infrastructure and public services that need to be combined with planning and regulation that ensures buildings and infrastructure meet needed standards and guide development away from high-risk areas. Urban governments have explicit responsibilities for many assets, some of which may be risk prone. The exact list differs between countries because of different allocations of responsibilities between government levels but it often includes schools, hospitals, clinics, water supplies, sanitation and drainage, communications and local roads and bridges. Where private provision for infrastructure and services is significant, it usually falls to local government to coordinate such provision and hence, enhance its role and responsibility for urban adaptation.

From the late 1980s, a new approach to reducing disaster risk in urban areas was developed in some Latin American nations that is relevant to climate adaptation. It involved three processes: detailed analyses of local records of disasters that include smaller disaster events than those reported in international databases; recognition that most disasters were the result of local failures to assess and act on risk; and the recognition of the central roles of local governments in disaster risk reduction but with support from national and local civil defence organizations working with civil society and community organizations within the settlements most at risk (United Nations 2009, IFRC 2010). These led to institutional and legislative changes at national or regional level to support disaster risk reduction (Gavidia 2006, IFRC 2010). In Colombia, a national law supports disaster risk reduction and a National System for Prevention and Response to Disasters with a shift in the main responsibility for action to municipal administrations. In Nicaragua, the National System for Disaster Prevention, Mitigation and Response (SINAPRED) was set up in 2000 to work with local governments to strengthen disaster preparedness and management by integrating disaster mitigation and risk reduction into local development processes (Von Hesse, et al., 2008). There are other initiatives and action programmes in Central and South America on urban risk management and disaster preparedness, including the influence of La Red (IFRC 2010), the DIPECHO project, “Developing Resilient Cities” and UNDP and GOAL in Central America.

In growing numbers of cities in Asia (Shaw and Sharma, 2011) and Africa (Pelling and Wisner 2009), experiences with community-driven ‘slum’ or informal settlement upgrading has led to a recognition of the potential of these to reduce risk and deep rooted vulnerability to extreme weather events. This is most effective when supported by local government and civil defence/emergency response agencies (see Boonyabancha 2005 for urban centres in Thailand; also Archer and Boonyabancha 2011, Carcellar et al. 2011).

The Homeless People’s Federation of the Philippines developed a series of effective responses following major disasters, which included: community-rooted data gathering (assessing the severity and scope of destruction and victims’ immediate needs); trust and contact building; support for savings; the registering of community organizations; and identifying needed interventions, including building materials loans for house repairs. The effectiveness of risk reduction is also much enhanced where local governments work to support these (Carcellar et al. 2011) and experiences such as these have helped inform community-based adaptation (see 8.4).

There are also international networks supporting innovation in disaster risk reduction and/or climate change adaptation and inter-city learning. These include la Red in Latin America that has been operating for 3 decades (IFRC 2010), the Earthquakes and Megacities project which includes multi-hazard risk assessment and the cities

programme of the Asian Disaster Preparedness Centre. As donor interest has grown in supporting disaster risk management as a vehicle for climate change adaptation, a number of resilience oriented urban programmes have developed including the Asian Cities Climate Change Resilience Network (Brown et al. 2012), the UN ISDR Resilient City network (Johnson and Blackburn,2013) ICLEI's city adaptation network and UN-Habitat's Cities and Climate Change Initiative.

Despite growing international support for urban disaster risk management, it can be difficult for local governments to access the human and financial resources needed to make real change on the ground (Von Hesse et al. 2008). Local governments do not get recognition for the disasters their programmes prevented – so risk reduction investments are not seen as priorities and have to compete for scarce resources with what are judged to be more pressing needs. Effective policies are often tied to the terms in office of particular mayors or political parties (Mansilla et al. 2008, Hardoy et al. 2011). In most cases, disaster risk reduction is still not integrated into development plans and not drawing in all relevant departments and divisions of local government. Manizales in Colombia is an exception as disaster risk reduction has long been seen as part of local development and where collective interests overcome individual and party political interests (Hardoy and Velásquez Barreto 2014)

As detailed in IPCC SREX (2012), disaster risk management is increasingly positioned as a frontline sector for the integration of climate change adaptation into everyday decision-making and practices. This can be seen in the plans of municipalities such as Tegucigalpaand Montevideo (Aragón-Durand 2011). Where disaster risk management is taken seriously by government or civil society this offers real opportunities for synergy as the long-range nature of climate change concerns and its policy visibility can enhance local support for disaster risk management. The still common disjuncture in international frameworks and national responsibilities mean there is much scope for better coordinated efforts to make urban disaster risk management climate smart (SREX 2012, Aragón-Durand 2008).

8.3.3. Adapting Key Sectors

8.3.3.1. Adapting the Economic Base of Urban Centres

8.2 described how climate change will bring changes to the comparative advantages of cities and regions – for instance through influencing climate sensitive resources and changes in locations of extreme weather, water availability and flooding risks. Many case studies show how extreme weather and storm surges can impede economic activities such as damaging industrial infrastructure and disrupting coastal ports and supply chains (see 8.2.3.4).Vugrin and Turnquist (2012) discuss how to design for resilience in infrastructure distribution networks such as electric power, gas, water, food production and manufacturing supply chains. Increasing the resilience of networks (and settlements) needs absorptive capacity (for instance to withstand extreme weather), adaptive capacity (for instance service provision through alternative paths) and restorative capacity (quick and cheap recovery).

The importance of effective climate adaptation is that it can help reduce risks from such changes, deepen resilience and limit disadvantages. For urban centres facing climate-related risks, a failure to adapt may discourage new investments. Over the long term this could lead enterprises moving or expanding to other safer, better adapted locations. Multinational corporations and many national businesses have long been adept at changing the location of their production (and regional headquarters) in response to changing opportunities and risks so they can choose to avoid urban centres facing high risks linked both to climate change and a failure to adapt. Investments in urban centres with higher risks may also be discouraged by high insurance costs,

Disasters can change perceptions of risk and discourage new investments. For instance, businesses may avoid disaster impacts in their own facilities but find that the disaster has impacted other businesses and services that they use (including utilities) or impacted their workforce and the services they use (including schools, and hospitals) (Hallegatte et al, 2011). A lack of capacity within an urban centre to reconstruct means increased vulnerability to succeeding extreme weather events and less new investment that in turn weakens the urban economic base (Benson and Clay 2004, Hallegatte et al. 2007, Hallegatte et al. 2011).

Past experience of de-industrialization in cities in the U.S. and Europe show the difficulties facing city governments in attracting new investment. When the main activity of a city or region weakens, incomes, employment and local authority revenues decrease, making it more difficult to re-invest in new business and reducing attractiveness for new investments. If climate change forces many regions to change their economic structure and business models, transitions may prove difficult to manage (Berger 2003). Specific adaptation policies may be useful to help make the transition more rapid and less painful.

Climate change adaptation is generally cheaper and easier to implement in greenfield sites – for instance as low-risk sites are chosen, trunk infrastructure to appropriate standards installed and building and land-use regulations enforced. Retrofitting existing infrastructure and industries is generally more expensive (McGranahan et al.,2007).

Within and around urban centres, local governments may need to utilise several strategies to strengthen urban centres' resilience including selective relocation, land use planning to reduce exposure, shifting development from floodplains, and revised building regulations to retrofit or flood-proof structures (Hanson *et al*. 2011). There are also synergies to be encouraged in peri-urban or nearby rural areas where land-use management around a city supports rural livelihoods (and where appropriate urban agriculture and forestry) and protects ecosystem services (see 8.3.3.7). There may be opportunities for proactive adaptation outside larger cities where much of the future urban growth will occur. For instance, in Manizales, Colombia, local government has begun incorporating climate change and environmental management into its local development agenda, including the establishment of city climate monitoring systems, although this is a city that has long had innovative environmental and disaster risk reduction policies (Hardoy and Velásquez Barreto 2014). However, smaller urban centres are often institutionally weaker and lack investment capacity and critical infrastructure.

Adapting the urban economic base may require short- and long-term strategies to assist vulnerable sectors and households. The consequences of climate change for urban livelihoods may be particularly profound for low-income households who generally lack assets or insurance to help them cope with shocks (Moser and Satterthwaite 2008). For most urban centres, the informal sector is a significant part of its economy and provides employment for large sections of the population. But the effects of extreme weather on the informal economy are rarely considered as in the case of 2003 floods in Santa Fe, Argentina (Hardoy and Pandiella 2009). One example where it was considered was in Kelurahan Pabean Pekalongan in Central Java where batik production provides livelihoods for three quarters of adults and this is disrupted by floods that residents suggest are becoming increasingly frequent (UN-Habitat 2011b). Cash transfers and safety nets for vulnerable groups and those with inadequate incomes may be needed to help them cope with the short-term impacts of climate change (Sánchez and Poschen 2009) as well as climate variability. But these do not address the risks they face or support the needed collective or public investments in risk-reducing infrastructure and services (Mitlin and Satterthwaite 2013).

There is a growing discussion and literature of the importance of support for a 'green economy' combined with green infrastructure to help shift nations' economic and employment base towards lower carbon, more climate resilient patterns that also respect regional and global ecological and resource limits. For urban centres, this seeks to highlight new business opportunities as it requires existing and new businesses and employment opportunities to help limit anthropogenic climate change, resource depletion and environmental degradation. Other goals are sometimes added – for instance also supporting social inclusivity and eco-efficiency as mutually reinforcing principles (e.g. Allen and Clouth, 2012). The literature has begun to explore the changes that are needed in production systems (especially in regard to carbon intensity, waste generation and management), buildings, transport systems and electricity generation and in consumption patterns by wealthier groups (Hammer,*et al*. 2011, UNEP 2011a and b, UN-Habitat 2012 a,b,c and d, World Economic Forum 2013). But as yet, there is too little detailed discussion of how a green economy can be fostered in relation to particular cities or in regard to the incentives and regulations needed to shift private investment to this.

The 'waste economy' in cities in low- and middle-income nations should be an important sector in the green economy as it provides livelihoods to a large number of people (Hasan et al 2001, Hardoy et al. 2001, Medina 2007) along with contributing to waste reduction and GHG emission reduction (Ayers and Huq 2009). In Brazil's main cities, over 0.5 million people are engaged in waste picking and recycling (Fergutz et al. 2011); an estimated 17,000 people in Lima and 40,000 in Cairo earn their livelihoods from informal recycling (Scheinberg et al.2011). The

mechanisms by which city governments choose to work with those working in this waste economy or ignore them have obvious implications for employment and for resource use.

For some cities, there is documentation of the kinds of adaptation needed to protect or enhance their economic base. For instance, in Mombasa, local authorities may need to redesign and reconstruct the city's ports, protect cement industries and oil refineries and relocate some industries inland, all of which requires major capital investments (Awuor et al. 2008).There are many parts of Rio de Janeiro's diverse economy (including manufacturing, oil refineries, shipyards and tourism) that adaptation will need to protect along with the urgent need to address the vulnerability of large populations living in informal settlements (favelas) on land at risk of landslides (de Sherbinin et al. 2007). Defences needed to help safeguard coastal industries and residential areas could threaten the city's beach tourist industry and cause further erosion to other unprotected areas. It is also difficult to focus the attention of politicians and civil servants on adaptation when their planning for city development is focused on hosting the World Cup and the Olympics. As in most cities, making Rio's economic base more resilient to climate change will need to resolve such tensions and trade-offs, necessitating dialogue amongst local stakeholders (Ruth 2010).

As yet, there is little evidence that climate-change related risks or cities' adaptive capacities have an influence on the location of private sector investments. They are however, influenced by the availability of infrastructure and services that are an essential part of adaptive capacity. Many cities in Asian high growth economies are located in low-elevation coastal zones which are undergoing rapid urbanisation and economic transformation (McGranahan et al., 2007).Many of these coastal settlements are also within areas where cyclones are common. Without adaptive measures and with rising concentrations of population, infrastructure, and industries along India's coasts, there could be a non-linear increase in coastal vulnerability over the next two decades (Revi 2009). The same is true for China (McGranahan et al. 2007). In most nations, urban governments have found it difficult to prevent new developments on sites at risk of flooding, especially where these are attractive locations for housing or commerce; this is even when there is legislation and plans to that regulate land use (see Olcina Cantos et al 2010 for a study of this in Alicante in Spain)

Few economic assessments of climate change risks have been completed in West African coastal cities. National and city governments will face difficulties protecting many cities or particular districts and their industries, infrastructure and tourism as in the case of Cotonou (Doussou and Gléhouenou-Doussou 2009) . Lagos, Dakar, and other important economic centres in the Gulf of Guinea have large areas on the coast that are close to mean sea level, leaving them highly vulnerable to erosion and rising sea levels (Simon 2010). Compounding the climate change-induced flooding risks are the cities' rapid coastal construction, destruction of mangrove swamps, and inadequate refuse collection (ibid.).

8.3.3.2. Adapting Food and Biomass for Urban Populations

Large sections of the urban population in low- and middle-income countries suffer hunger while a larger number face food and nutrition insecurity (Montgomery et al. 2004, Ahmed et al. 2007, Cohen and Garrett 2010, Crush et al., 2012). This is due more to their low incomes and limited capacities to access food than to overall food shortages (Cohen and Garrett 2010, Crush et al.,2012). Among low-income urban households in such nations, food expenditures generally represent more than half of total expenditures (Cohen and Garrett 2011). This makes them particularly at risk from food price inflation.

Climate change impacts can have far-reaching influences on food security and safety, but these "will crucially depend on the future policy environment for the poor" (Schmidhuber and Tubiello 2007: 708, see also Douglas 2009). Globally, agriculture has managed to keep up with rising demands worldwide, including the rapid growth in the population, the rapid increase in the proportion of non-agricultural workers to agricultural workers that accompanies urbanisation and consumer dietary shifts that are far more meat and carbon intensive and often land intensive (Satterthwaite et al. 2010). However, food security may be eroded by competing pressures for water or bio-fuels (Godfray *et al,* 2010). Although adjustments in farming practices are essential, adapting urban food systems represents a major challenge and will necessitate radical changes in food production, storage, processing, distribution, and access (ibid).

Urban food-related adaptation needs to consider both supply and demand side constraints. Climate-change related constraints on agricultural production and the food supply chain can impact urban consumers through reduced supplies or higher prices. Falling agricultural production or farmer incomes also reduces their demand for the urban producer and consumer goods and services they use. Disruption to urban centres may also mean disruption to the markets, services or remittance flows on which agricultural producers rely (Tacoli 2003). Thus, food policies for climate change adaptation need to take account of complex rural-urban linkages (Revi 2009). Thus, a portfolio of responses that can bridge rural and urban boundaries, as well as action at the household, local, national, and international levels, is needed to strengthen urban food security.

Urban centres that are seriously impacted by extreme weather also face serious challenges in ensuring that the affected population have access to adequate and safe food and water supplies. Flooding, drought, or other extreme events often lead to food price shocks in cities (Bartlett 2008) as well as spoiling or destroying food supplies for many households. After the 2004 floods in Bangladesh, Dhaka's rice prices increased by 30 percent and vegetable prices more than doubled (Douglas 2009**).** Bangladesh's urban slum-dwellers and rural landless poor were the groups worst-affected by food insecurity (*ibid*.).

When facing increased food prices, the urban poor in low and most middle-income nations adopt a range of coping strategies such as reduced consumption, fewer meals, purchasing less nutritious foods, or increasing income earning work or work hours, particularly by women and children (Cohen and Garrett 2011). But these erode nutrition and health status, especially of the most vulnerable and fail to strengthen resilience, particularly in the context of more frequent disasters.

Adaptive local responses have included support for urban or peri-agriculture, green roofs, local markets and enhanced safety nets. Food price increases may be moderated by improving the efficiency of urban markets, regulations to promote farmers' markets, or investing in infrastructure and production technologies (Cohen and Garrett 2011). Food security may be enhanced by government support for urban agriculture and street food vendors (ibid., Lee-Smith 2011**).** Food security for urban dwellers with low incomes is also increased if they have access to cheaper food or to social incomes – for instance cash transfers (e.g. Brazil's Bolsa familia programme) or, for older groups pensions (Soares et al. 2010). While initially rural-focused, cash transfer programmes have been expanded in urban areas and in some nations reach a large proportion of the low-income urban population (Johanssen *et al*. 2009, Niño-Zarazúa 2010**,** Satterthwaite and Mitlin 2013).

8.3.3.3. Adapting Housing and Urban Settlements

Urban adaptation will be built on the bedrock of good quality and affordable housing that conforms to appropriate health and safety and climate-resilient building standards and has sufficient residual structural integrity over its service life to protect its occupants against extreme weather (United Nations 2009, 2011).

Section 8.2.4.4 noted how poor quality housing is often at risk from extreme weather. Its resilience can be enhanced via a range of structural interventions (for instance retrofitting existing buildings and revising standards for new-build), interventions that reduce risks (for instance expanding drainage capacity to limit or remove flood risks) and non-structural interventions (including insurance). The need for attention to all three of these are obviously greatest where housing quality is low, where settlements have developed on high-risk sites and for cities in locations where climate change impacts are greatest. However, enhancing the resilience of the buildings that house low-income groups also faces many political challenges (see Roaf et al., 2009).

Most of the city governments that have developed climate change adaptation strategies include measures to adapt the building stock. But even in the cities with such discussions, there is still a need to act on the risks and vulnerabilities identified. The range of actors in the housing sector, the myriad connections to other sectors and the potential to promote mitigation, adaptation and development goals all suggest the need for well-coordinated strategies that can support resilience (Maller and Strengers 2011).

An increasing number of cities have undertaken or commissioned studies to identify measures needed to adapt housing (and other buildings) although there is less evidence of the detailed action plans, budget commitments and regulation changes needed to implement them. A climate change assessment for Bangkok Metropolitan Administration identified a range of measures including a need to flood-proof homes, build elevated basements, and relocate power-supply boxes upstairs; also for households to maintain sufficient food, water, fuel, and other supplies to ensure 72 hours of self-sufficiency (BMA and UNEP 2009). It also pointed to regulatory changes that may be needed to bolster resilience including land use restrictions in floodplains and other at-risk sites and revised safety and fire codes for buildings and other structures (ibid). Cape Town's climate change framework (2006) proposed housing interventions including improving construction and regulations for building informal housing, in part to reduce the need for emergency response and anticipate projected climate change. Regulations in New York and Boston are being updated to address climate-related risks to the built environment (see Boston 2011, PlaNYC 2011). London and Melbourne's adaptation plans discuss climate-related impacts on the housing sector, as well as detailing extensive adaptation measures. London's draft plan considers management strategies at city level, neighbourhood, and building scale, which combine green infrastructure and housing interventions (GLA 2010). Approved in 2009, Melbourne's plan similarly combines housing, water, and green infrastructure strategies to promote cooling and long-term adaptation (UN-Habitat 2011a).

Housing and extreme heat:More attention is being paid to understanding and addressing risks from extreme heat in particular cities – see for instance Chicago 2008 and 2010, Tomlinson et al 2011 for Birmingham, Matzarakis and Endler 2011 for Freiburg and Giguère 2009 for Quebec. Attention is needed to buildings that provide protection from heat waves, especially in urban heat islands and for populations that are more vulnerable to extreme heat. In locations that have large daily variations in temperature, this includes upgrading homes with limited ventilation and with low thermal mass. Interventions that reduce heat gain are also needed including passive cooling and other design measures (Roberts 2008b, Hacker and Holmes 2007) as well as modifications to buildings and open spaces in areas that are heat islands (see later discussion on green and white roofs).Chicago's 2008 Climate Action Plan discussed the need to "pursue innovative cooling," which will "seek out innovative ideas for cooling the city and encourage property owners to make green landscape and energy efficiency improvements" (Chicago 2008: 52). Air conditioning and other forms of mechanical cooling can provide relief but these are too expensive or not available for the many urban households with no electricity supplies. They are also mal-adaptive if they rely on electricity whose generation is contributing to greenhouse gas emissions. Residents' vulnerabilities may be exacerbated if electricity supplies are unreliable and "if blackouts occur on the hottest days when peak demand is at its worst" (Maller and Strengers 2011: 3). To date, the literature on adapting housing and neighbourhoods to extreme heat focuses on cities in high-income nations although many of the cities already experiencing periods of extreme heat are in low- and middle-income nations.

Passive cooling can be used in both new-build and retrofitted structures to reduce solar gain and internal heat gains, while enhancing natural ventilation or improving insulation (Roberts 2008b and 2008c). Although developments such as the Beddington Zero Energy Development (BedZED) in London (Chance 2009) or Germany's PassiveHaus standard (Rees 2009) have set precedents for mitigating household emissions, these passive designs can simultaneously contribute to adaptation. The designers of BedZED sought to reduce energy demand for heating, cooling and ventilation while also utilising super-insulation, ventilation, and other measures to ensure energy is not required for most of the year (Chance 2009). Thermal mass can be used for residential cooling, "because it introduces a time-delay between changes in the outside temperature and the building's thermal response necessary to deal with the high daytime temperatures" (Hacker and Holmes 2007: 103). Structures in southern Europe already utilise solar shading, ventilation, and thermal mass in the building fabric to promote cooling (ibid.). Simulations for London buildings (under UKCIP02 Medium-High emissions scenarios) suggest that utilising shade, thermal mass, control of ventilation and other advanced passive designs are an "eminently viable option for the UK, at least over the next 50 years or so" (*ibid.,* : 111). Nevertheless, there are several obstacles to the incorporation of passive designs. Opening windows may be hampered by security concerns or noise pollution in cities (Hacker and Holmes 2007). Modern windows "often do not ventilate well," and site restrictions, cost, or other constraints may impede the use of passive cooling "particularly in the refurbishment of existing buildings" (Roberts 2008b: 4554).

Housing and disaster-preparedness measures:If populations are displaced by disasters or need to be evacuated temporarily from their homes, provision for emergency shelters and services need to be able to respond with

particular attention to vulnerable residents. For instance, housing agencies established shelters and recovery centres after Cyclone Larry in Queensland (in 2006) and New South Wales' coastal flooding (in 2007). Interviews with officials recalled the strains facing 24-hour providers in the shelters and coordination difficulties with emergency health workers, police, insurance, and other agencies (Jacobs and Williams 2011). While not addressing climate change explicitly, the study helps highlight the range of social support, structural strategies, and interagency efforts that local authorities may need to develop to adapt to climate change. For many urban centres, there is also the issue of how to move populations at risk when needed (and to get their agreement to do so) and this presents many challenges (Roaf et al., 2009).

Urban centres facing extreme heat need heat-wave plans that warn citizens of what is anticipated and what measures they can take and ensure adequate water provision, emergency healthcare, and other public services that focus on vulnerable residents. This includes special attention to infants and to the elderly in hospitals, residential facilities (Hajat et al. 2010, Brown and Walker 2008) or living alone. It should include back-up electricity although large sections of the urban population in low- and middle-income nations do not have electricity (Johansson et al., 2012) and this also means no access to devices that help with cooling. Here too, the examples of cities with responses to heat waves that focus on those most at risk (see for instance Toronto 2012) are mainly from high-income nations.

8.3.3.4. Adapting Urban Water, Storm, and Waste Systems

The challenge of this section (and this chapter), is summarizing key adaptation issues drawn from examples that come from a highly heterogeneous mix of urban areas across the globe with order of magnitude variations in the quality and extent of provision for water, sanitation and drainage. In high-income and some middle-income nations, virtually all the urban population is served by drinking quality water piped to the home 24 hours a day, by sewers or other systems of sanitation that minimize risks of faecal contamination and by storm and surface drainage. As noted in 8.2, there are many urban centres in such nations that face serious climate change-related challenges for water. But their plans do not have to address the fact that a significant proportion of their population do not have piped water or toilets in their homes, or storm drains. They also have in place billing systems that generate a substantial proportion of the funds needed for water provision and management.

At the other extreme are a very large number of urban centres in low-income and middle-income nations with very large deficits in provision for water, sanitation and drainage and with weak, under-resourced institutions (UN Habitat 2003, WHO and UNICEF 2012). There is also the billion or so people living in informal settlements where authorities or companies responsible for water and sanitation provision are often unwilling to invest or not allowed to do so. In considering how to adapt water and waste water systems to climate change, there are not only large differences between nations and cities in the scale and nature of likely impacts but also in the quality and extent of provision and resources available to local water and sanitation providers. New York City can develop a ten billion dollar plan to assure it receives adequate water supplies (Solecki 2012) while many cities in sub-Saharan Africa not only have very large deficits in piped water provision, sewers and drains but also very limited investment capacities (see for instance Kiunsi 2013 for Dar es Salaam).

Some studies have sought to estimate the costs of adapting urban water and sanitation systems. Muller 2007 discusses the direct and indirect impacts of changes in rainfall patterns and stream flows on sub-Saharan African cities. He suggests that $1-2.7 billion is needed annually to adapt existing urban water infrastructure and this does not include the cost of addressing deficient infrastructure. Another $1-2.6 billion a year is needed to adapt new developments (including water storage, waste-water treatment and electricity generation). Other research also suggests significant investments needed in low- and middle-income nations to overcome current shortfalls in water and sanitation as well as to cope with climate change (Arnell et al. 2009).

8.3.3.4.1. Adapting urban water supply systems

Major et al (2011) lists a range of cities that have begun to plan for and adapt water systems and other infrastructure including Boston, London, Halifax (Canada), New York, Seattle and Toronto. For cities with climate change

adaptation plans, water and waste water management are usually important components (see for instance Helsinki Region Environmental Services Authority 2012). But developing such measures is not yet commonplace.

Supply-side approaches to seasonal water shortages such as increasing reservoirs are frequently advocated. An analysis of 21 draft Water Resources Management Plans in the UK found that agencies usually favoured reservoirs and other supply-side measures to adapt to climate change (Charlton and Arnell 2011). The authors suggest that additional demand-side interventions may be needed to cope with reductions in water availability. Although based upon draft plans from 2008 rather than implemented strategies, the study indicates some key trade-offs and a portfolio of responses currently under consideration. To expand its reservoir capacity, Rotterdam developed plans that combine the goals of adaptation and urban renewal (van der Brugge and de Graaf 2010). Floods in 1998 exposed the inadequacies of existing water infrastructure, particularly in the context of climate change, and municipal water authorities committed to expand retention capacity by mixing economic activities with water-based adaptive designs, including 'water retention squares' and green roofs; floating houses; and networks of channels. Seattle has utilised demand-side strategies to curtail water consumption including aggressive conservation measures, system savings and price increases linked to consumption levels (Vano et al. 2010). A simulation exercise suggested the system can withstand climate change-induced alterations in reservoir inflows, and the authors note that the "primary reason" for such robustness is the successful reductions in demand (ibid. p. 283).

In Mexico City, government programmes on climate change have suggested actions regarding the water sector although some of these have been proposed many times since the 1950sbut not acted on. These include measures to decrease water use and the restoration and management of urban and rural micro-basins (Romero-Lankao 2010). Since these programmes prioritize mitigation over adaptation, adaptation measures for the water sector have been conceived as too general and with a lack of institutional commitment. In Durban, the importance of getting climate change adaptation within the water sector was recognized as a priority – and the water sector is influential within the city government because of its importance in delivering development benefits and also it is revenue-earning, well-resourced and retains skilled staff (Roberts 2010). The water sector has also shown an interest in developing its municipal adaptation programme (ibid).

Cape Town faces profound challenges in ensuring future supplies (Mukheibir and Ziervogel 2007). The city responded by commissioning water management studies, which identified the need to consider stresses including climate change as well as population and economic growth (*ibid*.). During the 2005 drought, the local authority substantially increased water tariffs, and such mechanisms may represent "one of the most effective ways" to promote efficient water usage (Mukheibir 2008: 1271). Additional measures may include water restrictions; reuse of grey water; consumer education; or technological solutions such as low-flow systems or dual flush toilets (*ibid*).

Research in Phoenix, Arizona sought to improve water forecasting data and inform adaptation interventions (Gober et al.2010). This rapidly-expanding desert city is projected to reach 11 million people by 2050, with most growth in peripheral areas that depend on groundwater (Bolin et al.2010). Simulations explored how water usage may be reduced to achieve safe yield while accommodating future growth (ibid). Reducing current high per capita water use may be achieved through urban densification, increased water prices and water conservation measures (ibid). Gober et al 2010 agree that stringent demand and supply policies can forestall "even the worst climate conditions and accommodate future population growth, but would require dramatic changes to the Phoenix water supply system" (ibid: 370).Quito's local government has formulated a range of adaptation plans to address water shortages (Hardoy and Pandiella 2009). The city is projected to experience reduced freshwater supplies as a result of glacier retreat and other impacts of climate change. Among the municipality's responses are developing dams; encouraging a culture of rational water use; reducing water losses; and developing mechanisms to reduce water conflicts (ibid.). However, Quito has not sought to incorporate community participation in planning and implementation (ibid.). Participatory water planning has occurred elsewhere in Latin America: stakeholders in Hermosillo, Mexico, identified and prioritized specific adaptations such as rainwater harvesting and water-saving technologies (Eakin et al.2007).

Several cities are considering the potential of rainwater harvesting to enhance water supplies. In Sydney, new houses are required under a 2004 law to save 40% of reticulated water for use in gardens and toilets and subsidies were available to install household roof tanks (Warner 2009: 235). Many low-income Caribbean households rely on rainwater collection systems for domestic use, yet upper-income groups in Barbados have voiced resistance to the

practice (Cashman et al. 2010). Extending existing communal collection and distribution systems would require community financing or governmental interventions, as well as overcoming such resistance *(ibid.)*.

8.3.3.4.2. Waste and storm water management

Most of theadaptations mentioned above are to help ensure sufficient water supplies. Less attention has been given to adaptations needed in sewer and drainage systems whose capacities will often need to be increased substantially and, for coastal cities, adapted to allow for the impacts of sea-level rise. We noted earlier the very large deficiencies in provision for drainage for urban centres in low- and many middle-income nations.

In St. Maarten, Netherlands Antilles, the government initiated a storm water modelling study and is developing a flood warning system (Vojinovic and Van Teeffelen 2007). Other options under consideration include institutional adaptations such as a new decision-support framework, centralised GIS to enhance all infrastructure planning measuresand public education, alongside structural measures such as improving the channel network and draining of areas with a high groundwater table (ibid).City management in Toronto, Canada has prioritised an upgrade of storm water and wastewater systems to circumvent the direct and indirect stresses from climate change (Kessler 2011). Deak and Bucht (2011) analyse past hydrological structures in the city of Lund, Sweden and use the concept of indigenous blue infrastructure to raise questions concerning current storm water management in the urban core. Cities in California have a range of flood management methods but will need to augment these with forward-looking reservoir operation planning and floodplain mapping, less restrictive rules for raising local funds, and improved public information on flood risks (Hanak and Lund 2012).

The last 20 years have seen more attention by most governments to water sector reform (UN Water 2012). Many have developed integrated water resource management (ibid) with linkages between provisions for water, sanitation and drainage and other sectors, This recognizes that water adaptation plans need to work with a range of partners, consider broader development goals, identify tensions or trade-offs and implement low-regret anticipatory solutions, For cities, this often has to include groundwater use management and water catchment management in areas that are outside their jurisdiction and thus collaboration with other local governments in integrated flood management (WMO 2009). Most examples of this are in high-income nations (for an exception see Bhat et al., 2013).

Urban water systems usually depend on reliable electricity supplies and can be energy intensive – for instance utilizing water from distant or low-quality sources that require high levels of energy for conveyance or treatment.Water adaptation planning will need to be developed in concert with energy conservation, water catchment management and green infrastructure strategies. Integrated strategies can minimize possible conflicts between water-intensive parks or gardens, support local industries, and ensure equitable access to water in cities.

8.3.3.5. Adapting Electric Power and Energy Systems

The heavy dependence of urban economies, infrastructure, services and residents on electricity and fossil fuels means far-reaching consequences if supplies are disrupted or unreliable (see 8.2.4.2). With the energy literature and urban energy policy discussions dominated by mitigation concerns, “relatively few assessments in the energy sector focus on adaptation issues” (Mdluli and Vogel 2010: 206; see also Carmin et al 2009). The UNFCCC’s estimates for investment to address climate change (UNFCCC 2007) did not estimate the costs of adapting the energy sector (Fankhauser 2010). Key issues relating to adaptation for the energy sector including electricity generation and distribution are usually national or regional and so are discussed in Chapter 10. But urban governments and urban dwellers’ responses still have importance. Research has suggested that “private autonomous measures will dominate the adaptation response as people adjust their buildings, [or] change space-cooling and -heating preferences...” (Hammer et al 2012,27) so this suggests a need for policies that encourage these measures to contribute to adaptation and mitigation and serve those with limited incomes. A few cities have adaptation initiatives underway for energy systems while some others have begun to consider the steps needed to adapt local energy systems (ibid).

The interrelations between energy and other sectors suggests the need for an integrated approach in understanding energy poverty and vulnerability to climate change and shaping appropriate responses (Gasper et al. 2011). One issue of relevance to urban households, businesses and institutions is the extent to which they will need autonomous provision or back-up generating capacity, if grid supplies become unreliable. This represents a high additional cost and less efficient electricity production. Another issue is the extent to which emergency services can function when energy supplies are disrupted.

There is also the adaptation agenda needed for industries related to the supply of fossil fuels that involve or should involve urban governments. For instance, in the State of Veracruz, Gulf of Mexico, cities such as Coatzacoalcos and Minatitlan are surrounded by oil, gas and petrochemical plants that can be affected by the impact of weather-related events REF. Even though there is a growing concern about the potential impact that climate change and extreme weather events will have in the oil industry in Canada, US and Mexico and how floods and sea level rise will disrupt oil, gas and petrochemical installations, few climate change adaptation studies on this theme have been undertaken.There are also important potential co-benefits between mitigation and reduced air pollution from thermal power stations, motorized transport and other industries.

8.3.3.6. Adapting Transport and Telecommunications Systems

Adapting urban transport and telecommunications systems to the many impacts of climate change (including rising average temperatures, more or more intense heat waves and storms and sea-level rise) poses many challenges (Mehrotra et al 2011b). Urban centres depend on road and often rail, air and waterway transport systems for daily functioning – including the movement in and out of the urban centre or core by commuters and consumers and daily deliveries. Many cities depend on underground electric rail systems which may be at considerable risk from flooding including New York and London (Eichhorst 2009).

The development of reliable low-cost transport has also increased the dependence of prosperous cities and businesses on regional, national and international supply chains; for instance, 80 percent of the food consumed in London is imported (Bioregional and London Sustainable Development Commission 2010). Most large and successful cities have also spread spatially with the expansion of transport systems supporting a decentralization of the workforce and businesses, most of which depend on a well-functioning transport system. The importance of adapting transport infrastructure to climate change is highlighted by the 60,000 jobs and US$ 3 billion worth annual movement of goods in the Great Lakes–St. Lawrence route in the USA (Ruth 2010). This includes a need to adapt to lower water levels. The study also notes the scale of indirect and direct job losses that could result from decreased connectivity of the shipping network (Ruth 2010).

Transport systems:Cities that have developed climate change adaptation plans usually include attention to more resilient transport systems (UN Habitat 2011a). Melbourne's adaptation plan notes that intense storms and wind may lead to blocked roads and disrupt traffic lights, trains, and trams and how the extent of the disruption may be "further exacerbated by any additional compounding factors such as large-scale events, power disruptions or emergency situations, such as multiple deaths or injuries" (Melbourne 2009:60).

Adaptation will require transport planners to account for climate uncertainties, utilise a whole-of-life approach to managing infrastructure, and constantly update risk assessments (Love et al. 2010: 144). An interdisciplinary approach can incorporate not only changing meteorological hazards but also consider the social and political values and governance framework that can shape more resilient transportation systems (Jaroszweski et al. 2010).

Adapting roads:Climate change may increase the costs of maintaining and repairing road transport networks (see Hayhoe et al. 2010 for a discussion of this for Chicago due to rising average temperatures and more severe rainfall). In Durban, "it may be necessary to revise road construction standards and avoid routes at high risk of flooding" (Roberts 2008a: 531). Coastal road adaptation may require strengthening barriers, increasing design parameters to cope with sea-level rise, or realigning existing roads to a higher location (Regmi and Hanaoka 2011).

To adapt road networks, transport planners are beginning to reassess maintenance costs and traditional materials – for instance stiffer bituminous binding materials to help cope with rising temperatures and softer bitumen for colder regions (Regmi and Hanaoka 2011: 28). However, current cost considerations may impede their use. The Chicago Department of Transportation decided not to use more permeable, adaptive road materials instead of asphalt and concrete because of higher cost, although it recognised costs may fall with greater economies of scale as demand rises for such materials (Hayhoe *et al*. 2010: 104).Road maintenance costs vary widely, depending upon the season, local context, and future climate scenarios. In Hamilton, New Zealand, changes in rainfall were projected to increase repair costs in spring and winter, but reduced rainfall in spring and autumn partly balanced out the cost; results depend upon the scenario and further investigation was recommended (Jollands et al. 2007).

Informal settlements frequently lack all weather roads and paths within the settlement and connection to the wider road system for emergency vehicle access and rapid evacuation. For instance, informal settlements in Chittagong have extremely narrow roads so that "ambulance and fire services cannot enter most of these neighbourhoods, thus exacerbating the existing health and fire risks at household level" (Rahman et al.,2010: 572). Roads in Lagos's informal settlements are often poorly maintained and lack all-weather surfaces; a 2006 resident survey ranked roads second to drainage in terms of needed facilities (Adelekan 2010). Evacuations in low-income areas may be hampered by hazardous locations, poor quality roads, absence of public transport, prevailing insecurity, and inadequate governance. Following the 2003 and 2006 floods in Santa Fe, Argentina, the lack of information and official evacuation mechanisms prevented a timely response while some low-income residents chose to stay in their homes to protect these and their possessions from looters (Hardoy and Pandiella 2009).

Low-income urban residents can also be profoundly affected by transport disruptions during and after extreme weather events that damage critical public transit links, prevent access to work, and heighten exposure to health risks. Interviews in Georgetown, Guyana, found that low-income households mainly rely on public transport and their limited transport access during floods made them more likely to lose time from work or school, as compared to wealthier households (Linnekamp et al. 2011). Better-off households were more likely to possess their own vehicles, while poorer households rarely owned cars, waded through floodwaters in bare feet, and were thereby exposed to waterborne pathogens (*ibid*.). Some studies suggest that urban women are more likely than men to walk or utilise public transport (World Bank 2010d), so that the gendered impacts of transport disruptions may merit greater consideration (see also UN Habitat 2011a, Levy 2013).

Adapting surface and underground railways: Underground transport systems are specific to urban areas and may have "particular vulnerabilities related to extreme events, with uniquely fashioned adaptation responses" (Hunt and Watkiss 2011: 14). Heat impacts are often significant in underground railways, as these systems may be gradually warming due to engine heat, braking systems, and increased passenger loads (Love et al., 2010). To cope with increasing frequency of hot days due to climate change, "substantial investment" in ventilation or cooling may be necessary (ibid.). Some of New York City's subways are located in coastal or river floodplains, and the system's age, fragmented ownership, and current overcapacity may augment the challenge of adaptation (Zimmerman and Faris 2010: 69-70). Pumps have been installed throughout the subway system and these helped to cope with severe floods in August 2007 during the morning commute (ibid.).

Rail systems that have struggled to cope with existing climate variability may need considerable investment to withstand changes in extreme events and higher temperatures (see Baker et al 2010). Railway systems may also be more vulnerable to climate variability and change than the road system, as the latter can more easily redirect traffic during extreme weather events (Lindgren et al. 2009). The costs of delays and lost trips due to extreme weather events were analysed in Boston (Kirshen et al. 2008) and Portland (Chang et al.2010) and were found to be small relative to the damages upon infrastructure and other property. Portland's nuisance flooding is projected to increase although floodplain restoration, use of porous pavements, or detention ponds may help address this (ibid).

In flood-prone cities, more stringent construction standards, design parameters, or relocation may be needed to adapt transport systems. Much of central Mumbai is built on landfill (as the area was originally seven islands); the landfill areas are prone to flooding, but they contain the main train stations and train lines as well as large populations and a large part of the city's economy (de Sherbinin et al. 2007). Rising sea levels may cause shifts at the sub-surface level of landfill areas and structural instabilities (ibid).

Telecommunications:8.2.2.2 noted how key elements in cities' communications systems may be at risk from climate change impacts so they may need to be strengthened to avoid toppling due to strong winds and electrical support facilities may need to be moved or protected against flooding (see Zimmerman and Faris 2010: 74).

8.3.3.7. Green Infrastructure and Ecosystem Services within Urban Adaptation

The greater attention to understanding, utilizing and protecting ecosystem services includes examples of ecosystem-based adaptation in urban and peri-urban areas. These use opportunities for the management, conservation and restoration of ecosystems to provide needed services and increase resilience to climate extremes. They can also deliver multiple development co-benefits (e.g. purifying water, absorbing runoff for flood control, cleansing air, moderating temperature, preventing coastal erosion) while helping contribute to food security and carbon sequestration (Newman 2010, Foster et al 2011, GLA 2011, Roberts et al 2012; see also Wilson et al. 2011, Oliveira, Andrade and Vaz 2011, Tallis et al 2011, City of New York 2011, Helsinki Region Environmental Services Authority 2012, Institute for Sustainable Communities, undated). An ecosystem services based approach is particularly important in low- and many middle-income countries where livelihoods for sections of the urban population and much of the peri-urban population depend on natural resources. Box 8-1 describes how ecosystem based adaptation is being developed in Durban. Another example is the contribution of catchment management to addressing flood risk that includes community-based partnerships supported by full cost accounting and payment for ecosystem services – rather than the more conventional canalisation of rivers (Kithiia and Lyth 2011, Roberts et al. 2012).

_____ START BOX 8-1 HERE _____

Box 8-1. Ecosystem-based Adaptation in Durban

In Durban, ecosystem based adaptation is part of its climate change adaptation strategy. This seeks to move beyond a focus on street trees and parks to a more detailed understanding of the ecology of indigenous ecosystems. From this can be identified the ways in which biodiversity and ecosystem services can help reduce the vulnerability of ecosystems and people in the face of the adverse effects of climate change. Strategies to achieve biodiversity goals such as developing corridors to facilitate species migration, enlarging core conservation areas and identifying areas for improved matrix management to enhance ecological viability of these core areas can have adaptation co-benefits. There is also a recognition that the adaptation deficit is both in the lack of conventional infrastructure and the loss of ecological infrastructure (wetlands, forests, grasslands, soil). It includes an interest in how ecosystem restoration and conservation can contribute to food security, urban development, water purification, waste water treatment climate change adaptation and mitigation.

The development of ecosystem based adaptation in Durban requires a series of steps that include:

1) A better understanding of the impacts of climate change on local biodiversity and how to manage Durban's open space system of 75,000 hectares. The projected warmer and wetter conditions seem to favour invasive and woody plant species.
2) A local research capacity that includes generating needed local data
3) Reducing the vulnerability of indigenous ecosystems as a short term precautionary measure
4) Enhancing protected areas already owned by local government and developing land-use management interventions and agreements with landowners to protect privately-owned land areas critical to biodiversity and ecosystem services. This needs government incentives and regulation to stop development on environmentally sensitive properties, the removal of perverse incentives and support for landowners affected by this.
5) The promotion of local initiatives that contribute jobs, promote business and life skills development and environmental education with ecosystem management and restoration programmes. Durban has initiated a large scale Community Reforestation Programme where community level 'tree-preneurs' produce indigenous seedlings and are involved in the planting and managing of the restored forest areas. This is part of a larger strategy to enhance biodiversity refuges and water quality, river flow regulation, flood

mitigation, sediment control and improved visual amenity. Local level advantages include employment creation and improved food security and educational opportunities.

_____ END BOX 8-1 HERE _____

"Green infrastructure" refers to interventions that seek to preserve the functionality of existing green landscapes (including parks, forests, wetlands or green belts) as well as transforming the built environment through the use of photo-remediation and water-management techniques and by introducing productive landscapes (La Greca et al. 2011, Zhang et al 2011, Foster et al 2011). Its importance for adaptation is increasingly recognized, although much of the early innovation was in response to the need for cost effective and sustainable mechanisms to addresswater shortages or flooding and not directly linked to climate change adaptation. Case studies of green infrastructure aim to measure their effectiveness and assess the potential of urban planning and environmental conservation policies to create cityscapes that can adapt to a changing climate.

Green spaces in cities are considered beneficial for absorbing rainfall and moderating high temperatures. For instance, in the USA, the cities of Portland and Philadelphia have used green infrastructure (including encouragement of green roofs, porous pavements and disconnection of downspouts) to reduce storm waters at much lower costs than increasing storm water capacity (Foster et al 2011).Some cities have made investments in green infrastructure, linked both to regeneration and to climate change adaptation. For instance, the Green Grid for East London seeks to create "a network of interlinked, multi-purpose open spaces" to support the wider regeneration of the sub-region. It is being developed to enhance the potential of existing and new green spaces to connect people and places, absorb and store water, cool the vicinity, and provide a diverse mosaic of habitats for wildlife (GLA 2008:80). New York has a well-established programme to protect and enhance its water supply through watershed protection. This includes city ownership of land that allows crucial natural areas to remain undeveloped and work with land owners and communities to balance protecting drinking water quality with facilitating local economic development and improving waste water treatment. To this has been added an ambitious green infrastructure plan (that includes porous pavements and streets, green and blue roofs and other measures to control stormwater (New York 2010). The city government suggests that while the Program is costly, compared to the costs of constructing and operating a filtration plant, as well as the environmental impacts of the additional energy and chemicals required by filtration, it is the most cost-effective choice for New York (Foster et al 2011, New York 2010).

The coastal city of QuyNhon in Vietnam is seeking to reduce flood risks by restoring a 150 hectare zone of mangroves (Brown et al. 2012). Singapore has used several anticipatory plans and projects to enhance green infrastructure including its Streetscape Greenery Master Plan, constructed wetlands or drains and community gardens (Newman 2010). Authorities in England and the Netherlands are recognising the linkages between spatial planning and biodiversity, though "there is less evidence of direct response to the needs of climate change adaptation" (Wilson and Piper 2008: 143). Barriers to action included short-term planning horizons, uncertainty of climate change impacts, and problems of creating habitats due to inadequate resources, ecological challenges, or limited authority and data (ibid.,145).

In Mombasa, the Bamburi Cement Company rehabilitated 220 hectares of quarry land now known as Haller Park (Kithiia and Lyth 2011). The park attracts over 150,000 visitors per year, with "the potential to create adaptation co-benefits despite this not being the original intent" (ibid.,260). Cape Town has initiated community partnerships to conserve biodiversity, including the Cape Flats Nature project with the para-statal South African National Biodiversity Institute (Ernstson *et al*. 2010: 539). The participating schools and local organisations explore ecosystem services (such as flood mitigation and wetland restoration), and the project facilitates "champion forums" to support conservation efforts *(ibid.)*.

Dedicated green areas within urban environments compete for space with other city-based needs and developer priorities. The role of strategic urban planning in mediating among competing demands for land use is highlighted as potentially useful for the governance of adaptation as presented in planning forerunnersLondon, Toronto, and Rotterdam (Mees and Driessen 2011). The experience in Durban discussed in Box 8-1 also faces many challenges

(Roberts et al. 2012). These include an assumption that ecosystem based adaptation is an easy answer to the technological, financial, institutional and skill constraints that limit the implementation and effectiveness of "hard engineering" solutions (ibid., Kithiia and Lyth, 2011). Experience in Durban shows that implementing an ecologically functional and well-managed, diverse network of bio-infrastructure needs knowledge, new data collection, expertise and resources. It needs to have direct and immediate developmental co-benefits for local communities and ensure integration across institutional and political boundaries. Substantial knowledge gaps need to be addressed, such as the need to determine where the limits or thresholds lie; many ecosystems have been degraded to the point where their capacity to provide useful services may be drastically reduced(TEEB 2010).

Burley et al's (2011) review of the wetlands of South East Queensland, Australia indicates that adaptations focused on wetland and biodiversity conservation may impact urban form in coastal areas. A study of the change in tree species composition, diversity and distribution across old and newly established urban parks in Bangalore, India aims to find ways to increase ecological benefits from these biodiversity hotspots (Nagendra and Gopal 2011).A new methodology that seeks to evaluate the impacts on local climate of current land uses and proposed planning policies using evapotranspiration and land surface emissivity as indicators when applied in Leipzig found that green areas and water surfaces had cooling effects, as expected but some policies were found to increase local temperatures (Schwarz et al 2011).

It is generally accepted that mitigating climate change will require a dense urban form to maximize agglomeration economies in more efficient resource use and waste reduction and to reduce land for urban expansion, reliance on motorized transport and building energy use. But adaptation requires an urban form that favours green infrastructure and requires provision of open space for storm water management, species migrationand urban cooling (Hamin and Garrun, 2009, Mees and Driessen 2011). This suggests that there is a "density conundrum" (Hamin and Garrun 2009: 242) in that higher densities can prevent the maintenance of ecologically viable and biodiverse systems and exacerbate the urban heat island which in turn generates the need for more cooling and may increaseenergy use,further escalating the urban heat island effect. But at which point will densities be too high to maintain ecologically viable and biodiverse systems, especially given that urbanization has already compromised the ability of ecosystems to buffer urban development from hazards? This situation will be further exacerbated by new hazards (e.g. floods, fires) to which systems are or will be exposed as the result of climate change (Depietri et al. 2012).

Green and white roofs:Green and white roofs have been introduced in a range of cities, with the potential to create synergies between mitigation and adaptation.Rooftop vegetation helps decrease solar heat gainwhile cooling the air above the building (Gill *et al*. 2007). This improves the energy performance of buildings (Mees and Driessen, 2011, Parizotto and Lamberts 2012) and can reduce cooling demand and often the use of air conditioning with its local contribution to heat gain (Zinzi and Agnoli 2011, Jo et al. 2010) and its implications for greenhouse gas emissions if utilizing electricity from fossil fuelled power stations. Rooftop vegetation can also retain water during storms, reducing storm water run-off (see studies conducted by Palla et al 2011, Schroll et al 2011, Voyde et al. 2010) and promote local biodiversity and food production (adaptation). Studies which measure the thermal and hydrological responses of green roofs have compared the performance of living roofs across different plant cover types, levels of soil water, and climatic conditions (see e. g. Jim 2011, Simmons et al. 2008). Hodo-Abalo et al. (2012) confirmed that a dense foliage green roof has a greater cooling effect on buildings in Togolese hot-humid climate conditions. Several field experiments combined with simulated modelling of impacts in the US also confirmed the positive thermal behaviour of green roofs when compared to alternative roof coverings (for example Getter et al. (2011) compared green roofs with a traditional gravel inverted roof, Scherba et al. (2011) compared the heat flux into the urban environment of vegetated roofs, white roofs and black membrane roofs, with PV panels elevated above various roofs, Susca et al. (2010) compared black, green and white roofs, in four areas of New York City and assessed the positive effects of vegetation at both urban and building level.

Durban has a pilot green roof project on a municipal building; indigenous plants are also being identified for the project and rooftop food production is being investigated (Roberts 2010). New York's lack of space for street-level planting helped encourage the adoption of living roofs, which can provide additional area for cooling vegetation (Corburn 2009). Under its Skyrise Greenery project, Singapore has provided subsidies and handbooks for rooftop and wall greening initiatives (Newman 2010).

Based on field tests in the UK, Castleton et al. (2010) suggests that older buildings with poor existing insulation stand to benefit most from green roofs compared to newer structures built to higher insulation standards. Wilkinson and Reed (2009) suggest that the physical property of buildings in city centres causes significant overshadowing, which may mean lower potential for green roof retrofits when compared to installations in suburban areas and smaller towns with lower rise buildings. Benvenuti et al. (2010) highlight the availability of water as the most limiting factor in the realisation of green roofs.

However, a recent meta-analysis suggests that green roofs and parks may have limited effects on cooling (Bowler *et al*. 2010). Findings on green roofs were "mixed, with some evidence of lower air temperatures above green sections in some studies, but not in others" (ibid., 153). Additionally, an urban park was found to be "around 1◦C cooler than a non-green site" (ibid.) and larger parks had a greater cooling effect. Yet studies were mainly observational, lacking rigorous experimental designs, and "it is not clear if there is a minimum size threshold or if there is a simple linear relationship" between the park's size and cooling impact (ibid.). While different types of vegetation have stronger effects, the analysis could not demonstrate "exactly how green infrastructure should be designed in terms of the abundance, type, and distribution of greening" *(ibid)*

Cool roofs or white reflective roofs use bright surfaces to reflect short-wave solar radiation, which lowers the surface temperature of buildings compared to conventional (black) roofs with bituminous membrane (Saber et al 2012). There is also some work on roads and pavements with increased reflectivity (Foster et al 2011). Quantification of the cooling benefits from white roofs in various urban settings has been undertaken - for instance the study in Hyderabad (Xu et al. 2012), comparison of white and black roofs in the North American climate (Saber et al. 2012) and a Sicilian case study (Romeo and Xinzi 2011). Comparisons between green and white roofs have been undertaken in various climatic zones: Ismail et al. (2011) investigated their cooling potential on a single-storey building in Malaysia and Zinzi and Agnoli (2011) explored the comparative applicability of the two roof treatments in a Mediterranean climate. Results suggest that local conditions play a dominant role in determining which treatment is best for improving internal conditions as well as moderating the urban heat-island phenomenon. For instance, Hamdan et al. (2011) found a layer of clay on top of the roof as the most efficient for passive cooling purposes in the Jordanian climate, compared to two different types of reflective roofs.

8.3.3.8. Adapting Public Services and Other Public Responses

It will fall to the public services network and public policy to ensure that climate change adaptation addresses the needs of those most at risk and most vulnerable. Many aspects of this have already been covered – for instance ensuring adequate provision for water, sanitation, drainage and solid waste collection and provision for rapid response to disasters. Health care services and emergency services (including ambulance, police and fire fighting) will have their workload increased while also needing to ensure that their systems can themselves adapt. They also need good working relationships with other key government sectors and with civil protection services – including the armed forces and Red Cross and Red Crescent societies.

As city risk and vulnerability assessments become more common and detailed, these provide a basis for assessing how public policies and services need to adapt – for instance, the levels of risk exposure of key health care facilities from flooding. Availability of data on and the personnel to reach vulnerable urban populations with effective responses e.g. protecting groups particularly vulnerable to heat waves which will be challenging in many cities. There is little evidence of consideration being given to needed changes in public services in response to climate change e.g. the risk of fires is likely to increase in and around many urban centres because of increased drought and rising temperatures.

Enhanced emergency medical services may help cope with extreme events while health officials can also improve surveillance, forecast the health risks and benefits of adaptation strategies, and support public education campaigns. Public health systems may need to increase attention to disease vector control (e.g. screening windows, eliminating breeding grounds for the mosquitoes that are vectors for malaria and dengue) and bolster food hygiene measures linking to increased flooding and temperatures.

The costs of adapting health care systems may be considerable – for instance, where needed modifying buildings and equipment at all levels and training staff and, setting up comprehensive surveillance and monitoring systemsand the use of modelling software that can capture the health risks of Climate Change. Risk and vulnerability assessments also need to look at the complete range of schools and day-care centres to assess their vulnerability to climate change. School buildings can be designed and built to serve as safe centres during floods or storms to which those at risk can move temporarily – although it is also important after a disaster to quickly re-establish functioning schools both for the benefits for children and for their parents (Bartlett 2008).

For cities without a robust emergency response network, adapting to Climate Change may require significant improvements in staffing, resources, and preparedness plans. This will include particular attention to providing emergency services in informal settlements lacking adequate roads or infrastructure and where needed, temporary evacuation plans that serve all those that have to move.

Many sections of 8.2 noted health impacts that can arise or be exacerbated by climate change that will increase demands on health care systems – including those linked to air pollution, extreme weather, food or water contamination and climate sensitive disease vectors. For air quality, additional research is still needed to understand the complex links between weather and pollutants in the context of climate change (Harlan and Ruddell 2011). Important synergies can be achieved through combining mitigation and adaptation strategies to improve air quality, reduce private transport and promote healthier lifestyles (*ibid.*,also Bloomberg and Aggarwala 2008).

8.4. Putting Urban Adaptation in Place: Governance, Planning, and Management

This section discusses what we have learnt about introducing adaptation strategies into the core of urban government investment and management with a buy-in from key sectors and departments within local government and support from non-state actors. This includes experiences with integrating development, disaster risk reduction and climate change adaptation. It includes consideration of household and community based adaptation and of where local processes are or can be supported by higher levels of government and for low- and middle-income nations, by international agencies. It also includes a review of the resources needed to adapt to climate change at urban levels, ranging from human to financial resources.

A share of what is needed for effective urban adaptation falls within the responsibilities of municipal governments. Many aspects of adaptation can only be implemented at the urban level through what local governments do, encourage, allow, support and control. This requires support from regional (sub-national) and national institutions and policies, suggesting that urban adaptation will necessarily be nested and policy-centric, with overlapping responsibilities and authority operating across levels of governance, relevant sectors and themes (Ostrom 2009, Dietz et al., 2003; Blanco et al., 2011; Corfee-Morlot et al. 2011; McCarney et al., 2011; Kehew et al. 2013, forthcoming). There are important precedents here in the way that new national legislation and institutions on disaster risk reduction have helped to strengthen and support local government capacity (see 8.3.2.2), though these often show that without associated budgetary support and increases in human resources, legislation has limited effect on local planning and practice (Johnson, 2011).

Approaches to adaptation include new urban policies and incentives for action as well as measures to mainstream climate considerations or auditing for climate impacts through existing policies to ensure that they reduce risk and vulnerability (Urwin and Jordan 2008, Brugmann 2012, OECD 2008, Satterthwaite et al. 2009). This can include consideration of transformation (where development is a main determinant of risk or risk mitigation), as well as difficult decisions over what can be done where there are limits to adaptation (Pelling and Navarrete, 2011). These limits might include, for example, resettlement or abandonment of previously developed land (see Section 8.3). Capacity constraints, including limited funding and technical expertise, ill-designed or inadequate institutional mechanisms, limited information on climate predictions and risk and lack of leadership will limit the ability of local authorities to work effectively on this (see Gupta et al., 2010) as well as working with others at the local, regional and national level on adaptation. Many national governments face comparable capacity constraints and still do not recognize the importance of local governments in climate change adaptation (OECD 2010a).

8.4.1. Urban Governance and Enabling Frameworks, Conditions, and Tools for Learning

Enabling conditions and frameworks to support urban adaptation are grounded in local-national institutional structures and local competences and interests. Key dimensions of adaptation include awareness, analytical capacity (e.g. assessments of vulnerability and policy options) and action (Moser and Luers 2008). Each presents a different set of challenges and requires specific types of capacity and enabling conditions at city and municipal levels.

As stressed in 8.1, the context for adaptation decisions will inevitably vary by country and location but preconditions for sound urban decision-making and accumulated resilience can be generalised from the literature and experience to date. These relate to principles of good urban government (what government does) and governance (how they work with other institutions and actors including the private sector and civil society). These generally include science-policy deliberative practice and vulnerability assessment to support adaptation (Adger et al. 2009, NRC 2007, 2008, 2009, Renn 2008, Moser 2009, Kehew 2009, Corfee-Morlot et al. 2011). Civil society - including non-governmental and community-based organizations - has important roles in good urban governance and environmental management including community risk assessment and contribution to adaptation, incorporation of local knowledge and understanding local preferences and norms (e.g. Krishnamurthy et al. 2011, Fazey et al. 2010, Shaw et al. 2009, Tompkins et al. 2008, Van Aalst et al. 2008). It is important to recognize that human behaviour and social norms are not static and can evolve through dialogue and understanding (Moser 2006, Dietz et al.2003, Ostrom 2009), hence engagement with stakeholders over time is key to effective adaptation (Kehew et al. 2013 forthcoming). Furthermore, the capacity to act at urban levels varies with organisational form including the level of decentralisation for funding and decisions such as land use and infrastructure (Blanco et al. 2011; Corfee-Morlot et al. 2011; McCarney et al. 2011), which in turn may relate to the context for development (Bicknell et al. 2009).

Section 8.3 made clear how building local adaptation capacity also means enabling disaster risk reduction to limit vulnerability to current and future hazards such as floods, water shortage or heatwaves (e.g. Schipper and Pelling 2006, UNISDR 2008). It includes the capacity to address the physical drivers of vulnerability, such as through upgrading informal settlements and implementing appropriate infrastructure standards and zoning laws, urban planning and early warning systems as well as through better education or information provision (Adger et al. 2007, 2009). The high vulnerability of often-large numbers of the urban poor to extreme weather events and their limited adaptive capacity makes the design and implementation of anticipatory adaptation action, including disaster risk management a key function of urban policy.

8.4.1.1. Multi-Level Governance and the Unique Role of Urban Governments

A framework for urban governance emerges from the challenges climate change brings to multilevel risk governance. Figure 8-1 summarises the key interests and their relationships in the production of urban adaptation governance. In this framework, urban governments (operating at municipal and/or local levels) are provided with authority for relevant policy decisions (Blanco et al., 2011; Corfee-Morlot et al. 2011; McCarney et al., 2011; Kehew et al. 2013, forthcoming). This is combined with the mandates and capacities of quasi-governmental institutions including local water authorities or insurance regulators (in the “inner circle”). Quasi- governmental organisations may operate at a regional scale but include responsibility for urban areas within their remit. Other local stakeholders are ideally included, such as businesses, communities and expert advisors in adaptation decisions, referred to here as part of the “outer circle”. Media and other forms of civil-social infrastructure act as filters of substantive knowledge and help to join expert information with local knowledge to build understanding and engagement on climate change (Carvalho and Burgess 2005; Leiserowitz 2006). Good practice hinges in part upon the credibility, legitimacy and salience of science-policy processes, a strong local evidence base of historical and projected data on climate change, and ongoing, open processes to support dialogue between government, civil society and expert advisors (Cash 2001, Cash et al. 2006, NRC 2007, Preston et al. 2011; Kehew 2013; see also Ch.2). Communication efforts are also essential (Moser and Dilling 2006, Moser and Luers 2008, Moser 2006). Good governance depends in part on how well policy and decision processes mediate across these different actors, spheres of influence, sources of information and resources to co-produce knowledge, support learning and action over time (see Figure 8-1).

[INSERT FIGURE 8-1 HERE
Figure 8-1: Circulation of power for public decisionmaking on climate change.]

From an institutional and policy perspective, urban governments have authority in relevant domains for adaptation decisions but many of their decisions will be enabled, bounded or constrained by national, sub-national or supra-national laws and policies, land use and infrastructure planning decisions (ARUP/ C40 report; OECD 2010; Kehew et al. 2013). Large metropolitan areas raise the level of complexity of managing climate adaptation, especially when they are growing rapidly – and this requires action to be coordinated across multiple urban jurisdictions; the number of relevant jurisdictions varies by city but they are often in the dozens (e.g. Mexico City, Sao Paulo, London and Buenos Aires) and occasionally in the hundreds (e.g. Abidjan and Tokyo) (McCarney et al. 2011). Although there is some evidence of innovative responses at the sub-national levels to plan for extreme weather events and climate change, limited capacity and experience at the local government level also suggests a need for support from higher levels of government (Norman and Nakanishi 2011, Guran et al 2012). In large metropolitan areas, it will also be ineffective for a single urban jurisdiction to act in isolation of neighbouring jurisdictions; there is a need to coordinate and harmonise actions across metropolitan jurisdictions – for instance to implement flood protection of contiguous land areas or evacuation planning in response to an approaching storm or in the event of a disaster.

Adaptive capacity in cities therefore depends upon the alignment of policies and incentives such that they work coherently across multiple levels of government and on multilevel governance to define and deliver effective urban adaptation (McCarney et al. 2011; Corfee-Morlot et al. 2011, Mukheibir and Ziervogel 2007, Urwin and Jordan 2008, Cash et al. 2006, Young 2002, Bulkeley and Kern 2006, Kern and Gotelind 2009). Institutions operating at different levels and with different scopes of authority may be responsible for key decisions in relevant urban adaptation sectors (e.g. coastal zone management and buildings). Water authorities may operate at waterbasin level and as such represent both national and local interests while also operating independently of urban authorities. This points to a need to audit and align (pre)existing policies and screen new policies across levels of government to ensure the consistent integration of urban climate change risk management. Failing to do so can lock-in outcomes that raise the vulnerability of urban populations, infrastructure and natural systems to climate change (mal-adaptation) even where pro-active adaptation policies exist (Benzie et al. 2011; OECD 2009, Urwin, Jordan 2008). Raising urban adaptive capacity requires local government capacity as well as the institutions that facilitate coordination across multiple, nested and poly-centric authorities in making decisions to address urban vulnerability and risk, and which have potential to mainstream adaptation measures.

Opportunities for accelerating learning and action may stem from horizontal coordination and networking across actors, professions and institutions in different municipalities and metropolitan areas, many of whom are facing similar challenges (Lowe et al., 2009, Aall et al., 2007, Schroeder and Bulkeley 2008). Local contexts and implementation agendas also underscore the need for tailoring of national goals and policies to local circumstances and preferences. Consultation and awareness raising are essential to avoid the kind of public backlash that occurred in response to the French government's attempt to ban urban development and require strategic retreat in areas of current and increasing risk to coastal flooding following the storm Xynthia in 2010 (Laurent 2010; Pryzyluski and Hallegatte, 2012). Urban adaptation planning has also to recognise the influence of vested interests and trade-offs, where near-term development may appear to conflict with longer-term adaptation and resilience goals. Public engagement, openness and transparency about climate change information and its risks can help to ensure democratic debate to balance public interests and longer-term sustainability goals against the short-term benefits of unconstrained development.

Urban governments are uniquely situated to understand local contexts, raise local awareness, respond to citizens and civil society pressures, strengthen planning and build capacity to take actions in some areas. They can work closely with local stakeholders through an analytic-deliberative process to build a policy space (Brunner 1996, Brunner et al. 2005, Cash and Moser 2000, Grindle and Thomas 1991, Healy 1997). Within this, it is possible to generate a good understanding of local contextual factors that will matter to decisions about how to manage climate change adaptation (Healy 1997, Ostrom 2009). Urban governments can also promote understanding of climate change risk and drivers of vulnerability for adaptation and help to create a common vision for the future (Corfee-Morlot et al. 2011, Moser 2006, Moser and Dilling 2006, Ostrom 2009). The fact that preferences of different actors tend to be

more homogenous across smaller than larger units (Ostrom 2009) provides opportunities for leadership and flexibility to innovate that may not exist at higher levels of governance. Thus, some evidence suggests that urban governments may be unique in their ability to provide accountableleadership, to innovate and to promote learning-by-doing (OECD 2010).

Beyond setting out a vision for the future, urban governments are central to the interface between climate change and development, including provision for essential services (water, sanitation, drainage, solid waste management, shelter, mobility services as well as education and health services) (Bulkeley 2010; Bulkeley and Kern 2006). Urban governments often have responsibilities for a substantial share of urban infrastructure to provide these services (ARUP/C40 2012). An essential step is to integrate and mainstream adaptation plans and risk management into urban and development planning from local to national levels with a clear time frame, mandate and resources for implementation (Brugmann 2012, OECD 2008, Satterthwaite et al. 2009). This includes influencing territorial development planning and infrastructure planning even if functional authority is at the national or sub-national regional levels (Vigue and Hallegatte 2012, Hall et al. 2012).

Despite the unique opportunities to support adaptation, local government decisions are often driven by short-term priorities of economic growth and competitiveness (Carmin and Dodman 2012, Moser and Luers 2008). Addressing climate change requires shifting ways of thinking about the future to take a longer-term perspective and reconcile this with near-term priorities (Leichencko 2011, Pelling 2011a, Romero-Lankao and Quin 2011). Tension also exists between focusing on economic growth and the large and often growing numbers of the urban poor that are ill-served or unserved by infrastructure and services; for much of the urban population, resilience to climate change will depend on this being addressed (Bicknell et al. 2009). The challenges of advancing adaptation through urban governance processes in low- and middle-income countries are exacerbated by inattention from international donors to urban policy and development concerns, as they work almost uniquely with national governments. Donors may also have preferences for physical infrastructure projects with visible results over local institution and capacity building investments. Similarly, national governments in high-income countries have yet to fully embrace and find ways to support local adaptation initiatives (McCarney et al. 2011).

While there is evidence of growing awareness and analytical capacity (i.e. in the form of adaptation planning) within many urban governments and governance processes, there is much less evidence of action in the form of adaptation implementation and influence on key sectors (Roberts 2010). This may be because adaptation planning is often done separately from urban and territorial development planning making it difficult to gauge progress in efforts to mainstream adaptation into urban planning.

8.4.1.2. Mainstreaming Adaptation into Municipal Planning

Whether and how urban governments mainstream climate change into municipal planning and land-use management and legal and regulatory frameworks for development is key to successful adaptation in all countries (Lowe *et al,* 2009: 6; Kehew et al. forthcoming). Mainstreaming has particular importance in countries where much of the vulnerability and risk from climate change comes from inadequate provision of infrastructure and services (Kithiia 2010, Roberts 2008a). Integrating climate change adaptation in urban development could help planners rethink traditional approaches to land use and infrastructure design based on past trends and move towards a new approach of forward looking risk-based design for a range of future climate conditions (Kithiia 2010; Solecki, Leichenko and O'Brien 2011). Important opportunities also exist in high-income countries to use ongoing planning processes to climate-proof infrastructure, spatial form and land use decisions in cities and to build resilience through existing policy channels (Benzie et al. 2011; Blanco et al. 2011; Urwin and Jordan 2008).

Some have argued that adaptation planning should be an integrated, cross-sectoral process (Parry et al. 2007; Sanchez-Rodiguez 2011) yet initiating mainstreaming may best be achieved through encouraging pilot projects and supporting key sectors to take initiatives. Assigning responsibilities and actions to specific departments can make the climate message easier to understand and more transparent (Roberts 2010, UN-Habitat 2011a). Pilot projects ground the imperative of adaptation in practical reality (Roberts 2010, Tyler et al. 2010; Brown et al. 2012). Sectoral approaches and pilot projects can be a pragmatic way to build more comprehensive and cross-sectoral and

approaches. Urban authorities in India can see climate change adaptation as a priority if they see co-benefits between adaptation and measures to address development and environmental health concerns (Sharma and Tomar 2010) (see also section 8.4.3). Local governments may be able to address both adaptation and mitigation using the same policy levers such as building standards, transport infrastructure, and other urban planning tools (Hallegate et al., 2011). Addressing adaptation and mitigation together can also avoid tradeoffs when designing policies and build response capacity by developing institutional links (Swart and Raes, 2007). A further challenge is to develop methods to evaluate emerging adaptation measures in a timely manner (Hedger et al.2008, Preston et al. 2011).

Despite the potential for change, evidence from the literature suggests that opportunities to mainstream climate change into urban planning and development are so far largely missed (Sanchez-Rodriguez, 2009). Challenges include lack of leadership, inadequate information, institutional compartmentalization and fragmentation, and resource constraints (Sanchez-Rodriguez, 2009; Wilson, et al, 2011). It is difficult to introduce an additional layer of climate change planning to already complex (and often fragmented) planning systems (Kithiia 2010, Roberts 2008a). The planning agenda can be already full, which in turn makes it difficult to find institutional space for climate change adaptation (Measham et al. 2010). Climate change policies may also be seen merely as "add-ons to the overall strategies driven by economic and spatial concerns" (Kithiia and Dowling 2010: 474). In all instances, where progress on adaptation planning is observed, local leadership is a central factor (Carmin and Anguelovski 2009, Measham et al. 2010).

8.4.1.3. Delivering Co-Benefits

Co-benefits of adaptation and development for urban contexts include delivering safer, more comfortable and healthier urban environments and reducing the vulnerability of low-income groups to wider concerns of environmental and public health and local development capacity – livelihoods, skills training, leadership capacity (Burch 2010, Clapp et al., 2010, Hallegatte et al., 2011, Kousky and Schneider 2003, Carmin and Anguelovski 2009, Roberts 2010). Co-benefits also extend beyond the urban core where hazard is driven in part by local environmental conditions such as land-use on hill-slopes or in wetlands – and also influenced by what is done in water-basin management and coastal defence regimes.

Co-benefits may be particularly important to highlight and plan around in low and middle income countries, where lack of policy buy-in is associated with limited local capacity to make changes to policy agendas capacity (UN-Habitat 2011a) and where current climate change challenges appear marginal when compared with the deficits in infrastructure and service provision outlined earlier and other socio-economic problems faced by authorities responsible for urban development and security (Kithiia and Dowling 2010, Roberts 2008a).

Development and climate change adaptation are often seen as separate challenges in a sub-national, regional planning context. A review in OECD countries revealed that only Japan and South Korea are championing climate action as an integral part of sub-national development planning, however Finland and Sweden also have innovative sub-national climate policies and action programmes that are incentivised and funded by the central government (OECD 2010, Ch. 8). For most OECD countries, however, the two issues of urban development and adaptation are tackled separately. Policy research argues that successful adaptation has to be rooted within development context of the city or country and harmonised with its development priorities, such as poverty reduction, food security and disaster management (Moser and Luers 2008, Satterthwaite et al. 2009, Lwasa, 2010, Measham et al. 2011).

8.4.1.4. Urban Vulnerability and Risk Assessment Practices: Understanding Science, Socio-Economics, and Policy Interactions

Principles of good practice in public decision-making and urban climate risk governance include an important component of science. This includes policy exchange and deliberation where good adaptation decisions will necessarily be based on credible scientific and expert information to consider future predictions and uncertainty around these (Bourque et al 2009, NRC 2009, Rosenzweig and Solecki 2010; Government of South Africa,2010). Climate science shows that future changes will need to vary in some cases significantly from past trends, so the past

is no longer a sufficient basis for future planning. Understanding climate risks and vulnerabilities at the urban scale demands a continuous re-assessment of the scientific knowledge about local climate conditions and translating this into useable local knowledge. This will depend upon local capacity to access and use climate change information as it becomes available and processes for local stakeholder engagement in science-policy exercises to understand and assess climate change risk and uncertainties in national, regional and local contexts (Hallegatte et al. 2011; Carmin, Dodman and Chu 2013 forthcoming).

Urban climate science refers to the ability to understand past climate conditions, monitor and attribute historical and present climate change to anthropogenic forcings, and project future changes in temperature, sea level and precipitation sufficiently well that urbanites and urban governments can plan for and adapt to these changes (McCarthy et al. 2010). The paths by which climate change alters local climatic conditions and who is exposed to risk and impacted, will vary with local contextual factors such as local physical and socio-economic conditions (e.g. the size of the local population and its distribution across the land; age structure, the quality, thermal characteristics and location of the built environment; and altitude, soil and vegetation conditions, proximity to the sea or river basins of the area). Urban climate science requires the integration of different kinds of detailed information and projections from physical science and socio-economic domains (Hallegatte et al. 2011, McCarthy et al. 2010). Attention to credibility, legitimacy and salience increase the usability of science and other expert knowledge in policy assessments (from local to global) (e.g. NRC 2007, Preston et al. 2011).

On science-policy issues, such as climate adaptation, research demonstrates the key role of boundary organisations to interpret and shape scientific inputs such that they become more useable in a political context (Cash 2001, Jasanoff 1990, Gieryn 1999, Guston 2001, Driessen et al 2010). In urban adaptation planning, local or regional boundary organisations have also been shown to have influence and support policy decisions (Bourque et al 2009, Corfee-Morlot et al. 2011, Horton et al. 2011). Boundary activities designed to support urban decision-making can take a variety of institutional forms (NRC 2009) and receive funding and support from different sources (e.g. national or sub-national public sources, and in some cases private funding) (Corfee-Morlot et al. 2011). In many instances, key boundary functions are carried out by nearby academic or research communities; local scholars in these institutions can also be a source of leadership for urban adaptation efforts (Molnar et al., 2012; Sanchez-Rodriguez 2009; Government of South Africa 2010).

Even where detailed quantitative and technical urban climate vulnerability or risk assessments exist, the influence of these may be limited if the timing is mis-matched with major policy decisions or if decision-makers do not access and use this information. For example, urban master plans or strategic plans with a time horizon of ten or more years into the future have the potential to incorporate climate risks and vulnerabilities, but timely assessments need to be made available to influence such plans. Beyond timeliness, Moser and Tribbia (2006) explore how decision makers access or use scientific information and the sources they rely upon. Resource managers are more likely to rely upon informal sources, such as maps or in-house experts, media and internet, thanon scientific journals. This emphasises the need to work closely with decision makers in the production and communication of scientific information (ibid, Moser 2006, Cash et al. 2003 and 2006). This demonstrates a need for two-way communication between producers and consumers of scientific and expert information early in any urban climate change assessment and adaptation planning process (Carmin et al. 2012, Horton et al. 2011, McCarthy et al. 2010).

8.4.1.5. Assessment Tools: Risk Screening, Vulnerability Mapping, and Urban Integrated Assessment

Assessments of risk and vulnerability to climate change's direct and indirect impacts are often the first step in getting the attention of governments, especially where these are assessed in the context of general development policy objectives (Hallegatte et al. 2011; see also 8.2). Including risk management information in infrastructure design at the planning or early design phase including that associated with climate change, can avoid higher costs of retrofit at a later date (Baker, 2012, Dickson et al. 2012). This can be assisted through a variety of planning and assessment tools including environmental impact assessment, vulnerability mapping and urban integrated assessment as part of public investment planning and as used by community organisations (UN-Habitat 2007). Governments can ensure that up to date climate information is available to the private sector to support adaptation (Agrawala et al. 2011; see also section below).

A wide range of tools have been developed and used to assess the environmental performance of urban areas including environmental impact assessment tools, environmental audits, strategic environmental assessments and local agenda 21s (Haughton 1999) as well as disaster risk assessment and management tools (Baker 2012). These have potential to support adaptation planning, as they provide useful entry points for adaptation and a means for participatory engagement; however in practice they often give little or no consideration to adaptation (Gurran et al 2012). More reliable, specific and downscaled projections of climate change and tools for risk screening and management can help engage not only relevant public sector actors but also the interest of businesses and consumers (AGF 2010a, UNEP-FI 2011).

Local climate change risk assessments, vulnerability and risk mapping can identify vulnerablepopulations and locations at risk and provide a tool for urban adaptation decision makers (Ranger et al 2009, Hallegatte et al. 2010, Livengood and Kunte 2012). One example is the LOCATE methodology (Local Options for Communities to Adapt and Technologies to Enhance Capacity) that is being tested in eight African countries; in each, a non-governmental organisation is working with one or more communities on project design and implementation, as well as monitoring, evaluation and learning phases. It integrates hazard and vulnerability mapping to inform choices about which populations, infrastructure and areas to prioritise for action (Annecke 2010). Elsewhere, Halsnaes and Traerup (2009) recommend the use of a limited set of indicators, engagement with representatives of local development policy objectives, and a stepwise approach to address climate change impacts, development linkages, and the economic, social and environmental dimensions. There is also a need for assessment tools that go beyond spatial and multi-criteria assessment in order to consider the urban environment as a system; this will allow better understanding of the inter-connections between root causes and risk production, cascading impacts and vulnerabilities (da Silva et al, 2012, UN-ISDR, 2011).

Tools that organize and rank information on vulnerability in different locations often aim to identify relative and absolute differences in risk and resilience capacity (Manuel-Navarrete et al. 2011, Hahna et al. 2009, Posey 2009, Milman and Short 2008). A review of risk screening and assessment tools, and of experience with their use by different donors and their partner countries (Hammil and Tanner 2011) show how these vary from a quick screening to identify risks to a fuller risk analysis and evaluation of adaptation options. In another review, Preston et al. (2011) consider 45 vulnerability mapping studies highlighting two broad functions: problem orientation (i.e. assessing and understanding the problem) and decision support. Noting the wide variety of functions and methods in the mapping exercises, the review suggests that effectiveness is guided by: identifying clear goals; framing vulnerability in a way that is meaningful to users; choice of robust technical methods; and ensuring engagement of the appropriate stakeholder (user) communities.

Downscaling of climate scenarios, systems models and urban integrated assessment modelling at local scales integrate different types of information in a forward-looking framework to support policy assessment in an urban context (e.g. Dawson et al. 2009, Hall et al. 2010, Hallegatte et al. 2011, Van Vuuren 2007, Viguie and Hallegatte 2012, Walsh et al., 2011). Integrated assessment modelling considers the driving forces of urban vulnerability and climate change impacts alongside possible policy responses and their outcomes. By integrating knowledge, this modelling provides a tool for use in urban areas by policy-makers to examine and better understand synergies and trade-offs across policy strategies. From this, policies can be identified that will deliver benefits across multiple criteria (Viguie and Hallegatte 2012, Dawson et al. 2009). These modelling frameworks take time to build and to be integrated into decision maker processes but early results are promising (e.g. Viguie and Hallegatte 2012, Dawson et al. 2009, Walsh et al., 2011).

Despite growing attention, useful information and assessment of climate change at urban spatial scales is generally still lacking (Hunt and Watkiss 2011; Kehew 2009). Only a small number of cities, largely in high-income countries, have quantified risks in local contexts and even fewer have quantified possible costs of climate change risks under different climate, adaptation and/or socio-economic scenarios. Some exceptions exist – as in the case of Durban and the development of a benefit-cost model for climate change adaptation options (Cartwright et al 2013). Other exceptions include urban climate risk assessments carried out in low- or middle-income countries as part of targeted development cooperation programmes and thus supported by external partners (World Bank 2011). Sea level rise and coastal flood risk, health and water resources are among the most studied sectors, while energy, transport and

built infrastructure receive far less attention (ibid, Hunt and Watkiss 2011, Roy et al. 2012). While science and climate change information is increasingly available, socio-economic drivers of vulnerability and impacts, as well as opportunities and barriers to adaptation, are less well studied or understood (Romero-Lankao and Qin 2011; Measham et al. 2011).

8.4.2. Engaging Citizens, Civil Society, the Private Sector, and Other Actors and Partners

8.4.2.1. Engaging Stakeholders in Urban Planning and Building Decision Processes for Learning

If the goal is a resilient, safe and healthy city, having a common understanding or vision of what such a future might comprise at urban scale is a first step to achieving it (Corfee-Morlot et al. 2011, Moser 2006, Moser and Dilling 2006, UN-Habitat 2011a). Participatory processes figure prominently across cities that have demonstrated leadership on urban adaptation (Carmin et al. 2012, Brown et al. 2012, Rosenzweig and Solecki 2010; see also below). This experience is consistent with the conceptual literature that suggests that participatory decision-making is essential where uncertainty and complexity characterise scientific understanding of the policy problem (Funtowicz and Ravetz 1993, Liberatore and Funtowicz 2003). Further, many have argued that, the institutional features of the risk management decision-making process -- notably participatory inclusiveness, equity, awareness raising, deliberation, argument, and persuasion -- will determine the legitimacy and effectiveness of action (Dietz 2003, Corfee-Morlot et al. 2011,Lim et al. 2005, Mukheibir and Ziervogel 2007). Yet a recent review of 45 vulnerability mapping exercises found that only 40 percent included stakeholder participation; this raises questions about procedural justice, legitimacy and salience of contemporary approaches to support adaptation investments and other adaptation decisions (Preston et al. 2011). It also highlights the challenge that local governments face to garner resources, including technical expertise and institutional capacity, to organise and effectively use participatory processes to strengthen rather than delay adaptation decision-making (Carmin, Dodman and Chu, 2013).

In many urban settings, civil society and the private sector already have significant and positive roles in support of adaptation planning and decisions. For example, some studies show that despite limited information, some action is moving ahead on adaptation at urban scale particularly through initial planning and awareness raising (Hunt, Watkiss 2011, Anguelovski, Carmin 2011, Lowe et al 2009, Carmin, Anguelovski 2009). Experience in a handful of cities – e.g. Cape Town, Durban, London, New York -- demonstrate that engaging a wide number and variety of stakeholders at early stages in the risk assessment helps to create political support and momentum for follow-on research and ultimately adaptation planning (Hunt and Watkiss 2011, Anguelovski and Carmin 2011; Rosenzweig and Solecki 2010). In informal settlements where there is little or no formal infrastructure and services, stakeholder engagement provides a means for participatory community risk assessment, where local capacity to adapt is built in part through accessing local knowledge (Livengood and Kunte 2012, Kiunsi 2013). Overtime, it is possible to establish institutional mechanisms that support innovation, collaboration and learning within and across sectors to advance urban adaptation action but this takes time and resources (Mukheibir, Ziervogel 2007, Burch 2010, Anguelovski and Carmin 2011, Roberts 2010).

8.4.2.2. Supporting Household and Community-Based Adaptation

In well governed cities, community groups and municipal governments are mutually supportive providing information, capacity and resources in maintaining local environmental and public safety. Where local government has not yet formulated adaptation strategy, community groups can be important in raising political visibility for climate risks and in providing front-line coping (Wilson, 2006; Granberg and Elander, 2007) including highlighting gender disparities in urban risks (Björnberg and Hansson, 2013). Where cities are less well managed and governed, community organizations may be discouraged and seen as a threat to formal urban planning. They may have to lobby an under-resourced municipality in the hope of getting some provision for infrastructure. Or they may have to address the deficit in roads, drains, good quality buildings and other infrastructure and services themselves (and thus it also falls to them to build local resilience to climate change impacts). This has been observed in rapidly urbanizing middle-income (Redclift, et al 2011) and low-income countries (Pelling, 2011a). But it is generally only in middle

and upper income residential developments that the full range of infrastructure and services needed for resilience can be afforded.

However, in many cities, community organizations formed by lower-income groups offer a rich resource of flexible capacity that can adapt to take on local priorities for development under climate change (Mitlin and Satterthwaite 2013). They are active in coping that better uses current resources to live with risk and at adaptation that seeks to realign resource options to prepare for future risks. But shifting the burden of adaptation to the community level is unlikely to bring success. Work from the Caribbean and Latin America has indicated the necessity of supportive linkages to wide community networks and/or local government for community level adaptation to be sustainable (Pelling 2011b)

Individuals and households in informal settlements are well used to coping with environmental hazards and the human vulnerabilities that generate risk; they have been shown to take multiple measures to mitigate the impact of extreme weather, especially where there is a history of floods, heat waves or high winds (Wamsler 2007, Adelekan 2010, Jabeen et al. 2010, Livengood and Kunte 2012, Kiunsi 2013). Some seek to modify the hazard itself e.g. ventilation and roof covering to reduce high temperatures during heat waves or barriers built to prevent floodwater entering homes) or reduce their exposure e.g. by sleeping and keeping food stores on top of high furniture and moving temporarily to safer locations. Exposure reduction measures are the most common *(*Douglas et al 2008).

There is an important distinction to be made between coping and adapting. SREX (IPCC 2012) distinguishes between coping as acts that bring together existing resources and entitlements to protect against a current threat, and adaptation, which seeks to adjust entitlements and future resource portfolios in the expectation of future risk. Many studies show the importance of coping mechanisms for low-income households because they lack the resources or capacities for adaption. A study in Korail, one of the largest informal settlements in Dhaka, showed that diverse household responses to flood risk (see Figure 8-2 for one example of this). Measures include barriers across door fronts, increasing the height of furniture, making floors or shelves to store goods above the flood line. Provision for ventilation, creepers or other material on roofs and false ceilings helped to keep down temperatures. Households also used portable cookers that can be used on shelves or furniture (Jabeen et al. 2010). These are important coping responses (and comparable responses are found in many informal settlements – see for instance Adelekan 2010 and Kiunsi 2013) but they do not articulate capacity to adapt – to influence future coping.

[INSERT FIGURE 8-2 HERE
Figure 8-2: Household adaptation - a cross section of a shelter in an informal settlement in Dhaka (Korail) showing measures adapting the dwelling to better cope with flooding and high temperatures.]

There are also constraints on the capacity of low-income households to act. For instance, in Korail, many inhabitants did not move to safer locations when floods are anticipated because this risked loss of assets from theft and disrupting livelihoods (Jabeen et al. 2010). They also worried whether they would be allowed to return to their original location. Similar concerns were expressed by the inhabitants of informal settlements during flooding in Santa Fe, Argentina (Hardoy et al. 2011). There is some recognition that strengthening and supporting the asset base of low-income households helps increase their resilience to stresses and shocks, including those related to climate change (Moser and Satterthwaite 2008.).

Community-based adaptation arises when a group of residents in a particular settlement agree to work together to address a perceived risk they face that the city government is not addressing (Boyd et al. 2009, Dodman and Mitlin 2011). These responses to climate change can be autonomous of, or engage with, local governments, sometimes via networks of community organization or with brokerage from NGOs (Mitlin, 2012). There is typically far less need for comprehensive community action in well governed cities, as shown in Table 8-2. In low and most middle-income nations where capacity and resources are most stretched as well as cities in high-income countries with inadequate governance and resource base, enabling community based adaptation and building resilience is more relevant. This is because of the limited capacity of governments to provide much needed risk-reducing infrastructure and services or their unwillingness to work in informal settlements. A range of studies documents how local populations have a depth of knowledge and capacities to mitigate their vulnerabilities (Dodman and Mitlin 2011, Anguelovski and Carmin 2011, Livengood and Kunte 2012). Close to a billion people live in informal settlements in

urban areas across the world and for a high proportion of these, community-based adaptation is their only means of response.

Community-based responses are often reactive – also more coping than adaptation facing - as residents within a particular settlement work together to install or repair infrastructure or provide services or action to engage local government and if possible work with it. There are many precedents for this engagement with local governments, including many upgrading programmes in informal settlements that have improved housing quality and infrastructure provision. Most upgrading programmes also mean that those living in these settlements became incorporated into 'the formal' city and this often means other measures by the state to reduce their risks – for instance though access to schools, health care and safety nets (Almansi 2009, Boonyabancha 2005, Fernandes 2007, Ferguson and Navarrete 2003, Imparato and Ruster 2003, Some et al , 2009, UN Millennium Project 2005). In many informal settlements, the issue of land tenure is difficult to resolve and this impedes upgrading programmes and local level adaptation action (Boonyabancha 2005, 2009, Almansi 2009). Where upgrading is able to deliver basic needs and services including security of tenure this can act as a foundation for coping and potentially adaptive capacity. Where adapting to or coping with climate change dovetails with the meeting of existing priorities and reducing existing risks, considerable local scope can exist. But where climate change or disaster risk are seen as distant or low probability then the immediate pressures of poverty tend to dominate local agendas (Banks et al. 2011). The studies noted above highlight how the willingness of individuals to invest in collective action is influenced by their tenure status. Tenants and those with the least secure tenure are often amongst the most vulnerable and exposed to hazards but also are usually unwilling to invest in improving the housing they live in and less willing to invest in community initiatives. But the contribution of community-level organization, DRR and climate change adaptation can be greatly enhanced where local governments and other agencies like civil defence organizations recognize the potential role of community organization and action and support them.

It has become more common for local governments to work with community-based organizations not only in upgrading but also in disaster risk reduction (Pelling 2011b, United Nations 2009, 2011, IFRC 2010). Community-based adaptation will probably be preceded by community-based actions to reduce risks and vulnerabilities to flooding, storms and heat waves in the past (Archer and Boonyabancha 2011, Carcellar et al 2011). But there are limits to what community action can do in urban areas. For instance it may be able to build and maintain community water sources, toilets and washing facilities or construct or improve drainage (see for instance the large community-driven sewers and drains programmes in cities in Pakistan Hasan 2006) but it cannot provide the network infrastructure on which these depend (e.g. the water, sewer and drainage mains and water treatment) or city-region management (Satterthwaite et al. 2009). Most informal settlements are embedded in a larger built up area so there is no space in their periphery to which to channel flood waters or dispose of household wastes. But here, supportive local governments or utilities can help – for instance in Karachi, the water and sanitation utility supported the community-driven provision mentioned above by providing the trunk infrastructure into which it could integrate. There are also many examples of where community organizations in informal settlements negotiated inclusion into formal water and sanitation systems (Boonyabancha 2005), such as in in Penjaringan, a low-income informal settlement in North Jakarta, where community groups organized to gain connection to the city piped water network (Prabaharyaka and Pooroe 2010).

Urban resilience to climate change impacts requires actions, investments and governance frameworks that only local governments can provide, even though private sector and community-based action may support this. A focus on community-action may mean a lack of attention to the structural and institutional inequalities or failures that underpin local vulnerabilities and the failure of local governments and agencies to address these (Dodman and Mitlin 2011). Table 8-3 illustrates the contemporary limits of community based action across key sites of coping and adaptation – highlighting where strategic partnerships, especially with a supportive municipal government have key advantages.

[INSERT TABLE 8-3 HERE
Table 8-3: The possibilities and limitations of focused activity for community groups on climate change.]

The IFRC (2011) identify three broad requirements for successful urban community based disaster risk reduction, work that can be extended to assess coping and adaptive capacity. These requirements are: (1) the motivation and

partnerships of stakeholders; (2) the levels of community ownership, wider integration and flexibility in project design, and (3) having sufficient time, funding and management capacity.]

The effectiveness of community-based action is also dependent on how representative and inclusive the community leaders and organizations are. There are examples of its effectiveness where there are representative organizations formed by those living in informal settlements (Appadurai 2004, Mitlin 2012) but also examples of local political structures that inhibit this (Banks 2008 and Houtzager and Acharya 2011). There are also wider constraints on the capacity of community organizations to act. For instance, discussions in El Salvador with the inhabitants of 15 disaster-prone "slum" communities and with local organizations showed many making individual and household responses – but difficulties in getting community action as there were no representative community organizations through which to design and implement settlement-measures. In addition, there was a lack of support from government agencies and from civil society organizations (Wamsler 2007).

The effectiveness of community-based adaptation in urban areas depends on the extent to which community organization (and the larger networks or federations they form) can generate pressure for larger changes within government and for relations between community organizations and government (Boonyabancha and Mitlin 2012). Community-based adaptation can engage with key development agendas that reduce poverty and vulnerability (Sabates-Wheeler et al. 2008) and potentially be effective in light of local inequalities and adverse power relations at district, city, national and transnational levels (Mohan and Stokke 2000). But urban governance regimes are often resistant to challenge and civil society organizations can be marginalized or co-opted reducing scope for adaptive action at the level of governance (Pelling and Manuel-Navarrete, 2011)..

There are new methods of documenting and mapping risks and vulnerabilities in informal settlements that serve and support community based adaptation. Even though it is common for a third or more of the inhabitants of cities in low- and middle-income nations to live in informal settlements, these are often not included in official government records and maps. In a growing number of cities, the mapping and enumeration of informal settlements has been undertaken by residents organizations supported by grassroots leaders and local NGOs – with city governments coming to support these and recognizing the validity of the data and maps produced (Patel and Baptist 2012). These provide the household and settlement data and maps needed to plan the installation or upgrading of infrastructure and services that reduce risks from extreme weather. Some of these community-driven enumerations also collect data for each informal settlement on risks and vulnerabilities to extreme weather and other hazards (Pelling 2011b, Carcellar et al. 2011, Livengood and Kunte 2012, UNHABITAT 2007). For instance, community surveys in the Philippines identified at risk communities under bridges, near cliffs and other landslide-prone areas, on coastal shorelines and river banks, in public cemeteries near open dumpsites, and on those in flood-prone locations (Carcellar et al. 2011). This mapping also helps raise awareness among the inhabitants of informal settlements of the risks they face, as well as getting their engagement in planning risk reduction and making early warning systems and when needed emergency evacuation effective (Pelling 2011b).

8.4.2.3. Private Sector Engagement and the Insurance Sector

Cities represent a particular interest for companies because much business activity, private investment and demand is concentrated there and because of their dependence on the functioning of infrastructure and usually a wide range of services. Brugmann (2012) notes how cities concentrate a high proportion of global investment and value added in global supply chains of production, and therefore a high proportion of what requires adaptation (and the funding needed to realize it). He argues that the costs of effective adaptation reaches far beyond what governments or international agencies can provide and depends on catalysing market-based investments in adaptation and financial instruments that reward investors who contribute to resilience. There is also a large number of private service providers and professional associations -- including architects, engineers and urban planners – positioned to influence the pace and quality of adaptation efforts (McBain et al. 2010).

Others argue that most of the investment required for sound adaptation will come from a multitude of private decisions spanning individuals, households and firms (Bowen, Fankhauser et al. 2008, OECD 2008). In contrast, international discussions often assume that the public goods nature of adaptation will require a major public

investment to cover the principal adaptation needs in low- and middle-income countries (AGF 2010b and c). Even when considering this more political set of questions around how to support adaptation efforts internationally, it is clear that the need for adaptation investments will far exceed available funds from public budgets (Hedger 2011, OECD 2008, World Bank 2010e). This underscores the need for both public and private engagement to address adaptation.

For markets to work in favour of urban adaptation, the private sector will need to see financial value in getting involved. In a survey of the most serious risks that companies face (Aon 2011), the top ranked risks were economic slowdown, regulatory/legislative change, increasing competition and damage to reputation. Weather and natural disasters came16th and climate change 44th – even if some risks that were ranked higher may be associated with climate change impacts (business interruption was 5th, commodity price risk 8th and distribution or supply chain failure 12th). It is not clear that private sector actors are well positioned to consider the big questions of urban development that climate change adaptation requires (Redclift et al. 2011). For example, in Cancun, Mexico close relationships between government and the corporate private sector, and the push for lucrative urban development, have led to a failure to reflect on the urban development model and generates climate change risk through hazard exposure of capital intensive and large-scale coastal development. Private sector investments in adaptation in this context are limited to superficial changes, for example in building design to withstand hurricanes; most investment in risk management comes from the state sector through for example beach replenishment and a focus on policies for rapid disaster recovery (Manuel-Navarrete et al. 2011).

The Private Sector Initiative of the UNFCCC Nairobi Work Programme offers support for businesses to integrate climate change science into their business planning, including urban infrastructure and high technology developments (see http://unfccc.int/adaptation/nairobi_work_programme/private_sector_initiative/items/6547.php). This experience has shown that both public and private (including civil society) actors can have a role in providing regional and local climate predictions and hazard mapping e.g. data and projections on socio-economic trends, climate change, urban water supply and management practices and land use and building trends (UNEP-FI, 2011). A recent review of private sector engagement in adaptation shows anecdotal evidence of some large businesses beginning to invest in vulnerability assessments, yet few have begun to invest in adaptation; these include business with assets at risk to climate change, or with dependence on natural resources that are particularly exposed to climate change e.g. freshwater resources (Agrawala et al. 2011). While some private sector actors may be pro-active in taking action against climate change risks, many more will postpone upfront investments for longer-term benefits against uncertain risks. Eakin et al. (2010) and Chu and Schroeder (2010) suggest that the private sector may become more prominent when local governments and civil society action is limited but this raises the issue of what incentives private sector enterprises require to do so and whether they will do so for the public good.

Insurance markets can play a unique role in urban adaptation by sharing and spreading financial risk from climate change, for example, to help limit damages and manage risks of climate change in urban flood prone areas (Rosenzweig and Solecki 2010). Risk-differentiated property insurance premiums can incentivise individuals and businesses to invest in adaption or to avoid being or building in high-risk areas (e.g. flood prone or fire hazard areas) and retro-fit property to reduce risk (Fankhauser et al. 2008, Mills 2007). Relevant insurance instruments include provision of health and life insurance to individuals; property and possessions insurance for home and commercial property owners, and micro insurance or micro finance mechanisms to support those in low-income urban communities that are not covered by commercial insurance (see Box 8-2) Catastrophe bonds may also be developed to cover some urban climate risks, however experience to date suggests that they are written quite narrowly - for specific events in specific locations - and thus may not provide the broad protection necessary to limit catastrophic risk as warranted in a changing climate and urban context (Brugmann 2012, Keogh et al. 2010).

Where risk levels exceed certain thresholds, insurers will abandon coverage or set premiums that cannot be afforded by most of those at risk. Private investment or standard insurance markets will not protect low-income urban dwellers, many of whom live in informal settlements where risk levels are high, where insurance is often inappropriate (few assets are legally owned), inaccessible (they are unable to get bank accounts that are required), or unaffordable (premiums set too high so that the up-front costs of insurance prevent its take up) (Ranger et al., 2009, Hallegatte et al. 2010). For example, around half of Mumbai's population currently live in informal settlements, most of which have inadequate provision of basic infrastructure and are at risk to floods today (Hallegatte et al.

2010, Ranger et al. 2011, McFarlane 2008). The risk profile for this informal settlement population is set to increase under most scenarios of climate change. This population will not be served by insurance mechanisms unless the risks they face are greatly reduced (and thus insurance costs lowered). They will rely instead upon government assistance and local solidarity, such as family and community support, to respond when disaster hits (Hallegatte et al. 2010). So insurance while reducing net risk and loss potential in urban areas can increase inequality in security across the city and within neighbourhoods or across regions (da Silva 2010).

In many informal settlements, informal savings groups are active and provide members with quick access to funds. Most savers and most savings managers are women and these groups have particular importance for providing their members with rapid access to emergency loans (Mitlin 2008). Where access to formal banking is limited by poverty, but where social capital is high, slum dwellers have pooled their savings and used these for collective investments that reduce risk within their existing settlement or reduce risk by allowing them to negotiate land and support where they can build new homes (d'Cruz et al 2013, Manda 2007, Mitlin and Muller 2004).

_____ START BOX 8-2 HERE _____

Box 8-2. Microfinance for Urban Adaptation

Microfinance schemes may contribute to pro-poor, urban adaptation through a variety of different instruments including micro-credit, micro-insurance and micro-savings to help households and small entreprenuers that do not have access to formal insurance or commercial credit markets. To date, these have been applied mostly in rural areas generally benefitting those with some property status (and thus not the poorest of rural populations). As Hammill et al. (2008: 117) state: "*The value of MFS holds for climate change adaptation is in its outreach to vulnerable populations through a combination of direct and in-direct financial support, and through the long-term nature of its services that help families build assets and coping mechanisms over time, especially through savings and increasingly through micro insurance – products and sharing of knowledge and information to influence behaviours*." Although typically more costly than commercial bank loans, micro-finance can support entrepreneurial undertakings by those unable to get bank loans, help diversify local economies and empower women in particular, which can in turn contribute to adaptive capacity in a local context (World Bank 2010c, Agrawala and Carraro 2010). But micro-finance may focus on short-term gains by encouraging growth in risk-prone areas and sustaining livelihoods with little resilience to climate change (Agrawala and Carraro 2010). This suggests a need for "climate-proofing" microfinance practices and targeting its use to priority tasks that will deliver adaptation and development benefits in the nearer term including disaster risk reduction and community based technical training and education (ibid.). Microfinance also provides a means for donors to deliver support to low-income groups without creating an ongoing dependence on aid (ibid., Hammill et al. 2008). But one limitation of micro-finance for adaptation is that it typically provides credit to individuals for their use only, so it is not easily used to help finance collective investments - for instance to improve drainage - and can be a route into indebtedness especially during disaster recovery. There has been some experience of pooling savings, e.g. in low-income communities to set up City Development Funds in Asia, from which they can draw loans for disaster rehabilitation among other things (Archer 2012).

_____ END BOX 8-2 HERE _____

For the private sector to fulfil its potential to facilitate adaptation, public policy needs to establish enabling conditions in markets (see 8.3). For example, urban policies can target payment for provision of ecosystem services that will otherwise fall outside of the market system to provide adaptation benefits; such services include storm buffering and flood protection through payments for mangrove protection in coastal zones or payment for protection of urban green space along river-ways (Fankhauser et al., 2008, Roberts et al. 2012). In the buildings sector, well-documented examples of market failure exist where optimal investment in weather proofing new construction and retrofitting existing stock will not occur without regulatory intervention; this is also an area where municipal governments often have authority to act. Public policy and funding is also needed to protect the poorest and most vulnerable populations, who are least able to protect themselves through private action. More generally, where information is highly uncertain or not consistent with past experience, as is the case for the prediction of extreme weather events and potential losses, public policy has a role to help provide information about risks and to ensure

action e.g. to fill gaps in insurance markets where insurers are unable or unwilling to act (Fankhauser et al., 2008, Mills 2007, SREX 2012, UN-Habitat 2011). For example, regulations can require pro-active engagement of the private sector, as in the UK, where vulnerability assessment is required for infrastructure investments with implications for urban planning and investments (Agrawala et al., 2011). Other examples exist where urban governments lead by example by requiring the integration of adaptation considerations into public operations and infrastructure investments through procurement requirements, which in turn affects private sector providers of services and products in the supply chain of these operations. Thus even where markets exist and are well-functioning, public intervention – spanning local to national level action - is warranted as a means to engage the private sector in adaptation. There will also be a role for public-private initiatives to provide educational and skill development resources to ensure that professional networks of private service providers (i.e. architects, engineers and urban planners) are trained in the latest decision tools, assessment methods and practices (McBain et al., 2010, da Silva, 2012)

8.4.2.4. Civil Society Partnerships and Philanthropic Engagement

Philanthropic and other civil society support for urban adaptation is gaining rapid momentum at all levels of operation. The most diverse are local actions undertaken by community based organisations, and these often build on long experience of working with the urban poor on livelihoods, governance and basic needs fulfilment. The greatest learning process has taken place amongst international philanthropic and civil society humanitarian organisations that now take urban adaptation seriously and build from experiences in urban climate change mitigation and rural adaptation respectively. These are sectors where lessons are not easily transferred so that new experimentation and practice development is underway.

An expression of international civil society as an enabling framework is the role played by philanthropic organizations.

One example of this is the Rockefeller Foundation's support for the Asian Cities Climate Change Resilience Network (ACCCRN). This is supporting partner institutions in ten cities in India, Indonesia, Thailand and Vietnam to build local knowledge, capacity and strategies to institutionalise climate change adaptation and resilience in local planning and development. This includes prioritising support for interventions to guide future investments to build resilience into the measures to meet the diverse needs of residents, businesses and the urban economy (Moench et al. 2011, Brown et al 2012). Others, such as the Bill and Melinda Gates Foundation approach urban adaptation indirectly through interests in poverty and disaster response and emphasise capacity building through education including programme support for universities in disaster-prone regions in Africa and Asia to establish a network of education and development programs in disaster resilience and leadership organized from Tulane University, New Orleans. The growth in philanthropic foundation spending has as yet largely unresearched implications for the direction of knowledge and capacity building on urban adaptation (Buchner et al. 2011).

Many civil society initiatives have developed models of infrastructure delivery; these are not centered on adaptation but they do have relevance for it. For instance, the installation of community-managed sewers and drains supported by the Orangi Pilot Project Research and Training Institute in urban areas in Pakistan shows capacity at community level but also how the scale and scope of what could be achieved was much increased by supportive investments by government (Hasan 2006). Elsewhere ad-hoc coalitions of civil society actors, or uncoordinated activity in many other cities provide a de facto delivery mechanism for accessing basic infrastructure and rights as part of development and disaster response (Pelling 2003). Here, while individual community groups may be foresightful and adaptive, the lack of coordination across communities limits the scale and scope of adaptive capacity. Adding to the argument for enhanced civil society coordination is the recognition that many disaster events are small, local but have a widespread and cumulative impact on the development prospects of low-income households and communities (United Nations 2009). The scale and range of recent disaster events in Asian cities suggest a growing need for new support mechanisms to facilitate action among local stakeholders – one that should include local government as well as local civil society organisations (Shaw and Izumi 2011). One experiment in this regard, though not exclusively focused on urban contexts, is the Global Network of Civil Society Organizations for disaster risk reduction. This has organised community groups at national and then (supra-national) regional and global levels

in a structured assessment of the local delivery for disaster risk reduction goals, as set out in the Hyogo Framework, as a means of verifying claims made by national government submissions to the ISDR.

Where urban-based civil society is well coordinated and has high degrees of legitimacy, it can reach beyond this to offer alternative models for urban governance and for adapting to climate change as part of the development struggle (Mitlin 2012). These are alternatives that need not be in confrontation with local government. Evidence from Santo Domingo, the Dominican Republic has shown the importance of partnerships between local urban government and local civil society actors in achieving longevity, in options for upscaling local disaster risk reduction initiatives and for building on trust generated by such projects to deliver other gains, in this case improved policing and reduction in gang related violence (Pelling 2011b). In the Philippines, many local governments now work with the Philippines Homeless People's Federation in identifying those most at risk to natural disasters and acting to address this (Carcellar et al., 2011)

The coming together of grassroots civil society organisations to form international collaborations strengthens the framing role of civil society while retaining its local accountability and focus. The local situatedness of adaptation and the need to both address local conditions and structural root causes of vulnerability makes such organisations well placed. Amongst the most active with a dedicated urban focus is Shack/Slum Dwellers International (SDI), a network of community-based organizations and federations of the urban poor in 33 countries in Africa, Asia, and Latin America and their local support NGOs. Its member federations share experiences, lobby and undertake practical upgrading and risk reduction initiatives as well as seeking to influence the policies of development assistance agencies. Regional networks of organisations also contribute to the emerging international architecture of civil society movements working on risk reduction - for example, the Asian Coalition for Community Action Program managed by the Asian Coalition for Housing Rights is supporting community-driven upgrading initiatives in 150 cities in 18 different nations and supporting improved relations between community organizations and local governments (REF). Other civil society networks have broader interests but include urban risk reduction, for example the Asian Disaster Reduction and Response Network (ADRRN), which aims to strengthen local civil society groups in the region.

8.4.2.5. University Partnerships and Research Initiatives

Since AR4, interest in urban aspects of adaptation has grown amongst researchers and universities and some associated national research funding agencies. This is also evident in the number of conferences on this topic and in the number of professional societies (including architects, urban planners and engineers) that are considering their roles and responsibilities. Parallel agendas from social and behavioural sciences and policy on one hand and engineering and city planning sciences on the other are beginning to integrate. Examples of this include the Urban Climate Change Research Network (UCCRN), which brings together researchers and city planners to exchange knowledge and build a coalition of awareness and policy – particularly important when national level policymaking on adaptation is slow (Rosenzweig et al, 2010).

The Urban Global Environmental Change Programme (UGEC) of the International Human Dimensions Programme of the Earth Systems Science Partnership (ESSP) was a pioneer in promoting social science and knowledge exchange and has built international networks in adaptation, mitigation and relationships between these two. Urbanization and adaptation has become a thematic issue dealt with by the Land-Ocean Interface at the Coastal Zone (LOICZ) programme through its interest on megacities and costal urban regions. The role of adaptation and its interaction with disaster risk reduction is also highlighted by the International Scientific Union project, Integrated Research on Disaster Risk (IRDR). There is also the IDRC funded research on urban adaptation in Africa and the START programme supporting research on global environmental change in Africa and Asia-Pacific.

Individual academic institutes have also begun to champion and support urban adaptation efforts. For example the Urban Observatory in Manila has become a regional hub for climate change science and urban adaptation, though interests in mitigation and rural adaptation are much more developed. In Malaysia the Universiti Kebangsaan Malaysia hosts a Malaysian Network for Research on Climate, Environment and Development (MyCLIMATE) and has focused on building awareness and capacity amongst industry and civil society (Izumi and Shaw, 2011). The

Climate and Disaster Resilience Initiative (Kyoto University, CITYNET and UNISDR) has focused on working with city managers and practitioners (Shaw and IEDM Team 2009). Centres for capacity building are also emerging such as the International Centre for Climate Change and Development (ICCCAD) in Dhaka which offers short course on urban adaptation planning (Mehrotra et al. 2009, Anguelovski and Carmin 2011, Molnar et al. 2010). In Latin America networks such as FLACSO provide leadership across the region in disaster risk reduction, management and climate change adaptation. Such networks can bring knowledge across urban centres and connect to international knowledge. Individual centres have also become more engaged in urban adaptation from established expertise in urban climate change mitigation (eg UNAM in Mexico).

8.4.2.6. City Networks and Urban Adaptation Learning Partnerships

The growing interest in urban adaptation among researchers and urban governments is also seen in the growth of transnational networks where urban actors work across organisational boundaries to influence outcomes (Bulkeley and Betsill 2005, Bulkeley and Moser 2007, Rosenzweig et al 2010). Some of these have been created through formalised information networks and coalitions acting both nationally and internationally, including ICLEI's Cities for Climate Protection, the Climate Alliance, the C-40 Large Cities Climate Leadership Group, and the Urban Leaders Adaptation Initiative in the US. The United Cities and Local Governmentsthat represents local governments within the United Nations have a growing interest in climate change adaptation. The Asian Cities Climate Change Resilience Network (ACCCRN) mentioned above also encourages inter-city learning for officials and local researchers (Brown et al. 2012). The Making Cities Resilient network supported by the UN International Strategy for Disaster Risk Reduction seeks to catalyse city governments to take action based on a ten-point priority agenda that includes a call to adapt to climate change by building on good risk reduction practices (UNISDR 2008; see also Johnson and Blackburn 2013).

The role of these networks have received increasing attention in social research on climate policy. For example, ICLEI's Cities for Climate Protection network has been extensively analyzed in the literature (Aall et al. 2007, Betsill and Bulkeley 2004, 2006, Lindseth 2004). The initial focus of some of these networks was on mitigation but attention to adaptation is growing (as in the US Urban Leaders Adaptation Initiative - Foster et al. 2011). These groups have given an institutional foundation to concerted effort and collaboration on climate change at city level (Aall et al. 2007, Kern and Gotelind 2009, Romero Lankao 2007).

8.4.3. Resources for Urban Adaptation and their Management

Resources for urban adaptation action can come from domestic and international public and private sectors. Table 8-4 summarizes the main financial instruments that can help fund adaptation in cities. For high-income countries, estimates show that local governments are responsible for about 70 percent of public spending and roughly 50 percent of the public spending on environment infrastructure – although often operating in partnership with other levels of government (OECD 2010). The scale and source of funds that might contribute to adaptation varies widely by city and location. The local revenue sources available to an urban government depends upon the national institutional and legislative framework that devolves some authority to tax or imposes other fiscal policies on local residents, property owners and businesses. Some of the environmental innovation shown in cities in Latin America over the last 20 years is associated with decentralization that has strengthened fiscal bases for cities, as well as elected mayors and more accountable city governments (Campbell 2003, Cabannes 2004). Much less is known about urban fiscal policies in Africa and Asia except that a high proportion of urban governments have very limited investment capacities as most of their revenues go on salaries and other recurrent expenditures (UCLG 2011).

[INSERT TABLE 8-4 HERE
Table 8-4: Main sources of funding and financial instruments for urban adaptation.]

Table 8-4 highlights how large cities with strong economies and administrative capability are most able to attract external funding (including transfers from higher levels of government) and raise internal funding for adaptation. There are far fewer possibilities for less prosperous and smaller urban centres and for cities with fragmented

governance structures or where administration is manifestly lacking in capability. One key issue here is 'unfunded mandates.' In many nations, local governments have been assigned responsibilities without the needed increase in funding and capacity (UCLG 2011) – and this may now also happen in relation to new responsibilities for adapting to (or mitigating) climate change (Kehew et al. 2012). The implication is that the funding regime and supportive legal frameworks need to integrate climate change risk management and adaptation into development.

8.4.3.1. Domestic Financing: Tapping into National or Sub-national Regional Sources of Funding and Support

Domestic public funding is one of the most significant and sustainable source of funding for adaptation in many countries. In recent years, initiatives to green local fiscal policies have spread. These include congestion charges on automobiles and value-capture land taxes that make visible the cost of environmental externalities and/or the benefits of infrastructure and services provided to property owners (e.g. transport, water and wastewater services). Such measures can promote private investment in risk management while mobilising local revenue sources (where a portion could be targeted to support urban adaptation). Local fiscal incentives for mal-adaptation may also exist, e.g. in China and parts of Québec, urban government budgets and actions are financed by land sales, which in turn promote urban sprawl or development in areas at risk (Merk, 2012; Drejza et al. 2012). Greening local fiscal policies will need to identify and address pre-existing policies that incentivise mal-adaptation.

Another important source of funding for local adaptation is grants, loans or other forms of revenue transfers from national or regional (sub-national) governments (OECD 2010: Ch 9, Hedger and Bird 2011). OECD (2010:239) states: "*In cases where environmental policies with large spillovers are assigned to local governments, intergovernmental grants could make sense in order to compensate local governments for the external benefits of its expenditures*." One example of this is municipal funding in Brazil that is influenced by ecosystem management quality; in this case the allocation of tax revenues is performance based (see Box 8-3).

_____ START BOX 8-3 HERE _____

Box 8-3. Environmental Indicators in Allocating Tax Shares to Local Governments in Brazil

In Brazil, part of the revenues from a value-added tax (ICMS) collected by state governments must be redistributed among municipalities. Three-quarters of this is defined by the federal constitution, but the remaining 25% is allocated by each state government. The state of Paraná introduced the ecological ICMS (ICMS-E) in 1992, followed by several other states. It was introduced against the background of state-induced land-use restrictions (protected areas) for several municipalities, which prevented them from developing land but provided no compensation. For example, 90 percent of the municipality of Piraquara is designated as a protected area for conserving a watershed to supply the Curitiba metropolitan region with water (May et al. 2002).

Although the states have different systems in place, there are many commonalities in the allocation mechanism. Revenues are allocated according to an ecological index based on the proportion of a municipality's area set aside for protection. Protected areas are weighted according to different categories of conservation management ranging from 1.0 (for ecological research centres and biological reserves) to 0.1 (for special local areas of tourist interest, and buffer zones). Paraná and some other states include an evaluation of the quality of the protected areas in the calculation of the index based on physical quality, biological quality (fauna and flora), quality of water resources, physical representativeness and quality of planning, implementation and maintenance.

Evaluations in Paraná and Minas Gerais show that the introduction of the ICMS-E has been associated with improved environmental management and the creation of new protected areas (May et al. 2002). The ICMS-E has also improved relations between protected areas and the surrounding inhabitants, as they start to see these as an opportunity to generate revenue, rather than an obstacle to development. The ICMS-E has built on existing institutions and administrative procedures, and thus has had very low transaction costs (Ring 2008).

_____ END BOX 8-3 HERE _____

A number of other innovative financial mechanisms may be used to support urban adaptation. These include revolving funds and the energy services company (or the "ESCO") model (OECD 2010:Ch. 8 and Ch 9). Revolving funds can be developed from a variety of different revenue streams, say from a Clean Development Mechanism project (Puppim de Oliveira 2009) or financial savings from energy efficiency investments in municipal buildings, to feed a public fund that can support public investments that yield adaptation benefits. Local governments in high and some middle income countries may also have direct access to debt instruments such as bond markets or loans from national (or regional) development banks or financial institutions (OECD 2010, EIB 2011). Local access to capital markets to fund adaptation investments can also be facilitated through risk-sharing mechanisms or financial guarantees provided by external or domestic development banks e.g. Kfw provides low-interest loans to local banks which in turn finance energy efficiency renovations in residential and commercial building (OECD 2010, Kfw 2011). Funding for climate change adaptation in cities is usually oriented towards technological investment and capital projects, rather than to integrating economic and social approaches. A key challenge is to determine how far adaptation funding should be recalibrated to better take advantage of inputs from social, economic and behavioural sciences and target associated policy realms. For example, the very high costs brought by extreme weather events in urban areas, described in earlier sections, and the fact that climate change increases these risk indicates the need for increased funding and attention from national budgets for disaster risk reduction, early warning and evacuation procedures within urban areas, alongside other adaptation measures (World Bank 2010a, 2010f, Hallegatte and Corfee-Morlot 2011). The urban funding gap may be particularly wide for "soft" rather than "hard" infrastructure investments yet they can be a motor for resilience.

8.4.3.2. Multilateral Humanitarian and Disaster Management Assistance

The international humanitarian community is increasingly active in urban contexts. The scale and scope of action is often impressive, particularly when large disasters unfold in major urban areas. There is opportunity for humanitarians to learn from non-climate related disasters (earthquakes, tsunamis and technological or military events), and the sector is beginning to review experience and develop appropriate tools and guidelines for urban contexts (eg ALNAP, 2012). In 2009 the Inter-agency Standing Committee, an umbrella group of humanitarian groups that sets policy for the aid community, formed a reference group on meeting humanitarian challenges in urban areas, setting a two-year action plan in 2010. It has developed a database of urban specific aid tools, the Urban Humanitarian Response Portal (http://www.urban-response.org/). The complexity faced by humanitarians working in urban areas makes it difficult to target aid to risk reduction or response. One report concludes that the humanitarian sector needs to make better use of social sciences and urban planning in humanitarian teams to better understand urban settings (Grűnewald et al, 2011). Amongst the biggest challenges facing the sector working in urban contexts is to develop policies sensitive to the needs of internally displaced urban populations, and how this can be managed in contexts where the resident population is chronically poor (Zetter and Deikun, 2010); also how international agencies can respond appropriately to the prospect of a significant increase in urban food insecurity (see IRIN, 2013).

The systematic programming of climate change adaptation into multilateral humanitarian, disaster response and management funding is in its infancy and urban dimensions are largely under-developed although this is changing (see United Nations 2009, 2011, IFRC 2010). The World Bank's Global Facility for Disaster Reduction and Recovery (GFDRR) explicitly includes adaptation to climate change and its Country Programmes for Disaster Risk Management and Climate Change Adaptation 2009-2011 also seek to deepen engagement in selected priority countries (GFDRR 2009). The GFDRR has also worked with UNISDR to advocate for more joined up policy and advisory services at the technical level (see Mitchell et al. 2010). A survey of 2009-2011 reports from 82 governments on how they were advancing disaster risk reduction and the treatment of urban and climate change issues within this, found that some progress has been made in both areas, across different types of countries (i.e. from low to high income) (Figure 8-3, United Nations 2011).

[INSERT FIGURE 8-3 HERE
Figure 8-3: Progress reported by 82 governments in addressing some key aspects of disaster risk reduction by countries' per capita income.]

Despite such progress, many urban governments lack the capacity to address disaster risk reduction and management. Almost 60 percent of the countries surveyed by the UN and almost 80 percent of lower-middle income countries reported that local governments have legal responsibility for disaster risk management, but only about a third confirmed dedicated budget allocations and these were mostly in upper middle and high income countries (United Nations 2011). Figure 8-3 highlights a relative lack of attention to urban and land-use planning and greater attention to investments in drainage infrastructure. As a whole, attention to these linkages is lower in low and lower-middle income nations, yet in more than half the high to lower middle-income nations, governments reported progress to integrate climate change policies into disaster risk reduction.

8.4.3.3. International Financing and Donor Assistance for Urban Adaptation

To date international adaptation financing has largely overlooked urban areas (UN HABITAT 2011) and most of the most vulnerable cities and municipalities are not well positioned to access available funding (ICLEI, 2010, Paulais and Pigey 2010). This generates a double funding gap – low availability of fundsfor adaptation and often very large deficits in risk-reducing infrastructure and services.

While more international funding for adaptation and mitigation is being committed (see for instance the Cancun Agreements) and there are some indications that governments are broadly on track to deliver on these (Clapp et al. 2012 , Buchner et al. 2011), there is less in evidence is the institutional arrangements by which such support is available to urban governments for adaptation – and thus to support work that can build adaptive systems for urban management, systems that evolve with changing social and environmental dynamics as indicated in the IPCC SREX report (IPCC, 2012). The failure to explicitly recognise urban adaptation needs is also the case for new dedicated climate change funds. In addition, international public funding for adaptation may be difficult to discern from development finance (Tirpak et al. 2010, Buchner et al. 2011).

Recent data suggest that a notable yet still minor share of development finance targets climate adaptation (UNEP 2010, OECD 2012). The extent to which urban adaptation is explicitly or even indirectly covered in donor portfolios is largely unknown, although many bilateral agencies choose to have a very limited engagement with urban initiatives (Satterthwaite and Mitlin, 2013). OECD estimates that between 23-38% of reported ODA commitments from bilateral donors for climate change target adaptation (OECD 2012). In an in-depth assessment of five major donors, with coverage of concessional (ODA) and non-concessional finance, adaptation was estimated to be 30% of the climate change portfolio, most of it targeted to water and sanitation (about 75%) while the remainder targeted urban relevant sectors (i.e. transport, policy loans, disaster risk reduction) with energy and health seemingly largely overlooked (UNEP 2010, see also Atteridge et al. 2007). Conventional multilateral and bilateral channels for development finance appear to have the biggest role in adaptation financing, though several new vertical funds are also emerging. The proliferation of multiple, single purpose funding mechanisms runs contrary to long-standing principles of sound development cooperation notably harmonisation and alignment (McKenzie Hedger 2011). This also creates a more complex funding architecture, making it difficult for smaller actors, such as local authorities, to access available sources for timely adaptation investments.

Reconciling external resources with bottom-up, locally based planning and project preparation could provide a means to better target development assistance (i.e. to urban planning processes that take climate risks into account), while also ensuring that limited funding is directed to programmes that aim to be mainstreamed into urban development over time (Brugmann 2012). Yet research shows that partner countries typically lack defined priorities for the use of funds; when combined with a donor tendency to “control” funds to ensure short-term results, and a large variety of different funding instruments, the result is highly fragmented delivery systems that lead to unclear outcomes (Peskett and Brown 2011). Even where national leadership and climate strategies exist to guide action – as in the case of Bangladesh, an “early mover” on adaptation planning – the plan is not yet costed nor is it sequenced. This makes it difficult to use as a framework for delivery of international climate finance (McKenzie Hedger 2011). A key to improving effectiveness of international public finance will be building the capacity for country-led planning processes that identify priority projects and programmes for the targeting of adaptation funds that include urban adaptation.

National Adaptation Plans of Action (NAPAs) have become a principal way of organising an integrated, climate change aware approach to development but the majority of plans do not explicitly include urban adaptation projects.UN-Habitat's review of a quarter of submitted NAPAs in 2011 found that only 14 per cent of the resources called for by those NAPAs were for projects that were largely or exclusively urban (UN HABITAT 2011c). NAPAs remain essentially top down, led by the national government. Urban governments typically only have access to international public finance through their national governments. One possible approach is for national governments to set up funds that are supported by international finance and on which urban governments can draw (Paulais and Pigey 2010).

A growing consensus among authors concludes that international development finance is failing to tackle urban adaptation financing needs (Parry et al 2009,Paulais and Pigey 2010, UN-Habitat 2011c, ICLEI 2011a). In some middle income countries, such as Indonesia, rather than focusing on large amounts of new external funding to support climate action, a more effective and sustainable strategy may be national fiscal policy reforms and incentives to steer investment to priority needs (Peskett and Brown, 2011). Beyond better delivery and use of development finance, there is also a need to mobilise domestic public and private investment to ensure delivery of adaptation at national and urban levels (Hedger 2011a & b, Hedger and Bird 2011, OECD 2012). Accessing international development finance for urban adaptation will require building routine institutional mechanisms for supporting multilevel planning and risk governance (Corfee-Morlot et al. 2011, Carmin et al, 2013).

8.4.3.4. Institutional Capacity and Leadership, Staffing, and Skill Development

A critical factor of generating interest in urban adaptation is leadership, for example from the Mayor's office or from entrepreneurial staff that understand the challenge and champion awareness raising and institutional change to bring action (Anguelovski, Carmin 2011, Carmin et al. 2012). Creation of a climate change and environmental focal point or office in a city can help to champion and coordinate climate action across government departments or line management agencies (Roberts 2008a, 2010, Anguelovski, Carmin 2011, Hunt and Watkiss 2011, OECD 2011, Brown et al. 2012). Yet there may be downsides when the urban climate change function is housed by the environmental line department (e.g. Durban - Roberts, 2008 :523, Boston see Boston 2010, Sydney see Measham et al. 2010). Roberts (2010) notes that urban environment line managers or departments are typically among the weakest parts of city government. This in turn can marginalise the climate change coordination function to the low or lower priority and limited resources are usually assigned to environmental departments within government structures, which results in limited institutional influence.

Although there is growing evidence of adaptation leadership in urban contexts (Anguelovski and Carmin 2011, Lowe et al 2009, Carmin and Anguelovski 2009, Foster et al., 2011b), there are also important political constraints to making adaptation decisions at the local level. Local government decisions are often driven by short term priorities and nearer term concerns about economic growth and competitiveness, making it difficult for them to focus on the more distant implications of climate change (OECD 2009, Romero Lankao and Qin 2011, Pelling 2011A). Powerful vested interests may oppose attention to adaptation and can promote development on sites at risk (e.g. coastal or river-side real estate developments). A key step forward is to work towards institutionalising different types of behaviour and norms to recognise and act upon climate and disaster risk (Figure 8-4).

[INSERT FIGURE 8-4 HERE
Figure 8-4: The basic challenge of effective climate change communication to change behavior and norms.]

Beyond goal setting and planning for adaptation and disaster risk management, governments also need a regulatory framework that ensures relevant behaviour and investment, creates job descriptions that require actions and provide incentives to act in new ways (e.g. for line managers and sector policymakers); they also need to provide training for staff and clear guidance on what to do (Moser 2006). Establishing budgetary transparency and metrics to measure progress on adaptation will also help to institutionalised changes in planning and policy practice (OECD 2012).

8.4.3.5. Monitoring and Evaluation to Assess Progress

Tools for monitoring and evaluation of urban adaptation actions are needed to assist adaptation leaders and funding institutions to justify investments. Monitoring urban adaptation activities and their effectiveness requires indicators that show if adaptation is taking place, at what pace, and in what locations. Among the relevant evaluation criteria to track are: cost, feasibility, efficacy, co-benefits (direct and indirect), and institutional considerations (Jacob et al. 2010). Assessment methods can capture outcomes of adaptation decisions, or the decision-making processes themselves, and ideally both. Monitoring is particularly challenging for urban adaptation given that there are no standard metrics to assess progress (Lamhauge et al. 2011, GIZ et al. 2012).

City authorities, NGOs and researchers have begun to design adaptation monitoring and evaluation frameworks. Coordinated development of tools offers scope for international benchmarking and comparison and coordination across scales of assessment, for example by associating local indicators of resilience with international ones attributed to the Hyogo Framework for Action and post-2015 agenda (IFRC, 2011). Box 8-4 presents the experience of monitoring from New York City.

_____ START BOX 8-4 HERE _____

Box 8-4. Adaptation Monitoring: Experience from New York City

Jacob et al. (2010) describe an adaptation monitoring approach developed for New York City. This has four indicator elements: (1) physical climate change variables; (2) risk exposure, vulnerability and impacts; (3) adaptation measures; and (4) new research within each of these categories. Examples of climate change adaptation indicators arising from these four categories include: the percentage of building permits issued in any given year in current FEMA coastal flood zones, and in projected 2080 coastal flood zones; an exact tally of building permits that have measures to reduce precipitation runoff; an index based on insurance data that measures the insurer's perception of New York City's infrastructure-coping capacity; an index that measures the rating of bonds issued by the City or infrastructure operators for capital projects with climate change risk exposure; the detailed trend of weather-related emergency/disaster losses (whether insured or uninsured, relative to the total asset volume); and the number of days with major telecommunication outages (wireless versus wired), correlated with weather-related power outages.

_____ END BOX 8-4 HERE _____

The New York experience has demonstrated that once monitoring is in place new demands for data can refine existing data collection systems including a preference for long-term data sets that span a range of disciplines. This has additional benefits for adaptive planning. In the New York case this need was resolved through data criteria decided through a scientist-stakeholder consensus with designated groups used to evaluate prospective indicators and their values. With its focus on data and processes required to monitor progress on urban adaptation, this case study shows the need for interdisciplinary and longitudinal data collection and analysis systems along with an inclusive and transparent process for stakeholder engagement to interpret the data as part of new monitoring programmes.

A more established aspect of monitoring and evaluation focuses on the effectiveness of donor aid on climate adaptation (Chaum et al. 2011). Recent work shows that consistent and internationally harmonised data collection is urgently needed to support monitoring, this is a concern for adaptation and wider disaster risk reduction spending suggesting a systemic challenge to the architecture of international finance (Kellett and Sparks, 2012). Steps are being made in this direction through multi-site assessment programmes and in some instances this includes treatment of urban issues. For example, the World Bank has recently included an adaptive capacity index as part of an analysis of risk and adaptation options for five cities in Latin America and the Caribbean; the methodology was applied before this to Guyana where it demonstrated a gap between national and city level adaptive capacity (Pelling and Zaidi, 2013).

Monitoring also needs to consider the delivery and use in cities of available international climate finance to ensure that funds are being directed in an effective manner (Hedger 2011, Buchner et al. 2011). This is especially important for cities at an early stage of planning, implementing and monitoring of adaptation, as they can learn from one another's experiences. There is some evidence of an increasing burden of reporting falling on partner organizations and countries, in some cases city authorities, who receive international support, where partners have to devote significant time and human capacity to reporting on progress; reporting may carry high transaction costs, which in turn can detract from further programme design and implementation.

Thus, in reviewing the development of urban adaptation interventions and strategies, do or will they:

- Have potential co-benefits with sound development, disaster risk reduction and ecosystem-based adaptation?
- Reduce mortality and help reduce illness and injury and/or their impacts especially on low-income and vulnerable groups?
- Make livelihoods more resilient and improve choices on employment and livelihoods?
- Meduce negative impacts on economic output and urban centres' capital stock?
- Increase the resilience of lifeline physical and social infrastructure and services?
- Increase the resilience of housing, especially for people with limited incomes and assets?
- Mitigate impact and improve the productivity and resilience of ecosystem services?
- Have potential co-benefits with poverty reduction and mitigation interventions and prepare the base for transformatory adaptation and the reduction of intergenerational risk transfer

8.5. Conclusions

8.5.1. Introduction

Urban areas are and increasingly need to be at the forefront of climate change adaptation and mitigation agendas. They house more than half the world's population and concentrate most of its assets and economic activities. Urban-based activities generate a high proportion of global greenhouse gas emissions so urban policies are key to addressing mitigation. Urban centres also concentrate a high proportion of the populationand economic activities most at risk from climate change and most in need of adaptation. Most of the increase in the world's population and much of the increment in capital formation, economic activity, infrastructure development, ecosystem degradation and emissions is projected to take place in urban areas in low- and middle income countries.Urban centres are thus places where the present and future well-being and safety of humanity must be secured in the face of the increasing uncertainty generated by climate change and other socio-ecological challenges (da Silva et al 2012).

The key role of urban governments in climate change adaptation has become more widely recognized. One example of this is the signing of the Durban Adaptation Charter in December 2011 by 107 mayors representing over 950 local governments at COP17. This signalled their intention to begin addressing climate change adaptation in a more concerted and structured way and is indicative of the climate change leadership being shown by local governments around the world (Rosenzweig et al 2010). But as this chapter has described, the way forward is not simple, with both climate change and climate change adaptation being acknowledged as highly complex and difficult to resolvein most urban contexts (Martins and Ferreira 2011, Fünfgeld and McEvoy 2011). As yet, only a small proportion of urban governments have begun to act on adaptation, often with variable levels of national support.

Because of the complexities and uncertainties involved, action has been limited and focused mostly 'no-risk' and 'low cost' interventions that have adaptation as a co-benefit of existing work streams, rather than a new, stand alone work area (Roberts 2008a, Toronto Environment Office 2008, Runhaar et al 2012). This 'business-as-usual with climate benefits' approach has resulted in a focus on interventionist and reactive infrastructure or asset-oriented adaptation (e.g. LCCP 2006, Awuor, et al., 2008, Mehrotra et al. 2011a, Mees and Driessen 2011) rather than on the 'soft' or process (i.e. human, institutional and ecological) elements of adaptation, such as resilient development, good governance, poverty reduction, livelihood security, social cohesion and ecosystem based adaptation (Lwasa 2010, Jones et al. 2010). A focus on adaptation measures rather than on building adaptive capacity or resilience is especially problematic in urban areas of the global South where it is "limited by resources, weak institutions,

poor/inadequate infrastructure and poor governance" (Kithiia 2009:19). This suggests a need to shift from looking at "what a system *has* that enables it to adapt, to recognising what a system *does* to enable it to adapt" (Jones, et al2010:1). This in turn implies a need for more open-ended and flexible concepts such as adapting well, climate smart, sustainable adaptation and resilience (Eriksen and Brown 2011, Wilson and Termeer 2011, Brown et al. 2012).

This socio-institutionalemphasis also encourages a more transformative view of adaptation. It shifts from being a tool of last resort, or an 'end-of-the-pipe' and incremental intervention (Roberts, et al. 2012:2; Foster et al. 2011) that supports the prioritisation of existing coping strategies (Heindrichs et al, 2011:216) to one that underscores the need for "bouncing forward" (Shaw and Theobald, 2011; Manyena et al 2012) and a departure from the norm. This is characterised in Table 8-2 as a shift from adaptation to resilience and then transformation (Pelling 2011a). This 'business-unusual' approach is especially important in a world where transgressions of key planetary boundaries such as climate change and biodiversity will take humanity out of the globe's "safe operating" space (Rockström et al. 2009: 1) into an unsafe and unpredictable future. If effective adaptation in urban centres is good development conceived and implemented with adaptation in mind, transformation is adaptation that helps achieve the needed global reductions in greenhouse gas emissions and other drivers of anthropogenic climate change. This requires changes to the "fundamental attributes" of existing technological, governance, planning, economic, cultural and value systems(IPCC 2011; Costanza et al 2012, O'Brien, 2011, Pelling 2011a).

8.5.2. What Hinders Adaptation Progress in Urban Areas?

Lack of mandate: There is a need to clarify which sphere (national, provincial, metropolitan and urban) of government has a legal mandate to act on climate change through the promulgation and assignment of appropriate constitutional and legal powers. Without these formal mandates, adaptation becomes an optional and discretionary extra, dependent on local level interest and resources and particularly vulnerable to leadership change. Although much of the innovation in adaptation and mitigation has come from particular local governments, for these to become effective at a national scale and to ensure coherence and widespread implementation, support from higher levels of government is required (Kazmierczak and Carter 2010, also Carter 2011, Brown 2011, Martins and Ferreira 2011). Where mandates exist, they have been important in driving local level action (Kazmierczak and Carter 2010) but they need increased co-ordination and co-operation if they are shared between the different spheres of government (Martins and Ferreira 2011, Carter 2011) or cross jurisdictional boundaries. New mandates (formal or informal) may also require institutional changes(Lowe *et al*. 2009, Roberts 2008a, Kazmierczak and Carter 2010).

Political obstacles: Decisions in urban centres including those related to climate change adaptation, are affected by political interests and competition for support (Mees and Driessen, 2011, Brown et al, 2012). Those who are most at risk from climate change are often those with the least voice and influence on these decisions. Addressing constraints such as information and resources alone will not ensure transformation if there is political resistance, particularly as politicians control local level resources (Roberts 2008a). A further complication is the disjuncture between political and climate time lines (Mees and Driessen, 2011). This sets short-term (often personal advancement) priorities against the inter-generational and public good impacts of climate change adaptation, making communicating and negotiating climate change related objectives in the political space often very difficult to achieve (UN-Habitat 2010).

The weakness of climate change focal points within local government: These are often housed in or championed by environmental line department which usually leads to marginalisation (Roberts 2010, Hardoy and Romero Lankao 2011) and limited institutional influence and access to resources given the low priority usually assigned to environmental departments. There is also a concern that in the current recession, that local authorities(with already limited resources) will prioritise conventional economic and development goals over 'environmental' issues including climate change adaptation(Shaw and Theobald 2011, Solecki 2012).

Undervaluing community resources and social capital: Although 8.4 gives examples of the effectiveness of household and community based adaptation in urban contexts, there is still limited work and limited understanding of the potentials and limitations (Jones et al. 2010). This is a critical gap given that social capital and community

based adaptation may provide opportunities to achieve the "bouncing forward" required by adaptation, as community collaboration, relationships and trust can provide a platform to generate material interventions directed at reducing vulnerability (Kithiia 2009). The issue of social capacity has been identified as important to urban resilience in a number of urban areas (TARU 2011, Roberts 2010) but there is also a need to determine the limits of community based intervention; for example, communities cannot install, maintain and fund trunk infrastructure and the scale and scope of needed service provision at city and city-region scales.

The complexities of developing locally relevant adaptation plans: Mitigation-focused interventions provided the first experiential training for most local governments engaging with climate change. These were often based on step-wise guidebooks or programmes (e.g. ICLEI's Cities for Climate Protection Programme, UN-Habitat's Planning for climate change manual) (Anguelovski and Carmin 2011, Martins and Ferreira 2011). Experience with adaptation programmes show they are less open to a standard set of requirements, given that actions are oftencross-sectoral, cross-institutional, complex, operating across a range of scales and timelines,rooted in local contexts,involve more stakeholders and include high levels of uncertainty (Roberts et. al. 2012, Roberts and O'Donoghue 2013). More than standardised guidelines, urban adaptation practitioners need clarity, creativity, and courage (ICLEI Oceania 2008).

Dealing with uncertainty: Adaptation costs areimmediate, a fact which contrasts with the uncertainty associated with climate change projections (see 8.2.5.1.) and the possible delay in the benefits (OECD 2010). A pragmatic approach is therefore to focus on existing vulnerabilitiesand to use those to identify 'no-regrets' options with near and long-term co-benefitssuch as enhanced competitiveness, improved service delivery, economic resilience (and success), job creation and risk management as these help get the attention of politicians and decision makers (e.g. Durban, London, New York and Copenhagen) (Foster et al. 2011, Roberts 2010, GLA 2011, City of New York 2011, City of Copenhagen 2011, Runhaar et al , 2011).The use of scenario planning as a possible alternative to scaled down projections, the undertaking of further studies to develop better local data and understand the costs of inaction, avoiding maladaptation and increasing awareness also contribute to increased adaptive capacity (Tyler et al. 2010, OECD 2010, TARU 2010, Neimi 2009). Facilitating networking and learning between adaptation practitioners also assists in improving the capacity to deal with uncertainty (Mees and Driessen, 2011).

The issue of thresholds and conflicting agendas: Most local governments acknowledge the value of mitigation and adaptation, but to lead with one or the other depending on circumstances, priorities, resources and institutional affiliations (Roberts 2010, Carmin et al. 2012, Hamin 2011, Moser 2012). The result is that little progress has been made in ensuring that adaptation and mitigation policy goals are not in conflict (Hamin and Gurran 2009, Moser 2012). Section 8.3.3.7 discussed what Hamin and Gurran, 2009 described as the "density conundrum" where the densities that serve mitigation can prevent or limit the possibilities of ecosystem based adaptation and may also exacerbate the urban heat island and limit the possibility of utilizing solar energy. There is therefore an urgent need for research to determine the thresholds for unacceptable biodiversity change and to derive from these locally specific limits to urban densificationand ensure that climate actions do not undermine other global environmental change agendas such as biodiversity protection (Moser 2012). The issue of thresholds is also relevant beyond biodiversity concerns, for example, determining when and where adaptation is no longer possible in urban areas, due to technical difficulties or cost (or both) resulting in residual damage (UN-Habitat 2011c, Parry et al. 2009). This knowledge about limits within existing systems will be vital in developing appropriate planning responses to future climate challenges, especially as there is increasing concern that the current state of global inaction and lack of ambition on mitigation could result in 4 degrees or more of global warming, necessitating a "more substantial, continuous and transformative process" of adaptation (Smith et. al. 2011:196). This also raises the possibility of abrupt, non-linear and unpredictable global environmental change (Rockström et al. 2009) that will stretch the adaptive capacity not only of existing urban systems, but of the whole global system.

8.5.3. What Contributes to the Development of Effective Transformative Adaptation Plans?

Building on future urbanization opportunities: United Nations projections suggest that in the next 40 years, the world's urban population will nearly double (United Nations 2012) requiring the same scale of urban infrastructure be built in 40 years as in the past 4000 years (ICLEI, 2011b). This provides a transformative opportunity at a global level, especially in the global South with its large infrastructural deficits, to break away from unsustainable lifestyles

and patterns of development and ensure that urban areas develop in ways that acknowledge that "natural capital and ecosystem services are not infinitely substitutable, and real limits exist" (Costanza et al 2013). This represents a significant opportunity to urbanise the adaptation agenda, and converge climate mitigation and adaptation actions within an understanding of a "full-world" context (Costanza et al 2013).

Prioritising poverty reduction within climate change responses: While cities like Boston and London consider low-income groups among the vulnerable groups in their planning (Boston 2011, GLA 2011) for most cities and smaller urban centres in low and middle-income nations, poverty reduction needs more attention because of its greater scale and depth and because of the strong association between poverty and poor environmental health (Hardoy et al. 2001), disaster risk (United Nations 2009) and climate change risks (Hardoy and Pandiella 2009). Given this and the pressing development needs in these urban centres (e.g. infrastructure, health care and emergency services, education, housing and energy), climate change adaptation needs are often viewed as marginal in comparison. There is therefore a need to work within the development context of each country and urban area (Kithiia and Dowling 2010, Roberts 2008a) and to demonstrate how adaptation can support development that is safe and cost effective (Kazmierczak and Carter 2010) and prioritises poverty reduction, disaster risk reduction and resilient service provision (Kithiia 2010, da Silva et al 2012).

*Reducing risk can provide a compelling vehicle for adaptation action (*see 8.3.2.2). This can occur by responding to existing challenges (for instance extreme weather events) and opportunities (for instance disaster risk reduction after a disaster that 'builds back better' - see Lyons 2009) in ways that enhance adaptive capacity (Kazmierczak and Carter, 2010, Solecki 2012). Experience to date on this is mixed. It is influenced by differences in risk perception and how successfully disaster risk reduction and adaptation become embedded within local development processes and the extent to which they address the structural causes of vulnerability(UN-Habitat 2010, Pelling 2011a, Roberts and O'Donoghue 2013). There is also a widespread assumption that sound urban development and the provision of basic services is sufficient to reduce risk to climate change, but there is a need to interrogate the effectiveness and limitations of current models of infrastructure and service provision. Adaptation can benefit from disaster risk reduction's more detailed, locally rooted analyses of risk and vulnerability and its recognition that most disasters are the result of a failure to identify problems and act. It can also benefit from multi-level government responses to disaster risk reduction that recognize the central role of local government and other local institutions but also the importance of supportive policies, institutions and legislation at higher levels of government. But disaster risk reduction is informed by analyses of past disasters,while adaptation also has to be informed by knowledge of new risks, vulnerabilities and uncertainties.

Incorporating ecosystem based adaptation: 8.3 noted how a growing number of cities are recognizing that biodiversity and ecological integrity can be used to protect people and the resources on which they depend. Ecosystem-based adaptation is regarded as one of the more cost effective and sustainable approaches to adaptation given what needs to be spent to manage and preserve ecosystems and the climate adaptation value derived from that spend (Nature Conservancy TNC 2009, Mees and Driessen, 2011, da Silva et al 2012, Brown et al 2012). But there are considerable knowledge gaps in determining the limits or thresholds to adaptation of various ecosystems and where and how ecosystem based adaptation is best integrated with other adaptation measures. There is also some indication that the costs of ecosystem based adaptation in urban contexts might be higher than expected, in large part because costs are higher for land acquisition and ecosystem management (Roberts et al 2012, Cartwright et al 2013).

Engaging all stakeholders and awareness raising: There is a need for dialogue and opportunities to advance the adaptation agenda through internal and external collaboration. These range from cross-cutting technical advisory groups often with sectoral or task group focal areas (Lowe et al. 2009, Parzen 2008, Boston 2011, City of New York 2011, Mees and Driessen, 2011, Solecki, 2012) to more broadly representative multi-stakeholder or multi-departmental groups with a core working group (Tyler et al. 2010, Roberts 2010, Brown et al. 2012, Boston 2010, Kazmierczak and Carter 2010, Anguelovski and Carmin 2011). Equally important is building public awareness and support for adaptation as transformation "neighborhood by neighborhood" (Foster et al. 2011, also Kazmierczak and Carter 2010). This is especially important where large sections of the population live and work in informal settlements and include a high proportion of those most at risk from climate change.

Institutional and social learning: For all urban centres, successful adaptation requires a learning organization that adapts to changing environmental factors and incorporates new data on a regular and flexible basis – producing an iterative process of learning about changing risks and opportunities and drawing in different stakeholders (Brown et al 2012). This is difficult to achieve with weak governmental structures, lack of funding and trained staff, where "decisions are delayed, correspondences lost in bureaucratic black-holes and ascription of responsibility is obfuscated" (Kithiia 2009, also Brown 2011). Social learning is also critical to ensure new ideas are popularized and commonly articulated in society (Pelling 2011a), translating stakeholder engagement into adaptation action.

The importance of mainstreaming climate change adaption requirements into municipal planning and land-use management systems: This chapter opened with an acknowledgement that local governments must provide the planning, management and regulatory frameworks to ensure that investments and actions by businesses and households contribute to adaptation (Kazmierczak and Carter 2010, Brown 2011, Mees and Driessen, 2011, Sussman et al., 2010). But this must avoid overloading already complex and inadequate planning systems (Kithiia 2010, Roberts 2008a) stressed by lack of information, institutional constraints and resource limitations with unrealistic new requirements. Mainstreaming adaptation ensures that limited financial resources are spent "with adaptation needs in mind" (Lowe et al. 2009) and fosters a move to a risk-based design for a range of future projected climate conditions. This can be enhanced by encouraging each sector to consider its need for and role in adaptation action. A sectoral approach makes the climate message easier for local governments and other stakeholders to understand and the associated responsibilities and actions clearer and simpler to identify and assign (Roberts 2010, UN-Habitat 2011a, Roberts and O'Donoghue 2013). As each sector in local government comes to understand its roles and responsibilities, so the basis for integration and cross-sectoral coordination is formed.

The importance of champions. Champions, regardless of their location or affiliation are important in driving successful adaptation action (Kazmierczak and Carter 2010). The role of local government champions has often proved critical in providing initial leadership (e.g. Sydney, Chicago, New York, Durban, London) and promoting and sustaining the adaptation agenda both at a sectoral level (e.g. Durban) and in buildingbroader institutional memory and purpose (e.g. Chicago, Toronto)(Lowe et al. 2009, Roberts 2008a, Parzen 2008, Rosenzweig and Solecki 2010, Shaw and Theobald 2011, Anguelovski and Carmin 2011, Carmin et. al. 2012, Mees and Driessen, 2011, Martins and Ferreira 2011, Roberts and O'Donoghue 2013). This may face a lack of continuityas champions change position orleave office. It is important to plan for this so that progress is not stalled or undermined. This can be helped by developing a broad base of support for adaptation across many sectors - within and outside government and other local stakeholders such as civil society groups or universities can help ensure continuity (Hardoy 2013).

The need for scientific support andan evidence base for adaptation action (Lowe et al*,* 2009, Roberts 2008a, Kazmierczak and Carter 2010, Horton et al 2011, Blake et. al, 2011, Moffet et al 2011):Despite growing attention, useful information and assessment of climate change at urban spatial scales is still lacking (Hunt and Watkiss 2011; Kehew 2009). Local governments need to access reliable, accurate, useable scientific data. Even where these are available, their staff often cannot utilize them because of the language gap between information producers (scientists) and information users (local decision makers) (Lowe et al. 2009, Opitz-Stapleton 2010). Practitioners often relymore on informal information sources and formats such as colleagues and the internet (Corfee-Morlot et al. 2011). Here, local risk assessments of existing hazards, challenges and vulnerabilities that could be exacerbated by climate change offer a useful alternative starting point and facilitate the creation of an appropriate evidence base (Tyler et al. 2010, Kazmierczak and Carter 2010). Collaboration and partnership with researchers and research institutes (especially those with local knowledge) (e.g. Durban,Chicago, Seattle, Manchester) can help each urban centre gainknowledge about climate impacts (Lowe et al. 2009, Kazmierczak and Carter 2010).

Catalytic role of multilateral and bilateral funding: While conventional multilateral development banks and bilateral agencies appear have the biggest role in adaptation financing (Ayers 2009), there is an emerging argument that finance for urban resilience and adaptation needs to respond to local demands, contexts and possibilities. This poses a challenge to conventional global finance mechanisms that work through national governments to determine which local actions are eligible for funding (ICLEI 2011a, Brugmann 2012). There is also evidence of substantial spend on adaptation from local and national governments in some nations (Kazmierczak and Carter 2010).

Phased approaches: A phased approach is more likely to attract local government attention (Foster et al. 2011, City of Copenhagen 2011, Boston 2011, Wajih et al. 2010, Solecki 2012). In each urban centre, this prioritizes the most urgent matters (usually rapid onset disasters) or near term climate impacts, leaving a longer time period to plan for those impacts that may occur in the future and be associated with greater uncertainty (including slow onset disasters). For slow-onset impacts, strategic forward planning is critical, and existing planning instruments such as land use planning may need to be altered to take changes in climatic stressors into account. Often the initial phases of action are made possible by the existence of previous or current environmental initiatives, or strong environmental traditions at the local level (Kazmierczak and Carter 2010).

Poorly developed Monitoring and Evaluation systems: Monitoring and evaluating the development and implementation of adaptation plans is still evolving (Jacob et al 2010) and not well developed or widely implemented in urban areas (Kazmierczak and Carter 2010). Work is required in this regard, but it is likely to be challenging given the localized nature of adaptation and hence the difficulty of standardizing performance requirements and measurements (Anguelovski and Carmin 2011).

Role of international institutions: The lack of skills and resources in local governments gives international institutions an important role in initiating and shaping the adaptation agenda. These international programmes are often the main form of institutional and financial support to mitigation and adaptation work at local level, although in some local governments internal motivations (e.g. perception of threat, city agendas, leadership, improving city image) (Anguelovski and Carmin, 2011, Carmin et. al. 2012, Kazmierczak and Carter 2010) appear equally influential. The danger of the donor driven model is that the funding agency's agenda may not coincide with local priorities, resulting in little lasting local ownership once support is withdrawn.

Local action involving all local stakeholders, addressing local issues, tapping local knowledge and other resources and respecting local limits is the key to transformative adaptation. Urban areas, because of their size, number, economic importance and social and environmental characteristics, are the geography where this has to happen. So they will have a critical role in the success or failure of the global adaptation project. Mobilising this local level capacity is challenging for international agencies. But if done in ways that are equitable and co-operative and that respect the limits of natural ecosystems, it has the potential to improve human well-being, maximize innovation and help define and implement development paths that converge in a more sustainable and low carbon future.

Frequently Asked Questions

FAQ 8.1: How does disaster risk reduction relate to climate change adaptation?

There is a long experience with urban governments implementing disaster risk reduction that is underpinned by locally-driven identification of key hazards, risks and vulnerabilities to disasters and that identifies what should be done to reduce or remove disaster risk. Its importance is that it encourages local governments to act before a disaster – for instance for risks from flooding, to reduce exposure and risk as well as being prepared for emergency responses prior to the flood (eg temporary evacuation from places at risk of flooding) and rapid response and building back afterwards. In some nations, national governments have set up legislative frameworks to strengthen and support local government capacities for this (see 8.3.2.2). This is a valuable foundation for assessing and acting on climate-change related hazards, risks and vulnerabilities, especially those linked to extreme weather. So urban governments with effective capacities for disaster risk reduction (with the needed integration of different sectors) provides an important component of adaptive capacity. But climate change adaptation needs to take account of how hazards, risks and vulnerabilities will or might change over time. Disaster risk reduction also covers disasters resulting from hazards not linked to climate or to climate change such as earthquakes.

FAQ 8.2: Doesn't good development produce urban adaptation?

Adaptation is well served by good quality infrastructure and services that reach all of an urban centre's population and the institutional capacity to provide, and manage these and expand them when needed. Poverty reduction can also support adaptation by increasing individual and household resilience to stresses and shocks and enhancing their capacities to adapt. These provides a foundation for building climate change resilience but additional knowledge,

resources, capacity and skills are generally required, especially to build resilience to changes beyond the ranges of what have been experienced in the past.

FAQ 8.3: Wouldn't urban problems be lessened by rural development?

The movement of rural dwellers to live and work in urban areas is mostly in response to the concentration of new investments and employment opportunities in urban areas. All high-income nations are predominantly urban and increasing urbanization levels are strongly associated with economic growth. Economic success brings an increasing proportion of GDP and of the workforce in industry and services, most of which are in urban areas. While rapid population growth in any urban centre provides major challenges for its local government, the need here is to develop the capacity of local governments to manage this with climate change adaptation in mind. Rural development and adaptation that protects rural dwellers and their livelihoods and resources has high importance as stressed in other chapters – but this will not necessarily slow migration flows to urban areas, although it will help limit rural disasters and those who move to urban areas in response to these.

FAQ 8.4: Shouldn't urban adaptation plans wait until there is more certainty about local climate change impacts?

More reliable, locally specific and downscaled projections of climate change impacts and tools for risk screening and management are needed. But local risk and vulnerability assessments that include attention to those risks that climate change will or may increase provide a basis for incorporating adaptation into development now, including supporting policy revisions and more effective emergency plans. In addition, much infrastructure and most buildings have a life of many decades so investments made now need to consider what changes in risks could take place during their lifetime. In addition, the incorporation of climate change adaptation into each urban centre's development planning and investments is well served by an iterative process within each locality of learning about changing risks and uncertainties that informs an assessment of policy options and decisions

Source: Derived from statistics in United Nations 2012.

Table 8-2: The large spectrum in the capacity of urban centres to adapt to climate change. One of the challenges for this chapter is to convey the very large differences in adaptive capacity between urban centres. There are tens of thousands of urban centres worldwide with very large and measureable differences between them in population, area, economic output, human development, ecological footprint and greenhouse gas emissions. The differences in adaptive capacity are far less easy to quantify. This Table seeks to illustrate differences in adaptive capacity and factors that influence it.

<table>
<tr><th>Indicator Clusters</th><th>Very little adaptive capacity or recovery/ 'bounce-back' capacity</th><th>Some adaptive capacity and recovery/ 'bounce-back' capacity</th><th>Adequate capacity for adaptation and recovery/ 'bounce-back' but needs to be acted on</th><th>Climate Resilience and capacity to bounce forward</th><th>Transformation</th></tr>
<tr><td>Population served with risk-reducing infrastructure (paved roads, storm and surface drainage, piped water ….) and services relevant to resilience (including health care, emergency services, policing/rule of law) and the institutions needed for such provision</td><td rowspan="2">0-30% of the urban centre's population served; most of those unserved or inadequately served living in informal settlements</td><td rowspan="2">30-80% of the urban centre's population served; most of those unserved or inadequately served living in informal settlements</td><td rowspan="2">80-100% of the urban centre's population served; most of those unserved or inadequately served living in informal settlements</td><td>Most/all of the urban centre's population with these and with an active adaptation policy identifying current and probable future risks and with an institutional structure to encourage and support action by all sectors and agencies. In many cities, also address and upgrade ageing infrastructure</td><td>Urban centres that have integrated their development and adaptation policies and investments within an understanding of the need for mitigation and limited ecological footprints</td></tr>
<tr><td>The proportion of the population living in legal housing built with permanent materials (meeting health and safety regulations)</td><td>Active programme to improve conditions, infrastructure and services to informal settlements; identify and act on areas with higher/increasing risks. Revise building standards.</td><td>Land use planning and management successfully providing safe land for housing, avoiding areas at risk and taking account of mitigation</td></tr>
<tr><td>Proportion of urban centres covered</td><td>Most urban centres in low-income and many in middle-income nations</td><td>Many urban centres in many low-income nations; most urban centres in most middle income nations</td><td>Virtually all urban centres in high-income nations, many in middle-income nations</td><td>A small proportion of cities in high-income and upper-middle income nations</td><td>A few innovative city governments thinking of this and taking some initial steps</td></tr>
<tr><td>Estimated inhabitants of such urban centres</td><td>One billion</td><td>1.5 billion</td><td>1 billion</td><td colspan="2">Very small</td></tr>
<tr><td>Infrastructure deficit</td><td colspan="3">Much of the built up area lacking infrastructure</td><td colspan="2">Most or all the built up area with infrastructure (paved roads, covered drains, piped water…..)</td></tr>
<tr><td>Local government investment capacity</td><td colspan="3">Very little or no local investment capacity</td><td colspan="2">Very substantial local investment capacity</td></tr>
<tr><td>Occurrence of disasters from extreme weather[1]</td><td colspan="3">Very common</td><td colspan="2">Uncommon (mostly due to risk-reducing infrastructure, services and good quality buildings available to almost all the population</td></tr>
</table>

[1] See text in regard to disasters and extensive risk (United Nations 2011)

Indicator Clusters	Very little adaptive capacity or recovery/ 'bounce-back' capacity	Some adaptive capacity and recovery/ 'bounce-back' capacity	Adequate capacity for adaptation and recovery/ 'bounce-back' but needs to be acted on	Climate Resilience and capacity to bounce forward	Transformation
Examples	Dar es Salaam; Dhaka	Nairobi, Mumbai	Cities in high-income nations	New York?; London? Manizales?	
Implications for climate change adaptation	Very limited capacity to adapt. Very large deficits in infrastructure and in institutional capacity. Very large numbers exposed to risk if these are also in locations with high levels of risk from climate change	Some capacity to adapt, especially if this can be combined with development but difficult to get city governments to act. Particular problems for those urban centres in locations with high levels of risk from climate change	Strong basis for adaptation but needs to be acted on and to influence city government	City government that is managing land-use changes as well as having adaptation integrated into all sectors	City government with capacity to influence and work with neighbouring local government units. Also with land-use changes managed to protect eco-system services and mitigation
NB: For cities that are made up of different local government areas, it would be possible to apply the above at an intra-city or intra-metropolitan scale. For instance, for many large Latin American, Asian and African cities, there are local government areas that would fit in each of the first three categories					

Table 8-3: The possibilities and limitations of focused activity for community groups on climate change coping and adaptation.

Capacity/Focus of Action	Coping (drawing on existing resources to reduce vulnerability, hazardousness and contain impacts from current and expected risk)	Adaptation (using existing resources and especially information to reorganize future asset profiles and entitlements to better position the household in the light of anticipated future risk, and to prepare for surprises)
Physical – buildings and critical community-level infrastructure	Often possible to improve these although tenants will have little motivation to do so	Amber; limits in how much risk reduction is possible within settlement
Physical – land and environment	Local hazard reduction through drain cleaning, slope stabilization etc is a common focus of community based action(although there are less incentives where the majority of residents are short-term tenants or threatened with eviction) (Green)	External input required to design local hazard reduction works in ways that will consider the impacts of climate change 20 years or more in the future (Amber)
Social – health, education	Many examples of community based action to improve local health and education access and outcomes, often with strong NGO and/or local government support (Green)	Health care and education are amenable to supporting adaptation by providing long-term investments in capacity building. They are rarely framed in climate change adaptation terms (Amber)
Economic – local livelihoods	Livelihoods routinely assessed as part of assessments of coping capacity in urban areas. More rarely is there a local livelihood focus for community based coping (Amber)	Livelihoods and wider economic entitlements are key to individual adaptive profiles, but are seldom considered as part of urban community based adaptation programmes (Red)
Institutional – community organization	Local community strengthening is a common goal of interventions aimed at building coping capacity. Risk mapping, early warning, risk awareness, community health promotion and shelter training are common foci increasingly applied to urban communities. Local savings groups may have important roles. Green	Local community strengthening is a core element of planning for adaptation but there are few assessments of the medium/long-term sustainability of outcomes. Where these have been undertaken close ties to wider civil society networks or supportive local government is evident for community organizations to persist Amber
Institutional – external influence	It is unusual for coping programmes to include an element of external advocacy aimed at changing policy or practices in local government. Amber	Despite being core to determining future adaptation there are very few examples of urban community based adaptation projects that include a targeted focus or parallel activity aimed at shifting priorities and practices in local government and beyond to support community capacity building Red

Key: green = many cases of activity, amber = few cases of activity, red = very few cases of activity

Table 8-4: Main sources of funding and financial instruments for urban adaptation.

Sources of funding	Types	Instruments	Examples of what can be funded	Urban capacity required to access funding
Local - public	Local revenue raising policies: Taxes, fees and charges, or use of local bond markets	♦ Local taxes (eg on property, land value capture, sales, businesses, personal income, vehicles….) ♦ User charges (eg water, sewers, public transport, refuse collection) ♦ Other charges or fees (eg parking, licenses)	♦ Urban infrastructure and services ♦ Urban adaptation programmes and planning processes ♦ Urban capacity building	♦ Cities with well-functioning administrative and institutional capacity and adequate funding from local revenue generation and inter-governmental transfers
Local – public-private	Public-Private-Partnerships (PPP) contracts and concessions	♦ Concessions and private finance initiatives (PFIs) to build, operate and/or maintain key infrastructure ♦ Energy performance contracting	♦ Medium to large-scale infrastructure with strong private goods (to allow rents for private sector)	♦ Cities with strong capacity for legal oversight and management
Local or national - Private or Public	National or local financial markets	♦ Commercial loans, ♦ Private bonds ♦ Municipal bonds	♦ Basic Physical Infrastructure (need for collateral)	♦ Well-functioning local or national financial markets that city governments can access
National - public	National (or state/provincial) revenue transfers or incentive mechanisms	♦ Revenue transfers from central or regional government ♦ PES or other incentive measures	♦ Urban Payment for Environmental Services in Brazil ♦ Sweden's KLIMP Climate Investment programme	♦ Cities with good relations with national governments, strong administrative capacity to design and implement policies and plans
International – private	Market-based investment	♦ Foreign Direct Investment, Joint Ventures	♦ Industrial infrastructure ♦ Power generation infrastructure	♦ Cities with strong national enabling conditions and policies for investment
International sources	Grants, concessional financing (e.g. Adaptation Fund)	♦ Grants, concessional loans and loan guarantees through bilateral and multilateral development assistance ♦ Philanthropic grants	♦ Urban capacity building ♦ Urban infrastructure adaptation planning	♦ Typically requires strong MLG – cities with good relations with national governments ♦ Cities with low levels of administrative and financial market capacity

Executive Summary

Rural areas still account for almost half the world's population, about 75% of the developing world's poor people and 80% of the world's hungry. [9.1.1] There is a lack of clear definition of what constitutes rural areas, and definitions that do exist depend on definitions of the urban. [9.1.2] Across the world, the importance of peri-urban areas and new forms of rural-urban interactions are increasing. [9.1.3] However, rural areas, seen as a dynamic, spatial category remain important for assessing the impacts of climate change and the prospects of adaptation. [9.1.1] A lack of focus on rural areas in policy making increases their vulnerability to climate change. [9.2]

Climate change in rural areas will take place in the context of many important economic, social and land-use trends *(very high confidence)*. In different regions, rural populations have peaked or will peak in the next few decades. [9.3.1] The proportion of the rural population depending on agriculture is extremely varied across regions, but declining everywhere. Poverty rates in rural areas are falling more sharply than overall poverty rates, and proportions of the total poor accounted for by rural people are also falling: in both cases with the exception of sub-Saharan Africa, where these rates are rising.

Rural people in developing countries are subject to multiple non-climate stressors, including under-investment in agriculture (though there are signs this is improving), problems with land policy, and processes of environmental degradation *(high to very high confidence)*. Hunger and malnutrition remain prevalent among rural children in South Asia and Sub-Saharan Africa. In developing countries,the levels and distribution of rural policies are affected in complex and interacting ways by processes of commercialisation and diversification, food policies, and policies on land tenure. In industrialized countries, there are important shifts towards multiple uses of rural areas, especially leisure uses, and new rural policies based on the collaboration of multiple stakeholders, the targeting of multiple sectors and a change from subsidy-based to investment-based policy. [9.3.1, Table 9-1]

Prevailing development constraints, such as low levels of educational attainment, environmental degradation and gender inequality create additional vulnerabilities to climate change [9.4.4] *(high confidence)*. There are low levels of agreement on some of the key factors associated with vulnerability or resilience in rural areas [9.3.5.2], including rainfed as opposed to irrigated agriculture [9.3.5.2.1], small-scale and family-managed farms [9.3.5.2.2], and integration into world markets. [9.3.5.2.4]. There is greater agreement on the importance for resilience of access to land and natural resources [9.3.5.2.5], flexible local institutions [9.3.5.2.6], and knowledge and information [9.3.5.2.7], and the association of gender inequalities with vulnerability. [9.3.5.2.9]. Specific livelihood niches such as pastoralism, mountain farming systems, and artisanal fisheries are vulnerable and at high risk of adverse impacts

(medium to high confidence), partly due to neglect, misunderstanding or inappropriate policy towards them on the part of governments.

Cases in the literature of observed impacts on rural areas often suffer from methodological problems of attribution, but evidence for observed impacts, both of extreme events and other categories, is increasing. [9.3.2] *(medium confidence).* Impacts attributable to climate change include declining yields of major crops, extreme events such as droughts and storms, and geographically-specific impacts such as glacier melt in the Andes.

Future impacts of climate change on the rural economic base and livelihoods, land-use and regional interconnections are at the latter stages of complex causal chains *(high confidence).* These flow through changing patterns of extreme events and/or effects of climate change on biophysical processes in agriculture and less-managed ecosystems. This increases the uncertainty associated with any particular projected impact. [9.3.3]

Major impacts of climate change in rural areas will be felt through impacts on water supply, food security [9.3.3.1] and agricultural incomes. [9.3.4.1] *(high confidence).* In certain countries shifts in agricultural production, of food and non-food crops, could take place. [9.3.3.1] Price rises, which may be induced by climate shocks apart from other factors [9.3.3.3.2], have a disproportionate impact on the welfare of the poor in rural areas, such as female headed households and those with limited access to modern agricultural inputs, infrastructure and education. [9.3.3.1]

Climate change will lead to higher prices and increased volatility in agricultural markets, which might undermine global food supply security while affecting rural households depending on whether they are net-buyers or net-sellers of food. [9.3.3.3] (*medium to high confidence).* There is medium level agreement that deepening agricultural markets through trade reform and institutional efforts to improve the predictability and the reliability of the world trading system as well as by investing in additional supply capacity of small-scale farms in developing countries could help reduce market volatility and manage food supply shortages which might be caused by climate change [9.3.3.3.2]

Migration patterns will be driven by multiple factors of which climate change is only one [9.3.3.3.1] *(high confidence).*Given these multiple drivers of migration and the complex interactions which mediate migratory decision-making by individual or households, the detection of the effects of climate change on intra-rural and rural-to-urban migration remains a major challenge.

Climate policies, such as encouraging cultivation of biofuels, and payments under REDD, will have significant secondary impacts on land-use, and resulting negative impact on livelihoods, in some rural areas. [9.3.3.4] *(medium confidence).* These secondary impacts, and trade-offs between mitigation and adaptation in rural areas, have implications for governance.

Most studies on valuation highlight that climate change impacts will be significant especially for the developing regions, due to their economic dependence on agriculture and natural resources, low adaptive capacities, and geographical locations. [9.3.4] *(high confidence).* Valuation of climate impacts needs to draw upon both monetary and non-monetary indicators. The valuation of non-marketed ecosystem services [9.3.4.6] and the limitations of economic valuation models which aggregate across multiple contexts [9.3.4] pose challenges for valuing impacts in rural areas.

There is a growing body of literature on successful adaptation in rural areas, including documentation of practical experience [9.4.3]. Gender, the supply of information for decision-making, and the role of social capital in building resilience, are all key issues. [9.4.1] Constraints to adaptation come from lack of access to credit, land, water, technology, markets and information; and are particularly pronounced in developing countries. [9.4.4] *(high confidence)*

9.1. Introduction

9.1.1. Rationale for the Chapter

Rural areas, even after significant demographic shifts, still account for 3.3 billion people or almost half (47.9%) of the world's total population (UN-DESA Population Division 2012). The proportion of people in developing countries living in rural areas is higher than the global average, with 71.5% of the population (or about 608 million people) living in rural areas in the least developed countries, and 50.3% of the population (or about 2.5 billion people) living in rural areas in other less developed countries (excluding LDCs), – compared to only 22.3% of the population (or about 276 million people) in more developed countries.

The overwhelming majority of the world's rural population (3.1 billion people, or 91.7% of the world's rural population, or 44.0% of the world's total population) live in rural areas in less developed or least developed countries. Rural dwellers also account for about 75% of the developing world's poor people (Ravaillon *et al.*, 2007) and 80% of the world's hungry (UNDP, 2005). At the same time, changes in land-use and livelihoods in rural areas make it less straightforward to link rural areas with agriculture or food production. Given the association of climate vulnerability with poverty and food insecurity, and the number of people living in rural areas in developing countries, these areas are significant sites for vulnerability to climate change. Much of the literature reviewed in this chapter therefore reflects these conditions, in which rural development issues (especially in developing countries) are closely intertwined with the physical impacts of climate change and the vulnerability of rural populations.

The Fourth Assessment Report (AR4) of the IPCC contains no specific chapter on "rural areas". Material on rural areas and rural people is found throughout the AR4, but rural areas are approached from specific viewpoints and through specific disciplines. Agriculture and food production, the impacts of which are assessed by Easterling *et al.* (2007), clearly take place mainly in rural areas, but that chapter was not able to cover impacts on other human activities taking place in rural areas or of significance to rural people. Many rural people follow livelihoods directly dependent on unmanaged or less-managed ecosystems, such as forests. However, the AR4 chapter on ecosystems (Fischlin *et al.*, 2007) was not able to cover the indirect impacts of ecosystem change on such livelihoods. The chapter on industry, settlement and society (Wilbanks *et al.*, 2007) reaches important conclusions about specific vulnerabilities of both urban and rural systems to climate change, but much of the literature reviewed and the most important conclusions, on high-density settlements, industry and infrastructure, are implicitly concerned with urban areas.

This chapter, under the general heading of "Human Settlements, Industry, and Infrastructure" assesses the impacts of climate change on, and the prospects for adaptation in, rural areas, seen as diverse patterns of settlement, infrastructure and livelihoods, in complex relations of interdependence with urban areas. Some of the key considerations will be as follows.

- Rural areas are largely defined in contradistinction to urban areas, but that distinction is increasingly seen as problematic.
- Rural areas are a spatial category, associated with certain patterns of human activity, but with those associations being subject to continuous change.
- Rural populations have, and will have, a variety of income sources and occupations, within which agriculture and the exploitation of natural resources have privileged but not necessarily predominant positions.
- Rural areas suffer from specific vulnerabilities to climate change, both through their dependence on natural resources and weather-dependent activities, and through their relative lack of access to information, decision-making, investment and services. Adaptation strategies will need to address these vulnerabilities.

The chapter will complement the treatment of issues also dealt with in Chapter 7 "Food Production Systems and Food Security" and Chapter 4 "Terrestrial and Inland Water Systems", but will primarily look at how biophysical impacts of climate change on agriculture and on less-managed ecosystems translate into impacts on human systems (and in this regard will complement sections of Chapter 12 "Human Security"). It will also address issues dealt with in Chapter 12 "Human Security" and Chapter 13 "Poverty and Livelihoods", but primarily from the point of view of

rural areas as spatial categories with particular characteristics. It will also draw out rural implications of climate change in different regions as covered in chapters 23-29.

9.1.2. Definitions of the Rural

"Rural" and "rural areas", in both policy-oriented and scholarly literature are terms often taken for granted or left undefined, in a process of definition that is often fraught with difficulties (IFAD 2010). Ultimately, however, in developing countries as well as developed countries, the rural is defined as the inverse or the residual of the urban (Lerner and Eakin, 2010). Human settlements in fact exist along a continuum from 'rural' to 'urban', with 'large villages', 'small towns' and 'small urban centres' not clearly fitting into one or the other. The populations of these ambiguous settlements tends to range from a few hundred to approximately 20,000 inhabitants, with 20 to 40 percent of the population in many nations living in settlements in this category (Satterthwaite, 2006). The variations in definitions from country-to-country can best be described through several examples (from both developed and developing countries of different sizes):

- In Australia, "major urban areas" are defined as having a population of 100,000 and over; while "other urban areas" have a population of 1,000 to 99,999. "Rural areas" included small towns with a population of 200 to 999. (Australian Bureau of Statistics n.d.).
- In India, urban areas are defined essentially as those with populations of 5,000 or more, or where at least 75% of the male working population is non-agricultural, or having a density of population of at least 400 people per km^2 (Government of India, 2012).
- In Jamaica, a place is considered to be urban if it has a population of more than 2,000 people and provides a certain set of amenities and facilities that are deemed to indicate "modern living" (Statistical Institute of Jamaica, 2012).
- In the United States, rural areas are defined by the Bureau of the Census as consisting of all territory outside of defined urbanized areas and urban clusters, that is open country and settlements with fewer than 2,500 residents. Such areas can in practice have population densities as high as 999 persons per square mile (386 persons/km^2) (Womach, 2005).

Definitions of the rural are therefore variable between countries, recognized as problematic, and subject to various attempts at refinement and sub-classification. While remaining aware of these issues, this chapter will in general assess literature on current trends in rural areas, and on climate impacts, adaptation and vulnerability, using whatever definitions of the rural are used in that literature.

9.1.3. Between 'Rural' and 'Urban': the Peri-Urban Interface

Authors have increasingly recognized that the simple dichotomy between 'rural' and 'urban' has "long ceased to have much meaning in practice or for policy-making purposes in many parts of the global South" (Simon *et al.*, 2006:4). One approach to reconciling this is through the increasing application of the concept of "peri-urban areas" (Simon *et al.*, 2006; Simon, 2008). These areas can be seen as rural locations that have "become more urban in character" (Webster 2002: 5); as sites where households pursue a wider range of income-generating activities while still residing in what appear to be "largely rural landscapes" (Learner and Eakin 2010: 1); or as locations in which rural and urban land uses coexist, whether in contiguous or fragmented units (Bowyer-Bower, 2006). A more elaborate conceptualization is offered by the Bahasa Indonesian term *desakota*, which is used in academic literature to incorporate arecognition of the diversified economic systems that exist across the urban-rural spectrum, and the closely interlinked, co-penetrating rural/urban livelihoods, communication, transport and economic systems (Desakota Study Team 2008; McGee 1991; Moench and Gyawali 2008).

Peri-urban or *desakota* systems therefore incorporate a change in the type of relationships between human society and ecosystems, and create shifts in the geographical and social distribution of risk and vulnerability (Pelling and Mustafa, 2010). The characteristics of these regions can both increase and decrease disaster and climate risk, and can pose both opportunities and challenges for disaster response and reconstruction (Pelling and Mustafa, 2010). Increased transport connectivity in peri-urban areas can reduce disaster risk by providing a greater diversity of

livelihood options and improving access to education – but can also encourage land expropriation to enable commercial development (hence increasing vulnerability of those who are made landless). Similarly, the expansion of local labour markets and wage labour in these areas can strengthen adaptive capacity through providing new livelihood opportunities – but can simultaneously increase disaster risk as reliance on wage labour can increase dependence on the external economy and exposure to systemic shocks (Pelling and Mustafa, 2010: 7, Figure 2).

While there have been some assessments of "land degradation" and "sustainability" in peri-urban areas (e.g. Allen, 2006; Diaz-Chavez, 2006; Gough and Yankson, 2006; Binns and Maconachie, 2006), these have not yet focused on how these areas will be affected by climate change, or how the process of peri-urbanization will shape vulnerability or resilience. However, ecosystem services are particularly important in these areas, and environmental degradation – again, including the impacts of climate change (Desakota Study Team, 2008) – will influence ecosystems services and their role as a foundation for livelihood systems across developing countries in these systems, with particularly important consequences for the poor.

9.2. Findings of Recent Assessments

Table 9-1 summarises key findings on rural areas from AR4 (particularly Easterling *et al*., 2007 on agriculture, Wilbanks *et al*., 2007 on industry, settlement and society, and Klein *et al*. 2007 on links between adaptation and mitigation), and relevant findings from the International Assessment of Agricultural Knowledge, Science and Technology for Development (McIntyre, 2009). All these sources stress uncertainty, the importance of non-climate trends, complexity and context-specificity, in any findings on rural areas and climate change.

[INSERT TABLE 9-1 HERE

9.3. Assessing Impacts, Vulnerabilities, and Risks

9.3.1. Current and Future Economic, Social, and Land-Use Trends in Rural Areas

Climate change in rural areas will take place against the background of the trends in demography, economics and governance which are shaping those areas. While there are major points of contact between the important trends in developing and industrialized countries, and the analytical approaches used to discuss them, it is easier to discuss trends separately for the two groups of countries.In particular there is a close association in developing countries between rural areas and poverty. Table 9-2 summarizes and compares the most important trends across the two groups of countries. Figure 9-1, Table 9-3, and Figure 9-2 focus on two specific trends in developing countries: demographic trends and trends in poverty indicators.

[INSERT TABLE 9-2 HERE

9.3.2. Observed Impacts

Documentation of observed impacts of climate change on rural areas involves major questions of detection and attribution. Much discussion of vulnerability and adaptive capacity in rural areas, especially work based on qualitative fieldwork at community level, reports local perceptions of climate change, or uses local meteorological data without systematic attempts to distinguish between decadal trends and manifestations of anthropogenic climate change (see for example chapters in Ensor and Berger, 2009, and Castro *et al*., 2012). Similarly, impacts, vulnerability and adaptive capacity are frequently discussed in the context of extreme events, and perceived increases in their frequency, without systematic discussion of the difficulties of attributing extreme events to anthropogenic climate change (see Paavola, 2008 as an example). Exposure to non-climate trends and shocks further complicate the issue (Nielsen and Reenberg, 2010). Warner and van der Geest (submitted), use the UNFCC terminology of "loss and damage" for evidence of observed impacts of changes in monsoon patterns, drought, flooding, coastal erosion and saline intrusion on rural livelihoods in nine countries in Africa, Asia and the Pacific, but specify that the research methods employed do not allow attribution of climatic stressors to underlying causes such as anthropogenic climate change. Box 18-4 of this report discusses the considerable potential of using Traditional Ecological Knowledge to detect climate trends, but also the difficulties of using it to attribute trends to anthropogenic climate change. Implied equivalence between perceptions, local decadal trends and global change is not a problem in the context of detailed social-scientific analysis of vulnerability, adaptive capacity and their determinants, but becomes more problematic if such work is implied to be evidence for observed impact.

The impacts of climate change on patterns of settlement, livelihoods and incomes in rural areas will be the result of multi-step causal chains of impact. Typically, those chains will be of two sorts. One sort will involve extreme events, such as floods and storms, as they impact on rural infrastructure and cause direct loss of life. The other sort will involve impacts on agriculture or on ecosystems on which rural people depend. These impacts may themselves stem from extreme events, from changing patterns of extremes due to climate change, or from changes in mean conditions. The detection and attribution of extreme events is discussed by by the IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (IPCC 2012, Seneviratne *et al.,* 2012). The detection and attribution of impacts on ecosystems and on agriculture are dealt with in Chapters 4 and 7 of this report. Both exercises are complex.

Seneviratne *et al*. (2012) give a detailed and critical assessment of the detection and attribution of observed patterns of extreme events, which shows greatly varying levels of confidence in the attribution to climate change of global and regional trends. For example they state that it is *likely* there has been a worldwide increase in extreme high-water events during the late 20th century, and it is *likely* that there has been an anthropogenic influence on this. They have *medium confidence* in detecting trends towards more intense and frequent droughts in some parts of the world (Southern Europe and West Africa) since 1950. They note that opposite trends exist elsewhere, and that there is *low confidence* in any trend in drought in, for example, East Africa, although other authors, such as Lyon and DeWitt (2012) see a "recent and abrupt decline in the East African long rains" since 1999. Seneviratne *et al*. (2012) assign *low confidence* to any observed long-term increases in tropical cyclone activity, or attribution of any changes in cyclone activity to anthropogenic influence. They state that "attribution of single extreme events to anthropogenic climate change is challenging" (2012:112).

Handmer *et al*., (2012) discuss both observed and projected impacts of extreme events on human systems and ecosystems. Numerous examples are given of observed impacts of extreme events – especially heatwaves, droughts and floods – on water, ecosystems, and agriculture (particularly smallscale farming), though these are not explicitly attributed to climate change. The impacts of droughts on African agriculture in recent decades are noted. Significant impacts on settlement, infrastructure and tourism are discussed, though the major focus is on urban areas.
