Table 5-1: Main climate-related drivers for coastal systems, their trends due to climate change, and their main physical and ecosystem effects.

Climate-related Driver	Physical/chemical effects	Trends	Projections	Progress since AR4
Sea Level	Submergence, flood damage, erosion; saltwater intrusion; rising water tables/impeded drainage; wetland loss (and change).	GMSL very likely increase (5.3.2.2, AR5 WG1 Ch 3.7.2, 3.7.3;)	GMSL very likely increase (see Table 5.1, WG1 Ch. 13.5.1) Regional variability (5.3.2.2, WG1 Ch. 13)	Improved confidence in contributions to observed sea level. More information on regional and local SLR.
Storms (Tropical cyclones (TC's), extratropical cyclones (ETC's)	Storm surges and storm waves, coastal flooding, erosion; saltwater intrusion; rising water tables/impeded drainage; wetland loss (and change). Coastal infrastructure damage and flood defense failure.	TC's (Box 5.1, WG1 2.6.3) Low confidence in trends in frequency and intensity due to limitations in observations and regional variability ETC's (5.3.3.1 AR5 WG1 2.6.4) Likely poleward movement of circulation features but low confidence in intensity changes.	TC's (Box 5.1) Likely decrease to no change in frequency; Likely increase in the most intense TC's ETC's (5.3.3.1) High confidence that reduction of ETC's will be small globally. Low confidence in changes in intensity.	Lowering of confidence of observed trends in TC's and ETC's since AR4. More basin-specific information on storm track changes.
Winds	Wind waves, storm surges, coastal currents, land coastal infrastructure damage.	Low confidence in trends in mean and extreme wind speeds (5.3.3.2, SREX, WG1 Ch 3.4.5).	Low confidence in projected mean wind speeds. Likely increase in TC extreme wind speeds (5.3.3.2, SREX).	Winds not specifically addressed in AR4.
Waves	Coastal erosion, overtopping and coastal flooding.	Likely positive trends in Hs in high latitudes (5.3.3.2, WG1, Ch 3.4.5).	Low confidence for projections overall but medium confidence for southern ocean increases in Hs (5.3.3.2).	Large increase in number of wave projection studies since AR4.
Extreme Sea Levels	Coastal flooding erosion, saltwater intrusion	High confidence of increase due to GMSL rise (5.3.3.3, WG1 Chapter 13).	High confidence of increase due to GMSL rise, low confidence of changes due to storm changes (5.3.3.3, AR5 WG1 Ch13.5)	Local subsidence is an important contribution to RSL rise in many locations.

Sea Surface Temperature	Changes to stratification and circulation; reduced incidence of sea ice at higher latitudes; increased coral bleaching and mortality, poleward species migration; increased algal blooms.	High confidence that coastal SST increase is higher than global SST increase. (5.3.3.4,).	High confidence that coastal SSTs will increase with projected temperature increase (5.3.3.4).	Emerging information on coastal changes in SSTs.
Freshwater Input	Altered flood risk in coastal lowlands; altered water quality/salinity; altered fluvial sediment supply; altered circulation and nutrient supply.	Medium confidence (*limited evidence*) in a net declining trend in annual volume of freshwater input (5.3.3.6).	Medium confidence for general increase in high latitudes and wet tropics and decrease in other tropical regions (5.3.3.6).	Emerging information on freshwater input.
Ocean Acidity	Increased CO2 fertilisation; decreased seawater pH and carbonate ion concentration (or ‘ocean acidification’)	High confidence of overall increase, with high local and regional variability (5.3.3.5).	High confidence of increase at unprecedented rates but with local and regional variability (Box CC-OA).	Coastal ocean acidification not specifically addressed in AR4. Considerable progress made in chemical projections and biological impacts.

Table 5-2: Projections of global mean sea level rise in meters relative to 1986–2005 are based on ocean thermal expansion calculated from climate models, the contributions from glaciers, Greenland and Antarctica from surface mass balance calculations using climate model temperature projections, the range of the contribution from Greenland and Antarctica due to dynamical processes, and the terrestrial contribution to sea levels, estimated from available studies. For sea levels up to and including 2100, the central values and the 5-95% range are given whereas for projections from 2200 onwards, the range represents the model spread due to the small number of model projections available. Source: WGI AR5 SPM and Sections 12.4.1, 13.5.1, and 13.5.4.

	RCP	**2100 CO_2 Concentration (ppm)**	**Temperature increase (C)**	**Mean Sea Level Rise (m)**				
			2081-2100	2046–2065	2100	2200	2300	2500
Low	2.6	421	1.0 [0.3 to1.7]	0.24 [0.17 to 0.31]	0.43 [0.28 to .60]	0.35–0.72	0.41–0.85	0.50–1.02
Medium	4.5	538	1.8 [1.1 to 2.6]	0.26 [0.19 to 0.33]	0.52 [0.35 to .70]	0.26–1.09	0.27–1.51	0.18–2.32
High	6.0	670	2.2 [1.4 to 3.1]	0.25 [0.18 to 0.32]	0.54 [0.37 to .72]			
	8.5	936	3.7 [2.6 to 4.8]	0.29 [0.22 to 0.37]	0.73 [0.53 to .97]	0.67–1.92	0.92–3.59	1.51–6.63

Table 5-3: Main impacts of relative sea level rise. Source: Adapted from Nicholls et al., 2010.

Biophysical impacts of relative sea level rise	**Other climate-related drivers**	**Other human drivers**
Dryland loss due to erosion	Sediment supply, wave and storm climate	Activities altering sediment supply (e.g., sand mining)
Dryland loss due to submergence	Wave and storm climate, morphological change, sediment supply	Sediment supply, flood management, morphological change, land claim
Wetland loss and change	Sediment supply, CO_2 fertilization,	Sediment supply, migration space, direct destruction
Increased flood damage through extreme sea level events (storm surges, tropical cyclones, etc.)	Wave and storm climate, morphological change, sediment supply	Sediment supply, flood management, morphological change, land claim
Saltwater intrusion into surface waters (backwater effect)	Runoff	Catchment management and land use (e.g., sand mining and dretching)
Saltwater intrusion into ground waters leading to rising water tables and impeded drainage	Precipitation	Land use, aquifer use

Table 5-4: Community-based adaptation measures.

Impact	Type of option	Measures	Brief description	References
Salinity	New and diversified livelihoods	Saline-tolerant crop cultivation	Farmer production of saline-tolerant multi-vegetable varieties and non-rice crops.	Rabbani *et al.* 2013; Ahmed 2010
	New and diversified livelihoods	Keora nursery	Mangrove fruit production to develop local female entrepreneurship.	Ahmed 2010
	New and diversified livelihoods	Crab fattening	Collection, rearing and feeding of crabs for 15 days to increase local market value.	Pouliotte *et al.* 2009

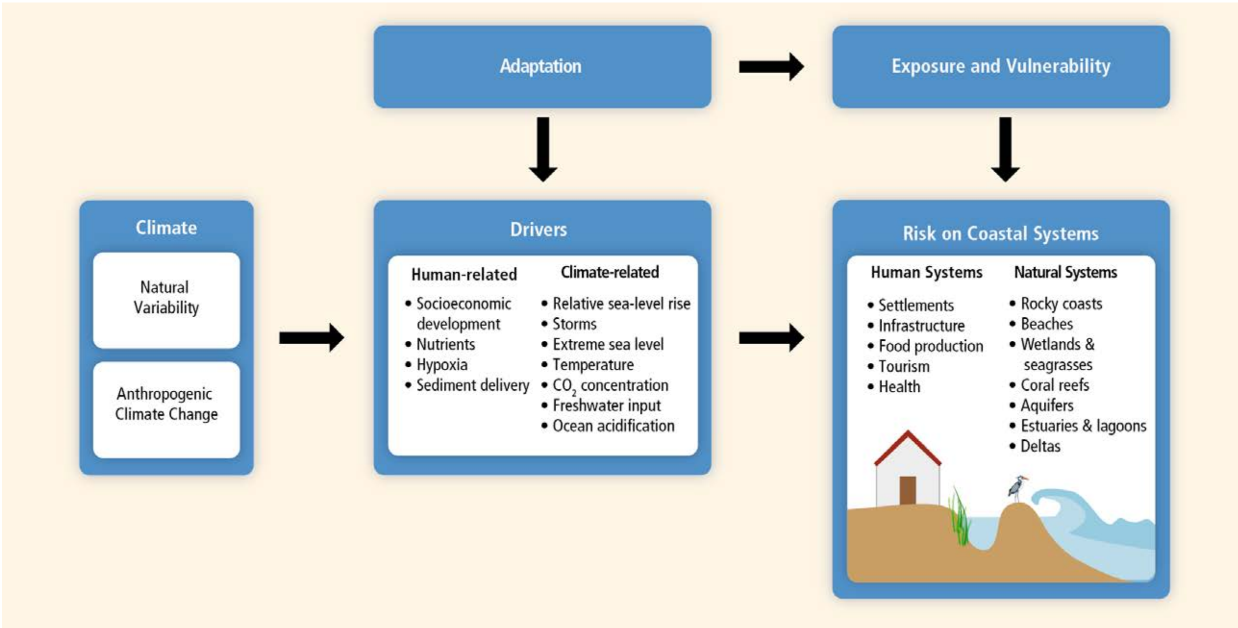

Figure 5-1: Climate, just as anthropogenic or natural changes, affects both climate and human related drivers. Risk on coastal systems is the outcome of integrating drivers and exposure and vulnerability. Adaptation options can be implemented either to modify the drivers or exposure and vulnerability or both.

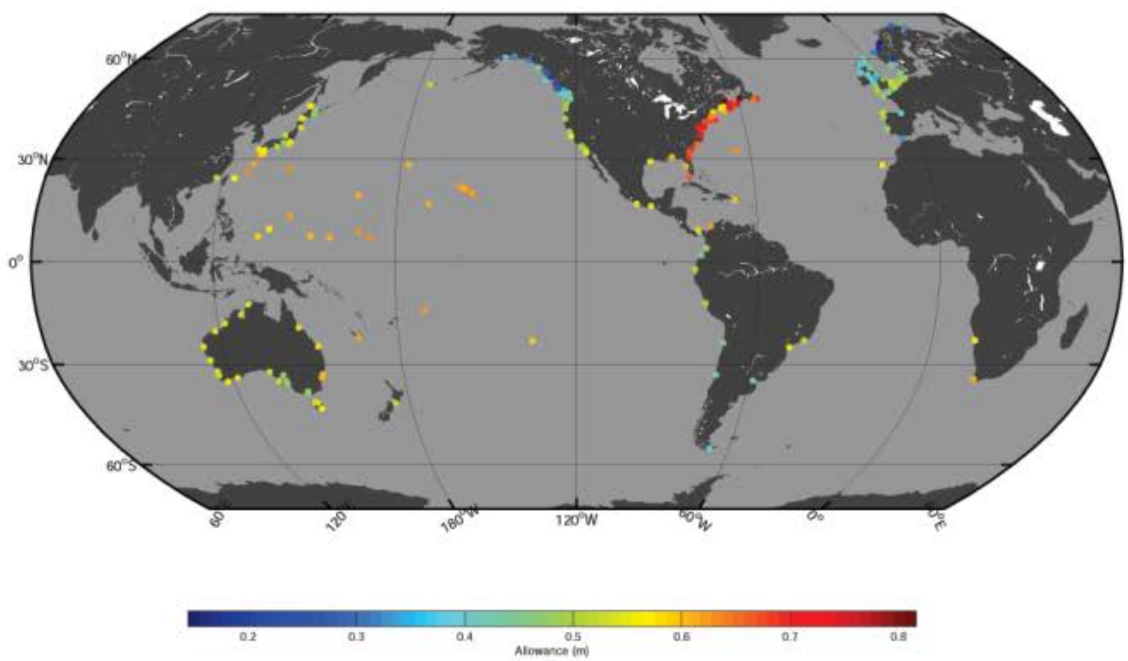

Figure 5-2: The estimated increase in height (m) that flood protection structures would need to be raised in the 2081-2100 period to preserve the same frequency of exceedences that was experienced for the 1986-2005 period, shown for 182 tide gauge locations and assuming regionally-varying relative sea level rise projections under an RCP4.5 scenario (adapted from Hunter *et al*., 2013).

[Illustration to be redrawn to conform to IPCC publication specifications.]

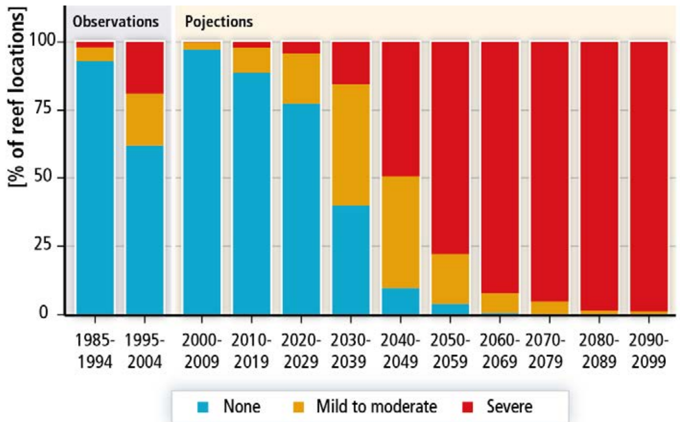

Figure 5-3: Percent of reef locations (1°x1° grid cells which have at least one reef) that experience no bleaching, at least one mild bleaching event, or at least one severe bleaching event for each decade. Observed bleaching events are summarized from the ReefBase dataset (Kleypas *et al.*, 2008). In the observations, some of the "no bleaching" cells may have experienced bleaching but it was either not observed or not reported. Modeled bleaching events are averages of data from four ensemble runs of the Community Climate System Model version 3 using the SRES A1B CO_2 scenario and the standard degree heating month formula (Teneva *et al.*, 2011). The labels of values ≤ 1% are not shown.

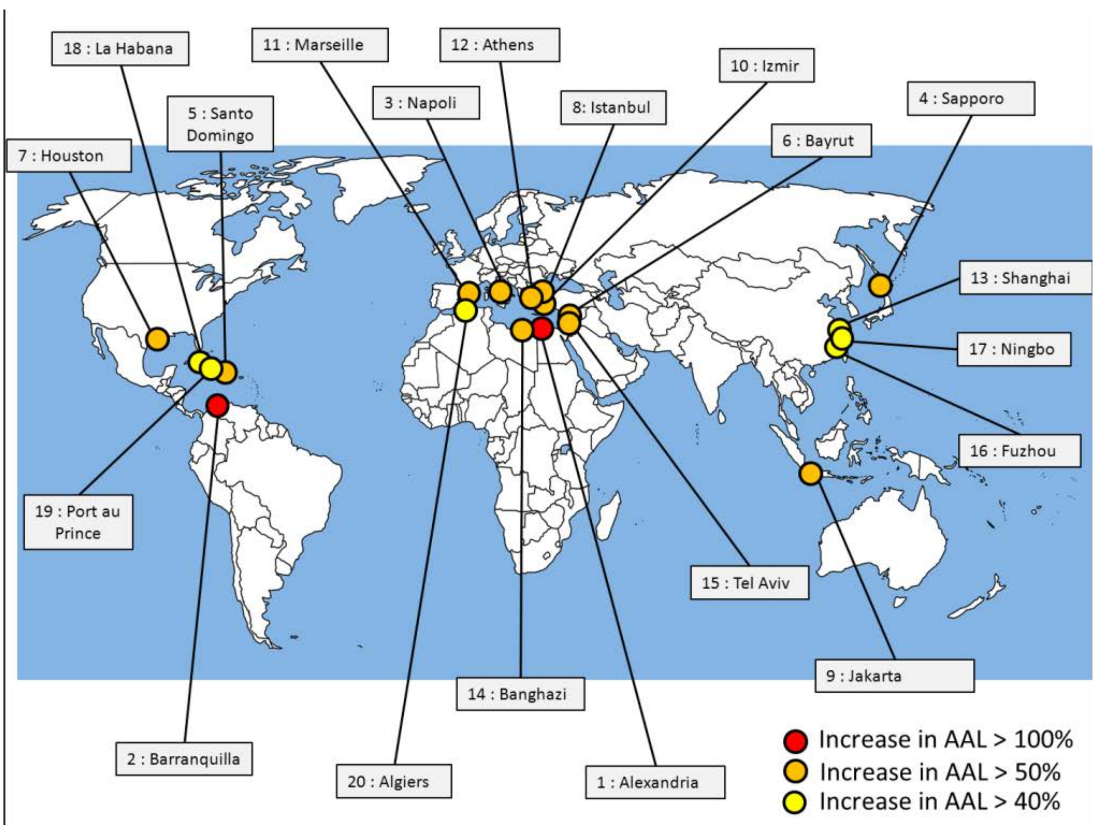

Figure 5-4: The 20 cities where average annual losses (AAL) increase most (in relative terms in 2050 compared with 2005) in the case of optimistic sea level rise, if adaptation maintains only current defense standards or flood probability (PD). Source: Hallegatte *et al*., 2013.

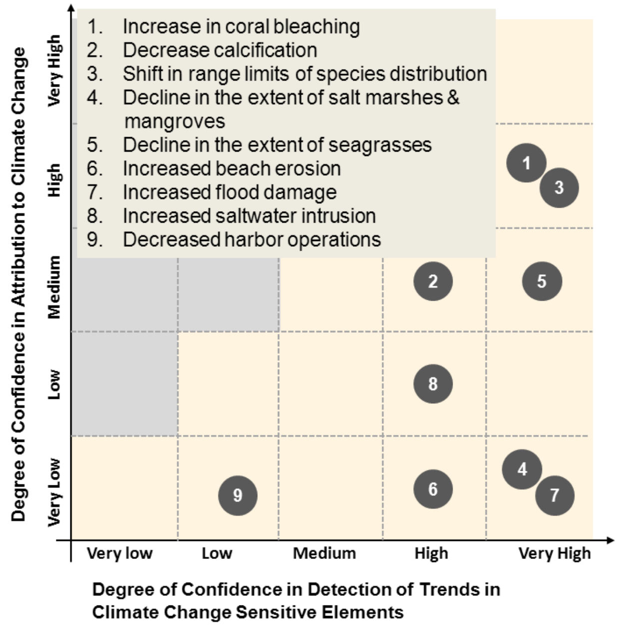

Figure 5-5: Summary on detection and attribution in coastal areas.
[Illustration to be redrawn to conform to IPCC publication specifications.]

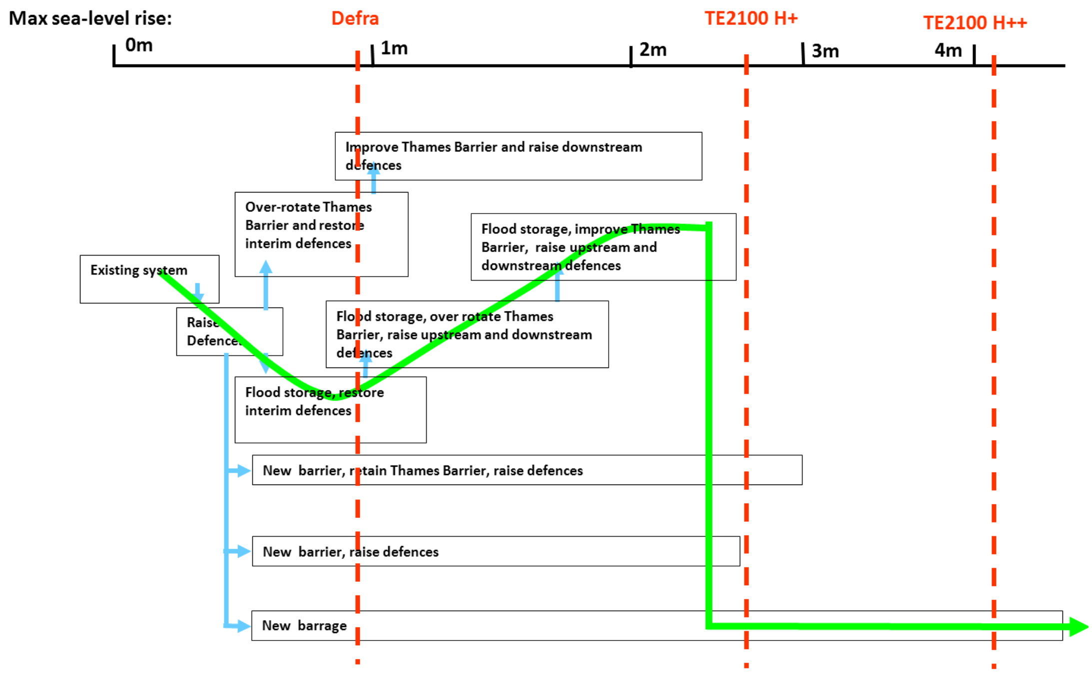

Figure 5-6: Adaptation measures and pathways considered in the TE2100 project. The boxes show the measures and the range of sea level rise over which the measures are effective. The blue arrows link to alternative measures that may be applied once a measure is no longer effective. The red lines show the various 21st century sea level rise scenarios used in the analysis including a conservative estimate of about 0.9 m by the UK Department for Environment Food and Rural Affairs (Defra), a high-level scenario of 2.6 m (H+) and an extreme scenario of over 4 meters (H++). The fat green line shows a possible future adaptation pathway that allows for lower-end sea level rises but also for the unlikely event of extreme change.
[Illustration to be redrawn to conform to IPCC publication specifications.]

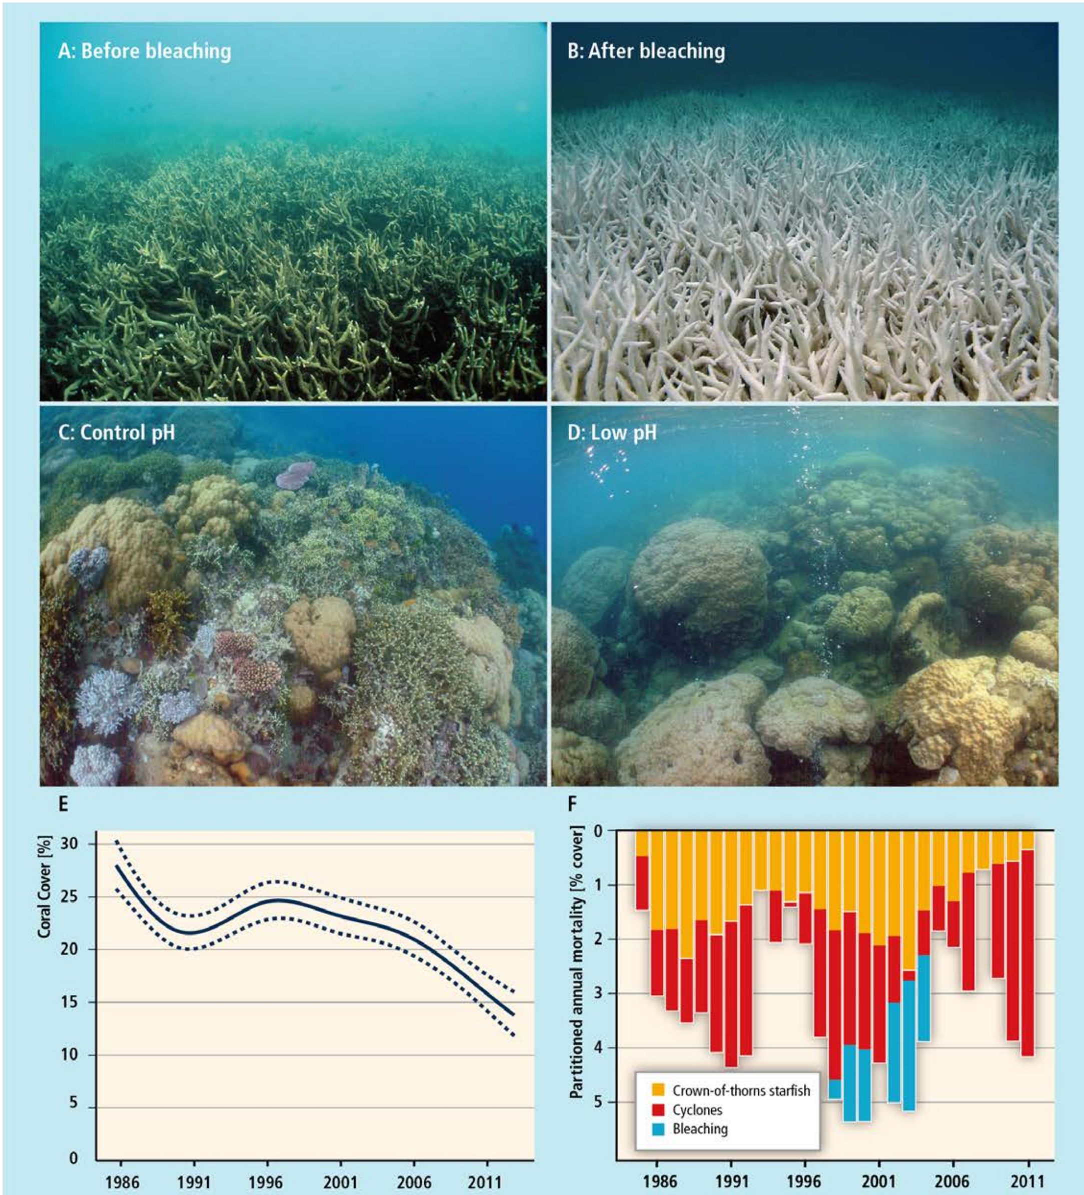

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge *et al*., 2004). Mortality was comparatively low due in part because these coral communities were able to shuffle their symbiont to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones *et al*., 2008). C and D: three CO_2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO_2 is related to fundamental changes in the ecology of coral reefs (Fabricius *et al*., 2011), including reduced coral diversity (-39%), severely reduced structural complexity (-67%), lower density of young corals (-66%) and fewer crustose coralline algae (-85%). At high CO_2 sites (panel D; median pH_T ~7.8), reefs are dominated by massive corals while corals with high morphological complexity are underrepresented compared with control sites (D; median pH ~8.0). Reef development ceases at pH_T values below 7.7. pH_T: pH on the total scale. E: temporal trend in coral cover for the whole Great Barrier Reef over the period 1985–2012 (N, number of reefs, mean ± 2 standard errors; De'ath et al., 2012). F: composite bars indicate the estimated mean coral mortality for each year, and the sub-bars indicate the relative mortality due to crown-of-thorns starfish, cyclones, and bleaching for the whole Great Barrier Reef (De'ath et al., 2012). Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

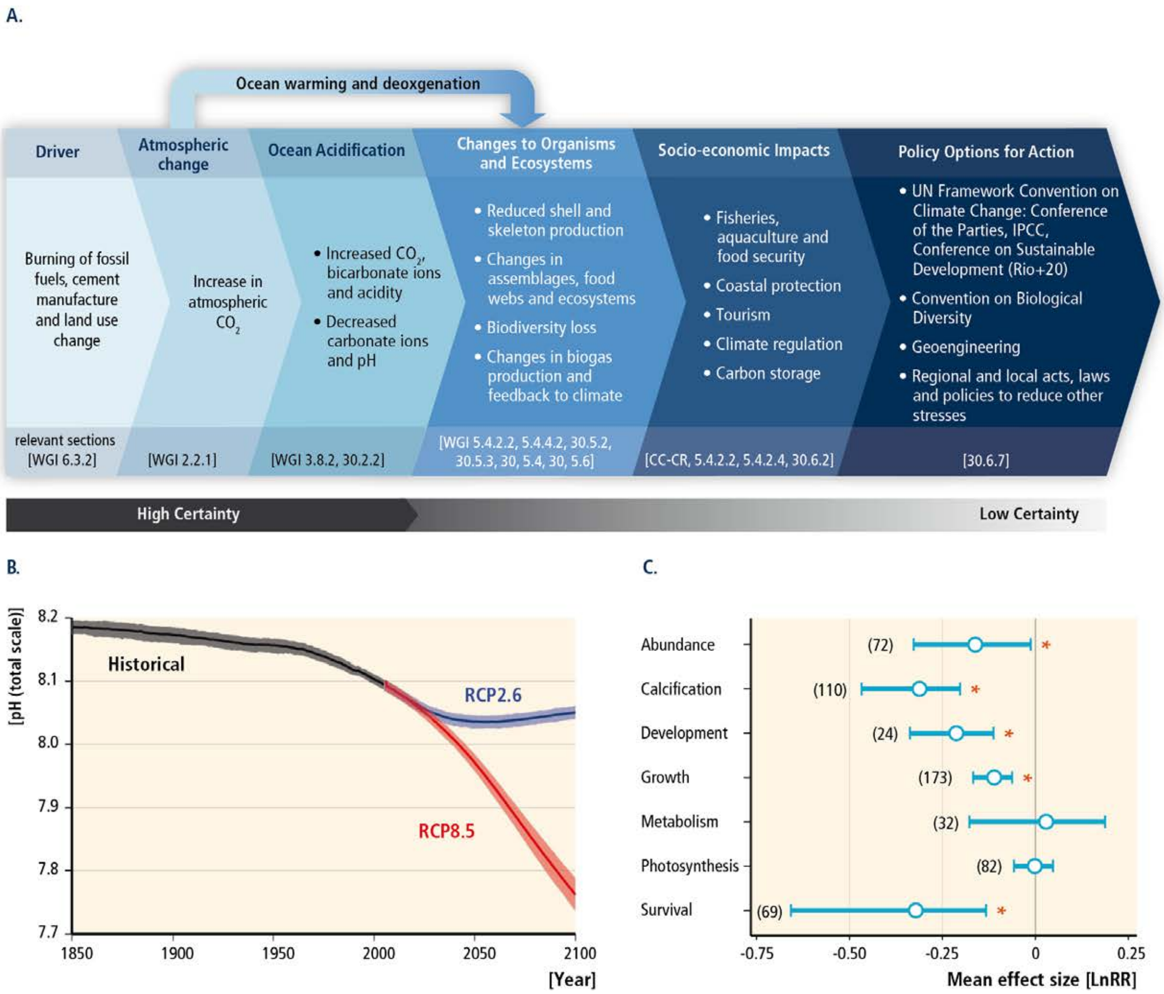

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.

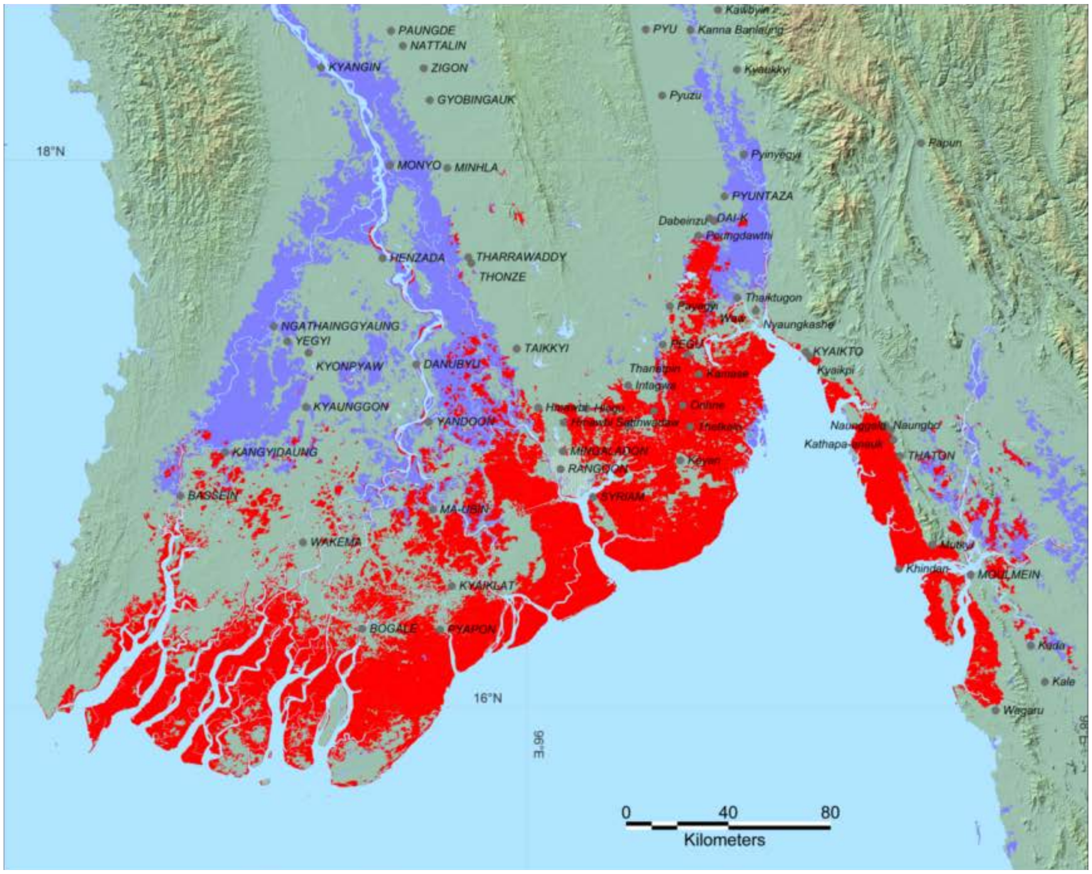

Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. Source: Brakenridge et al., 2013.

6.4: What changes in marine ecosystems are likely because of climate change?

Executive Summary

Ocean ecosystems have responded and will continue to respond to climate changes of different rates, magnitudes, and durations (*virtually certain*). Human societies depend on marine ecosystem services, which are sensitive to climate change (*high confidence*), in particular the provisioning of food (fisheries and aquaculture) and other natural resources, nutrient recycling, regulation of global climate (including production of oxygen and removal of atmospheric CO_2), protection from extreme weather and climate events, aesthetic, cultural, and supporting services. [6.3, 6.4, 6.5]

Climate change alters physical, chemical, and biological properties of the ocean (*very high confidence*). Oceanic drivers include salinity, circulation, temperature, carbon dioxide (CO_2), oxygen (O_2), nutrients, and light. These drivers shape the physiological performance of individual cells and organisms and ultimately determine ecosystem composition, spatial structure and functioning. [6.1.1, 6.3]

The fossil record and present field and laboratory observations confirm links between key environmental drivers and responses of ocean ecosystems to climate change (*high confidence*). For millions of years in Earth history, natural climate change at rates slower than today's anthropogenic change has led to significant ecosystem shifts (*high confidence*), including species emergences and extinctions (*high confidence*). Contemporary multidecadal natural climate variations associated with regional transient warming periods by 1°C have led to fundamental restructuring of ecosystems and large socioeconomic implications (*high confidence*). [6.1.2, 6.3.1, 6.4]

Vulnerability of most organisms to warming is set by their physiology which defines their limited temperature ranges and hence their thermal sensitivity (*high confidence*). Temperature defines the geographic distribution of many species and their responses to climate change. Shifting temperature means and extremes alter habitat (e.g., sea ice and coastal), and cause changes in abundance through local extinctions and latitudinal expansions or shifts (*very high confidence*). Vulnerability is greatest in polar animals due to their narrow temperature ranges (*medium confidence*) and in tropical species living close to upper thermal limits (*medium confidence*). Although genetic adaptation occurs (*medium confidence*), the capacity of present-day fauna and flora to compensate for or keep up with the rate of ongoing thermal change is limited (*low confidence*). [6.3.1, 6.3.5, 6.5.2]

The warming-induced shifts in the abundance, geographic distribution, migration patterns, and timing of seasonal activities of species (*very high confidence*) have been and will be paralleled by a reduction in their maximum body size (*medium confidence*). This has resulted and will further result in changing interactions between species, including competition and predator-prey dynamics (*high confidence*). Numerous observations over the last decades in all ocean basins show global-scale changes including large-scale distribution shifts of species (*very high confidence*) and altered ecosystem composition (*high confidence*) on multidecadal time scales, tracking climate trends. The distribution and abundance of many fishes and invertebrates have shifted poleward and/or to deeper, cooler waters (*high confidence*). Poleward displacements of phyto- and zooplankton have occurred by hundreds of km's per decade (*high confidence*). Some warm-water corals and their reefs have responded with species replacement, bleaching and a decreased coral cover causing habitat loss (*high confidence*). While marine reptiles such as turtles encounter direct effects of warming, impacts to seabirds and marine mammals are mostly indirect through effects of warming on their prey (*high confidence*) [6.3.1, 6.3.7, 6.5, CC-CR, CC-MB].

In response to further warming by 1°C or more by the mid 21st century and beyond, ocean-wide changes in ecosystem properties are projected to continue (*high confidence*). Large irreversible shifts in the spatial distribution of species and seasonal timing of their activities (feeding, growth, development, behaviors, and productivity) will have implications for species composition, and ecosystem goods and services. [6.3.1, 6.4, 6.5, 6.6]

By the mid 21st century, the spatial shifts of marine species will cause species richness to increase at mid and high latitudes (*high confidence*) and to decrease at tropical latitudes (*medium confidence*), resulting in global redistribution of catch potential for fishes and invertebrates, with implications for food security (*medium*

***confidence*).** Animal displacements are projected to lead to high-latitude invasions and high local-extinction rates in the tropics and semi-enclosed seas. This will cause a 30–70% increase in the fisheries yield of some high-latitude regions by 2055 (relative to 2005), a redistribution at mid latitudes, but a drop of 40%- 60% in the tropics and the Antarctic, based on 2°C warming above pre-industrial values (*medium confidence* in the direction of trends in fisheries yields, *low confidence* in the magnitude of change). If a decrease in global net primary production (NPP) or a shift towards smaller primary producers occurs, the overall fisheries catch potential may also decrease. [6.3.1-4, 6.4.1, 6.5.1-4]

Open ocean NPP is projected to fall globally depending on RCP scenario (*medium confidence*). The estimated decrease will occur by up to 9% by 2100 under the RCP 8.5 business-as-usual climate scenario (relative to 1990, *low confidence*). The oceans currently provide about half of global net primary production (NPP). Environmental controls on NPP include temperature, CO_2, nutrient supply and light (through cloud cover, mixed layer depth), all of which will be altered (WGI, Ch. 6.3). Present observations indicate increasing NPP at high (Arctic) latitudes (*medium confidence*), projected to continue beyond 2100 (*medium confidence*). This increase is offset by a decrease at temperate and tropical latitudes (*medium confidence*). Poor representation of shelf and coastal regions hamper projections in global NPP models for near-shore waters, reducing confidence in global projections. [6.3.4, 6.5.1, CC-PP]

Large-scale processes and climatic feedbacks sustained by microbes (bacteria, archaea, unicellular algae and protozoans) play key roles in marine ecosystems (e.g., carbon and nitrogen fixation, nutrient recycling) and will be altered by climate change (*medium confidence*). Identifying which microbial species, groups and processes are being affected and how these will be altered is difficult as these organisms and their responses to environmental change are extremely diverse and often modulated by biological interactions or changes in circulation and nutrient supply (*limited evidence* and *low agreement*). Warming will cause species-specific responses, such as enhancing metabolic rates and exceeding thermal tolerances, which will affect abundance, distribution, and community structure. Warmer, CO_2- and nutrient-enriched coastal oceans may stimulate harmful algal blooms (*medium confidence*), and the redistribution of certain microbes causing diseases like cholera (*medium confidence*). [6.3, 6.4.2]

Rising atmospheric CO_2 over the last century and into the future not only causes ocean warming but also changes carbonate chemistry in a process termed ocean acidification (WGI, Chs. 3.8.2, 6.4.4). Impacts of ocean acidification range from changes in organismal physiology and behavior to population dynamics (*medium* to *high confidence*) and will affect marine ecosystems for centuries if emissions continue (*high confidence*). Laboratory and field experiments as well as field observations show a wide range of sensitivities and responses within and across organism phyla (*high confidence*). Most plants and microalgae respond positively to elevated CO_2 levels by increasing photosynthesis and growth (*high confidence*). Within other organism groups, vulnerability decreases with increasing capacity to compensate for elevated internal CO_2 concentration and falling pH (*low* to *medium confidence*). Among vulnerable groups sustaining fisheries, highly calcified corals, mollusks and echinoderms, are more sensitive than crustaceans (*high confidence*) and fishes (*low confidence*). Trans-generational or evolutionary adaptation has been shown in some species, reducing impacts of projected scenarios (*low* to *medium confidence*). Limits to adaptive capacity exist but remain largely unexplored. [6.3.2, CC-OA]

Few field observations conducted in the last decade demonstrate biotic responses attributable to anthropogenic ocean acidification, as in many places these responses are not yet outside their natural variability and may be influenced by confounding local or regional factors. Shell thinning in planktonic foraminifera and in Southern Ocean pteropoda has been attributed fully or in part to acidification trends (*medium* to *high confidence*). Coastward shifts in upwelling CO_2-rich waters of the Northeast-Pacific cause larval oyster fatalities in aquacultures (*high confidence*) or shifts from mussels to fleshy algae and barnacles (*medium confidence*), providing an early perspective on future effects of ocean acidification. This supports insight from volcanic CO_2 seeps as natural analogues that macrophytes (seaweeds and seagrasses) will outcompete calcifying organisms. During the next decades ecosystems, including cold- and warm-water coral communities, are at increasing risk of being negatively affected by ocean acidification (OA), especially as OA will be combined with rising temperature extremes (*medium* to *high confidence*, respectively). [6.1.2, 6.3.2, 6.3.5]

The expansion of hypoxic regions termed Oxygen Minimum Zones (OMZs) and anoxic "dead" zones, observed over the last 50 years and projected into the future under climate change, especially if combined with nutrient enrichment (eutrophication), will constrain the habitat of O_2-dependent organisms and benefit anaerobic microbes (*medium confidence*). Hypoxia tolerance varies among species and is influenced by temperature, elevated CO_2, food consumption, and O_2-demand (*high confidence*). Warming-induced stratification limits the exchange of gases between water layers. Enhanced oxygen consumption by heterotrophic organisms depletes the oxygen further, causing a community shift toward lower species richness and hypoxia-tolerant specialists. Under extreme hypoxia ecosystems are dominated by microbes. These OMZs are also characterized by microbial removal of fixed nitrogen (denitrification), which can significantly reduce the low latitude nutrient inventories with implications for regional productivity. [6.3.3, 6.3.5]

The climate-change-induced intensification of ocean upwelling in some eastern boundary systems, as observed in the last decades, may lead to regional cooling rather than warming of surface waters and cause enhanced productivity (*medium confidence*), but also enhanced hypoxia, acidification, and associated biomass reduction in fish and invertebrate stocks. Due to contradictory observations there is currently uncertainty about the future trends of major upwelling systems and how their drivers (enhanced productivity, acidification, and hypoxia) will shape ecosystem characteristics (*low confidence*). [6.1.1, 6.3.2, 6.3.3, 6.3.5-6, CC-UP]

Environmental drivers acting simultaneously on ocean biota* often lead to interactive effects and complex responses (*high confidence*). Interactions of temperature, ocean acidification, and hypoxia narrow thermal ranges and enhance sensitivity to temperature extremes in organisms like corals, coralline algae, mollusks, crustaceans, and fishes (*high confidence*). In primary producers light and individual nutrients can also interact with temperature and acidification. Combined warming and ocean acidification reduce calcification in warm-water corals (*high confidence*). Ocean acidification will alter availability of trace metals (*low confidence*). (*The term biota encompasses the organisms of a region, habitat, or geological period.) [6.3.2.2, 6.3.5, 6.5.2]

The combination and often amplification of global and regional climate change and local anthropogenic drivers result in enhanced vulnerability of natural and human systems (*high confidence*). Major regional and local drivers include fishing, pollution, and eutrophication. [6.3.5, 6.4, 6.5]

The progressive redistribution of species and the reduction in marine biodiversity in sensitive regions and habitats puts the sustained provision of fisheries productivity and other ecosystem services at risk, which will increase due to warming by 1°C or more by 2100 compared to the present (*high confidence*). Human societies respond with limited adaptive capacity. Socio-economic vulnerability is highest in developing tropical countries involving a risk of reduced supplies, income, and employment from marine fisheries (*high confidence*). This emphasizes disparities in food security between developed and underdeveloped nations. [6.4.1, 6.5]

With continuing climate change, local adaptation measures (such as conservation) or a reduction in human activities (such as fishing), may not sufficiently offset global-scale effects on marine ecosystems (*high confidence*). Effects of climate change will thus complicate management regimes such as of marine protected areas once species undergo distributional shifts. This increases the vulnerabilities of marine ecosystems and fisheries. [6.4.2.1]

Geoengineering approaches involving manipulation of the ocean to ameliorate climate change (such as nutrient fertilization, binding of CO_2 by enhanced alkalinity, or direct CO_2 injection into the deep ocean) have very large environmental and associated socioeconomic consequences (*high confidence*). Some actually require purposeful alteration of ocean ecosystems for implementation. Alternative methods focusing on solar radiation management (SRM) leave ocean acidification largely unabated as they cannot mitigate CO_2 emissions. [6.4.2]

6.1. Introduction: Point of Departure, Observations, and Projections

The oceans cover about 71% of Earth's surface to an average depth of 3,700 m. Their importance for life on Earth, including humans, is vast (FAQ 6.1). Marine habitats display natural variability on various spatial and temporal scales but a dearth of long-term observational data from the vast open oceans limits our understanding of the causes and ecological consequences of this variability. The available information indicates that climate controls ocean temperatures, chemistry, circulation, upper ocean stratification, nutrient supply, and sunlight exposure. These drivers affect marine ecosystems through direct effects on organisms, amplified by their changing interactions with other species. Food webs are modified by changes in phytoplankton growth and the availability of live organisms or their decomposing bodies, i.e. debris or dissolved organic matter, as food to (chemo-) heterotrophs (organisms gaining energy by feeding on organic matter). Organismal responses lead to changes in biogeochemical processes, such as the carbon cycle, and in biological diversity and the services the oceans provide.

Some impacts of climate change on marine ecosystems and their services were addressed in the 4th IPCC assessment report (AR4), WGII, chapters 4-6 (ecosystems, food, coastal areas), and regional chapters, e.g., 15 (polar regions) and 16 (small islands). The ecosystem assessment in chapter 4 focused on terrestrial, coastal, and marine systems, their properties, goods, and services. It emphasized the difficulty in assessing future ecosystem responses as a result of ecosystem complexity, different vulnerabilities of species, and ecosystem-specific, critical thresholds associated with non-linear responses to environmental change. Focusing on terrestrial ecosystems, Ch. 4 concluded that more than 2-3°C warming above pre-industrial levels causes high extinction risks to 20 to 30% of present-day species (*medium confidence*), paralleled by substantial changes in ecosystem structure and functioning (*high confidence*). Authors projected that a wide range of planktonic and benthic calcifiers will be impacted by ocean warming (*very high confidence*) and acidification (*medium confidence*), particularly in the Southern Ocean. They characterized sea ice and coral reef biomes as highly vulnerable. Key uncertainties identified in AR4 were the incomplete knowledge of ocean acidification (addressed in present chapter 6.3.2), synergistic effects and their mechanisms (6.3.5), biotic feedbacks to the climate system (6.4), and the impacts of interactions between climate change, human uses, and ecosystem management (6.4.2).

Much more than in previous IPCC reports (Figure 1-2), impacts on the oceans are a focus in AR5. This allows for a more comprehensive discussion of phenomena and impacts, as well as the associated uncertainties and the levels of confidence in observed and projected changes. The present chapter focuses on the general principles and processes characterizing climate change impacts on ocean systems and on the uses of these systems by human societies. For projections of responses to climate change, the chapter also assesses our understanding of underlying functional mechanisms causing change across all levels of biological organization, from molecules to organisms to ecosystems. As the ocean is a heterogeneous environment, the comparison of major ocean regions is required to understand variability and differences in key processes and carbon inventories (Box CC-PP, Figure 1). We discuss the changes and variability in the ocean's principal physical and chemical properties and assess knowledge drawn from paleo- and historical to present observations. We develop a conceptual framework for analyzing effects on organisms and ecosystems and assess present knowledge derived from experiments, field studies, and numerical model projections mostly using Representative Concentration Pathways (RCP) of climate change scenarios to provide trajectories of climate change drivers (Moss *et al*., 2010). Finally, we assess the implications of such changes for ecosystem services, and identify plausible socioeconomic consequences.

Assessing climate change impacts on coastal systems is the topic of chapter 5. An integrative treatment of regional climate changes and impacts in seven key ocean regions is the focus of regional chapter 30. Marine issues are also included in regional chapters 22 to 29, with a focus on polar oceans (Ch. 28) and small island nations (Ch. 29). Topics important to several chapters, such as ocean acidification, upwelling systems, primary productivity, changes in biogeography, and coral reefs, are discussed in joint assessments presented in the respective cross chapter boxes.

6.1.1. Changes in Physical and Chemical Variables

Trends in ocean conditions over the last 60 years reflect significant human impacts beyond natural variability on temperature, salinity, dissolved inorganic carbon and oxygen content, pH, and other properties of the upper ocean (e.g., Pierce *et al*., 2012; Sen Gupta and McNeil, 2012; WGI, Ch. 3.8., WGI, Table 10.1). With climate change, marine ecosystems are and will be exposed to rising temperature, ocean acidification, expansion of hypoxic zones, and other environmental drivers changing concomitantly.

6.1.1.1. Temperature and Salinity

Over the last 39 years, oceans have warmed at average rates of >0.1 °C per decade in the upper 75 m and 0.015 °C/ decade at 700 m depth (WGI, Ch. 3.2.2, Figure 3.1). Trends differ regionally, seasonally, and interannually (WGI, Ch. 2.7, for ocean regions see 30.5). Temperature changes are particularly large at ENSO (El Nino-Southern Oscillation) with high (3 to 4 year) and low (5 to 7 year) frequencies, and on multidecadal scales (>25 years, Figure 6-1). The strongest warming trends are found at high latitudes where most of the interdecadal variability occurs, while tropical oceans are dominated by interannual frequencies. Global climate models have explored changes in different frequency domains, but their spatial resolution is poor (WGI, Ch. 11.3.3, WGI, Ch. 12.4.7).

Temperature variations are often accompanied by changes in salinity. Increased salinity results from reduced precipitation relative to evaporation, e.g., above the thermoclines (layer separating the upper mixed layer from deeper water where temperature and density change rapidly with depth) of subtropical gyres at mid to low latitudes since 1950 (WGI, Ch. 3). Decreased salinity due to enhanced precipitation relative to evaporation has occurred at some tropical and higher latitudes, exacerbated by sea-ice melt (Durack *et al*., 2012). Both warming and freshening cause enhanced density stratification, a trend projected to continue into the 21^{st} century (WGI, Figure 12.34; Helm *et al*., 2010; WGI, Ch. 3, Ch. 11.3.3). Mean sea surface temperature in 2090 will be by 2.7°C warmer than in 1990 (RCP8.5, WGI, Ch.12, Bopp *et al*., 2013).

[INSERT FIGURE 6-1 HERE
Figure 6-1: Sea surface temperature variability between 1911 and 2011. The top left map shows the sea surface temperature average for the period. The top right map illustrates the temperature range calculated as the difference between the maximum and minimum values for each grid component during the century. The spatial distribution of variability by time scales (left hand map series, based on the Extended Reynolds Sea Surface Temperature, NOAA, 2012) corresponds to the multidecadal (25 to 40 years), bidecadal (15 to 25 years), decadal (8 to 15 years), low ENSO (El Niño Southern Oscillation) frequency (5 to 8 years), high ENSO frequency (3 to 5 years), and very high frequency (2 to 3 years) scales. The summed variabilities from the same 2°x2° box in all six maps corresponds to 100% of the time series variability. The areas of the right hand bubbles show the spectral density of some of the most widely used climate indices, accumulated in the same frequency windows: the Global Average Temperature and SST (sea surface temperature) Anomalies (GSST), the Southern Oscillation Index (SOI), the North Atlantic Oscillation (NAO), the Multidecadal Atlantic Oscillation (AMO), and the Pacific Decadal Oscillation (PDO). The sum of bubble surface areas for each vertical column (each climate index) corresponds to 100% of the time series variability between the 2 and 40 year periods. Climate indices where obtained from the NOAA ESRL Physical Sciences Division website.]

6.1.1.2. CO_2-Induced Acidification

Rising carbon dioxide (CO_2) concentrations in air (given as partial pressures, pCO_2, in µatm) cause increasing upper ocean CO_2 levels (Watson *et al*., 2009). Starting from a pre-industrial value of 280 µatm atmospheric pCO_2 levels will have reached around 500 µatm by 2050 under SRES scenarios (IPCC, 2000) and all RCPs (Moss *et al.*, 2010; Meinshausen *et al*., 2011). By 2100 values are projected to reach between 420 µatm and 940 µatm depending on the RCP. The rise in pCO_2 causes ocean acidification (OA), measured as a decline in water pH (negative log of proton concentration), accompanied by a fall in both carbonate ion (CO_3^{2-}) concentration and the saturation states (Ω) of various calcium carbonates ($CaCO_3$; Zeebe and Westbroek, 2003; WGI Ch. 3.8.2, Box 3.2, Ch. 6, Figure 6.29). Hence, the seawater solubilities of three forms of calcium carbonate, namely calcite, Magnesium-calcite, and aragonite, increase. These minerals are important components of shells and skeletons of many marine organisms (6.3.2).

Ocean acidification occurs on a background of natural temporal and spatial variability of pH, pCO_2, and Ω. In the open ocean, the mean pH (total scale, pH_T) of surface waters presently ranges between 7.8 and 8.4 (WGI Ch. 3.8.2). In stratified mid-water layers, largely isolated from gas exchange between surface waters and air, decomposition of organic material leads to lowered oxygen (O_2) and elevated CO_2 levels (Paulmier *et al*., 2011) associated with lower pH values. The few existing field data of sufficient duration, resolution, and accuracy (WGI Figure 3.18) show that trends in anthropogenic OA clearly deviate from the envelope of natural variability (Friedrich *et al*., 2012). OA presently ranges between -0.0013 and -0.0024 pH_T units per year (WGI, Ch. 3.8.2, Table 3.2, Box 3.2; Dore *et al.*, 2009). Average surface ocean pH has decreased by more than 0.1 units below the pre-industrial average of 8.17. By 2100 pH is expected to change by -0.13, -0.22, -0.28, -0.42 pH_T units, at CO_2 levels of 421, 538, 670, and 936 ppm under RCP 2.6, 4.5, 6.0 and 8.5 climate scenarios, respectively (WGI, Figure 6.28). The rate of acidification in surface waters varies regionally and is 50% higher in the northern North Atlantic than in the subtropical Atlantic (Olafsson, 2009). Salinity reduction caused by ice melt or excess precipitation (Jacobs and Giulivi, 2010; Vélez-Belchí *et al*., 2010) exacerbates OA by diluting the concentrations of substances acting as buffers (Steinacher *et al*., 2009; Denman *et al*., 2011). At high sustained CO_2 concentrations the changes in ocean chemistry will take thousands of years to be buffered by the natural dissolution of calcium carbonate from sediments and tens to hundreds of thousands of years to be eliminated completely by the weathering of rocks on land (Archer *et al.*, 2009).

6.1.1.3. Hypoxia

The average dissolved oxygen concentration in the ocean is presently 162 µmol kg^{-1} (Sarmiento and Gruber, 2006). Concentrations range from over 500 µmoles kg^{-1} in productive Antarctic waters super-saturated with oxygen (Carrillo *et al.*, 2004) to zero in coastal sediments and in permanently anoxic deep layers of isolated water bodies, such as the Black Sea and the Cariaco Basin. Hypoxia results from oxygen depletion in excess of supply as in stratified water bodies (6.1.1.2). Vast oxygen minimum zones (OMZ) exist between less than 100 and more than 900 m depths in Eastern Atlantic and Pacific tropical oceans. The ecological literature applies the term hypoxia (see 6.3.3) to O_2 concentrations below 60 µmoles kg^{-1} (estimated at ~5 % of global ocean volume; Deutsch *et al*., 2011). Pacific OMZs regularly reach oxygen levels below 20 µmoles kg^{-1} (about 0.8% of global ocean volume; Paulmier and Ruiz-Pino, 2009), lower than Atlantic ones. Suboxic waters at < 4.5 µmoles O_2 kg^{-1} occupy about 0.03 % of the ocean volume, mainly in the northeastern tropical Pacific (Karstensen *et al*., 2008).

OMZs are naturally present in many habitats including marine sediments, but are also expanding due to anthropogenic influences. Over the past 50 years, open ocean O_2 concentrations have decreased by a mean rate of 0.1 to over 0.3 µmoles kg^{-1} $year^{-1}$ (WGI, Ch. 3.8.3, Stramma *et al*., 2008). In some OMZs the rate has been much higher due to warming, increased stratification, and rising biological O_2 demand (WGI, Box 6.5, Figure 1). Long-term declines in O_2 by about 7 µmoles kg^{-1} $decade^{-1}$ have been documented at mid-water depths over much of the subarctic North Pacific (Keeling *et al*., 2010). In coastal regions, extremely hypoxic 'dead zones' that exclude animal life, have increased from 42 reported in the 1960s to over 400 in 2008 and been attributed to high oxygen demand from eutrophication, the local enrichment of nutrients, resulting in organic matter loading and its decay as well as nitrous oxide formation and release (Naqvi *et al*., 2000; Díaz and Rosenberg, 2008; Zhang *et al*., 2010).

Future warming will *likely* accelerate the spread of hypoxic zones, especially in temperate to subpolar regions. Most models project decreasing global ocean oxygen contents by 1 to 7 % from present-day concentrations in 2100 (Keeling *et al.*, 2010; WGI Figure 6.30 under RCP 8.5), with a mean decline by 3.4 % in 2090 compared to the 1990s (Bopp *et al*., 2013). Warming and freshening of the surface layer will increase stratification and reduce the depth of winter mixing. The evolution of low O_2 zones will be linked to changes in fluvial runoffs (e.g. Milly *et al.*, 2008; 5.3.4.3), the wind regime (e.g., Vecchi and Soden, 2007), as well as the intensity, duration and seasonal timing of upwelling events (Snyder *et al.*, 2003, 30.5.2). The potential contributions of destabilized methane hydrates and bacterial methane oxidation to exacerbate hypoxia and acidification at high latitudes remain to be explored (Westbrook *et al*., 2009). Currently, there is no consensus on the future volumes of hypoxic and suboxic waters because of large uncertainties in potential biogeochemical effects and in the evolution of tropical ocean dynamics due to both natural and anthropogenic causes (WGI, Ch. 6). While volumes with O_2 concentrations below 80 µmoles kg^{-1} are projected to increase by several %, suboxic waters <5 µmoles O_2 kg^{-1} may undergo a 30 % increase by 2100 compared to 2005 (*low confidence*, Bopp *et al*., 2013).

6.1.1.4. Light and Nutrients

Most models project that the mixed layer at the ocean surface (see Figure 6-2) will become shallower in the coming decades through a strengthening of the vertical density gradient (e.g. Sarmiento *et al.*, 1998; Sallée *et al*., 2013). Mean light levels encountered by phytoplankton are set by incoming light from solar radiation, the depth of the mixed layer, and the degree to which underwater light is attenuated by living and non-living particles (Kirk, 1994). A shallower mixed layer will *likely* result in the resident phytoplankton receiving higher mean underwater light levels if the organisms are physically mixed through this stratum (Figure 6-2).

Enhanced, seasonally prolonged stratification (Holt *et al*., 2010), especially in the tropics, the North Atlantic, the Northeast Pacific, and the Arctic (Capotondi *et al*., 2012), will lead to decreased vertical transport of nutrients to surface waters (Doney, 2010; Figure 6-2). River plumes (Signorini *et al*., 1999), nutrient accumulation in the pycnocline as reported for North Pacific waters (Whitney, 2011), human-induced eutrophication, enhanced upwelling (Box CC-UP), and tidal mixing and estuarine circulation in coastal oceans could partly compensate for the projected reduction in nutrient supply in the oceans (*limited evidence, medium agreement*).

[INSERT FIGURE 6-2 HERE
Figure 6-2: Projected alteration (magnitude and frequency) of oceanic fluxes and atmospheric events due to a changing climate in the coming decades. Ocean properties will be altered from the sunlit surface layer to the mid-water stratum. In the surface ocean, the depth of the mixed layer (solid horizontal line) will shallow resulting in higher mean light levels. Increased density stratification (i.e., a strengthening sea water density gradient represented by the increasing thickness of the solid horizontal line) will reduce the vertical supply of nutrients for photosynthesizing organisms residing in the mixed layer. Anthropogenic CO_2 will acidify, i.e., lower the pH of the surface ocean (note this happens in a pH range higher than 7 such that oceans will remain alkaline but less so due to acidification). The penetration of acidified waters to depth will result in a shallower depth (dashed horizontal line) at which calcium carbonate structures, such as shells, dissolve. At depth, the location of low oxygen waters will progressively become shallower. In addition, changes in storm activity and dust deposition will influence ocean physics and chemistry, with consequent effects on ocean biota and hence ecosystems (courtesy of Reusch and Boyd, 2013).]

6.1.2. Historical and Paleo-Records

6.1.2.1. Historical Observations

Ocean ecosystems are variable in time and space, and in a non-steady-state, reflected in indices such as the North Atlantic Oscillation Index (NAO), the Atlantic Multidecadal Oscillation (AMO), the Arctic Climate Regime Index (ACRI), Pacific Decadal Oscillation (PDO), or the El Niño-Southern Oscillation (ENSO) (WGI, Box 2.5; Figure 6-1, 30.5). The combination of large, global data sets such as Reynolds, NCAR (National Center for Atmospheric Research), ICOADS (International Comprehensive Ocean-Atmosphere Data Set), with multidecadal time-series, for example near Hawaii (HOT), Bermuda (BATS), the Ligurian Sea (DYFAMED), the Canaries (ESTOC), Kerguelen Island (KERFIX), Hokkaido Island (KNOT), and Taiwan (SEATS) has provided data on the physical and biogeochemical state of the oceans (Karl *et al*., 2003). These have been augmented by the limited-term, high resolution programs World Ocean Circulation Experiment (WOCE) and Joint Global Ocean Flux Study (JGOFS).

Historical data sets provide baseline information on ecosystem states and document the responses of biota to both, natural variability in the ocean system and surface ocean warming since the 1970s (Figure 6-3; 6.3.1). Such datasets are rare and regionally biased. Examples include changes in geographic ranges of plankton and seasonal timing (phenology) of different components of the ecosystem detected by the Continuous Plankton Recorder (CPR: e.g., Edwards *et al.*, 2001; Richardson *et al.*, 2006; Box 6-1) or multidecadal shifts in pelagic ecosystems (CalCOFI) including higher parts of the food chain such as sardines and anchovies (Brinton and Townsend, 2003; Lavaniegos and Ohman, 2003; Chavez *et al.*, 2003, 6.3.1) and the skeletal archives of long-lived organisms such as coralline algae (Halfar *et al*., 2011), bivalves (Schöne *et al*., 2003), and corals (De'ath *et al*., 2009).

Systematic, long-term interdisciplinary observations using repeated, highly calibrated measurements at a given field site are required to capture high- and low-frequency events, e.g., regime shifts (abrupt changes between contrasting, persistent states of any complex system, deYoung *et al*., 2008). Direct observations are complemented by satellite remotely-sensed datasets. Ocean color data (e.g. Coastal Zone Color Scanner [1978-1986], SeaWiFS [1997-2010], and MODIS-AQUA [2002-present], McClain, 2009) provide estimates of chlorophyll concentrations (a proxy for phytoplankton stocks and Net Primary Production, NPP, 6.2.1, 6.3.4; Saba *et al*., 2011). Total chlorophyll cannot be measured from space; therefore, the near-surface value (approximately one optical depth) is extrapolated to whole water-column chlorophyll based on vertical distribution using region-specific algorithms. Large uncertainties persist, as these estimates reflect both phytoplankton stocks and their physiological status (Dierssen, 2010; Behrenfeld, 2011). The ~15 year archived time series of SeaWiFS is too short to reveal trends over time and there causes. It is an example for the general issue that undersampling of ocean phenomena in time and space limits our current ability to assess present states, to distinguish effects of anthropogenic change from natural variability and to project future changes (Henson *et al*., 2010; Beaulieu *et al*., 2013; Box CC-PP).

6.1.2.2. Paleontological Records

Paleontological records in marine sediments provide long-term, low-resolution data on the spatial distributions of organisms and their abundances from all ages and latitudes. This information can be readily related to the concurrent shifts in multiple environmental properties that are also recorded in these sediments. The records provide insights into shifts, expansions and contractions of biogeographic ranges, species extinctions and emergences, and changes in species abundance, as well as the environmental forcings to which organisms respond. Temporal trends reveal influences of temperature, hypoxia, CO_2, and food availability on organisms and ecosystems (6.1.1, Figure 6-3).

Due to insufficient resolution the geological record often does not allow the direct attribution of a biological change to a single driver or the identification of various drivers and their relative importance. Support for projections of future changes in present-day ecosystems and their services is thus limited (6.4, 6.5, *low confidence*). Nonetheless, information gained from the geological record is invaluable as both paleo and present climatic shifts share the same combination and sign of environmental changes: increasing atmospheric CO_2 causing warming and CO_2 enrichment in the surface ocean, leading to enhanced stratification of the upper ocean and a decrease in dissolved O_2 (WGI, Chs 3, 5.3). A combination of models (WGI, Chs 3, 6, 12) and geological data can be used to forecast future impacts on ocean biota (*medium confidence)*.

[INSERT FIGURE 6-3 HERE
Figure 6-3: Environmental changes (bottom) and associated biological responses (top) for the Paleocene Eocene Thermal Maximum (PETM, left) and the industrial era (right). The PETM represents the best geological analogue for the future ocean in terms of biological responses. Episodes of largest environmental change are indicated with yellow bars. Note the different time scale between the two columns. Both time intervals are characterized by rapid warming both on land and in the ocean and increases in CO_2. Atmospheric CO_2 and temperature are described with direct measurements (black), proxy reconstructions (grey) and model results (light grey). For the recent anthropocenic record, the AMO is shown to highlight high frequency natural temperature fluctuations (Enfield *et al.*, 2001) and their influence on marine biota. Biological responses to the environmental forcing are divided into calcification, extinction and migration. Note the highly group-specific responses to the environmental change, especially with regards to calcification with decreases, increases and high variability. While there was extinction during the PETM, there is currently no evidence for climate-related extinction in the marine record. The warming led to migration of warm water species into previous cold water habitats indicating range expansion due to warming (modern: planktic foraminifera, *G. ruber* Field *et al.*, 2006; PETM: coccolithophores, *Discoaster* spp. Bralower, 2002). CO_2 data: Mauna Loa (Keeling *et al.*, 2005), ice core records (Etheridge et al. 1996) and model output for the PETM (Zeebe *et al*., 2009; Ridgwell and Schmidt, 2010). Sea surface temperatures modern: Wilson *et al.*, 2006 and PETM: Kennett and Stott, 1991. Biotic responses: growth changes in coralline algae (Halfar *et al.*, 2011, bottom)

and corals (Vásquez-Bedoya *et al.*, 2012, middle, De'ath *et al.*, 2009 [corrigendum], top); calcification changes (Foster *et al*., 2013) and extinction in benthic foraminifers (Thomas, 2003) for the PETM.]

The last glacial-interglacial transition is associated with an average increase in atmospheric CO_2 of ~1 µatm/century between 18 and 10 thousand years before present (kyr BP) (WGI Ch. 5), a significantly slower increase than the ~90 µatm in the last century (WGI Chs. 5, 6). Consequently, the average pH change of 0.002 pH units per century during the glacial-interglacial transition is small relative to the ongoing anthropogenic perturbation of >0.1 pH unit per century (WGI, Ch. 3.8.2). Overall the upper glacial ocean was more O_2 rich than today's ocean (Jaccard and Galbraith, 2012) and between 0.7 and 2.7°C colder, with strong regional differences of up to 10°C cooling in the North Atlantic and 2-6°C in the Southern Ocean (WGI Ch. 5, Table 5.2). During warming from the glacial into the interglacial marine plankton such as foraminifera, coccolithophores, diatoms, dinoflagellates, and radiolarians showed marked poleward range expansion (*high confidence*, see WGI, Ch. 5.7; CLIMAP Project Members, 1976; MARGO Project Members, 2009). Under the lower glacial CO_2 concentrations, calcification in planktonic foraminifera was higher (*limited evidence, medium agreement)*.

The most prominent abrupt climate change periods in the recent geological record, developing within 10-100 years, are associated with Dansgaard-Oeschger (DO) and Heinrich events (WGI, Ch. 5.7), which occurred repetitively during the last 120 kyrs. While the atmospheric changes happened within a few decades, the sea surface temperature in the North Atlantic changed by up to 5°C within decades to centuries (WGI, Ch. 5.7). Southern Ocean temperature changes were slower (hundreds to thousands of years, Barker *et al*., 2009). The cold phase of a DO event led to the migration of polar foraminiferal species towards the equator, in the North Atlantic as far south as the Iberian Peninsula (Martrat *et al*., 2004). Abrupt (~100 year) abundance changes in the Southern Ocean were associated with latitudinal shifts in the Antarctic Circumpolar Current and associated species (Barker *et al*., 2009) akin to modern changes in plankton range due to warming (Box CC-MB, Box 6-1). During the DO warm phases the Monsoon-driven Arabian Sea upwelling records show enhanced primary and export production, reduced oxygenation, and denitrification, all within ~200 years (Higginson *et al*., 2004).

The last time the atmospheric CO_2 content approached that of today was during the Pliocene warm period (3.3 to 3.0 Ma, i.e., million years ago), with long periods of atmospheric CO_2 levels between 330-400 µatm (Pagani *et al.*, 2010; Seki *et al.*, 2010) and equlibrated temperatures ~2°C warmer than today (Haywood *et al.*, 2009, WGI Ch. 5) (*medium confidence*). The Mid-Pliocene Warm Period saw a poleward expansion of tropical planktonic foraminifera (Dowsett, 2007) (*high confidence*). Coccolithophores (Bown *et al.*, 2004), corals (Jackson and Johnson, 2000) or mollusks (Vermeij and Petuch, 1986) remained unaffected with respect to rates of species extinction or emergences compared to background rates.

Perhaps the best analogue for the future ocean is the Paleocene-Eocene Thermal Maximum (PETM, 55.3 Ma). The PETM was an event of warming (Dunkley Jones *et al*., 2013), and ocean acidification (Zachos *et al*., 2005) over millennia (Stassen *et al*., 2012; Cui *et al*., 2011) with increased runoff and nutrients into the shelf ecosystems. Model simulations for the PETM show 10 times lower rates of CO_2 input and hence ocean acidification compared to today (Ridgwell and Schmidt, 2010) (*medium confidence*). Depending on the assumed rate and magnitude of the CO_2 release, models project pH declined by 0.25 to 0.45 units in PETM surface waters and a reduction in surface ocean aragonite saturation from Ω=3 to Ω=2 or even as low as 1.5 (Ridgwell and Schmidt, 2010). Warming caused range expansions of warm-water taxa towards higher latitudes (*high confidence)*. The composition of plankton assemblages changed both within and between phytoplankton groups (Gibbs *et al.*, 2006; Sluijs and Brinkhuis, 2009), possibly reflecting the warming trend and/or changes in nutrient availability (6.2.2.-3). There was no bias in extinction towards more heavily calcifying species, possibly as slow CO_2 input led to minor surface water acidification. By contrast, benthic foraminifera, the dominant deep water eukaryote, recorded up to 50% extinction (Thomas, 2007). In contrast to sediment dwellers, more mobile pelagic crustaceans (ostracods) did not show any significant change in species composition (Webb *et al.*, 2009). In shallow coastal waters, calcareous algae and corals were replaced by symbiont-bearing benthic foraminifera (Scheibner and Speijer, 2008) (*medium confidence*).

The warm climates of the Mesozoic (251 to 65 Ma) led to a number of anoxic events in the oceans (Jenkyns, 2010). In some cases, OMZs expanded vertically leading to anoxia in upper water layers (Pancost *et al.*, 2004). Some of the Cretaceous oceanic anoxic events were associated with extinctions or increased species turnover (normalized sum of originations and extinctions) of planktonic foraminifera and radiolarians (30%). Such turnover was very small in other groups of organisms, (e.g., a maximum of 7% of coccolithophores, Leckie *et al.*, 2002). The attribution of these evolutionary changes to reduced O_2 is tenuous as warming, changes in nutrient supply and, possibly, ocean acidification occurred concomitantly (Hönisch *et al*., 2012).

Global-scale collapse of marine ecosystems is rare, even in the geological record. Some mass extinctions, in particular the Permian Period extinction 251 Ma ago, have been associated with large-scale inputs of carbon into the atmosphere and ocean, with associated warming and deep-sea O_2 decline (Knoll *et al.*, 2007; Kiessling and Simpson, 2011). The end-Permian mass extinction preferentially affected reef organisms such as corals and sponges resulting in a 4 Myr period without reef builders (Kiessling and Simpson, 2011), and underscores that vulnerabilities differ among organisms depending on anatomy, physiology, and ecology (Knoll and Fischer, 2011). The rates of environmental change and any potential acidification have not yet been accurately constrained for these events.

Of the last 100 Myr, only the last 2 Myr had CO_2 levels of ~190 to 280 ppm, comparable to preindustrial values. Values like those predicted by the mid and end of this century can solely be found in the geological record older than 33 Ma, with large uncertainties in the absolute numbers (WGI, Ch. 5.3; Hönisch *et al*., 2012). That marine biota thrived throughout high CO_2 times cannot imply that marine organisms will remain unaffected in a future warm, high-CO_2 world. The key environmental issue of the 21st century is one of an unprecedented rate of change, not simply magnitude, of CO_2 levels (Hönisch *et al*., 2012). The current rate and magnitude of ocean acidification are at least 10 times faster than any event within the last 65 Ma (*high confidence*, Ridgwell and Schmidt, 2010) or even 300 Ma of Earth history (*medium confidence*, Hönisch *et al*., 2012). The slower events in geological history provide *robust evidence* (*high agreement*) for environmentally-mediated changes in biogeographic ranges of fauna and flora, their compositional changes, extinctions, and, to much lesser degree, emergences (*very high confidence*). No past climate change event perfectly parallels future projections of anthropogenic climate change, which is unprecedented in evolutionary history. Existing similarities indicate, however, that future challenges (6.1.1, 6.3.1-8) may be outside the adaptive capacity of many organisms living in today's oceans (*low to medium confidence*).

6.2. Diversity of Ocean Ecosystems and their Sensitivities to Climate Change

Global-scale observation and modeling studies provide *robust evidence* of present and future climate-mediated alterations of the ocean environment (*high agreement*, 6.1.1, WGI, Chs. 3, 6; Bopp *et al*., 2013), which in turn impact ocean ecosystems (*high confidence*; Boyd and Doney, 2002; Hoegh-Guldberg and Bruno, 2010; Drinkwater *et al*., 2010). An assessment of present findings and projections requires knowledge of the characteristics of ocean biota and ecosystems and their climate sensitivity.

Life on Earth is diverse as a result of nearly 4 billion years of evolutionary history. Marine microorganisms are the oldest forms of life and the most functionally diverse; multicellular organisms are constrained to limited functional abilities. Knowledge of overarching similarities across the organism domains Archaea, Bacteria, and Eukarya (Woese *et al*., 1990) or kingdoms Bacteria, Protozoa, Fungi, Plantae, Animalia, and Chromista (Cavalier-Smith, 2004) would facilitate projections of climate impacts. The phylogenetic and metabolic diversity of microbes (i.e., viruses, archaea, bacteria, protists and microalgae) sustains key ecosystem processes such as primary production, CO_2 fixation and O_2 production, the conversion of nitrogen into ammonia (N_2 fixation), and the use of nitrate, sulphate, CO_2, and metals (Fe and Mn) in metabolism instead of O_2 when it is absent. Microbes enhance the horizontal transfer of genetic information between unrelated individuals, thereby enhancing biodiversity (McDaniel *et al*., 2010). Microbes may respond to climate change by exploiting their large diversity, undergoing species replacements (Karl *et al*., 2001), and thereby sustain their biogeochemical roles. Species replacements also occur among plants and animals, but in most cases research has focused on their resilience, well-being, abundance, survival, and conservation under climate change (FAQ 6.2).

6.2.1. Pelagic Biomes and Ecosystems

Pelagic organisms are key to biogeochemical processes in the ocean. The base of the marine food web is the photosynthetic fixation of CO_2 by phytoplankton, a process termed (net) primary production (NPP, Box CC-PP). Photosynthesis is controlled by light, temperature, inorganic nutrients (CO_2, nitrate, phosphate, silicate, and trace elements including iron), and the density-dependent stability of the surface mixed-layer depth (MLD) (6.1.1; Figure 6-2; Sverdrup, 1953; González-Taboada and Anadón, 2012). Environmental variability and the displacement of organisms by ocean currents cause variability in phytoplankton productivity, competitiveness, and natural selection (Margalef, 1978) and result in changes in carbon sequestration (Box CC-PP, Figure 6-4). Nutrient limitation leads to a decrease in NPP or chlorophyll levels and a reduction in the amount of energy supplied to higher trophic levels, including fish and invertebrates (*high confidence*, Ware and Thomson, 2005; Brander, 2007), affecting fishery yields (Cheung *et al*., 2008; Friedland *et al*., 2012). The wide range of trophic structures in marine food webs and the potentially non-linear changes in energy transfer under different NPP and temperature scenarios (Stock and Dunne, 2010) hamper accurate projections of changes in higher trophic levels.

[INSERT FIGURE 6-4 HERE
Figure 6-4: A schematic representation of the ocean's biological pump, which will be influenced by climate change and is a conduit for carbon sequestration. It is difficult to project how the pump might be altered (Table 6-1) and whether it would represent a positive or negative feedback to climate change through the cumulative effects of affected processes, surface to depth (Table 6-1): shifts in Net Primary Production, floristic and faunistic community composition in the pelagic realm, and in grazing rates; alterations to the ballasting of settling particles and the proportion of NPP released as DOM (Dissolved Organic Matter); modified bacterial enzymatic rates and particle solubilization; faunistic shifts at depth. Modified from Buesseler *et al.* (2008) by J. Cook (WHOI).]

[INSERT TABLE 6-1 HERE
Table 6-1: To assess how a changing climate will alter the ocean's biological pump (Figure 6-4) and determine the resulting biogeochemical feedbacks on global climate, changes in a wide range of processes from cellular to ocean basin scale, and from epipelagic to mesopelagic, must be quantified. This table illustrates the complexity of the integrated knowledge platform needed to provide evidence of these biogeochemical ramifications and thus the present limits to clear conclusions about climate-induced effects on the biological pump (C, Carbon; TEP, Transparent Exopolymer Particle; DOM, Dissolved Organic Matter; POM, Particulate Organic Matter).]

6.2.2. Benthic Habitats and Ecosystems

The ocean's primary production is inextricably linked with benthic (sea floor) communities via the biological pump (Figure 6-4), the chemical exchange of nutrients and gases, and the existence of organisms with both pelagic and benthic life history stages. Even in abyssal habitats, a continuous rain of organic detritus serves as the primary source of carbon and energy. Therefore climate impacts on surface marine ecosystems will impact even the deepest benthic communities, even if direct changes to their physical habitat do not occur (Smith *et al.*, 2009).

Benthic organisms living in shallow waters or the intertidal zone (where they encounter temporary exposure to air) are exposed to widely fluctuating and progressively changing means and extremes of environmental variables, such as temperature, oxygen, CO_2, salinity, and sea level (WGI, Chs. 3, 13; 6.3.1-3, 6.3.5). Sessile or slow moving plants and animals may be unable to escape from unfavorable changes except by means of advection of fertilized eggs or planktonic larvae. If climate change harms those species engineering benthic habitats, the entire ecosystem may be impacted. This concerns those ecosystem engineers, which form habitat from the structures they produce (e.g., corals forming skeletons, 6.3.1) and those forming habitat through their behaviour (e.g., worms reworking and irrigating sediment in a process termed bioturbation). Effects on both types of ecosystem engineers (6.3.1 to 8) influence the regeneration of nutrients and affect benthic-pelagic coupling.

6.3. Climate Change Impacts from Organism to Ecosystem

Understanding climate-induced alterations in the functioning of individual organisms, species populations, communities (assemblages of various species) and ecosystems builds on studies in the laboratory, in micro- and mesocosms (closed small- to medium-sized experimental systems approximating natural conditions, holding selected biological communities), and of biota or communities in the field as well as modeling. These data inform us which taxonomic groups in what regions are more susceptible to climate change (Boyd *et al.*, 2011). Empirical studies of marine organism and ecosystem sensitivities have begun identifying the mechanisms and processes linking climate to ecosystem changes (Drinkwater *et al.*, 2010; Ottersen *et al.*, 2010). Changes in ecological community composition, species interactions, and food web dynamics often build on organismal effects elicited by climate forcing (e.g., 6.3.1.5; Boyd *et al*., 2010; Ottersen *et al.*, 2010). The underlying mechanisms respond to climate-related factors in a hierarchy from organism (highest), tissue, cell to molecular (lowest) levels of biological organization (Pörtner, 2002a; Pörtner and Knust, 2007; Raven *et al*., 2012). Such knowledge aids the interpretation and attribution to climate change of observed effects and is a major asset for projections of future impacts.

The genetic and physiological underpinning of climate sensitivity of organisms sets the boundaries for ecosystem response and provides crucial information on sensitivities, resilience, and the direction and scope of future change. As anthropogenic climate change accelerates, a key issue is whether and how quickly organisms can compensate for effects of individual or multiple drivers, by short-term acclimatization or long-term evolutionary adaptation across generations. Evolutionary adaptation depends on the genetic variation within a population, from which the environment selects the fittest genotypes (Rando and Verstrepen, 2007; Reusch and Wood, 2007). Genetic variation depends on mutation rates, generation time, and population size (Bowler *et al*., 2010). However, epigenetic mechanisms, such as modifications of the genome by DNA methylation, can also influence fitness and adaptation (Richards, 2006) and can be remarkably rapid as seen in terrestrial ecosystems (Bossdorf *et al*., 2008). In plants and animals the rate of evolutionary adaptation is constrained by long generation times, but enhanced by high phenotypic variability and high mortality rates among early life stages as a selection pool (e.g., Sunday *et al*., 2011). The limits to acclimatization or adaptation capacity are presently unknown. However, mass extinctions occurring during much slower rates of climate change in Earth history (6.1.2) suggest that evolutionary rates in some organisms may not be fast enough to cope.

Comprehensive understanding of climate change effects on ecosystems requires addressing the effects of individual drivers across organism taxa (6.3.1 – 6.3.4), the integrated action of multiple drivers (6.3.5), the consequences for food webs (6.3.6), and the specific effects on animals breathing in air (6.3.7) and operating at the highest trophic levels.

6.3.1. Temperature Effects

The effects of temperature on ecosystems largely result from organismal responses. This requires that information on organisms' thermal sensitivities, limits, and functional properties is used to assess how temperature changes have affected and will continue to affect species distributions, abundances, diversity, trophic interactions, community assemblages, risks of species extinctions, and ecosystem functioning. Organisms also respond to temperature-driven changes in the physical environment such as stratification, reduced sea-ice cover and freshening. Ambient temperature interacts with other drivers such as ocean acidification and hypoxia (6.3.5). Ambient temperature plays a more limited role for marine mammals and seabirds (6.3.7).

6.3.1.1. Principles

All organisms including marine ones have limited temperature ranges within which they live and function. Organismal performance is related to temperature by curves called thermal reaction norms (Figure 6-5) which *likely* apply across all organisms (Chevin *et al.*, 2010), from viruses (Knies *et al*., 2006), bacteria (Ratkowsky *et al*., 1983), and phytoplankton (Eppley, 1972; Thomas *et al*., 2012) to macroalgae and plants (Bolton and Lüning, 1982; Müller *et al.*, 2009; Vitasse *et al*., 2010), and animals (Huey and Kingsolver, 1989; Angilletta, 2009). Heat tolerance thresholds differ greatly between organisms and are hypothesized to be lowered by rising organizational complexity and body size (Pörtner, 2002a,b). Maximum heat limits of animals and plants are close to the maximum temperature found in the warmest oceans (Figure 6-6). Knowledge of reaction norms, thermal limits, and underlying mechanisms is most advanced in animals (Pörtner *et al*., 2012; 6.3.1.4). Their role in underpinning biogeography has not been explored systematically in other organisms (e.g., Green *et al*., 2008), reducing the confidence level in assessments of thermal impacts. In animals, changes in physiological performances influence growth, body size, behavior, immune defense, feeding, reproductive success, biogeography, phenology and therefore, ecosystem structure and functioning. Shape and width of the curves can shift through acclimatization and evolutionary adaptation (Figure 6-5A) and during life history (Figure 6-5B) with implications for the distribution boundaries of species or populations (6.3.1.5).

For any species, tracking the climate-induced displacement of tolerated ambient temperatures by undergoing shifts in biogeographical ranges to, e.g., higher latitudes during warming (6.3.1.5: Figure 6-7), can be understood as a simple mode of adaptation, implemented through dispersal (e.g., of pelagic life stages), active movements (e.g., of migrating adult fishes) or passive displacement (e.g., of early lifestages or plankton with drifting water masses). Conversely, fully completed acclimatization or evolutionary adaptation (Figure 6-5) would involve shifting thermal tolerance ranges and allow species to resist the temperature trend (e.g., warming) and to sustain fitness in their previous habitat.

[INSERT FIGURE 6-5 HERE
Figure 6-5: Thermal specialization of an organism explains the why, how, when, and where of climate sensitivity. (A) The thermal tolerance range and performance levels of an organism are described by its performance curve (exemplified for an animal). Each Performance (e.g., exercise, growth, reproduction) is maximal at its optimum temperature (T_{opt}), and becomes progressively constrained during cooling or warming. Surpassing the first low and high temperature thresholds (T_p, p, pejus: getting worse) means going into time-limited tolerance. Once further cooling or warming surpasses the next low or high thresholds (T_c, c, critical), oxygen availability becomes insufficient and an anaerobic metabolism begins. Denaturation temperatures (T_d) are even more extreme and characterized by the onset of damage to cells and proteins. Horizontal arrows indicate that T_p, T_c, and T_d-thresholds of an individual can shift, within limits, between summer and winter (seasonal acclimatization) or when the species adapts to a cooler or warmer climate over generations (evolutionary adaptation). Under elevated CO_2 levels (ocean acidification) and in hypoxic waters performance levels can decrease and thermal windows narrow (dashed grey curves). (B) The width of the thermal range (horizontal arrows) also changes over time when an individual develops from egg to larva to adult and gains weight and size. Blue to red colour gradients illustrate the range between cold to warm temperatures (after Pörtner, 2002a, 2012; Pörtner and Farrell, 2008).]

[INSERT FIGURE 6-6 HERE
Figure 6-6: Maximal values of temperature covered by various domains and groups of free-living marine organisms (bacteria to animals, domains, and groups modified after Woese *et al*.,1990). High organizational complexity is hypothesized to be associated with decreasing tolerance to heat and to enable an increase in body size which in turn, decreases heat tolerance further (Alker *et al*., 2001; Baumgartner *et al*., 2002; Campbell *et al*., 2006; Chevaldonné *et al*., 2000; De Jonckheere *et al*., 2009, 2011; Pörtner, 2002a,b; Sorokin and Kraus, 1962). In the domain Bacteria, the Thermotogales are less complex and most tolerant to high temperatures (Abed *et al*., 2002; Huber *et al*., 1986; Takai *et al*., 1999; Tenreio *et al*., 1997; Ventura *et al*., 2000). The highest temperature, at which growth can occur is 122°C for hydrothermal vent archaea, seen under elevated hydrostatic pressure in laboratory experiments (Kashefi and Lovley, 2003; Takai *et al*., 2008.)]

6.3.1.2. Microbes

Temperature effects on growth, abundance, distribution, phenology, and community structure of highly diverse microbes might have large implications for ecosystem functioning (6.3, Box CC-PP). A warming ocean may initially enhance the metabolic rates of microbes (Banse, 1991) and stimulate their overall growth (Bissinger *et al*., 2008). Data from the Continuous Plankton Recorder (6.1.2) in the Northeast Atlantic confirm that warming from 1960 to 1995 enhanced phytoplankton growth (Edwards *et al*., 2001). Eventually, with warming, the thermal tolerance of some groups will be challenged (Chevin *et al*., 2010), leading to the replacement of species. This is reflected in increasing fractions of smaller phytoplankton in warmer relative to colder waters (Morán *et al*., 2010; Flombaum *et al*., 2013).

In response to transient warming, phytoplankton distribution in the North Atlantic shifted poleward by hundreds of km per decade since the 1950s. Phenology of plankton in the North Atlantic was also affected, with differences in sensitivity between groups (6.3.1.5; Box 6-1, *high confidence*). Coccolithophore blooms (*E. huxleyi*) in the Bering Sea were reported for the first time during the period 1997-2000, probably in response to a 4°C warming, combined with a shallower mixed layer depth, higher light levels and low zooplankton grazing (Merico *et al*., 2004). Loss of multi-year Arctic sea ice has had a profound effect on the diversity, structure, and function of the epipelagic microbial assemblage (i.e., found in the layer into which enough light penetrates for photosynthesis) (Comeau *et al*., 2011), and further warming is likely to have even greater impacts on the food web and on ecosystem services (*medium confidence*). Warming may also have caused the southward range extension of coccolithophores in the Southern Ocean in the 2000s (Cubillos *et al*., 2007). However, further experimental and field observations (Giovannoni and Vergin, 2012) are required to validate model projections (Taucher and Oschlies, 2011) of differential responses to warming by different microorganisms.

6.3.1.3. Macroalgae and Seagrasses

Macrophytes in coastal waters (WGII, Ch. 5) cover 0.6 % of the world's marine areas and supply about 2-5 % of total oceanic production (Smith, 1981; Charpy-Roubaud and Sournia, 1990; Field *et al*., 1998). They have limited temperature ranges and are sensitive to temperature extremes (*high confidence)* resulting in changes of photosynthesis, growth, reproduction and survival (following the principles of Figures 6-5, 6-6, Harley *et al*., 2012), with consequences for their abundance, distribution, and productivity. Ice retreat in polar areas leads to an expansion of macroalgal distribution, e.g. in the Antarctic (Quartino *et al*., 2013).

Warm- *versus* cold- water adapted species may have different sensitivities to warming and show a range of responses in distribution shifts (Lima *et al*., 2007). Temperate macroalgae with wide windows of thermal tolerance acclimatize by shifting these windows following seasonal temperature changes (Kübler and Davison, 1995). Antarctic and tropical macroalgae are exposed to permanently low or high temperatures, respectively, and have consequently specialized in a limited temperature range, paralleled by a low acclimatization potential (Pakker *et al*., 1995; Eggert *et al*., 2006; Gómez *et al*., 2011). Thus, Antarctic and tropical macroalgae appear to be most vulnerable to warming (*high confidence*, Short and Neckles, 1999). While observations in the tropics indicate that seagrasses tolerate higher temperatures than seaweeds (Campbell *et al*., 2006), an increase in maximum temperature by over 1°C from 1988-1999 to 2002-2006 (30.5.3.1.5) led to increased seagrass shoot mortality in the Mediterranean Sea (Marbà and Duarte, 2010). The molecular basis of acclimatization and evolutionary adaptation, as well as their limitation in relation to the climate regime require further study in the macrophytes.

6.3.1.4. Animals

The mechanisms shaping the thermal performance curve and, thereby, an animal's thermal niche have been explained by the concept of "oxygen and capacity limited thermal tolerance" (OCLTT), applicable to marine invertebrates and fishes (Pörtner *et al*., 2010; Figure 6-5A; FAQ 6.2). The temperature range at which animals can function best, results from optimal oxygen supply at minimal oxygen usage. At temperature extremes, oxygen supply capacity becomes constrained in relation to demand, and metabolism becomes thermally limited. Beyond upper and lower temperature thresholds (T_p, Figure 6-5A), growth, reproduction, and other key functions decrease. These thresholds change during the individual life cycle, and with body size. At large body size, limitations in oxygen supply are exacerbated and heat tolerance limits shift to lower temperatures.

Surpassing species-specific heat tolerance limits (Figure 6-5, T_p) during warming causes a reduction of abundance (Pörtner and Knust, 2007; Katsikatsou *et al*., 2012), coral losses (Donner *et al*., 2005), shifts in the seasonal timing of (zooplankton) biomass formation (Mackas *et al*., 1998; Schlüter *et al*., 2010), and changes in growth (Lloret and Rätz, 2000; Brunel and Dickey-Collas, 2010). During early life, due to incomplete development, or as adult spawners, due to large body size, animals may become more sensitive to warming because of narrower thermal windows (Pörtner *et al*., 2008). This may cause high vulnerability of winter-spawning Atlantic cod to warming winter to spring temperatures (Table 6-2). In contrast, adult bigeye, bluefin, and skipjack tuna spawn at high temperature. They need to prevent overheating by moving to cooler (deeper) waters (Lehodey *et al*., 2011).

Although temperature means are still most commonly used when attributing responses of marine organisms to climate effects, temperature extremes rather than means are most often mediators of effects (e.g., Easterling *et al.*, 2000; Wethey *et al.*, 2011; Wernberg *et al*., 2013; Figure 6-5). During heat exposure near the borders of the distribution range (including the high intertidal or warming surface waters), reductions in growth, activity, and abundance accompany even small (<0.5°C) shifts in ambient temperature extremes (e.g., Takasuka and Aoki, 2006; Pörtner and Knust, 2007; Nilsson *et al.*, 2009; Neuheimer *et al.*, 2011). Local extinction events follow due to mortality or behavioral avoidance of unfavorable thermal environments (Breau *et al.*, 2011). Shifted species distribution ranges follow temperature clines from high to low, usually along latitudes, a lateral gradient at basin scale (Perry *et al*., 2005; Poloczanska *et al*. 2013), or a vertical temperature gradient to deeper waters (Dulvy *et al*., 2008; Figure 6-5B, Box CC-MB, *high confidence*).

Adopting OCLTT principles has enabled modeling studies to project climate effects (6.5), and paleo-studies to explain climate-induced mass extinction events and evolutionary patterns in Earth history (Pörtner *et al.*, 2005; Knoll *et al.*, 2007). For example, long-term observations show that warming affects the body size of marine fishes (*medium confidence*). Assessing effects of warming on body size may be complicated by effects on the animal's energy budget, the changing availability and body size of prey species, community structure, species interactions, or effects of fishing (Genner *et al*., 2010; Cheung *et al*., 2013a). Below the thermal optimum, warming causes growth and weight-at-age of some juvenile or younger fish populations to increase (e.g., Brunel and Dickey-Collas, 2010; Neuheimer and Grønkjær, 2012). However, OCLTT predicts that small individuals are more heat tolerant than large ones, in line with observations of falling animal body sizes in warming oceans ((Box 6-1, e.g., Daufresne *et al.*, 2009). This trend is projected to continue into the 21st century (*medium to high confidence*; Cheung *et al*., 2013a).

Thermal windows of fishes and invertebrates roughly match ambient temperature variability (Figure 6-1) according to climate regime and seasonality (Pörtner and Peck, 2010; Sunday *et al*., 2012). Sub-Arctic, small or highly mobile species are eurytherms. They function across a wide temperature range, i.e., they have wide thermal windows and distribution ranges, at the expense of higher energetic costs and associated lifestyles (Pörtner, 2002a, 2006). Conversely, high polar species are stenotherms, i.e., they have narrow thermal windows and low energy demand lifestyles, making them sensitive to temperature change. In a warming world, polar stenotherms will be marginalized, with no possibility to escape to colder regions (*high confidence*). However, extinction of polar species has not yet been reported. As marine fishes and invertebrates in the Southern hemisphere are adapted to less variable ocean temperatures than those in the Northern hemisphere (Jones *et al*., 1999; Figure 6-1), they may generally be more vulnerable to warming extremes than northern ones. Tropical species (with thermal windows of intermediate width) live close to the highest temperatures tolerated by marine animals (Figure 6-6). Vulnerability is, therefore, highest for polar stenotherms, similar or lower for tropical and lowest for temperate species (*high confidence*).

Short-term shifts in thermal thresholds of an individual organism may happen over days and weeks, such as during seasonal acclimatization. Long-term shifts occur over many generations during evolutionary adaptation of a population to cooler or warmer climates (Figure 6-5A, Pörtner, 2006; Pörtner *et al.*, 2008; Eliason *et al.*, 2011). Both acclimatization and adaptation involve adjustments in biochemical characters (membranes, enzymes); however, the capacity to shift those boundaries is limited and depends on the species and the prevailing climate regime (Pörtner *et al.*, 2008, 2012). Ocean acidification, hypoxia, food availability, and stress affect those limits (6.3.5, Figure 6-5A).

Local adaptation may reduce climate vulnerability at the species level, by causing functional and genetic differentiation between populations, thereby enabling the species to cover wider temperature ranges and live in heterogeneous environments. Local adaptation on small spatial scales is particularly strong in intertidal organisms (Kelly *et al*., 2012). On larger scales, the widening biogeographic and roaming ranges of Northern hemisphere eurytherms into Arctic waters (Pörtner *et al*., 2008) are supported by the differentiation into populations with diverse thermal ranges, combined with high acclimatization capacity. By contrast, such capacity is small in high polar, e.g. Antarctic species (Peck *et al*., 2010). Tropical reef fishes undergo rapid warm acclimation across generations

(Donelson *et al.*, 2012) but some may approach animal heat limits. The rates, mechanisms and limits of thermal acclimatization and evolutionary adaptation are poorly understood (*low confidence*).

[INSERT TABLE 6-2 HERE
Table 6-2: Selected examples of species responses and underlying mechanisms to changing temperature, oxygen level and ocean acidification (OA). References are indicated by superscript numbers and in the footnote.]

Warm- and cold-water coral communities

Tropical corals live in shallow water and differ from most other animals by hosting dinoflagellates (*Symbiodinium sp.*) in their tissues, which provide the host with organic carbon from photosynthesis and with nitrogen and enable the corals to build and sustain carbonate reefs (Box CC-CR). High light, rapid salinity changes and small increases in temperature can trigger 'coral bleaching', the loss of symbionts and tissue color. In case of warming, early steps involve shifts in the photosynthetic processing of light, generating Reactive O_2 Species (ROS) that may in turn damage the symbionts (Glynn and D'Croz, 1990; Hoegh-Guldberg and Smith, 1989; Hoegh-Guldberg, 1999; Jones *et al*., 1998). Mass bleaching is correlated with small temperature anomalies (+1-2 °C of the long-term summer maximum, satellite observations), causing mortalities (Goreau and Hayes, 1994; Strong *et al*., 2011) and decreasing coral abundance, on average by 1-2 % per year (Bruno and Selig, 2007; Box CC-CR, 30.5.6, *high confidence*).

The degree of impact will depend on the coral reefs' adaptability to thermal stress and the interaction of multiple drivers (Meissner *et al*., 2012; Teneva *et al*., 2012; Box CC-CR). Such capacity is suggested by different heat tolerances among coral genera (Hoegh-Guldberg and Salvat, 1995; Loya *et al*., 2001), the exchange of genetic clades of *Symbiodinium* with more tolerant varieties (Baker, 2001; Jones *et al*., 2008), as well as acclimatization phenomena (Howells *et al*., 2012).

Studies of the thermal sensitivity of deeper-living cold-water corals (without endosymbionts) are scarce. One species, *Lophelia pertusa* responds to about 3°C warming with a three-fold increase in metabolic rate (Dodds *et al.*, 2007), indicating a narrow thermal window in the cold (cf. Pörtner, 2006).

6.3.1.5. Ecosystems

Heat exposure of ecosystem engineers may threaten the existence of a whole ecosystem. During the last warm interglacial period equatorial coral reefs deteriorated and retreated (Kiessling *et al*., 2012), a finding emphasizing their thermal sensitivity (Veron *et al*., 2009) and showing that warming oceans can reach temperatures well beyond the upper heat limits of distinct animal groups and marine animals overall (Figure 6-6). In present-day Great Barrier Reef, a large-scale survey found diverse coral types along a climatic gradient, with no consistent response to climatic drivers (Hughes *et al*., 2012). However, warm-induced bleaching has contributed to the progressive decrease in live coral cover observed over the last decades (Box CC-CR, 30.5.6; De'ath *et al*., 2012).

Within ecosystems, shifting competitive or trophic interactions, differential risks for species extinctions and, thereby, scenarios of community-level responses to temperature change (Urban *et al*., 2012; Milazzo *et al*., 2013) can be traced back to changing differences in the performance of participating animal species (Figure 6-7, e.g., Cairns *et al*., 2008; Harley, 2011; Pörtner, 2012). Knowledge is insufficient to assess interactions of species from different domains, impeding a deeper understanding of shifting distributions, abundances, community assemblages, and food webs in space and time (Parmesan and Matthews, 2005, *low confidence* in current understanding).

For example, in a coastal microcosm (small-scale, simplified experimental ecosystem) resident heterotrophic bacteria were stimulated by warming more than a laboratory-reared phytoplankter (Wohlers-Zöllner *et al*., 2011). Also, high- to low-latitude transects in both the North and South Atlantic revealed a shift between cold and warm waters, from photoautotrophs (gaining energy from photosynthesis) to chemo-heterotrophs (Hoppe *et al*., 2002). Thermal stimulation of bacteria over phytoplankton has biogeochemical implications, for example, microbially-mediated carbon dioxide flow to the atmosphere might increase (Sarmento *et al*., 2010). The principles and wider applicability of these findings require further investigation (*limited evidence, low agreement*, Kirchman *et al*., 2009).

[INSERT FIGURE 6-7 HERE
Figure 6-7: Role of thermal tolerance and performance of organisms at ecosystem level. (A) Thermal tolerance ranges (Figure 6-5) differ between species across polar, temperate and tropical climate zones, then overlapping between coexisting species. Shifting temperatures and specific effects of additional drivers on the respective performance curves (dashed lines) change the fitness of coexisting species relative to each other as well as their temperature range of coexistence (after Pörtner and Farrell, 2008). Warming alters the timing of seasonal activities (e.g., elicited by spring warming cues) earlier, or can benefit only one of two interacting species (e.g., in predator-prey dynamics or competition) causing shifts in predominance. (B) During climate warming a largely unchanged thermal range of a species causes it to follow its normal temperatures as it moves or is displaced, typically resulting in a poleward shift of the biogeographic range (exemplified for the Northern hemisphere, modified after Beaugrand, 2009). The polygon delineates the distribution range in space and seasonal time; the level of grey denotes abundance. The southern time window of tolerated temperatures shifts to earlier and contracts, while the northern one dilates (indicated by arrows). Species display maximum productivity in low latitude spring, wide seasonal coverage in the center, and a later productivity maximum in the North. The impact of photoperiod (length of daily exposure to light) increases with latitude (grey arrow). Water column characteristics or photoperiod may overrule temperature control in some organisms (e.g. diatoms), limiting northward displacement.]

Observations of shifting distributions and phenologies, reproduction, and range shifts of phytoplankton, zooplankton, other invertebrates, fishes, and seabirds in pelagic and coastal marine ecosystems have at least partly been attributed to temperature-mediated biological responses (*high confidence,* Figure 6-8; Box 6-1; Box CC-MB). In the North Atlantic as a key example, many biological events have been occurring earlier in the year (*robust evidence*, *high agreement,* Box 6-1, 30.5.1.1.1). Species richness has increased due to shifts in ranges and abundances. In the Norwegian and Barents Seas a time series (1959 to 2006) of four commercial fish species and their zooplankton prey showed that climate shapes population growth rates through complex influences early in life, including direct temperature effects on growth, indirect effects via the biomass of zooplankton prey, and delayed feedback effects through predators (Stige *et al.,* 2010). Differential species responses to temperature and trophic amplification were demonstrated to modify species interactions at five trophic levels, primary producers (phytoplankton), primary, secondary, and tertiary consumers (zooplankton, fishes and jellyfishes), and benthic detritivores (echinoderms and bivalves) (Kirby and Beaugrand, 2009). Also, the responses of various plankton functional groups, such as diatoms, dinoflagellates, and copepods, to warming are not synchronous, resulting in predator-prey mismatches that carry over to higher trophic levels (Figure 6-7A; Edwards and Richardson, 2004; Costello *et al.*, 2006; 6.3.6, *high confidence*). In the intertidal, warming-induced changes in relative species ranges lead to shifts in dominance through competitive interactions and to modifications in predator pressure (Poloczanska *et al*., 2008; Harley, 2011). Trans-Arctic interchange of species between Atlantic and Pacific has happened repeatedly in warm periods of the Pleistocene (Dodson *et al*., 2007) and may occur again, now facilitated by ballast transport by enhanced trans-Arctic shipping (*low* to *medium confidence*).

Warming may increase the risk of disease outbreaks or parasite infections, in marine organisms and ecosystems, and ultimately, humans (Burge *et al*., 2013; Altizer *et al*., 2013 *medium confidence*). Some marine pathogens and protist diseases are shifting their distribution poleward as oceans warm (e.g., Baker-Austin *et al*., 2013; Burge *et al*., 2013). Climate change may weaken the immune response of hosts, particularly fishes and invertebrates and increase their susceptibility to disease, as observed during warming in coral reefs of the Pacific and Caribbean (Harvell *et al*., 2009). Global outbreak frequencies of jellyfish aggregations may follow rising sea surface temperatures (SSTs) (*low confidence,* Mills, 2001; Purcell and Decker, 2005), but evidence is inconclusive. Some studies report an increasing trend (Brotz *et al*., 2012) and others do not support this view (Condon *et al*., 2013).

In conclusion, organisms live in limited temperature ranges and are sensitive to temperature extremes (*very high confidence*). Temperature governs the biogeography, diversity, development, reproduction, behavior and phenology of marine species as well as the composition of communities in both pelagic and benthic systems and the seasonal timing of relevant processes (phenology) (*very high confidence*). Ecosystems functioning at the coldest temperatures and warm adapted ones existing at their upper thermal limits are more sensitive (*medium confidence*).

[INSERT FIGURE 6-8 HERE
Figure 6-8: Multi-decadal changes in ecosystem structure in the NE Atlantic driven by warming from both anthropogenic climate change and natural climate variability. **A.** Index of temperature change over the North Atlantic (31°N-65°N and 99°W-11°E) reflecting climate change. This index is the first principal component (i.e., explaining 30.5% of observed variability) based on a Principal Component Analysis (PCA) performed on sea surface temperature. **B.** Index of temperature change (17.5% of observed variability) reflecting the Atlantic Multidecadal Oscillation (AMO). The index is the second principal component. **C-D.** Observed mean annual sea surface temperature in the North Sea during 1960-1981 (**C**) and 1988-2005 (**D**). The location of the critical thermal boundary (9-10°C) is indicated by '+'. **E**. Long-term changes in the mean number of warm-temperate pseudo-oceanic species from 1958 to 2005. **F**. Long-term changes in the mean number of temperate pseudo-oceanic species from 1958 to 2005. The period 1958-1981 was a period of relative stability and the period 1982-1999 was a period of rapid northward shifts, indicating that the abrupt ecosystem shift observed in the North Sea was part of a large-scale response of the zooplankton biodiversity to warming temperatures (see **A**-**D**). Average values are below 1 because they are annual averages. Note that the color bar is 10-fold smaller for warm-temperate pseudo-oceanic species because these species are less frequently observed than their temperate counterparts. Panels A. and B. from Edwards *et al*. (2013), and C. to F. from Beaugrand *et al*. (2008), and Beaugrand *et al*. (2009).]

_____ START BOX 6-1 HERE _____

Box 6-1. An Atlantic Ocean Example:
Long-Term Responses of Pelagic Organisms and Communities to Temperature

Long-term observations (6.1.2, 30.5.1.1.1) encompassing the pelagic Northeast Atlantic over a 50-year period and longer (Figures 6-8, 6-9) show changes in the seasonal abundance of phytoplankton, rapid northerly displacements of temperate and subtropical zooplankton (e.g. calanoid copepods), and phytoplankton (e.g. dinoflagellates and diatoms), and the resulting changes in the ecosystem functioning and productivity (Edwards *et al.*, 2001; Beaugrand *et al.*, 2002; Edwards and Richardson, 2004, *high confidence*). The range limit of warm water copepods shifted by 10° north since 1960 (Beaugrand *et al.*, 2009), with attendant mismatch in the seasonal timing of trophic levels (predators and prey) and functional groups (Edwards and Richardson, 2004). Modes of climate variability reflected in climate indices like the Northern Hemisphere Temperature (NHT) and the North Atlantic Oscillation (NAO) over multidecadal periods accompanied these changes (Figure 6-1). In cooler regions, increased phytoplankton activity caused by warming favored growth resulting in the observed increase in phytoplankton biomass, whereas a decrease in nutrient supply would have prevented growth in warmer regions and caused a decrease in biomass (6.3.4; Richardson and Schoeman, 2004). Hinder *et al*. (2012) attributed a recent decline in North Sea dinoflagellates relative to diatoms to warming, increased summer windiness and thus, water column turbulence. The ecosystem response to natural climate variability in the past provides a glimpse into the climate-induced changes of the near future (Figure 6-9).

In regions of high vulnerability to climate, mild warming can trigger rapid and substantial ecosystem shifts, offering a way to anticipate future changes (Figure 6-9). In line with the increased understanding of physiology (6.3.1.1), warming in the temperate to polar North Atlantic was paralleled by a reduction in the average body lengths of about 100 copepod species, from 3-4 mm to 2-3 mm (Beaugrand *et al.*, 2010). Warming was also correlated with an increase in species richness among copepods and within the dinoflagellate genus *Ceratium*. In diatoms, which are major contributors to carbon export (Armbrust, 2009), warming and decreasing annual variability in SST resulted in lower diversity, smaller size and reduced abundance (Beaugrand *et al*., 2010). Morán *et al.* (2010) found that temperature alone explained 73% of the variance in the contribution of small cells (picophytoplankton) to total phytoplankton biomass in the eastern and western temperate North Atlantic from -0.6 to 22°C. More recently, Marañón *et al*. (2012) analysed data from polar, sub-polar and tropical regions and suggested that nutrient availability may influence cell size more than temperature.

The ecosystem regime shift observed in North Sea plankton in the late 1980s involved an increase in phytoplankton and changes in species composition and abundance among holozooplankton (animals that are planktonic for their entire lifecycle) (Reid *et al.*, 2001; Kirby and Beaugrand, 2009; Kirby *et al.*, 2009; Lindley *et al.*, 2010). This shift was paralleled by the northward propagation of a critical thermal boundary (CTB, i.e., the boundary of the subpolar gyre) between the temperate and the polar biomes (Box CC-PP, Figure 1; Beaugrand *et al*., 2008). Warming to above the CTB coincided with pronounced and large-scale variations in phytoplankton productivity, an increase in calanoid copepod diversity (Beaugrand *et al*., 2008) and herring abundance (Schlüter *et al*., 2008), a reduction in the mean size of calanoids, and a decrease in the abundance of southern Atlantic cod populations in the North Atlantic Ocean (e.g., the North Sea, Pörtner *et al*., 2008; Beaugrand *et al*., 2010). These patterns also extend to the southern North Sea, where elevated salinities and average warming by 1.6°C, both in summer and winter between 1962 and 2007, expanded the time window for growth of microalgae and possibly supported the invasion and increase in numbers of warm-adapted silicified diatoms (Wiltshire *et al*., 2010). Recent findings indicate a regime shift in the Bay of Biscay, the Celtic and the North Seas, in the mid to end 1990s (Luczak *et al.*, 2011). Changing plankton composition and changing abundances of both sardine and anchovies (Raab *et al*., 2013) paralleled stepwise warming.

Northward range extensions or redistributions in fishes were largest along the European Continental shelf and attributed to regional warming, e.g. by 1.0°C from 1977 to 2001 in the North Sea, with winter warming being closely correlated with the shift of Atlantic cod (Perry *et al*., 2005; 6.3.1). Similar trends were observed due to warming by 1–2 °C in the waters south and west of Iceland during the past 15 years (Valdimarsson *et al*., 2012). In the Northwest Atlantic Arctic and sub-Arctic, winter and spring warming caused expansion of the area matching the thermal optimum of Atlantic salmon at 4–8°C and caused greater growth (Friedland and Todd, 2012). Pelagic sardines and anchovies entered the North Sea in the early to mid-1990s, after about 40 years of absence, in response to intensified NAO and AMO (Alheit *et al.*, 2012). Red mullet and bass extended into western Norway; Mediterranean and north-west African species extended to the south coast of Portugal (Brander *et al.*, 2003; Beare *et al.*, 2004; Genner *et al.*, 2004; 30.5.1.1.4).

In the Northwest Atlantic cooling and freshening occurred during the late 1980s-early 1990s and seemed to have the opposite effect, as capelin and their predator, Atlantic cod, shifted farther south (Rose and O'Driscoll, 2002). Between the early 1990s and mid-2000s in the Northwest Atlantic sub-polar gyre, phytoplankton biomass increased, due to warming. At the same time, Arctic copepod species became more abundant, due to increased influx of Arctic water (Head and Pepin, 2010). Although temperatures have risen on the Newfoundland Shelf (Colbourne *et al*., 2011), capelin and cod remain scarce for reasons probably unrelated to climate (DFO 2011a, b). Farther south, Arctic freshwater inflows caused freshening and increased stratification of the area around the Gulf of Maine throughout the 1990s, resulting in enhanced phytoplankton abundance, a larger and later fall bloom, increased abundance of small copepods, and a decrease in the large copepod *Calanus finmarchicus* (deYoung *et al*., 2004; Pershing *et al*., 2005, 2010). Various fish species showed poleward shifts in distribution (Table 6-2) which were associated with reduced survival of larval cod (Mountain and Kane, 2010) and fewer right whale calves (Greene *et al*., 2003), but increased herring abundance (Greene and Pershing, 2007).

[INSERT FIGURE 6-9 HERE
Figure 6-9: Schematic depiction of observed effects of ~1°C ocean warming in the northern North Atlantic driven by climate variability (A, C) versus effects expected from anthropogenic climate change (B, D). A) Transient warming and cooling associated with AMO variability (Drinkwater, 2006), based on the Kola Section temperatures (0-200 m; Stations 3-7, 71.5°-72.5°N, 33.5°E) in the Barents Sea obtained from http://www.pinro.ru and filtered using a 20-year running mean. Similar trends occurred across most of the northern North Atlantic although the amplitude and timing of the peaks and troughs varied spatially. B) Warming driven by climate change for the same region (RCP 8.5 simulations averaged from CMIP5 models, computed as the mean over the upper 200 m in the grid box (2.5x2.5 degrees) centered at 71.25N and 33.75E). C) Warming and subsequent cooling in the northern North Atlantic during the period shown in A resulted in complex multi-faceted changes (shown schematically) in NPP (green curve), zooplankton biomass (red curve) and fish stock abundances (blue curve). There was a general poleward shift and range expansion of many commercial (e.g., Atlantic herring, Atlantic cod, haddock) and non-commercial species, reversed during the subsequent cooling period (denoted by black dashed curve). Polewards shifts in spawning areas (e.g., Atlantic cod) were also reversed as the waters cooled. The purple and grey dashed curve represents shifts in seasonal timing (phenology) and community composition, respectively, that were influenced by earlier arrivals and later retreat of migratory fish (not shown). For more details see Drinkwater (2006). D) Projected effects of climate mediated warming on northern sub-polar and polar biota based on model projections of altered NPP (Bopp *et al*.,

2013), and of the range shift of exploited fishes and invertebrates (Cheung *et al*., 2009, 2013a). The projected trends in panel D will differ with latitude, e.g., decreased NPP at lower latitudes and no significant change to NPP in temperate waters (Bopp *et al*., 2013). Higher NPP supported and is projected to support higher trophic levels at high latitudes (C, D, 6.3.4). Note that climate variability will be superimposed on anthropogenic warming (B, see Figure 6-1, 6-8A,B). Dotted lines indicate projected changes to continue beyond the range of historical observations.]

_____ END BOX 6-1 HERE _____

6.3.2. CO_2 Effects

Evidence for biological effects of ocean acidification (OA) stems from paleo-observations (6.1.2), few observations in the field (6.3.2.5), studies at volcanic CO_2 seeps as natural analogues, and mostly from short- to medium-term (hours to months) experiments in the laboratory or field, exposing organisms to projected future CO_2 levels (6.3.2.1-4). A surging number of studies is providing evidence that rising CO_2 levels will increasingly affect marine biota and interfere with ecological and biogeochemical processes in the oceans (*high confidence*, FAQs 6.2, 6.3).

6.3.2.1. Principles

The absorption of rising atmospheric CO_2 by oceans and organisms changes carbonate system variables in the water and in organism internal fluids, i.e., the relative proportions of CO_2, carbonate, bicarbonate, and hydrogen ions (pH). Internal pH must be tightly controlled, as some processes, such as calcification, release protons thereby affecting pH and as other biochemical processes are pH-sensitive. Accumulation of CO_2 and the resulting acidification can also affect a wide range of organismal functions, such as membrane transport, calcification, photosynthesis in plants, neuronal processes in animals, growth, reproductive success, and survival. Effects translate from organism to ecosystem.

The capacity of organisms to resist and compensate for the CO_2 induced acidification of internal fluids depends on acid-base regulation, i.e., the capacity of ion exchange to accumulate bicarbonate internally, an aspect unexplored in many phyla (Figure 6-10A, *low* to *medium confidence*; e.g., animals: Heisler, 1986; Pörtner, 2008; Claiborne *et al*., 2002; phytoplankton: Taylor *et al*., 2011) (FAQ 6.3).

In unicellular microbes the regulation of intracellular pH may play a key role in modulating CO_2 responses (Taylor *et al*., 2011). Findings in invertebrates and fish indicate an additional role for extracellular pH (Figure 6-10A); effective pH values may vary between species. Organisms pre-adapted to elevated CO_2 may minimize the decrease in pH (acidosis). They may also modify their sensitivity such that they respond less or not at all to the acidosis. Recent evidence, however, emphasizes a role for acid-base regulation in a natural low-pH setting. Between two urchin species, only the one successful in maintaining its setpoints of extracellular pH is able to settle close to volcanic CO_2 seeps (Calosi *et al.*, 2013). Compensating for the acidosis may cause increased energy demand and respiration rates. In general, such capacity rises with metabolic energy turnover, e.g., it is higher in more active marine animals, such as fishes, cephalopods and pelagic copepods, and in mobile coastal crabs compared to sessile species (Table 6-3, Pörtner *et al*., 2005, 2011; Ishimatsu *et al.*, 2008; Melzner *et al.*, 2009; Ishimatsu and Dissanayake, 2010). This matches the sensitivity distribution seen among animals at the phylum level (Figure 6-9B, *medium confidence*).

Some species have lower metabolic rates in response to acidosis (Pörtner *et al*., 1998; Michaelidis *et al*., 2005; Pörtner, 2008; Liu and He, 2012; Navarro *et al*., 2013); others display increased energy turnover and food ingestion rates, possibly indicating a capacity to resist acidification effects (Parker *et al.*, 2011; Saba *et al*., 2012). The effects of the acidosis on various processes relevant to fitness may explain changes in whole-organism energy demand, probably paralleled by modified ion exchange, protein synthesis, growth and feeding rates. The magnitude of effect depends on the CO_2 concentrations reached (Figure 6-10B).

The internal formation of carbonate from bicarbonate is essential to calcification, which is the formation of solid $CaCO_3$ in internal or external calcified structures, used for defense and structural support. Calcification usually occurs in separate body or cell compartments, where pH and thus, CO_3^{2-} concentration and saturation Ω (6.1.1) are maintained at values higher than in other body fluids or ambient water (Trotter *et al*., 2011; Taylor *et al*., 2011; McCullough *et al*., 2012; Venn *et al*., 2013). CO_2 impedes the formation of carbonate such that calcification rate decreases. It may be maintained by enhanced transport of ions, incurring elevated energetic costs (Figure 6-10).

External carbonate structures like shells rely on ambient seawater being supersaturated with carbonates. Decreasing oceanic carbonate levels reduce the saturation levels (Ω) of calcite or aragonite in the water. Reduction to below unity may lead to the corrosion of carbonate shells (FAQ 6.3). However, many species protect their shells from direct contact with seawater by various types of organic coating (e.g., a periostracum in mollusks and brachiopods, an epicuticle covering the carapace of crustaceans; an epidermis covering the tests of urchins, epithelial tissue covering aragonite in corals, coralline algae precipitating calcium carbonate (mostly Mg-calcite) within their cell wall). A meta-analysis of the effects of ocean acidification on biological processes indicates that reductions in the rate of net calcification (calcification minus dissolution) and survival are the most uniform responses across organisms studied, relative to other, more variable impacts such as reduced growth, development, and abundance (Box CC-OA, Kroeker *et al*., 2013).

Some organisms benefit from elevated CO_2 partial pressures (pCO_2). Photosynthesis and/or nitrogen fixation in selected microorganisms are impacted by OA, but effects are species- or taxon-specific, possibly depending on how they acquire carbon (i.e., the presence and in particular the type, capacity, and energetic costs of carbon-concentrating mechanisms (CCM's, Giordano *et al.*, 2005; Kranz *et al.*, 2011).

A comprehensive picture of responses to CO_2 requires consideration of variable sensitivities between species and life stages and taxon-specific sensitivity distributions, as shown by a meta-analysis of animal data (Figure 6-10B, Wittmann and Pörtner, 2013). Echinoderms, bivalves, gastropods, and corals begin to respond negatively at lower CO_2 levels than crustaceans or cephalopods (Figure 6-10B). This sensitivity pattern resembles the one seen in the Permian mass extinction (Knoll *et al.*, 2007; Knoll and Fischer, 2011). The picture for fishes is less clear, as the present findings of high vulnerability are not met by similar observations in the fossil record. Evolutionary adaptation may thus eliminate or minimize reported effects.

The capacity for pH and ion regulation and other relevant processes can be upregulated by gene expression, as seen in acclimation studies in echinoderm larvae (O'Donnell *et al*., 2010; Martin *et al.*, 2011) and fishes (Deigweiher *et al*., 2008; Tseng *et al*., 2013), in warm-water coral branches (Kaniewska *et al*., 2012) but not in a study of warm-water coral larvae (Moya *et al*., 2012). Few studies address whether and to what extent species undergo evolutionary adaptation to high pCO_2, as seen in the coccolithophore *Emiliania huxleyi* over 500 asexual generations (Lohbeck *et al*., 2012). In organisms with longer generation times, perturbation studies in the laboratory measure tolerance and acclimation, but not adaptation or natural selection. Animal adaptation is accelerated by high functional variability among larvae, enabling selection of resistant genotypes (*low* to *medium confidence*, Parker *et al*., 2012; Sunday *et al*., 2011; Pespeni *et al*., 2013). This may explain the selective mortality seen in Atlantic cod larvae under elevated CO_2 (Frommel *et al*., 2012). Both acclimatization and adaptation will shift sensitivity thresholds but the capacity and limits of species to acclimatize or adapt remain largely unknown and hence impacts of acute exposures cannot easily be scaled up to effects on the longer, evolutionary timescales of ocean acidification (Wittmann and Pörtner, 2013). Observations in ecosystems characterized by permanently elevated or fluctuating CO_2 levels, like upwelling areas, OMZs (6.1.1), or seeps, reflect the existence of sensitivity thresholds (*high confidence*, 6.3.2.5) but organisms may have evolved a higher resistance to increased CO_2 levels than elsewhere (*low confidence*).

[INSERT FIGURE 6-10 HERE
Figure 6-10: A: Responses of a schematized marine animal (left) and a phytoplankter (right) to ocean acidification (OA). Effects are mediated via diffusive CO_2 entry (black arrows) into body and cell compartments, resulting in a rise in pCO_2 (highlighted in red), a drop in compartmental pH (highlighted in blue) and their effects (red arrows) on various processes (red text) in tissues and cellular compartments, as well as on calcium carbonate saturation state (Ω) at calcification sites (after Pörtner, 2008; Taylor *et al*., 2011). Variable sensitivity relates to the degree of pH decline and compensation, depending on the capacity of pH and ion regulation. B: Distribution of sensitivities across

species within animal phyla, under progressively rising water CO_2 levels, as percent of studied scleractinian coral, echinoderm, molluskan, crustacean and fish species affected negatively, positively or not at all (for effects considered see text). As not all life stages, variables and pCO_2 ranges were covered in all species two assumptions partially compensate for missing data: 1) Negative effects at low pCO_2 will remain negative at high pCO_2. 2) A positive or neutral outcome at both low and high pCO_2 will be the same at intermediate pCO_2. As responses reported for each species vary for each CO_2 range, variable species numbers result (on top of columns). The total number of species studied in a group is shown as the number above the control column. Horizontal lines above columns represent frequency distributions significantly different from controls (Wittmann and Pörtner, 2013). C: Areas with reported annual catches of marine calcifiers (crustaceans and mollusks) >0.001 t km^{-2}, depicted on a global map showing the distribution of ocean acidification in 2100 according to RCP8.5 (WGI AR5 SPM) as well as the distribution of warm-water (green dots) and cold-water coral communities (pink dots).]

Table 6-3 compiles effects of ocean acidification observed across taxa in laboratory and field experiments. The latter include studies in mesocosms and at natural analogues, submarine CO_2 venting areas at locales like Ischia, Italy (Hall-Spencer *et al*., 2008), Papua New Guinea (Fabricius *et al*., 2011), and Puerto Morelos, Mexico (Crook *et al*., 2012). It should be noted that anthropogenic CO_2 accumulation according to RCPs adds to the natural variability of CO_2 concentrations in marine environments. Many groups, especially sessile or non-photosynthetic calcifiers have sensitive species with vulnerability thresholds surpassed under RCP6.0 by 2100 (*low* to *medium confidence*).

Recent meta-analyses also summarize OA effects, two for biogeochemical processes and relative effect sizes (Kroeker *et al*., 2013; Harvey *et al*., 2013), one for the distribution of sensitivity between species within major animal phyla and its change depending on ambient pCO_2 (Figure 6-10, Wittmann and Pörtner, 2013). All of these analyses consider the interaction of warming and CO_2 accumulation (6.3.5). Present limitations in understanding the mechanisms of effect and their long-term persistence compounds accurate projections of the long-term effects of OA (*medium confidence*, Wittmann and Pörtner, 2013).

[INSERT TABLE 6-3 HERE
Table 6-3: Tolerances to ocean acidification in marine taxa, assessed from laboratory and field studies of species in the pCO_2 range from <650 to >10 000 µatm, compared to present day atmospheric levels of 400 µatm. (It should be noted that anthropogenic CO_2 emissions add to the natural variability of CO_2 concentrations in marine environments, which can reach much higher than atmospheric levels). Variables studied include growth, survival, calcification, metabolic rate, immune response, development, abundance, behavior and others. Neither all life stages, nor all variables, including the entire range of CO_2 concentrations, were studied in all species. *Confidence* is based on the number of studies, the number of species studied and the agreement of results within one group. +: denotes that possibly more species or strains (genetically distinct populations of the same species) were studied, as only genus or family were specified; beneficial: most species were positively affected; vulnerable: more than 5% of species in a group will be negatively affected by 2100; tolerant: more than 95% of species will not be affected by 2100. RCP 6.0: representative concentration pathway with projected atmospheric pCO_2 = 670 µatm; RCP 8.5: pCO_2 = 936 µatm in 2100 (Meinshausen *et al.*, 2011). *Confidence* is limited by the short- to medium-term nature of various studies and the lack of sensitivity estimates on evolutionary timescales, i.e., across generations (see separate reference list, online supplementary material). Note that the assessment of variability between species from the same animal phylum has revealed an increase in the fraction of sensitive species with rising CO_2 levels, see Figure 6-10. *Rather than a sensitivity threshold the entire range of investigated pCO_2 values is given for groups of photosynthetic organisms. In all studies photosynthetic rates are stimulated to different, species-specific degrees by elevated pCO_2, indicating low vulnerability. Coccolithophores and calcifying algae are assessed as being more sensitive than other photosynthetic organisms due to reduced calcification and shell dissolution. NA, not availaible, +confidence levels for fishes were converted from medium to low, in light of uncertainty on the long-term implications of behavioral disturbances.]

6.3.2.2. Microbes

The physiology of both calcifying (coccolithophores) and non-califying phytoplankton can be influenced by changes in carbonate system variables caused by ocean acidification (Figure 6-10A). Growth and photosynthetic rates of diatoms in laboratory cultures are considered relatively insensitive to elevated CO_2 (Rost *et al.*, 2003; Trimborn *et al.*, 2008). Dinoflagellate sensitivity to elevated CO_2 is poorly studied (Hansen *et al.*, 2007), but in one species carbon fixation rates were enhanced at 750 µatm CO_2 while growth remained unaffected (Fu *et al.*, 2008). Indirect effects of ocean acidification on phytoplankton physiology include altered availability of trace metals needed for many biochemical cycles (Hoffmann *et al*., 2012).

Harmful algal blooms are a growing problem in coastal waters worldwide (6.4.2.3), and many of the various phytoplankton species that produce bio-accumulated toxins are sensitive to changes in the seawater carbonate buffer system (Hallegraeff, 2010, Fu *et al*., 2012). For example, the dominance and community structure of harmful bloom dinoflagellates can be profoundly altered by changing pCO_2 (Tatters *et al*., 2013), and both toxic dinoflagellates and diatoms have been shown to produce higher toxin levels under near-future levels of ocean acidification (Fu *et al*., 2010, Sun *et al*., 2011).

Some planktonic N_2-fixing cyanobacteria (diazotrophs), e.g., strains (genetically distinct populations of the same species) of offshore cyanobacteria of the genera *Trichodesmium* and *Crocosphaera*, respond to rising CO_2 with increased rates of both carbon and N_2 fixation (Fu *et al*., 2008; Lomas *et al*., 2012). In contrast, laboratory studies using the bloom-forming cyanobacteria *Nodularia* (an organism largely found in coastal stratified, eutrophic waters) revealed decreased growth and N_2 fixation under elevated CO_2 conditions (Czerny *et al.,* 2009). The wide range of responses in N_2 fixation (e.g., Hutchins *et al.*, 2007; Levitan *et al*., 2007; Kranz *et al.*, 2010) may be explained by different CO_2 affinities (i.e., dependences of growth rates on CO_2 concentration) of a range of N_2-fixing cyanobacteria (*Trichodesmium* and *Crocosphaera*) from different oceanic biomes. Some species/strains operate at close to maximum growth rates at present-day oceanic CO_2 levels, whereas others had sub-optimal growth rates under these conditions (Hutchins *et al*., 2013). To date, the physiological mechanisms underlying these responses remain unknown, especially in open-ocean nitrogen fixers. Cyanobacteria may reallocate energy from their energetically expensive CCMs toward N_2 fixation and the acquisition of growth limiting nutrients (Kranz *et al.*, 2010; Levitan *et al*., 2010), but evidence for such diversion of energy is lacking. Whether nitrogen fixation will increase with progressive ocean acidification remains to be explored (*low confidence*, *limited in situ evidence*, *medium agreement*).

The responses of coccolithophore calcification to OA are species-specific and highly variable. The function(s) of calcification are not well understood, making it difficult to evaluate the consequences of lowered calcification (e.g., Rost *et al*., 2008). Reductions, increases, and unchanged calcification rates (and shell structure) have all been found in different coccolithophore species for RCP 8.5 CO_2 conditions projected around 2100 (Riebesell *et al.*, 2000; Zondervan *et al.*, 2001; Langer *et al.*, 2006; Iglesias-Rodriguez *et al.*, 2008). Calcification in coccolithophores is species- (Langer *et al.*, 2006) and in *Emiliana huxleyi* even strain-specific (Langer *et al.*, 2009, 2011; Hoppe et al., 2011). It thus remains unclear whether OA will result in exoskeletons that are insufficiently calcified for sustained structural support and protection in coccolithophores (*medium evidence, low agreement*).

Foraminifera display decreasing calcification and shell weight under elevated CO_2 (Lombard *et al.*, 2010). Changes in historical specimens (Moy *et al*., 2009, see below) and during glacial-interglacial cycles (Barker and Elderfield, 2002) support projections of future reductions in net calcification by foraminifera (*medium* to *high confidence*).

6.3.2.3. Macroalgae and Seagrasses

Primary production, shoot density, reproductive output, and below-ground biomass of seagrasses generally respond positively to elevated pCO_2, indicating CO_2 limitation of their productivity. Such effects were identified in both laboratory and field above 720 to 1800 µatm (*high confidence,* e.g., Palacios and Zimmerman, 2007; Hall-Spencer *et al.*, 2008; Andersson *et al.*, 2011, cf. 5.4.2.3). Production, growth, and recruitment of most but not all non-calcifying seaweeds also increased at CO_2 levels from 700 to 900 µatm (RCP8.5; Porzio *et al.*, 2011; Kroeker *et al.*, 2013). Some non-calcifying seaweeds and seagrasses will thus benefit from future ocean acidification (*high confidence*) but OA exposes them to higher than usual grazing as a consequence of losing deterrent phenolic substances (*low confidence,* Arnold *et al*., 2012).

Calcifying algae (corallines) show complex and species-specific responses of photosynthesis to elevated CO_2, but calcification is impacted once species-specific pCO_2 thresholds are surpassed (*medium confidence*, Anthony *et al.*, 2008; Martin and Gattuso, 2009). At habitat temperature calcification by temperate coralline red and calcareous green algae increased at CO_2 levels up to 900 µatm and only decreased at the highest concentration applied (2850 µatm), but did not fall below rates found at present-day pCO_2 (Ries *et al.*, 2009). During 3 months of exposure, growth of *Lithothamnion glaciale*, a cold-water calcareous red alga, decreased progressively with rising CO_2 levels, and its structural integrity was weakened beyond 590 µatm (Ragazzola *et al*., 2012), potentially influencing ecosystem function. Some calcifying algae may thus be impacted by future ocean acidification (*medium confidence*).

6.3.2.4. Animals

Studies of marine animals and their life stages show a high diversity and variability of processes affected by ocean acidification. Many variables studied reflect physiological performance (O_2 consumption, exercise, behavior, calcification, growth, immune response, acid-base balance, gene expression, fertilization, sperm motility, developmental time, production of viable offspring, and morphology; Table 6-3, Figure 6-10). In some species growth may be stimulated by OA, in others depressed, or unaffected (cf. Gooding *et al.*, 2009; Munday *et al.*, 2009a, 2011a; Dupont *et al.*, 2010). The degree of CO_2-induced acidosis and its compensation by ion exchange may shape sensitivity (6.3.2.1). Full exploitation of the ability to resist pCO_2 increases depends on the availability and high quality of food and the strengthening of fitness (Gooding *et al.*, 2009; Melzner *et al*., 2011). However, food quality of prey organisms may decrease under elevated pCO_2. For example, slower reproduction and growth of the copepod *Acartia tonsa* under 760 µatm pCO_2 was related to the decreasing quality of its diatom food (Rossoll *et al*., 2012).

Changes in calcification rates reported from CO_2 manipulation experiments vary widely. Reduced calcification and weakened calcified structures were seen under elevated pCO_2 in corals (see below), echinoderms (Kurihara and Shirayama, 2004), mollusks (Gazeau *et al*., 2013), and larval crustaceans (Arnold *et al.*, 2009; Walther *et al*., 2011). Some adult limpets and urchins increased calcification rates at pCO_2 from 600 to 900 µatm, before it fell at even higher pCO_2. In some adult crabs, lobsters, and shrimps calcification rates increased further with rising pCO_2 (Ries *et al.*, 2009). Stronger internal structures such as cuttlebones and otoliths resulted from enhanced calcification under elevated pCO_2 in juvenile cuttlefish (cephalopods, Gutowska *et al.*, 2008) and fishes (Checkley Jr *et al.*, 2009; Munday *et al.*, 2011b), with unclear impacts on fitness. Energy costs in epithelia or calcification compartments may be enhanced by elevated pCO_2 causing a stimulation of metabolism (6.3.2.1). In some cases, this may indicate imbalances in energy budget rather than increased CO_2 resistance, for example, if costs are down-regulated in muscle or liver. Enhanced calcification can then occur at the expense of growth (*medium confidence*, Wood *et al.*, 2008; Beniash *et al.*, 2010; Thomsen and Melzner, 2010; Parker *et al.*, 2011).

Studies on calcifying zooplankton focused on pteropods (planktonic mollusks with aragonite shells). These form an integral part of the food web, both as grazers and prey, e.g., for pink salmon (Armstrong *et al*., 2005; Hunt *et al.*, 2008). In the Subarctic, the Arctic, and the Southern Ocean, pteropods will reduce calcification in response to OA until at least the end of the century (*medium confidence*, Orr *et al.*, 2005; Comeau *et al.*, 2009; Lischka *et al*., 2011).

Elevated CO_2 causes behavioral disturbances in fishes (studied mostly in larvae and juveniles, Munday *et al.*, 2010; Ferrari *et al*., 2011; Domenici *et al*., 2012; Jutfeld *et al*., 2013) through neural mechanisms (Nilsson *et al*., 2012). The long-term persistence and evolutionary relevance of these behavioral effects need further study before general conclusions can be drawn (*low confidence*, Wittmann and Pörtner, 2013, Table 6-3).

6.3.2.4.1. Animal life cycles

It is generally held that early lifestages are always more sensitive to environmental stress than adults. In the context of ocean acidification this statement is supported by findings like larval oyster fatalities in aquaculture caused by upwelled CO_2-rich waters (*high confidence*; Barton *et al*., 2012). A key aspect may also be that larvae growing or developing more slowly under elevated CO_2 as in various groups including fishes (Baumann *et al*., 2012, 6.3.2.1) may encounter enhanced mortalities due to prolonged predator exposure. Comparative studies of animal sensitivities to OA over a complete life cycle or during critical transition phases (e.g. fertilization, egg development and hatching, metamorphosis, moulting) are scarce and do not support generalized conclusions (*low confidence*).

Effects of elevated CO_2 on one life stage or transition phase may affect or carry over to the next one. Moulting success into the final larval stage was reduced in a crab species (Walther *et al.*, 2010). In a sea urchin species, negative impact was found to accumulate during 4 months acclimation of adults reducing reproductive success. This impact was, however, compensated for during extended acclimation of female urchins for 16 months (Dupont *et al*., 2012). Negative impact was still transferred from urchin larvae to juveniles under elevated pCO_2. Conversely, adult oysters acclimated to high CO_2 acquired resistance which was carried over to their offspring (Parker *et al.*, 2012). More long-term acclimation studies to realistic emission scenarios are needed for generalized conclusions. Furthermore, the preposition that juvenile lifestages are always more sensitive than adults needs thorough re-investigation in the context of ocean acidification, especially in the context of the notion that larvae may provide a selection pool for survival of the most suitable phenotypes (6.3.2.1, *low confidence*).

6.3.2.4.2. Warm- and cold-water coral communities

In warm-water reef-building corals, OA causes genus-specific reductions in calcification (Leclercq *et al*., 2002; Langdon and Atkinson, 2005; Kleypas and Langdon, 2006). Nutrient availability to symbionts may sustain calcification. Heterotrophic feeding by the corals also supports energy-dependent calcification and acid-base regulation and thus, resilience (Edmunds, 2011; Figure 6-10). Females may sacrifice calcification more than males due to energetic tradeoffs with reproduction (Holcomb *et al.,* 2012). Warm-water corals are sensitive to future OA (*high confidence*, Table 6-3)

The cold-water coral, *L. pertusa* shows resilience to ocean acidification. In short-term ship-board incubations pH reductions between 0.15 and 0.3 units (540 and 790 µatm) led to calcification rates reduced by 30-56 % (Maier *et al.,* 2009), especially in young, fast growing polyps. However, net calcification was maintained at seawater aragonite saturation <1. Exposure to a pCO_2-induced pH reduction by 0.1 units or even to the projected end of century pCO_2 of 930 µatm led to calcification rates being maintained over six to nine months (Form and Riebesell, 2012; Maier *et al*., 2013). This ability is probably due to a regulated upward shift of pH and carbonate saturation at organismal calcification sites (Figure 6-10; McCulloch *et al*., 2012). Natural distribution of other cold-water species covers wide natural pH gradients in Chilean fjords (*Desmophyllum dianthus*; Jantzen *et al*., 2013) and ranges into waters with undersaturated carbonates as in Australian waters (4 scleractinian corals, Thresher *et al*., 2011). Pre-adaption to elevated pCO_2 apparently exists, however species vulnerabilities to further increases in pCO_2 have not been investigated. Again, vulnerability is species specific, colonial scleractinians may be limited to water saturated or near-saturated with aragonite, whereas others are not (Thresher *et al*., 2011). Conclusions on the relative vulnerability of the group appear premature (Table 6-3). To what extent a further lowering of carbonate saturation values will influence the future distribution of various calcite or aragonite forming cold-water corals is not clear (*low confidence*, Guinotte *et al*., 2006).

6.3.2.5. Ecosystems

For insight into ecosystem level processes, laboratory studies have been supplemented with experimental studies in large volume mesocosms (i.e., > 1000 L) and in the field, and with long- term field observations. Together they inform the debate over the attribution of field observations to ocean acidification.

6.3.2.5.1. Evidence from field observations

Contributions of anthropogenic ocean acidification to climate-induced alterations in the field have rarely been established and are limited to observations in individual species (see also 30.5.1.1.3). Shell thinning in modern planktonic foraminifera (collected 1997 to 2004) in the Southern Ocean compared to those from the Holocene and before was attributed to anthropogenic ocean acidification (Moy *et al*., 2009). Both anthropogenic OA and the upwelling of CO_2-rich deep waters (30.5.4.1.4) were held responsible for shell thinning in planktonic foraminifera in the Arabian Sea over the last century (de Moel *et al.*, 2009) or in live pteropods collected in 2008 in the Southern ocean (Bednaršek *et al.*, 2012; *medium evidence*, *medium agreement*). However, no changes were observed in a 57-year record of the composition and abundance of calcifying zooplankton in the increasingly acidified California Current System (Ohman *et al.*, 2009). Possible explanations for the absence of significant responses in some studies include insufficient lengths of time series (6.1.2), organisms being preadapted to naturally high CO_2 in upwelling or other systems, linked to a low signal-to-noise ratio, or the difficulty of detecting small OA effects in comparison with larger ecosystem effects of other drivers such as temperature, e.g., in calcifying plankton, Beaugrand *et al*. (2013). Similarly, declines in coral calcification and performance in the field (De'ath *et al.*, 2009) were attributed to thermal extremes, but may also include an as-yet unclear contribution from OA.

6.3.2.5.2. Microbial communities and nutrient cycles

Laboratory experiments, coastal mesocosm studies (Weinbauer *et al*., 2011) and field experiments (Beman *et al.*, 2011; Law *et al*., 2012) have yielded various, sometimes conflicting results on the effects of CO_2 on microbial processes. From a meta-analysis of available data, Liu *et al.* (2010) conclude that the rates of several microbial processes will be affected by OA, some positively, others negatively. The potential of the microbial community to adapt to ocean acidification and maintain functionality, either by genetic change at the species level or through the replacement of sensitive species or groups at the community level, remains to be explored further. At the present time there is insufficient field-based evidence to conclude that elevated CO_2 will affect natural assemblages of microorganisms (*limited evidence, low agreement*) with the possible exception of the negative impact on calcification (Joint *et al*. 2011).

Experimental studies on OA effects (through reduced pH or increased CO_2) on autotrophic and heterotrophic microbial production have provided inconsistent results. Microbes are characterized by large diversity and broad environmental adaptation, and hence may respond to environmental challenges by exploiting such diversity via species replacements (Krause *et al*., 2012). This makes it difficult to project the findings of laboratory experiments investigating the response of microbes to OA to the ecosystem level. Relevant variables include cellular elemental stoichiometry (C-N-P ratios, Riebesell, 2004; Fu *et al*., 2007), rates of CO_2 and N_2 fixation (Riebesell, 2004; Hutchins *et al*., 2007; Hutchins *et al*., 2009), rates of nitrification (Beman *et al*., 2011), changes in the proportion of dissolved (i.e., DOC) to particulate photosynthate produced during carbon fixation (Kim *et al*., 2011), and the response of viruses (Danovaro *et al.,* 2011).

Field experiments led to the projection that nitrification rates (ammonia oxidation to nitrite and nitrite oxidation to nitrate) of bacteria and archaea will be reduced by 3–44% when pH is reduced by 0.05–0.14 (Beman *et al.*, 2011), corresponding to a mean rise in CO_2 by ~100 µatm. The reported decrease in nitrification occurred regardless of natural pH variability, providing no evidence for acclimation of the nitrifiers to reduced pH, e.g., in upwelling areas. Potential changes in microbial cell abundance, possibly as a result of lower cellular nitrification rates, could further decrease the total rate of nitrification.

It remains unclear whether OA has contributed to the systematic changes in phytoplankton abundance and community structure observed over recent decades, which have largely been attributed to warming (Chavez *et al.*, 2011). In natural assemblages from coastal and polar waters, NPP is stimulated by increased CO_2 (*medium confidence*; Riebesell *et al.*, 2008; Tortell *et al.*, 2008). Small differences in CO_2 sensitivity may lead to pronounced shifts in the dominance of species (Tortell *et al.*, 2008; Beaufort *et al*., 2011). Quantification of the calcite mass of the coccolithophore community in the present ocean and over the last 40,000 years were in large part attributed to shifts between differently calcified species and morphotypes according to carbonate chemistry (Beaufort *et al.*, 2011). The same study, however, also observed heavily calcified *E. huxleyi* morphotypes in upwelling systems characterised by low pH, a finding which highlights the complexity of assemblage-level responses and may indicate pre-adaptation to elevated pCO_2. Due to the complex response patterns, it is not possible to project ecosystem-level effects from effects on coccolithophore calcification in monospecific culture experiments (*low confidence*). Projections of OA impacts on phytoplankton become even more complicated by synergistic interactions with other drivers (Boyd, 2011; 6.3.5).

6.3.2.5.3. Macrophytes and macrofauna

Macrofauna and macrophyte communities have been studied in mesocosms and in ecosystems exposed to shifted upwelling regimes or at natural volcanic CO_2 vents (Kroeker *et al*., 2011; Fabricius *et al*., 2011). The latter are considered as natural analogues of future ocean acidification. An eight-year trend of (variable) pH decline in upwelled waters along the Northeast Pacific coast was paralleled by shifts in community composition, where shelled species like mussels were replaced by fleshy algae and barnacles (Wootton *et al*., 2008). Macrofaunal calcifiers at CO_2 vents (Hall-Spencer *et al.*, 2008; Fabricius *et al.*, 2011) and in mesocoms (Christen *et al.*, 2013) display a lowering of species richness. These findings suggest that non-calcifiers increasingly outcompete calcifiers once pH_T decreases to a mean of 7.8 to 7.7 (*medium confidence*). Finally, a loss of calcifiers from mesocosms occurred around 0.5 units below the pH values expected from OA under RCP 8.5 by 2100 (*medium confidence*, Christen *et al.*, 2013). At CO_2 seeps, calcitic bryozoans replace coralline algae, which have more soluble high-calcite skeletons (Martin *et al.*, 2008). Seagrasses and non-calcifying algae gain a competitive advantage (Fabricius *et al.*, 2011). Coral communities exposed to high pCO_2 waters (from upwelling or seeps) have lower growth, calcification and biodiversity (Manzello *et al*., 2008; Fabricius *et al*., 2011), resulting in a shift from net accretion to erosion (Box CC-CR). The use of seeps as analogues of future OA is limited as pH variability is high at these sites, such that effective values may be lower than indicated by the average change (Hall-Spencer *et al.*, 2008; Porzio *et al.*, 2011). During periods of high pH at the seeps, they are recolonized by invertebrates and fishes from neighboring areas with normal pH, compromising assessments of long-term sensitivity thresholds. Overall, findings available from mesocosms and natural analogues indicate losses in diversity, biomass and trophic complexity of benthic marine communities due to elevated CO_2 (*high confidence*) and support the projection of similar shifts in other systems with continued OA (*medium confidence*).

Enhanced freshwater input by poorly buffered rivers or by precipitation, into estuaries, brackish oceans like the Baltic (30.5.3.1.4), and into freshening polar oceans, reduces salinity and alkalinity at rising atmospheric pCO_2 and thereby, alters the carbonate system and enhances OA (6.1.1). Estuaries usually have OMZs, where background pCO_2 is elevated. Its reduction by dilution causes the acidification effect to be somewhat less. Enhanced pH reduction and variability in hyposaline waters may constrain the distribution of sensitive species further (*low confidence*, Miller *et al.*, 2009; Denman *et al.*, 2011).

6.3.2.5.4. Conclusions

Natural analogues, laboratory and mesocosm experiments provide evidence for differential effects of ocean acidification on species and communities. Sensitivity to OA is species-specific (*high confidence*); differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (*low* to *medium confidence*). OA may stimulate global net primary production (*low confidence*) and nitrogen fixation (*medium confidence*). OA will increase the abundance and primary production of non-calcifying macrophytes, but will be harmful to calcifying algae and heterotrophs (*medium confidence*). Ecosystems relying on calcified structures and at risk of dissolution under OA include warm-water coral reefs (*high confidence*) and their cold-water equivalent (*medium confidence*). Further studies need to explore how OA may change the composition of communities, impact food webs and affect higher trophic levels.

6.3.3. Life in Hypoxia and Anoxia

6.3.3.1. Principles

Hypoxia constrains organisms which rely on aerobic metabolism (6.1.1, FAQ 6.2). Below O_2 concentrations of 60 µmoles kg^{-1}, commonly termed hypoxic (6.1.1.3), communities undergo species losses and replacements and are transformed into communities with species showing characteristic hypoxia adaptations. However, O_2 can limit animal life at even higher levels, just below air saturation (Gilly *et al*., 2013). Organisms' tolerance thresholds have been defined by either the critical O_2 partial pressure (P_c) or concentration (O_2crit). Thresholds vary across domains and are highest for large multicellular organisms. Among these, the P_c at rest varies depending on species, body size, and lifestage. In animals below the P_c aerobic metabolic rate fails to be maintained and anaerobic metabolism contributes to energy production (Pörtner and Grieshaber, 1993). The critical oxygen threshold is set by the capacity of ventilatory and circulatory systems to supply O_2 and cover demand. The threshold increases once metabolism is stimulated by muscular activity, temperature, or food uptake (Pörtner, 2002a; Ekau *et al.*, 2010; Seibel, 2011; Figure 6-11). At extreme temperatures, O_2crit approaches the oxygen content of air-saturated water (Pörtner, 2010; McBryan *et al*., 2013), indicating high sensitivity to hypoxia in the warmth. Most animals can only sustain anaerobic metabolism temporarily, even if they are energy-efficient and survive long periods of anoxia (Grieshaber *et al.*, 1994). Such time-limited tolerance is higher in large than in small individuals or larvae, related to the higher capacity of anaerobic metabolism in large specimens (Gray *et al.*, 2002; Jessen *et al*., 2009).

6.3.3.2. Microbes

Bacteria and protists consume ambient oxygen down to very low levels in ‘oxygen minimum zones’ and sustain OMZs by their metabolic diversity (Figure 6-11; WGI Box 6.5, Figure 1). OMZs form habitat for both anaerobic and aerobic microbes which can utilize very low (< 1 µmoles kg^{-1}) O_2 concentrations (Stolper *et al.*, 2010). Hypoxia is paralleled by elevated pCO_2 and enhanced acidification. Microbial life will benefit from expanding OMZs (*high confidence*) .

6.3.3.3. Animals and Plants

In mesopelagic OMZs, zooplankton also contribute to the development of hypoxia (Robinson *et al*., 2010, FAQ 6.2). During daytime zooplankton congregate at the upper margin of OMZs, where the degradation of organic material causes intensified respiration and oxygen depletion (Bianchi *et al*., 2013). Animals living permanently in the OMZ cover virtually all energy demand by aerobic metabolism. This requires special adaptations leading to a reduction in O_2 and energy demand, and the improved ability to efficiently use available O_2. Enhanced hypoxia tolerance reflected in low O_2crit values is supported by small body size and by cold temperature (Vetter *et al.*, 1994; Pörtner, 2002b; Levin *et al.*, 2009). Accordingly, low O_2 levels support abundant meiofauna (very small fauna, <1mm) which benefit from abundant food and reduced predation by larger organisms (Levin, 2003). Under suboxia only specialists can survive (Vaquer-Sunyer and Duarte, 2008). Expansion of suboxic and anoxic centres of pelagic OMZs and benthic dead zones will lead to loss of habitat for animal life (*high confidence*).

Large, more active animals like fishes, crustaceans, and muscular (as opposed to ammoniacal) squids tend to have high O_2 demands associated with high O_2crit thresholds, and are therefore excluded from permanently hypoxic water bodies. However, even in high-activity animal groups some specialists such as Humboldt squid or bigeye tuna have adapted to enter hypoxic environments though only temporarily (Richards *et al.*, 2009; Seibel, 2011). The time-limited tolerance of animals to hypoxia below the O_2crit is maximized by the depression of energy demand, for example during periods of metabolic arrest (e.g. developmental arrest or diapause of copepods; Auel *et al.*, 2005). Hypoxia-adapted lifeforms will benefit from expanding OMZs (*high confidence*).

There is little information on the hypoxia sensitivity of macrophytes or their O_2crit values. In eelgrass (*Zostera marina*), warming causes the hypoxia threshold to rise due to a strong increase in tissue respiration. Concomitant water or sediment hypoxia can elicit tissue anoxia and sudden die-offs (Raun and Borum, 2013). By contrast, macroalgae attached to rocks rarely encounter anoxia (Raven and Scrimgeour, 1997). Expanding benthic OMZs will constrain the distribution of macrophytes (*medium confidence*).

6.3.3.4. Ecosystems

OMZs, shoaling and expanding vertically and laterally (Gilly *et al*., 2013), will cause habitat and abundance losses for intolerant taxa such as mesopelagic (Koslow *et al*., 2011) and epipelagic fishes with a high O_2 demand (*medium* *confidence,* Prince *et al*., 2010; Stramma *et al*., 2012, FAQ 6.2). In line with the distribution of hypoxia sensitivities (Figure 6-11, 6.3.3.1, 6.3.3.3), expanding OMZs will further constrain the distribution of key zooplankton and nekton species and influence their diurnal and ontogenetic vertical migrations (*medium confidence*, Ekau *et al*., 2010). The composition of microbial and faunal pelagic communities will shift from diverse mid-water assemblages to migrant biota that return to oxygenated surface waters at night (Seibel, 2011). Dissolved O_2, among other factors, plays an important role in shaping large alternating fluctuations of sardine and anchovy abundances, particularly off Peru. Anchovies are not strongly affected by a shallow oxycline (<10m), while sardines actively avoid such conditions (Bertrand *et al*., 2010). Where OMZs intersect the continential shelves, groundfishes (McClatchie *et al.*, 2010) and large benthic invertebrates like crabs display high mortalities (Chan *et al.*, 2008). Susceptibility of early life stages to hypoxia in both pelagic and benthic ecosystems (Ekau *et al*., 2010) threatens population survival. Effects of hypoxia propagate along the food chain, constraining fish stocks and top predators (Stramma *et al.*, 2010; *high confidence*). Hypoxia reduces biodiversity (Levin *et al.*, 2009; Gooday *et al.*, 2010) and causes the marginalization of calcifiers, due to low metabolic rates and high pCO_2 (Levin, 2003; Levin *et al.*, 2009; *high confidence*).

The expansion and enhanced variability of OMZs increases dissimilatory nitrate reduction and anaerobic ammonium oxidation (anammox), both releasing N_2 into the atmosphere, reducing the availability of fixed nitrogen and limiting oceanic primary productivity (*medium confidence*). Water column denitrification and N_2 fixation are spatially and temporally variable (*limited evidence, low confidence*), suggesting that climate effects on these processes are *unlikely* to operate uniformly (Brandes *et al.*, 2007; Fernandez *et al*., 2011; Franz *et al*., 2012).

If O_2 levels decline and OMZs expand, tolerant taxa, such as anaerobic bacteria (Ulloa *et al*., 2012), gelatinous zooplankton (medusae, ctenophores), selected fishes (gobies, hake), and possibly selected cephalopods (Gilly *et al.*, 2006; Bazzino *et al*., 2010), will respond with range expansions or population growth. Similar phenomena are expected with intensified upwelling causing extensive mortalities of coastal fishes and invertebrates (Box CC-UP). A community change toward hypoxia-tolerant fauna will occur in mid-water (*high confidence*). The diversity of macroorganisms will decrease and, finally, higher marine organisms will disappear and heterotrophic microorganisms will dominate (*high confidence*). In isolated water bodies like the Black Sea, warming will lead to the expansion of anoxia and H_2S poisoning, reduce pelagic and bottom faunal distributions, and shape trophic relations, energy flows, and productivity (Daskalov, 2003; Fashchuk, 2011).

[INSERT FIGURE 6-11 HERE
Figure 6-11: (A) Principal mechanisms underlying the formation of hypoxic conditions and their biological background (modified from Levin *et al.,* 2009; Levin and Sibuet, 2012). The buoyancy flux from fluvial discharges produces sharp density stratification at the base of the freshened layer (also valid for ice melt and high precipitation) near the surface and, hence, vertical mixing is greatly reduced. In consequence, the nutrient inputs from the river and the atmosphere accumulate in a narrow upper layer, leading to blooms of phytoplankton, possibly including harmful algae. The enhancement of oxygen consumption due to aerobic decomposition of sinking organic matter results in hypoxic conditions of benthic and midwater OMZs. Enrichment of nutrients (eutrophication) results in coastal dead zones. In the open oceans, heating of the upper layer increases stratification, while the wind-driven upwelling of hypoxic, nutrient-rich water from deeper layers adds to the formation of the OMZs (Box CC-UP) (B) Distribution of free-living marine organisms (microbes such as archaea, bacteria, protists, small and large multicellular animals, and plants) across the ranges of O_2 concentrations in various water layers. Hypoxia tolerance is enhanced in small compared to large organisms, allowing unicellular species and small animals to thrive in extremely hypoxic habitats. Species richness and body size of animals increases with rising O_2 levels.]

6.3.4. Mixed Layer Depth and Light Shaping Net Primary Production

The upper ocean is characterized by physical and chemical gradients in the surface mixed layer that influence the magnitude of photosynthetic carbon fixation, often termed Net Primary Production (NPP). The availability of light and nutrients to photoautotrophs sets daily rates of NPP and may be altered directly or indirectly, through changing mixed layer depths, shifts in the circulation regime at different spatial scales and the physical displacement of organisms (6.1.1.4, Box CC-PP, Figure 6-2). A changing climate will affect mixed layer depth, cloudiness, and/or sea-ice areal extent and thickness and thereby, modulate NPP (*high confidence*). A stronger vertical density gradient will reduce the communication between the sunlit upper ocean where photosynthesis takes place and the underlying nutrient-rich waters (Figure 6-2). The supplies of plant nutrients (macro-nutrients) such as nitrate, and of micro-nutrients such as iron (Pitchford and Brindley, 1999) vary seasonally (Boyd, 2002) and regionally (Moore *et al.*, 2002), such that NPP may be simultaneously limited (co-limited) by more than one resource (6.3.5; Saito *et al.*, 2008).

The changing range and intensity of underwater light will lead to changes in NPP as well as in phytoplankton community composition (Doney, 2006; Boyd *et al*., 2010). The response of phytoplankton to changing sunlight involves photo-physiological acclimation via changes in cellular chlorophyll, but such acclimation is constrained by unidentified limits (Falkowski and Raven, 1997). A longer growing season, with more sea-ice free days between 1998 and 2009, may have increased NPP in open Arctic waters (Arrigo and van Dijken, 2011; Box CC-PP), complemented by massive under-ice blooms as seen in 2011, favored by light that penetrates surface melt ponds and thinner, e.g., first-year ice (Arrigo *et al*., 2012). There are also reports of increased incidences of high phytoplankton stocks, and hence of greater NPP, deeper in the water column (i.e., where it cannot be detected by satellite) during summer in the Arctic, which have implications to assessing changes in NPP from space (Hill *et al.*, 2013). Little is known about shifts from sea-ice algae to free-drifting phytoplankton expected with a decrease in sea-ice cover and effects of increased light in polar waters in the coming decades (*low confidence*). In the Arctic, summer ice melt led to a rapid export of sea-ice algae to the deep ocean (Boetius *et al.*, 2013). As some krill feed primarily on sea-ice algae, it is unclear (*low confidence*) whether they will adapt to feeding mainly on free-drifting phytoplankton (Smetacek and Nichol, 2005).

A range of time-series observations, from in situ phytoplankton abundances to satellite remotes-sensing, have been used to assess whether phytoplankton stocks and hence rates of NPP have altered over recent decades. Increases in phytoplankton stocks were found in regions where colder waters had warmed in the Northeast Atlantic, whereas the opposite trend was observed for warm water regions from a phytoplankton abundance time-series (Richardson and Schoeman, 2004). Lower chlorophyll concentrations at warmer SSTs in nutrient-poor low-latitude waters, based on satellite ocean color data, have been interpreted as an effect of increased stratification on phytoplankton stocks. It has thus been suggested that expanding, permanently stratified, low-chlorophyll, tropical regions (WGI, Ch. 3) indicate declining phytoplankton stocks in the warming oligotrophic waters of the N and S Pacific and N and S Atlantic (*limited evidence*, *low agreement* due to methodological uncertainties, Box CC-PP; Polovina *et al.*, 2008; Signorini and McClain, 2012; 30.5.1.1.2). Furthermore, a transition to conditions favoring increased frequency or even permanence of El Niño in a warmer future (Wara *et al.*, 2005) and further expansion of subtropical ocean gyres (Polovina *et al.*, 2008; 30.5.6), may lead to lower global ocean NPP (*low* to *medium confidence*).

However, these long-term ‘blended’ projections (i.e., constructing a biomass time-series using multiple proxies such as ocean transparency) of a global decrease in phytoplankton biomass (Boyce *et al.*, 2010) have been refuted (McQuatters-Gollop *et al*., 2011; Mackas, 2011; Rykaczewski and Dunne, 2011). Time series shorter than 20 years do not resolve impacts of bidecadal variation such as the Pacific Decadal Oscillation or the lunar nodal cycle (e.g., Watanabe *et al*., 2008; Henson *et al*., 2010). Analysis of continental shelf ecosystems, including field data in the most productive upwelling areas covering the last 20 years (e.g. Chavez *et al*., 2011), revealed a large variety of trends at scales of several decades but a general increase in NPP on most shelves (Sherman and Hempel, 2009; Bode *et al*., 2011), possibly caused by natural climate variability, anthropogenic climate change, and/or anthropogenic eutrophication. Recent field measurements document an increasing rate of both anthropogenic fixed N (Duce *et al*., 2008) and biological fixation of atmospheric nitrogen (Mouriño-Carballido *et al*., 2011) entering the open ocean, which could lead to increased NPP especially in warm, stratified tropical and subtropical oceans provided sufficient phosphate and other growth requirements are present (*low confidence*, e.g., Sohm *et al*., 2011).

For heterotrophs, from bacteria to fish, mammals and birds, the uptake of organic material as food, ultimately provided by NPP, is central not only to productivity but also for fueling energy consuming functions including the resistance of organisms to environmental change and pathogens (6.3.1-2). Any direct influence of climate on the abundance and quality of feed organisms will thus translate to indirect effects on the productivity and well-being of foraging animals (*high confidence*, Figure 6-5A, 6-7A, 6-12).

Overall, pelagic systems respond to climate change by region-specific changes in productivity with the projection of a small net reduction in global ocean NPP by 2100 (*medium confidence*, Box CC-PP). The spatial reorganization of NPP between latitudes affects higher trophic levels by alteration of the composition and functioning of pelagic communities (*medium confidence*).

6.3.5. Concurrent Responses to Multiple Drivers

Climate change alters oceanic properties globally, with concurrent changes in temperature, dissolved CO_2 and O_2, light, and nutrient concentrations (e.g., Sarmiento *et al.*, 1998; Matear and Hirst, 1999; Boyd and Doney, 2002; Ekau *et al.*, 2010; Figure 6-2). Additional direct human interventions at regional scale comprise the introduction of non-native species, overfishing, pollution, long-range atmospheric transport of nitrogen, point-source eutrophication, and habitat destruction (Carlton, 2000; Boyd and Hutchins, 2012). Worldwide alterations in marine ecosystems (Pauly *et al.*, 1998; Österblom *et al.*, 2007) have been linked to direct human activities, especially fishing (Frank *et al.*, 2005; deYoung *et al.*, 2008; Casini *et al.*, 2009), but may also be caused to some extent by climate variability and change (Cheung *et al*., 2013a).

Alteration of each individual property has pronounced effects on organisms from microbes to animals, and hence on ecosystems (6.3.1-4). The cumulative effects of these factors will result in complex patterns of change, from organismal physiology to the areal extent and boundaries of biogeographic regions (Table 6-4). In many organisms, effects of ocean acidification interact with those of other key drivers like temperature and hypoxia (Pörtner, 2012; Boyd, 2011; Gruber, 2011) and translate from molecular to ecosystem level impacts. In phytoplankton, low light (Zondervan *et al.*, 2002) or nitrogen limitation (Sciandra *et al.*, 2003) limit beneficial OA effects on photosynthesis, and have a strong negative effect on plankton calcification (Rokitta and Rost, 2012). Nutrients and light support functional adjustments to OA through gene expression changes (Dyhrman *et al*., 2006; Richier *et al*., 2009).

Similar to today, paleo-events such as the Palaeocene-Eocene Boundary demonstrate concurrent warming, enhanced stratification of the oceans, deoxygenation of deeper waters, and OA, albeit at a rate more than 10 times slower than today's rate (6.1.2). Both the complexity of paleo-ecosystem changes and the complexity of present effects confound the clear attribution of biological trends to individual drivers (Parmesan *et al.*, 2011). For warming and hypoxia, changes are accelerated by effects of shifting seasonal or even diurnal extremes and their frequency on organisms and ecosystems (*medium evidence* and *agreement*) (e.g. Pörtner and Knust, 2007; Díaz and Rosenberg, 2008). This may also apply to effects of anthropogenic OA (*limited evidence* and *low agreement*).

6.3.5.1. Principles

Effects of various climate drivers on ocean ecosystems are intertwined and effects may be exacerbated by responses of biota. For example, warming reduces O_2 solubility and enhances biotic O_2 demand, which exacerbates hypoxia, produces CO_2 and causes acidification (Millero, 1995; Brewer and Peltzer, 2009). Drivers act with either additive, synergistic (i.e., amplification of) or antagonistic (i.e., diminution of) effects. A meta-analysis of 171 experimental studies that exposed marine systems to two or more drivers identified cumulative effects that were either additive (26%), synergistic (36%), or antagonistic (38%) (Crain *et al*., 2008). Effects range from direct impacts of ocean warming on organismal physiology (Pörtner and Knust, 2007), to ocean acidification acting together with warming, e.g., on coccolithophore calcite production and abundances (Feng *et al.*, 2009), or with hypoxia and/or salinity changes (Table 6-4). Interactions of predominantly temperature, ocean acidification, and hypoxia have *likely* been involved in climate-driven evolutionary crises during Earth history (Pörtner *et al*., 2005; 6.1.2).

[INSERT TABLE 6-4 HERE
Table 6-4: Potential interactions between modes of anthropogenic forcing (environmental; foodwebs, harvesting) on different levels of biological organisation. These interactions, from simple to complex, are illustrated with examples from the literature. E, O, and M denote Experiments (lab or field), Observations, or Modeling approaches, respectively. Unknown denotes no published information is available for each of these categories. NA denotes Not Applicable for this category.]

Effects on individual organisms may also reflect intertwined impacts of ocean warming, acidification and hypoxia, which may operate through interrelated functional principles (Pörtner, 2012). Such knowledge helps to reconcile apparently contrasting findings. For example, warming toward the thermal optimum (Figure 6-5A) stimulates resistance to OA; CO_2-induced disturbances of growth and calcification were reversed by concomitant warming (Sheppard-Brennand *et al.*, 2010; Findlay *et al.*, 2010; Walther *et al.*, 2011). Warming to above optimum temperatures, however, constrains performance and exacerbates sensitivity to hypoxia (see below) and/or elevated CO_2 (Figure 6-5, e.g., via decreased calcification, Rodolfo-Metalpa *et al*., 2011), Both hypoxia and/or elevated CO_2 in turn enhance heat sensitivity, as seen for CO_2 in crustaceans (via decreased heat limits, Walther *et al.*, 2009; Findlay *et al.*, 2010), coral reef fishes (via reduced performance, Munday *et al.*, 2009b) and corals (via decreased calcification and CO_2-enhanced bleaching; Reynaud *et al*., 2003; Anthony *et al.*, 2008). This translates into a narrowing of the thermal niche (Walther *et al.*, 2009; Figure 6-5), which will shrink biogeographic ranges, affect species interactions and shift phenologies (Figure 6-7A). Hence, extreme warming and hypoxia exacerbate CO_2 effects and vice versa (*medium confidence*). Such principles need to be reconfirmed across organism taxa (Pörtner, 2012).

Differences in organism adaptation to a climate zone's characteristic temperatures, temperature variability, oxygen content, and ocean chemistry may shape vulnerability to climate change. In high polar species evolutionary cold adaptation enhances vulnerability to warming (*medium confidence*). In oxygen minimum zones, marine sediments, and in polar waters (due to high solubility in the cold), CO_2 levels are elevated and adaptation may reduce sensitivity and reliance on calcified structures (Clark *et al.*, 2009; Walther *et al.*, 2011; Maas *et al*., 2012). The observed shift from 'overcalcified' to 'weakly calcified' coccolithophores *Emiliania huxleyi* in cold waters may reflect a related shift in ecotype dominance (Cubillos *et al.*, 2007, *limited evidence, medium agreement*).

Despite such potential adaptation, polar calcifiers exposed to higher CO_2 and lower carbonate saturation levels have been hypothesized to be highly sensitive to further CO_2 accumulation (*limited evidence, high agreement*; Orr *et al.*, 2005). Here it appears relevant that cold temperature reduces energy demand and thereby lowers resistance to ocean acidification. Both energy demand and resistance are higher in eurytherms than in high polar and deep sea stenotherms (Pörtner, 2006; e.g. crustaceans, Pane and Barry, 2007, cf. Whiteley, 2011; *limited evidence, medium agreement*). In turn, tropical species may be more sensitive than temperate zone species (Pörtner *et al.*, 2011). This rough differentiation of sensitivity is complicated by the local adaptation of populations from within-species genetic variability (*low confidence*).

Temperature influences hypoxia sensitivity (6.3.3). Warming causes the minimum tolerated O_2 level to rise, enhancing vulnerability (*high confidence*). Conversely, hypoxia enhances vulnerability to warming in animals. This may occur fastest in warm oceans, where metabolic rates are higher and animals live closer to upper thermal limits (*medium confidence*, Pörtner, 2010). However, evolutionary adaptation has led to high hypoxia tolerance (low P_c or O_2crit values) in some warm-adapted coral reef fishes. Further warming then causes a rise in P_c which cannot be compensated for (Nilsson *et al*., 2010). Limits to hypoxia adaptation coincide with upper thermal limits (*medium confidence*).

Complexity in responses rises with the number of drivers involved. Enhanced river runoff and increased precipitation cause a shift from marine to more brackish and even freshwater communities, with unclear consequences for effects of other drivers. Falling primary production reduces resilience of higher trophic levels (Kirby and Beaugrand, 2009; Stock *et al.*, 2011). The introduction of non-indigenous species, when supported by climate-induced shifts in interactions, may promote the displacement of ecotypes and shifts in ecosystem functioning, e.g., in the Mediterranean Sea (Occhipinti-Ambrogi, 2007; Coll *et al.*, 2010).

6.3.5.2. Microbes

Both synergistic and antagonistic effects of multiple drivers on microbial biota in the surface ocean have been observed in manipulation or modeling experiments (Boyd *et al.*, 2010; Folt *et al.*, 1999; Gruber, 2011). The productivity of many microbes was simultaneously limited by, for example, availability of nitrate and phosphate, cobalt and iron (Saito *et al.*, 2002; Bertrand *et al.*, 2007), or iron and light (Boyd *et al.*, 2010; 6.2.2). Warming and high CO_2 synergistically enhanced photo-physiological rates of the cyanobacterium *Synechococcus*, whereas the cyanobacterial group *Prochlorococus* showed no change (Fu *et al.*, 2007). The magnitude of CO_2 effects on growth, fixation rates or elemental ratios within single species is often strongly modulated by nutrient availability and light conditions (e.g., Zondervan *et al.*, 2002; Sciandra *et al.*, 2003; Kranz *et al.*, 2010). Such differences cause floristic shifts in phytoplankton with the potential to restructure predator-prey interactions (Table 6-4).

Co-limiting factors vary by group, such as nitrogen fixers (e.g., Hutchins *et al*., 2007; Kranz *et al.*, 2010), diatoms (Boyd *et al*., 2010), and coccolithophores (e.g., Feng *et al*., 2009; Rokitta and Rost, 2012). This limits the ability to project climate change effects (Boyd *et al.*, 2010). The most reliable projections at ocean basin scale come from modeling, which mainly points to synergistic effects, such as those of elevated CO_2, hypoxia, and warming. For example, OA is projected to alter sinking particles (C:N ratio and/or reduced calcite content and slower sinking) with a consequent knock-on effect on water column O_2 demand already stimulated by warming, thereby causing expansion of OMZs (Gruber, 2011).

6.3.5.3. Animals and Plants

High oxygen availability alleviates thermal stress as seen in fish and mollusks (Mark *et al.*, 2002; Pörtner *et al.*, 2006). Conversely, hypoxia reduces heat tolerance (6.3.5.1), but acclimation to hypoxia compensates for this and increases thermal tolerance (Burleson and Silva, 2011), for example by enhancing blood pigment content or reducing energy demand. Tolerances to hypoxia and to high temperature may be positively correlated in some fishes, indicating potential for adaptive evolution under climate change (*low confidence*; McBryan *et al*., 2013).

As a consequence of hypoxia narrowing thermal ranges (6.3.5.1), combined warming and expanding hypoxia may cause mid-water mesopelagic and demersal fish stocks to decline at rates much quicker than anticipated in the California Current Ecosystem (Koslow *et al*., 2011; McClatchie *et al*., 2010). In benthic fauna, warming will also increase vulnerability to hypoxia. Experiments showed a rise in lethal oxygen concentrations by 25 % and thereby reducing survival by 36 % at 4 °C warmer temperatures (Vaquer-Sunyer and Duarte, 2011). Hence, warming is expected to expand the area of ecosystems affected by hypoxia even if oxygen concentrations remain unchanged (*high confidence*). Under combined hypoxia and warming, CO_2 can extend short-term passive tolerance (despite constraining long-term tolerance). It facilitates a reduction in energy demand (Reipschläger *et al*., 1997; Pörtner *et al.*, 2000), thereby extending survival of transient extremes of temperatures or hypoxia (*medium confidence*).

In macroalgae (non-calcifying) light availability modulates the response to elevated pCO_2 and temperature levels (Russell *et al*., 2011; Sarker *et al*., 2013). In warm-water corals, warming acting synergistically with CO_2 reduces calcification and increases sensitivity to bleaching (*high confidence*; Anthony *et al*., 2008). Combined warming and OA following B1 (~RCP4.5, reduced emission) and A1FI (~RCP8.5, business as usual) scenarios in mesocosms caused losses of symbionts and corals, and a nocturnal decalcification of the reef community in summer. Present day conditions already imply reduced resilience to episodic extreme events such as cyclones (Dove *et al.,* 2013, Box CC-CR).

6.3.5.4. Ecosystems

The cumulative impacts of climate change drivers underlie alterations of species interactions and ecosystem structure and functioning, including changes in trophodynamics and the physical and chemical characteristics of habitats (*high confidence*). These effects combine with more indirect effects, such as shifts in stratification and productivity, expanding oxygen minimum zones, and the changing composition and biomass of food (partly resulting from direct effects on prey organisms) (*high confidence*). These complexities reduce the precision and reliability of quantitative projections (6.5), including uncertainties concerning shifts in upwelling and their future role in global primary production and the development of fish stocks (Box CC-UP).

At the level of animal communities, effects of various drivers remain largely unexplored, some are highly complex. For example, the net eastward shift of Pacific skipjack tuna between 1980 and 2009 was linked to the shifting aggregation of macrozooplankton and micronekton, involving complex interactions of climate variability (due to ENSO, 30.5.2), warming ocean surface, shallowing mixed layer depth relative to the position of the warm pool, and the convergence of the pool with the Pacific Equatorial Divergence Province (30.5.6.1.1, Lehodey *et al*., 2011). Interactive drivers will affect the relative performance of interacting species, thereby shifting species ranges, interactions and food webs (*medium confidence*, Figure 6-7A). Adaptation to various climate zones modifies the roles of light and temperature in seasonalities and species interactions (Bradshaw and Holzapfel, 2010). Moderate hypoxia expansion in warming seas, e.g. as the stratified central North Sea (Queste *et al*., 2013) may well influence the degree of temperature-induced species displacements (Figure 6-7B).

Impacts of climate change on benthic ecosystem engineers can also profoundly alter ecosystems. Tropical corals respond to ocean warming and acidification by increased bleaching, impeded calcification rates, and increased incidence of disease (6.3.1-2; 30.5.6; Veron *et al.*, 2009; Veron, 2011, Box CC-CR, *high confidence*). In coral reefs under multiple stressors, differentiation of these large-scale phenomena into species-specific sensitivities is highly uncertain as trend data are virtually non-existent (Brainard *et al*., 2011). Little is known about impacts on deep-water or cold-water corals and sponges, tropical calcified algae, bryozoans, sponges, and tube-forming serpulid worms (Wood, 1999). The reliance of all of these on surface productivity makes them vulnerable to any alteration in food supply. Projected severe stress from increased temperature, hypoxia and ocean acidification will cause reduced performance and increasing mortality in ecosystem engineers (*high confidence*), and a deterioration of habitat characteristics for other organisms (*medium* to *low confidence*).

As a corollary, shifts in the geographical distributions of marine species (e.g., to higher latitudes or deeper waters; Figures 6-7B, 6.5.2) cause changes in community composition and interactions (Simpson *et al*., 2011; Harley, 2011; Hazen et al., 2013). Some species may gain predominance and abundance from fitness benefits (Figure 6-7) while others become less competitive or easier prey (Occhipinti-Ambrogi, 2007). Thereby, climate change will reassemble communities and affect biodiversity, with differences over time and between biomes and latitudes (*high confidence*, Box CC-PP; 6.5, Sala and Knowlton, 2006; Cheung *et al.*, 2009; Parmesan and Matthews, 2005; Parmesan *et al*., 2011).

6.3.6. Food Web Consequences

Community re-assembly under climate change involves a change in species composition and strongly alters food web structure, e.g., causing shifts in trophic pathways (Figure 6-12; Kirby and Beaugrand, 2009; Moloney *et al.*, 2011), some of which are irreversible (Jarre and Shannon, 2010). Through trophic cascades (Cury *et al.*, 2003; Luczak *et al.*, 2011), climate affects predation, competition, and food availability (e.g., via changes in NPP; Figure 6-12; Utne-Palm *et al.*, 2010), including fish resources (Parsons and Lear, 2001; Brown *et al.*, 2010). Trophic amplification then drives an ecosystem towards a new stable structure or regime, which may be difficult to reverse (Folke *et al*., 2004). Warming may result in consumer control of food web structure because respiration of heterotrophic zooplankton and bacteria increases more strongly with warming than does photosynthesis of autotrophic phytoplankton (*medium confidence*, O'Connor *et al*., 2009).

[INSERT FIGURE 6-12 HERE
Figure 6-12: Schematic diagram of expected responses to climate change in a marine food web. A coupled pelagic and benthic food web is structured by the body size spectrum of species. Combined warming, hypoxia and ocean acidification reduce body size, shift biogeographies, change species composition and abundance, and reconfigure trophic linkages and interaction dynamics. Fishing generally removes large-bodied species and truncates the body-size spectrum of the community. This confounds the detection and attribution of food web responses to climate change. Arrows represent species interactions (e.g., between predator and prey or competitors for food or space). Broken lines reflect the potential loss of populations and trophic linkages due to climate change.]

Many impacts of climate change on food webs resemble those caused by fishing, pollution, eutrophication, and associated hypoxia (6.3.3), and habitat change (Brander, 2007); unambiguous attribution to climate remains difficult (*low* to *medium confidence*; Parmesan *et al*., 2011). Some of these factors also affect food web responses to climate change. Fishing truncates the age and size structure of populations, making them more dependent on annual recruitment and reducing their ability to buffer environmental fluctuations (Genner *et al*., 2010; Botsford *et al.*, 2011; Planque *et al.*, 2010, Figure 6-12). Both adult and larval fishes show greater variability in abundance in exploited compared to unexploited populations (Hsieh *et al.*, 2008). Warming, acidification, and removal of top or competing predators may all contribute to large fluctuations in gelatinous plankton (e.g., jellyfish) populations (*low confidence*, Molinero *et al*., 2005; Richardson and Gibbons, 2008; Richardson *et al*., 2009; Condon *et al*., 2012).

Analyzing impacts on key species provides insight into how individual components of a food web will respond to perturbations. However, projections of future states must include the complex food web interactions that influence the species, and system-level responses, which affect stability and resilience of the overall ecosystem (Neutel *et al.*, 2007; Dunne and Williams, 2009; Romanuk *et al.*, 2009). There is no single approach currently available that includes the complex links within and among ecosystems, biogeochemistry, and climate as needed for projections of future states of marine food webs (Fulton, 2011; Moloney *et al.*, 2011). In conclusion, there is *low confidence* in the quantitative projections of such changes (for further discussion see 6.5).

6.3.7. Marine Reptiles, Mammals, and Birds

6.3.7.1. Principles

Marine reptiles (turtles, snakes, crocodiles), mammals, and seabirds breathe air but live mostly in water; some shift or expand their ranges as a result of climate warming. The body temperature of ectothermic reptiles is set by ambient conditions; only at large body size may their body store heat and temperature be higher than ambient. Reptiles are thus more responsive to temperature than homeothermic seabirds and marine mammals (McMahon and Hays, 2006), which regulate their body temperature by adjusting metabolic heat production and insulation from the environment, a trait beneficial especially in the cold. Various degrees of body core insulation in mammals and birds constrain their distribution to either warmer or colder waters (by poor or high insulation, respectively). However, large body sizes enable some aquatic air breathers to travel across the widest temperature ranges possible in some of the largest migrations on Earth.

Changes in water chemistry and hypoxia have minimal direct influences on the air-breathing vertebrates, reflecting their large independence from physical and chemical drivers in the oceans. There is evidence for increased sound propagation in a CO_2-enriched ocean, but no evidence yet for any effect on biota (Ilyina *et al*., 2010). If habitat structures offering retreat or ambush disappear, this will increase the energetic costs of life. Warming waters increases the cost of pursuit-diving as prey fishes increase swimming velocity. The predation success of such mammals (e.g., sea lions) and seabirds (e.g., penguins, cormorants) is thus constrained to waters ≤20 ºC (Cairns *et al*., 2008), a trend that extrapolates into the future (*low* to *medium confidence*). As prey distributions shift, foragers tied to land between trips may be constrained by the physiological costs of finding prey (Hazen *et al*., 2013; Péron *et al*., 2012). If food items are only found in thermally restricted areas or move to greater depths, mammals and birds may become constrained to certain distribution ranges or to the physiological limits of their diving ability (McIntyre *et al*., 2011). Conversely, hypoxic habitat compression for fishes may facilitate foraging opportunities for their air-breathing predators (Hazen *et al*., 2009). Accordingly, many air-breathers encounter changing habitat and food availability with climate change (*high confidence*).

6.3.7.2. Field Observations

Some species of seabirds, marine mammals, and sea turtles have responded to the anomalous ocean climate of the 20th century (*high confidence*, Hughes, 2000). There is insufficient information to assess effects on sea snakes or crocodiles. Poleward distribution shifts of turtles consistent with recent warming have been recorded in almost all marine groups. Decadal-scale climate fluctuations affect their recruitment success and nesting abundance (Van Houtan and Halley, 2011), with an inverse correlation between warming and abundance in various species and regions (Balazs and Chaloupka, 2004; Chaloupka *et al.*, 2008; Mazaris *et al.,* 2009). Extreme weather causes nest flooding, considerably reducing hatching success (Van Houtan and Bass, 2007), projected sea level rise (WGI, ch. 13) will exacerbate such impact. Those with high fidelity to nesting and foraging sites (Cuevas *et al*., 2008) are impacted more than those capable of changing those sites (Fish *et al*., 2009; Hawkes *et al*., 2009). Continued warming, modulated by changing rainfall (Santidrián Tomillo *et al*., 2012), may skew turtle sex ratios towards females, increase egg and hatchling mortality (Fuentes *et al.,* 2009), cause earlier onset of nesting (Pike *et al*., 2006; Mazaris *et al.,* 2008), decrease nesting populations (Chaloupka *et al.,* 2008), and shift dietary breadths (Hawkes *et al.,* 2009), leading to projected recruitment declines (e.g., leatherback turtles; Saba *et al*., 2012). Vulnerability due to shifting sex ratio alone remains unclear, as nesting beaches have persisted with low production of male hatchlings over decades or longer (*low confidence*, Broderick *et al*., 2000; Godfrey *et al*., 1999; Hays *et al*., 2003). The absence of sea turtles in certain regions may be best explained by the temporal unavailability of food resources or strong thermoclines restricting their bottom foraging abilities (Braun-McNeill *et al.,* 2008; Gardner *et al.,* 2008).

Seabird range modifications probably caused by climate change were recorded in polar areas and the temperate zone of the North Atlantic (Grémillet and Boulinier, 2009). Temperate species have shifted their ranges to higher latitudes in both hemispheres (Robinson *et al.,* 2005; La Sorte and Jetz, 2010; Bunce *et al.,* 2002). Some species, like the king penguin, follow shifting foraging zones (Péron *et al*., 2012); others, like the emperor penguin, are affected by changing habitat structure (sea ice, Jenouvrier *et al*., 2012). Warming causes many bird species to breed earlier (Sydeman and Bograd, 2009). High-latitude, cool-water species undergo extended breeding seasons (Chambers *et al.,* 2011). There is often no agreement, whether changes reflect solely ocean warming, or a combination of factors, such as fishing pressure on seabirds' prey species, sea level rise, and pollution (Heath *et al.,* 2009; Galbraith *et al.,* 2005; Votier *et al.,* 2005). Most shifts in range and seasonal activity involve shifts in trophic relationships (*medium confidence*). Seabirds with narrow geographic domains are expected to be more susceptible to climate change (Chambers *et al.,* 2005; Grémillet and Boulinier, 2009), even leading to local extinctions (e.g., the Galápagos penguin, Vargas *et al.*, 2007; or the marbled murrelet, Becker *et al*., 2007).

The distribution, phenology, and migratory timing of marine mammals is also shaped by predator-prey dynamics and climate impacts on specific habitats (Calambokidis *et al.,* 2009; Salvadeo *et al*., 2011). Some marine mammals, i.e. dolphin, porpoise, and whale species shift their distribution poleward to follow the movement of their prey (*medium confidence,* Simmonds and Isaac, 2007; Salvadeo *et al.,* 2010; MacLeod *et al.,* 2005; Springer *et al*., 1999). As in birds, vulnerability to climate change is high for marine mammals with narrow geographic ranges and high habitat dependence. For example, the critically endangered vaquita, endemic to the Northern Gulf of California, cannot move north because of the land barrier (MacLeod, 2009). The polar bear (Laidre *et al.,* 2008; Rode *et al.,* 2012) and the walrus depend on sea ice as a platform for hunting, resting, and giving birth. For polar bears, access to prey such as ringed seals has been disrupted by the later formation and earlier breakup of sea ice in the eastern Canadian Arctic. Seasonal migrants into the Arctic (fin, minke, gray, killer, humpback whales) may increasingly compete with species adapted to operate in habitat with sea ice (some seals, narwhal, bowhead whale, beluga). Both may benefit from the net loss of sea ice, which will offer them better access to foraging in a pelagic-dominated ecosystem (Moore and Huntington, 2008).

6.3.8. Summary and Conclusions

An organism's capacity to perform, but also its access to food energy fueling that performance, shape its sensitivity to climate change (*high confidence*). Extreme temperatures surpassing the fringes of the thermal envelope cause local abundance losses, extinction and shifts in temperature-dependent distribution ranges (6.3.1, *high confidence*).

Some climate change effects detected in the field can be attributed to temperature, but few allow clear attribution to other drivers (6.3.1-5, 6.6). In fishes and invertebrates, specialization in regional climate regimes co-defines sensitivity to warming, acidification and hypoxia (6.3.5, *high confidence*). In marine mammals, birds, and ectothermic reptiles changes in life history and population dynamics have often not been directly attributed to climate drivers (*low confidence*), but rather to the availability of habitat and food (6.3.7, *high confidence*).

Natural climatic variability (Figure 6-1) and anthropogenic change, with a strong role of warming, cause large-scale changes in biogeography, abundance, diversity, community composition and structure of marine species (6.3.1, *very* *high confidence*). Warming reduces body size (6.3.1, *medium confidence*). Differential species responses modify their interactions across trophic levels through trophic amplification (6.3.6, *medium* to *high confidence*).

Some tropical species and ecosystems exist close to upper thermal limits placing them among the marine ecosystems most affected by climate change (6.3.1, *high confidence*). Corals and coral reefs are primary examples. However, other factors change concomitantly, such that quantifying the ecosystem change attributable to warming or other drivers has not always been possible (6.3.5).

Under future climate change ocean acidification will affect marine organisms and ecosystems for centuries (6.3.2, 6.3.5, *high confidence*). To date, very few ecosystem-level changes in the field have been attributed to anthropogenic or local ocean acification (6.3.2, *medium confidence*). Concomitant trends of warming, O_2 depletion, OA, and other drivers prevent clear attribution to OA (6.3.5).

Elevated CO_2 levels stimulate primary production of some macroalgae and seagrass species (*high confidence*), causing them to be more competitive than calcifying organisms (6.3.2, *medium confidence*). High sensitivities to OA are associated with low capacities to maintain pH in internal fluids (*high confidence*). Calcification rates in sensitive invertebrates, including corals, echinoderms, and mollusks, decrease under OA, especially if combined with temperature extremes (6.3.5, *high confidence*). Thresholds beyond which effects occur can be quantified only with *low confidence*; there are differential sensitivities and thresholds between taxa and species (6.3.2, *high confidence*).

Expansion of OMZs leads to community shifts clearly attributable to extreme hypoxia (6.3.3, *high confidence*). Gradual effects of a progressive decline in ocean O_2 levels on communities have not been sufficiently explored.

In general, community re-assembly with new species coming in will occur in the transition to future climates (*medium confidence*) and lead to new ecosystem states (6.3.6, *low confidence*). Climate change interacts with top-down human interferences, like fisheries or other forms of harvesting, which accelerate impacts (*medium confidence*). Non-linearities challenge the projection of marine ecosystem trajectories (FAQ 6.4).

In microbes, a conceptual foundation suitable to support an integrated understanding of climate impacts on individual species and communities is lacking. Specific physiological responses, such as in primary production, N_2 fixation, or calcification, can be attributed to multiple environmental drivers associated with climate change (6.3.1-5, *high confidence*).

6.4. Human Activities in Marine Ecosystems: Adaptation Benefits and Threats

Human societies benefit from resources and processes supplied by marine ecosystems, so-called ecosystem services. Attributing and projecting ecosystem changes and their effects on human communities caused by climate change including ocean acidification (OA) is challenging. Insufficient observations compound an understanding of long-term changes and the definition of baseline conditions. Some of the challenges are related to the difficulty of projecting how human communities will adapt to changing marine ecosystem benefits.

6.4.1. Ecosystem Services

Marine ecosystem services (e.g., WGII, Ch. 5) include products (food, fuel, and biochemical resources), climate regulation and biogeochemical processes (CO_2 uptake, carbon storage, microbial water purification), coastal protection, provision of space and waterways for maritime transport, cultural services (recreational and spiritual opportunities, aesthetic enjoyment), and functions supporting all other ecosystem services (nutrient cycling, photosynthesis, and habitat creation). Most components of the marine environment contribute to more than one major category of ecosystem service: for example, ocean primary productivity is classified as a supporting service, but it affects provisioning services via changes in fisheries, generation of fossil fuel resources, regulating services via the global carbon cycle and climate regulation, and cultural services via the enjoyment of a healthy ecosystem. Rarely has economic damage of climate change to a whole ecosystem been evaluated and projected. The projected loss of tropical reef cover due to ocean acidification under A1 and B2 SRES scenarios will cause damages of 870 and 528 billion USD (year 2000 value) by 2100, respectively (cost rising with parallel economic growth, Brander *et al*., 2012; Box CC-OA). Such loss is felt most strongly in the respective regions.

6.4.1.1. Food from the Sea

Fisheries provide 3 billion people with almost 20 % of their average per capita intake of animal protein (FAO, 2012a), 400 million depend critically on fish for their food (Garcia and Rosenberg, 2010). Total world marine capture fisheries catches stabilized in the mid-1990s at about 90 million tons per year. Marine aquaculture of primarily mollusks and crustaceans contributes over 63 million tons annually to seafood production, mostly concentrated in coastal areas (FAO, 2012b). The growth of aquaculture has decelerated, but is still considered a development opportunity and a strong need in regions such as Africa and Latin America (WGII, Ch. 7.4.2.2).

Climate-induced shifts in ecosystems and fisheries production will create significant challenges to sustainability and management (7.5.1.1.3), particularly for countries with fewer resources and lower adaptive capacity, including many low-latitude and small island nations (*high confidence,* Allison *et al.,* 2009; Worm *et al.*, 2009; Cooley *et al*., 2012; 7.2.1.2, 7.4.2.1, 30.6.2, WGIII, Ch. 2.1.4). Vulnerability will be exacerbated by increases in the frequency and severity of extreme events (e.g. floods or storms) damaging infrastructure, homes, health, livelihoods or non-marine food security (Kovats *et al.*, 2003; Rosegrant and Cline, 2003; Adger *et al.*, 2005; Haines *et al.*, 2006).

The projected trends in fish stocks will widen the disparity in food security between developing and developed nations. Fish migrations due to warming (6.3.1) have already shifted the composition of fisheries catches (Pinsky and Fogarty, 2012; Cheung *et al*., 2013a) and altered stock distributions (Sabatés *et al*., 2006). Further warming may be beneficial for fisheries productivity in some regions such as the North Atlantic, because of the poleward shift of exploited species and changes in primary productivity (Box 6-1, 30.5.1.1.1; Arnason, 2007; Stenevik and Sundby, 2007; Cheung *et al*., 2010), or for some Pacific Islands due to the eastward redistribution of tuna stocks (Lehodey, 2000; Lehodey *et al.,* 2011). Resulting changes in accessibility and fishing operations costs are projected to straddle economic zones, perturb international fishery agreements and cause excessive exploitation (Hannesson, 2007; Sumaila *et al*., 2011; 7.3.2.6; WGIII, Ch. 4.3.7).

Invertebrate fisheries and aquaculture appear very vulnerable to the impacts of ocean acidification (Barton *et al*., 2012; Box CC-OA; Figure 6-10). This concerns especially shelled mollusks, with a substantial decline in their global production projected between 2020 and 2060 under the A2 business as usual scenario (Cooley and Doney, 2009; Cooley *et al*., 2012). Effects on calcifying plankton will propagate through the food web, making estimates of economic impact on fish catch by OA difficult, also due to complex interactions with other stressors like warming and fisheries management (Branch *et al*., 2013; Griffith *et al.,* 2012). Model projections suggest a potential loss of up to 13% (A1F1 scenario) to annual total fishery value in the US, or globally over 100 billion USD annually by 2100 (Cooley and Doney, 2009; Narita *et al*., 2012). Vulnerability differs highly between nations according to the contribution of such fisheries to their economy (Cooley *et al*., 2012; 7.3.2.6). These projections are sensitive to the projected vulnerabilities of the organisms to ocean acidification (6.3.2, *medium confidence*).

Fishing reduces abundances at high trophic levels, but increases abundances at mid trophic levels. It reduces species numbers, simplifies ecosystem structure, and increases ecosystem sensitivity to climate change (Perry *et al*., 2010). Exploitation of fish stocks and the alteration of their demography, population dynamics, and life history traits (Planque *et al.*, 2010; Petitgas *et al.*, 2006; Perry *et al*., 2010) can reduce the capacity of fish populations to buffer changes in climate variability (Ottersen *et al.,* 2006; Genner et al., 2010), and increase variability in population size. Interactions between warming, OA, and human activities such as fishing may thus exacerbate climate impacts on a wide range of ocean processes and services, including marine fisheries (*medium confidence*, Table 6-4, 6-6; 30.6.2).

A 2°C global temperature increase by 2050 is estimated to cause global losses in landed value of USD 17-41 billion annually (in 2005 value), with an estimated cost of adaptation for the fisheries of $7 - 30 billion annually over a 40-year timeframe between 2010 and 2050. The largest loss in landed value is projected to occur in East Asia and the Pacific (*low confidence,* Sumaila and Cheung, 2010). Overall impacts and the regional manifestations will partially depend on the flexibility and response capacities of food production systems (Elmqvist *et al.*, 2003; Planque *et al.*, 2011a). Specific implications for the fishing industry are still poorly known, as future projections of shifts in primary production and knock-on effects through food webs and into fisheries remain uncertain (*low confidence* in effects of changing NPP; Planque *et al.*, 2011b; Stock *et al.*, 2011).

6.4.1.2. Other Provisioning Services

Reductions in marine biodiversity due to climate change and other anthropogenic stressors (Tittensor *et al.*, 2010), like OA (CBD, 2009) and pollution, might reduce the discovery of genetic resources from marine species useful in pharmaceutical, aquaculture, agriculture, and other industries (Arrieta *et al.*, 2010), leading to a loss of option value from marine ecosystems. Climate change increases the demand for marine renewable energy such as wind and wave power, though with potential ecosystem impacts of their infrastructure (6.4.2).

6.4.1.3. Climate Regulation and Extreme Events

The effect of climate change on marine biota will alter their contribution to climate regulation, i.e., the maintenance of the chemical composition and physical processes in the atmosphere and oceans (*high confidence*, Beaumont *et al.*, 2007). Regulatory mechanisms in which organisms (especially phytoplankton) play a key role, include control of the level of atmospheric CO_2 through the balance between photosynthesis and respiration (Johnson *et al.*, 2010), and through the biological and alkalinity pump (Feely *et al.*, 2008; Falkowski, 1997). They also include the modulation of further greenhouse gases such as nitrous oxide (N_2O; Jin and Gruber, 2003; Law, 2008; 6.1.1.3), and the modulation of other climatically reactive gases such as dimethylsulphide (DMS; Vogt *et al.*, 2008). A projected decrease in global ocean NPP (6.5.1) may result in decreased export of biogenic carbon to the deep ocean (Bopp *et al.*, 2002; Boyd and Doney, 2002; Hashioka and Yamanaka, 2007). A positive feedback on climate change may result, however, many of the factors controlling the pump are poorly understood (Figure 6-4; WGI, Ch. 6).

Coastal marine ecosystems reduce the effects of floods and storm surges which account for most of the natural disasters affecting people in coastal regions (IPCC, 2012a). Empirical and modeling studies show that coral reefs contribute to buffering the impact of tsunamis (Fernando *et al.*, 2005; Gravelle and Mimura, 2008; 5.4.2.4, 30.5; Box CC-CR). Experiments and models indicate that warming and OA slow coral growth by nearly 50% by 2050 (Box CC-CR, 5.4.2.4), making some islands and coastal areas more vulnerable to tsunamis, storm surges, wave energy and coastal erosion (*high confidence*). Wetlands and mangroves provide biologically diverse buffer zones (5.4.2.3). The combined impacts of climate change, pollution, deoxygenation and other overlapping stressors, on mangroves and wetlands have not been determined (Cooley *et al.*, 2009; Cooley, 2012). Some of these stressors enhance each other's effects in coastal systems (Cai *et al.*, 2011; Howarth *et al.*, 2011; Feely *et al.*, 2010).

6.4.1.4. Cultural Services

Cultural services encompass a wide array of services with marine biodiversity as a core component supporting recreation and tourism as the economically most relevant. Tropical coral reefs and their enormous biodiversity sustain substantial tourist industries, presently with global annual net benefits of about 9.6 billion USD (Cesar *et al.*, 2003; Box CC-CR; 30.6.2.2). If reef services degrade, coastal visitors might choose alternative attractions (UNWTO, 2008). Increased travel to see disappearing ecosystem types (e.g., Antarctica, Liggett *et al.*, 2011) or in previously inhospitable areas or seasons (Amelung *et al.*, 2007; Moore, 2010) create new pressures and are unsustainable as the locations of key attractors shift (e.g., cetaceans, Lambert *et al.*, 2010; Salvadeo *et al.*, 2013).

Climate change may endanger harvests of marine species with spiritual and aesthetic importance to indigenous cultures, raising ethical questions about cultural preservation (e.g., Nuttall, 1998). In coastal communities, losing the aesthetic values of marine ecosystems may harm local economies: better water quality and fewer harmful algal blooms are related to higher shellfish landings and real estate prices (Jin *et al.*, 2008).

Some heritage benefits of preserving marine ecosystems consist of the economic value of a healthy, diverse ecosystem to future generations. Any climate-related biodiversity loss or pollution of marine ecosystems would decrease the bank of resources for future opportunities. For example, the research and conservation value of coral reef biodiversity and its non-use value are estimated together at US$ 5.5 billion annually (Cesar *et al.*, 2003). As with spiritual and aesthetic benefits, maintaining heritage benefits under climate change poses challenges for managers concerning equity and ethics as well as multigenerational (and possibly multi-cultural) ethical questions.

6.4.1.5. Supporting Services

Fully identifying the services supporting other ecosystem benefits is virtually impossible, as they are diverse in nature and scale. Ecosystem engineers play an important role in these services. Damage to calcifying algae and corals will reduce habitat for other species (6.3.5), biodiversity, cultural and leisure values and their climate regulation capacity.

Waterways for shipping are expected to change in the next several decades (*very high confidence*, 28, 30.6.2.3). Reductions in Arctic sea ice allow new trade routes such as the Northwest Passage (Wilson *et al.*, 2004; Granier *et al.*, 2006), enabling economically viable trans-Arctic shipping, and access to regional resources for exploitation and tourism. This development would increase emission of greenhouse gases and other pollutants (Lauer *et al.*, 2009; Corbett *et al.*, 2010), and facilitate the invasion of non-indigenous species carried on hulls and in ballast waters (Lewis *et al.*, 2004).

6.4.2. Management-Related Adaptations and Risks

6.4.2.1. Ecosystem Management

A changing climate will have both positive and negative consequences for managing ocean resources (*high confidence*) (6.4.1; Eide and Heen, 2002; Eide, 2007). Ecosystem-based management (EBM, an approach recognizing all, including human interactions within an ecosystem), or the ecosystem approach (EA, a strategy for the integrated management of living resources promoting both conservation and sustainable use), are increasingly adopted globally (FAO, 2003) to deal with the multitude of human pressures on marine ecosystems (Sherman *et al.*, 2005; Hoel, 2009). Extended EBM addresses changes driven by climate and human activities, considering that diverse drivers will interact and confound each other (6.3.5, Planque *et al.*, 2010; Eero *et al.*, 2011). Human activities will undermine resilience to other, including climate, impacts or undermine the effectiveness of mitigation and adaptation measures, by increasing variability (thereby reducing predictability), and limiting scope for adaptation (*high confidence*, e.g., Hughes, 2004; Eero *et al.*, 2011; Sissener and Bjørndal, 2005). Thus, managing ecosystems under climate change increases the resilience of ecosystems and adaptive capacity of management systems through reducing other human perturbations (e.g., overfishing) (Brander, 2008; 7.5.1.1.3). Managing ecosystems also reduces the consequences of ocean acidification until CO_2 emission reduction becomes effective (Box CC-OA; Rau *et al*., 2012; Billé *et al*., 2013; McLeod *et al*., 2013). Ecosystem resilience is enhanced by reducing regional eutrophication (Falkenberg et *al*., 2013), or in aquaculture by avoiding acidified water (Barton *et al*., 2012) and by selecting and cultivating pre-adapted strains (Parker *et al*., 2012).

However, effects of climate change cannot be reversed by reducing the impacts of non-climatic drivers, emphasizing the need for adaptive management. Increased variability of ecosystem responses to climate change and the low predictability of some biological responses undermine the effectiveness of management and conservation measures. A particular risk is that climate change may contribute to large-scale ecosystem regime shifts (6.3.1.5; Box 6-1). Detecting and forecasting such shifts from time-series of environmental and biological data (Carpenter and Brock, 2006; deYoung *et al*., 2008), is constrained by an insufficient number of observations and limited quantitative understanding (6.1.2). Biogeographic shifts challenge spatial management (Box CC-MB; 6.3.1., 6.5), which is a fundamental part of EBM (Douvere, 2008), and demand that “fixed in law forever” site-attached zoning to protect specific species may need to become more flexible to maintain the original objectives as species move or community structures shift (*high confidence*, Soto, 2001; Hawkins, 2012).

6.4.2.2. Geoengineering Approaches

Geoengineering approaches to mitigate climate change and its effects, include Solar Radiation Management (SRM) and Carbon Dioxide Removal (CDR; see Table 6-5; IPCC, 2012b). SRM aims to reduce warming by increasing albedo, for example via stratospheric injection of sulphate aerosol (Crutzen, 2006). SRM may affect marine ecosystems through changes in precipitation. With continued CO_2 emissions it leaves ocean acidification largely unabated as it cannot mitigate rising atmospheric CO_2 concentrations (Vaughan and Lenton, 2011; Williamson and Turley, 2012). Termination of SRM after its implementation involves the risk of rapid climate change and more severe effects on ecosystems (Russell *et al*., 2012).

Proposed CDR techniques include both ocean- and land-based approaches (Vaughan and Lenton, 2011; 30.6.4). CO_2 storage in geological reservoirs may occur beneath the seafloor, e.g., in porous marine aquifers, and includes the risk of CO_2 leakage to the marine environment. Proposals to directly or indirectly sequester CO_2 into the ocean (Table 6-5; Caldeira *et al*., 2005; Boyd, 2008; Shepherd *et al*., 2009; WGIII, Ch. 7.5.5) include, among others, the use of ocean fertilization techniques by nutrient addition, the direct storage of biomass in the deep ocean, the addition of alkalinity for build-up of DIC (dissolved inorganic carbon, i.e. carbonate), and the direct CO_2 injection into the deep ocean (Williamson *et al*., 2012). All of these approaches have potentially negative consequences for marine ecosystems.

[INSERT TABLE 6-5 HERE
Table 6-5: Challenges for the oceans that will arise from the employment of a range of geoengineering methods (SRM, solar radiation management, CDR, carbon dioxide removal).]

Ocean fertilization by adding iron to high-nutrient low-chlorophyll (HNLC) oceanic waters could increase productivity and the net export of organic material to the deep ocean and its consecutive decomposition, causing deep-water accumulation of CO_2. Fertilization would affect all major marine biogeochemical cycles of the ocean with unclear side effects that could include the formation of methane (CH_4) and N_2O (Law, 2008) or the stimulation of harmful algal blooms (Trick *et al*., 2010). The enhanced NPP would add more carbon to the base of food webs (de Baar *et al.*, 2005) and stimulate growth, e.g., of deep-sea benthos (Wolff *et al*., 2011). Any regional increase in organic material (through fertilization or intentional storage of biomass) would cause enhanced O_2 demand and deep-water O_2 depletion (Sarmiento *et al.*, 2010; Table 6-5), increasing the level and extent of hypoxia and associated impacts on marine ecosystems (6.3.3., 6.3.5, 30.5.7). The synergistic effects CO_2-induced acidification will exacerbate the biological impacts (*high confidence*).

Neutralizing the acidifying water by the addition of alkalinity, e.g., calcium oxide, would require large-scale terrestrial mining with associated consequences (Caldeira *et al*., 2005). The biological effects of increased concentrations of Ca^{2+} ions and dissolved inorganic carbon remain insufficiently explored. Direct injection of CO_2 or its localized disposal in the ocean (e.g. as a lake in a deep-sea valley) cause locally highly increased CO_2 and acidification effects on deep-sea organisms (6.3.3.4., *high confidence*, Caldeira *et al.*, 2005). In contrast to long-term ocean fertilization or storage of biomass, this technique leaves the oxygen inventory of the deep ocean untouched (*limited evidence, medium agreement*, Pörtner *et al.*, 2005).

The knowledge base on the implementation of SRM and CDR techniques and associated risks is presently insufficient. Comparative assessments suggest that the main ocean-related geoengineering approaches are very costly and have large environmental footprints (*high confidence*, Boyd, 2008; Vaughan and Lenton, 2011; Russell *et al.*, 2012).

6.4.2.3. Health Issues

Human health and near-shore ecosystems may be directly impacted by climate change effects on harmful algal blooms (HABs, Edwards *et al.*, 2006; 30.6.3) or disease vectors. Planktonic time-series archives and nearshore sediment cores containing HAB cysts have revealed few examples of strong linkages between altered HABs and climate fluctuations (Dale *et al.*, 2006; 30.5.3.1.2). HABs can be stimulated by warming, nutrient fluctuations in upwelling areas, eutrophication in coastal areas, and enhanced surface stratification (*medium confidence*). Species-specific responses involve shifts in seasonal cycles and blooms (Johns *et al.*, 2003). Ocean acidification may exacerbate the toxicity of species in coastal oceans under nutrient-limited conditions (Tatters *et al*., 2012; Sun *et al*., 2011). Suitable adaptation measures include appropriate monitoring of biotoxin problems (Hallegraeff, 2010).

Continued warming of tropical and temperate coastal habitats, excessive nutrient loading leading to phytoplankton and zooplankton blooms, and sea water inundation due to sea level rise are all projected to exacerbate the expansion and threat of cholera (*medium confidence*, 11.5.2.1; 30.6.3), although attribution to climate change is confounded by climate variability and non-climate drivers (Lafferty, 2009; Dobson, 2009). Cholera and its pathogen, the marine bacterium, *Vibrio cholera*, have been widely studied. The pathogen associates with marine organisms, especially chitinized zooplankton (Vezzulli *et al.*, 2010). Where cholera is endemic (e.g, India, Bangladesh, Latin America), outbreaks are correlated with warming and high zooplankton abundance (Lobitz *et al.*, 2000; Lipp *et al.*, 2002). Based on an 18-year climate record for Bangladesh, Pascual *et al.* (2000) reported cholera outbreaks at ENSO events, and the recent reappearance of cholera in Peru has also been linked to the intense 1991-1992 ENSO (Lipp *et al.*, 2002). An increase in sustained maximum temperatures of the Baltic Sea (30.5.3.1.4) has been related to an increase in reported *Vibrio* infections; highest human mortality rates were associated with *V. vulnificus* infections (Baker-Austin *et al*., 2013). Continued warming of tropical and temperate coastal habitats, excessive nutrient loading leading to phytoplankton and zooplankton blooms, and seawater inundation due to sea level rise are all projected to exacerbate the expansion and threat of cholera (*medium confidence*).

Ciguatera poisoning may occur when people consume fish, mainly from tropical reefs, that have ciguatoxins from the epiphytic dinoflagellate *Gambierdiscus* sp. Historical records show significant correlations between ciguatera poisoning and sea surface temperature in South Pacific nations (Hales *et al*., 1999). However, the relationship is non-linear and dependent on the thermal window of the specific dinoflagellate (Llewellyn, 2010). This casts doubt on the accuracy of projected increases in ciguatera poisoning using linear extrapolations from observations (*low confidence*).

6.4.3. Conclusions

Human societies benefit from and depend on marine ecosystem services, including the provisioning of food and other goods, regulation of climate and extreme events, and cultural and supporting services (6.4.1). Attributing and projecting climate-change-mediated shifts in these services remains a challenge, due to the intrinsic difficulty of assessments, lack of baseline and long time-series data and confounding human impacts. However, empirical and modeling studies indicate that climate change impacts on marine ecosystems lead to changes in provisioning, regulating and supporting services (*high confidence*), as well as cultural services (*limited evidence, medium agreement*).

Food production from the sea is facing diverse stressors (6.4.1.1), such as overfishing and habitat degradation, which interact with climate change phenomena, including warming (6.3.1), ocean acidification (6.3.2), and hypoxia (6.3.3). Projections of impacts on capture fisheries are constrained by uncertainties in marine primary production (*medium evidence* and *agreement*, 6.5.1). Negative effects are projected to be most significant in developing nations in tropical regions (*high confidence*). Nations at higher latitudes may even benefit from climate change effects on ocean ecosystems, at least initially (6.5.3).

Climate change effects on biota will alter their climate regulation through mechanisms such as carbonate production, the biological pump, the balance between photosynthesis and respiration, and the modulation of greenhouse gases (6.4.1.3, *high confidence*). However, projections of the direction and magnitudes of feedbacks are at an early stage (*low confidence*).

Future management of ecosystems and fisheries might have to aim for increasing ecosystem resilience to climate change, e.g., through reductions of other human perturbations (6.4.2.1). Active ocean geoengineering strategies to ameliorate climate change may prove detrimental to the functioning of ecosystems, which highlights the need for further research and careful governance (6.4.2.2). There is limited understanding of how harmful algal blooms and pathogens affecting human health will respond to climate change (6.4.2.3, *medium* to *low confidence*).

6.5. Projections of Future Climate Change Impacts through Modeling Approaches

A range of models explore climate change effects on marine biota, from primary producers to higher trophic levels, and test hypotheses about responses of marine species, food webs and ecosystems (Rose *et al.*, 2010; Stock *et al*., 2011; Fulton *et al.*, 2011, FAQ 6.2). Both empirical and mechanistic approaches are used over a range of temporal and spatial scales (Barange *et al*., 2010; Stock *et al*., 2011). There is an increasing need for upscaling from molecular and physiological to ecosystem level (e.g., Le Quesne and Pinnegar, 2012). Uncertainty in projections of changes in marine ecosystems is partly contingent on the level of confidence in climatic and oceanographic projections (6.1.1; WGI, Ch. 9.8). Models are currently useful for developing scenarios of directional changes in net primary productivity, species distributions, community structure and trophic dynamics of marine ecosystems, as well as their implications for ecosystem goods and services under climate change. However, specific quantitative projections by these models remain imprecise (*low confidence*, Rose *et al.*, 2010; Hannah *et al.,* 2010; Stock *et al*., 2011; FAQ 6.4).

Earth System Models couple atmosphere, cryosphere, and hydrosphere (including the oceans), as well as climate and carbon cycles and project changes in ocean biogeochemistry under a range of CO_2 emission scenarios (WGI, Ch. 6). Models focusing on population and species level responses comprise models of population dynamics, models of species distribution, and models which explicitly link effects of changes in ocean physics and chemistry to changes in interactions between species at different trophic levels, or human activities such as fishing and aquaculture (Rose *et al*., 2010).

6.5.1. Oceanic Primary Production

Climate induced effects on global ocean NPP comprise changes in its long-term average, seasonal timing, and peak amplitude (Henson *et al*., 2013). The magnitude, direction, and pattern of projected changes vary with differences in model structure and parameterization (Box CC-PP; Figure 6-13). Unknown accuracy of current NPP observations further increases the uncertainty of projections, as does the incomplete understanding of effects of multiple drivers on NPP (6.3.1-5, 6.4). Global coupled climate-ocean biogeochemical Earth System Models (WGI Ch. 6) project an increase in NPP at high latitudes but a decrease in permanently stratified oceans at mid-latitudes, in the tropics (west tropical Pacific, tropical Indian Ocean, tropical Atlantic) and in the North Atlantic (Steinacher *et al*., 2010; Bopp *et al*., 2013, *medium confidence*) (Figure 6-13). The overall result is a reduction in global mean NPP under all RCP scenarios (*medium confidence* in the direction of projected trends, *low confidence* in the magnitude of change).

[INSERT FIGURE 6-13 HERE
Figure 6-13: Multi-model annual mean changes of projected vertically-integrated net primary production (small and large phytoplankton) under the low emission scenario RCP2.6 (A) and the high emission scenario RCP8.5 (B) for the period 2090 to 2099 relative to 1990 to 1999 (after Bopp *et al.*, 2013). To indicate consistency in the sign of change, regions are stippled where 80% of the ten models from the Coupled Model Intercomparison Project Phase 5 (Bopp *et al*. 2013) agree on the sign of change.]

6.5.2. Higher Trophic Levels

Projected future changes in temperature and other physical and chemical oceanographic factors are expected to affect the distribution and abundance of marine fishes and invertebrates, as elaborated by species distribution models. Limits of distribution ranges of 1066 exploited species are projected to undergo shifts by a median of around 50 km per decade to higher latitudes by 2050 relative to 2000 under the SRES A1B (RCP6.0) scenario (Cheung *et al.*, 2009). Some species shift towards the equator following a regional temperature gradient (Burrows *et al*., 2011;

Cheung *et al.*, 2013b; Pinsky *et al.*, 2013). The rate of range shifts is projected to be three times higher for pelagic than for demersal fishes (Cheung *et al.*, 2009), the latter shifting at a rate of around 27 – 36 km per decade (Cheung *et al.*, 2013b). However, the expansion of hypoxic waters may have a greater impact than warming on demersal fishes (Koslow *et al.*, 2011). As a result of distribution shifts, high-latitude regions (the Arctic, Southern Ocean) are projected to have high rates of species invasions. Intermediate latitudes are expected to undergo both invasions and local extinctions. High rates of local extinction are projected for the tropics and semi-enclosed seas (e.g. Mediterranean Sea, Persian Gulf). In addition, the future productivity and distribution of higher trophic level organisms are projected to change due to changes in primary productivity (6.3.6). For example, the migration route of Pacific sardine is projected to shift because of changes in primary productivity and food availability (Ito *et al.* 2010). The global pattern of distribution shifts is generally consistent with regional-scale projections and past observations (e.g., Lenoir *et al.*, 2011; Cheung *et al.*, 2013a). However, detailed quantitative projections are sensitive to model structure and assumptions (Hare *et al.*, 2012; Jones *et al.*, 2013) and responses of specific populations may differ from average species responses (Hazen *et al.*, 2013).

[INSERT FIGURE 6-14 HERE
Figure 6-14: Climate change effects on the biogeography, body size and fisheries catch potential of marine fishes and invertebrates. (A) Shifts in distribution range and reduction in body size of exploited fish driven by projected warming, oxygen depletion and sea-ice retreat (cf. Figure 6-7). Whenever the shift in distribution does not fully compensate for warming and hypoxia, the result will be a decrease in body size. Shifts in (B) latitudinal and (C) depth distribution of 610 exploited demersal fishes are projected to have a median (central line of the box) of 31 km decade^{-1} and 3.3 m decade^{-1}, respectively, with variation between species (box boundary: 25th and 75th percentiles) from 1991-2010 to 2041 - 2060 under the SRES A2 (between RCP6.0 - 8.5) scenario (Cheung *et al*., 2011; Cheung *et al*., 2013b). (D) Combining species' range shift with projected changes in NPP leads to a projected global redistribution of maximum catch potential (Analysis includes ~1,000 species of exploited fishes and invertebrates, under warming by 2°C according to SRES A1B (~RCP6.0), comparing the 10-year averages 2001-2010 and 2051-2060; redrawn from Cheung *et al*. 2010). (E) Changes in species distribution and individual growth are projected to lead to reduced maximum body size of fish communities at a certain site. The analysis includes 610 species of marine fishes, from 1991-2010 to 2041-2060 under the SRES A2 (~RCP6.0 to 8.5, Cheung *et al.*, 2013b). Key assumptions of the projections are that current distribution ranges reflect the preferences and tolerances of species for temperature and other environmental conditions and that these preferences and tolerances do not change over time. Catch potential is determined by species range and net primary production. Growth and maximum body size of fishes are a function of temperature and ambient oxygen level.]

Coral reefs are projected to undergo long-term degradation by 2020 to 2100 relative to the 2000s under RCP 2.6, 4.5 and 8.5 or their equivalent (30.5.6). Reefs projected to be threatened most by bleaching under the SRES A1B scenario by 2100 include the Central and Western Equatorial Pacific, Coral Triangle and parts of Micronesia and Melanesia (Teneva *et al*., 2012). These projections assume that coral bleaching occurs when SST exceeds a certain threshold, and that there is limited potential to shift such threshold by adaptation. Reef degradation will impact ecosystem services (Hoegh-Guldberg, 2011; 6.4; Box CC-CR).

Some groups of marine air-breathing fauna are projected to shift in distribution and abundance (6.3.7). Cetacean richness will increase above 40° latitude in both hemispheres, while at lower latitudes both pinniped and cetacean richness are projected to decrease by 2040-2049 relative to 1990-1999 under the SRES A1B scenario (Kaschner *et al*., 2011). Using SST as a predictor, the distribution of loggerhead turtles is projected to expand poleward in the Atlantic Ocean and to gain habitat in the Mediterranean Sea by 2070-2089 relative to 1970-1989 (Witt *et al*., 2010). Leatherback turtle may decrease in abundance at a rate of 7% per decade because of reduced hatching success with warming following the SRES A2 scenario (Saba *et al*., 2012). Abundances of some seabirds such as European breeding seabirds (Huntley *et al*., 2007), Cassin's auklet in the California Current ecosystem or Emperor penguin in Antarctica, are projected to decline because of climate induced changes in oceanographic conditions, such as temperature and upwelling intensity (Box CC-UP; Wolf *et al.*, 2010), or summer sea ice conditions (Jenouvrier *et al*., 2012). The diversity of megafaunal responses to climate change will have cascading ecosystem impacts, and will affect ecosystem services such as tourism (6.3.7, 6.4.1, *high confidence*).

6.5.3. Ecosystems and Fisheries

One of the most direct impacts of climate change on marine ecosystem services is through fisheries (6.4.1; 7.2.1.2, 7.3.2.4, 7.4.2). Projected climate impacts on fisheries are based on recruitment, growth, mortality, abundance and distribution of fish stocks as well as changes in ocean NPP (Cheung *et al*., 2008), evaluated from chlorophyll concentration and other variables such as sea surface temperature (Campbell *et al*., 2002). Friedland *et al*. (2012) suggested that chlorophyll concentration, indicating both phytoplankton production and biomass, is a better predictor of the fishery yield in large marine ecosystems than NPP. While the principle holds that catch potential is dependent on energy from primary production, quantitative projections of catch potential are limited by residual uncertainty on the best possible indicators of primary production and biomass.

Assuming that the potential fish catch is proportional to NPP, the fish catch in the North Pacific Ocean subtropical biome is projected to increase by 26% through expansion of the biome, while catches in the temperate and equatorial biomes may decrease by 38 and 15%, respectively, through contraction of the biomes by 2100 relative to 2000 under the SRES A2 (RCP6.0 to 8.5) scenario (Polovina *et al*., 2011). Changes in phytoplankton size structure are projected to affect fisheries catch potential (Cheung *et al*., 2011), resulting in a 0 up to 75.8% decrease in the potential catch of large fishes in the central North Pacific and increases of up to 43% in the California Current region over the 21st century under the SRES A2 scenario (Woodworth-Jefcoats *et al*., 2013). Globally, climate change is projected to cause a large-scale redistribution of global catch potential, with an average 30 - 70 % increase in yield at high latitudes and up to 89% in some regions, after 2°C warming from pre-industrial periods following SRES A1B (RCP6.0) (Figure 6-14; Cheung *et al.*, 2010; Blanchard *et al*., 2012). Redistribution between areas, with average catch potential remaining unchanged, will occur at mid latitudes. A 40 - 60% drop will occur in the tropics and in Antarctica by the 2050s relative to the 2000s (*medium confidence* for direction of trends in fisheries yields, *low confidence* for the magnitude of change). This highlights high vulnerabilities in the economies of tropical coastal countries (Allison *et al*., 2009; 6.4).

Fisheries targeting specific species may show more complex responses to climate change. For example, driven by changes in temperature and primary production, catches of skipjack and bigeye tuna in the south Pacific are projected to increase by 2035 relative to 1980-2000 under the SRES B1 and A2 scenario, but for 2100, skipjack tuna catch is projected to decrease under the A2 scenario, while bigyeye tuna catch decreases under both A2 and B1 scenarios (Lehodey *et al*., 2011). Regionally, tuna catches in the western Pacific are projected to decrease, while those in the eastern Pacific will increase (Lehodey *et al*., 2011). Mollusk fisheries under ocean acidification is discussed under 6.4.1.

Identifying responses to climate change is complicated by species interactions and multiple stressors. Major marine habitats and biodiversity hotspots are projected to encounter cumulative impact from changes in temperature, pH, oxygen and primary productivity by the end of the 21st century (RCP4.5 and 8.5) (Mora *et al*. 2013). Acidification and hypoxia will reduce maximum catch potential over 50 years from about 2000 onward in both the North Atlantic and Northeast Pacific (Ainsworth *et al*., 2011; Cheung *et al*., 2011). Changes in O_2 content as well as warming will drive a global decrease of community-averaged maximum body size of 14-24% of exploited demersal marine fishes by 2050 relative to the 2000s under the SRES A2 (RCP6.0 to 8.5) scenario (Cheung *et al*., 2013b, Figure 6-14). The decrease in maximum body size may affect natural mortality rates, trophic interactions, and reduce yield-per-recruit and, thus, potential catch. Responses of exploited marine species and their fisheries may interact with other human stressors such as overfishing, exacerbating their impacts (e.g., Lindegren *et al*., 2010; Ainsworth *et al*., 2011). Through species shifts climate change may also cause overlap of habitats of species targeted by fishing with habitat of threatened species, potentially increasing the chances of the latter of being caught as bycatch (Jones *et al*. 2013). Moreover, differences in vulnerability and adaptive capacity of species to changing environmental and ecosystem conditions will affect the responses of fisheries to climate change (e.g., Griffith *et al*., 2011; Le Borgne *et al*., 2011).

The complex and non-linear interactions and responses of both biophysical and socio-economic systems to climate change may lead to changes that have a low probability of occurrence based on empirical data (Doak *et al*., 2008). The risk of such low probability but potentially high impact events may be under-estimated in existing model projections (Williams and Jackson, 2007; Lindenmayer *et al*., 2010). Projected changes in the distribution and production potential of fisheries resources are expected to affect economics, human livelihood and food security

(Allison *et al*., 2009; Sumaila and Cheung, 2010; *low confidence* in the magnitude and direction of the projected socio-economic impacts).

6.5.4. Conclusions

Modeling projects that the distribution of invertebrates, fishes, and some marine mammals, birds and reptiles will shift further under most emission scenarios, with rates and directions of shifts consistent with those observed in the last century (*high confidence*, 6.3.1-7). These projections are valid for those species that adapt not at all or incompletely to warmer temperatures and the associated ecosystem changes, as indicated by present trends (6.3.1, Box CC-MB). For non-adapting species rates of shift will thus increase with increasing rates of warming and higher emission scenarios (*high confidence*), unless the shift is blocked by geographic or other barriers (e.g., light regime, Figure 6-7). The average shift in distribution will continue to be poleward at large spatial scales (6.5.2, Box CC-MB, *high confidence*). Species richness and the abundance of warm-water species will increase at high latitudes (*high confidence*) and decrease in the tropics (6.5.2, *medium confidence*). Projections for individual species and populations are more variable and sensitive to model parameters.

Maximum fisheries catch potential is projected to increase at high and decrease at low latitudes by 2050 under SRES B1 (RCP4.5) and A1B (RCP6.0) climate scenarios (6.5.3, *medium confidence*). Quantifying such projections is constrained by uncertainties in projected primary production rates (6.3.4, 6.5.1), biological responses such as species interactions (6.3.6), and in projected effects of multiple climate drivers and human activities (6.3.5, *low confidence*).

Models that integrate climate and ocean changes with biological responses and interactions, and with current human activities, have led to agreement on species and food web responses to climate change (6.5.3). However, most of these models do not include trophic interactions. They insufficiently consider physiological principles and none include evolutionary adaptation that affect responses of biota to physical and chemical changes.

Projections of ocean biogeochemistry represent the open oceans rather well, but coastal and shelf regions only poorly. From a global perspective, open ocean NPP will decrease moderately by 2100 under both low (SRES B1 or RCP4.5) and high emission scenarios (A2 or RCP6.0 - 8.5; 6.3.4, 6.5.1, *medium confidence*), paralleled by an increase in NPP at high latitudes and a decrease in the tropics (6.3.4, 6.5.1, Box CC-PP, *medium confidence*).

Overall, the projected responses of marine organisms and ecosystems to climate change include changes in primary productivity (*medium confidence*), species' life history (*medium confidence*), distribution, abundance and diversity across marine food webs (*high confidence*) in a time frame of 20 to 80 years from 2010, with substantially larger long-term (end of 21st century) responses under high emission scenarios (*high confidence*). These changes will be largest under business as usual scenarios (RCP8.5) and increase the vulnerability of human societies, by affecting income, employment and food security through their effects on fisheries, tourism, and regulatory services such as coastal protection (6.4.1.3, Box CC-CR, *medium confidence*).

6.6. Chapter Conclusions and Key Uncertainties

This section provides an overview of confidence levels in the detection and projection of climate change effects on ocean systems, and of confidence levels in their attribution to different forcings. It distinguishes between effects previously observed and those projected, and considers confidence in the knowledge of underlying principles as discussed in this chapter. While the anthropogenic signal is conspicuous in the oceans (6.1.1), clear attribution to anthropogenic influences on climate is not always possible in individual case studies, due to the inherent variability of the system (Figure 6-15. Acronyms of relevant processes, capitalized, link between text and figure).

Present day observations and those from the Geological Record (GR, Figure 6-15) show similar signs of response to environmental changes, e.g., warming at high CO_2 levels, and similar ecological consequences in the ocean (*robust evidence, medium agreement* and *confidence*). However, the ongoing rate of anthropogenic CO_2 release and hence ocean acidification is unprecedented in the last 65 Ma (*high confidence*) and probably the last 300 Ma (6.1.2).

[INSERT FIGURE 6-15 HERE
Figure 6-15: Overview of the levels of confidence in detection (left), as well as in projection (right) of climate change effects on ocean systems, in relation to the levels of confidence in attributing these effects to the respective climate forcings. Case studies, processes, and concepts relevant in assessing the effects of climate change are represented by their acronyms in both text and figure. While confidence in the presence of effects is often high, the direct attribution to one driver in field experiments is difficult, as drivers are often highly correlated with each other (e.g., warming with changes in stratification and hence reduced nutrient supply). Some climate change impacts have been condensed into broad categories to avoid overpopulating the figures (e.g., Bio-Geochemical processes, BG). Note that the term "attribution" is used for both present-day detections in the field and future projections, the latter including qualitative and quantitative extrapolations and simulations from fundamental principles and models. Firm knowledge from experiments (field, laboratory and modeling) simulating future conditions enhances the respective confidence levels to those for detection or projection. The empirical observations resulting from those experiments are directly attributable to the respective drivers. Confidence in attribution is enhanced if these experiments identify the underlying mechanisms and their responses. See text for the discussion of depicted examples and categories. Confidence assignments focus on the nature and size of effects, not on model capacity to reliably quantify their magnitude.]

6.6.1. Key Risks Related to Climate Change: Constraints on Ecosystem Services

Empirical studies provide evidence that climate change has impacted marine ecosystems (*high confidenc*e, FAQ 6.4, Table 6-6) and has caused changes in provisioning, regulating, and supportive Ecosystem Services (ES, *medium confidence*). Climate change may also have affected cultural services (*limited evidence* and *medium agreement*) but attribution of impacts to these services remains a challenge (*low confidence*), due to the intrinsic difficulties of assessing these services, the lack of long time-series data and confounding human impacts. In light of available understanding of cause and effect of climate change impacts on marine ecosystems (*high confidence)*, future climate change will affect some ecosystem services (*high confidence* in projection, *medium confidence* in attribution). Projected changes in the availability of marine resources and ecosystem services are expected to affect economics, human livelihood and food security. Vulnerability is highest for the national economies of tropical coastal countries (*high confidence*).

[INSERT TABLE 6-6 HERE
Table 6-6: Coastal and oceanic key risks from climate change and the potential for risk reduction through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments made by authors of the various WGII AR5 chapters, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols. Acronyms for oceans sub-regions are as follows: HLSBS: High-Latitude Spring Bloom Systems; EUS: Equatorial Upwelling Systems; SES: Semi-Enclosed Seas; CBS: Coastal Boundary Systems; EBUE: Eastern Boundary Upwelling Ecosystems; STG: Sub-Tropical Gyres, DS: Deep Sea (>1000 m).]

Redistribution and constraints on microbial functions and primary productivity
Laboratory and mesocosm studies have identified various microbially mediated processes responding to climate-induced changes in light, nutrient supply, temperature, CO_2, and hypoxia (*high confidence*). Such processes include nitrogen fixation and the nitrogen cycle, carbon sequestration and export production, calcification, respiration, O_2 production, climate-feedback by DMS (dimethylsulphide) production, and nutrient recycling. However, changes in these Bio-Geochemical processes (BG) in the field are difficult to detect, project and attribute to climate change (*low confidence* 6.3.1-5).

The trends in Net Primary Production (NPP) recently reported for much of the low-latitude ocean using satellite observations differ considerably from those few long-term direct estimates of NPP at oceanic time-series sites (6.1.2, 6.3.4). Increased NPP at high latitudes (hNPP, detected and attributable to climate change with *medium confidence*, 6.3.4, Box CC-PP) are indicated by satellite images (*medium confidence*) and due to reduction and thinning of sea ice. Trends in NPP will be strengthened with further warming (*medium confidence*). Modeling projects that global NPP (gNPP) will decrease by 2100 under RCP scenarios (6.5.1, Box CC-PP, *medium confidence*).

Warming-induced species redistribution, loss of biodiversity and fisheries catch potential

Long-term observations show variability in oceanographic conditions with a key role of temperature and changing oceanographic regimes causing observed changes in ecosystem structure and fish stocks (*very high confidence,* cf. 30.7.1.1). Temperature Effects (TE) reflect the differential specialization of all life forms in limited ambient temperature ranges (*very high confidence*). Temperature exerts strong MAcroorganism Effects (MAE), i.e. on animals and plants. Warming is presently causing and will cause species displacements and largely poleward shifts in biogeographic distribution of zooplankton and fishes, paralleled by altered seasonal activity, species abundance, migration, and body size (6.3.1., *high* to *very high confidence*), and leading to shifts in Community Composition (CC, *high confidence*, Box 6-1). Causes and effects are understood for fishes and most invertebrates via their Oxygen and Capacity Limited Thermal Tolerance (OCLTT, 6.3.1, *robust evidence, medium agreement* and *high confidence*). Such knowledge supports projections into the future (6.5, *high confidence*), which are influenced by the limited potential of organisms to adapt. Alterations in species ABundance (AB) result when organisms encounter shifting mean and extreme temperatures (*high confidence* in detection and attribution). Such trends will be exacerbated during future warming (*high confidence,* 6.5.1).

Among prominent examples, warming has caused and will cause northward shift and expansion of the geographic distribution of North Atlantic Cod (AC, 6.3.1, *high confidence* in detection or projection, *medium confidence* in detection or projection and attribution) and shifting growth patterns in relation to the distribution of Banded Morwong around New Zealand (BM, *high confidence* in detection or projection, *medium confidence* in detection or projection and attribution). Warming has shifted dominant species from Sardines to Anchovies in the Sea of Japan (SAJ, 6.3.1, 6.3.6, *medium confidence* in detection, *medium confidence* in detection and attribution). Warming extremes have reduced and will further reduce the abundance of Eelpout in the Wadden Sea (EWS, 6.3.1, *high confidence* in detection or projection, *high confidence* in detection or projection and attribution). Extreme warming events increase mortalities of Pacific Salmon during spawning migrations (PS, 6.3.1, *high confidence* in detection, *high confidence* in detection and attribution) in Fraser River, Canada. At temperate and high latitudes, communities display increasing fish Species Richness (SR) resulting from latitudinal shifts of species and attributed to warming and loss of sea ice, although the relative contributions of regional climate variation and long-term global trends have not been quantified (6.3.1, 6.5.2, *high confidence* in detection, *medium confidence* in detection and attribution). Latitudinal species shifts are projected to continue in the 21st century under all IPCC emission scenarios (*high confidence*, 6.3.1, 6.3.5, 6.3.7, 6.4.1, 6.5.2).

Climate-induced regime shifts and regional changes in Plankton Phenology (PP, *medium confidence*) have caused and will cause changes in food composition and availability to animals. Species shifts and changing species composition lead to changes in Fishery Catch Potential (FCP, *high confidence*, 5a in Figure 6-15), partly attributable to climate change (*high confidence*) and to sustained fishing pressure (6.5.3). Fisheries Catch Potentials (FCP) will be redistributed, decrease at low latitudes and increase at high latitudes (*high confidence*, 5a in figure). These trends will possibly be strengthened by the projected decrease in NPP at low latitudes and increase in NPP at high latitudes (*medium confidence*, 6.5.2-3, 5b in Figure 6-15). Polar Organisms (PO) that are unable to migrate to cooler waters, and to acclimatize or to adapt to warming, will become marginalized, contributing to the projected high species turnover in polar areas (*high confidence*, 6.3.1, 6.5.2).

Detected effects on Marine Air Breathers (MAB: mammals, seabirds and reptiles) include changing abundances and phenology, shifts in species distribution, and in sea turtle sex ratios (*high confidence*), all of which are partly attributed to climate change (*high confidence*). However, few effects are directly linked to climate drivers (e.g., temperature-driven turtle sex ratio); most effects are due to shifts in habitat structure (e.g., loss of sea ice), changing availability of prey organisms, or changes in foraging efficiency, in both mammals (polar bears, walruses) and birds (penguins, albatrosses). Such trends will be exacerbated by future warming (*high confidence*, 6.3.7, 6.5.2).

Expanding hypoxia affecting marine resources
Hypoxic Zones in marine sediments and pelagic OMZs will continue to expand in the future, due to climate-induced warming trends (6.1.1). Local and regional Hypoxia Effects (HE) have been observed (*medium confidence*) and will be exacerbated in the future (*high confidence*, 6.3.3) causing habitat loss for groundfishes and pelagic predators and affecting the distribution of key zooplankton and nekton species (*medium confidence*). Progressive hypoxia is causing shifts in community composition toward hypoxia-tolerant species, excluding calcifiers due to elevated pCO_2 (*high confidence*), benefiting specialized microbes, and leading to reduced biodiversity and the loss of higher life forms (*high confidence*) (6.3.3). Loss of deep habitat and biomass of Mid-Water Fishes (MWF, 6.3.3, *medium confidence* in detection) off California is also attributed to hypoxia (*medium confidence*). These trends will continue into the future (*medium confidence*).

Constraints on marine calcifiers and associated fisheries and aquaculture due to ocean acidification
Ocean acidification will exert negative effects on species and whole ecosystems and their services, especially those relying on carbonate structures such as warm-water coral reefs (*high confidence*, cf. 30.7.1.2). Presently, only a small number of field observations have detected Ocean Acidification Effects (OAE) (*medium confidence*), but experiments and natural analogues support reliable but qualitative projections and attribution (*high confidence*). A specific glimpse into the future of anthropogenic OA is provided by negative Effects of upwelled CO_2-rich waters on Pacific Oysters (EO) introduced to aquaculture along the North American west coast (*high confidence* in detection, *low confidence* in attribution to anthropogenic causes). Findings in experimental laboratory and field studies as well as at natural analogues support attribution of projected effects to future CO_2 concentrations (*medium confidence*), with species-specific sensitivities across phyla (*high confidence*). Projected effects are most harmful to strong Calcifiers (CAL, *high confidence*), e.g., some echinoderms, bivalves, gastropods, warm-water corals, and crustose algae, and less harmful to some crustaceans and, possibly, fishes. Projections from experimental studies and observations at natural analogues indicate shifts in Community Composition (CC) to more active animals and from calcifiers (CAL) to non-calcifiers in all organism groups (*high confidence* in both projection and attribution to increased CO_2, 6.3.2, Table 6-3).

Interactions of climate-related drivers exacerbating impacts on organisms, ecosystems, and their services
Climate change involves interactions of temperature with other climate related drivers and their effects (ocean acidification, hypoxia, freshening, nutrient supply, organism shifts resulting in changing interactions between species, changes in habitat structure, e.g., loss of sea ice). Strong interactions with other human impacts like eutrophication, fishing, and other forms of harvesting accelerate and amplify climate-induced changes (*high confidence*, 6.3.5; 30.7.1.1). Harmful algal blooms (HABs) will be stimulated by warming, nutrient fluctuations in upwelling areas, eutrophication in coastal areas (Table 6-6), ocean acidification, and enhanced surface stratification (*medium confidence*). Synergistic Effects (SE) will be exacerbated in the future (*medium confidence*), but have not yet been clearly detected and attributed in the field (*low confidence*). For projected future effects, attribution of observed impacts to such synergisms is supported by experimental evidence, especially in animals and plants (*medium confidence*).

Increased bleaching and decreased calcification displayed by several Reef-building Warm-water Corals (RWC, *very high confidence*) over the last three decades are attributed to the ongoing warming trend, and the associated rise in extreme temperature events and amplitudes (*high confidence*, 6.3.1; Box CC-CR; 30.5.6). Such trends will be exacerbated by future warming and synergistic effects (*high confidence*, cf. 30.5.4.2), with some amelioration by latitudinal shifts and evolutionary adaptation (6.3.1, *low confidence*). Ocean acidification will have an increasing influence on reefs (*high confidence*), as indicated by similar phenomena during mass extinctions in Earth history.

6.6.2. Key Uncertainties

Key uncertainties result from insufficient knowledge of ocean systems. International organizations (both inter- and non-governmental) have the opportunity to play a key role in coordinating research concepts and approaches, working toward a coherent picture of climate change effects on the global ocean. Countries around the world have limited capacity and infrastructure to study the ocean's response to climate change. Long-term observational time series are especially lacking, in both quantity and quality. Research has provided valuable insights, but a unifying approach addressing principles across organism domains and ecosystems is still missing. Processes investigated so far differ largely by study organisms (plants, animals, phytoplankton, and bacteria) and by level of organization (ecosystem, whole organism, tissue, cell, molecular). Especially for microbes, available data are patchy and reported trends are often in different directions, partly due to different experimental protocols and/or over-reliance on species or strains of microbes that are readily culturable, and hence have been used for decades in laboratory research. The knowledge base of climate impacts on species, strains or communities in the field is insufficient. Scaling from physiological studies on individual species to ecosystem changes has been successful in individual cases but has not been widely implemented, e.g., to shifts in species interactions or food webs. An integrated framework of climate sensitivity at the ecosystem level that considers multiple drivers and their interactive effects needs to be developed further. This includes an in depth understanding of ecosystem structure (physical and biological) and functioning, of ecosystem complexity and species interactions, and of the resulting implications for biogeochemical processes. For all climate drivers, especially ocean warming, acidification, and hypoxia, studies integrating mechanistic knowledge and evolutionary adaptation over generations are needed. Research should also cover various climate zones and biomes. Laboratory and modeling experiments are needed to test hypotheses building on long-term field observations and observations at natural or paleo-analogues. Models should better integrate observations and mechanism-based understanding, and better project future interactions between human and natural systems in a changing climate.

Frequently Asked Questions

FAQ 6.1: Why are climate impacts on oceans and their ecosystems so important?
[to be placed in 6.1, before 6.1.1

Oceans create half the oxygen (O_2) we use to breathe and burn fossil fuels. Oceans provide on average 20% of the animal protein consumed by more than 1.5 billion people. Oceans are home to species and ecosystems valued in tourism and for recreation. The rich biodiversity of the oceans offers resources for innovative drugs or biomechanics. Ocean ecosystems such as coral reefs and mangroves protect the coastlines from tsunamis and storms. About 90% of the goods the world uses are shipped across the oceans. All these activities are affected by climate change.

Oceans play a major role in global climate dynamics. Oceans absorb 93% of the heat accumulating in the atmosphere, and the resulting warming of oceans affects most ecosystems. About a quarter of all the carbon dioxide (CO_2) emitted from the burning of fossil fuels is absorbed by oceans. Plankton converts some of that CO_2 into organic matter, part of which is exported into the deeper ocean. The remaining CO_2 causes progressive acidification from chemical reactions between CO_2 and seawater, acidification being exacerbated by nutrient supply and with the spreading loss of oxygen content. These changes all pose risks for marine life and may affect the oceans' ability to perform the wide range of functions that are vitally important for environmental and human health.

The effects of climate change occur in an environment that also experiences natural variability in many of these variables. Other human activities also influence ocean conditions, such as overfishing, pollution, and nutrient runoff via rivers that causes eutrophication, a process that produces large areas of water with low oxygen levels (sometimes called 'Dead Zones'). The wide range of factors that affect ocean conditions and the complex ways these factors interact make it difficult to isolate the role any one factor plays in the context of climate change, or to identify with precision the combined effects of these multiple drivers.

FAQ 6.2: What is different about the effects of climate change on the oceans compared to the land, and can we predict the consequences? *[to be placed in 6.3, before 6.3.1]*

The ocean environment is unique in many ways. It offers large-scale aquatic habitats, diverse bottom topography, and a rich diversity of species and ecosystems in water in various climate zones that are found nowhere else.

One of the major differences in terms of the effect of climate change on the oceans compared to land is ocean acidification. Anthropogenic CO_2 enters the ocean and chemical reactions turn some of it to carbonic acid, which acidifies the water. This mirrors what is also happening inside organisms once they take up the additional CO_2. Marine species that are dependent on calcium carbonate, like shellfish, seastars and corals, may find it difficult to build their shells and skeletons under ocean acidification. In general, animals living and breathing in water like fish, squid, and mussels, have between five and 20 times less CO_2 in their blood than terrestrial animals, so CO_2 enriched water will affect them in different and potentially more dramatic ways than species that breathe in air.

Consider also the unique impacts of climate change on ocean dynamics. The ocean has layers of warmer and colder water, saltier or less saline water, and hence less or more dense water. Warming of the ocean and the addition of more freshwater at the surface through ice melt and higher precipitation increases the formation of more stable layers stratified by density, which leads to less mixing of the deeper, denser, and colder nutrient-rich layers with the less dense nutrient-limited layers near the surface. With less mixing, respiration by organisms in the mid-water layers of stratified oceans will produce oxygen-poor waters, so-called oxygen minimum zones (OMZs). Large, more active fish can't live in these oxygen poor waters, while more simple specialized organisms with a lower need for oxygen will remain, and even thrive in the absence of predation from larger species. Therefore, the community of species living in hypoxic areas will shift.

State-of-the-art ecosystem models build on empirical observations of past climate changes and enable development of estimates of how ocean life may react in the future. One such projection is a large shift in the distribution of commercially important fish species to higher latitudes and reduced harvesting potential in their original areas. But producing detailed projections, e.g. what species and how far they will shift, is challenging because of the number and complexity of interactive feedbacks that are involved. At the moment, the uncertainties in modeling and complexities of the ocean system even prevent any quantification of how much of the present changes in the oceans is being caused by anthropogenic climate change or natural climate variability, and how much by other human activities such as fishing, pollution, etc.

It is known, however, that the resilience of marine ecosystems to adjust to climate change impacts is likely to be reduced by both the range of factors and their rate of change. The current rate of environmental change is much faster than most climate changes in the Earth's history, so predictions from longer term geological records may not be applicable if the changes occur within a few generations of a species. A species that had more time to adapt in the past may simply not have time to adapt under future climate change.

FAQ 6.3: Why are some marine organisms affected by ocean acidification? *[to be placed in 6.3.2, before 6.3.2.1]*

Many marine species, from microscopic plankton to shellfish and coral reef builders, are referred to as calcifiers, species that use solid calcium carbonate ($CaCO_3$) to construct their skeletons or shells. Seawater contains ample calcium but to use it and turn it into calcium carbonate, species have to bring it to specific sites in their bodies and raise the alkalinity (lower the acidity) at these sites to values higher than in other parts of the body or in ambient seawater. That takes energy. If high CO_2 levels from outside penetrate the organism and alter internal acidity levels, keeping the alkalinity high takes even more energy. The more energy is needed for calcification, the less is available for other biological processes like growth or reproduction, reducing the organisms' weight and overall competitiveness and viability.

Exposure of external shells to more acidic water can affect their stability by weakening or actually dissolving carbonate structures. Some of these shells are shielded from direct contact with seawater by a special coating that the animal makes (as is the case in mussels). The increased energy needed for making the shells to begin with impairs the ability of organisms to protect and repair their dissolving shells. Presently, more acidic waters brought up from the deeper ocean to the surface by wind and currents off the Northwest coast of the United States are having this effect on oysters grown in aquaculture.

Ocean acidification not only affects species producing calcified exoskeletons. It affects many more organisms either directly or indirectly and has the potential to disturb food webs and fisheries. Most organisms that have been investigated display greater sensitivity at extreme temperatures, so as ocean temperatures change, those species that are forced to exist at the edges of their thermal ranges will experience stronger effects of acidification.

FAQ 6.4: What changes in marine ecosystems are likely because of climate change? [*to be placed after 6.3.8]*

There is general consensus among scientists that climate change significantly affects marine ecosystems and may have profound impacts on future ocean biodiversity. Recent changes in the distribution of species as well as species richness within some marine communities and the structure of those communities have been attributed to ocean warming. Projected changes in physical and biogeochemical drivers such as temperature, CO_2 content and acidification, oxygen levels, the availability of nutrients, and the amount of ocean covered by ice, will affect marine life.

Overall, climate change will lead to large-scale shifts in the patterns of marine productivity, biodiversity, community composition and ecosystem structure. Regional extinction of species that are sensitive to climate change will lead to a decrease in species richness. In particular, the impacts of climate change on vulnerable organisms such as warm water corals are expected to affect associated ecosystems, such as coral reef communities.

Ocean primary production of the phytoplankton at the base of the marine food chain is expected to change but the global patterns of these changes are difficult to project. Existing projections suggest an increase in primary production at high latitudes such as the Arctic and the Southern Ocean (because the amount of sunlight available for photosynthesis of phytoplankton goes up as the amount of water covered by ice decreases). Decreases are projected for ocean primary production in the tropics and at mid-latitudes because of reduced nutrient supply. Alteration of the biology, distribution, and seasonal activity of marine organisms will disturb food web interactions such as the grazing of copepods (tiny crustaceans) on planktonic algae, another important foundational level of the marine food chain. Increasing temperature, nutrient fluctuations, and human-induced eutrophication may support the development of harmful algal blooms in coastal areas. Similar effects are expected in upwelling areas where wind and currents bring colder and nutrient rich water to the surface. Climate change may also cause shifts in the distribution and abundance of pathogens such as those that cause cholera.

Most climate change scenarios foresee a shift or expansion of the ranges of many species of plankton, fish and invertebrates towards higher latitudes, by tens of kilometres per decade, contributing to changes in species richness and altered community composition. Organisms less likely to shift to higher latitudes because they are more tolerant of the direct effects of climate change or less mobile may also be affected because climate change will alter the existing food webs on which they depend.

In polar areas, populations of species of invertebrates and fish adapted to colder waters may decline as they have no place to go. Some of those species may face local extinction. Some species in semi-enclosed seas such as the Wadden Sea and the Mediterranean Sea, also face higher risk of local extinction because land boundaries around those bodies of water will make it difficult for those species to move laterally to escape waters that may be too warm.

Cross-Chapter Boxes

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water ecosystems that consist of reefs made of calcium carbonate which is mostly secreted by reef-building corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics, housing high levels of biological diversity as well as providing key ecosystem goods and services such as habitat for fisheries, coastal protection and appealing environments for tourism (Wild *et al*., 2011). About 275 million people live within 30 km of a coral reef (Burke *et al*., 2011) and derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including provisioning (food, livelihoods, construction material, medicine), regulating (shoreline protection, water quality), supporting (primary production, nutrient cycling) and cultural (religion, tourism) services. This is especially true for the many coastal and small island nations in the world's tropical regions (29.3.3.1).

Coral reefs are one of the most vulnerable marine ecosystems (*high confidence*; 5.4.2.4, 6.3.1, 6.3.2, 6.3.5, 25.6.2, and 30.5) and more than half of the world's reefs are under medium or high risk of degradation (Burke *et al*., 2011). Most human-induced disturbances to coral reefs were local until the early 1980s (e.g., unsustainable coastal development, pollution, nutrient enrichment and overfishing) when disturbances from ocean warming (principally mass coral bleaching and mortality) began to become widespread (Glynn, 1984). Concern about the impact of ocean acidification on coral reefs developed over the same period, primarily over the implications of ocean acidification for the building and maintenance of the calcium carbonate reef framework (Box CC-OA).

[INSERT FIGURE CR-1 HERE
Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge *et al*., 2004). Mortality was comparatively low due in part because these coral communities were able to shuffle their symbiont to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones *et al*., 2008). C and D: three CO_2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO_2 is related to fundamental changes in the ecology of coral reefs (Fabricius *et al*.,

2011), including reduced coral diversity (-39%), severely reduced structural complexity (-67%), lower density of young corals (-66%) and fewer crustose coralline algae (-85%). At high CO_2 sites (panel D; median pH_T ~7.8), reefs are dominated by massive corals while corals with high morphological complexity are underrepresented compared with control sites (D; median pH ~8.0). Reef development ceases at pH_T values below 7.7. pH_T: pH on the total scale. E: temporal trend in coral cover for the whole Great Barrier Reef over the period 1985–2012 (N, number of reefs, mean ± 2 standard errors; De'ath et al., 2012). F: composite bars indicate the estimated mean coral mortality for each year, and the sub-bars indicate the relative mortality due to crown-of-thorns starfish, cyclones, and bleaching for the whole Great Barrier Reef (De'ath et al., 2012). Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

A wide range of climatic and non-climatic drivers affect corals and coral reefs and negative impacts have already been observed (5.4.2.4, 6.3.1, 6.3.2, 25.6.2.1, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae, which live in the coral tissues and play a key role in supplying the coral host with energy (see 6.3.1. for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies (*high confidence*), is the most widespread and conspicuous impact of climate change (Figure CR-1A and B, Figure 5-3; 5.4.2.4, 6.3.1, 6.3.5, 25.6.2.1, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Ocean acidification reduces biodiversity (Figure CR-1C and D) and the calcification rate of corals (*high confidence*; 5.4.2.4, 6.3.2, 6.3.5) while at the same time increasing the rate of dissolution of the reef framework (*medium confidence*; 5.2.2.4) through stimulation of biological erosion and chemical dissolution. Taken together, these changes will tip the calcium carbonate balance of coral reefs towards net dissolution (*medium confidence*; 5.4.2.4). Ocean warming and acidification have synergistic effects in several reef-builders (5.2.4.2, 6.3.5). Taken together, these changes will erode habitats for reef-based fisheries, increase the exposure of coastlines to waves and storms, as well as degrading environmental features important to industries such as tourism (*high confidence*; 6.4.1.3, 25.6.2, 30.5).

A growing number of studies have reported regional scale changes in coral calcification and mortality that are consistent with the scale and impact of ocean warming and acidification when compared to local factors such as declining water quality and overfishing (Hoegh-Guldberg *et al*., 2007). The abundance of reef building corals is in rapid decline in many Pacific and SE Asian regions (*very high confidence*, 1-2% per year for 1968-2004; Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner *et al*., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and thermal stress-related coral bleaching and mortality have led to a decline in coral cover on the Great Barrier Reef by about 51% between 1985 and 2012 (Figure CR-1E and F). Although less well documented, benthic invertebrates other than corals are also at risk (Przeslawski *et al*., 2008). Fish biodiversity is threatened by the permanent degradation of coral reefs, including in a marine reserve (Jones *et al*., 2004).

Future impacts of climate-related drivers (ocean warming, acidification, sea level rise as well as more intense tropical cyclones and rainfall events) will exacerbate the impacts of non-climate related drivers (*high confidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9 to 60%, 68% uncertainty range) of the world’s coral reefs are projected to be subject to long-term degradation (next few decades) under the RCP3-PD scenario (Frieler *et al*., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30 to 88%, 68% uncertainty range). If present day corals have residual capacity to acclimate and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*; Logan *et al*., 2013). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs account for 10 to 12% of the fish caught in tropical countries, and 20 to 25% of the fish caught by developing nations (Garcia and Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton *et al*. (2007) are already exploiting their coral reef fisheries in an unsustainable way and the production of coral reef fish in the Pacific is projected to decrease 20% by 2050 under the SRES A2 emissions scenario (Bell *et al*., 2013).

- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard *et al*., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4.1, 30.5).
- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke *et al*., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).

Coral reefs make a modest contribution to the Global Domestic Product but their economic importance can be high at the country and regional scales (Pratchett *et al*., 2008). For example, tourism and fisheries represent 5% of the GDP of South Pacific islands (average for 2001-2011; Laurans *et al*., 2013). At the local scale, these two services provided in 2009-2011 at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans *et al*., 2013).

Isolated reefs can recover from major disturbance, and the benefits of their isolation from chronic anthropogenic pressures can outweigh the costs of limited connectivity (Gilmour *et al*., 2013). Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod *et al*., 2009). Although they are key conservation and management tools, they are unable to protect corals directly from thermal stress (Selig *et al*., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau *et al*., 2012; Billé *et al*., 2013). While MPA networks are a critical management tool, they should be established considering other forms of resource management (e.g., fishery catch limits and gear restrictions) and integrated ocean and coastal management to control land-based threats such as pollution and sedimentation. There is *medium confidence* that networks of highly protected areas nested within a broader management framework can contribute to preserving coral reefs under increasing human pressure at local and global scales (Salm *et al*. 2006). Locally, controlling the input of nutrients and sediment from land is an important complementary management strategy (Mcleod *et al*., 2009) because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann *et al*., 2012) and coastal pollutants enriched with fertilizers can increase acidification (Kelly *et al.*, 2011). In the long term, limiting the amount of ocean warming and acidification is central to ensuring the viability of coral reefs and dependent communities (*high confidence*; 5.2.4.4, 30.5).

Box CC-MB. Observed Global Responses of Marine Biogeography, Abundance, and Phenology to Climate Change

[Elvira Poloczanska (Australia), Ove Hoegh-Guldberg (Australia), William Cheung (Canada), Hans O. Pörtner (Germany), Michael Burrows (UK)]

WGII AR4 presented detection and attribution of a global climate change fingerprint on natural systems (AR4, Ch 1, SPM Figure 1), but studies from marine systems were mostly absent. Since AR4, there has been a rapid increase in studies that focus on climate change impacts on marine species, which represents an opportunity to move from more anecdotal evidence to examining and potentially attributing detected changes within the Ocean to climate change (6.3, Figure MB-1). Recent changes in populations of marine species and the associated shifts in diversity patterns are resulting, at least partly, from climate change-mediated biological responses across ocean regions (6.2, Table 6.7, 30.5) (*robust evidence, high agreement, high confidence*).

Poloczanska *et al*. (2013) assess a potential pattern in responses of ocean life to recent climate change using a global database of 208 peer-reviewed papers. Observed responses (n=1735) were recorded from 857 species or assemblages across regions and taxonomic groups, from phytoplankton to marine reptiles and mammals (Figure MB-1). Observations were defined as those where the authors of a particular paper assessed the occurrence change in a biological parameter (including distribution, phenology, abundance, demography or community composition) and, if change occurs, the consistency of the change with that expected under climate change. Studies from the peer-reviewed literature were selected using three criteria: (1) authors inferred or directly tested for trends in biological and climatic variables; (2) included data after 1990; and (3) observations spanned at least 19 years, to reduce bias resulting from biological responses to short-term-climate variability.

[INSERT FIGURE MB-1 HERE
Figure MB-1: 1735 observed responses to climate change from 208 single- and multi-species studies. Changes attributed to climate change (blue), inconsistent with climate change (red) and are equivocal (yellow). Each circle represents the centre of a study area. Where points fall on land, it is because they are centroids of distribution that surround an island or peninsula. Pie charts show the proportions within regions bounded by red squares and in the Mediterranean; numbers indicate the total (consistent, opposite or equivocal) observations within each region. Note: 57% of the studies included were published since AR4 (from Poloczanska *et al.*, 2013).]

The results of this meta-analysis show that climate change has already had widespread impacts on species' distribution, abundance, phenology, and subsequently, species richness and community composition across a broad range of taxonomic groups (plankton to top predators). Of the observations that showed a response in either direction, changes in phenology, distribution and abundance were overwhelmingly (81%) in a direction that was consistent with theoretical responses to climate change (6.2). Knowledge gaps exist, especially in equatorial sub-regions and the Southern Hemisphere (Figure MB-1).

The timing of many biological events (phenology) had an earlier onset. For example, over the last 50 years, spring events shifted earlier for many species with an average advancement of 4.4 ± 0.7 days decade^{-1} (mean ± SE) and summer events by 4.4 ± 1.1 days decade^{-1} (*robust evidence, high agreement, high confidence*) (Figure MB-2). Phenological observations included in the study, range from shifts in peak abundance of phytoplankton and zooplankton, to reproduction and migration of invertebrates, fishes and seabirds (6.3.2, 30.5).

The distributions of benthic, pelagic and demersal species and communities have shifted by 10s to 1000s of km, although the range shifts have not been uniform across taxonomic groups or ocean regions (6.3.2, 30.5) (*robust evidence, high agreement, high confidence*). Overall, leading range edges expanded in a poleward direction at 72.0 ± 13.5 km decade^{-1} and trailing edges contracted in a poleward direction at 15.8 ± 8.7 km decade^{-1} (Figure MB-2) revealing much higher current rates of migration than the potential maximum rates reported for terrestrial species (Figure 4.6) despite slower warming of the Ocean than land surface (WG1 3.2).

[INSERT FIGURE MB-2 HERE
Figure MB-2. Rates of change in distribution (km decade^{-1}) for marine taxonomic groups, measured at the leading edges (red) and trailing edges (brown). Average distribution shifts calculated using all data, regardless of range

location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward). Means ± standard error are shown, along with number of observations (from Poloczanska et al., 2013).]

Poleward distribution shifts have resulted in increased species richness in mid to high latitude regions (Hiddink and ter Hofstede, 2008) and changing community structure (Simpson *et al.*, 2011) (28.2.2). Increases in warm-water components of communities concurrent with regional warming have been observed in mid to high latitude ocean regions including the Bering Sea, Barents Sea, Nordic Sea, North Sea, and Tasman Sea (Box 6.1, 30.5). Observed changes in species composition of catches from 1970–2006 that is partly attributed to long-term ocean warming suggest increasing dominance of warmer water species in sub-tropical and higher latitude regions, and reduction in abundance of sub-tropical species in equatorial waters (Cheung *et al*., 2013), with implications for fisheries (6.5, 7.4.2, 30.6.2.1)

The magnitude and direction of distribution shifts can be related to temperature velocities (i.e., the speed and direction at which isotherms propagate across the Ocean's surface (30.3.1.1, Burrows *et al.* 2011). Pinsky *et al.* (2013) showed that shifts in both latitude and depth of benthic fish and crustaceans could be explained by climate velocity with remarkable accuracy, using a database of 128 million individuals across 360 marine taxa from surveys of North American coastal waters conducted over 1968 to 2011. Poloczanska *et al.* (2013) found that faster distribution shifts generally occur in regions of highest surface temperature velocity, such as the North Sea and sub-Arctic Pacific Ocean. Observed marine species shifts, since approximately 1950s, have generally been able to track observed velocities (Fig MB-3), with phyto- and zooplankton distribution shifts vastly exceeding climate velocities, but with considerable variability within and among taxonomic groups (Poloczanska *et al.* 2013).

Biogeographic shifts are also be influenced by other factors such as nutrient and stratification changes, species' interactions, habitat availability and fishing (6.3). Rate and pattern of biogeographic shifts in sedentary organisms and benthic macroalgae are complicated by the influence of local dynamics and topographic features (islands, channels, coastal lagoons, e.g., of the Mediterranean (Bianchi, 2007), coastal upwelling e.g., Lima *et al.* (2007)). Geographical barriers constrain range shifts and may cause a loss of endemic species (Ben Rais Lasram *et al.*, 2010), with associated niches filled by alien species, either naturally migrating or artificially introduced (Philippart *et al.*, 2011).

Whether marine species can continue to keep pace as warming rates, hence climate velocities, increase (Fig MB-3b) is a key uncertainty. Climate velocities on land are expected to outpace the ability of many terrestrial species to track climate velocities this century (4.3.2.5, Figure 4.6) For marine species, the observed rates of shift are generally much faster than those land for land species, particularly for primary producers and lower trophic levels (Poloczanska *et al. 2013*). Phyto- and zooplankton communities (excluding larval fish) have extended distributions at remarkable rates (Figure MB-3b), such as in the North-east Atlantic (30.5.1) with implications for marine food webs.

Geographical range shifts and depth distribution vary between coexisting marine species (Genner *et al*., 2004; Perry *et al*., 2005; Simpson *et al*., 2011) as a consequence of species-specific thermal window widths and associated vulnerabilities (Figure 6.5). Warming therefore causes differential changes in growth, reproductive success, larval output, early juvenile survival, and recruitment, implying shifts in the relative performance of animal species and, thus, their competitiveness (Pörtner and Farrell, 2008; Figure 6.7A). Such effects may underlie abundance losses or local extinctions, "regime shifts" between coexisting species, or critical mismatches between predator and prey organisms. Changes in local and regional species richness, abundance, community composition, productivity, energy flows and invasion resistance result. Even among Antarctic stenotherms such differences related to mode of life, phylogeny and associated metabolic capacities exist (6.3.1.4). As a consequence, marine ecosystem functions may be substantially reorganized at the regional scale, potentially triggering a range of cascading effects (Hoegh-Guldberg and Bruno, 2010). A focus on understanding the mechanisms underpinning the nature and magnitude of responses of marine organisms to climate change can help forecast impacts and the associated costs to society and facilitate adaptive management strategies effective in mitigating these impacts (6.3, 6.4).

[INSERT FIGURE MB-3 HERE
Figure MB-3. A. Rate of climate change for the Ocean (sea surface temperature (SST) °C); B. corresponding climate velocities for the Ocean and median velocity from land (adapted from Burrows et al., 2011); and C. observed rates of displacement of marine taxonomic groups over several decades until 2010. The thin dotted red arrows give an example of interpretation. Rates of climate change of 0.008 °C yr^{-1} correspond to ca. 2.4 km yr^{-1}median climate velocity in the Ocean. When compared to observed rates of displacement, many marine taxonomic groups have been able to track these velocities, except phyto- and zooplankton where rates of displacement greatly exceed climate velocity. All values are calculated for ocean surface with the exclusion of polar seas (Figure 30-1a). (A) Observed rates of climate change for Ocean SST (Black dotted line) are derived from HadISST1.1 data set, all other rates are calculated based on the average of the CMIP5 climate model ensembles (Table S30-3) for the historical period and for the future based on the four RCP emissions scenarios. Data were smoothed using a 20-year sliding window. (B) Median climate velocity calculated from HadISST1.1 dataset over 1960–2010 using the methods of Burrows et al., 2011. The three axes represent estimated median climate velocities are representative of areas of slow velocities such as Pacific subtropical gyre (STG) system (Purple line), the global Ocean surface (excluding polar seas, Blue line), and areas of high velocities such as the Coral Triangle and North Sea (Orange line). Figure 30-3 shows climate velocities over the ocean surface calculated over 1960–2010. The Red line corresponds to the median rate over global land surface calculated using historical surface temperatures from the CMIP5 model ensemble (Table S30-3). (C) Rates of displacement for marine taxonomic groups estimated by Poloczanska et al. 2013 using published studies (Figure MB-2 Black data set). Note the displacement rates for phytoplankton exceed the axis, so values are given.]

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Anthropogenic ocean acidification and global warming share the same primary cause, which is the increase of atmospheric CO_2 (Figure OA-1A; WGI, 2.2.1). Eutrophication, loss of sea ice, upwelling and deposition of atmospheric nitrogen and sulphur all exacerbate ocean acidification locally (5.3.3.6, 6.1.1, 30.3.2.2).

[INSERT FIGURE OA-1 HERE
Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.]

Chemistry and Projections

The fundamental chemistry of ocean acidification is well understood (*robust evidence, high agreement*). Increasing atmospheric concentrations of CO_2 result in an increased flux of CO_2 into a mildly alkaline ocean, resulting in a reduction in pH, carbonate ion concentration, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of the surface layers of the open ocean can be projected at the global scale with high accuracy using projections of atmospheric CO_2 levels (Fig. CC-OA-1B). Observations of changing upper ocean CO_2 chemistry over time support this linkage (WGI Table 3.2 and Figure 3.18; Figures 30.8, 30.9). Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGI, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration). Projections of regional changes, especially in the highly complex coastal systems (5.3.3.6, 30.3.2.2), in polar regions (WGI 6.4.4), and at depth are more difficult but generally follow similar trends.

Biological, Ecological, and Biogeochemical Impacts

Investigations of the effect of ocean acidification on marine organisms and ecosystems have a relatively short history, recently analyzed in several metaanalyses (6.3.2.1, 6.3.5.1). A wide range of sensitivities to projected rates of ocean acidification exists within and across diverse groups of organisms, with a trend for greater sensitivity in early life stages (*high confidence*; 5.4.2.2, 5.4.2.4, 6.3.2). A pattern of positive and negative impacts emerges (*high confidence*; Fig. OA-1C) but key uncertainties remain in our understanding of the impacts on organisms, life histories and ecosystems. Responses can be influenced, often exacerbated by other drivers, such as warming, hypoxia, nutrient concentration, and light availability (*high confidence*; 5.4.2.4, 6.3.5).

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*; 5.4.2.3, 6.3.2.2-3, 30.5.6). Harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may stimulate nitrogen fixation (*limited evidence, low agreement*; 6.3.2.2). It decreases the rate of calcification of most, but not all, sea-floor calcifiers (*medium agreement, robust evidence*) such as reef-building corals (Box CC-CR), coralline algae, bivalves and gastropods reducing the competitiveness with non-calcifiers

(5.4.2.2, 5.4.2.4, 6.3.2.5). Ocean warming and acidification promote higher rates of calcium carbonate dissolution resulting in the net dissolution of carbonate sediments and frameworks and loss of associated habitat (*medium confidence*; 5.4.2.4, 6.3.2.5, 6.3.5.4-5). Some corals and temperate fishes experience disturbances to behavior, navigation and their ability to tell conspecifics from predators (6.3.2.4). However, there is no evidence for these effects to persist on evolutionary timescales in the few groups analyzed (6.3.2).

Some phytoplankton and mollusks displayed adaptation to ocean acidification in long-term experiments (*limited evidence, medium agreement*; 6.3.2.1), indicating that the long-term responses could be less than responses obtained in short-term experiments. However, mass extinctions in Earth history occurred during much slower rates of ocean acidification, combined with other drivers changing, suggesting that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of future change (*medium confidence*; 6.1.2).

Projections of ocean acidification effects at ecosystem level are made difficult by the diversity of species-level responses. Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.3.2.5, 6.3.5-6), which could impact food webs and higher trophic levels (*limited evidence, high agreement*). Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities (Box CC-CR; 5.4.2.3, 6.3.2.5, 30.3.2.2, 30.5). Shifts in community structure have also been documented in regions with rapidly declining pH (5.4.2.2).

Due to an incomplete understanding of species-specific responses and trophic interactions the effect of ocean acidification on global biogeochemical cycles is not well understood (*limited evidence, low agreement*) and represents an important knowledge gap. The additive, synergistic or antagonistic interactions of factors such as temperature, concentrations of oxygen and nutrients, and light are not sufficiently investigated yet.

Risks, Socioeconomic Impacts and Costs

The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, include both the probability that ocean acidification will affect fundamental physiological and ecological processes of organisms (6.3.2.1), and the magnitude of the resulting impacts on ecosystems and the ecosystem services they provide to society (Box 19-2). For example, ocean acidification under RCP4.5 to RCP8.5 will impact formation and maintenance of coral reefs (*high confidence*; Box CC-CR, 5.4.2.4) and the goods and services that they provide such as fisheries, tourism and coastal protection (*limited evidence, high agreement*; Box CC-CR, 6.4.1.1,19.5.2, 27.3.3, 30.5, 30.6). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Global estimates of observed or projected economic costs of ocean acidification do not exist. The largest uncertainty is how the impacts on lower trophic levels will propagate through the food webs and to top predators. However, there are a number of instructive examples that illustrate the magnitude of potential impacts of ocean acidification. A decrease of the production of commercially-exploited shelled mollusks (6.4.1.1) would result in a reduction of US production of 3 to 13% according to the SRES A1FI emission scenario (*low confidence*). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (*limited evidence, medium agreement*). Models suggest that ocean acidification will generally reduce fish biomass and catch (*low confidence*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (6.4.1.1). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 528 billion USD, respectively for the A1 and B2 SRES emission scenarios (*low confidence*; 6.4.1). Although this number is small compared to global GDP, it can represent a very large GDP loss for the economies of many coastal regions or small islands that rely on the ecological goods and services of coral reefs (25.7.5, 29.3.1.2).

Mitigation and Adaptation

Successful management of the impacts of ocean acidification includes two approaches: mitigation of the source of the problem (i.e. reduce anthropogenic emissions of CO_2), and/or adaptation by reducing the consequences of past and future ocean acidification (6.4.2.1). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts (6.4.2.1). Climate geoengineering techniques based on solar radiation management will not abate ocean acidification and could increase it under some circumstances (6.4.2.2). Geoengineering techniques to remove carbon dioxide from the atmosphere could directly address the problem but are very costly and may be limited by the lack of CO_2 storage capacity (6.4.2.2). Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep-water oxygen levels (6.4.2.2; 30.3.2.3 and 30.5.7). A low-regret approach, with relatively limited effectiveness, is to limit the number and the magnitude of drivers other than CO_2, such as nutrient pollution (6.4.2.1). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Some adaptation strategies include drawing water for aquaculture from local watersheds only when pH is in the right range, selecting for less sensitive species or strains, or relocating industries elsewhere (6.4.2.1).

Box CC-PP. Net Primary Production in the Ocean

[Philip W. Boyd (New Zealand), Svein Sundby (Norway), Hans-Otto Pörtner (Germany)]

Net Primary Production (NPP) is the rate of photosynthetic carbon fixation minus the fraction of fixed carbon used for cellular respiration and maintenance by autotrophic planktonic microbes and benthic plants (6.2.1, 6.3.1). Environmental drivers of NPP include light, nutrients, micronutrients, carbon dioxide, and temperature (Panel A). These drivers in turn, are influenced by oceanic and atmospheric processes, including cloud cover, sea-ice extent, mixing by winds, waves and currents, convection, density stratification, and various forms of upwelling induced by eddies, frontal activity and boundary currents. Temperature has multiple roles as it influences rates of phytoplankton physiology and heterotrophic bacterial recycling of nutrients, in addition to stratification of the water column and sea-ice extent (Panel A). Climate change is projected to strongly impact NPP through a multitude of ways that depend on the regional and local physical settings (WGI, Ch. 3), and on ecosystem structure and functioning (*medium confidence*, 6.3.4, 6.5.1). The influence of environmental drivers on NPP causes as much as a 10-fold variation in regional productivity: from <50 g C m^{-2} $year^{-1}$ in nutrient-poor subtropical waters and light-limited Arctic waters to >> 300 g C m^{-2} $year^{-1}$ in productive upwelling regions and highly eutrophic coastal regions (Panel B).

The oceans currently provide ~50 x 10^{15} g C $year^{-1}$, or about half of global NPP (Field *et al*. 1998). Global estimates of NPP are mainly obtained from satellite remote-sensing (6.1.2), which provides unprecedented spatial and temporal coverage, and may be validated regionally against oceanic measurements. Observations reveal significant changes in rates of NPP when environmental controls are altered by episodic natural perturbations, such as volcanic eruptions enhancing iron supply, as observed in high-nitrate low-chlorophyll waters of the NE Pacific (Hamme *et al*., 2010). Climate variability can drive pronounced changes in NPP (Chavez *et al*., 2011), such as during El Niño to La Niña transitions in Equatorial Pacific, when vertical nutrient and trace element supply are enhanced (Chavez *et al*., 1999).

Multi-year time-series records of NPP have been used to assess spatial trends in NPP in recent decades. Behrenfeld *et al*. (2006) using satellite data, reported a prolonged and sustained global NPP decrease of 190 x 10^{12} g C $year^{-1}$, for the period 1999 to 2005 - an annual reduction of ~0.4 % of global NPP. In contrast, a time-series of directly measured NPP between 1988 to 2007 by Saba *et al*. (2010) (i.e. *in situ* incubations using the radiotracer ^{14}C-bicarbonate) revealed an increase (2 % $year^{-1}$) in NPP for two low latitude open ocean sites. This discrepancy between *in situ* and remotely-sensed NPP trends points to uncertainties in either the methodology used and/or the extent to which discrete sites are representative of oceanic provinces (Saba *et al*., 2010, 2011). Modeling studies have subsequently revealed that the <15 year archive of satellite-derived NPP is insufficient to distinguish climate-change mediated shifts in NPP from those driven by natural climate variability (Henson *et al*., 2010; Beaulieu *et al*., 2013). Although multidecadal, the available time-series of oceanic NPP measurements are also not of sufficient duration relative to the timescales of climate variability modes (up to 60-70 years for AMO, for example, Figure 6-1). Recent attempts to synthesize longer (i.e. centennial) records of chlorophyll as a proxy for phytoplankton stocks (e.g., Boyce *et al*., 2010) have been criticized for relying on questionable linkages between different proxies for chlorophyll over a century of records (e.g., Rykaczewski and Dunne, 2011).

Models in which projected climate-change alters the environmental drivers of NPP provide estimates of spatial changes and of the rate of change of NPP. For example, four global coupled climate-ocean biogeochemical Earth System Models (WGI Ch. 6) projected an increase in NPP at high latitudes as a result of alleviation of light and temperature limitation of NPP particularly in Northern and Southern Hemisphere 'subpolar gyre' biomes (Steinacher *et al*., 2010). However, this regional increase in NPP was more than offset by decreases in NPP at lower latitudes and at mid-latitudes due to the reduced input of macro-nutrients into the photic zone. The reduced mixed-layer depth and reduced rate of circulation may cause a decrease in the flux of macronutrients to the photic zone (Figure 6-2). These changes to oceanic conditions result in a reduction in global mean NPP by 2 to 13% by 2100 relative to 1860 under a high emission scenario (Polovina *et al*., 2011; SRES A2, between RCP6.0 and RCP8.5). This is consistent with a more recent analysis based on 10 Earth System Models (Bopp *et al*., 2013), which project decreases in global NPP by 8.6 (±7.9), 3.9 (±5.7), 3.6 (±5.7), 2.0 (±4.1) % in the 2090s relative to the 1990s, under the scenarios RCP8.5, RCP6.0, RCP4.5 and RCP2.6, respectively. However, the magnitude of projected changes varies widely between models (e.g. from 0 to 20% decrease in NPP globally under RCP 8.5). The various models show very large differences in NPP at regional (i.e. provinces, see panel B) scales.

Earlier model projections had predicted changes in global NPP from a decrease of > 10% (Field *et al*., 1998; Boyd and Doney, 2002) to an increase of up to 8.1% under an intermediate scenario (SRES A1B, similar to RCP6.0) (Sarmiento *et al*., 2004; Schmittner *et al*., 2008). These projections did not consider the potential contribution of primary production derived from atmospheric nitrogen fixation in tropical and subtropical regions, favoured by increasing stratification and reduced nutrient inputs from mixing. This mechanism is potentially important, although such episodic increases in nitrogen fixation are not sustainable without the presence of excess phosphate (e.g. Moore *et al*., 2009; Boyd *et al*., 2010). This may lead to an underestimation of NPP (Mohr *et al*., 2010; Mulholland *et al*., 2012; Wilson *et al*., 2012), however, the extent of such underestimation is unknown (Luo *et al*., 2012).

Care must be taken when comparing global, provincial (e.g. low latitude waters, for example Behrenfeld *et al*., 2006) and regional trends in NPP derived from observations, as some regions have additional local environmental influences such as enhanced density stratification of the upper ocean from melting sea ice. For example, a longer phytoplankton growing season, due to more sea-ice free days, may have increased NPP (based on a regionally validated time-series of satellite NPP) in Arctic waters (Arrigo and van Dijken, 2011) by an average of 8.1 Tg C year^{-1} between 1998 and 2009. Other regional trends in NPP are reported in 30.5.1-6. In addition, although future model projections of global NPP from different models (Steinacher *et al*., 2010; Bopp *et al*., 2013) are comparable, regional projections from each of the models differ substantially. This raises concerns as to which aspect(s) of the different model NPP parameterizations are responsible for driving regional differences in NPP, and moreover, how accurate model projections are of global NPP.

From a global perspective, open ocean NPP will decrease moderately by 2100 under both low (SRES B1 or RCP4.5) and high emission scenarios (A2 or RCP6.0 - 8.5, 6.3.4, 6.5.1, *medium confidence*), paralleled by an increase in NPP at high latitudes and a decrease in the tropics (*medium confidence*). However, there is *limited evidence* and *low agreement* on the direction, magnitude and differences of a change of NPP in various ocean regions and coastal waters projected by 2100 (*low confidence*).

[INSERT FIGURE PP-1 HERE
Figure PP-1: A) Environmental factors controlling Net Primary Production (NPP). NPP is mainly controlled by three basic processes: 1) Light conditions in the surface ocean, i.e. the photic zone where photosynthesis occurs, 2) upward flux of nutrients and micronutrients from underlying waters into the photic zone, 3) Regeneration of nutrients and micronutrients via the breakdown and recycling of organic material before it sinks out of the photic

zone. All three processes are influenced by physical, chemical and biological processes and vary across regional ecosystems. In addition, water temperature strongly influences the upper rate of photosynthesis for cells that are resource-replete. Predictions of alteration of primary productivity under climate change depend on correct parameterizations and simulations of each of these variables and processes for each region. B) Annual composite map of global areal NPP rates (derived from MODIS Aqua satellite climatology from 2003-2012; NPP was calculated with the Carbon-based Production Model (CbPM, Westberry *et al*., 2008)). Overlaid is a grid of (thin black lines) that represent 51 distinct global ocean biogeographical provinces (after Longhurst, 1998 and based on Boyd and Doney, 2002). The characteristics and boundaries of each province are primarily set by the underlying regional ocean physics and chemistry. Box CC-UP. Uncertain Trends in Major Upwelling Ecosystems

[Salvador E. Lluch-Cota (Mexico), Ove Hoegh-Guldberg (Australia), David Karl (USA), Hans O. Pörtner (Germany), Svein Sundby (Norway), Jean-Pierre Gatusso (France)]

Upwelling is the vertical transport of cold, dense, nutrient-rich, relatively low-pH and often oxygen-poor waters to the euphotic zone where light is abundant. These waters trigger high levels of primary production and a high biomass of benthic and pelagic organisms. The driving forces of upwelling include wind stress and the interaction of ocean currents with bottom topography. Upwelling intensity also depends on water column stratification. The major upwelling systems of the Planet, the Equatorial Upwelling System (EUS, 30.5.2, Figure 30.1A) and the Eastern Boundary Upwelling Ecosystems (EBUE, 30.5.5, Figure 30.1A), represent only 10% of the ocean surface but contribute nearly 25 % to global fish production (Figure 30.1B, Table S30.1).

Marine ecosystems associated with upwelling systems can be influenced by a range of ‘bottom-up’ trophic mechanisms, with upwelling, transport, and chlorophyll concentrations showing strong seasonal and interannual couplings and variability. These, in turn, influence trophic transfer up the food chain, affecting zooplankton, foraging fish, seabirds and marine mammals.

There is considerable speculation as to how upwelling systems might change in a warming and acidifying ocean. Globally, the heat gain of the surface ocean has increased stratification by 4% (WGI 3.2, 3.4.4, 3.8), which means that more wind energy is needed to bring deep waters to the surface. It is as yet unclear to what extent wind stress can offset the increased stratification, due to the uncertainty in wind speed trends (WGI, 3.4.4). In the tropics, observations of reductions in trade winds over several decades contrast more recent evidence indicating their strengthening since the early 1990s (WGI, 9.4.1.3.4). Observations and modelling efforts in fact show diverging trends in coastal upwelling at the eastern boundaries of the Pacific and the Atlantic. Bakun (1990) proposed that the the difference in heat gaining rates between land and ocean causes an increase in the pressure gradient, which results in increased alongshore winds and leads to intensified offshore transport of surface water through Ekman pumping, and the upwelling of nutrient rich, cold waters (Figure CC-UP). Some regional records support this hypothesis, others do not. There is considerable variability in warming and cooling trends over the past decades both within and among systems making it difficult to predict changes in the intensity of all Eastern Boundary Upwelling Ecosystems (30.5.5).

Understanding whether upwelling and climate change will impact resident biota in an additive, synergistic or antagonistic manner is important for projections of how ecological goods and services provided for human society will change. Even though upwellings may prove more resilient to climate change than other ocean ecosystems because of their ability to function under extremely variable conditions (Capone and Hutchins, 2013), consequences of their shifts are highly relevant since these are the most biologically active systems in the ocean. Increased upwelling would enhance fisheries yields. However, the export of organic material from surface to deeper layers of the ocean may increase and stimulate its decomposition by microbial activity, thereby enhancing oxygen depletion and CO_2 enrichment in deeper water layers. Once this water returns to the surface through upwelling benthic and pelagic coastal communities will be exposed to acidified and deoxygenated water which may combine with anthropogenic impact to negatively affect marine biota and ecosystem structure of the upper ocean (high confidence, 6.3.2, 6.3.3; 30.3.2.2, 30.3.2.3). Extreme hypoxia may result in abnormal mortalities of fishes and invertebrates (Keller *et al.*, 2010), reduce the fisheries catch potential and impact aquaculture in coastal areas (5.4.3.3, 6.3.7, 30.5.1.1.2, 30.5.5.1.3, Barton *et al.*, 2012). Shifts in upwelling also coincide with an apparent increase in the frequency of submarine eruptions of methane and hydrogen sulphide gas, caused by enhanced formation and sinking of phytoplankton biomass to the hypoxic or anoxic sea floor . This combination of factors has been implicated in the extensive mortality of coastal fishes and invertebrates (Bakun and Weeks, 2004), resulting in significant reductions in fishing productivity, such as Cape hake (*Merluccius capensis*), Namibia’s most valuable fishery (Hamukuaya *et al*., 1998).

Reduced upwelling would also reduce the productivity of important pelagic fisheries, such as for sardines, anchovies and mackerel, with major consequences for the economies of several countries (6.4.1, Chp 7, Figure 30.1A, B, Table S30.1). However, under projected scenarios of reduced upward supply of nutrients due to stratification of the open ocean , upwelling of both nutrients and trace elements may become increasingly important to maintaining upper ocean nutrient and trace metal inventories. It has been suggested that upwelling areas may also increase nutrient content and productivity under enhanced stratification, and that upwelled and partially denitrified waters containing excess phosphate may select for N_2-fixing microorganisms (Deutsch *et al*., 2007; Deutsch and Weber, 2012), but field observations of N2 fixation in these regions have not supported these predictions (Fernandez *et al*., 2011; Franz *et al*., 2012). The role of this process in global primary production thus needs to be validated (*low confidence*).

The central question therefore is whether or not upwelling will intensify, and if so, whether the effects of intensified upwelling on O_2 and CO_2 inventories will outweigh its benefits for primary production and associated fisheries and aquaculture (*low confidence*). In any case increasing atmospheric CO_2 concentrations will equilibrate with upwelling waters that may cause them to become more corrosive, depending upon pCO_2 of the upwelled water, and potentially increasingly impact the biota of Eastern Boundary Upwelling Ecosystems.

[INSERT FIGURE UP-1 HERE
Figure UP-1: Upper panel: Schematic hypothetic mechanism of increasing coastal wind-driven upwelling at eastern boundary systems, where differential warming rates between land and ocean results in increased land-ocean pressure gradients (1) that produce stronger alongshore winds (2) and offshore movement of surface water through Ekman transport (3), and increased upwelling of deep cold nutrient rich waters to replace it (4). Lower panel: potential consequences of climate change in upwelling systems. Increasing stratification and uncertainty in wind stress trends result in uncertain trends in upwelling. Increasing upwelling may result in higher input of nutrients to the euphotic zone, and increased primary production, which in turn may enhance pelagic fisheries, but also decreased coastal fisheries due to an augmented exposure of coastal fauna to hypoxic, low pH waters. Decreased upwelling may result in lower primary production in these systems with direct impacts on pelagic fisheries productivity.]

Table 6-1: To assess how a changing climate will alter the ocean's biological pump (Figure 6-4) and determine the resulting biogeochemical feedbacks on global climate, changes in a wide range of processes from cells to ocean basins, and from epipelagic to mesopelagic, must be quantified. This table illustrates the complexity of the integrated knowledge platform needed to provide evidence of these biogeochemical ramifications and thus the present limits to clear conclusions about climate-induced effects on the biological pump (C, Carbon; TEP, Transparent Exopolymer Particle; DOM, Dissolved Organic Matter; POM, Particulate Organic Matter).

Alteration of physiological rates	**Biogeographical changes / community shifts**	**Altered foodweb structure - Trophodynamics**	**Changes to particle dynamics**	**Biogeochemical changes / climatic feedbacks**
NPP (Bopp *et al*., 2002, 2013)	Microbial community structure (Giovannoni and Vergin, 2012)	Altered prey-predator linkages (Lewandowska,and Sommer, 2010)	Faecal pellet geometry (Wilson *et al*., 2008)	Particle flux/C sequestration (Bopp *et al*., 2002)
Particle solubilization through bacterial ectoenzymes (Christian and Karl, 1995)	Phytoplankton community structure – biomes (Boyd and Doney, 2002)		C partitioning between DOM vs. POM – TEP (Riebesell *et al*., 2007)	Shifts in elemental stoichiometry of planktonic communities (Karl *et al*., 2003)
TEP production (Engel *et al*., 2004)	Alteration of zooplankton biomes (Beaugrand *et al.*, 2009)		Sinking rates/seawater viscosity (Lam and Bishop, 2008)	Remineralization rate – [O_2]; hypoxia; nutrient resupply (Gruber, 2011)
Microzooplankton grazing rates (Rose *et al*., 2009)	Faunistic shifts at depth (Jackson and Burd, 2001)		Ballasting - calcite versus opal (Klaas and Archer, 2002)	Activity of the microbial loop; vertical carbon export (Grossart *et al.*, 2006; Piontek *et al*., 2010)

Table 6-2: Selected examples of species responses and underlying mechanisms to changing temperature, oxygen level and ocean acidification (OA). References are indicated by superscript numbers and in the footnote.

Phenomenon	**Key drivers**	**Mechanism / Sensitivity**
<u>*Biogeography*</u>		
Northward shift in the distribution of North Sea cod (*Gadus morhua*) stocks between 1977 and 2001 [1,2]	Temperature	Bottlenecks of high sensitivity during early life stages as well as adult spawning stage in winter/early spring
Shift from sardines (*Sardinops melanostictus*) to anchovies (*Engraulis japonicus*) in the western North Pacific observed between 1993 and 2003 [3,4]	Temperature	Thermal windows of growth and reproductive output are found at higher temperatures for anchovies than sardines, food preferences of the competing species being similar.
Variable sensitivity of Pacific tuna species to the availability of dissolved O_2. Bigeye tuna routinely reach depths where ambient O_2 content is below 1.5 ml L^{-1} (≈ 60 µmoles kg^{-1}) [5, 6]	Oxygen	Oxygen transport via hemoglobin is adapted to be highly efficient supporting high metabolic rates as needed during feeding in the OMZ.
Northward movement of species and the conversion of polar into more temperate and temperate into more subtropical system characteristics in the European Large Marine Ecosystems between 1958–2005 [7, 8]	Warming and current advection	Effects are attributed to climate change but may be influenced by nutrient enrichment and overfishing.

<u>*Abundance*</u>		
Increase in abundance of arctic boreal plankton species, notably the copepods *Calanus hyperboreus*, *Calanus glacialis* and the dinoflagellate *Ceratium arcticum* between 1960 and 2000 in the Newfoundland Shelf, Northwest Atlantic [9,10]	Temperature	Temperature sensitivity of phyto- and zooplankter resulting from cooling due to increased influx of Arctic water
A benthic fish species, the eelpout (*Zoarces viviparus*) at its southern distribution limit, the German Wadden Sea, displayed abundance losses during warming periods and rising summer extreme temperatures between 1993 and 2005, with early disappearance of the largest individuals [11]	Temperature	Temperature extremes exceed organism's thermal windows, with largest individuals being relatively less tolerant to high temperature than smaller individuals.
Variable sensitivities to OA within and across animal phyla (Figure 6-10 B) [12 - 21]	Anthropogenic OA, Sea water acidification by elevated pCO_2 in OMZs, upwelling areas, involving anthropogenic ocean acidification.	– Lowered extracellular (blood plasma) pH causing a lowering of the rates of ion exchange and metabolism in muscle or liver (hepatocytes) of vertebrates and invertebrates. – High sensitivity at reduced energy turnover in tissues and/or whole organism by reduced ion exchange, – use of more energy efficient transport mechanisms, – reduced protein synthesis, enhanced nitrogen release from amino acid catabolism and protein degradation, – slower growth
<u>*Phenology*</u>		
Migration time of pink salmon (*Oncorhynchus gorbuscha*) in Alaska is almost two weeks earlier in 2010s relative to 40 years ago [22]	Warming	Rapid microevolution for earlier migration timing.
In the waters around the U.K., during a period of warming between 1976 and 2005, the seasonal timing of biological events of all major marine taxonomic groups (plant/phytoplankton, invertebrate and vertebrates) advanced on average, by 0.31 to 0.43 days year^{-1} [23]	Warming	Sensitivity to seasonal temperature changes as a result of specific thermal windows of different organisms;
Body size and growth		
Asymptotic size of different populations of Atlantic cod (*Gadus morhua*) and Atlantic Herring (*Clupea harengus*) are negatively related to temperature [24, 25]	Warming	At large body size, oxygen supply limitations are exacerbated and the organism reaches its long-term heat tolerance limits at lower temperatures, thus limiting the maximum body size that can be reached.

Philippart *et al.*, 2011; 9. Johns *et al.*, 2001;10. Greene and Pershing, 2003; 11. Pörtner and Knust, 2007; 12. Reipschläger and Pörtner, 1996; 13. Pörtner *et al.*, 2000; 14. Vezzoli *et al.*, 2004; 15. Langenbuch and Pörtner, 2003; 16. Fernández-Reiriz *et al.*, 2011; 17. Langenbuch and Pörtner, 2002;18. Langenbuch *et al.*, 2006; 19. Michaelidis *et al.*, 2005; 20. Pörtner *et al.*, 1998; 21. Stumpp *et al.*, 2012; 22. Kovach *et al*., 2012; 23. Thackeray *et al*., 2010; 24. Taylor 1958; 25. Brunel and Dickey-Collas, 2010.

Table 6-3: Tolerances to ocean acidification in marine taxa, assessed from laboratory and field studies of species in the pCO_2 range from <650 to >10 000 µatm, compared to present day atmospheric levels of 400 µatm. (It should be noted that anthropogenic CO_2 emissions add to the natural variability of CO_2 concentrations in marine environments, which can reach much higher than atmospheric levels). Variables studied include growth, survival, calcification, metabolic rate, immune response, development, abundance, behavior and others. Neither all life stages, nor all variables, including the entire range of CO_2 concentrations, were studied in all species. *Confidence* is based on the number of studies, the number of species studied and the agreement of results within one group. +: denotes that possibly more species or strains (genetically distinct populations of the same species) were studied, as only genus or family were specified; beneficial: most species were positively affected; vulnerable: more than 5% of species in a group will be negatively affected by 2100; tolerant: more than 95% of species will not be affected by 2100. RCP 6.0: representative concentration pathway with projected atmospheric pCO_2 = 670 µatm; RCP 8.5: pCO_2 = 936 µatm in 2100 (Meinshausen *et al.*, 2011). *Confidence* is limited by the short- to medium-term nature of various studies and the lack of sensitivity estimates on evolutionary timescales, i.e., across generations (see separate reference list, online supplementary material). Note that the assessment of variability between species from the same animal phylum has revealed an increase in the fraction of sensitive species with rising CO_2 levels, see Figure 6-10. *Rather than a sensitivity threshold the entire range of investigated pCO_2 values is given for groups of photosynthetic organisms. In all studies photosynthetic rates are stimulated to different, species-specific degrees by elevated pCO_2, indicating low vulnerability. Coccolithophores and calcifying algae are assessed as being more sensitive than other photosynthetic organisms due to reduced calcification and shell dissolution. NA, not availaible, [+]confidence levels for fishes were converted from medium to low, in light of uncertainty on the long-term implications of behavioral disturbances.

Taxon	No. of studies	No. of para-meters studied	Total no. of species studied	pCO_2 where the most vulnerable species is negatively affected or investigated pCO_2 range* (µatm)	Assessment of tolerance to RCP 6.0 (*confidence*)	Assessment of tolerance to RCP 8.5 (*confidence*)
Cyanobacteria	17	5	9+	180-1250*	Beneficial (*low*)	Beneficial (*low*)

Table 6-4: Potential interactions between modes of anthropogenic forcing (environmental; foodwebs, harvesting) on different levels of biological organisation. These interactions, from simple to complex, are illustrated with examples from the published literature. E, O, and M denote studies using manipulation Experiments (lab or field), Observations, or Modelling approaches, respectively. Unknown denotes no published information is available for each of these categories. NA denotes Not Applicable for this category.

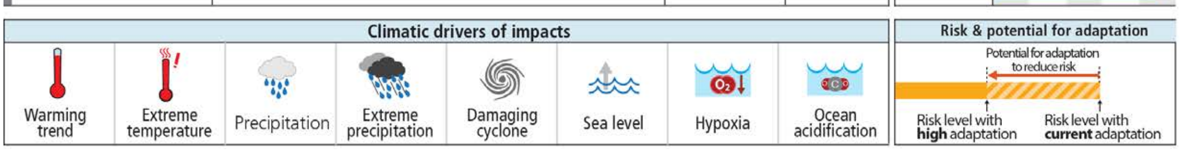
Biological Organisation studied at ecosystem level	**Anthropogenic Forcing**			
	Single Environmental Driver	*Multiple Environmental Drivers*	*Fishing / Foodwebs*	*Fishing / Climate change*
Individuals	Lab experiments and field observations show that warming alters organismal physiology and thereby, growth (Pörtner and Knust, 2007) E & O	Shipboard manipulation experiment addressing interactive effects of temperature and CO_2 on coccolithophore calcification (Feng *et al.*, 2009) E	NA	Unknown
Population	Physiological effects of warming change population abundance *in situ*, (Pörtner and Knust, 2007) E & O. Lab cultures show how altered pH elicits different responses of coccolithophore species (Langer *et al.*, 2006) E	Lab cultures show differential responses of cyanobacterial groups to temperature and CO_2 (Fu *et al.*, 2007) E	Altered maturation age and growth rate of populations due to fishing (Fairweather *et al.*, 2006; Hseih *et al.*, 2006) O	Interactive effects on cod populations of fishing and alteration of salinity (Lindegren *et al.*, 2010) M
Ecosystem	Mesocosm experiments simulating the effect of individual drivers (e.g. ocean acidification effects on benthos: Christen *et al*. 2013; and on pelagic communities: Riebesell *et al.*, 2013) E, O or M	Mesocosm experiments studying differential effects of light and temperature, on copepods versus diatoms (Lewandowska and Sommer, 2010) E	Effects of fishing on ecosystem structure – trophic cascades (Frank *et al.*, 2005) O	Interplay of fishing and climate pressures on ecosystems promotes lower trophic levels (Kirby *et al.*, 2009) O; enhances diversity loss in benthic communities (Griffith *et al.*, 2011) M
Biome	Time-series observations on warming and geographical shifts of zooplankton biomes (Beaugrand *et al.*, 2009) O	Unknown	Unknown	Unknown

Table 6-5: Challenges for the oceans that will arise from the employment of a range of geoengineering methods (SRM, solar radiation management, CDR, carbon dioxide removal).

Topic	**Brief Description**	**Challenge and Impact**	**References**
Solar radiation management techniques	Deflection of approximately 1.8 per cent of sunlight, by various techniques, is able to offset the global mean temperature effects of a doubling of atmospheric carbon dioxide content from preindustrial values	Will leave ocean acidification unabated (*high confidence*). Response of primary production to light reduction unclear.	Crutzen, 2006; Caldeira and Wood, 2008
Ocean storage by direct injection	Capture of CO_2 post-combustion from mainly coastal power plants, followed by injection of liquid CO_2 by pipeline or from a ship into the deep ocean.	Will add to ocean acidification and create localized harm to marine life (*high confidence*). Quantities will be small relative to the atmospheric invasion signal. CO_2 injected will dissolve and be transported by ocean circulation with eventual surface exposure.	Caldeira *et al.*, 2005
Sub-sea geologic storage	Capture of CO_2 from extracted gas or from post-combustion followed by well injection into a porous submarine aquifer beneath impermeable geologic strata.	Extensive experience in place from the Norwegian Sleipner field activity in the North Sea. No evidence of ocean impact from leakage to date.	Benson *et al.*, 2005
Ocean Fertilization	Spreading of trace amounts of reduced iron, over very large areas of the surface ocean where excess nutrients occur. Overcoming the local iron deficiency creates extensive phytoplankton blooms drawing down sea surface pCO_2. Fertilization can also be carried out by using direct or indirect (ocean pipes) addition of macronutrients to oceanic regions where they are depleted.	Much of the exported organic matter is remineralized at shallow depths creating local oxygen stress and shallow CO_2 enrichment, methane and N_2O production. These effects are temporary and the effective retention time is short. If sustained, reduced surface-ocean and increased deep-ocean acidification. O_2 loss in ocean interior (*medium confidence*).	de Baar *et al.*, 1995; de Baar *et al.*, 2005; Pörtner *et al.*, 2005; Boyd *et al.*, 2007; Buesseler *et al.*, 2008; Law, 2008; Cao and Caldeira, 2010
Artifical upwelling or downwelling	Ocean fertilization by bringing nutrient rich deep water (from 200 - 1000 m) to the surface. Downwelling occurs in parallel, transporting physically dissolved CO_2 into the deep ocean.	Deep water contains high levels of CO_2, which if released counteracts the binding of CO_2 by fertilization. No evidence available.	Lovelock and Rapley, 2007 Oschlies *et al*., 2010
Sequestration of organic carbon	Storage of terrestrial biomass in the coastal or deep ocean	Physical impact, regional loss of oxygen, CO_2 accumulation and acidification during degradation, increases in methane, N_2O and H_2S. No evidence available.	Metzger and Benford, 2001; Strand and Benford, 2009
Carbonate neutralization	Dissolution of power plant flue gas into sea water yielding an acidic solution which is neutralized by addition of crushed limestone. The resulting bicarbonate rich fluid is discharged to the ocean.	Involves the transport and crushing to fine scale of large quantities of limestone and the processing of very large quantities of sea water. Environmental impact issues not yet explored.	Rau, 2011
Accelerated olivine weathering	Uses wind powered electrochemical processes to remove HCl from the ocean and neutralizes the acid with silicate minerals such as olivine for disposal. The net result is to add alkalinity to the ocean akin to natural silicate weathering processes.	Complex system as yet untested in pilot processes. Involves mining and crushing large quantities of silicate minerals. Very long time scale consequences uncertain.	House *et al.*, 2007; Köhler *et al.*, 2010

Table 6-6: Coastal and oceanic key risks from climate change and the potential for risk reduction through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments made by authors of the various WGII AR5 chapters, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols. Acronyms for oceans sub-regions are as follows: HLSBS: High-Latitude Spring Bloom Systems; EUS: Equatorial Upwelling Systems; SES: Semi-Enclosed Seas; CBS: Coastal Boundary Systems; EBUE: Eastern Boundary Upwelling Ecosystems; STG: Sub-Tropical Gyres, DS: Deep Sea (>1000 m).

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Risks to ecosystems and adaptation options					
Changes in ecosystem productivity associated with the redistribution and loss of net primary productivity in open oceans (*medium confidence*)	Adaptation options are limited to the translocation of industrial fishing activities due to regional decreases (low latitude) versus increases (high latitude) in productivity, or to the expansion of aquaculture.		6.5.1, 6.3.4, Box CC-NPP	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Distributional shift in fish and invertebrate species, fall in fishery catch potential at low latitudes, e.g., in EUS, CBS and STG regions (*high confidence*)	Evolutionary adaptation potential of fish and invertebrate species to warming is limited as indicated by their ongoing latitudinal shifts. Human adaptation options involve the large scale translocation of industrial fishing activities following the regional decreases (low latitude) versus (possibly transient) increases (high latitude) in catch potential as well deploying flexible management that can react to variability and change. Further options include improving fish resilience to thermal stress by reducing other stressors like pollution and eutrophication, or the expansion of aquaculture.		6.3.1, Box CC-Bio	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
High mortalities and loss of habitat to larger fauna including commercial species due to hypoxia expansion and effects (*high confidence*)	Human adaptation options involve the large scale translocation of industrial fishing activities as a consequence of the hypoxia induced decreases in biodiversity and fisheries catch of pelagic fish and squid. Special fisheries may benefit (Humboldt squid). Reducing the amount of organic carbon running of coastlines by controlling nutrients and pollution running off agricultural areas can reduce microbial activity and consequently limit the extent of the oxygen drawdown and the formation of coastal dead zones.		6.3.3, 30.5.3.2, 30.5.4.1-2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Ocean acidification: Reduced growth and survival of commercially valuable shellfish and other calcifiers, e.g., reef building corals, calcareous red algae (*high confidence*)	Evidence for differential resistance and evolutionary adaptation of some species exists but is likely limited by the CO2 concentrations and high temperatures reached; adaptation options include the shift to exploiting more resilient species or the protection of habitats with low natural CO2 levels, as well as the reduction of other stresses, mainly pollution and limiting pressures from tourism and fishing.		5.3.3.5, 6.X.X., 30.X.X, Box CC-OA	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Reduced biodiversity, fisheries abundance and coastal protection by coral reefs due to heat induced mass coral bleaching and mortality increases, e.g., in CBS, SES, and STG regions (*high confidence*)	Evidence of rapid evolution by corals is very limited or non-existent. Some corals may migrate to higher latitudes. However, the movement of entire reef systems is unlikely given estimates that they need to move at the speed of 10-20 km per year. Human adaptation options are limited to reducing other stresses, mainly enhancing water quality and limiting pressures from tourism and fishing. This option will delay the impacts of climate change by a few decades but is likely to disappear as thermal stress increases.		5.4.2.4, 6.4.2, 30.3.1.1, 30.5.2, 30.5.3, 30.5.4, 30.5.6, Box CC-CR	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Coastal inundation and habitat loss due to sea level rise and intensified precipitation events, e.g., in CBS and STG subregions *medium to high confidence*)	Options to maintain ecosystem integrity are limited to the reduction of other stresses, mainly pollution and limiting pressures from tourism, fishing and aquaculture. Loss of ecosystems such as sea grass, mangroves and coral reefs can be reduced by reducing deforestation and increasing reforestation of river catchments and coastal areas to retain sediments and nutrients.		5.5.2, 5.5.4, CC-CR, 30.5.6.1.3, 30.6.2.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Marine biodiversity loss with high rate of climate change (*medium confidence*)	Adaptation options are limited to the reduction of other stresses, mainly to reducing pollution and to limiting pressures from tourism and fishing.		Box CC-Bio, 6.3.1, 30.X.X	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Risks to fisheries					
Decreased production of global shellfish fisheries (*high confidence*)	Effective shift to alternative livelihoods, changes in food consumption patterns and adjustment of (global) markets.		6.3.2, 6.3.5, 6.4.1.1, 30.5.5, 30.6.2.1, CC-OA	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Global redistribution and decrease of low latitude fisheries yields are paralleled by a global trend to catches having smaller fishes (*medium confidence*)	Increasing coastal poverty at low latitudes as fisheries becomes smaller - partially compensated by the growth of aquaculture and marine spatial planning, as well as enhanced industrlalized fishing efforts.		6.3.1, 6.4.1, 6.5.3, 30.5.4, 30.5.6, 30.6.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Redistribution of catch potential of large pelagic-highly migratory fish resources, such as tropical Pacific tuna fisheries (*high confidence*)	International fisheries agreements and instruments, such as the tuna commissions, may have limited success in establishing sustainable fisheries yields.		6.3.1, 6.4.3, Table 30.4	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Variability of small pelagic fishes in Eastern Boundary Upwelling systems is becoming more extreme at interannual to multidecadal scales, making industry and management decisions more uncertain (*medium confidence*)	Development of new and specific management tools and models may have limited success to sustain yields. Reduction in fishing intensity increases resilience of the fisheries.		6.3.2, 6.3.3, 30.5.2, 30.5.5, CC-UP	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Decrease in catch and species diversity of fisheries in tropical coral reefs, exacerbated by interactions with other human drivers such as eutrophication and habitat destruction (*high confidence*)	Restoration of overexploited fisheries and reduction of other stressors on coral reefs delay ecosystem changes. Human adaptation includes the usage of alternative livelihoods and food sources (e.g., coastal aquaculture).		6.4.1, 30.5.3-4, 30.5.6, CC-CR	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Current spatial management units, especially the MPAs may fail in the future due to shifts in species distribution and community structure (*high confidence*)	Continuous revision and shifts of MPA borders, and of MPA goals and performance.		6.3.1, 6.4.2.1, 30.5.1, CC-BIO	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Risks to humans and infrastructure					
Coastal socio-economic security (*high confidence*)	Human adaptation options involve (1) Protection using coastal defences (e.g. seawalls) and soft measures (e.g. mangrove replanting and enhancing coral growth), (2) Accommodation to allow continued occupation of coastal areas by making changes to human activities and infrastructure, and (3) Managed retreat as a last viable option. Vary from large-scale engineering works to smaller scale community projects. Options are available under the more traditional CZM (coastal zone management) framework but increasingly under DRR (disaster risk reduction) and CCA (climate change adaptation) frameworks.		5.5.2, 5.5.4, 30.6.5, 30.7.1	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Reduced livelihoods and increased poverty (*medium confidence*)	Human adaptation options involve the large scale translocation of industrial fishing activities following the regional decreases (low latitude) versus increases (high latitude) in catch potential and shifts in biodiversity. Artisanal local fisheries are extremely limited in their adaptation options by available financial resources and technical capacities, except for their potential shift to other species of interest.		6.4.1-2, 30.6.2, 30.6.5	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

*high confidence in existence of adaptation measures, low confidence in magnitude of risk reduction

Climatic drivers of impacts

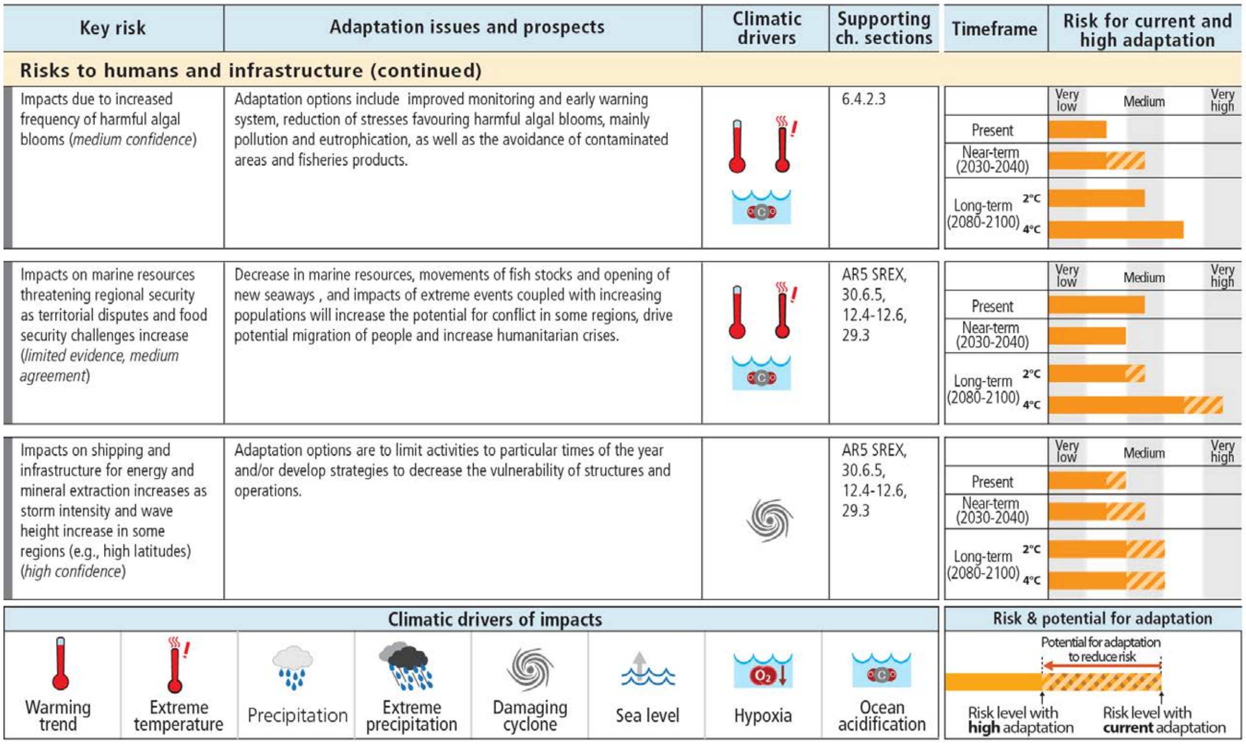
Risk & potential for adaptation

Potential for adaptation to reduce risk

Risk level with **high** adaptation | Risk level with **current** adaptation



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Risks to humans and infrastructure (continued)					
Impacts due to increased frequency of harmful algal blooms (*medium confidence*)	Adaptation options include improved monitoring and early warning system, reduction of stresses favouring harmful algal blooms, mainly pollution and eutrophication, as well as the avoidance of contaminated areas and fisheries products.		6.4.2.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Impacts on marine resources threatening regional security as territorial disputes and food security challenges increase (*limited evidence, medium agreement*)	Decrease in marine resources, movements of fish stocks and opening of new seaways , and impacts of extreme events coupled with increasing populations will increase the potential for conflict in some regions, drive potential migration of people and increase humanitarian crises.		AR5 SREX, 30.6.5, 12.4-12.6, 29.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Impacts on shipping and infrastructure for energy and mineral extraction increases as storm intensity and wave height increase in some regions (e.g., high latitudes) (*high confidence*)	Adaptation options are to limit activities to particular times of the year and/or develop strategies to decrease the vulnerability of structures and operations.		AR5 SREX, 30.6.5, 12.4-12.6, 29.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high

Figure 6-1: Sea surface temperature variability between 1911 and 2011. The top left map shows the sea surface temperature average for the period. The top right map illustrates the temperature range calculated as the difference between the maximum and minimum values for each grid component during the century. The spatial distribution of variability by time scales (left hand map series, based on the Extended Reynolds Sea Surface Temperature, NOAA, 2012) corresponds to the multidecadal (25 to 40 years), bidecadal (15 to 25 years), decadal (8 to 15 years), low ENSO (El Niño Southern Oscillation) frequency (5 to 8 years), high ENSO frequency (3 to 5 years), and very high frequency (2 to 3 years) scales. The summed variabilities from the same 2°x2° box in all six maps corresponds to 100% of the time series variability. The areas of the right hand bubbles show the spectral density of some of the most widely used climate indices, accumulated in the same frequency windows: the Global Average Temperature and SST Anomalies (GSST), the Southern Oscillation Index (SOI), the North Atlantic Oscillation (NAO), the Multidecadal Atlantic Oscillation (AMO), and the Pacific Decadal Oscillation (PDO). The sum of bubble surface areas for each vertical column (each climate index) corresponds to 100% of the time series variability between the 2 and 40 year periods. Climate indices where obtained from the NOAA ESRL Physical Sciences Division website. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

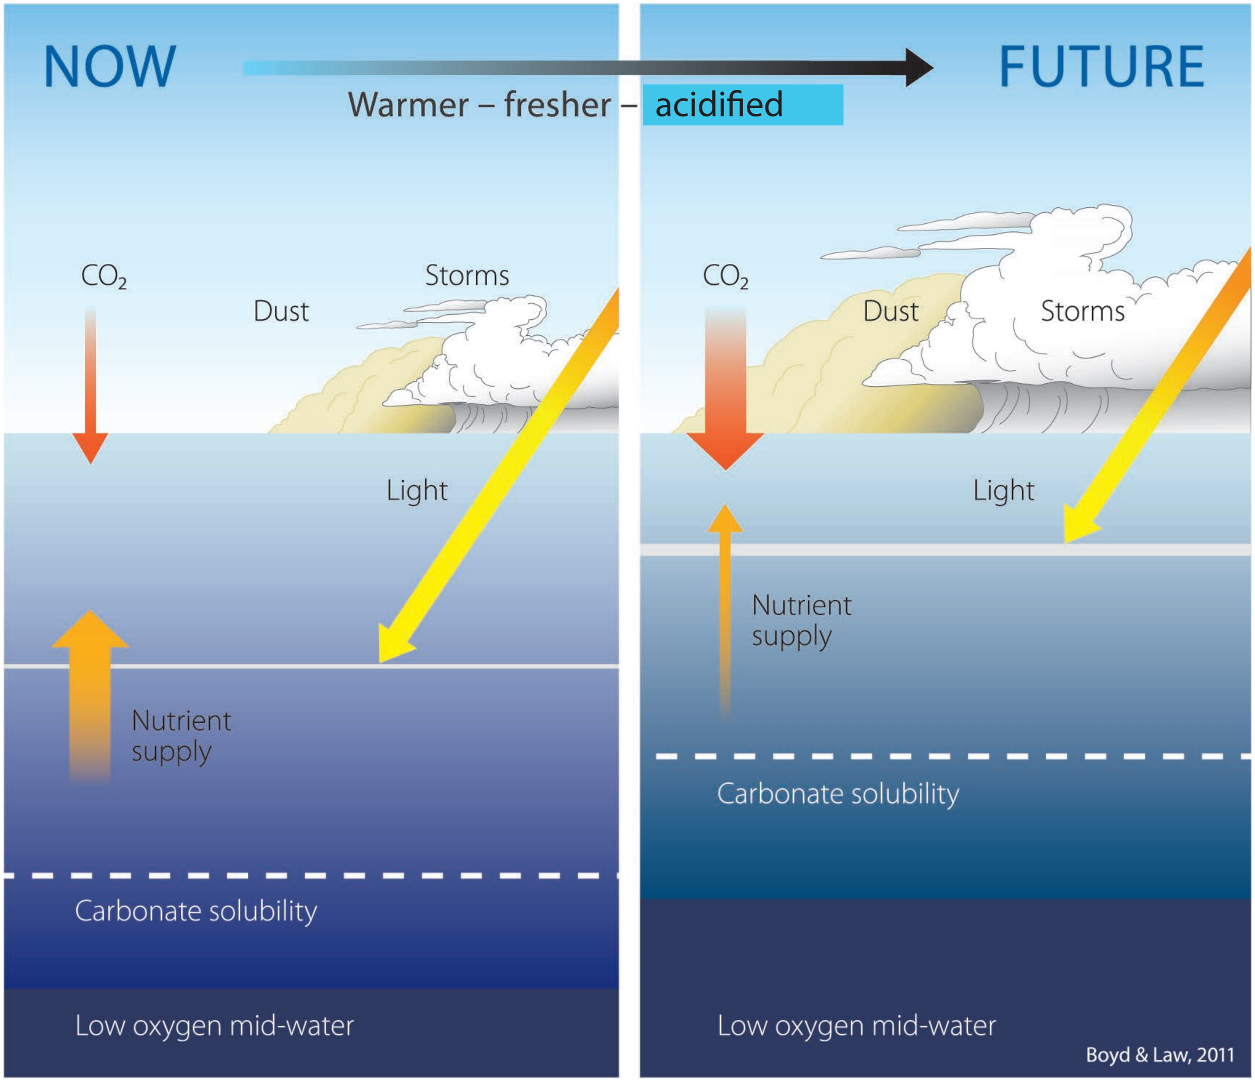

Figure 6-2: Projected alteration (magnitude and frequency) of oceanic fluxes and atmospheric events due to a changing climate in the coming decades. Ocean properties will be altered from the sunlit surface layer to the mid-water stratum. In the surface ocean, the depth of the mixed layer (solid horizontal line) will shallow resulting in higher mean light levels. Increased density stratification (i.e., a strengthening sea water density gradient represented by the increasing thickness of the solid horizontal line) will reduce the vertical supply of nutrients for photosynthesizing organisms residing in the mixed layer. Anthropogenic CO_2 will acidify, i.e., lower the pH of the surface ocean (note this happens in a pH range higher than 7 such that oceans will remain alkaline but less so due to acidification). The penetration of acidified waters to depth will result in a shallower depth (dashed horizontal line) at which calcium carbonate structures, such as shells, dissolve. At depth, the location of low oxygen waters will progressively become shallower. In addition, changes in storm activity and dust deposition will influence ocean physics and chemistry, with consequent effects on ocean biota and hence ecosystems (courtesy of Reusch and Boyd, 2013). **[Illustration to be redrawn to conform to IPCC publication specifications.]**

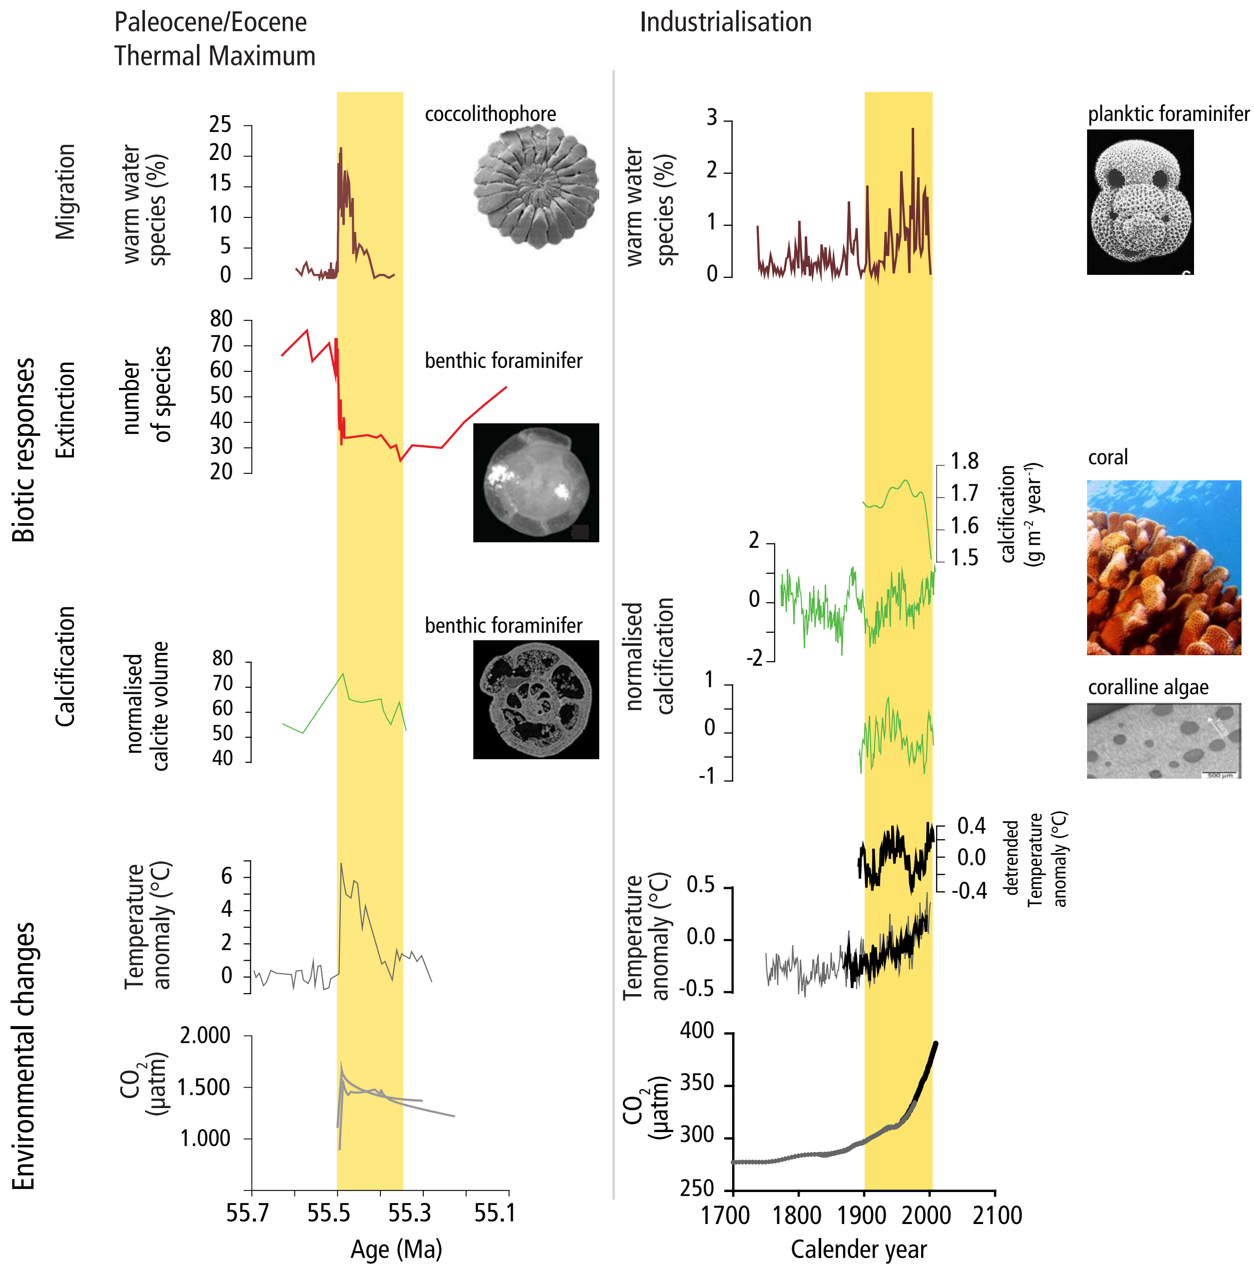

Figure 6-3: Environmental changes (bottom) and associated biological responses (top) for the Paleocene Eocene Thermal Maximum (PETM, left) and the industrial era (right). The PETM represents the best geological analogue for the future ocean in terms of biological responses. Episodes of largest environmental change are indicated with yellow bars. Note the different time scale between the two columns. Both time intervals are characterized by rapid warming both on land and in the ocean and increases in CO_2. Atmospheric CO_2 and temperature are described with direct measurements (black), proxy reconstructions (grey) and model results (light grey). For the recent anthropocenic record, the AMO is shown to highlight high frequency natural temperature fluctuations (Enfield *et al.*, 2001) and their influence on marine biota. Biological responses to the environmental forcing are divided into calcification, extinction and migration. Note the highly group-specific responses to the environmental change, especially with regards to calcification with decreases, increases and high variability. While there was extinction during the PETM, there is currently no evidence for climate-related extinction in the marine record. The warming led to migration of warm water species into previous cold water habitats indicating range expansion due to warming

(modern: planktic foraminifera, *Gs. ruber* Field *et al.*, 2006; PETM: coccolithophores, *Discoaster* spp. Bralower, 2002). CO_2 data: Mauna Loa (Keeling *et al.*, 2005), ice core records (Etheridge et al. 1996) and model output for the PETM (Zeebe *et al*., 2009; Ridgwell and Schmidt, 2010). Sea surface temperatures modern: Wilson *et al.*, 2006 and PETM: Kennett and Stott, 1991. Biotic responses: growth changes in coralline algae (Halfar *et al.*, 2011, bottom) and corals (Vásquez-Bedoya *et al.*, 2012, middle, De'ath *et al.*, 2009, top); calcification changes (Foster *et al*., 2013) and extinction in benthic foraminifers (Thomas, 2003) for the PETM.
[Illustration to be redrawn to conform to IPCC publication specifications.]

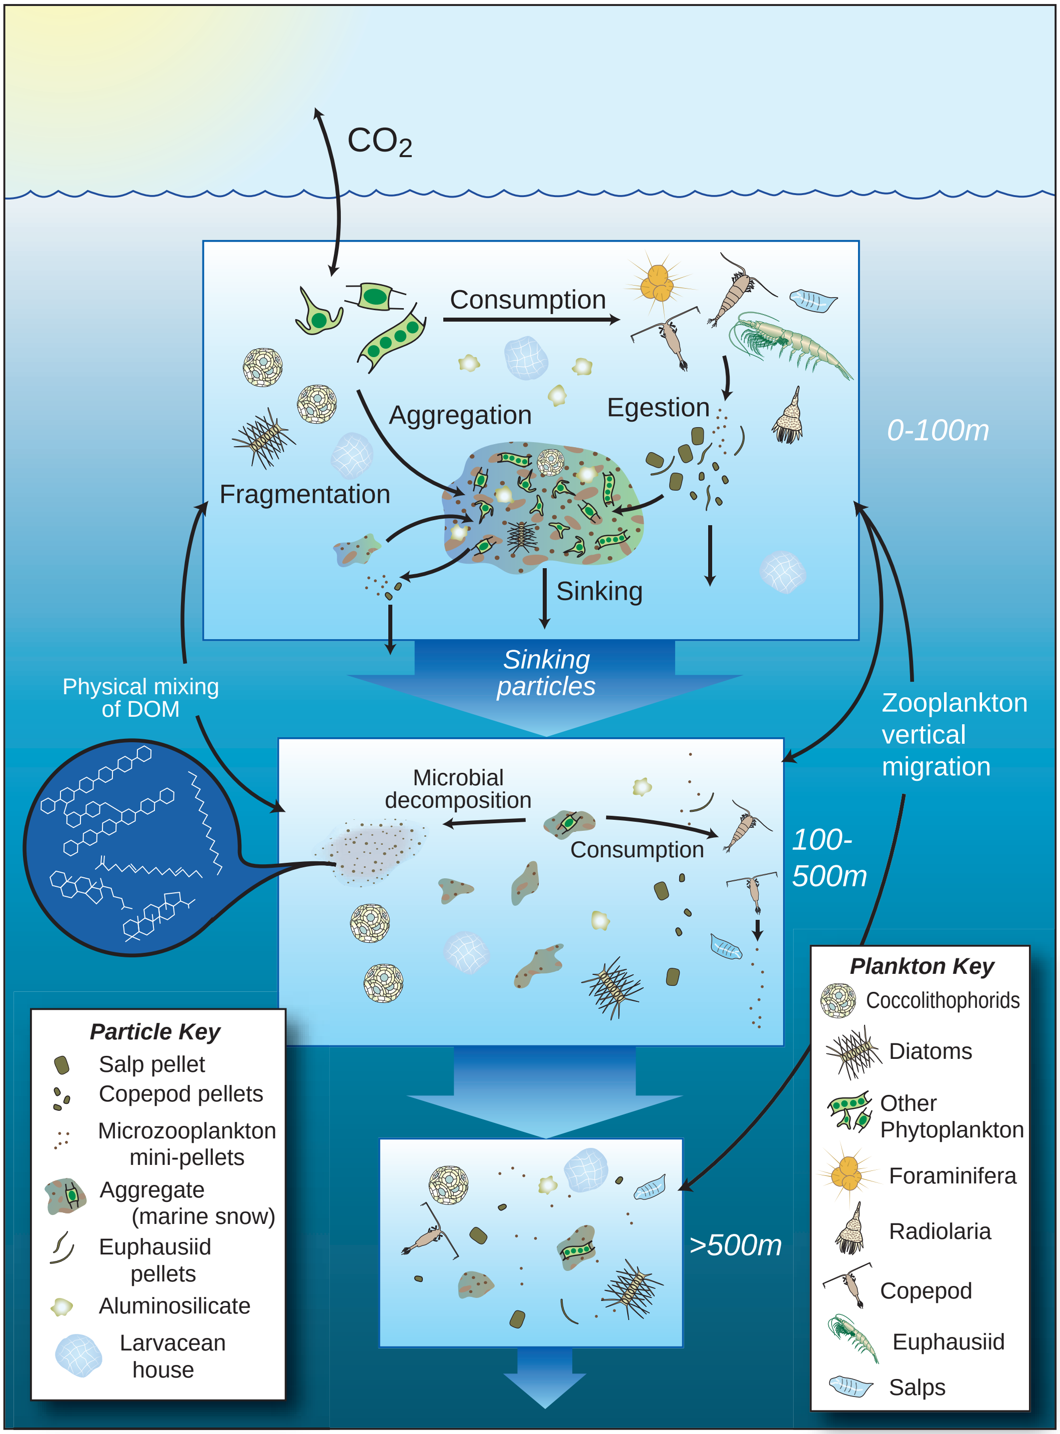

Figure 6-4: A schematic representation of the ocean's biological pump, which will be influenced by climate change and is a conduit for carbon sequestration. It is difficult to project how the pump might be altered (Table 6-1) and whether it would represent a positive or negative feedback to climate change through the cumulative effects of affected processes, surface to depth (Table 6-1): shifts in Net Primary Production, floristic and faunistic community composition in the pelagic realm, and in grazing rates; alterations to the ballasting of settling particles and the proportion of NPP released as DOM (Dissolved Organic Matter); modified bacterial enzymatic rates and particle solubilization; faunistic shifts at depth. Modified from Buesseler *et al.* (2008) by J. Cook (WHOI).
[Illustration to be redrawn to conform to IPCC publication specifications.]

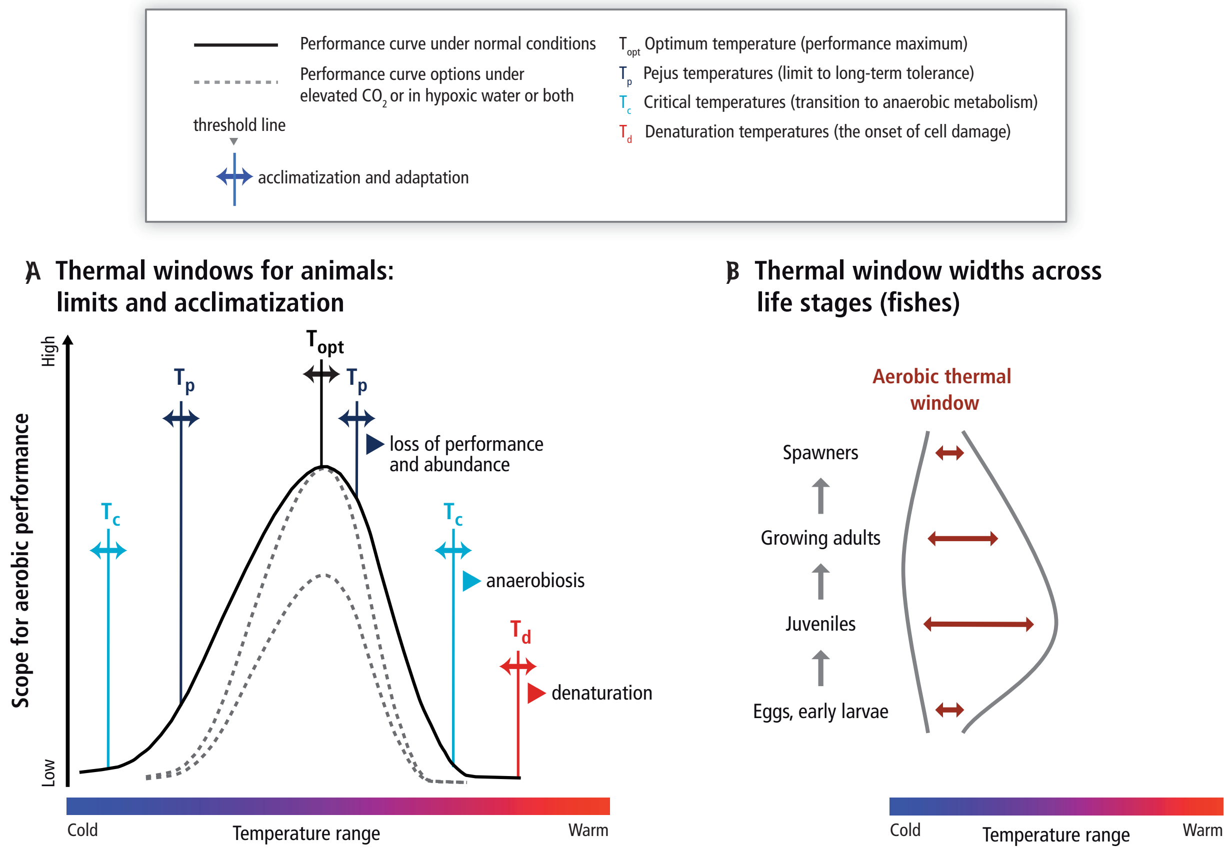

Figure 6-5: Thermal specialization of an organism explains the why, how, when, and where of climate sensitivity. (A) The thermal tolerance range and performance levels of an organism are described by its performance curve (exemplified for an animal). Each Performance (e.g., exercise, growth, reproduction) is maximal at its optimum temperature (T_{opt}), and becomes progressively constrained during cooling or warming. Surpassing the first low and high temperature thresholds (T_p, p, pejus: getting worse) means going into time-limited tolerance. Once further cooling or warming surpasses the next low or high thresholds (T_c, c, critical), oxygen availability becomes insufficient and an anaerobic metabolism begins. Denaturation temperatures (T_d) are even more extreme and characterized by the onset of damage to cells and proteins. Horizontal arrows indicate that T_p, T_c, and T_d-thresholds of an individual can shift, within limits, between summer and winter (seasonal acclimatization) or when the species adapts to a cooler or warmer climate over generations (evolutionary adaptation). Under elevated CO_2 levels (ocean acidification) and in hypoxic waters performance levels can decrease and thermal windows narrow (dashed grey curves). (B) The width of the thermal range (horizontal arrows) also changes over time when an individual develops from egg to larva to adult and gains weight and size. Blue to red colour gradients illustrate the range between cold to warm temperatures (after Pörtner, 2002a, 2012; Pörtner and Farrell, 2008).

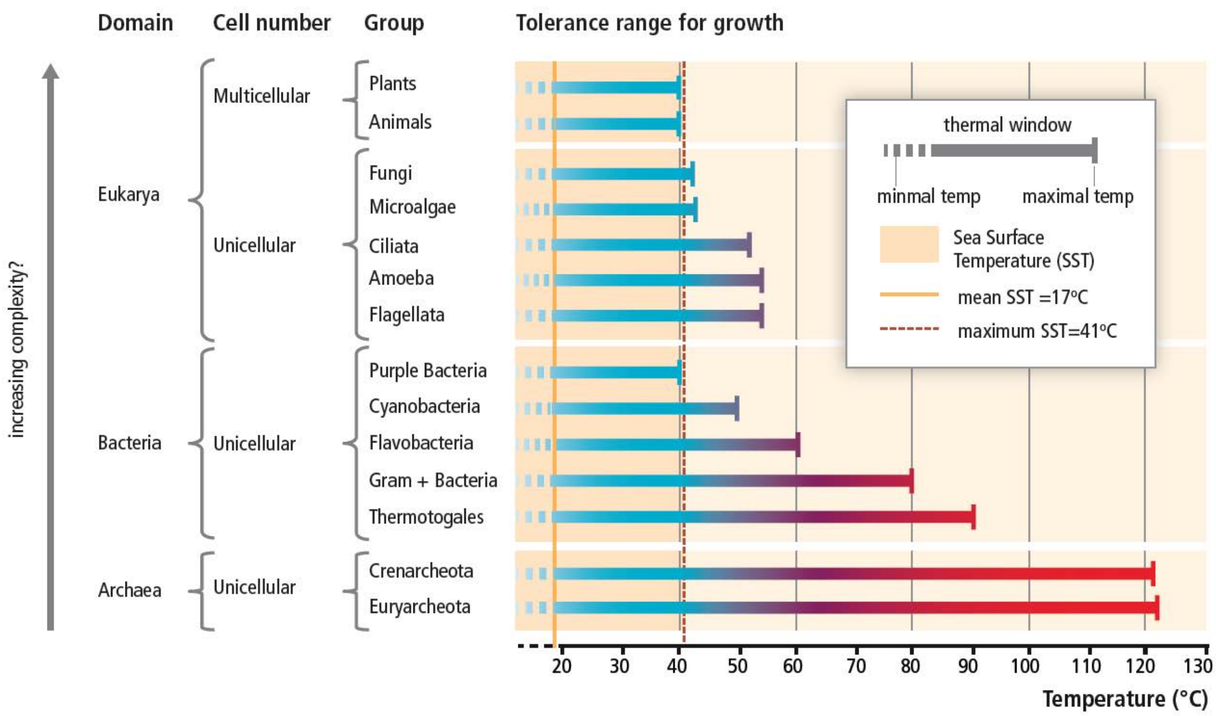

Figure 6-6: Maximal values of temperature covered by various domains and groups of free-living marine organisms (bacteria to animals, domains, and groups modified after Woese *et al*.,1990). High organizational complexity is hypothesized to be associated with decreasing tolerance to heat and to enable an increase in body size which in turn, decreases heat tolerance further (Alker *et al*., 2001; Baumgartner *et al*., 2002; Campbell *et al*., 2006; Chevaldonné *et al*., 2000; De Jonckheere *et al*., 2009, 2011; Pörtner, 2002a,b; Sorokin and Kraus, 1962). In the domain Bacteria, the Thermotogales are less complex and most tolerant to high temperatures (Abed *et al*., 2002; Huber *et al*., 1986; Takai *et al*., 1999; Tenreio *et al*., 1997; Ventura *et al*., 2000). The highest temperature, at which growth can occur is 122°C for hydrothermal vent archaea, seen under elevated hydrostatic pressure in laboratory experiments (Kashefi and Lovley, 2003; Takai *et al*., 2008.)

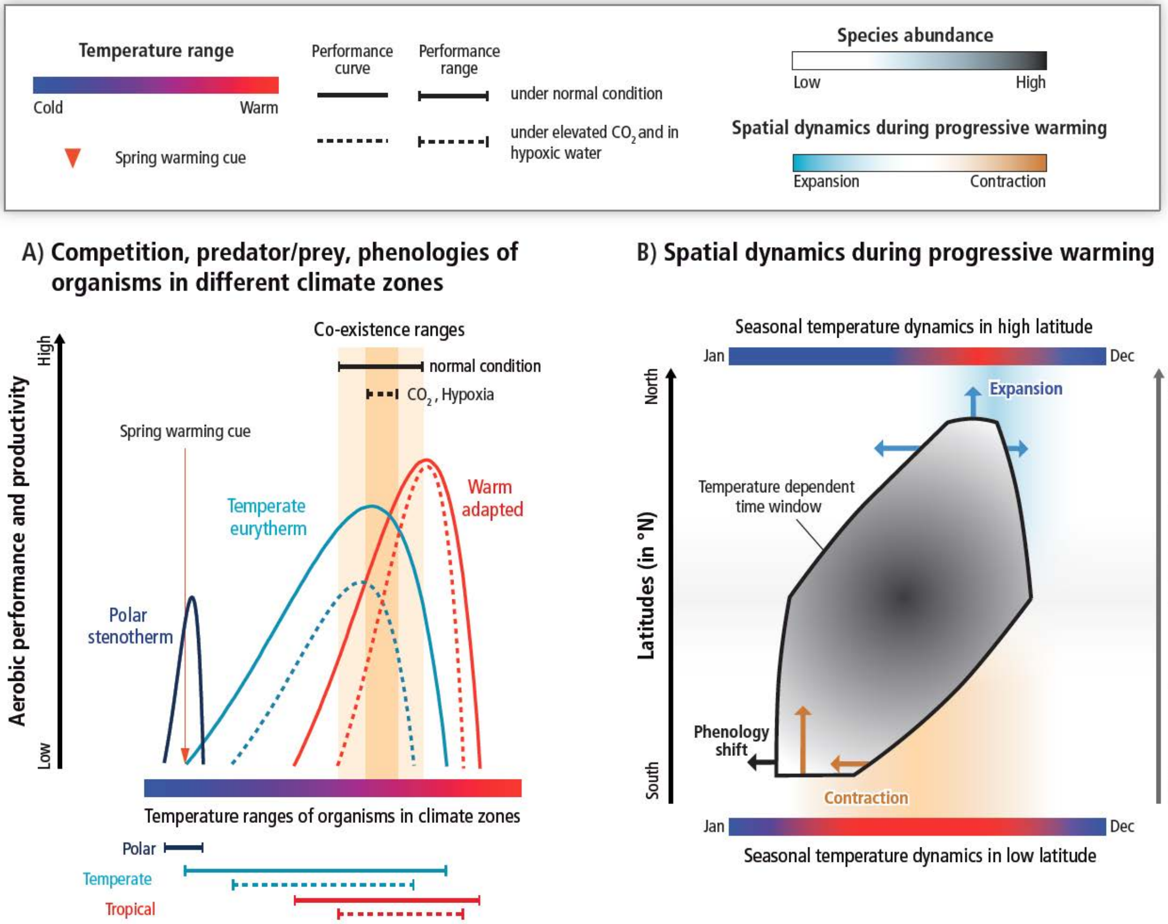

Figure 6-7: Role of thermal tolerance and performance of organisms at ecosystem level. (A) Thermal tolerance ranges (Figure 6-5) differ between species across polar, temperate and tropical climate zones, then overlapping between coexisting species. Shifting temperatures and specific effects of additional drivers on the respective performance curves (dashed lines) change the fitness of coexisting species relative to each other as well as their temperature range of coexistence (after Pörtner and Farrell, 2008). Warming alters the timing of seasonal activities (e.g., elicited by spring warming cues) earlier, or can benefit only one of two interacting species (e.g. in predator-prey dynamics or competition) causing shifts in predominance. (B) During climate warming a largely unchanged thermal range of a species causes it to follow its normal temperatures as it moves or is displaced, typically resulting in a poleward shift of the biogeographic range (exemplified for the Northern hemisphere, modified after Beaugrand, 2009). The polygon delineates the distribution range in space and seasonal time; the level of grey denotes abundance. The southern time window of tolerated temperatures shifts to earlier and contracts, while the northern one dilates (indicated by arrows). Species display maximum productivity in low latitude spring, wide seasonal coverage in the center, and a later productivity maximum in the North. The impact of photoperiod (length of daily exposure to light) increases with latitude (grey arrow). Water column characteristics or photoperiod may overrule temperature control in some organisms (e.g. diatoms), limiting northward displacement.

Figure 6-8: Multi-decadal changes in ecosystem structure in the NE Atlantic driven by warming from both anthropogenic climate change and natural climate variability. **A.** Index of temperature change over the North Atlantic (31°N-65°N and 99°W-11°W) reflecting climate change. This index is the first principal component (i.e., explaining 30.5% of observed variability) based on a Principal Component Analysis (PCA) performed on sea surface temperature. **B.** Index of temperature change (17.5% of observed variability) reflecting the Atlantic Multidecadal Oscillation (AMO). The index is the second principal component. **C-D.** Observed mean annual sea surface temperature in the North Sea during 1960-1981 (**C**) and 1988-2005 (**D**). The location of the critical thermal boundary (9-10°C) is indicated by '+'. **E**. Long-term changes in the mean number of warm-temperate pseudo-oceanic species from 1958 to 2005. **F**. Long-term changes in the mean number of temperate pseudo-oceanic species from 1958 to 2005. The period 1958-1981 was a period of relative stability and the period 1982-1999 was a period of rapid northward shifts, indicating that the abrupt ecosystem shift observed in the North Sea was part of a large-scale response of the zooplankton biodiversity to warming temperatures (see **A**-**D**). Average values are below 1 because they are annual averages. Note that the color bar is 10-fold smaller for warm-temperate pseudo-oceanic species because these species are less frequently observed than their temperate counterparts. Panels A. and B. from Edwards *et al*. (2013), and C. to F. from Beaugrand *et al*. (2008), and Beaugrand *et al*. (2009).
[Illustration to be redrawn to conform to IPCC publication specifications.]

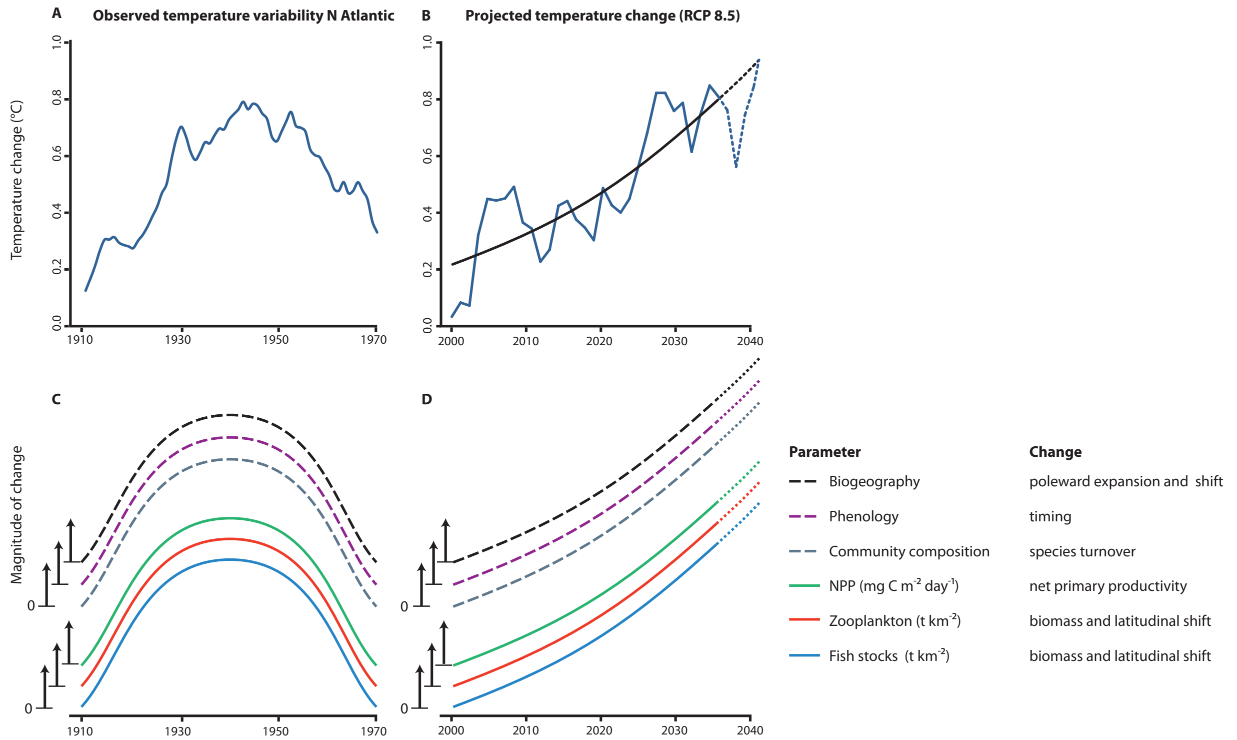

Figure 6-9: Schematic depiction of observed effects of ~1°C ocean warming in the northern North Atlantic driven by climate variability (A, C) versus effects expected from anthropogenic climate change (B, D). A) Transient warming and cooling associated with AMO variability (Drinkwater, 2006), based on the Kola Section temperatures (0-200 m; Stations 3-7, 71.5°-72.5°N, 33.5°E) in the Barents Sea obtained from http://www.pinro.ru and filtered using a 20-year running mean. Similar trends occurred across most of the northern North Atlantic although the amplitude and timing of the peaks and troughs varied spatially. B) Warming driven by climate change for the same region (RCP 8.5 simulations averaged from CMIP5 models, computed as the mean over the upper 200 m in the grid box (2.5x2.5 degrees) centered at 71.25N and 33.75E). C) Warming and subsequent cooling in the northern North Atlantic during the period shown in A resulted in complex multi-faceted changes (shown schematically) in NPP (green curve), zooplankton biomass (red curve) and fish stock abundances (blue curve). There was a general poleward shift and range expansion of many commercial (e.g., Atlantic herring, Atlantic cod, haddock) and non-commercial species, reversed during the subsequent cooling period (denoted by black dashed curve). Polewards shifts in spawning areas (e.g., Atlantic cod) were also reversed as the waters cooled. The purple and grey dashed curve represents shifts in seasonal timing (phenology) and community composition, respectively, that were influenced by earlier arrivals and later retreat of migratory fish (not shown). For more details see Drinkwater (2006). D) Projected effects of climate mediated warming on northern sub-polar and polar biota based on model projections of altered NPP (Bopp *et al.*, 2013), and of the range shift of exploited fishes and invertebrates (Cheung *et al.*, 2009, 2013a). The projected trends in panel D will differ with latitude, e.g., decreased NPP at lower latitudes and no significant change to NPP in temperate waters (Bopp *et al.*, 2013). Higher NPP supported and is projected to support higher trophic levels at high latitudes (C, D, 6.3.4). Note that climate variability will be superimposed on anthropogenic warming (B, see Figure 6-1, 6-8A,B). Dotted lines indicate projected changes to continue beyond the range of historical observations.

Figure 6-10: A: Responses of a schematized marine animal (left) and a phytoplankter (right) to ocean acidification (OA). Effects are mediated via diffusive CO_2 entry (black arrows) into body and cell compartments, resulting in a rise in pCO_2 (highlighted in red), a drop in compartmental pH (highlighted in blue) and their effects (red arrows) on various processes (red text) in tissues and cellular compartments, as well as on calcium carbonate saturation state (Ω) at calcification sites (after Pörtner, 2008; Taylor *et al*., 2011). Variable sensitivity relates to the degree of pH decline and compensation, depending on the capacity of pH and ion regulation. B: Distribution of sensitivities across species within animal phyla, under progressively rising water CO_2 levels, as percent of studied scleractinian coral, echinoderm, molluskan, crustacean and fish species affected negatively, positively or not at all (for effects considered see text). As not all life stages, variables and pCO_2 ranges were covered in all species two assumptions partially compensate for missing data: 1) Negative effects at low pCO_2 will remain negative at high pCO_2. 2) A positive or neutral outcome at both low and high pCO_2 will be the same at intermediate pCO_2. As responses reported for each species vary for each CO_2 range, variable species numbers result (on top of columns). The total number of species studied in a group is shown as the number above the control column. Horizontal lines above columns represent frequency distributions significantly different from controls (Wittmann and Pörtner, 2013). C: Areas with reported annual catches of marine calcifiers (crustaceans and mollusks) >0.001 t km^{-2} depicted on a global map showing the distribution of ocean acidification in 2100 according to RCP8.5 (WGI AR5 SPM) as well as the distribution of warm-water (green dots) and cold-water coral communities (pink dots).

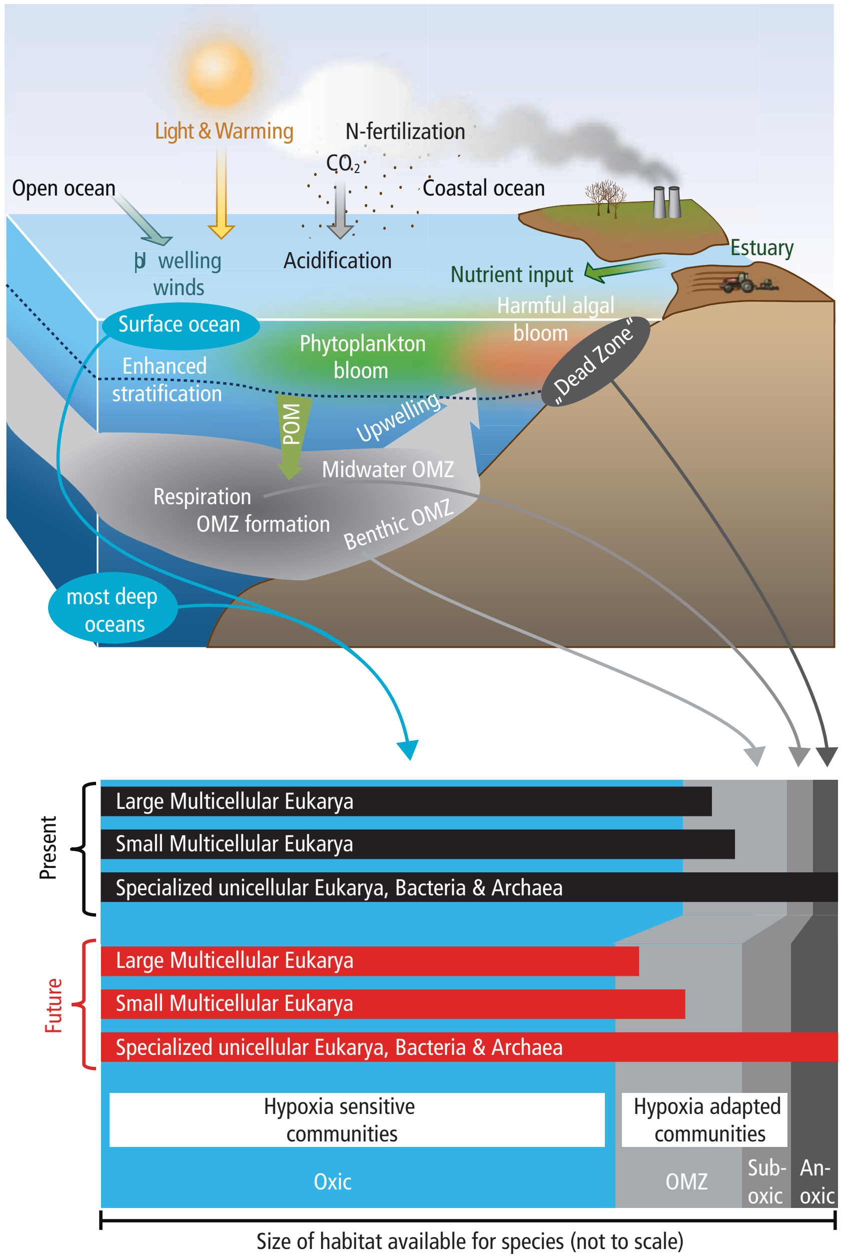

Figure 6-11: (A) Principal mechanisms underlying the formation of hypoxic conditions and their biological background (modified from Levin *et al.*, 2009; Levin and Sibuet, 2012). The buoyancy flux from fluvial discharges produces sharp density stratification at the base of the freshened layer (also valid for ice melt and high precipitation) near the surface and, hence, vertical mixing is greatly reduced. In consequence, the nutrient inputs from the river and the atmosphere accumulate in a narrow upper layer, leading to phytoplankton blooms. The enhancement of oxygen consumption due to aerobic decomposition of sinking organic matter results in hypoxic conditions of OMZs. OMZs also form in the open oceans. Heating of the upper layer increases stratification, while the wind-driven upwelling of hypoxic, nutrient-rich water from deeper layers adds to the formation of the OMZs (Box CC-UP) (B) Distribution of various free-living marine organisms (microbes such as archaea, bacteria, protists, small and large multicellular animals, and plants) across the ranges of O_2 concentrations in vaious water layers. Hypoxia tolerance is enhanced in small compared to large organisms, allowing unicellular species and small animals to thrive in extremely hypoxic habitats. Species richness and body size of animals increases with rising O_2 levels.
[Illustration to be redrawn to conform to IPCC publication specifications.]

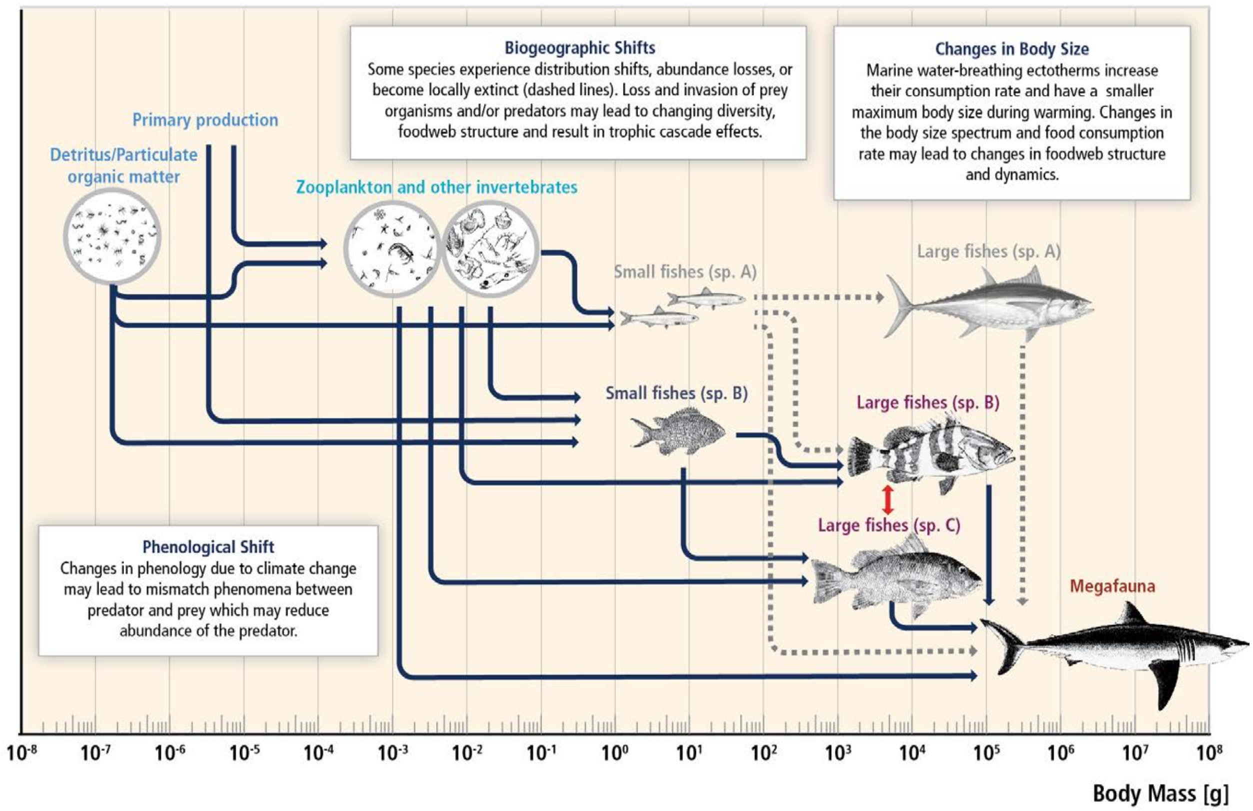

Figure 6-12: Schematic diagram of expected responses to climate change in a marine food web. A coupled pelagic and benthic food web is structured by the body size spectrum of species. Combined warming, hypoxia and ocean acidification reduce body size, shift biogeographies, change species composition and abundance, and reconfigure trophic linkages and interaction dynamics. Fishing generally removes large-bodied species and truncates the body-size spectrum of the community. This confounds the detection and attribution of food web responses to climate change. Arrows represent species interactions (e.g., between predator and prey or competitors for food or space). Broken lines reflect the potential loss of populations and trophic linkages due to climate change.

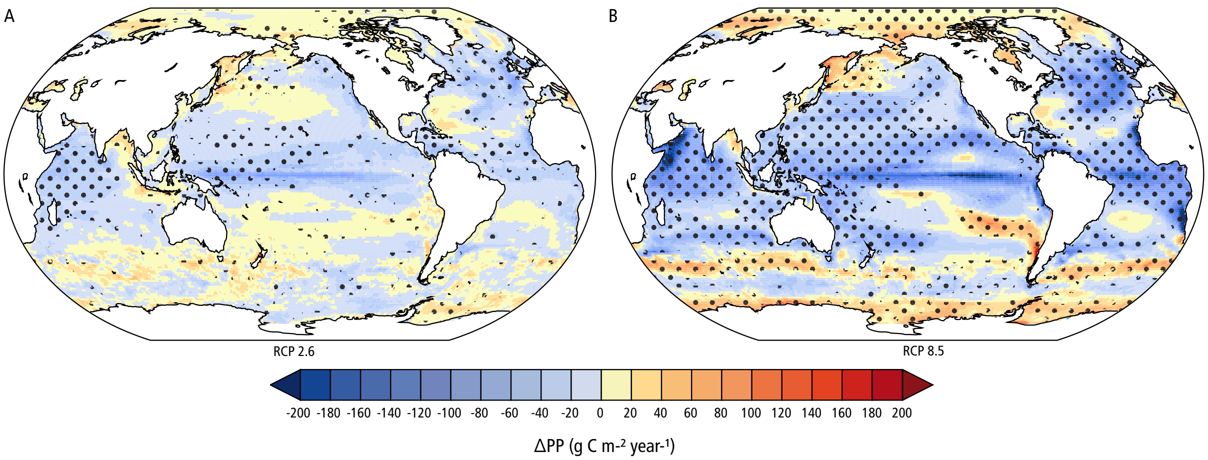

Figure 6-13: Multi-model annual mean changes of projected vertically-integrated net primary production (small and large phytoplankton) under the low emission scenario RCP2.6 (A) and the high emission scenario RCP8.5 (B) for the period 2090 to 2099 relative to 1990 to 1999 (after Bopp *et al.*, 2013). To indicate consistency in the sign of change, regions are stippled where 80% of the ten models from the Coupled Model Intercomparison Project Phase 5 (Bopp *et al*. 2013) agree on the sign of change.

Figure 6-14: Climate change effects on the biogeography, body size and fisheries catch potential of marine fishes and invertebrates. (A) Shifts in distribution range and reduction in body size of exploited fish driven by projected warming, oxygen depletion and sea-ice retreat (cf. Figure 6-7). Whenever the shift in distribution does not fully compensate for warming and hypoxia, the result will be a decrease in body size. Shifts in (B) latitudinal and (C) depth distribution of 610 exploited demersal fishes are projected to have a median (central line of the box) of 31 km decade^{-1} and 3.3 m decade^{-1}, respectively, with variation between species (box boundary: 25th and 75th percentiles) from 1991-2010 to 2041 - 2060 under the SRES A2 (between RCP6.0 - 8.5) scenario (Cheung *et al*., 2011; Cheung *et al*., 2013b). (D) Combining species' range shift with projected changes in NPP leads to a projected global redistribution of maximum catch potential (Analysis includes ~1,000 species of exploited fishes and invertebrates, under warming by 2°C according to SRES A1B (~RCP6.0), comparing the 10-year averages 2001-2010 and 2051-2060; redrawn from Cheung *et al*. 2010). (E) Changes in species distribution and individual growth are projected to lead to reduced maximum body size of fish communities at a certain site. The analysis includes 610 species of marine fishes, from 1991-2010 to 2041-2060 under the SRES A2 (~RCP6.0 to 8.5, Cheung *et al.*, 2013b). Key assumptions of the projections are that current distribution ranges reflect the preferences and tolerances of species for temperature and other environmental conditions and that these preferences and tolerances do not change over time. Catch potential is determined by species range and net primary production. Growth and maximum body size of fishes are a function of temperature and ambient oxygen level.

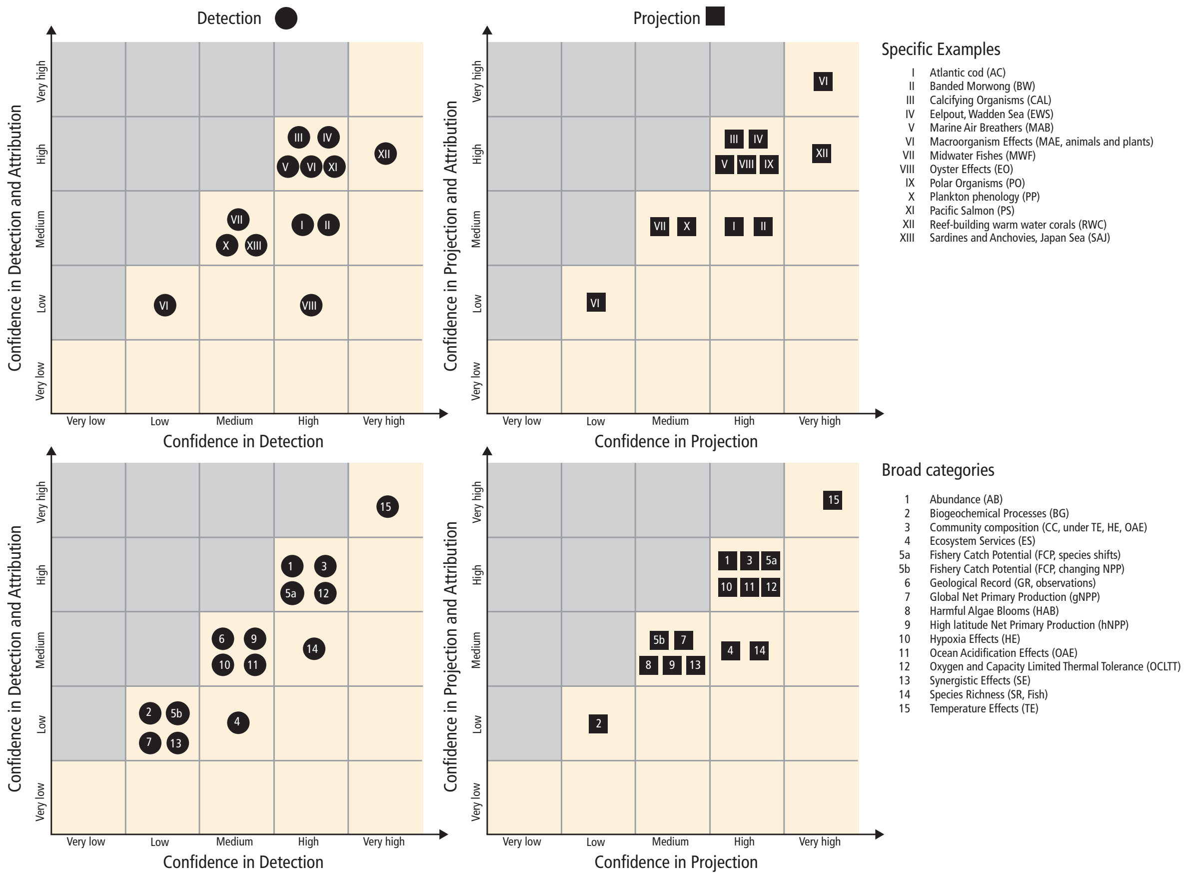

Figure 6-15: Overview of the levels of confidence in detection (left), as well as in projection (right) of climate change effects on ocean systems, in relation to the levels of confidence in attributing these effects to the respective climate forcings. Case studies, processes, and concepts relevant in assessing the effects of climate change are represented by their acronyms in both text and figure. While confidence in the presence of effects is often high, the direct attribution to one driver in field experiments is difficult, as drivers are often highly correlated with each other (e.g., warming with changes in stratification and hence reduced nutrient supply). Some climate change impacts have been condensed into broad categories to avoid overpopulating the figures (e.g., Bio-Geochemical processes, BG). Note that the term “attribution” is used for both present-day detections in the field and future projections, the latter including qualitative and quantitative extrapolations and simulations from fundamental principles and models. Firm knowledge from experiments (field, laboratory and modeling) simulating future conditions enhances the respective confidence levels to those for detection or projection. The empirical observations resulting from those experiments are directly attributable to the respective drivers. Confidence in attribution is enhanced if these experiments identify the underlying mechanisms and their responses. See text for the discussion of depicted examples and categories. Confidence assignments focus on the nature and size of effects, not on model capacity to reliably quantify their magnitude.
[Illustration to be redrawn to conform to IPCC publication specifications.]

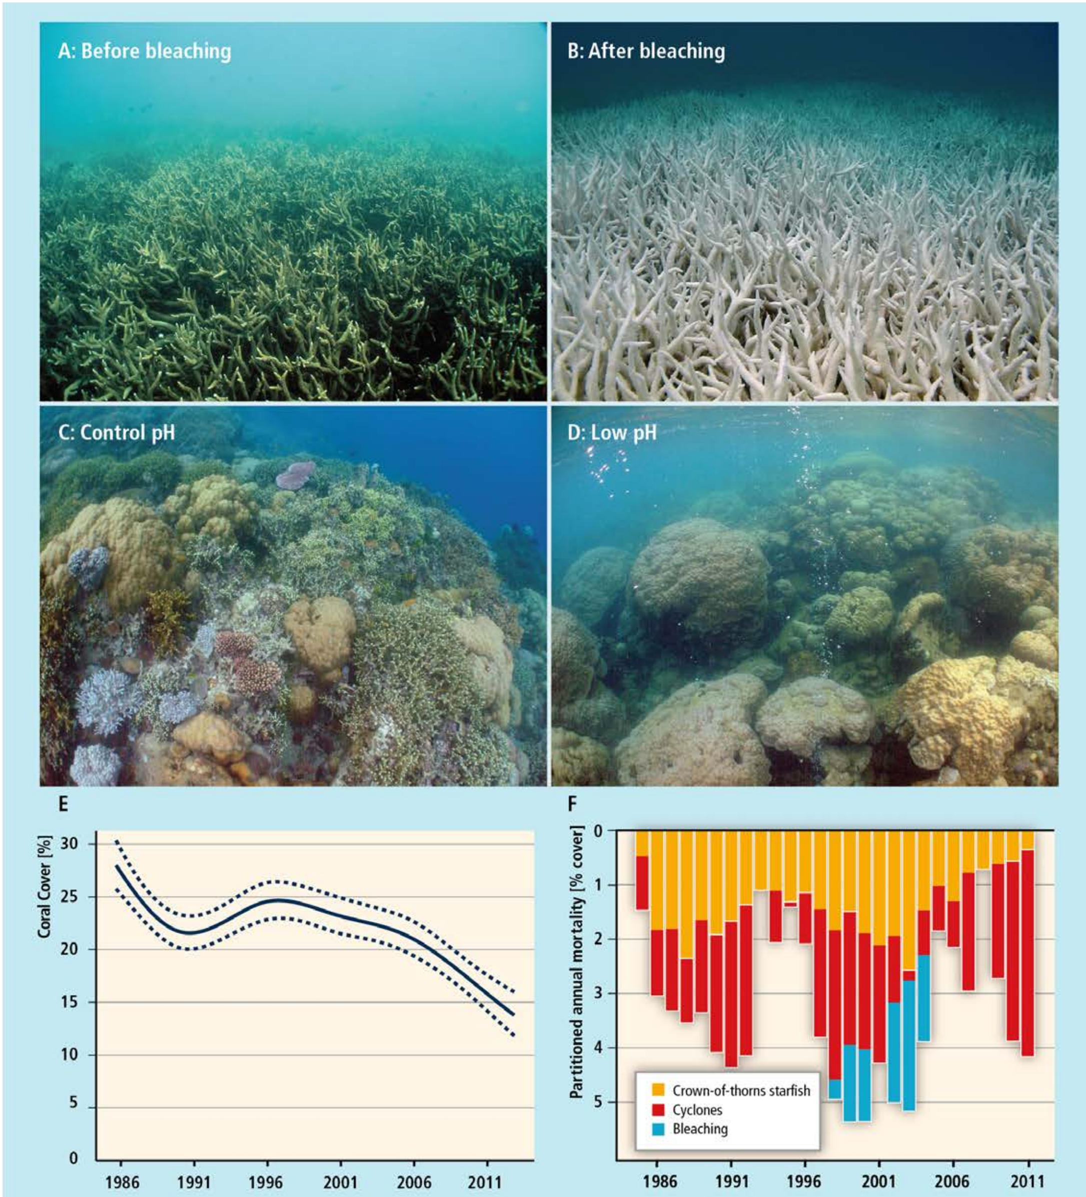

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge *et al*., 2004). Mortality was comparatively low due in part because these coral communities were able to shuffle their symbiont to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones *et al*., 2008). C and D: three CO_2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO_2 is related to fundamental changes in the ecology of coral reefs (Fabricius *et al*., 2011), including reduced coral diversity (-39%), severely reduced structural complexity (-67%), lower density of young corals (-66%) and fewer crustose coralline algae (-85%). At high CO_2 sites (panel D; median pH_T ~7.8), reefs are dominated by massive corals while corals with high morphological complexity are underrepresented compared with control sites (D; median pH ~8.0). Reef development ceases at pH_T values below 7.7. pH_T: pH on the total scale. E: temporal trend in coral cover for the whole Great Barrier Reef over the period 1985–2012 (N, number of reefs, mean ± 2 standard errors; De'ath et al., 2012). F: composite bars indicate the estimated mean coral mortality for each year, and the sub-bars indicate the relative mortality due to crown-of-thorns starfish, cyclones, and bleaching for the whole Great Barrier Reef (De'ath et al., 2012). Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

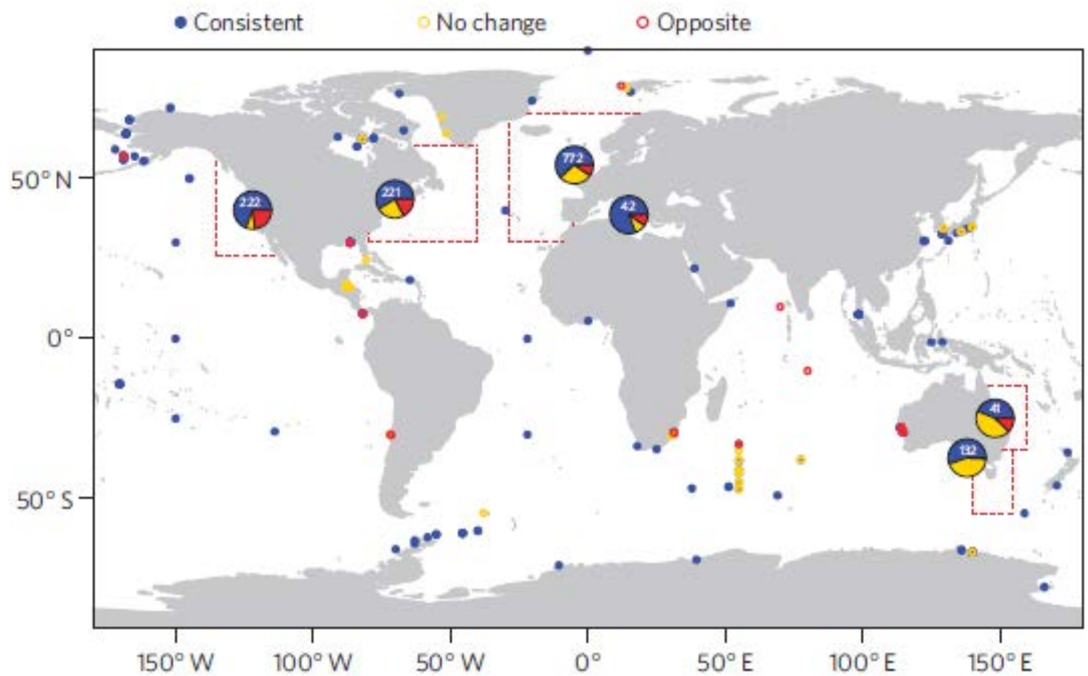

Figure MB-1: 1735 observed responses to climate change from 208 single- and multi-species studies. Changes attributed to climate change (blue), inconsistent with climate change (red) and are equivocal (yellow). Each circle represents the centre of a study area. Where points fall on land, it is because they are centroids of distribution that surround an island or peninsula. Pie charts show the proportions within regions bounded by red squares and in the Mediterranean; numbers indicate the total (consistent, opposite or equivocal) observations within each region. Note: 57% of the studies included were published since AR4 (from Poloczanska *et al.*, 2013).

[Illustration to be redrawn to conform to IPCC publication specifications.]

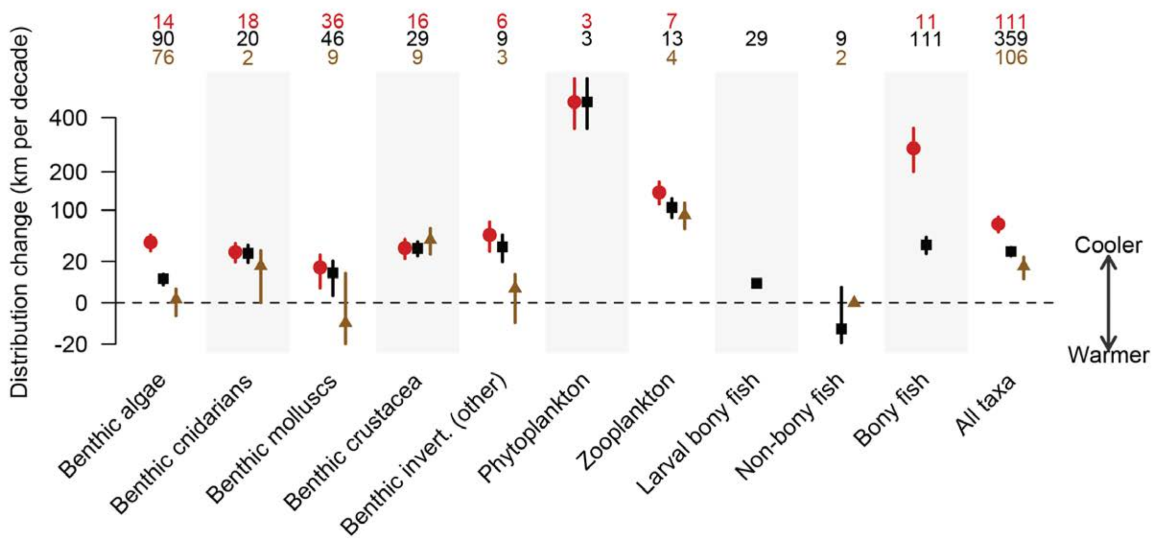

Figure MB-2. Rates of change in distribution (km decade^{-1}) for marine taxonomic groups, measured at the leading edges (red) and trailing edges (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward). Means ± standard error are shown, along with number of observations (from Poloczanska et al., 2013).

[Illustration to be redrawn to conform to IPCC publication specifications.]

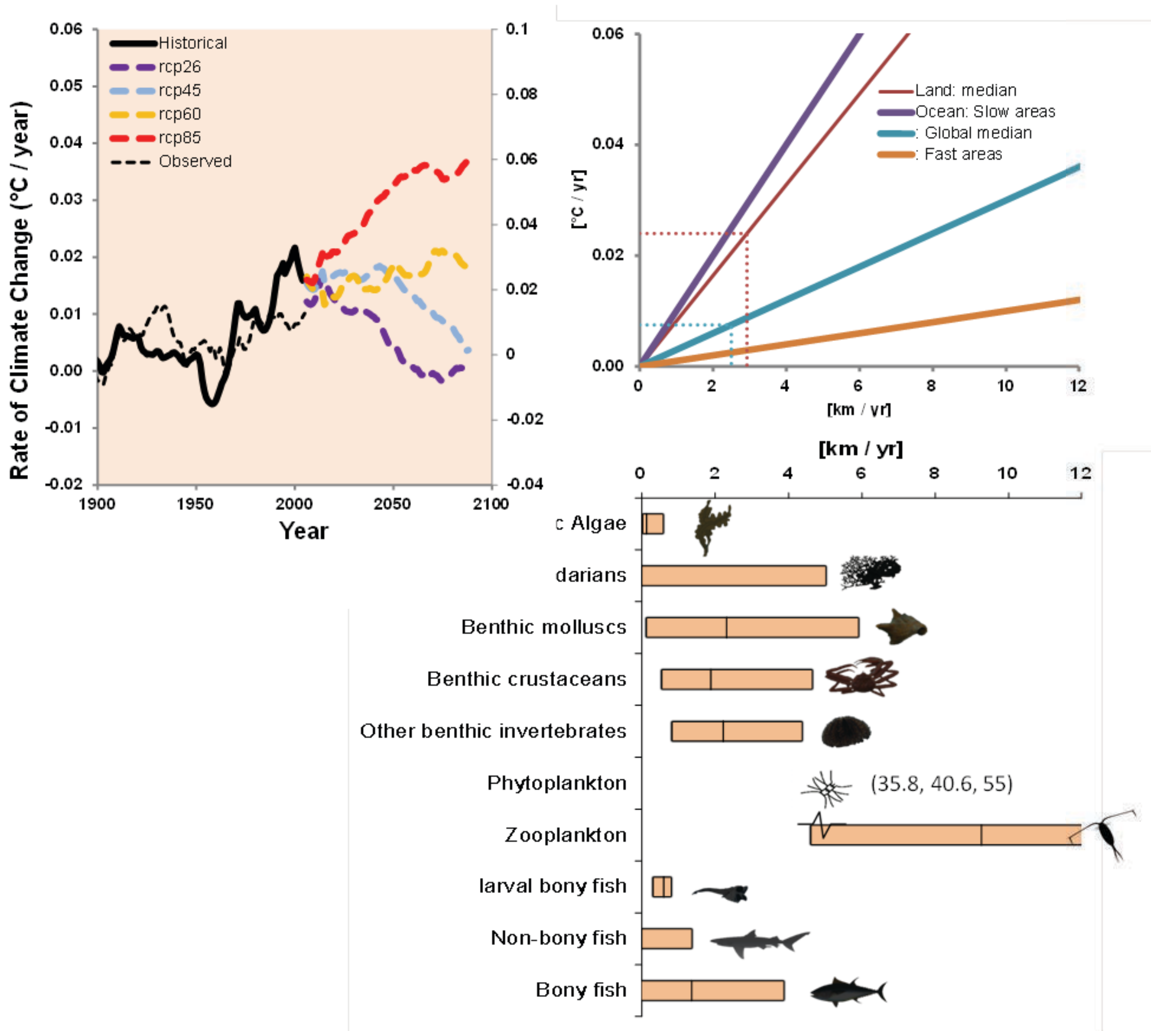

Figure MB-3. A. Rate of climate change for the Ocean (sea surface temperature (SST) °C); B. corresponding climate velocities for the Ocean and median velocity from land (adapted from Burrows et al., 2011); and C. observed rates of displacement of marine taxonomic groups over several decades until 2010. The thin dotted red arrows give an example of interpretation. Rates of climate change of 0.008 °C yr^{-1} correspond to ca. 2.4 km yr^{-1}median climate velocity in the Ocean. When compared to observed rates of displacement, many marine taxonomic groups have been able to track these velocities, except phyto- and zooplankton where rates of displacement greatly exceed climate velocity. All values are calculated for ocean surface with the exclusion of polar seas (Figure 30-1a). (A) Observed rates of climate change for Ocean SST (Black dotted line) are derived from HadISST1.1 data set, all other rates are calculated based on the average of the CMIP5 climate model ensembles (Table S30-3) for the historical period and for the future based on the four RCP emissions scenarios. Data were smoothed using a 20-year sliding window. (B) Median climate velocity calculated from HadISST1.1 dataset over 1960–2010 using the methods of Burrows et al., 2011. The three axes represent estimated median climate velocities are representative of areas of slow velocities such as Pacific subtropical gyre (STG) system (Purple line), the global Ocean surface (excluding polar seas, Blue line), and areas of high velocities such as the Coral Triangle and North Sea (Orange line). Figure 30-3 shows climate velocities over the ocean surface calculated over 1960–2010. The Red line corresponds to the median rate over global land surface calculated using historical surface temperatures from the CMIP5 model ensemble (Table S30-3). (C) Rates of displacement for marine taxonomic groups estimated by Poloczanska et al. 2013 using published studies (Figure MB-2 Black data set). Note the displacement rates for phytoplankton exceed the axis, so values are given. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

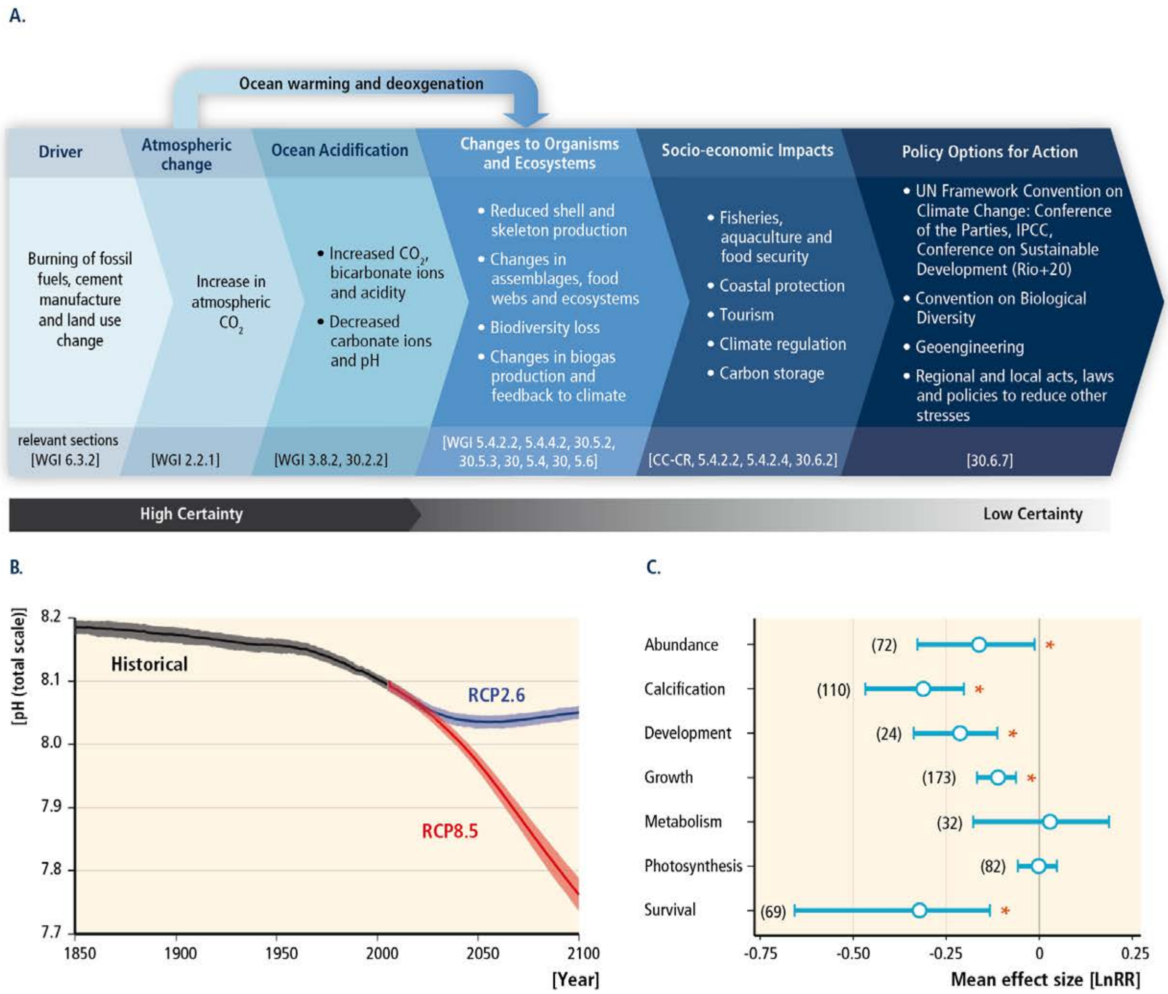

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.

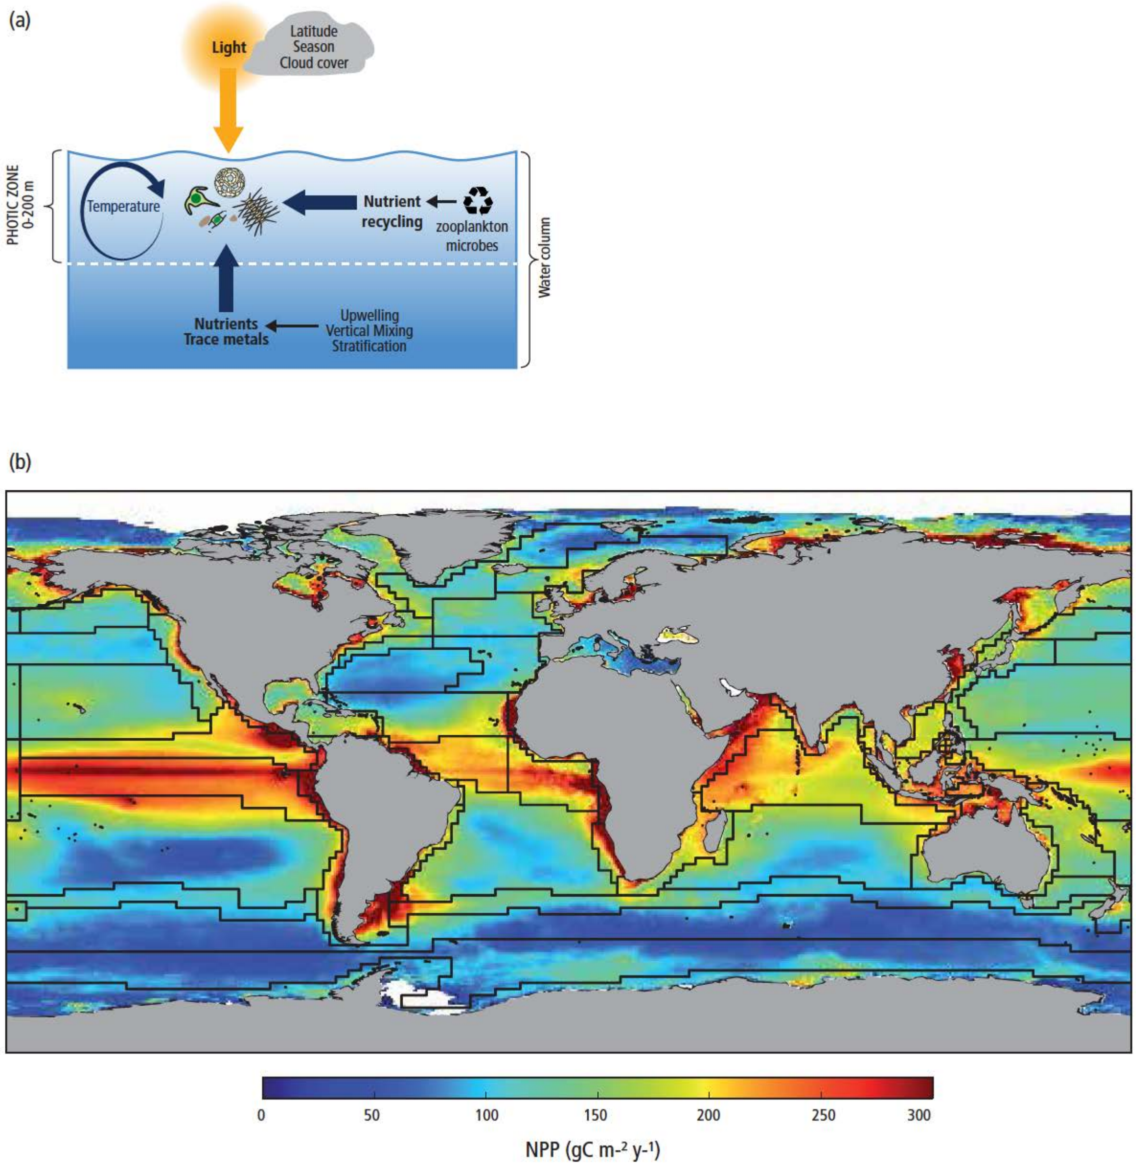

Figure PP-1: A) Environmental factors controlling Net Primary Production (NPP). NPP is mainly controlled by three basic processes: 1) Light conditions in the surface ocean, i.e. the photic zone where photosynthesis occurs, 2) upward flux of nutrients and micronutrients from underlying waters into the photic zone, 3) Regeneration of nutrients and micronutrients via the breakdown and recycling of organic material before it sinks out of the photic zone. All three processes are influenced by physical, chemical and biological processes and vary across regional ecosystems. In addition, water temperature strongly influences the upper rate of photosynthesis for cells that are resource-replete. Predictions of alteration of primary productivity under climate change depend on correct parameterizations and simulations of each of these variables and processes for each region. B) Annual composite map of global areal NPP rates (derived from MODIS Aqua satellite climatology from 2003-2012; NPP was calculated with the Carbon-based Production Model (CbPM, Westberry *et al*., 2008)). Overlaid is a grid of (thin black lines) that represent 51 distinct global ocean biogeographical provinces (after Longhurst, 1998 and based on Boyd and Doney, 2002). The characteristics and boundaries of each province are primarily set by the underlying regional ocean physics and chemistry. Figure courtesy of Toby Westberry (OSU) and Ivan Lima (WHOI), satellite data courtesy of NASA Ocean Biology Processing Group.
[Illustration to be redrawn to conform to IPCC publication specifications.]

A.

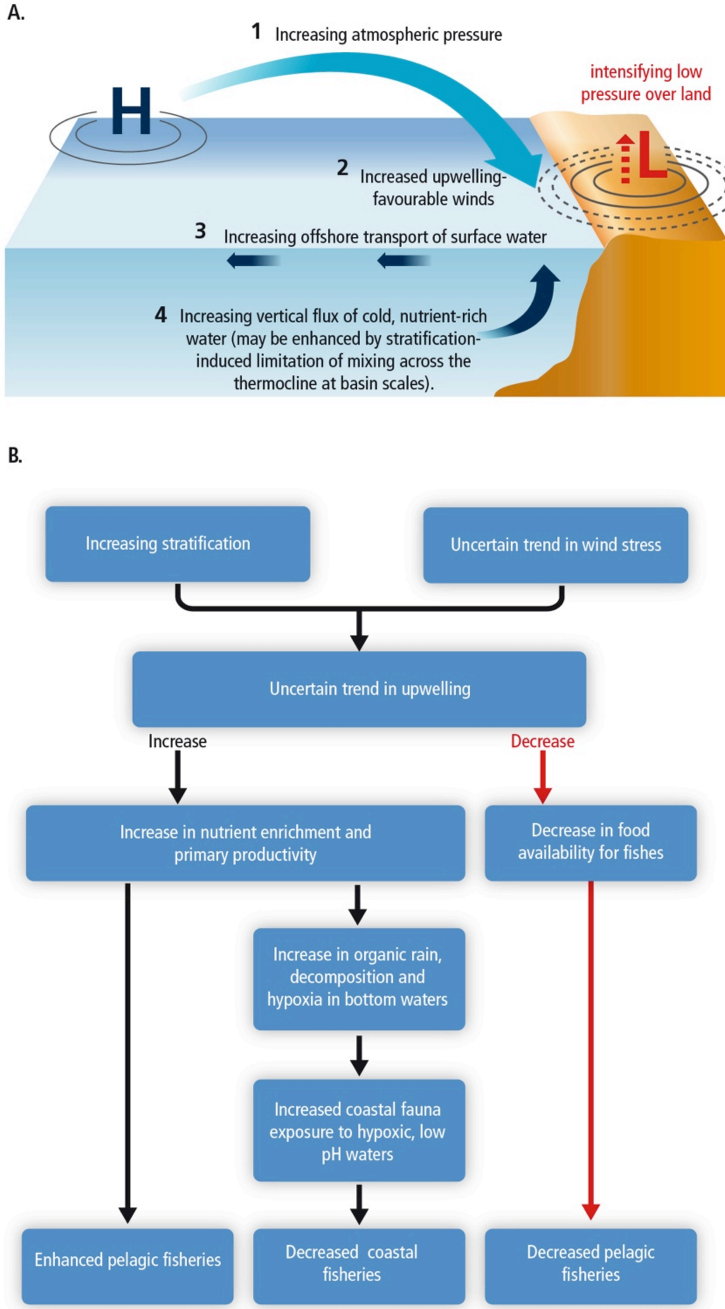

Figure UP-1: Upper panel: Schematic hypothetic mechanism of increasing coastal wind-driven upwelling at eastern boundary systems, where differential warming rates between land and ocean results in increased land-ocean pressure gradients (1) that produce stronger alongshore winds (2) and offshore movement of surface water through Ekman transport (3), and increased upwelling of deep cold nutrient rich waters to replace it (4). Lower panel: potential consequences of climate change in upwelling systems. Increasing stratification and uncertainty in wind stress trends result in uncertain trends in upwelling. Increasing upwelling may result in higher input of nutrients to the euphotic zone, and increased primary production, which in turn may enhance pelagic fisheries, but also decreased coastal fisheries due to an augmented exposure of coastal fauna to hypoxic, low pH waters. Decreased upwelling may result in lower primary production in these systems with direct impacts on pelagic fisheries productivity.

Executive Summary

The effects of climate change on crop and food production are evident in several regions of the world (*high confidence*). Negative impacts of climate trends have been more common than positive ones. [Figures 7-2, 7-7] Positive trends are evident in some high latitude regions (*high confidence*). Since AR4, there have been several periods of rapid food and cereal price increases following climate extremes in key producing regions, indicating a sensitivity of current markets to climate extremes among other factors. [Figure 7-3, Table 18-4] Several of these climate extremes were made more likely as the result of anthropogenic emissions (*medium confidence*). [Table 18-4]

Climate trends are affecting the abundance and distribution of harvested aquatic species, both freshwater and marine, and aquaculture production systems in different parts of the world. [7.2.1.2, 7.3.2.4, 7.4.2] These are expected to continue with negative impacts on nutrition and food security for especially vulnerable people, particularly in some tropical developing countries [7.3.3.2], but with benefits in other regions which become more favourable for aquatic food production (*medium confidence*). [7.5.1.1.3]

Studies have documented a large negative sensitivity of crop yields to extreme daytime temperatures around 30°C. [Chapter 5 AR4, 7.3.2.1.1] These sensitivities have been identified for several crops and regions and exist throughout the growing season (*high confidence*). Several studies report that temperature trends are important for determining both past and future impacts of climate change on crop yields at sub-continental to global scales (*medium confidence*). [7.3.2, Box 7-1] At scales of individual countries or smaller, precipitation projections remain important but uncertain factors for assessing future impacts (*high confidence*). [7.3.2, Box 7-1]

Evidence since AR4 confirms the stimulatory effects of CO_2 in most cases and the damaging effects of elevated tropospheric ozone on crop yields (*high confidence*). Experimental and modelling evidence indicate that interactions between CO_2 and ozone, mean temperature, extremes, water and nitrogen are non-linear and difficult to predict (*medium confidence*). [7.3.2.1.2, Figure 7-2]

Changes in climate and CO_2 concentration will enhance the distribution and increase the competiveness of agronomically important and invasive weeds (*medium confidence*). Rising CO_2 may reduce the effectiveness of some herbicides (*low confidence*). The effects of climate change on disease pressure on food crops is uncertain, with evidence pointing to changed geographical ranges of pests and diseases but less certain changes in disease intensity (*low confidence*). [7.3.2.3]

All aspects of food security are potentially affected by climate change, including food access, utilization, and price stability (*high confidence*). [7.3.3.1, Table 7-1] There remains limited quantitative understanding of how non-production elements of food security will be affected, and of the adaptation possibilities in these domains. Nutritional quality of food and fodder, including protein and micronutrients, is negatively affected by elevated CO_2, but these effects may be counteracted by effects of other aspects of climate change (*medium confidence*). [7.3.2.5] Climate change will increase progressively the inter-annual variability of crop yields in many regions (*medium confidence*). [Figure 7-6]

Without adaptation, local temperature increases in excess of about 1°C above pre-industrial is projected to have negative effects on yields for the major crops (wheat, rice and maize) in both tropical and temperate regions, although individual locations may benefit (*medium confidence*). [7.4, Figures 7-4,7-5,7-7] With or without adaptation, negative impacts on average yields become *likely* from the 2030s [Figure 7-5] with median yield impacts of 0 to -2% per decade projected for the rest of the century [Figure 7-7], and after 2050 the risk of more severe impacts increases (*medium confidence*). [Figure 7-5] These impacts will occur in the context of rising crop demand, which is projected to increase by about 14% per decade until 2050. [Figure 7-7] Regional chapters 22 (Africa), 23 (Europe), 24 (Asia), 27 (Central and South America) and Box 7-1 show crop production to be consistently and negatively affected by climate change in the future in low latitude countries, while climate change may have positive or negative effects in northern latitudes (*high confidence*).

Changes in temperature and precipitation, without considering effects of CO_2 will contribute to increased global food prices by 2050, with estimated increases ranging from 3-84% (*medium confidence*). Projections that include the effects of CO_2 changes, but ignore ozone and pest and disease impacts, indicate that global price increases are about as likely as not, with a range of projected impacts from -30% to +45% by 2050. [7.4.4]

Under scenarios of high levels of warming, leading to local mean temperature increases of 3-4 °C or higher, models based on current agricultural systems suggest large negative impacts on agricultural productivity and substantial risks to global food production and security (*medium confidence*). Such risks will be greatest for tropical countries, given the larger impacts in these regions, which are beyond projected adaptive capacity, and higher poverty rates compared to temperate regions. [7.4.1, Figures 7-4, 7-7]

The average benefit, as yield difference between the adapted and non-adapted cases, of adapting crop management is equivalent to about 15 to 18% of current yields. [Figure 7-8, Table 7-2] This response is, however, extremely variable, ranging from negligible benefit from adaptation and even potential dis-benefit to very substantial (*medium confidence*). [7.5.1.1.1] Projected benefits of adaptation are greater for crops in temperate, rather than tropical regions [7.5.1.1.1, Figures 7-4, 7-7] (*medium confidence*), with some adaptation options more effective than others [Table 7-2] (*medium confidence*) and wheat-based systems more adaptable than other crops [Figure 7-4] (*low confidence*). Positive and negative yield impacts associated with local temperature increases of about 2°C above pre-industrial maintain possibilities for effective adaptation in crop production [Figures 7-4,7-5,7-8]; local warming of about 4°C and higher above pre-industrial is projected to result in differences between crop production and its population-driven demand becoming increasingly large in many regions (*high confidence*), thus posing very significant risks and challenges to food security (*high confidence*). [Figure 7-7, Table 7-3]

Adaptation in fisheries, aquaculture and livestock production will potentially be strengthened by adoption of multi-level adaptive strategies to minimise negative impacts. Key adaptations for fisheries and aquaculture include policy and management to maintain ecosystems in a state that is resilient to change, enabling occupational flexibility and developing early warning systems for extreme events (*medium confidence*). [7.5.1.1.2] Adaptations for livestock systems centre on adjusting management to the available resources, using breeds better adapted to the prevailing climate and removing barriers to adaptation such as improving credit access (*medium confidence).* [7.5.1.1.3]

A range of potential adaptation options exist across all food system activities, not just in food production, but benefits from potential innovations in food processing, packaging, transport, storage and trade are insufficiently researched. [7.1, 7.5, 7.6, Figures 7-1, 7-7, 7-8] More observational evidence is needed on the effectiveness of adaptations at all levels of the food system. [7.6]

7.1. Introduction and Context

Many definitions of food security exist and these have been the subject of much debate. As early as 1992, Maxwell and Smith (1992) reviewed over 180 items discussing concepts and definitions, and more definitions have been formulated since (Defra, 2006). While many earlier definitions centred on food production, more recent definitions highlight access to food, in keeping with the 1996 World Food Summit definition (FAO, 1996) that food security is met when 'all people, at all times, have physical and economic access to sufficient, safe, and nutritious food to meet their dietary needs and food preferences for an active and healthy life'. World-wide attention on food access was given impetus by the food 'price spike' in 2007-08, triggered by a complex set of long- and short-term factors (von Braun and Torero, 2009). FAO's provisional estimates show that, in 2007, 75 million more people were added to the total number of undernourished relative to 2003–2005 (FAO, 2008); other studies report a lower number (Headey and Fan, 2010). More than enough food is currently produced *per capita* to feed the global population, yet about 870 million people remained hungry in 2012 (FAO *et al.*, 2012). The questions for this chapter are how far climate and its change affect current food production systems and food security and the extent that they will do so in the future (Figure 7-1).

7.1.1. Food Systems

A food system is all processes and infrastructure involved in satisfying a population's food security, i.e. the gathering/catching, growing, harvesting (production aspects), storing, processing, packaging, transporting, marketing, consuming food, and disposing of food waste (non-production aspects) It includes food security outcomes of these activities related to availability and utilization of, and access to, food as well as other socioeconomic and environmental factors (Ericksen, 2008; Ericksen *et al.*, 2010; Ingram 2011). This chapter synthesises and evaluates evidence for the impacts of climate on both production and non-production elements and their adaptation to climate change (Figure 7-1).

[INSERT FIGURE 7-1 HERE
Figure 7-1: Main issues of the chapter. Drivers are divided into climate and non-climate elements, affecting production and non-production elements of food systems, thereafter combining to provide food security. The thickness of the red lines is indicative of the relative availability of refereed publications on the two elements.]

The impacts of climate change on food systems are expected to be widespread, complex, geographically and temporally variable, and profoundly influenced by socio-economic conditions (Vermeulen *et al.*, 2012). Changes in food system drivers give rise to changes in food security outcomes, *(medium evidence, high agreement)* but often researchers only consider the impacts on the food production element of food security (Figure 7-1). Efforts to increase food production are nevertheless increasingly important as 60% more food will be needed by 2050 given current food consumption trends and assuming no significant reduction in food waste (FAO *et al.*, 2012).

7.1.2. The Current State of Food Security

Most people on the planet currently have enough food to eat. The vast majority of undernourished people live in developing countries *(medium evidence, medium agreement)*, when estimated based on aggregate national calorie availability and assumptions about food distribution and nutritional requirements. More precise estimates are possible with detailed household surveys, which often show higher incidence of food insecurity than estimated by FAO. Using food energy deficit as the measure of food insecurity, Smith et al. (2006) estimated average rates of food insecurity of 59% for 12 African countries, compared to a 39% estimate from FAO for the same period (Smith et al., 2006). While there is *medium evidence, medium agreement* on absolute numbers, there is *robust evidence, high agreement* that Sub-Saharan Africa has the highest proportion of food insecure people, with an estimated regional average of 26.8% of the population undernourished in 2010-2012, and where rates over 50% can be found (FAO et al., 2012). The largest numbers of food insecure are found in South Asia, which has roughly 300 million undernourished (FAO *et al.*, 2012. In addition to common measures of calorie availability, food security can be broadened to include nutritional aspects based on the diversity of diet including not only staple foods but also vegetables, fruits, meat, milk, eggs, and fortified foods (FAO, 2011). There is *robust evidence* and *high agreement* that lack of essential micronutrients such as zinc and vitamin A affect hundreds of millions of additional (Lopez *et al.*, 2006; Pinstrup-Andersen, 2009).

Food insecurity is closely tied to poverty; globally about 25 to 30 percent of poor people, measured using a $1 to $2 per day standard, live in urban areas (Ravallion *et al.*, 2007; IFAD, 2010). Most poor countries have a larger fraction of people living in rural areas and poverty rates tend to be higher in rural settings (by slight margins in South Asia and Africa, and by large margins in China). In Latin America, poverty is more skewed to urban areas, with roughly two-thirds of the poor in urban areas, a proportion that has been growing in the past decade *(medium evidence, medium agreement)*. Rural areas will continue to have the majority of poor people for at least the next few decades, even as population growth is higher in urban areas *(medium evidence, medium agreement)* (Ravallion *et al.*, 2007; IFAD, 2010).

The effects of price volatility are distinct from the effects of gradual price rises, for two main reasons. First, rapid shifts make it difficult for the poor to adjust their activities to favour producing higher value items. Second, increased volatility leads to greater uncertainty about the future, and can dampen willingness to invest scarce resources into productivity enhancing assets, such as fertilizer purchases in the case of farmers or rural infrastructure in the case of governments. Several factors have been found to contribute to increased price volatility: poorly articulated local markets, increased incidence of adverse weather events and greater reliance on production areas with high exposure to such risks, biofuel mandates, and increased links between energy and agricultural markets (World Bank, 2012). Vulnerability to food price volatility depends on the degree to which households and countries are net food purchasers, the level of integration into global, regional and local markets and their relative degree of volatility, which in turn is conditional upon their respective governance (HLPE, 2011; World Bank, 2012) with *robust evidence* and *medium agreement*.

7.1.3. Summary from AR4

Food systems as integrated drivers, activities and outcomes for food security did not feature strongly in AR4. Summary points from AR4 were that, with *medium confidence*, in mid- to high-latitude regions moderate warming will raise crop and pasture yields. Sight warming will decrease yields in low-latitude regions. Extreme climate and weather events will, with *high confidence*, reduce food production. The benefits of adaptation in crops enable avoidance of a 10-15% reduction in yield, corresponding to 1-2°C local temperature increase. Adaptive capacity is projected to be exceeded in low-latitude areas with temperature increases of more than 3°C. Local extinctions of particular fish species are expected with *high confidence* at the edges of their ranges and have serious negative impacts on fisheries with a *medium confidence* level.

7.2. Observed Impacts, with Detection and Attribution

7.2.1. Food Production Systems

Formal detection of impacts requires that observed changes be compared to a clearly specified baseline that characterizes behaviour in the absence of climate change (Chapter 18). For food production systems, the number and strength of non-climate drivers, such as cultivar improvement or increased use of irrigation and fertilizers in the case of crops, make defining a clear baseline extremely difficult. Most non-climatic factors are not very well characterized in terms of spatial and temporal distributions, and the relationships between these factors and specific outcomes of interest (e.g., crop or fish production) are often difficult to quantify.

Attribution of any observed changes to climate trends are further complicated by the fact that models linking climate and agriculture must, implicitly or explicitly, make assumptions about farmer behaviour. In most cases, models implicitly assume that farming practices or technologies did not adjust in response to climate over the period of interest. This assumption can be defended in some cases based on ancillary data on practices, or based on small differences between using models with and without adaptation (Schlenker and Roberts, 2009). However, in some instances the relationship between climate conditions and crop production has been shown to change over time because of management changes, such as introduction of irrigation or changes in crop varieties Zhang *et al,* 2008; Liu *et al.*,2009; Sakurai *et al.,* 2012).

7.2.1.1. Crop Production

Many studies of cropping systems have estimated impacts of observed climate changes on crop yields over the past half century, although they typically do not attempt to compare observed yields to a counterfactual baseline, and thus are not formal detection and attribution studies. These studies employ both mechanistic and statistical approaches (7.3.1), and estimate impacts by running the models with observed historical climate and then computing trends in modelled outcomes. Based on these studies, there is *medium confidence* that climate trends have negatively affected wheat and maize production for many regions (Figure 7-2) (*medium evidence, high agreement*). Since many of these regional studies are for major producers, and a global study (Lobell et al. 2011) estimated negative impacts on these crops, there is also *medium confidence* for negative impacts on global aggregate production of wheat and maize. Effects on rice and soybean yields have been small in major production regions and globally (Figure 7-2) (*medium evidence, high agreement*). There is also *high confidence* that warming has benefitted crop production in some high-latitude regions, such as Northeast China or the United Kingdom Jaggard *et al.*, 2007, Supit *et al.*, 2010; Chen *et al.,* 2010; Gregory and Marshall, 2012).

[INSERT FIGURE 7-2 HERE
Figure 7-2: Summary of estimates of the impact of recent climate trends on yields for four major crops. Studies were taken from the peer-reviewed literature and used different methods (i.e., physiological process-based crop models or statistical models), spatial scales (stations, provinces, countries, or global), and time periods (median length of 29 years). Some included effects of positive CO_2 trends (7.3.2.1.2) but most did not. (a) shows number of estimates with different level of impact (% yield per decade), (b) shows boxplot of estimates separated by temperate vs. tropical regions, modelling approach (process-based vs. statistical), whether CO_2 effects were included, and crop. Boxplots indicate the median (vertical line), 25th-75th percentiles (box), and 10th-90th percentiles (whiskers) for estimated impacts in each category, and n indicates the number of estimates. Studies were for China (Tao *et al.*, 2006; Tao *et al.,* 2008; Wang *et al.*, 2008; You *et al.,* 2009; Chen *et al.*, 2010; Tao *et al.*, 2012), India (Pathak *et al.*,2003; Auffhammer *et al.,* 2012), United States (Kucharik and Serbin, 2008), Mexico (Lobell *et al.,* 2005), France (Brisson *et al.*, 2010; Licker *et al.*, 2013) Scotland (Gregory and Marshall, 2012), Australia (Ludwig *et al.*, 2009), Russia (Licker *et al.,* 2013), and some studies for multiple countries or global aggregates (Lobell and Field, 2007; Welch *et al.,* 2010; Lobell *et al.,* 2011). Values from all studies were converted to percentage yield change per decade. Each study received equal weighting as insufficient information was available to judge the uncertainties of each estimate.]

More difficult to quantify with models is the impact of very extreme events on cropping systems, since by definition these occur very rarely and models cannot be adequately calibrated and tested. Table 18-4 lists some notable extremes over the past decade, and the impacts on cropping systems. Despite the difficulty of modeling the impacts of these events, they clearly have sizable impacts that are apparent immediately or soon after the event, and therefore not easily confused with effects of more slowly moving factors. For a subset of these events, climate research has evaluated whether anthropogenic activity has increased or decreased their likelihood (Table 18-4).

A sizable fraction of crop modelling studies were concerned with production for individual sites or provinces, spatial scales below which the changes in climate conditions are attributable to anthropogenic activity (AR5 WG1 Chapter 10). Similarly, most crop studies have focused on the past few decades, a time scale shorter than most attribution studies for climate. However, some focused on continental or global scales (Lobell and Field, 2007; You *et al.,* 2009; Lobell *et al.,* 2011), at which trends in several climatic variables, including average summer temperatures, have been attributed to anthropogenic activity. In particular, global temperature trends over the past few decades are attributable to human activity (AR5 WG1 Chapter 10), and the studies discussed above indicate that this warming has had significant impacts on global yield trends of some crops.

In general, little work in food production or food security research has focused on determining whether climate trends affecting agriculture can be attributed to anthropogenic influence on the climate system. However, as the field of climate detection and attribution proceeds to finer spatial and temporal scales, and as agricultural modelling studies expand to broader scales, there should be many opportunities to link climate and crop studies in the next few years. Importantly, climate attribution is increasingly documented not only for measures of average conditions over growing seasons, but also for extremes. For instance, Min *et al.*, (2011) attributed changes in rainfall extremes for 1951-99 to anthropogenic activity, and these are widely acknowledged as important to cropping systems (Rosenzweig *et al.,* 2002). Frost damage is an important constraint on crop growth in many crops, including for various high-value crops, and significant reductions in frost occurrence since 1961 have been observed and attributed to greenhouse gas emissions in nearly every region of the world (Zwiers *et al.,* 2011; IPCC, 2012).

Increased frequency of unusually hot nights since 1961 are also attributable to human activity in most regions (AR5 WG1 Chapter 10). These events are damaging to most crops, an effect that has been observed most commonly for rice yields (Peng *et al.*, 2004; Wassmann *et al.*, 2009; Welch *et al.*,2010) as well as rice quality (Okada *et al.*, 2011). Extremely high daytime temperatures are also damaging and occasionally lethal to crops (Porter and Gawith, 1999; Schlenker and Roberts, 2009), and trends at the global scale in annual maximum daytime temperatures since 1961 have been attributed to greenhouse gas emissions (Zwiers *et al.*, 2011). At regional and local scales, however, trends in daytime maximum are harder to attribute to greenhouse gas emissions because of the prominent role of soil moisture and clouds in driving these trends (Christidis *et al.,* 2005; Zwiers *et al.,* 2011).

In addition to effects of changes in climatic conditions, there are clear effects of changes in atmospheric composition on crops. Increase of atmospheric CO_2 by over 100 ppm since pre-industrial times has *virtually certainly* enhanced water use efficiency and yields, especially for C_3 crops such as wheat and rice, although these benefits played a minor role in driving overall yield trends (Amthor, 2001; McGrath and Lobell, 2011).

Emissions of CO_2 often are accompanied by ozone (O_3) precursors that have driven a rise in tropospheric O_3 that harms crop yields (Morgan *et al.*, 2006; Mills *et al.*, 2007; 7.3.2.1.2). Elevated O_3 since pre-industrial times has *very likely* suppressed global production of major crops compared to what they would have been without O_3 increases, with estimated losses of roughly 10% for wheat and soybean and 3-5% for maize and rice (Van Dingenen *et al.*, 2009). Impacts are most severe over India and China (Van Dingenen *et al.*, 2009, Avnery et al. 2011), but are also evident for soybean and maize in the United States (Fishman *et al.*, 2010).

7.2.1.2. Fisheries Production

The global average consumption of fish and other products from fisheries and aquaculture in 2010 was 18.6 kg per person per year, derived from a total production of 148.5 million tonnes, of which 86% was used for direct human consumption. The total production arose from contributions of 77.4 and 11.2 million tonnes respectively from marine and inland capture fisheries, and 18.1 and 41.7 million tonnes respectively from marine and freshwater aquaculture (FAO, 2012). Fisheries make particular contributions to food security and more than 90% of the people engaged in the sector are employed in small-scale fisheries, many of whom are found in the poorer countries of the world (Cochrane et al., 2011). The detection and attribution of impacts are as confounded in inland and marine fisheries as in terrestrial food production systems. Overfishing, habitat modification, pollution and inter-annual to decadal climate variability can all have impacts that are difficult to separate from those directly attributable to climate change.

One of the best studied areas is the North East Atlantic, where the temperature has increased rapidly in recent decades, associated with a poleward shift in distribution of fish (Perry *et al.*, 2005; Brander, 2007; Cheung *et al.*, 2010). There is *high confidence* in observations of increasing abundance of fish species in the northern extent of their ranges while decreases in abundance have occurred in the southern part (Chapter 30.5.1.1.1.1). These trends will have mixed implications for fisheries and aquaculture with some commercial species negatively and others positively affected (Cook and Heath, 2005). There is a similar well-documented example in the oceans off SE Australia with large warming trends associated with more southward incursion of the Eastern Australian Current, resulting in southward migration of marine species into the oceans around eastern Tasmania (Last *et al.*, 2011); *robust evidence, high agreement*). As a further example, coral reef ecosystems provide food and other resources to more than 500 million people and with an annual value of US$5 billion or more (Hoegh-Guldberg, 2011; Munday et al., 2008). More than 60% of coral reefs are considered to be under immediate threat of damage from a range of local threats, of which overfishing is the most serious (Burke *et al.*, 2011; Box CC-CR. Coral Reefs) and the percentage under threat rises to approximately 75% when the effect of rising ocean temperatures is added to these local impacts (Burke *et al.*, 2011). Wilson *et al.* (2006) demonstrated that declines in coral reef cover typically led to declines in abundance of the majority of fish species associated with coral reefs. There is *high confidence* that the availability of fish and invertebrate species associated with coral reefs that are important in many tropical coastal fisheries is *very likely* to be reduced (Chapter 30.6.2.1.2). Other examples around the world are described in Chapter 30.5.1.1.1.

These changes are impacting marine fisheries: a recent study that examined the composition of global fisheries catches according to the inferred temperature preferences of the species caught in fisheries found that there had been changes in the species composition of marine capture fisheries catches and that these were significantly related to changes in ocean temperatures (Cheung et al. 2013; Chapter 6.4.1.1). These authors noted that the relative contribution to catches by warmer water species had increased at higher latitudes while the contributions of subtropical species had decreased in the tropics. These changes have negative implications for coastal fisheries in tropical developing countries which tend to be particularly vulnerable to climate change (Cheung et al. 2013; Chapter 6.4.3; 7.5.1.1.3).

There is considerably less information available on climate change impacts on fisheries and fishery resources in freshwater systems and aquaculture. Considerable attention has been given to the impacts of climate change in some African lakes but with mixed interpretations (Chapter 22.3.3.1.4.). There is evidence that increasing temperature has reduced the primary productivity of Lake Tanganyika in East Africa and a study by O'Reilly et al. (2003) estimated that this would have led to a decrease of approximately 30% in fish yields. However, Sarvala et al. (2006) disagreed and concluded that observed decreases in the fish catches could be explained by changed fishery practices. There has been a similar difference of opinion for Lake Kariba where Ndebele-Murisa et al., (2011) argued that a reduction in fisheries productivity had been caused by climate change while Marshall (2012) argued that the declines in fish catches can only have been caused by fishing. There is *medium confidence* that in India, changes in a number of climate variables including an increase in air temperature, regional monsoon variation and a regional increase in incidence of severe storms have led to changes in species composition in the River Ganga and to have reduced the availability of fish spawn for aquaculture in the river Ganga while having positive impacts on aquaculture on the plains through bringing forward and extending the breeding period of the majors carps (Vass et al. 2009).

7.2.1.3. Livestock Production

In comparison to crop and fish production, considerably less work has been published on observed impacts for other food production systems, such as livestock or aquaculture, and to our knowledge nothing has been published for hunting or collection of wild foods other than for capture fisheries. The relative lack of evidence reflects a lack of study in this topic, but not necessarily a lack of real-world impacts of observed climate trends. A study of blue-tongue virus, an important ruminant disease, evaluated the effects of past and future climate trends on transmission risk, and concluded that climate changes have facilitated the recent and rapid spread of the virus into Europe (Guis *et al.*, 2012). Ticks that carry zoonotic diseases have also *likely* changed distribution as a consequence of past climate trends (Chapter 23.4.2).

7.2.2. Food Security and Food Prices

Food production is an important aspect of food security (7.1), and the evidence that climate change has affected food production implies some effect on food security. Yet quantifying this effect is an extremely difficult task, requiring assumptions about the many non-climate factors that interact with climate to determine food security. There is thus limited direct evidence that unambiguously links climate change to impacts on food security.

One important aspect of food security is the prices of internationally traded food commodities (7.1.3). These prices reflect the overall balance of supply and demand, and the accessability of food for consumers integrated with regional to global markets. Although food prices gradually declined for most of the 20th century (FAO, 2009) since AR4 there have been several periods of rapid increases in international food prices (Figure 7-3). A major factor in recent price changes has been increased crop demand, notably via increased use in biofuel production related both to energy policy mandates and oil price fluctuations (Roberts and Schlenker, 2010; Wright, 2011; Mueller *et al.*, 2011; Abbott *et al.*, 2011). Yet fluctuations and trends in food production are also widely believed to have played a role in recent price changes, with recent price spikes often following climate extremes in major producers (Figure 7-3). Moreover, some of these extreme events have become more likely as a result of climate trends (Table 18-4). Domestic policy reactions can also amplify international price responses to weather events, as was the case with export bans announced by several countries since 2007 (FAO, 2008). In a study of global production responses to climate trends (Lobell, Schlenker, Costas-Roberts, 2011) estimated a price increase of 19% due to the impacts of temperature and precipitation trends on supply, or an increase of 6% once the beneficial yield effects of increased CO_2 over the study period were considered. Since the price models were developed for a period ending in 2003, these estimates do not account for the policy responses witnessed in recent years which have amplified the price responses to weather.

[INSERT FIGURE 7-3 HERE
Figure 7-3: Since the AR4 report, international food prices have reversed historical downward trend. Plot shows history of FAO food and cereal price index (composite measures of food prices), with vertical lines indicating events when a top 5 producer of a crop had yields 25% below trend line (indicative of a seasonal climate extreme). Australia is included despite not being a top five producer, because it is an important exporter and the drops were 40% or more below trend line. Prices may have become more sensitive to weather-related supply shortfalls in recent years. At the same time, food prices are increasingly associated with the price of crude oil (blue line), making attribution of price changes to climate difficult. Thus, there is clear evidence since AR4 that prices can rise rapidly, but the role of weather in these increases remains unclear. All indices are expressed as percentage of 2002-2004 averages. Food price and crop yield data from FAO (http://www.fao.org/worldfoodsituation/foodpricesindex and http://faostat.fao.org/) and oil price data from http://www.eia.gov.]

7.3. Assessing Impacts, Vulnerabilities, and Risks

7.3.1. Methods and Associated Uncertainties

7.3.1.1. Assessing Impacts

Methods developed or extended since AR4 have resulted in more robust statements on climate impacts, both in the literature and in 7.3.2. Two particular areas, which are explored below, are improved quantification and presentation of uncertainty; and greater use of historical empirical evidence of the relationship between climate and food production.

The methods used for field and controlled environment experiments remain similar to those at the time of AR4. There has been a greater use of remote sensing and geographic information systems for assessing temporal and spatial changes in land use particularly in agricultural land use for assessment of food security status (Goswami et al., 2012; Fishman et al., 2010; Thenkabail, 2009). There has also been an increase in the number of Free Air

Concentration Enrichment (FACE) studies that examine ozone instead of, or in addition to, CO_2. In agriculture, FACE experiments have been used for assessing impacts of atmospheric CO_2 on grain yield, quality characteristics of important crops (Erbs et al., 2010), elemental composition (Fernando et al., 2012) and diseases (Eastburn et al., 2011; Chakraborty et al., 2011). A number of meta-analyses of experimental studies, in particular FACE studies have been made since AR4. However, debate continues on the disparities between results from FACE experiments and non-FACE experiments, such as in open-top chambers or greenhouses. As reported in AR4, FACE studies tend to show lower elevated CO_2 responses than non-FACE studies. Although some authors have claimed that the results of the two are statistically indistinct, others have argued that the results are only similar when the FACE experiments are grown under considerably more water stress than non-FACE experiments (Kimball, 2010; Ainsworth et al., 2008). Hence comparisons between different methodologies must take care to control for differences in water availability and microclimate. Another reason for differences between experiments may be differences in the temporal variance of CO_2 – i.e. whether concentrations are fluctuating or constant (Bunce, 2012). Unfortunately, the FACE experiments are carried out mostly in the USA and in China, thus limited to specific environmental conditions, which do not fully reflect tropical or sub-tropical conditions, where CO_2 and soil nutrient interactions could lead to large differences in photosynthesis rate, water use and yield. Also, the number of FACE studies are still quite low, which limits statistical power when evaluating the average yield effects of elevated CO_2 or interactions with temperature and moisture (7.3.2).

Numerical simulation models can be used to investigate a larger number of possible environmental and management conditions than physical experiments. This, in turn, enables a broader range of statements regarding the possible response of food production systems to climate variability and change. Previous assessment reports have documented new knowledge resulting from numerical simulation of the response of food production to climate change. AR4 noted the increasing number of regional studies, which is a trend that has continued to date (Zhu et al., 2013; Craufurd et al., 2013). Since AR4, crop models have been used to examine a large number of management and environmental conditions, such as interactions among various components of food production systems (Lenz-Wiedemann et al., 2010), determination of optimum crop management practices (Soltani and Hoogenboom, 2007), vulnerability and adaptability assessments (Sultana et al., 2009), evaluation of water consumption and water use efficiency (Mo et al., 2009; Kang et al., 2009) and fostering communication between scientists, managers, policymakers and planners.

The trend towards quantification of uncertainty in both climate and its impacts has continued since AR4. Novel developments include methodologies to assess the impact of climate model error on projected agricultural output, particularly for crops (Ramirez-Villegas et al., 2013, Watson and Challinor, 2013). Models that integrate crop growth models as part of broader land surface and earth systems models (Bondeau et al., 2007; Osborne et al., 2007) are also increasingly common. Ensemble techniques for climate impacts, which were in their infancy at AR4, now include the use of Bayesian methods to constrain crop model parameters (Iizumi et al., 2009; Tao et al., 2009a). It is also increasingly common to assess both bio-physical and socio-economic drivers of crop productivity within the same study (Fraser et al., 2008; Reidsma et al., 2009; Tao et al., 2009b; Challinor et al., 2010). Finally, an important recent development is the systematic comparison of results from different modelling and experimental approaches for providing insights into model uncertainties as well as to develop risk management (Challinor and Wheeler, 2008; Kang et al., 2009; Schlenker and Lobell, 2010; Rosenzweig et al., 2013).

Increased quantification of uncertainty can lead to clear statements regarding climate impacts. Studies with different methods have been shown to produce convergent results for some crops and locations (Challinor et al., 2009; *medium evidence, medium agreement*). The methods used to describe uncertainty have also improved since AR4. The projected range of global and local temperature changes can be described by quantifying uncertainty in the temporal dimension, rather than that in temperature itself (Joshi et al., 2011), and a similar approach can be used for crop yield (Figure 7-5). Descriptions of uncertainty that present key processes and trade-offs, rather than ranges of outcome variables, have also proved to be useful tools for understanding future impacts (Thornton et al., 2009; Hawkins et al., 2012; Ruane et al., 2013). Section 7.3.2 reviews the results of such studies.
A considerable body of work since AR4 has used extensive datasets of country- regional- and farm- level crop yield together with observed and/or simulated weather time series in order to assess the sensitivity of food production to weather and climate. These statistical models offer a complement to more process-based model approaches, some of which require many assumptions about soil and management practices. Process-based models, which extrapolate

based on measured interactions and mechanisms, can be used to develop a causal understanding of the empirically determined relationships in statistical models (cf Shlenker and Roberts, 2010; Lobell et al., 2013b). Although statistical models forfeit some of the process knowledge embedded in other approaches, they can often reproduce the behaviour of other models (Iglesias et al., 2000; Lobell and Burke, 2010) and can leverage within one study a growing availability of crop and weather data (Welch et al., 2010; Lobell et al., 2011). However, statistical models usually exclude the direct impact of elevated CO_2, making multi-decadal prediction problematic. In determining future trends, crop models of all types can only extrapolate based on historically-determined relationships. Agro-climatic indices provide an alternative to crop models that avoid various assumptions by developing metrics, rather than providing yield predictions *per se* (Trnka et al., 2011). However, correlations between climate, or associated indices, and yield are not always statistically significant.

The robustness of crop model results depends on data quality, model skill prediction and model complexity (Bellocchi et al., 2010). Modelling and experiments are each subject to their own uncertainties. Measurement uncertainty is a feature of field and controlled environment experiments. For example, interactions between CO_2 fertilisation, temperature, soil nutrients, ozone, pests and weeds is not well understood (Soussana *et al.*, 2010) and therefore most crop models do not include all these effects, nor broader issues of water availability, such as competition for water between industry and households (Piao et al., 2010). There are also uncertainties associated with generalizing the results of field experiments, since each one has been conducted relatively few times under a relatively small range of environmental and management conditions, and for a limited number of genotypes. This limits breadth of applicability both through limited sample size and limited representation of the diversity of genotypic responses to environment (Craufurd et al., 2013). For example, yield increases normalised by increase in CO_2 have been found to vary between zero and over 30% among crop varieties (Tausz et al., 2011).

The uncertainty in climate simulation is generally larger than, or sometimes comparable to, the uncertainty in crop simulation using a single model (Iizumi et al., 2011), but can be less than crop model uncertainty when multiple crop models are used (Koehler et al, 2013). There is significant uncertainty in agricultural simulation arising from climate model error. Since AR4 the choice of method for GCM bias correction has been identified as a significant source of uncertainty (Hawkins et al., 2012). There is also a contribution to uncertainty in crop model output from yield measurement error, through the calibration procedure. Yield measurements rarely have associated error bars to give an indication of accuracy. Greater access to accurate regional-scale crop yield data can lead to decreased uncertainty in projected yields (Watson and Challinor, 2013)

The use of multiple crop models in impacts studies is relatively rare. Field-scale historical model intercomparisons have shown variations in yield and biomass of more than 100% (Palosuo et al., 2011). Early results from impacts studies with multiple crop models suggest that the crop model uncertainty can be larger than that caused by GCMs, due in particular to high temperature and temperature-by-CO_2 interactions (Asseng et al., 2013). However, in contrast to absolute values, yield changes can be consistent across crop models (Oleson et al 2007). Given these different strengths and weaknesses, and associated dependencies, it is critical that both experimental and modelling lines of evidence, and their uncertainties, are examined carefully when drawing conclusions regarding impacts, vulnerabilities and risks. This approach to assessment is applied to each of the topics described in the rest of the chapter.

The methods used for assessing impacts, vulnerabilities and risks in fisheries and aquaculture face the constraint that meaningful controlled experiments are usually not practical for fisheries in large rivers, lakes and marine environments because of the typical open and connected nature of these ecosystems. Experimentation has been used to examine responses to impacts at the scale of individual species, for example, to demonstrate the impacts of high atmospheric carbon dioxide in reducing coral calcification and growth (Hoegh-Guldberg et al. 2007) and to study the temperature tolerances of different cultured species (Ficke et al., 2007; De Silva and Soto, 2009). The far more common approach, however, is the empirical analysis of data collected in the field. This has been used to examine the effect of climate related factors on recruitment to a population, growth and population production of specific species, for example (Brander, 2010; Chapters 6 and 30). Different modelling approaches have also been used to integrate available information and assess the impacts of climate change on ecosystems and fish production at scales from national to global (Cheung et al., 2010; Fulton, 2011; Merino et al. 2012 et al.; Chapter 6.5). Efforts to assess the vulnerability of those dependent on fisheries and aquaculture have increased in recent years and range from studies that use available information on exposure, sensitivity and adaptive capacity to provide an index of vulnerability (Allison et al., 2009; Cinner at al., 2011) to more detailed social and economic studies focused on particular communities or localities (Daw et al. 2009).

7.3.1.2. Treatment of Adaptation in Impacts Studies

Adaptation occurs on a range of timescales and by a range of actors. Incremental adaptation, such as a change in crop management, can occur relatively autonomously within farming systems. It is the type of adaptation most commonly assessed in the impacts literature, and it is the only form of adaptation discussed in sections 7.3 and 7.4. Systemic and transformational adaptations are discussed in section 7.5. Methods exist to examine impacts and adaptation together in the context of non-climatic drivers (Mandryk et al., 2012), but conclusions are difficult to generalise.

7.3.2. Sensitivity of Food Production to Weather and Climate

7.3.2.1. Cereals and Oilseeds

7.3.2.1.1. Mean and extremes of temperature and precipitation

Both statistical and process-based models have widely been used since AR4 to assess the response of crop yield to temperature. Model results confirm the importance of known key physiological processes, such as the shortening of the time to maturity of a crop with increasing mean temperature (Iqbal et al., 2009), decline in grain set when high temperatures occur during flowering (Moriondo et al., 2011), and increased water stress at high temperatures throughout the growing cycle (Lobell et al., 2013b). Temperature responses are generally well-understood for temperatures up to the optimum temperature for crop development. The impacts of prolonged periods of temperatures beyond the optimum for development are not as well understood (Craufurd and Wheeler, 2009). For example, temperatures above 34 °C after flowering appear to rapidly speed senescence in wheat (Lobell et al., 2012; Asseng et al., 2011), but many crop models do not represent this process. Crop models can be used to quantify abiotic stresses such as these, although only by hypothesizing that the functional responses to weather derived from experiments are valid at regional scales. Thus, whilst many fundamental bio-physical processes are understood at the plant or field scale, it remains difficult to quantify the extent to which these mechanisms are responsible for the observed regional-scale relationships between crop yield and weather. Despite these particular areas where specific understanding is lacking, the evidence from regional-scale statistical analyses (Schlenker and Roberts, 2009) and process-based models shows clear negative impacts of temperatures above 30-34°C on crop yields (depending on the crop and region) (*high evidence, high agreement*).

The overall relationship between weather and yields is often crop and region specific, depending on differences in baseline climate, management and soil, and the duration and timing of crop exposure to various conditions. For example, rice yields in China have been found to be positively correlated with temperature in some regions and negatively correlated in others (Zhang et al., 2010). The trade-offs that occur in determining yield are therefore region-specific. This difference may be due to positive correlation between temperature and solar radiation in the former case, and negative correlation between temperature and water stress in the latter case. Similarly, although studies consistently show spikelet sterility in rice for daytime temperatures exceeding 33°C (Jadadish et al., 2007; Wassmann et al., 2009), some statistical studies find a positive effect of daytime warming on yields because these extremes are not reached frequently enough to affect yields (Welch et al., 2010). Responses to temperature may vary according whether yields are limited by low or high temperatures. However, there is evidence that high temperatures will limit future yields even in cool environments (Semenov et al., 2012; Teixeira et al., 2013).

The relative importance of temperature and water stress for crop productivity can be assessed using models, and can vary according to the criteria used for assessment (Challinor et al., 2010). There are also some cases where the sign of a correlation depends on the direction of the change. For example, Thornton et al. (2009) found that the response of crop yields to climate change in the drylands of East Africa is insensitive to increases in rainfall, since wetter climates are associated with warmer temperatures that act to reduce yields. Since precipitation exhibits more spatial variability than temperature, temporal variations in the spatial average of precipitation tend to diminish as the spatial domain widens. As a result, precipitation becomes less important as a predictor of crop yields at broad scales (Lobell and Field, 2007; Li et al., 2010). Similarly, projected changes in precipitation from climate models tend to be more spatially variable than temperature, leading to the greater importance of projected temperatures as the spatial scale of analysis grows wider (Lobell and Burke, 2008). There is also evidence that where irrigation increases over time the influence of temperature on yields starts to dominate over that of precipitation (Hawkins et al., 2012). The impact of drought on crop yield is a more common topic of research than the impact of floods.

Analysis of 66 yield impact studies for major cereals, including both pre- and post- AR4 contributions, gives broadly similar results to AR4 (Figure 7-4). Figure 7-4 shows that yields of maize and wheat begin to decline with 1-2^{o}C of local warming in the tropics. Temperate maize and tropical rice yields are less clearly affected at these temperatures, but significantly affected with warming of 3-5^{o}C. These data confirm AR4 findings that even slight warming will decrease yields in low-latitude regions (*medium evidence, high agreement*). However, whilst AR4 had few indications of yield reductions at less than 2^{o}C of local warming, the new analysis has, in the absence of incremental adaptation, more yield decreases than increases at all temperatures. Hence, whilst AR4 concluded with *medium confidence* that in mid- to high-latitude regions moderate warming will raise crop yields, new knowledge suggests that temperate wheat yield decreases are *about as likely as not* for moderate warming. A recent global crop model intercomparison for rice, wheat and maize shows similar results to those presented here, although with less impacts on temperate rice yields (Rosenzweig et al, 2013). That study also showed that crop models without explicit nitrogen stress fail to capture the expected response. Quantitative assessments of yield changes can be found in section 7.4. Across the globe, regional variability, which has not been summarised in meta-analyses except in contributing to the spread of data (Figure 7-4), will be important in determining how climate change affects particular agricultural systems.

[INSERT FIGURE 7-4 HERE
Figure 7-4: Percentage simulated yield change as a function of local temperature change temperature for the three major crops and for temperate and tropical regions. Dots indicate where a known change in atmospheric CO_2 was used in the study; remaining data are indicated by x. Note that differences in yield value between these symbols do not measure the CO_2 fertilisation effect, since changes in other factors such as precipitation may be different between studies. Non-parameteric regressions (LOESS, span=1 and degree=1) of subsets of these data were made 500 times. These bootstrap samples are indicated by shaded bands at the 95% confidence interval. Regressions are separated according to the presence (blue) or absence (red) of simple agronomic adaptation (Table 7-2). In the case of tropical maize the central regression for absence of adaptation is slightly higher than that with adaptation. This is due to asymmetry in the data – not all studies compare adaptated and non-adapted crops. Figure 7-8 presents a pair-wise adaptation comparison. Note that four of the 1048 datapoints across all six panels are outside the yield change range shown. These were omitted for clarity. Some of the studies have associated temporal baselines, with centre-points typically between 1970 and 2005. Note that local warming in cropping regions generally exceeds global mean warming (Figure 21-3). Data are taken from a review of literature: Abou-Hadid (2006); Abraha & Savage (2006); Aggarwal & Mall (2002); Alexandrov (1999); Alexandrov & Hoogenboom (2000); Alexandrov et al. (2002); Arndt et al. (2011); Brassard & Singh 2008); Brassard & Singh (2007); Butt et al. (2005); Byjesh et al. (2010); Chhetri et al. (2010); Chipanshi et al. (2003); Corobov (2002); Izaurralde et al. (2001); DeJong et al. (2001); Deryng et al. (2011); Droogers (2004); Easterling et al. (2003); El Maayar et al. (2009); El-Shaher et al. (1997); Ewert et al. (2005); Gbetibouo & Hassan (2005); Howden & Jones (2004); Iqbal et al. (2011); Izaurralde et al (2005); Jones & Thornton (2003); Kaiser (1999); Kapetanaki & Rosenweig (1997); Karim et al. (1996); Krishnan et al. (2007); Lal (2011); Lal et al. (1998); Li et al. (2011); Erda et al. (2005); Liu et al. (2010); Lobell & Ortiz-Monasterio (2007); Luo et al. (2003); Matthews & Wasmann (2003); Moya et al. (1998); Osborne et al. (2013); Piao et al. (2010); Porter & Semenov (2005); Reyenga et al. (1999); Rosenzweig et al. (1994); Rowhani et al. (2011); Sands & Edmond (2005); Schlenker & Roberts (2009); Shuang-He et al. (2011); Southworth et al. (2000); Tan et al. (2010); Tao & Zhang (2010); Tao & Zhang (2011); Tubiello et al. (2000); Thomson et al. (2005); Thornton et al. (2009); Thornton et al. (2011); Thornton et al. (2010); Tingem & Rivington (2009); Tingem et al. (2008); Walker & Schulze (2008); Winters et al. (1998); Xiao et al. (2005); Xiong et al. (2007); Yates & Strzepek (1998); Zhang & Liu (2005); Zhao et al. (2005).]

7.3.2.1.2. Impact of carbon dioxide and ozone

There is further observational evidence since AR4 that response to a change in CO_2 depends on plant type; C_3 or C_4 (DaMatta et al., 2010). The effect of increase in CO_2 concentration tends to be higher in C_3 plants (wheat, rice, cotton, soybean, sugar beets, and potatoes) than in C_4 plants (corn, sorghum, sugarcane), because photosynthesis rates in C_4 crops are less responsive to increases in ambient CO_2 (Leakey, 2009). The highest fertilization responses have been observed in tuber crops, which have large capacity to store extra carbohydrates in belowground organs (Fleisher et al., 2008; Högy and Fangmeier, 2009). There is observational evidence, new since AR4, that the response of crops to CO_2 is genotype-specific (Ziska et al. 2012). For example, yield enhancment at 200 ppm additional CO_2 ranged from 3 to 36 % among rice cultivars (Hasegawa et al., 2013).

FACE studies have shown that the impact of elevated CO_2 varies according to temperature and availability of water and nutrients, although the strong geographical bias of FACE studies towards temperate zones limits the strength of this evidence. FACE studies have shown that CO_2 enhancment is limited under both low (Shimono et al., 2008) (Hasegawa et al., 2013) and high temperature. Theory suggests that water-stressed crops will respond more strongly to elevated CO_2 than well-watered crops, because of CO_2 induced increases in stomatal resistance. This suggests that rain-fed cropping systems will benefit more from elevated CO_2 than irrigated systems. Thus both TAR and AR4 cited the expectation that rain-fed systems benefit more from elevated CO_2 than systems under wetter conditions. New evidence based on historical observations supports this notion by demonstrating that the rate of yield gains in rain-fed systems is higher in dry years than in wet years (McGrath and Lobell, 2011). However, this response is not seen consistently across models and FACE meta-analyses and there is some suggestion that the relationship between water stress and assimilation may vary with spatial scale, with canopy analyses showing a reversal of the expected leaf-level dry *vs* wet signal (Challinor and Wheeler, 2008).

Ozone in the stratosphere provides protection from lethal short-wave solar ultraviolet radiation, but in the troposphere it is a phytotoxic air pollutant. The global background concentration of ozone has increased since pre-industrial era due to anthropogenic emission of its precursors (carbon monoxide, volatile organic compounds and oxides of nitrogen), by vehicles, power plants, biomass burning and other sources of combustion. Like CO_2, O_3 is taken up by green leaves through stomata during photosynthesis but unlike CO_2, its concentration is significantly variable depending on geographic location, elevation and extent of anthropogenic sources. Being a powerful oxidant, ozone and its secondary by-products damage vegetation by reducing photosynthesis and other important physiological functions (Mills et al., 2009; Ainsworth and McGrath, 2010). This results in stunted crop plants, inferior crop quality and decreased yields (Booker et al., 2009; Fuhrer, 2009; Vandermeiren et al., 2009; Pleijel and Uddling, 2012) and posing a growing threat to global food security (*robust evidence, high agreement*).

The literature published since AR4 further corroborates the negative impacts of increasing concentrations of surface ozone on yield at global (Van Dingenen et al., 2009; Teixeira et al., 2011; Avnery et al., 2011a; Avnery et al., 2011b) and regional scales (Northern Hemisphere: Hollaway et al, (2011); USA: (Emberson et al., 2009; Fuhrer, 2009; Fishman et al., 2010); India (Roy et al., 2009; Rai et al., 2010; Sarkar and Agrawal, 2010); China: (Wang et al., 2007; Piao et al., 2010); Bangladesh: (Akhtar et al., 2010); Europe: (Hayes et al., 2007; Vandermeiren *et al.*, 2009; Fuhrer, 2009). Global estimates of yield losses due to increased ozone in soybean, wheat and maize in 2000 ranged from 8.5-14%, 3.9-15% and 2.2-5.5% respectively, amounting to economic losses of $11-18 billion (Avnery et al., 2011a). Ozone may have direct effect on reproductive process, leading to reduced seed and fruit development and abortion of developing fruit (Royal Society, 2008; *robust evidence, high agreement*).

The interactive effects of ozone with other environmental factors such as CO_2, temperature, moisture and light, are important but not well understood. Generally, the ambient and increasing concentrations of O_3 and CO_2 individually exert counteractive effects on C_3 plants (Tianhong et al., 2005; Ainsworth, 2008; Gillespie et al., 2012); but their interactive effect may compensate for each other (Ainsworth, 2008; Taub et al., 2008; Gillespie et al., 2012). However, the losses might be greater when elevated O_3 combines with high temperature (Long, 2012) particularly during grain filling of wheat, when elevated ozone causes premature leaf senescence (Feng et al., 2008; Feng et al., 2011). Periods of abundant radiation and adequate water supply are favourable for both agricultural production and the formation of surface ozone; thus the effects of ozone on crops, can be difficult to detect (Long, 2012).

7.3.2.2. Other Crops

Earlier flowering and maturity have been observed *(robust evidence, high agreement*) worldwide in grapes (García-Mozo et al., 2010; Duchêne et al., 2010; Jorquera-Fontena and Orrego-Verdugo, 2010; Sadras and Petrie, 2011; Webb et al., 2011), apples (Fujisawa and Koyabashi, 2010; Grab and Craparo, 2011) and other perennial horticultural crops (Glenn et al., 2013). Cassava (also known as manioc) is an important source of food for many people in Africa and Latin America and recent studies suggest (*medium evidence, medium agreement*) that future climate should benefit its productivity as this crop is characterized by elevated optimum temperature for photosynthesis and growth, and a positive response to CO_2 increases (Jarvis *et al.*, 2012; Rosenthal and Ort, 2012; El-Sharkawy, 2012).

7.3.2.3. Pests, Weeds, Diseases

As a world-wide average, yield loss in major crop species due to animal pests and (non-virus) pathogens, in the absence of any physical, biological or chemical crop protection, has been estimated at 18% and 16%, respectively (Oerke, 2006). Climate change will alter potential losses to many pests and diseases. Changes in temperature can result in geographic shifts through changes in seasonal extremes, and thus, for example, overwintering and summer survival. CO_2 and ozone can either increase or decrease plant disease, and can exhibit important interactions (Chakraborty and Newton, 2011; Garrett et al., 2011), suggesting the need for system-specific risk assessment (Chakraborty et al., 2008; Eastburn et al., 2011). Interactions with landscape effects may be particularly important in forests and grasslands (Pautasso et al., 2010).

The rarity of long-term studies of plant diseases and pests is a problem for the evaluation of climate change effects, but there are some examples of the potential for such analyses. On-going wheat experiments at Rothamsted Research Station UK, maintained for over 160 years, have revealed shifts in foliar wheat pathogens linked to rainfall, temperature, and SO_2 emissions (Bearchell et al., 2005; Shaw et al., 2008). Wheat rust risk has been observed to respond to ENSO (Scherm and Yang, 1995). Over almost seven decades, earlier and more frequent epidemics of potato late blight, and more frequent pesticide use, were observed in Finland, associated with changing climate conditions and lack of crop rotation (Hannukkala et al., 2007).

Changes in climate are expected to affect the geographic range of specific species of insects and diseases for a given crop growing region. For example, Cannon (1998) has suggested that migratory insects could colonize crops over a larger range in response to temperature increases, with subsequent reductions in yield. Climate change may also be a factor in extending the northward migration of agronomic and invasive weeds in North America (Ziska et al., 2011). Weed species also possess characteristics that are associated with long-distance seed dispersal, and it has been suggested (Hellman et al. 2008) that they may migrate rapidly with increasing surface temperatures. Predator and insect herbivores respond differently to increasing temperature, leading to possible reductions in insect predation and thus greater insect numbers. However, ecosystems are complex and insect and disease occurrence can go down as well as up. Overall, our ability to predict CO_2/climate change impacts on pathogen biology and subsequent changes on yield is limited because, with few exceptions (Savary et al., 2011), experimental data are not available and analyses focus on individual diseases rather than the complete set of important diseases (*medium evidence, medium agreement*).

Elevated CO_2 can reduce yield losses due to weeds for C_3 crops (soybean, wheat and rice), since many agricultural weeds are C_4 species; and the C_3 pathway, in general, shows a stronger response to rising carbon dioxide levels. However, both C_3 and C_4 weed species occur in agriculture, and there is a wide range of responses among these species to recent and projected CO_2 levels (Ziska 2010). For example, in the United States, every crop, on average, competes with an assemblage of 8-10 weed species (Bridges, 1992). CO_2 and climate can also affect weed demographics. For example, with field grown soybean, elevated CO_2 *per se* appeared to be a factor in increasing the relative proportion of C_3 to C_4 weedy species with subsequent reductions in soybean yields (Ziska and Goins, 2006). For rice and barnyard grass (C_4), increasing CO_2 favoured rice, but if both temperature and CO_2 increased simultaneously, the C_4 weed was favoured, primarily because higher temperatures resulted in increased seed yield loss for rice. For weeds that share physiological, morphological, or phenological traits with the crop, including those weeds that are wild relatives of the domesticated crop species, (often among the "worst" weeds in agronomic situations, e.g. rice and red rice) the decrease in seed yield from weeds may, be greater under elevated CO_2 (Ziska, 2010).

With respect to control, a number of studies have, to date, indicated a decline in herbicide efficacy in response to elevated CO_2 and/or temperature for some weed species, both C_3 and C_4 (Archambault, 2007; Manea et al., 2011). Some of the mechanisms for this are understood, for example for the invasive plant species Canada thistle (Cirsium arvense), elevated CO_2 results in a greater root biomass, thus diluting the active ingredient of the herbicide used and reducing chemical control (Ziska 2010). To date, studies on physical, cultural or biological weed control are lacking.

7.3.2.4. Fisheries and Aquaculture

The natural and human processes in fisheries and aquaculture differ from mainstream agriculture and are characterized by distinct impacts and interactions related to climate change. Capture fisheries in particular, comprising the largest remaining example of harvesting natural, wild resources, are strongly influenced by global ecosystem processes. The social, economic and nutritional requirements of the growing human population are already driving heavy exploitation of capture fisheries and rapid development of aquaculture (Chapter 6.4.1.1). This trend will continue over the next 20 to 30 years at least: (Merino et al., 2012) forecast that in addition to a predicted small increase in marine fisheries production, between 71 and 117 million tonnes (MT) of fish will need to be produced by aquaculture to maintain current average *per capita* consumption of fish. The impacts of climate change add to and compound these threats to the sustainability of capture fisheries and aquaculture development (FAO, 2009). Expected changes in the intensity, frequency and seasonality of climate patterns and extreme events, sea level rise, glacier melting, ocean acidification and changes in precipitation with associated changes in groundwater and river flows are expected to result in significant changes across a wide range of aquatic ecosystem types and regions with consequences for fisheries and aquaculture in many places (Chapter 30.5.1.1; FAO, 2009). Ocean acidification will also have negative impacts on the culture of calcifying organisms (Chapter 30.6.2.1.4), including mollusc species of which 14.2 MT were produced by aquaculture in 2010, equivalent to 23.6% of global aquaculture production (FAO, 2012). There are also concerns that that climate change could lead to the spread of pathogens with impacts on wild and cultured aquatic resources (De Silva and Soto, 2009).

Given the proximity of fishing and aquaculture sites to oceans, seas and riparian environments, extreme events can be expected to have impacts on fisheries and aquaculture with those located in low-lying areas at particular risk. The consequences of sea level rise and the expected increased frequency and intensity of storms include increased risks of loss of homes and infrastructure, increased safety risks while fishing and the loss of days at sea because of bad weather (Daw et al., 2009). In areas that experience water stress and competition for water resources, aquaculture operations and inland fisheries production will be at risk.

Food production from fisheries and aquaculture will be affected by the sensitivity of the caught and cultured species to climate change and both positive and negative outcomes can be expected. Changes in marine and freshwater mean temperatures, ocean acidification, hypoxia and other climate-related changes will influence the distribution and productivity of fished and farmed aquatic species (Chapter 6.4.3; 7.2.1.2; Chapter 30.6.2). Changes in temperature extremes are also likely to have impacts. Many aquatic species are routinely subjected to large daily and seasonal fluctuations in temperature and are able to cope with them: for example, temperatures in shallow coastal habitats in the tropical Pacific can vary by more than 14^{o}C diurnally (Pratchett et al., 2011). Nevertheless, distribution and productivity of aquatic species and communities are sensitive to changes in temperature extremes. A study on salmon populations in Washington State, USA (Mantua et al., 2010) demonstrated important impacts of seasonal variations and extremes. The study concluded that warming in winter and spring would have some positive impacts while increased summertime stream temperatures, seasonal low flows and changes in the peak and base flows would have negative impacts on the populations. Coral reefs are particularly susceptible to extremes in temperature: temperatures 1 or 2^{o}C in excess of normal maximums for 3 to 4 weeks are sufficient to disrupt the essential relationship between endosymbiotic dino-flagellates and their coral hosts leading to coral bleaching. Large scale bleaching of coral reefs has increased in recent decades both in intensity and frequency (Hoegh-Guldberg et al., 2007).

The impacts of climate change on the fisheries and aquaculture sector will have implications for the four dimensions of food security i.e. availability of aquatic foods, stability of supply, access to aquatic foods, and utilization of aquatic products (FAO, 2009). Where climate-driven ecological changes are significant, countries and communities will need to adapt through, for example, changes in fishing and aquaculture practices and operations (7.5.1.1.2.).

7.3.2.5. Food and Fodder Quality and Human Health

Food quality is any characteristic other than yield that is valuable to the producer or consumer. Examples include wheat protein and starch concentrations, which affect dough quality; amylose content in rice, which affects taste; and mineral concentrations, which affects nutrient intake of consumers. Climate change will have some adverse impacts on food quality through both biotic and abiotic stresses (Ceccarelli et al., 2010). These changes may affect crop quality by altering carbon and nutrient uptake and biochemical processes that produce secondary compounds or redistribute and store compounds during grain development and maturation. This in turn could impact human and livestock health by altering nutritional intake and/or affect economic value by altering traits valuable to processers or the consumers.

Change in nitrogen concentration, a proxy for protein concentration, is the most examined quality trait and since AR4 studies have been extended to almost all the major food crops. Cereals grown in elevated CO_2 show a decrease in protein (Piikki *et al.*, 2007; Hogy *et al.*, 2009; Erbs *et al.*, 2010; Ainsworth and McGrath, 2010; DaMatta *et al.*, 2010; Erda et al., 2010; Fernando *et al.*, 2012). Meta-analysis of 228 experimental observations finds decreases between 10 to 14 % in edible portions of wheat, rice, barley and potato, but only 1.5 % in soybeans, a nitrogen-fixing legume, when grown in elevated CO_2 (Taub et al., 2008).

Mineral concentration of edible plant tissues are affected by growth in elevated CO_2 in a similar manner to nitrogen. Although there are numerous studies measuring mineral concentration, there are relatively few measurements for any given mineral relevant to human health. Although there were several studies published before the release of AR4, this topic was not covered in any depth in AR4. Meta-analysis of studies prior to 2002 finds that P, Ca, S, Mg, Fe, Zn, Mn and Cu decline by 2.5 - 20 % in wheat grain and leaves of numerous species in elevated CO_2, but K increases insignificantly in wheat grain (Loladze, 2002; Hogy et al., 2009; Fernando et al., 2012). Since 2002, studies generally find decreases in Zn, S, P, Mg and Fe in wheat and barley grain, increase in Cu, Mo and Pb (from a limited number of studies) and mixed results for Ca and K (Hogy et al., 2009; Erbs et al., 2010; Fernando et al., 2012). Changes in mineral concentration due to elevated CO_2 are determined by several factors including crop species, soil type, tissue (tubers, leaves or grain) and water status.

Elevated CO_2 can lower the nutritional quality of flour produced from grain cereals (Hogy et al., 2009; Erbs et al., 2010) and of cassava (Gleadow et al., 2009). When coupled with increased crop and pathogen biomass, elevated CO_2 can result in increased severity of the *Fusarium pseudograminearum* pathogen, leading to shriveled grains with low market value (Melloy et al., 2010). Extreme temperatures and elevated CO_2 concentrations reduce milling quality of rice by increasing chalkiness, but can improve taste, through, for example, reduced amylase concentration (Yang et al., 2007). Cultivars vary in their susceptibility to these processes (Ambardekar et al., 2011; Lanning et al., 2011). Overall, there is *robust evidence* and *high agreement* that elevated CO_2 on its own likely results in decreased nitrogen concentrations. Combining knowledge of nitrogen and mineral studies, there is *medium evidence* and *medium agreement* that mineral concentrations will decline. The majority of these data are from wheat, with comparatively little information from key crops such as maize, rice, potato and cassava; thus magnitudes are uncertain for the species.

Elevated O_3 concentrations appear to have the opposite effect as elevated CO_2. Meta-analysis of about 50 wheat experiments found that elevated O_3 increased grain protein concentration by decreasing yield (Pleijel and Uddling, 2012). For other species, studies find both increases and decreases of N and several minerals (Taub et al., 2008), and as such no firm conclusions can be drawn, but they mostly respond similarly. Similarly, experiments examining the effect of drought on mineral concentrations find both decreases and increases in mineral concentrations (Ghorbanian et al., 2011; Sun et al., 2011).

Confidence in the impact of climate, CO_2 and O_3 on food quality does not imply confidence in changes regarding human health for several reasons. Post-processing of food affects nutrient concentrations, when the nutrient-rich outer layers of rice are removed, leaving the starch dense endosperm. Also, elevated CO_2 can increase crop yield, thus increasing the overall yield minerals (Duval et al., 2011) and permitting greater mineral consumption. Furthermore, since calorie intake is the primary concern in many food insecure populations, even if intake of minerals is decreased, those negative effects could be outweighed by increased calorie intake. In assessing impacts on health, current diets must be considered. Decreased mineral intake will matter for those who currently do not meet, or just barley meet, requirements, but will not affect those who already exceed requirements. Little is known about combined effects of climate change factors on food quality or the economic and behavioral changes that will occur. Thus, there is little confidence regarding effects of climate change on human health through changes in nutrient composition.

7.3.2.6. Pastures and Livestock

Pastures response to climate change is complex because, in addition to the direct major atmospheric and climatic drivers (CO_2 concentration, temperature, and precipitation), there are important indirect interations such as plant competition, perennial growth habits, seasonal productivity, and plant-animal interactions. Projected increases in temperature and the lengthening of the growing season should extend forage production into late fall and early spring, thereby decreasing the need for accumulation of forage reserves during the winter season in USA (Izaurralde et al., 2011). In addition, water availability may play a major role in the response of pasturelands to climate change although there are differences in species response (Izaurralde et al., 2011). There is general consensus that increases in CO_2 will benefit C_3 species; however, warmer temperatures and drier conditions will tend to favour C_4 species (Izaurralde et al., 2011; Hatfield et al., 2011; AR5 WG2 Chapter 4). While elevated atmospheric CO_2 concentrations reduce sensitivity to lower precipitation in grassland ecosystems and can reduce mortality and increase recovery during severe water stress events, it is still unclear how general this result is (Soussana et al., 2010).

Temperature is an important limiting factor for livestock. As productivity increases, be it increasing milk yield in dairy cattle or higher growth rates and leanness in pigs or poultry, so metabolic heat production increases and the capacity to tolerate elevated temperatures decreases (Zumbach *et al.*, 2008; Dikmen and Hansen, 2009). Over the long term, single-trait selection for productivity will tend to result in animals with lower heat tolerance (Hoffmann, 2010). Recent work adds to previous understanding (AR4 WG2 Chapter 5) and indicates that heat stress *(medium evidence, high agreement,*) in dairy cows can be responsible for the increase in mortality and economic losses (Vitali *et al.*, 2009); it affects a wide range of parameters in broilers (Feng et al, 2008); it impairs embryonic development and reproductive efficiency in pigs (Barati *et al.*, 2008); and affects ovarian follicle development and ovulation in horses (Mortensen *et al.*, 2009). Water stess also limits livestock systems. Climate change will affect the water resources available for livestock via impacts on runoff and groundwater (AR5 WG2 Chapter 3). Populated river basins may experience changes in river discharge, and large human and livestock populations may experience water stress such that proactive or reactive management interventions will almost certainly be required (Palmer *et al.*, 2008). Problems of water supply for increasing livestock populations will be exacerbated by climate change in many places in sub-Saharan Africa and South Asia.

7.3.3. Sensitivity of Food Security to Weather and Climate

7.3.3.1. Non-Production Food Security Elements

As indicated in the discussion in section 7.1.1 and Figure 7-1, food security is dependent on access and consumption patterns, food utilization and nutrition, and overall stability of the system as much as food production and availability. The overall impact of climate change on food security is considerably more complex and potentially greater than projected impacts on agricultural productivity alone. Figure 7-1 indicates the main components of food security and their key elements. All of these will be affected by climate change to some extent. For example, climate change effects on water, sanitation and energy availability have major implications for food access and utilization as well as availability. Likewise, changes in the frequency and severity of climate extremes can affect stability of food availability and prices, with consequent impacts on access to food.

7.3.3.2. Accessibility, Utilization, and Stability

7.3.2.2.1. Climate change impacts on access

As noted in the discussion in section 7.1.3, change in the levels and volatility of food prices is a key determinant of food access. Given the hypothesis that climate change will be a contributing factor to food price increases, and hence its affordability, the vulnerability of households to reduced food access depends on their channel of food access (*medium evidence, medium agreement).* Table 7-1 divides households into five main categories of food access, indicating their relative impacts of food price increases.

[INSERT TABLE 7-1 HERE
Table 7-1: Households divided into five categories of food access, indicating the impacts for them of food price increases.]

Concern about the impact of increased food prices on poverty and food security arises due to the high share of income that poor consumers spend on food, thus generating a disproportionately negative effect of price increases on this group (FAO, 2011). A study by the World Bank estimated a net increase of 44 million people in extreme poverty in low and middle income countries as a result of food price increases since June 2010 (Ivanic et al., 2011).

Tthe distribution of net food buyers and net food sellers varies considerably across countries and can be expected to change with the process of economic development (Zezza et al., 2008; Aksoy et al., 2010; FAO, 2011). Changing consumption patterns associated with dietary transitions that accompany income growth, urbanization, market development, and trade liberalization determine the rate and nature of food demand growth and nutritional levels, and thus is a key determinant of global and local food security (Kearney, 2010). However the evidence base on potential climate change impacts on consumption patterns, or on other non-production elements of food security is thin, particularly when compared with the literature on climate change impacts on food production and availability.

Current and future variation in the distribution and vulnerability to loss of food access across household types makes impacts assessment complex and difficult. Nonetheless, there are reasons for concern about food access due to the current high rates of food insecurity in many low income countries. Agricultural producers who are net food buyers are particularly vulnerable. Similarly, low income agricultural dependent economies that are net food importers, which are those that already have high rates of food insecurity, could experience significant losses in food access through a double negative effect on reduced domestic agricultural production and increased food prices on global markets.

7.3.2.2.2. Climate change impacts on stability

There is increasing evidence of and confidence in the effect of climate change on increasing the incidence and frequency of some types of climate extreme events (IPCC, 2012), and this will have significant impacts on food security (*medium evidence; medium agreement*). Recent experience of global climate patterns affecting food security indicate the potential nature and magnitude of increased variability. An impact assessment of the 2010 Pakistan floods surveyed 1800 households 6 months after the floods and found that 88% of the households reported income losses of up to 50%, with significantly higher rates in rural than urban areas (Kirsch et al., 2012). The same study indicated that loss of key services such as electricity, sanitation and clean water resulted in lower standards of living even in the wake of significant relief attempts, again with significantly heavier effects on rural populations (Kirsch et al., 2012). The Russian heat wave of 2010 and subsequent export ban contributed to the more than doubling of global wheat prices by the end of the year. The degree to which these price increases affected domestic consumers and poverty depended on national responses in importing countries, although a significant net negative effect on poverty was found (Ivanic et al., 2011).

Increased incidence of climate extremes reduces incentives to invest in agricultural production, potentially offsetting positive impacts from increasing food price trends. This is particularly true for poor smallholders with limited or no access to credit and insurance. Greater exposure to climate risk, in the absence of well-functioning insurance markets, leads to: 1) greater emphasis on low-return but low-risk subsistence crops (Roe and Graham-Tomasi, 1986; Fafchamps, 1992; Heltberg and Tarp, 2002), 2) a lower likelihood of applying purchased inputs such as fertilizer (Kassie et al., 2008; Dercon and Christiansen, 2011), 3) a lower likelihood of adopting new technologies (Feder *et al.*, 1985; Antle and Crissman., 1990), and 4) lower investments (Skees et al., 1999). All of these responses generally lead to both lower current and future farm profits *(robust evidence, high agreement*) (Rosenzweig and Binswanger, 1993; Hurley, 2010).

It is also well documented that in many rural areas, smallholders in particular do not have the capacity to smooth consumption in the face of climate shocks, particularly generalized shocks that affect a majority of households in the same location (Dercon, 2004; Skoufias and Quisumbing, 2005; Dercon, 2006; Fafchamps, 2009; Prakash, 2011). Any increases in climate extremes will exacerbate the vulnerability of all food insecure people, including smallholders (*robust evidence, high agreement*). Currently, smallholders rely to a large extent on increasing labor off-farm where possible (Fafchamps, 1999; Kazianga and Udry, 2006), but also by decreasing both food consumption and non-food expenditures, such as those on education and healthcare (Skoufias and Quisumbing, 2005) (*medium evidence, high agreement*). Furthermore, some evidence also suggests that poorer households are more likely to reduce consumption, while wealthier households liquidate assets to cover current deficits (*limited evidence, medium agreement*) (Kazianga and Udry, 2006; Carter and Lybbert, 2012). Reductions in food consumption, sales of productive assets, education and healthcare can lead to long-term losses in terms of income-generation and thus to future food security (*limited evidence, medium agreement*) (Hoddinot and Maluccio, 2008; Skoufias and Quisumbing, 2005). Increased uncertainty of future climate conditions and increases in climate extremes will increase food insecurity unless these significant barriers to consumption and asset smoothing can be addressed (*medium evidence, medium agreement*).

7.3.3.2.3. Climate change impacts on utilization

Climate change impacts on utilization may come about through changes in consumption patterns in response to shocks, as well as changes in nutrient content of food as well as food safety (*medium evidence; medium agreement*). Rationing consumption to prioritize calorie-rich, but nutrient poor foods is another common response (Bloem et al., 2010). The effects are a decrease in dietary quality as well as quantity, which are magnified by pre-existing vulnerabilities – and lead to long term loss of health, productivity capacity and low incomes (*medium evidence; medium agreement*) (Bloem et al., 2010; Alderman, 2010; Brinkman et al., 2010; Campbell et al., 2010; Sari et al., 2010). The biological effects of climate change on nutrient content of foods is one of main pathways for effects on utilization. A summary of recent literature on the impacts of climate change on the composition of nutrients in food items is given in HLPE (2012). Research on grains generally shows lowering of protein content with elevated temperature and CO_2 levels (Ainsworth and McGrath, 2010; Erda et al., 2005; Hatfield et al., 2011). There is good agreement that for plant-derived foods, mycotoxins are considered the key issue for food safety under climate change (Miraglia et al., 2009). The impacts of climate change on mycotoxins in the longer term are complex and region-specific; temperatures may increase sufficiently to eliminate certain mycotoxin-producing species from parts of the tropics, but in colder tropical regions and temperate zones, infections may increase (Cotty and Jaime-Garcia, 2007).

7.3.4. Sensitivity of Land Use to Weather and Climate

As noted in the AR4, changes in land use, for example adjusting the location of crop production, are a potential adaptation response to climate change. Studies since the AR4 have confirmed that high latitude locations will, in general, become more suitable for crops (Iqbal et al., 2009). Trnka et al. (2011), for example, examined projections of eleven agro-climatic indices across Europe, and found that declines in frost occurrence will lead to longer growing seasons, although temperature and moisture stress will often lead to greater inter-annual variability in crop suitability. The potential influence of pests and diseases is commonly beyond the scope of such studies (Gregory et al., 2009).

For tropical systems where moisture availability or extreme heat rather than frost limits the length of the growing season, there is a likelihood that the length of the growing season and overall suitability for crops will decline (*medium evidence, medium agreement*) (Jones and Thornton, 2009; Zhang and Cai, 2011). For example, half of the wheat-growing area of the Indo-Gangetic Plains could become significantly heat stressed by the 2050s, whilst temperate wheat environments will expand northwards as climate changes (Ortiz et al., 2008). Similarly, by 2050, the majority of African countries will experience climates over at least half of their current crop area that lie outside the range currently experienced within the country (Burke et al., 2009). The majority of these novel climates have analogues in other African countries. In mountainous regions, where temperature varies significantly across topography, changes in crop suitability can be inferred from the variation of temperature across topography. The resulting vertical zones of increasing, decreasing and unchanging suitability can be relatively robust in the face of uncertainty in future climate (Schroth et al., 2009).

The interaction between water resources and agriculture is expected to become increasingly important as climate changes. For example, whilst projected changes in crop productivity in China are uncertain, even within a single emissions scenario, irrigation has significant adaptation potential (Piao et al., 2010). However, limitations to availability of water will affect this potential. Changes in water use, including increased water diversion and development to meet increasing water demand, and increased dam building will also have implications for inland fisheries and aquaculture, and therefore for the people dependent on them (Ficke et al., 2007; FAO, 2009). In the case of the Mekong River basin, a large proportion of the 60 million inhabitants are dependent in some way on fisheries and aquaculture which will be seriously impacted by human population growth, flood mitigation, increased offtake of water, changes in land use and overfishing, as well as by climate change (Brander, 2007). Ficke et al. (2007) reported that at that time there were 46 large dams planned or already under construction in the Yangtze River basin, the completion of which would have detrimental effects on those dependent on fish for subsistence and recreation.

The models used in projections of land suitability and cropland expansion discussed above rely on assumptions about non-climatic constraints on crop productivity, such as soil quality and access to markets. These assumptions are increasingly amenable to testing as the climate system shifts, by comparing observed changes in cropland area with model predictions. The location of the margin between cropping land and extensive grazing in southern Australia has varied with decadal climate conditions and is projected to shift towards the coast with hotter and drier conditions, notwithstanding the positive impacts of elevated CO_2 (Nidumolu et al., 2011). Recent trends in climate have seen reductions in cropping activity consistent with these projections (Nidumolu et al., 2011).

7.4. Projected Integrated Climate Change Impacts

7.4.1. Projected Impacts on Cropping Systems

Crop yields remain the most well studied aspect of food security impacts from climate change, with many projections published since AR4. These newer studies confirm many of the patterns identified in AR4, such as negative yield impacts for all crops past 3°C of local warming without adaptation, even with benefits of higher CO_2 and rainfall (Figure 7-4).

Figure 7-5 shows projected impacts on mean crop yield in twenty-year bins, including cases with no adaptation and a range of incremental adaptations. The data indicate that negative impacts on average yields become *likely* from the 2030s. Negative impacts of more than 5% are *more likely than not* beyond 2050 and *likely* by the end of the century. Some important differences by emission scenario and region are masked in Figure 7-5. From the 2080s onwards, negative yield impacts in the tropics are *very likely,* regardless of adaptation or emission scenario. This is consistent with the meta-analysis of Knox et al. (2012), and a recent model intercomparison of global gridded crop models (Rosenzweig et al., 2013).

[INSERT FIGURE 7-5 HERE
Figure 7-5: Projected changes in crop yield as a function of time. The y-axis indicates percentage of studies and the colours denote percentage change in crop yield. The sum of absolute bar heights in each time period equals 100%. Data are plotted according to the 20-year period in which the centre point of the projection period falls. Data taken from Abraha & Savage, 2006; Alexandrov & Hoogenboom, 2000; Arndt et al., 2011; Berg et al., 2012; Brassard & Singh, 2008; Brassard & Singh, 2007; Butt et al., 2005; Calzadilla et al., 2009; Chhetri et al., 2010; Ciscar et al., 2011; Deryng et al., 2011; Giannakopoulos et al., 2009; Hermans et al., 2010; Iqbal et al., 2011; Izaurralde et al, 2005; Kim et al., 2010; Lal, 2011; Li et al., 2011; Lobell et al., 2008; Moriondo et al., 2010; Muller et al., 2010; Osborne et al., 2013; Peltonen-Sainio et al., 2011; Piao et al., 2010; Ringler et al., 2010; Rowhani et al., 2011; Schlenker & Roberts, 2009 ;Shuang-He et al., 2011; Southworth et al., 2000; Tan et al., 2010; Tao & Zhang, 2010; Tao & Zhang, 2011; Tao et al., 2009; Thornton et al., 2009; Thornton et al., 2011; Thornton et al., 2010; Tingem & Rivington, 2009 Tingem et al., 2008; Walker & Schulze, 2008; Wang et al., 2011; Xiong et al., 2009; Xiong et al., 2007.]

A few studies have explicitly compared projections for different regions or crops to identify areas at most risk. Lobell et al. (2008) used a statistical crop model with 20 GCMs and identified South Asia and Southern Africa as two regions that, in the absence of adaptation, would suffer the most negative impacts on several important crops. Yields changes have also been assessed by regional meta-analyses: Knox et al. (2012) synthesized projections from 52 studies and estimated an expected 8% negative yield impact in both Africa and South Asia by 2050 averaged over crops, with wheat, maize, sorghum, and millets more affected than rice, cassava, and sugarcane.

Changes in the interannual variability of yields could potentially affect stability of food availability and access. Figure 7-6 shows projected changes in the coefficient of variation (CV) of yield from some of the few studies that publish this information. The data shown are consistent with reports of CV elsewhere: Müller et al. (2013) conducted gridded simulations across the globe and reported an increase of more than 5% in CV in 64% grid cells, and a decrease of more than 5% in 29% of cases. Increases in CV can be due to reductions in mean yields and/or increases in standard deviation of yields, and often simulated changes are a combination of the two. Overall, climate change will increase crop yield variability in many regions (*medium evidence, medium agreement*).

[INSERT FIGURE 7-6 HERE
Figure 7-6: Projected percentage change in coefficient of variation (CV) of yield for wheat (gold), maize (green), rice (blue) and C_4 crops (red) taken from C2010 (Challinor et al., 2010), B2013 (Berg et al., 2013), T2009 (Tao et al., 2009), TZ2013 (Tao and Zhang, 2010), TZ2012 (Tao and Zhang, 2011) and U2012 (Urban et al., 2012). U2012 and C2012 plot multiple data points: U2012 shows the range (mean plus and minus one standard deviation) of percentage changes in CV. For C2012 paired CV changes were not available, so the box shows changes in the mean CV, the mean CV plus one standard deviation, and the mean CV minus one standard deviation. 81 datapoints are plotted in the figure, although the underlying data consist of many thousands of crop model simulations. The studies used a range of scenarios (SRES A1B, A2, A1F1 and B1). B2013 is a global study of the tropics, U2012 is for US maize, and the remaining studies are for China.]

Estimated impacts of both historical and future climate changes on mean yields are summarized along with projected impacts on yield variability in Figure 7-7, with all impacts expressed as the average percentage impact per decade. This comparison illustrates that future impacts are expected to be consistent with the trajectory of past impacts, with the majority of locations experiencing negative impacts while some locations benefit. Each additional decade of climate change is expected to reduce mean yields by roughly 1%, which is a small but nontrivial fraction of the antipicated roughly 14% increase in productivity per decade needed to keep pace with demand. For future projections, enough studies are available to assess differences by region and adaptation scenario, with significant adaptation effects apparent mainly in temperate systems (7.5).

[INSERT FIGURE 7-7 HERE
Figure 7-7: Boxplot summary of studies that quantify impact of climate and CO_2 changes on crop yields, including historical and projected impacts, mean and variability of yields, and for all available crops in temperate and tropical regions. All impacts are expressed as average impact per decade (a 10% total impact from a 50 year period of climate change would be represented as 2% per decade). References for historical impacts are given in Figure 7-2, for projected mean yields in Figure 7-5, and for yield variability in Figure 7-6. N indicates the number of estimates, with some studies providing multiple estimates. In general, decreases in mean yields and increases in yield variability are considered negative outcomes for food security. Also indicated on figure is the expected increase in crop demand of 14% per decade (Alexandratos and Bruinsma, 2012), which represents a target for productivity improvements to keep pace with demand.]

Relatively few studies have considered impacts on cropping systems for scenarios where global mean temperatures increase by 4^oC or more. An analysis for sub-Saharan Africa predicted overall decreases of 19% for maize yields, 68% decrease for bean yields and a small increase for fodder grass (*Brachiaria decumbens*) given 5^oC global average warming (Thornton et al., 2011). Rötter et al. (2011) conclude that positive effects of modest warming and increased CO_2 levels on crop yields in Finland will be reversed at global temperatures increases of 4^oC, leading to negative yield impacts in excess of 20% in relation to current conditions.

For perennial crops, winter chill accumulation that is important to many fruit and nut trees is projected to continue its decline, with for instance a 40 h per decade reduction projected for California for the period up to 2100 (Baldocchi and Wong, 2008). Averaging over three GCMs, annual winter chill loss by 2050 compared to 1970 would amount 17.7 % to 22.6 % in Egypt (Farag et al., 2010). Several studies have projected negative yield impacts of climate trends for perennial trees, including apples eastern Washington (Stöckle et al., 2010) and cherries in California (Lobell and Field, 2011), although CO_2 increases may offset some or all of these losses. Reductions in suitability for grapevine are expected in most of the wine producing regions (Hall and Jones, 2009; White et al., 2009; Jones et al., 2010). Wine grape production and quality will be affected in Europe, US, Australia (Jones et al., 2005; Wolfe et al., 2008; Cozzolino et al., 2010; AR5 WG2 Chapter 25), although it could be a benefit in Portugal (Santos et al., 2011) and British Columbia in Canada (Rayne et al., 2009). Important crops in Brazil like sugarcane and coffee are expected to migrate towards more favorable zones in the South (Pinto, 2007; Pinto et al., 2008; AR5 WG2 Chapter 27). Sugarcane fresh stalk mass is generally expected to gain from both warming and elevated CO_2 in Brazil (Marin et al., 2013). The suitability for coffee crops in Costa Rica, Nicaragua and El Salvador will be reduced by more than 40% (Glenn et al., 2013) while the loss of climatic niches in Colombia will force the migration of coffee crops towards higher altitudes by mid-century (Ramirez-Villegas et al., 2012). In the same way, increases in temperature will affect tea production, in particular at low altitudes (Wijeratne, et al., 2007).

Consideration of pest, weed, and disease impacts are omitted from most yield projections, yet other studies have focused on projecting impacts of these biotic stressors. For pests and diseases, range expansion has been predicted for the destructive *Phytophthora cinnamomi* in Europe (Bergot et al., 2004) and for phoma stem canker on oilseed rape in the UK (Evans et al., 2008). Increased generations under climate change for the coffee nematode have been predicted for the coffee nematode in Brazil (Ghini et al., 2008). Walnut pests in California are predicted to experience increased numbers of generations under climate change scenarios (Luedeling et al., 2011). Luck (2011) summarized the mixed results for the qualitative effects of climate change on pathogens that cause disease of four major food crops - wheat, rice, soybean and potato - where some diseases increased in risk while others decreased under climate change scenarios. In syntheses, there is a tendency for risk of insect damage to plants to increase (Deutsch et al., 2008; Paulson et al., 2009). Typical scenario analyses are limited by simplistic assumptions, and work remains to evaluate how conclusions will change as more complete scenarios, such as those including migration and invasion patterns and other types of global change, are considered (Savary et al., 2005; Garrett et al., 2011). Effects on soil communities represent an area that needs more attention (Pritchard, 2011). Mycotoxins and pesticide residues in food are an important concern for food safety in many parts of the world, and identified as an important issue for climate change effects in Europe (Miraglia et al., 2009).

Weed populations and demographics are expected to change (*medium confidence*), with an overall poleward migration in response to warming (Ziska et al., 2011a). An overview of crop and weed competitive studies indicate that weeds could limit crop yields to a greater extent with rising levels of carbon dioxide per se (Ziska, 2010). This may be related to the greater degree of phenotypic and genotypic plasticity associated with weedy species relative to the uniformity inherent in large cropping systems (Chapter 4.2.4.6). Chemical control of weeds, which is the preferred management method for large-scale farms, may become less effective (*limited evidence, medium agreement*), with increasing economic and environmental costs (7.3.2.3).

Climate change effects on productivity will alter land use patterns, both in terms of total area sown to crops and the geographic distribution of that area. For example, the suitability for potato crops is expected to increase in very high latitudes and high tropical altitudes towards 2100 (Schaefleitner et al., 2011). Given expected trends in population, incomes, bioenergy demand, and agricultural technology, global arable area is projected to increase from 2007 to 2050, with projected increases over this period of +9% (Bruinsma, 2009), +8% (Fischer et al., 2009), +10-20% (Smith et al., 2010), +18-23% (Lobell et al. 2013) (*medium evidence, medium agreement*). Not all such studies included the effects of global warming. Where this is the case, estimates range from a 20% increase in cropping area to a decline of 9% (Zhang and Cai, 2011), but with large regional differences (*limited evidence, low agreement*). Countries at northern latitudes and under the current constraint of low temperature may increase cultivated area (*limited evidence, low agreement*). The generally lower nutrient quality of soils and the lack of necessary infrastructure required to convert virgin land into productive arable land make estimates of cropping area increases highly uncertain.

7.4.2. Projected Impacts on Fisheries and Aquaculture

Many studies have projected impacts of climate change on capture fisheries (Chapters 6 and 30) and only a subset of the more indicative studies at different ecological and geographical scales is included here. Overall, there is *high confidence* that climate change will impact on fisheries production with significant negative impacts particularly for developing countries in tropical areas, while more northerly, developed countries may experience benefits (Chapter 6.4.3).

Simulation studies on skipjack and bigeye tuna in the Pacific under both the B1 and A2 scenarios indicate that catches of skipjack in the region as a whole are likely to increase by approximately 19% in 2035 compared to recent catch levels while catches of bigeye are projected to increase by 0.33%. By 2100, under the B1 scenario, catches of skipjack are projected to be 12.4% higher than recent levels but 7.5% lower under the A2 scenario, while catches of bigeye will be 8.8% and 26.7% lower under the B1 and A2 scenarios respectively. The models indicate important regional differences, with a general trend that catches of both species will decrease in the Western Pacific and increase in the Eastern Pacific (Lehodey et al, 2011; Chapters 6.5.3 and 30.6.2.1.1). These changes have important implications for the future of national fishing fleets and canneries in the western Pacific (Bell et al. 2011a) . Climate change is expected to impact directly on the productivity of coastal fisheries in the Pacific island countries and territories through increased sea surface temperature and ocean acidification and indirectly through climate-driven damage to coral reefs, mangroves, sea-grasses and intertidal flats (Pratchett et al., 2011). Extreme events such as increased severity of tropical cyclones could also impact on some species. Under both B1 and A2 emissions scenarios, the vulnerability of coastal fisheries as a whole in 2035 (as estimated through the framework described in Bell et al. (2011a)) is considered to be low. Extended to 2100, the projected impacts under the A2 emissions scenario are more severe, with reductions in coastal fisheries production by 20-35% in the west and 10-30% in the east (Pratchett et al., 2011).

Brown et al. (2010) project that, under the A2 emissions scenario, primary production in the ocean around Australia will increase over the 50-year period from 2000-2050 as a result of small increases in nutrient availability from changes in ocean stratification and temperature, although the authors acknowledge considerable model uncertainty. This increase is forecast, in general, to benefit fisheries catch and value. In a complementary study, Fulton (2011) used available end-to-end models to forecast the impacts of climate change under the A2 scenario across approximately two-thirds of Australia's exclusive economic zone. The results indicated that by 2060, the large-scale commercial fisheries, aided by their adaptive flexibility, would experience an overall increase of more than 90% in the value of their operations, although differing across sectors .The change in returns for the small-scale sector varied regionally from a decrease of 30-51% to a potential increase of 9-14% in another.

At the global scale, projections based on a dynamic bioclimate envelope model under the SRES A1B scenario suggested that climate change could lead to an average 30–70% increase in fisheries yield from high-latitude regions (>50° N in the northern hemisphere), but a decrease of up to 40% in the tropics by 2055 compared to yields obtained in 2005 (Cheung et al., 2010). Another study used a suite of models linking physical, ecological, fisheries, and bioeconomic processes projected that, under the A1B scenario, the global yield from 'large' fish could increase by 6% and that of the 'small fish' used in fishmeal production by approximately 3.6%, assuming that marine fisheries and fish resources would be managed sustainably (Merino et al., 2012).

There is limited information available on projected impacts on food production in inland fisheries. Xenopoulus et al. (2005) investigated the effect of climate change and water withdrawal on freshwater fish extinctions under the assumptions of two scenarios consistent with scenarios A2 and B2. They forecast that discharge would increase in between 65 and 70% of river basins in the world but it would decrease by as much as 80% in 133 rivers for which fish species data were available. In the latter group, by 2070 up to 75% of the local fish biodiversity would be 'headed toward extinction' because of changes in climate and water consumption, with the highest rates of extinction forecast mainly in tropical and subtropical areas. These results are not directly translatable into changes in fishery production but do give cause for concern for the likely affected areas (*limited evidence; low agreement*).

Information on future impacts on aquaculture is equally limited. Huppert et al. (2009) considered the impacts on the coast of Washington State, USA. They concluded that inundation of low-lying coastal areas from sea level rise, flooding from major storm events, and increased ocean temperatures and acidification would create significant challenges for the important shellfish aquaculture industry in the state. Inundation of existing shellfish habitats from sea level rise and increased incidence of harmful algal blooms were also contributory factors. Using a structured vulnerability framework and considering the B1 and A2 emission scenarios to project impacts on aquaculture in the tropical Pacific to 2035 and 2100, Pickering et al..(2011) concluded that production of freshwater species such as tilapia, carp and milkfish will probably benefit from the expected climate changes, while coastal enterprises are expected to encounter problems in the same time horizons, varying according to species. Aquaculture production of calcifying organisms such as molluscs will experience loss of suitable habitats through ocean acidification. This will be particularly pronounced at and in the vicinity of eastern boundary upwelling systems (Chapter 30.6.2.1.4).

The food security consequences of the different impacts on capture fisheries and aquaculture are more difficult to estimate than the biological and ecological consequences. A preliminary study by Allison et al., (2009) examined the vulnerability of the economies of 132 countries to climate change impacts on fisheries in 2050 under the A1FI and B2 scenarios. Vulnerability was considered as a composite of three components: exposure to the physical effects of climate change; the sensitivity of the country to impacts on fisheries; and adaptive capacity within the country. This analysis suggested that under both scenarios several of the least developed countries were also amongst the most vulnerable to climate change impacts on their fisheries. They included countries in central and western Africa, Peru and Columbia in South America and four tropical Asian countries.

7.4.3. Projected impacts on Livestock

Climate change impacts on livestock will include effects on forage and feed, direct impacts of changes in temperature and water availability on animals, and indirect effects via livestock diseases. Many of the relevant processes and projected impacts for rangelands are discussed in Chapter 4.3.3.2, as well as in chapters for regions with prominent livestock sectors (Chapters 22.3.4.2, 23.4.2, 25.7.2.1). In North American cattle systems, warming is expected to lengthen forage groing season but decrease forage quality, with important variations due to rainfall changes (Craine et al., 2010; Izaurralde et al., 2011, Hatfield et al., 2011). Simulations for French grasslands (Graux et al., 2013) and sown pastures in Tasmania (Perring et al., 2010) also project negative impacts on forage quality. Similarly, legume content of grasslands in most of southern Australia is projected to increase to the 2070s for SRES A2, with larger increases in wetter locations (Moore and Ghahramani, 2013).

There is *high confidence* that high temperatures tend to reduce animal feeding and growth rates (Andre et al., 2011; Renandeau et al. 2011). The impacts of a changing UK climate on dairy cow production were analysed by (Wall *et al.*, 2010), who showed that in some regions, milk yields will be reduced and mortality increased because of heat stress throughout the current century, with annual production and mortality losses amounting to some £40 million by the 2080s under a medium-high greenhouse gas emission scenario.

Existing challenges of supplying water for an increasing livestock population will be exacerbated by climate change in many places (*limited evidence, high agreement)*. For example, Masike and Urich (2008) project that warming under A1 SRES emission scenario will cause an annual increase of more than 20% in cattle water demand by 2050 for Kgatleng District, Botswana. At the same time, there is ample scope to improve livestock water productivity considerably (Molden et al., 2010); for example, in mixed crop-livestock systems of sub-Saharan Africa via feed, water and animal management (Descheemaeker et al., 2010).
Host and pathogen systems in livestock will change their ranges because of climate change (*high confidence)*. Species diversity of some pathogens may decrease in lowland tropical areas as temperatures increase (Mills et al., 2010). The temperate regions may become more suitable for tropical vector-borne diseases such as Rift Valley fever and malaria, which are highly sensitive to climatic conditions (Rocque et al., 2008). Vector-borne diseases of livestock such as African horse sickness and bluetongue may expand their range northwards in the northern hemisphere because rising temperatures increase the development rate and winter survival of vectors and pathogens (Lancelot et al., 2008). Diseases such as West Nile virus and schistosomiasis are projected to expand into new areas (Rosenthal, 2009). The distribution, composition and migration of wild bird populations that harbour the genetic pool of Avian Influenza viruses will all be affected by climate change, although in ways that are somewhat unpredictable (Gilbert et al., 2008). The changing frequency of extreme weather events, particularly flooding, will affect diseases too. For example, outbreaks of Rift Valley fever in East Africa are associated with increased rainfall and flooding due to El Niño-Southern Oscillation events (Gummow, 2010; Pfeffer and Dobler, 2010). In general, the impacts of climate change on livestock diseases remain difficult to predict and highly uncertain (Mills et al., 2010; Tabachnick, 2010).

Box 7-1 summarises impacts on a regional basis for crops and livestock. Developing countries rely heavily on climate-dependent agriculture and especially in conjunction with poverty and rapid increase in population they are vulnerable to climate change. While food insecurity is concentrated mostly in developing countries situated in the tropics (Berg et al. 2013; Ericksen et al, 2011; St. Clair and Lynch, 2010) global food supply may also be affected by heat stress in both temperate and subtropical regions (Teixeira et al. 2013). Chapter 22 identifies Africa as one of the regions most vulnerable to food insecurity. Climate change will also affect crop yields, food security and local economies in Central America, northeast Brazil and parts of the Andean region (Chapter 27) as well as in South Asia (Iqbal et al. 2009, Chapter 24). As shown in Box 7-1, in spite of uncertainties in responses at regional/national and sub-national level, there is high confidence that most developing countries will be negatively affected by climate change in the future, although climate change may have positive effects in some regions. In high latitudes (such as Russia, northern Europe, Canada, South America) global warming may increase yields and expand the growing season and acreage of agricultural crops, although yields may be low due to poor soil fertility and water shortages in some regions (Kiselev et al., 2013; Chapters 23, 24, 26, 27). Although there is slim evidence, some studies do indicate a significant increase in crops yields in some parts of China, Africa and India. Like crops, livestock is also negatively affected by climate change in almost all the continents, as evidenced by the regional chapters of Working Group 2. The dairy, meat and wool systems primarily rely on fodders, grasslands and rangelands. Climate change can impact the amount and quality of produce, profitability and reliability of production (Chapter 23, 25). Higher temperature would lead to decline in dairy production, reduced animal weight gain, stress on reproduction, increased cost of production and lower food conversion efficiency in warm regions. Disease incidence among livestock is expected to be exacerbated by climate change as most of the diseases are transmitted by vectors such as ticks and flies (Chapter 23) whose proliferation depends on climatic parameters of temperature and humidity.

7.4.4. Projected Impacts on Food Prices and Food Security

AR4 presented a summary of food price projections based on five studies that used projected yield impacts as inputs to general or partial equilibrium models of commodity trade. Many additional projections of this type have been made since AR4, expanding the number of trade models used, the diversity of yield projections considered, and the disaggregation of prices by commodity (Hertel et al., 2010; Baldos and Hertel, 2013; Calzadilla et al. 2013; Lobell et al., 2013; Nelson et al., 2013). Many of the studies did not include CO_2 effects, which is sometimes justified on the grounds that studies are concerned with “worst-case” scenarios, or that the bias from omitting positive CO_2 effects balances the known bias from omitting negative effects of elevated O_3 and increased weed and pest damage. Studies also typically ignore potential changes in yield variability (Figure 7-6) and policy responses such as export bans which have important international price effects (7.2.2).

Based on the studies cited above, it is *very likely* that changes in temperature and precipitation, without considering effects of CO_2, will lead to increased food prices by 2050, with estimated increases ranging from 3-84%. The combined effect of climate and CO_2 change (but ignoring O_3 and pest and disease impacts) appears *about as likely as not* to increase prices, with a range of projected impacts from -30% to +45% by 2050. One lesson from recent model intercomparison experiments (Nelson *et al.*, 2013) is that the choice of economic model matters at least as much as the climate or crop model for determining price response to climate change, indicating the critical role of economic uncertainties for projecting the magnitude of price impacts.

The AR4 concluded that climate changes are expected to result in higher real prices for food past 2050. This conclusion remains intact with *medium confidence*, albeit with a relative lack of new studies exploring price changes to 2100 or beyond. Of course, international prices are only one indicator of global food security, with the pathways by which price changes can affect food security outlined in section 7.3.3. A limited number of studies have estimated the effects of price changes on food security and related health outcomes. Nelson et al. (2009) project that, without accelerated investment in planned adaptations, climate change by 2050 would increase the number of undernourished children under the age of 5 by 20-25 million (or 17-22%), with the range including projections with and without CO_2 fertilization. Lloyd et al. (2011) used the projected changes in undernourishment from Nelson (2009) to project the impact of climate change on human nutrition, estimating a relative increase in moderate stunting of 1–29% in 2050 compared with a future without climate change. Severe stunting was projected to increase by 23% (central Africa) to 62% (South Asia). Baldos and Hertel (2013) estimate that, compared to a baseline scenario, climate change impacts result in an increase in global malnourished population by 49 million (11%) in 2050, but that the combined effects of climate change and CO_2, which result in yield increases in their study, reduces the number of malnourished.

In summary, if global yields are negatively impacted by climate change, an increase in both international food prices and the global headcount of food insecure people is expected (*limited evidence, high agreement*). However, it is only *about as likely as not* that the net effect of climate and CO_2 changes on global yields will be negative by 2050, but *likely* that such changes will occur later in the 21st century. At the same time, it is *likely* that socio-economic and technological trends, including changes in institutions and policies, will remain a relatively stronger driver of food security over the next few decades than climate change (Goklany, 2007; Parry et al., 2009). Importantly, all of the studies that project price impacts assume some level of on-farm agronomic adaptation, often by optimizing agronomic practices within the model. Most, but not all, also prescribe income growth rates as exogenous factors, despite the fact that incomes are heavily dependent on agriculture in many poor countries. One study that accounted for income effects found that, in countries such as Indonesia that had both a large share of poverty in agriculturally dependent households and yield impacts that were small relative to other regions, poverty was reduced by the effects of climate change (Hertel et al., 2010). However, in most countries the positive income effects of higher prices could not outweigh the costs of reduced productivity and higher food prices.

Recent work has also highlighted that productivity in many sectors besides agriculture are significantly influenced by warming, with generally negative effects of warming on economic output in tropical countries (Hsiang, 2010; Dell et al., 2012). Given the importance of incomes to food access, incorporating these effects into future estimates of food security impacts will be important. Conflict is also known to be an important factor in food security (FAO, 2010a), and evidence of climate variability effects on conflict risk (Hsiang et al., 2011) indicates a need to also consider this dimension in future work (Chapter 12).

Since the impacts of climate change on food production and food security depends on multiple interacting drivers, the timing of extreme events, which are expected to become more frequent (IPCC, 2012), is critical. Extremes contribute to variability in productivity (Figure 7-6) and can form part of compound events that are driven by common external forcing (e.g. El Niño), climate system feedbacks, or causally unrelated events (IPCC, 2012). Such compound events, where extremes have simultaneous impacts in different regions, may have negative impacts on food security, particularly against the backdrop of increased food price volatility (Figure 7-3). There are very few projections of compound extreme events and interactions between multiple drivers are difficult to predict. Effective monitoring and prediction, and building resilience into food systems, are likely to be two key tools in avoiding the negative impacts resulting from these interactions (Misselhorn et al., 2010).

7.5. Adaptation and Managing Risks in Agriculture and Other Food System Activities

7.5.1. Adaptation Needs and Gaps based on Assessed Impacts and Vulnerabilities

7.5.1.1. Methods of Treating Impacts in Adaptation Studies – Incremental to Transformational

The pervasiveness of climate impacts on food security and production (7.2), the commitment to future climate change from past greenhouse gas emissions (WGI SPM) and the very high likelihood of additional and likely greater climate changes from future greenhouse gas emissions (WGI SPM) means that some level of adaptation of food systems to climate change will be necessary. Here we take adaptation to mean reductions in risk and vulnerability through the actions of adjusting practices, processes and capital in response to the actuality or threat of climate change. This often involves changes in the decision environment, such as social and institutional structures, and altered technical options that can affect the potential or capacity for these actions to be realized. Adaptation can also enhance opportunities from climate change (AR4 WG2 Chapter 5; Chapter 17.2.3). These adaptations will need to be taken in the context of a range of other pressures on food security such as increasing demand as a result of population growth and increasing per capita consumption (7.1).

Following the AR4, the literature on adaptation and food production has increased substantially, although there has been less focus on adaptations to food systems and on value chains: the linked sets of activities that progressively add value as inputs are converted into products the market demands. Many adaptation frameworks or approaches have been published, informing the approach in the AR4 which addressed both autonomous and planned adaptations. Autonomous adaptations are incremental changes in the existing system including through the ongoing implementation of extant knowledge and technology in response to the changes in climate experienced. They include coping responses and are reactive in nature. Planned adaptations are proactive and can either adjust the broader system or transform it (Howden *et al.*, 2010). Adaptations can occur at a range of scales from field to policy. There is an increasing recognition in the literature that whilst many adaptation actions are local and build on past climate risk management experience, effective adaptation will often require changes in institutional arrangements and policies to strengthen the conditions favourable for effective adaptation including investment in new technologies, infrastructure, information and engagement processes (Chapters 14.3, 14.4, 15.2.4). Building adaptive capacity by decision-makers at all scales (Nelson *et al.*, 2008) is an increasingly important part of the adaptation discourse which has also further addressed costs, benefits, barriers and limits of adaptation (Adger *et al.*, 2009). The sector-specific nature of many adaptations means that sectors will initially be addressed separately below.

7.5.1.1.1. Cropping

Effective adaptation of cropping could be critical in enhancing food security and sustainable livelihoods, especially in developing countries (AR4 WG2 Chapter 5, Chapter 9.4.3.1). There is increasing evidence that farmers in some regions are already adapting to observed climate changes in particular altering cultivation and sowing times, crop cultivars and species) and marketing arrangements (Chapter 9.4.3.1, Fujisawa and Koyabashi; 2010, Olesen *et al.*, 2011) although this response is not ubiquitous (Bryan *et al.*, 2009). There are a large number of potential adaptations for cropping systems and for the food systems of which they are part, many of them enhancements of existing climate risk management and all of which need to be embedded in the wider farm systems and community contexts.

The possibility of extended growing seasons because of higher temperatures increasing growth in cooler months means that changing planting dates is a frequently identified option for cereals and oilseeds provided there is not an increase in drought at the end of the growing season (Krishnan *et al.*, 2007; Magrin *et al.*, 2009; Travasso *et al.*, 2009; Deressa *et al.*, 2009; Mary and Majule, 2009; Meza and Silva, 2009; Tingem and Rivington, 2009; Laux *et al.*, 2010; Stöckle *et al.*, 2010; Shimono *et al.*, 2010; Van de Geisen *et al.*, 2010; Tao and Zhang, 2010; Olesen *et al.*, 2011; Cho *et al.*, 2012). Aggregated across studies, changing planting dates may increase yields by a median of 3-17% but with substantial variation (Table 7-2). Early sowing is being facilitated by improvements in machinery and by the use of techniques such as dry sowing (Passioura and Angus, 2010), seedling transplanting and seed priming and these adaptations can be integrated with varieties with greater thermal time requirements so as to maximize production benefits and to avoid late spring frosts (Tingem and Rivington, 2009; Cho et al., 2012). There can however, be practical constraints to early sowing such as seedbed condition (van Oort et al. 2012). In some situations early sowing may allow double cropping or intercropping where currently only a single crop is feasible. For example, this could occur for irrigated maize in central Chile (Meza et al., 2008) and the double crop wheat/soybean in the southern pampas of Argentina (Monzon et. al., 2007), increasing productivity per unit land although increasing nitrogen and water demand at the same time. However, in Mediterranean climates, early sowing of cereals is dependent on adequate planting rains in autumn and climate projections indicate that this may decrease in many regions (WGI SPM), limiting the effectiveness of this adaptation and possibly resulting in later sowings than are currently practiced. In such circumstances, use of short duration cultivars could be desirable so as to reduce exposure to end of season droughts and high temperature events (Orlandini et al., 2008; Walter et al., 2010). There is *medium confidence* that optimisation of crop varieties and planting schedules appears to be effective adaptations, increasing yields by up to 23% compared with current managementwhen aggregated across studies (Table 7-2) (*medium evidence, high agreement*). This flexibility in planting dates and varieties according to seasonal conditions could be increasingly important with ongoing climate change (Meza et al., 2008; Deressa et al., 2009) and especially in dealing with projections of increased climate variability (Figure 7-6). Approaches that integrate climate forecasts at a range of scales in some cases are able to better inform crop risk management (Cooper et al., 2009; Sultan et al., 2010; Baethgen, 2010, Li et al. 2010) although such forecasts are not always useable or useful (Chapter 9.4.4; Lemos and Rood, 2010; Dilling and Lemos 2011)

[INSERT TABLE 7-2 HERE
Table 7-2: The simulated median benefit (difference between the yield change from baseline for the adapted and non-adapted cases) for different crop management adaptations: cultivar adjustment; planting date adjustment; adjusting planting date in combination with cultivar adjustment; adjusting planting date in combination with other adaptations; irrigation optimization; fertilizer optimization; other management adaptations. The numbers in parentheses are the 25th and 75th percentile. Data points where assessed benefit of management changes are negative are not included as farmers are unlikely to intentionally adopt these. Only studies with both a 'no adaptation' and an 'adaptation' assessment are used. Data taken from Abraha & Savage, 2006; Aggarwal & Mall, 2002; Alexandrov, 1999; Alexandrov et al., 2002; Butt et al., 2005; Challinor et al., 2009; Corobov, 2002; DeJong et al., 2001; Deryng et al., 2011; Droogers, 2004; Easterling et al., 2003; El-Shaher et al., 1997; Ewert et al., 2005; Gbetibouo & Hassan, 2005; Howden & Jones, 2004; Kaiser, 1999; Karim et al., 1996; Lal, 2011; Lal et al., 1998; Erda et al., 2005; Matthews & Wasmann, 2003; Moya et al., 1998; Reyenga et al., 1999; Rosenzweig et al., 1994; Southworth et al., 2000; Tao & Zhang, 2011; Tubiello et al., 2000; Thornton et al., 2010; Tingem & Rivington, 2009; Xiao et al., 2005; Yates & Strzepek, 1998; Zhang & Liu, 2005.]

Warmer conditions may also allow range expansion of cropping activities polewards in regions where low temperature has been a past limitation (*limited evidence, medium agreement*) provided varieties with suitable daylength response are available and soil and other conditions suitable. This may particularly occur in Russia, Canada and the Scandinavian nations although the potential may be less than earlier analyses indicated due to increased climate extremes, water limitations and various institutional barriers (Alcamo et al., 2007; Dronin and Kirilenko, 2011; Kulshreshtha, 2011; Kvalvik et al., 2011; Tchebakova et al., 2011; Bindi and Olesen, 2011). In many of these cases, the northerly range expansion may only offset the reduction in southerly cropping areas and yields due to lower rainfall, water shortages and high temperatures (*limited evidence, high agreement,*).

Improving cultivar tolerance to high temperature is a frequently identified adaptation for almost all crops and environments worldwide as high temperatures are known to reduce both yield and quality (Krishnan et al., 2007; Challinor et al., 2009; Wassmann et al., 2009; Luo et al., 2009; Shimono et al., 2010; Stöckle et al., 2010) noting that a new cultivar usually takes between eight and 20 years to deliver and so it is important to be selecting cultivars for expected future climate and atmospheric conditions (Ziska et al. 2012). Improving gene conservation and access to extensive gene banks could facilitate the development of cultivars with appropriate thermal time and thermal tolerance characteristics (Mercer et al., 2008; Wassmann et al., 2009) as well as to take advantage of increasing atmospheric CO_2 concentrations (Ziska et al., 2012) and respond to changing pest, disease and weed threats with these developments needing **t**o be integrated with *in situ* conservation of local varieties (IAASTD, 2009).

Similarly, the prospect of increasing drought conditions in many cropping regions of the world (Olesen et al., 2011) raises the need for breeding additional drought-tolerant crop varieties (Naylor et al., 2007; Mutekwa, 2009; Tao and Zhang, 2011), for enhanced storage and access to irrigation water, more efficient water delivery systems, improved irrigation technologies such as deficit irrigation, more effective water harvesting, agronomy that increases soil water retention through practices such as minimum tillage and canopy management, agroforestry, increase in soil carbon and more effective decision support (Verchot et al. 2007; Luo et al., 2009; Lioubimtseva and et al., 2009; Falloon and Betts, 2010; Piao et al., 2010; Olesen et al., 2011) amongst many other possible adaptations (Chapter 22.4.3.7.1). There is *medium confidence* (*limited evidence, high agreement*) that crop adaptations can lead to moderate yield benefits (mean of 10 to 20%) under persistently drier conditions (Deryng et al. 2011) and that irrigation optimisation for changed climate can increase yields by a median of 3.2% (Table 7-2) as well as having a range of other beneficial effects (Chapter 3.7).

Diversification of activities is another climate adaptation option for cropping systems (Lioubimtseva et al., 2009; Thornton et al., 2010). For example, Reidsma and Ewert (2008) found that regional farm diversity reduces the risk that is currently associated with unfavourable climate conditions in Europe. Diversification of activities often incorporates higher value activities or those that increase efficiency of a limited resource such as through increased water use efficiency (Thomas, 2008) or to reduce risk (Seo 2010). In some cases, increased diversification outside of agriculture may be favoured (Coulthard, 2008; Mary and Majule, 2009; Mertz et al., 2009a).

The above adaptations, either singly or in combination, could significantly reduce negative impacts of climate change and increase the benefit of positive changes as found in AR4 WG2 Chapter 5 (*medium evidence, high agreement,*). To quantify the benefits of adaptation, a meta-analysis of recent crop adaptation studies has been undertaken for wheat, rice and maize (see Figure 7-4). This meta-analysis adds more recent studies to that undertaken in the AR4 WG2 Chapter 5. It indicates that the average benefit (the yield difference between the adapted and non-adapted cases) of adapting crop management is equivalent to about 15 to 18% of current yields (Figure 7-8). This response is, however, extremely variable, ranging from negligible benefit from adaptation (even potential dis-benefit) to very substantial. The responses are dissimilar between wheat, maize and rice (Figure 7-4) with temperate wheat and tropical rice showing greater benefits of adaptation. The responses also differ markedly between adaptation management options (Table 7-2). For example, when aggregated over studies, cultivar adaptation (23%) and altering planting date in combination with other adaptations (3 to 17%) provide on average more benefit than optimizing irrigation (3.2%) or fertilisation (1%) to the new climatic conditions. These limits to yield improvements from agronomic adaptation and the increasingly overall negative crop yield impact with ongoing climate change (Figures 7-4 and 7-5) mean a substantial challenge in ensuring increases in crop production of 14% per decade given a population of nine billion people in 2050. This could be especially so for tropical wheat and maize where impacts from increases in temperature of more than 3ºC may more than offset benefits from agronomic adaptations (*limited evidence, medium agreement,*).

[INSERT FIGURE 7-8 HERE
Figure 7-8: Simulated yield benefit from adaptation calculated as the difference between the yield change from baseline (%) for paired non-adapted and adapted cases as affected by temperature and aggregated across all crops. The shaded bands at the 95% confidence interval are calculated as for Figure 7-4. Data points (n=31) where assessed benefit of management changes are negative are not included as farmers are unlikely to intentionally adopt these. Data sources are the same as for Table 7-2 and only studies that examine both a 'no adaptation' and an 'adaptation' scenario are used so as to avoid the issues arising from un-paired studies documented in Figure 7-4 for tropical maize.]

Potential increased variability of crop production means that other climate-affected aspects of food systems such as food reserve, storage and distribution policies and systems may need to be enhanced (IAASTD, 2009, Stathers et al. 2013) (*medium evidence, high agreement*) along with a range of broader, value-chain issues such as provision of effective insurance markets, clarity in property rights, building adaptive capacity and developing effective participatory research cultures (Chapter 9, AR4 WG2 Chapter 5).

It is notable that most of the above adaptations raised above and used in this analysis are essentially either incremental changes to existing agricultural systems or are systemic changes which integrate new aspects into current systems. Few could be considered to be transformative changes. Consequently, the potential adaptation benefits could be understated (*limited evidence, medium agreement*) (Rickards and Howden 2012).

7.5.1.1.2. Fisheries

Many of the resources for capture fisheries are already fully or overexploited with an estimated 30% of stocks overexploited in 2009 and 57% fully exploited (FAO, 2012). Comparable global statistics are not available for inland fisheries but the status of those stocks may not be any better. Overfishing is widely regarded as the primary pressure on marine fishery resources but other human activities including coastal and offshore mining, oil and gas extraction, coastal zone development, land-based pollution and other activities are also negatively impacting stock status and production (Rosenberg and Macleod, 2005; Cochrane *et al.,* 2009). In inland fisheries, overfishing is also widespread, coupled with many other impacts from other human activities (Allan et al., 2005). Climate change adds another compounding influence in both cases.

Adaptive responses to reduce the vulnerability of fisheries and fishing communities could include: management approaches and policies that strengthen the livelihood asset base; improved understanding of the existing response mechanisms to climate variability to assist in adaptation planning; recognising and responding to new opportunities brought about by climate change; monitoring biophysical, social and economic indicators linked to management and policy responses; and adoption of multi-sector adaptive strategies to minimise negative impacts (Allison *et al.,* 2009; Badjeck *et al.,* 2010; MacNeil *et al.,* 2010). Complementary adaptive responses include occupational flexibility, changing target species and fishing operations, protecting key functional groups and the establishment of insurance schemes (Coulthard, 2008; FAO, 2009; McNeil *et al.,* 2010; Koehn *et al.,* 2011; Daw *et al.,* 2009). Fishers and fish farmers will be vulnerable to extreme events such as flooding and storm surges which will require a range of adaptations including developing early warning systems for extreme events, provision of hard defences against flooding and surges, ensuring infrastructure such as ports and landing sites are protected, effective disaster response mechanisms and others (Daw *et al.,* 2009).

Governance and management of fisheries will need to follow an ecosystem approach to maximise resilience of the ecosystem, and to be adaptive and flexible to allow for rapid responses to climate induced change (Chapter 6.4.2; FAO, 2009; Daw *et al.,* 2009). Within an ecosystem approach, habitat restoration will frequently be a desirable adaptation option, particularly in freshwater and coastal environments (Koehn et al., 2011). A wide range of management tools and strategies have been developed to manage fisheries. These are all necessary but not sufficient for adaptation to climate change in fisheries (Grafton, 2010). Grafton argued that the standard tools for fisheries management were developed to control fishing mortality and to maintain adequate levels of recruitment to fishery stocks but without necessarily addressing the needs for resilience to change or to be able to function under changing climates. He therefore proposed that these conventional management tools must be used within processes that i) have a core objective to encourage ecosystems that are resilient to change and ii) that explicitly take into account uncertainties about future conditions and the effect of adaptation, and make use of models to explore the implications of these (Grafton, 2010). There are also opportunities for fisheries to contribute to mitigation efforts (FAO, 2009; Grafton, 2010).

Aquaculture is the fastest-growing animal-food-producing sector with per capita consumption of products increasing at an average rate of 7.1% p.a. between 1980 and 2010 (FAO, 2012). Adaptive responses in aquaculture include use of improved feeds and selective breeding for higher temperature tolerance strains to cope with increasing temperatures (De Silva and Soto, 2009) and shifting to more tolerant strains of molluscs to cope with increased acidification (Huppert *et al.*, 2009). Better planning and improved site selection to adapt to expected changes in water availability and quality; integrated water use planning that takes into account the water requirements and human benefits of fisheries and aquaculture in addition to other sectors; and improving the efficiency of water use in aquaculture operations are some of the other adaptation options (De Silva and Soto, 2009). Integrated water use planning will require making trade-offs between different land and water uses in the watershed (Mantua *et al.*, 2010). Insurance schemes accessible to small-scale producers would help to increase their resilience (De Silva and Soto, 2009). In some near-shore locations there may be a need to shift property lines as the mean high water mark is displaced landwards by rising sea level (Huppert *et al.*, 2009).

There are no simple, generic recipes for fisheries adaptation with Bell et al. (2011b) suggesting a list of 25 separate but inter-related actions, together with supporting policies to adapt fisheries and aquaculture in the tropical Pacific to climate change (Chapter 30.6.2.1.1). These actions fall into three categories according to the primary objective: economic development and government revenue; maintaining the contribution of fish to food security; and maximising sustainable livelihoods. Actions and policies for adaptation in fisheries and aquaculture must complement those for other sectors. Similar case-by-case, integrated planning will be required in all other regions and at scales from community to regional to achieve clearly defined adaptation goals.

7.5.1.1.3. Livestock

Extensive livestock systems occur over a huge range of biophysical and socio-ecological systems, with a consequent large range of potential adaptations. In many cases, these livestock systems are highly adapted to past climate risk, and there is *high confidence* that this provides a sound starting point for climate change adaptation (*medium evidence, high agreement*) (Thornton et al. 2009). These adaptations include matching stocking rates with pasture production, adjusting herd and water point management to altered seasonal and spatial patterns of forage production, managing diet quality (using diet supplements, legumes, choice of introduced pasture species and pasture fertility management), more effective use of silage, pasture spelling and rotation, fire management to control woody thickening, using more suitable livestock breeds or species, migratory pastoralist activities and a wide range of biosecurity activities to monitor and manage the spread of pests, weeds and diseases (Fitzgerald et al., 2008; Howden et al., 2008; Nardone et al., 2010; Ghahramani and Moore, 2013; Moore and Ghahramani, 2013). Combining adaptations can result in substantial increases in benefits in terms of production and profit when compared with single adaptations (Ghahramani and Moore, 2013; Moore and Ghahramani, 2013). In some regions, these activities can in part be informed by climate forecasts at differing time-scales to enhance opportunities and reduce risks including soil degradation (McKeon et al., 2009). Many livestock systems are integrated with or compete for land with cropping systems and one climate adaptation may be to change these relationships. For example, with increased precipitation, farmers in Africa may need to reduce their livestock holdings in favour of crops, but with rising temperatures, they may need to substitute small ruminants in place of cattle with small temperature increases or reduce stocking rates with larger temperature rises (Kabubo-Mariara, 2009; Thornton et al., 2010). As with other food systems there is a range of barriers to adaptation which could be addressed on-farm and off-farm by changes in infrastructure, establishment of functioning markets, improved access to credit, improved access to water and water management technologies, enhanced animal health services and enhanced knowledge adoption and information systems (Howden et al., 2008; Kabubo-Mariara, 2009; Mertz et al., 2009b, Silvestri et al. 2012).

Heat stress is an existing issue for livestock in some regions (*robust evidence, high agreement*), especially in higher productivity systems (7.3.2.6). For example, some graziers in Africa are already making changes to stock holdings in response to shorter term variations in temperatures (Chapter 9.4.3.1; Thornton et al. 2009). Breeding livestock with increased heat stress resistance is an adaptation often identified but there are usually trade-offs with productivity as well as benefits including animal welfare and so this option needs careful evaluation (Nardone et al., 2010) . Increased shade provision through trees or cost-effective structures can substantially reduce the incidence of high heat stress days, reduce animal stress and increase productivity, with spraying a less effective option (Gaughan et al. 2010; Nidumolu et al., 2011). In cooler climates, warming may be advantageous due to lesser need for winter housing and feed stocks.

7.5.1.1.4. Indigenous knowledge

Indigenous Knowledge (IK) has developed to cope with climate hazards contributing to food security in many parts of the world. Examples in the Americas include Alaska, where the Inuit knowledge of climate variability assured the source of food to hunters and reduced various risks (Ford 2009; Alessa et al., 2008; Weatherhead et al., 2010) down to the southern Andes where the Inca traditions of crop diversification, genetic diversity, raised bed cultivation, agroforestry, weather forecasting and water harvesting are still used in agriculture (Chapters 9.4.3.1, 27.3.4.2; Goodman-Elgar, 2008; Renard, 2011; McDowell and Hess, 2012). In Africa, weather forecasting, diversity of crops and agropastoralism strategies have been useful in the Sahel (Nyong et al., 2007). Rainwater harvesting has been a common practice in Sub-Saharan Africa (Biazin et al., 2012) to cope with dry spells and improve crop productivity, while strategies from agropastoralists in Kenya are related to drought forecasting based on the fauna, flora, moon, winds and other factors (Speranza et al., 2010). In South Africa, farmer's early warming indicators of wet or dry periods in Namibia based on animals, plants and climate observations contributed to deal with climatic variability (Newsham and Thomas, 2011). In the same way, in Asia and Australia IK plays an important role to assure food security of certain groups (Salick and Ross, 2009; Marin, 2010; Speranza et al., 2010; Green et al., 2010; Kalanda et al., 2011; Pareek and Trivedi, 2011; Biazin et al., 2012), although IK and the opportunities to implement it can differ according to gender and age in some communities (Chapter 9.3.5; Rengalakshmi, 2007; Turner and Clifton, 2009; Kalanda et al., 2011) leading to distinct adaptive capacities and options.

In addition to changes already occurring in climate (seasonal changes, changes in extreme events: IPCC 2012) projected changes beyond historical conditions could reduce the reliance on IK (Speranza et al., 2010; Kalanda et al., 2011; McDowell and Hess, 2012) affecting the adaptive capacity of a number of peoples globally (*medium evidence, medium agreement*). Moreover, there is *medium confidence* that some policies and regulations leading to limit the access to territories, promoting sedentarization, the substitution of traditional livelihoods, reduced genetic diversity and harvesting opportunities as well as loss of transmission of IK, may contribute to limit the adaptation to climate change in many regions (Nakashina et al., 2012) (*medium evidence, medium agreement*).

7.5.1.2. Practical Regional Experiences of Adaptation, including Lessons Learned

Given the early stages of climate change, there are relatively few unequivocal examples of adaptation (7.5.2) additional to existing climate risk management. Where there have been management changes these have often been in response to several driving variables of which climate is only one (Chapter 9.4.3.1; Smit and Wandel, 2006; Mertz et al., 2009a; Chen et al., 2011; Odgaard and et al., 2011. The preparedness to consider adaptation even within an industry varies regionally (Battaglini et al., 2009) and in some regions there already appears to be adaptation to climate change occurring (Chapter 9.4.3.1; Fujisawa and Koyabashi, 2010; Olesen et al., 2011; Bohensky et al., 2012). Activities to build adaptive capacity to better manage climate change are more widespread (Twomlow et al., 2008) but there remain questions as to how this capacity will evolve and be maintained (Nelson et al., 2009). Crucial in this will be devolution of the decision-making process so as to integrate local, contextual information into adaptation decision-making (Nelson et al., 2008).

7.5.1.3. Observed and Expected Barriers and Limits to Adaptation

Adaptation is strongly influenced by factors including institutional, technological, informational and economic and there can be barriers (restrictions that can be addressed) and limits in all these factors (Chapters 14, 15 and 16: *robust evidence, high agreement*). Several barriers to adaptation of food systems have been raised including inadequate information on the climate, climate impacts and on the risks and benefits of the adaptation options, lack of adaptive capacity, inadequate extension, institutional inertia, cultural acceptability, financial constraints including access to credit, insufficient fertile land, infrastructure, lack of functioning markets and insurance systems (Chapter 16; Bryan et al., 2009; Deressa et al., 2009; Kabubo-Mariara, 2009; De Bruin and Dellink, 2011, Silvestri et al. 2012). Limits to adaptation can occur for example where crop yields drop below the level required to sustain critical infrastructure such as sugar or rice mills (Park et al., 2012). In some cases, these can be effectively irreversible. Some studies have shown that access to climate information is not the principal limitation to improving decision making and it can result in perverse outcomes, increasing inequities and widening gender gaps (Coles and Scott, 2009). Incomplete adoption of adaptations may also occur.

Lack of technical options can also be a barrier to adaptation. New varieties of crops or breeds of livestock provide possible core adaptations of production systems (*medium evidence, high agreement;* Mercer et al., 2008; Tingem and Rivington, 2009) however, there is substantial investment needed to develop these along with delays before they are available, both of which can act as adaptation barriers. This may be addressed in part by investments to improve local crop varieties or livestock breeds that are easily adopted (IAASTD, 2009). There also can be physiological limits to performance such as upper temperature limits for heat tolerance (AR4 WG2 Chapter 5).

7.5.1.4. Facilitating Adaptation and Avoiding Maladaptation

Adaptation actions would usually be expected to provide benefits to farmers, the food industry along the value chain or perhaps to a broader community. However, there are possible maladaptations that arise from adapting too early or too late, by changing the incorrect elements of the food system or changing them by the incorrect amount (Chapter 14.7). A key maladaptation would be one which increased emissions of greenhouse gases, this making the underlying problem worse (Smith and Olesen, 2010); AR4 WG3 Chapter 11, *robust evidence, high agreement*). A recent review of agricultural climate change adaptation options found they tend to reduce greenhouse gas emissions (Smith and Olesen, 2010; Falloon and Betts, 2010) (*medium evidence, medium agreement*). These adaptations include measures that reduce soil erosion and loss of nutrients such as nitrogen and phosphorus, for increasing soil carbon, measures for conserving soil moisture and reducing temperature extremes by increasing vegetative cover.

There is a strong focus on incremental adaptation of existing food systems in the literature since AR4 (see above) however, and this may result in large opportunity costs that could arise from not considering more systemic adaptation or more transformative change (Howden et al., 2010; Kates et al., 2012) (*limited evidence, medium agreement*). For example, in the USA, changes in farming systems (i.e. the combination of crops) have been assessed as providing significant adaptation benefit in terms of net farm income (Prato et al., 2010) although in other regions this might be minor (Mandryk *et al*. 2012). There is a need to also engage farmers, policymakers and other stakeholders in evaluating transformative, pro-active, planned adaptations such as structural changes (Mäder et al., 2006; McCrum, 2009; Olesen et al., 2011). This could involve changes in land allocation and farming systems, breeding of functionally-different crop varieties, new land management techniques and new classes of service from lands such as ecosystem services (Rickards and Howden 2012). In Australia, industries including the wine, rice and peanut industries are already attempting transformative changes such as change in location so as to be early adopters of what are perceived as opportunities arising from change (Park et al., 2012).

There is substantial commonality in adaptation actions within different agricultural systems. For example, changing varieties and planting times are incremental adaptations found in studies of many different cropping systems as evidenced by the sample size in the meta-analysis in this chapter. Collating information on the array of adaptation options available for farmers, their relative cost and benefit and their broad applicability could be a way of initiating engagement with decision-makers. In the climate mitigation domain, this has been attempted using marginal abatement cost curves which identify mitigation options, their relative cost and the potential size of emission-reductions (AR4 WG3 Chapter 11). These curves can be used in setting investment priorities and informing policy discussions. The local nature of many adaptation decisions, their interactions with other highly contextual driving factors and the time and climate change-sensitive nature of adaptation decisions mean however, that global, time-independent curves are not feasible. The studies aggregated in Table 7-2 indicate that there are some options which may be more relevant and useful to consider than others. These results illustrate the potential scope and benefit of developing effective adaptation options if implemented in an adaptive management approach.

7.5.2. Food System Case Studies of Adaptation – Examples of Successful and Unsuccessful Adaptation

Incremental, systemic and transformational adaptation to climate change is beginning to be documented, though the peer-reviewed literature largely covers vulnerability assessments and intentions to act, not adaptation actions (Berrang-Ford et al., 2010).

Case 1: Incremental adaptation in the Sahel
Much of the literature covers incremental, reactive adaptation, but given actors are constantly adapting to changing social and economic conditions, incremental adaptation to climate change is difficult to distinguish from other actions (Berrang-Ford et al., 2010; Speranza, 2010), and in fact is usually a response to a complex of factors. This case, of the zaï soil management practice in the Sahel region, is an example where a complex of factors drives local actions, and factors such as growing land scarcity and new market opportunities, rather than climate, may be the primary factors (Barbier et al., 2009; Mertz, 2009b). Inherent poor soil quality and human activities have resulted in soil degradation – crusting, sealing, erosion by water and wind, and hardpan formation (Fatondji et al., 2009; Zougmoré et al., 2010). Zaï, a traditional integrated soil and water management practice, can combat land degradation and improve yield and decrease yield variability by concentrating runoff water and organic matter in small pits (20-40 cm in diameter and 10-15 cm deep) dug manually during the dry season and combined with contour stone bunds to slow runoff. A handful of animal manure or compost is placed in each pit. By breaking the soil crust, the pits facilitate greater water infiltration, while the applied organic matter improves soil nutrient status and attracts termites, which have a positive effect on soil structure. The zaï technique is very labour intensive requiring some 60 days of labour per hectare. Innovations to the system, involving animal-drawn implements, can reduce labour substantially.

Case 2: Mixed farming systems in Tanzania
In Morogoro, Tanzania, farming households have adapted in many ways to climatic and other stresses (Paavola, 2008). They have extended cultivation through forest clearance or reducing the length of the fallow period. Intensification is under way, through change in crop choices, increased fertiliser use and irrigation, and especially greater labour inputs. Livelihood diversification has been the main adaptation strategy – this has involved more non-farm income-generating activities, tapping into natural resources for subsistence and cash income (e.g. charcoal production), and has included artisanal gold and gemstone mining. Households have also altered their cropping systems, for example, by changing planting times. Migration is another frequently used strategy – with farmers moving to gain land, access markets or get employment. Parents also send children to cities to work for upkeep and cash income to reduce the household numbers that need to be supported by uncertain agricultural income. While many of these strategies help in terms of the short-term needs, in the longer term they may be reducing the capacity of households to cope. For instance, land cover change interacting with climate changes has negative impacts on current and future water supplies for irrigation (Natkhin *et al.*, 2013), and deforestation and forest degradation means faltering forest-based income sources. This will be particularly problematic to the more vulnerable groups in the community, including women and children.

7.5.3. Key Findings from Adaptations – Confidence Limits, Agreement, and Level of Evidence

There have been many studies of crop adaptation since the AR4. In aggregate these show that adaptations to changed temperature and precipitation will bring substantial benefit, (*robust evidence, high agreement*) with some adaptations (e.g. cultivar adaptation and planting date adjustment) assessed as on average being more effective than others (e.g. irrigation optimisation; 7.5.1.1.1). Most studies have assessed key farm-level adaptations such as changing planting dates and associated decisions to match evolving growing seasons and improving cultivar tolerance to high temperature, drought conditions and elevated CO_2 levels. Limits to adaptation will increasing emerge for such incremental adaptations as the climate further changes, raising the need for more systemic or transformational changes (*limited evidence, medium agreement,*; 7.5.1, 7.5.1.1). An example of transformational change is latitudinal expansion of cold-climate cropping zones polewards but this may be largely offset by reductions in cropping production in the mid-latitudes due to rainfall reduction and temperature increase (*medium confidence, limited evidence;* 7.5.1.1.1*).* Adaptations to food systems additional to the production phase have been identified and sometimes implemented but the benefits of these have largely not been quantified.

Livestock and fisheries systems also have available a large range of possible adaptations often tailored to local conditions but there is not adequate information to aggregate the possible value of these adaptations although there is *high confidence* (*medium evidence, high agreement*) that they will bring substantial benefit, particularly if implemented in combination (7.5.1.1.2, 7.5.1.1.3). Key livestock adaptations include matching stocking rates with pasture availability, water management, monitoring and managing the spread of pests, weeds and diseases, livestock breeding and adjusting to changed frequencies of heat stress and cold conditions (7.5.1.1.2). Fishery adaptations include management approaches and policies that strengthen the livelihood asset base, take a risk-based ecosystem approach to managing the resource and adoption of multi-sector adaptive strategies to minimise negative impacts. Importantly, there is an emerging recognition that existing fishery management tools and strategies are necessary but not sufficient for adaptation to climate (7.5.1.1.2).

Indigenous knowledge is an important resource in climate risk management and is important for food security in many parts of the world. Climate changes may be reducing reliance on indigenous knowledge in some locations but also some policies and regulation may be limiting the contribution that indigenous knowledge can make to effective climate adaptation (*medium evidence, medium agreement*; 7.5.1.1.4).

The focus on incremental adaptations and few studies on more systemic and transformational adaptation or adaptation across the food system mean that there may be underestimation of adaptation opportunities and benefits (*limited evidence, medium agreement;* 7.5.1.1). In addition to this, there is a range of limits and barriers to adaptation and many of these could be addressed by devolution of the decision-making process so as to integrate local, contextual information into adaptation decision-making. A schematic summary of these issues is given in Table 7-3.

[INSERT TABLE 7-3 HERE
Table 7-3: Schematic key risks for food security and the potentials for adaptation in the near- and long-term for high and low levels of warming.]

7.6. Research and Data Gaps – Food Security as a Cross-Sectoral Activity

Research and data gaps reflect that most work since AR4 has continued to concentrate on food production and has not included other aspects of the food system that connect climate change to food security. Features such as food processing, distribution, access and consumption have recently become areas of research interest in their own right but only tangentially attached to climate change.

Many studies either do not examine yield variability or do not report it. Closer attention should be paid to yield variability in the quantity and quality of food production, especially given observed price fluctuations associated with climate events. We expect environmental thresholds and tipping points, such as high temperatures, droughts and floods, to become more important in the future. Specific recommendations are for food production experiments in which changes in variability reflect predicted changes for given warming scenarios. Including thresholds in impact models, for especially high levels of global warming (i.e. 4-5 ^{o}C above pre-industrial), are highly likely to result in lower projections of yield, given changes in climate variability and increasing mean temperatures. Important gaps in knowledge continue to be studies of weeds, pests, and diseases, including animal diseases, in response to climate change and how related adaptation activities can be robustly incorporated into food security assessments. Yield and other agronomic data, at a range of spatial scales, are crucial to the development, evaluation and improvement of models. Model development is currently limited by lack of data.

Adaptation studies for cropping systems typically assess relatively minor agronomic management changes under future climate conditions only. Forthcoming studies should examine the impact of proposed adaptations when employed in the current climate. In this way management changes that are beneficial in a range of environments can be separated from management changes that are specificly targeted at climate change. Further, studies should be inclusive of the broader range of systemic and transformational adaptation options open to agriculture.

Current forecasts of changes in distribution and productivity of marine fish species and communities are typically at global or regional scale and include adaptations to only a limited extent. Increasing the resolution to forecast impacts and changes at the national and local ecosystem scale would provide valuable information to governments and stakeholders and enable them to prepare more effectively for expected impacts on food production and security offered by fisheries.

Possibilities for agronomic and breeding adaptations of food production to global warming are possible up to high levels of climate change. However, food security studies are urgently required to estimate the actual range of adaptations open to farmers and other actors in the food system and the implementation paths for these especially when possible changes in climate variability are included.

Frequently Asked Questions

FAQ 7.1: What factors determine food security and does low food production necessarily lead to food insecurity?
[to be placed in Section 7.2]
Observed data and many studies indicate that a warming climate has a negative effect to crop production, generally reduce yields of staple cereals such as wheat, rice and maize, which, however, differs between regions and latitudes. Elevated CO_2 could benefit crops yields in short term by increasing photosynthesis rates, however, there is big uncertainty in the magnitude of the CO_2 effect and that interactions with other factors. Climate change will affect fisheries and aquaculture through gradual warming, ocean acidification and through changes in the frequency, intensity and location of extreme events. Other aspects of the food chain are also sensitive to climate but such impacts are much less well known. Climate-related disasters are among the main drivers of food insecurity, both in the aftermath of a disaster and in the long run. Drought is a major driver of food insecurity, and contributes to a negative impact on nutrition. Floods and tropical storms also affect food security by destroying livelihood assets. The relationship between climate change and food production depends to a large degree on when and which adaptation actions are taken. Other links in the food chain from production to consumption are sensitive to climate but such impacts are much less well known.

FAQ 7.2: How could climate change interact with change in fish stocks, ocean acidification?
[to be placed in Section 7.4]
Millions of people rely on fish and aquatic invertebrates for their food security and as an important source of protein and some micronutrients. However, climate change will affect fish stocks and other aquatic species. For example, increasing temperatures will lead to increased production of important fishery resources in some areas but decreased production in others while increases in acidification will have negative impacts on important invertebrate species, including species responsible for building coral reefs which provide essential habitat for many fished species in these areas. The poorest fishers and others dependent on fisheries and subsistence aquaculture will be the most vulnerable to these changes, including those in small-island developing States, central and western African countries, Peru and Columbia in South America and some tropical Asian countries.

FAQ 7.3: How could adaptation actions enhance food security and nutrition? *[to be placed in Section 7.5]*
Over 70 per cent of agriculture is rain-fed. This suggests that agriculture, food security and nutrition are all highly sensitive to changes in rainfall associated with climate change. Adaptation outcomes focusing on ensuring food security under a changing climate could have the most direct benefits on livelihoods, which have multiple benefits

for food security, including: enhancing food production, access to markets and resources, and reduced disaster risk. Effective adaptation of cropping can help ensure food production and thereby contributing to food security and sustainable livelihoods in developing countries, by enhancing current climate risk management. There is increasing evidence that farmers in some regions are already adapting to observed climate changes in particular altering cultivation and sowing times and crop cultivars and species. Adaptive responses to climate change in fisheries could include: management approaches and policies that maximize resilience of the exploited ecosystems, ensuring fishing and aquaculture communities have the opportunity and capacity to respond to new opportunities brought about by climate change, and the use of multi-sector adaptive strategies to reduce the consequence of negative impacts in any particular sector. However, these adaptations will not necessarily reduce all of the negative impacts of climate change, and the effectiveness of adaptations could diminish at the higher end of warming projections.

Cross-Chapter Boxes

Box CC-HS. Heat Stress and Heat Waves

[Lennart Olsson (Sweden), Dave Chadee (Trinidad and Tobago), Ove Hoegh-Guldberg (Australia), John Porter (Denmark), Hans-O. Pörtner (Germany), Kirk Smith (USA), Maria Isabel Travasso (Argentina), Petra Tschakert (USA)]

Heat waves are periods of abnormally and uncomfortably hot weather during which the risk of heat stress on people and ecosystems is high. The number and intensity of hot days have increased markedly in the last three decades (Coumou et al., 2013) (*high confidence*). According to WG I, it is *likely* that the occurrence of heat waves has more than doubled in some locations due to human influence and it is *virtually certain* that there will be more frequent hot extremes over most land areas in the latter half of the 21st century. Coumou et al. (2013) predicted that, under a medium warming scenario, the number of monthly heat records will be over 12 times more common by the 2040s compared to a non-warming world. In a longer time perspective, if the global mean temperature increases to +10C or more, the habitability of large parts of the tropics and mid-latitudes will be at risk (Sherwood and Huber, 2010). Heat waves affect natural and human systems directly, often with severe losses of lives and assets as a result, and they may act as triggers for tipping points (Hughes et al., 2013). Consequently, heat waves play an important role in several key risks noted in Chapter 19 and CC-KR.

Economy and Society [Ch 10, 11, 12, 13]

Environmental heat stress has already reduced the global labor capacity to 90% in peak months with a further predicted reduction to 80% in peak months by 2050. Under a high warming scenario (RCP8.5), labor capacity is expected to be less than 40% of present day conditions in peak months by 2200 (Dunne et al., 2013). Adaptation costs for securing cooling capacities and emergency shelters during heat waves will be substantial.

Heat waves are associated with social predicaments such as increasing violence (Anderson, 2012) as well as overall health and psychological distress and low life satisfaction (Tawatsupa et al., 2012). Impacts are highly differential with disproportional burdens on poor people, elderly people, and those who are marginalized (Wilhelmi et al., 2012). Urban areas are expected to suffer more due to the combined effect of climate and the urban heat island effect (Fischer et al., 2012). In LICs and MICs, adaptation to heat stress is severely restricted for most people in poverty and particularly those who are dependent on working outdoors in agriculture, fisheries, and construction. In small-scale agriculture, women and children are particularly at risk due to the gendered division of labor (Croppenstedt et al., 2013). The expected increase in wildfires as a result of heat waves (Pechony and Shindell, 2010) is a concern for human security, health, and ecosystems. Air pollution from wildfires already causes an estimated 339,000 premature deaths per year worldwide (Johnston et al., 2012).

Human Health [Ch 11]

Morbidity and mortality due to heat stress is now common all over the world (Barriopedro *et al.*, 2011; Rahmstorf and Coumou, 2011; Nitschke et al., 2011; Diboulo et al., 2012; Hansen et al., 2012). People in physical work are at particular risk as such work produces substantial heat within the body, which cannot be released if the outside temperature and humidity is above certain limits (Kjellstrom et al., 2009). The risk of non-melanoma skin cancer from exposure to UV radiation during summer months increases with temperature (van der Leun, Jan C et al., 2008).

Increase in ozone concentrations due to high temperatures affects health (Smith et al., 2010), leading to premature mortality, e.g. cardiopulmonary mortality (Smith et al., 2010). High temperatures are also associated with an increase in air-borne allergens acting as a trigger for respiratory illnesses such as asthma, allergic rhinitis, conjunctivitis, and dermatitis (Beggs, 2010).

Ecosystems [Ch 4, 5, 6, 30]

Tree mortality is increasing globally (Williams et al., 2012) and can be linked to climate impacts, especially heat and drought (Reichstein et al., 2013), even though attribution to climate change is difficult due to lack of time series and confounding factors. In the Mediterranean region, higher fire risk, longer fire season, and more frequent large, severe fires are expected as a result of increasing heat waves in combination with drought (Duguy et al., 2013), Box 4.2.

Marine ecosystem shifts attributed to climate change are often caused by temperature extremes rather than changes in the average (Pörtner and Knust, 2007). During heat exposure near biogeographical limits, even small (<0.5°C) shifts in temperature extremes can have large effects, often exacerbated by concomitant exposures to hypoxia and/or elevated CO_2 levels and associated acidification (Hoegh-Guldberg et al., 2007), Figure 6-5, (*medium confidence*) [Ch 6.3.1, 6.3.5; 30.4; 30.5; CC-MB]

Most coral reefs have experienced heat stress sufficient to cause frequent mass coral bleaching events in the last 30 years, sometimes followed by mass mortality (Baker et al., 2008). The interaction of acidification and warming exacerbates coral bleaching and mortality (*very high confidence*).Temperate seagrass and kelp ecosystems will decline with the increased frequency of heat waves and through the impact of invasive subtropical species (*high confidence*). [Ch 5, 6, 30.4-30.5, CC-CR, CC-MB]

Agriculture [Ch 7]

Excessive heat interacts with key physiological processes in crops. Negative yield impacts for all crops past +3C of local warming without adaptation, even with benefits of higher CO_2 and rainfall, are expected even in cool environments (Teixeira et al., 2011). For tropical systems where moisture availability or extreme heat limits the length of the growing season, there is a high potential for a decline in the length of the growing season and suitability for crops (*medium evidence, medium agreement*) (Jones and Thornton, 2009). For example, half of the wheat-growing area of the Indo-Gangetic Plains could become significantly heat-stressed by the 2050s.

There is *high confidence* that high temperatures reduce animal feeding and growth rates (Thornton et al., 2009). Heat stress reduces reproductive rates of livestock (Hansen, 2009), weakens their overall performance (Henry et al., 2012), and may cause mass mortality of animals in feedlots during heat waves (Polley et al., 2013). In the U.S., current economic losses due to heat stress of livestock are estimated at several billion USD annually (St-Pierre et al., 2003).

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Anthropogenic ocean acidification and global warming share the same primary cause, which is the increase of atmospheric CO_2 (Figure OA-1A; WGI, 2.2.1). Eutrophication, loss of sea ice, upwelling and deposition of atmospheric nitrogen and sulphur all exacerbate ocean acidification locally (5.3.3.6, 6.1.1, 30.3.2.2).

[INSERT FIGURE OA-1 HERE
Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.]

Chemistry and Projections

The fundamental chemistry of ocean acidification is well understood (*robust evidence, high agreement*). Increasing atmospheric concentrations of CO_2 result in an increased flux of CO_2 into a mildly alkaline ocean, resulting in a reduction in pH, carbonate ion concentration, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of the surface layers of the open ocean can be projected at the global scale with high accuracy using projections of atmospheric CO_2 levels (Fig. CC-OA-1B). Observations of changing upper ocean CO_2 chemistry over time support this linkage (WGI Table 3.2 and Figure 3.18; Figures 30.8, 30.9). Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGI, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration). Projections of regional changes, especially in the highly complex coastal systems (5.3.3.6, 30.3.2.2), in polar regions (WGI 6.4.4), and at depth are more difficult but generally follow similar trends.

Biological, Ecological, and Biogeochemical Impacts

Investigations of the effect of ocean acidification on marine organisms and ecosystems have a relatively short history, recently analyzed in several metaanalyses (6.3.2.1, 6.3.5.1). A wide range of sensitivities to projected rates of ocean acidification exists within and across diverse groups of organisms, with a trend for greater sensitivity in early life stages (*high confidence*; 5.4.2.2, 5.4.2.4, 6.3.2). A pattern of positive and negative impacts emerges (*high confidence*; Fig. OA-1C) but key uncertainties remain in our understanding of the impacts on organisms, life histories and ecosystems. Responses can be influenced, often exacerbated by other drivers, such as warming, hypoxia, nutrient concentration, and light availability (*high confidence*; 5.4.2.4, 6.3.5).

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*; 5.4.2.3, 6.3.2.2-3, 30.5.6). Harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may stimulate nitrogen fixation (*limited evidence, low agreement*; 6.3.2.2). It decreases the rate of calcification of most, but not all, sea-floor calcifiers (*medium agreement, robust evidence*) such as reef-building corals (Box CC-CR), coralline algae, bivalves and gastropods reducing the competitiveness with non-calcifiers (5.4.2.2, 5.4.2.4, 6.3.2.5). Ocean warming and acidification promote higher rates of calcium carbonate dissolution resulting in the net dissolution of carbonate sediments and frameworks and loss of associated habitat (*medium confidence*; 5.4.2.4, 6.3.2.5, 6.3.5.4-5). Some corals and temperate fishes experience disturbances to behavior, navigation and their ability to tell conspecifics from predators (6.3.2.4). However, there is no evidence for these effects to persist on evolutionary timescales in the few groups analyzed (6.3.2).

Some phytoplankton and mollusks displayed adaptation to ocean acidification in long-term experiments (*limited evidence, medium agreement*; 6.3.2.1), indicating that the long-term responses could be less than responses obtained in short-term experiments. However, mass extinctions in Earth history occurred during much slower rates of ocean acidification, combined with other drivers changing, suggesting that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of future change (*medium confidence*; 6.1.2).

Projections of ocean acidification effects at ecosystem level are made difficult by the diversity of species-level responses. Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.3.2.5, 6.3.5-6), which could impact food webs and higher trophic levels (*limited evidence, high agreement*). Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities (Box CC-CR; 5.4.2.3, 6.3.2.5, 30.3.2.2, 30.5). Shifts in community structure have also been documented in regions with rapidly declining pH (5.4.2.2).

Due to an incomplete understanding of species-specific responses and trophic interactions the effect of ocean acidification on global biogeochemical cycles is not well understood (*limited evidence, low agreement*) and represents an important knowledge gap. The additive, synergistic or antagonistic interactions of factors such as temperature, concentrations of oxygen and nutrients, and light are not sufficiently investigated yet.

Risks, Socioeconomic Impacts and Costs

The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, include both the probability that ocean acidification will affect fundamental physiological and ecological processes of organisms (6.3.2.1), and the magnitude of the resulting impacts on ecosystems and the ecosystem services they provide to society (Box 19-2). For example, ocean acidification under RCP4.5 to RCP8.5 will impact formation and maintenance of coral reefs (*high confidence*; Box CC-CR, 5.4.2.4) and the goods and services that they provide such as fisheries, tourism and coastal protection (*limited evidence, high agreement*; Box CC-CR, 6.4.1.1,19.5.2, 27.3.3, 30.5, 30.6). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Global estimates of observed or projected economic costs of ocean acidification do not exist. The largest uncertainty is how the impacts on lower trophic levels will propagate through the food webs and to top predators. However, there are a number of instructive examples that illustrate the magnitude of potential impacts of ocean acidification. A decrease of the production of commercially-exploited shelled mollusks (6.4.1.1) would result in a reduction of US production of 3 to 13% according to the SRES A1FI emission scenario (*low confidence*). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (*limited evidence, medium agreement*). Models suggest that ocean acidification will generally reduce fish biomass and catch (*low confidence*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (6.4.1.1). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 528 billion USD, respectively for the A1 and B2 SRES emission scenarios (*low confidence*; 6.4.1). Although this number is small compared to global GDP, it can represent a very large GDP loss for the economies of many coastal regions or small islands that rely on the ecological goods and services of coral reefs (25.7.5, 29.3.1.2).

Mitigation and Adaptation

Successful management of the impacts of ocean acidification includes two approaches: mitigation of the source of the problem (i.e. reduce anthropogenic emissions of CO_2), and/or adaptation by reducing the consequences of past and future ocean acidification (6.4.2.1). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts (6.4.2.1). Climate geoengineering techniques based on solar radiation management will not abate ocean acidification and could increase it under some circumstances (6.4.2.2). Geoengineering techniques to remove carbon dioxide from the atmosphere could directly address the problem but are very costly and may be limited by the lack of CO_2 storage capacity (6.4.2.2). Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep-water oxygen levels (6.4.2.2; 30.3.2.3 and 30.5.7). A low-regret approach, with relatively limited effectiveness, is to limit the number and the magnitude of drivers other than CO_2, such as nutrient pollution (6.4.2.1). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Some adaptation strategies include drawing water for aquaculture from local watersheds only when pH is in the right range, selecting for less sensitive species or strains, or relocating industries elsewhere (6.4.2.1).

Box CC-WE. The Water-Energy-Food/Feed/Fiber Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Kenneth M. Strzepek (UNU / USA), Blanca Elena Jimenez Cisneros (Mexico), Andy Reisinger (New Zealand), FerencToth (IAEA / Hungary), Taikan Oki (Japan)]

Water, energy, and food/feed/fiber are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure WE-1. The depth and intensity of those linkages vary enormously between countries, regions and production systems. Energy technologies (e.g. biofuels, hydropower, thermal power plants), transportation fuels and modes, and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops and forages) may require significant amounts of water (Sections 3.7.2, 7.3.2, 10.2, 10.3.4, 22.3.3, 25.7.2; Allan, 2003; King and Weber 2008; McMahon and Price, 2011; Macknick *et al*., 2012a). In irrigated agriculture, climate, irrigating procedure, crop choice and yields determine water requirements per unit of produced crop. In areas where water (and wastewater) must be pumped and/or treated, energy must be provided (Asano et al., 2006; Khan and Hanjra, 2009; USEPA, 2010; Gerten et al., 2011). While food production, refrigeration, transport and processing require large amounts of energy (Pelletier et al., 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (Section 7.3.2, Box 25-10; Diffenbaugh et al., 2012; Skaggs et al., 2012) *(robust evidence, high agreement)*. Food and crop wastes, and wastewater, may be used as sources of energy, saving not only the consumption of conventional non-renewable fuels used in their traditional processes, but also the consumption of the water and energy employed for processing or treatment and disposal (Schievano et al., 2009; Sung et al., 2010; Olson, 2012). Examples of this can be found in several countries across all income ranges. For example, sugar cane by-products are increasingly used to produce electricity or for cogeneration (McKendry, 2002; Kim and Dale 2004) for economic benefits, and increasingly as an option for greenhouse gas mitigation.

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change. The interlinkages of supply/demand, quality and quantity of water, energy and food/feed/fiber with changing climatic conditions have implications for both adaptation and mitigation strategies.]

Most energy production methods require significant amounts of water, either directly (e.g., crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Sections 10.2.2 10.3.4, 25.7.4; van Vliet et al., 2012; Davies et al., 2013) *(robust evidence, high agreement)*. Water for biofuels, for example, under the IEA Alternative Policy Scenario, which has biofuels production increasing to 71 EJ in 2030, has been reported by Gerbens-Leenes et al. (2012) to drive global consumptive irrigation water use from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water is also required for mining (Section 25.7.3), processing, and residue disposal of fossil and nuclear fuels or their byproducts. Water for energy currently ranges from a few percent in most developing countries to more than 50% of freshwater withdrawals in some developed countries, depending on the country (Kenny et al., 2009; WEC, 2010). Future water requirements will depend on electricity demand growth, the portfolio of generation technologies and water management options employed (WEC, 2010; Sattler et al., 2012) *(medium evidence, high agreement)*. Future water availability for energy production will change due to climate change (Sections 3.4, 3.5.1, 3.5.2.2) *(robust evidence, high agreement)*.

Water may require significant amounts of energy for lifting, transport and distribution and for its treatment either to use it or to depollute it. Wastewater and even excess rainfall in cities requires energy to be treated or disposed. Some non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced potable water from ground/surface water sources vs. desalinated seawater (Box 25-2, Tables 25-6 and 25-7; Macknick et al., 2012b; Plappally and Lienhard, 2012). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user; Döll et al., 2012) is generally more energy intensive than surface water. In India, for example, 19% of total electricity use in 2012 was for agricultural purposes (Central Statistics Office, 2013), with a large share for groundwater pumping. Pumping from greater depth increases energy demand significantly– electricity use (kWhr/m^3 of water) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard, 2012). The reuse of appropriate wastewater for irrigation (reclaiming both water and energy-intense nutrients) may increase agricultural yields, save energy, and prevent soil erosion (Smit and Nasr, 1992; Jimenez, 1996; Wichelns et al., 2007; Raschid-Sally and Jayakody, 2008) *(medium confidence)*. More energy efficient treatment methods enable poor quality ("black") wastewater to be treated to quality levels suitable for discharge into water courses, avoiding additional fresh water and associated energy demands (Keraita et al, 2008). If properly treated to retain nutrients, such treated water may increase soil productivity, contributing to increased crop yields/food security in regions unable to afford high power bills or expensive fertilizer (Oron, 1996; Lazarova and Bahri, 2005; Redwood and Huibers, 2008; Jimenez, 2009) *(high confidence)*.

Linkages among water, energy, food/feed/fiber and climate are also strongly related to land use and management (Section 4.4.4, Box 25-10) *(robust evidence, high agreement)*. Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and compromises food security (Sections 3.7.2, 4.4.4). On the other hand, afforestation activities to sequester carbon have important co-benefits of reducing soil erosion and providing additional (even if only temporary) habitat (see Box 25-10) but may reduce renewable water resources. Water abstraction for energy, food or biofuel production or carbon sequestration can also compete with minimal environmental flows needed to maintain riverine habitats and wetlands, implying a potential conflict between economic and other valuations and uses of water (Sections 25.4.3 and 25.6.2, Box 25-10) *(medium evidence, high agreement)*. Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water and climate (McCornick et al., 2008; Bazilian et al., 2011; Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy and water demand, bioproductivity and other factors (see Figure WE-1 and Wise et al., 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this report.

The interconnectivity of food/fiber, water, land use, energy and climate change, including the perhaps not yet well understood cross-sector impacts, are increasingly important in assessing the implications for adaptation/mitigation policy decisions. Fuel-food-land use-water-GHG mitigation strategy interactions, particularly related to bioresources for food/feed, power, or fuel, suggest that combined assessment of water, land type and use requirements, energy requirements and potential uses and GHG impacts often epitomize the interlinkages. For example, mitigation scenarios described in the IPCC Special Report on Renewable Energy Sources and Climate Change Mitigation (IPCC, 2011) indicate up to 300EJ of biomass primary energy by 2050 under increasingly stringent mitigation scenarios. Such high levels of biomass production, in the absence of technology and process/management/operations change, would have significant implications for land use, water and energy, as well as food production and pricing. Consideration of the interlinkages of energy, food/feed/fiber, water, land use and climate change is increasingly recognized as critical to effective climate resilient pathway decision making *(medium evidence, high agreement)*, although tools to support local- and regional-scale assessments and decision-support remain very limited.

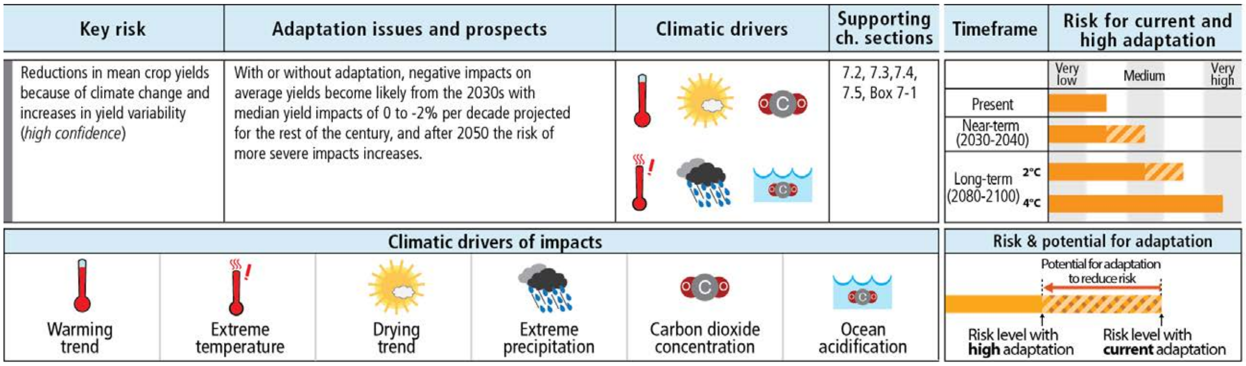
Table 7-1: Households divided into five categories of food access, indicating the impacts of food price increases.

Food Access Category	**Characteristics**	**Impacts of food price increase on food access**
Primarily subsistence (autarkic)	Subsistence farmers, herders, fishers and forest dependent populations; generally low share of population (Karfakis et. al. 2011)	Limited impact.
Food producers: net sellers	Generally lower share of population compared with net buyers (Aksoy and Sid-Dimelik; 2008; Zezza et al. 2008; FAO 2011)	Positive impact through increased income effect. Major beneficiaries are those with greatest surplus (e.g. larger, more commercialized farms) (FAO 2011)
Food producers: net buyers	Majority of poor rural households (IFAD, 2010; FAO, 2011)	Ambiguous: depends on relative size of income and price effects, but generally expected to be negative due to high share of income spent on food (Ivanic and Martin 2008; FAO, 2011; Ivanic et. al., 2011)
Rural non-farming households	Rural landless: characterized by high rates of food insecurity; average share of population for 15 low income countries was 22% (Aksoy et. al.)	Negative impact due to high share of income spent on food; however some limited evidence that wage increases may accompany price increases in which case overall effects are ambiguous. (FAO 2011; Aksoy and Sid-Dikmelik 2008).
Urban consumers	Growing share of population in most countries (IFAD 2010)	Negative impact by reducing food affordability. Especially vulnerable to changes in global food prices, as they are more likely to consume staple foods derived from tradable commodities (FAO, 2008a; Ivanic et al. 2011).

Table 7-2: The simulated median benefit (difference between the yield change from baseline for the adapted and non-adapted cases) for different crop management adaptations: cultivar adjustment; planting date adjustment; adjusting planting date in combination with cultivar adjustment; adjusting planting date in combination with other adaptations; irrigation optimization; fertilizer optimization; other management adaptations. The numbers in parentheses are the 25th and 75th percentile. Data points where assessed benefit of management changes are negative are not included as farmers are unlikely to intentionally adopt these. Only studies with both a 'no adaptation' and an 'adaptation' assessment are used. Data taken from Abraha & Savage, 2006; Aggarwal & Mall, 2002; Alexandrov, 1999; Alexandrov et al., 2002; Butt et al., 2005; Challinor et al., 2009; Corobov, 2002; DeJong et al., 2001; Deryng et al., 2011; Droogers, 2004; Easterling et al., 2003; El-Shaher et al., 1997; Ewert et al., 2005; Gbetibouo & Hassan, 2005; Howden & Jones, 2004; Kaiser, 1999; Karim et al., 1996; Lal, 2011; Lal et al., 1998; Erda et al., 2005; Matthews & Wasmann, 2003; Moya et al., 1998; Reyenga et al., 1999; Rosenzweig et al., 1994; Southworth et al., 2000; Tao & Zhang, 2011; Tubiello et al., 2000; Thornton et al., 2010; Tingem & Rivington, 2009; Xiao et al., 2005; Yates & Strzepek, 1998; Zhang & Liu, 2005.

Management option	Cultivar adjustment (n=56)	Planting date adjustment (n=19)	Planting date and cultivar adjustment (n=152)	Irrigation optimisation (n=17)	Fertiliser optimisation (n=10)	Other (n=9)
Benefit (%) from using adaptation	23 (6.8, 35.9)	3 (2.1, 8.3)	17 (9.9, 26.1)	3.2 (2, 8.2)	1 (0.25, 4.8)	6.45 (3.2, 12.8)

Table 7-3: Schematic key risks for food security and the potentials for adaptation in the near- and long-term for high and low levels of warming.



Box 7-1 Table

Projected Impacts for Crops and Livestock in Global Regions and Sub-Regions under Future Scenarios

Crop yield impacts in () correspond to () in the scenario column. - CO_2, without CO_2 effects; + CO_2, with CO_2 effects; I, irrigated; R, rainfed. In Europe: Atl., Atlantic; Cont., continental; Med., Mediterranean. pp, precipitation. N, north; E, east; W, west; S, south; C, central.

Regional Impacts on Livestock

Region	Sub-region	Climate change impacts	Scenarios	Reference
Africa	Botswana	Cost of supplying water from boreholes could increase by 23% due to increased hours of pumping, under drier and warmer conditions.	2050	Chapter 22
	Lowlands of Africa	Reduced stocking of dairy cows, a shift from cattle to sheep and goats, due to high temperature.	2050	Chapter 22
		Livestock keeping could benefit from increased temperature.		
	Highlands of East Africa	Maize stover availability head per head of cattle may decrease due to water scarcity.	2050	Chapter 22
	East Africa	Dairy yields decrease by 10-25%.	2050	Chapter 22
	South Africa		2046-2065/2080 - 2100 ECHAM5/MPI-OM, GFDL-CM2.0/2, MRI-CGCM2.3.2 (A2)	Nesamvuni et al. 2012
Europe	Netherlands	Dairy production affected at daily mean temperatures above 18°C.		Chapter 23
	Italy	Mortality risk to dairy cattle increased by 60%by exposure to high air temp. and high air humidity during breeding.		Chapter 23
	France	No impact on dairy yields.	ARPEGE (A2) 1970-1999, 2020-2049, 2070-2099	Graux et al, 2011
	French Uplands	Annual grassland production system significantly reduced by four year exposure to climatic conditions.	A2, 2070s	Graux et al, 2011
	Ireland, France	Grassland dairy system increases potential of dairy production, with increased risk of summer-autumn forage failure in France.	A1B, by the end of century	Graux et al, 2011
	Overall Europe	Spread of bluetongue virus (BTV) in sheep and ticks in cattle due to climate warming.	2080	Graux et al. 2011
		No increase in risk of incursion of Crimean-Congo haemorrhagic fever virus in livestock		Chapter 23

Austral-asia	Northern Australia	3ºC increase will cause 4% reduction in gross value of beef, sheep and wool sector.	Rainfall: - or + 10%, A1B, 2030	Chapter 25
	Australia (other than Tasmania)	Dairy output will decline under 1ºC increase in temperature.	2030	Chapter 25
	25 sites in southern Australia	Profitability of fodder supply production decline at most sites due to shorter growing season.	2050	Chapter 25
	Southern Australia	Decline in NPP of grassland from historical climate will be 7% in 2030, 9% in 2050 and 14% in 2070. Operating profit to fall by 27% in 2030, 32% in 2050 and 48% in 2070.	SRES A2; 2030, 2050, 2070	Moore and Ghahramani, 2013
	Tasmania Victoria NSW S. Australia	Dairy yields increase 0.5-6.2% Dairy yields decrease 1.3-6.7% Dairy yields decrease 1.4-6.6% Dairy yields decrease 2.2-8.1%	ECHAM5/MPI-OM (A1B) 2050	Hanslow et al. 2012
	New Zealand	National pasture production for dairy, beef and sheep will decrease by 4%.	2030	Wratt et al., 2008
Central and South America	Andean Mountain countries	Beef and dairy cattle, pigs and chicken could decrease between 0.9 and 3.2% while sheep could increase by 7%.	Hot and dry scenario, 2060	Chapter 27
	Columbia Venezuela Ecuador	Beef cattle choice declined.	Milder and wet scenario, 2060	Chapter 27
	Argentina & Chile	Beef cattle choice increased.	Future climate change	Chapter 27
	Brazil	Milk production and feed intake in cattle strongly affected.		Silva et al., 2009
North America	Central USA	Dairy yields decrease 16-30%.	CGCMI/Hadley, Baseline CO_2/2x CO_2/3x CO_2	Mader et al, 2009

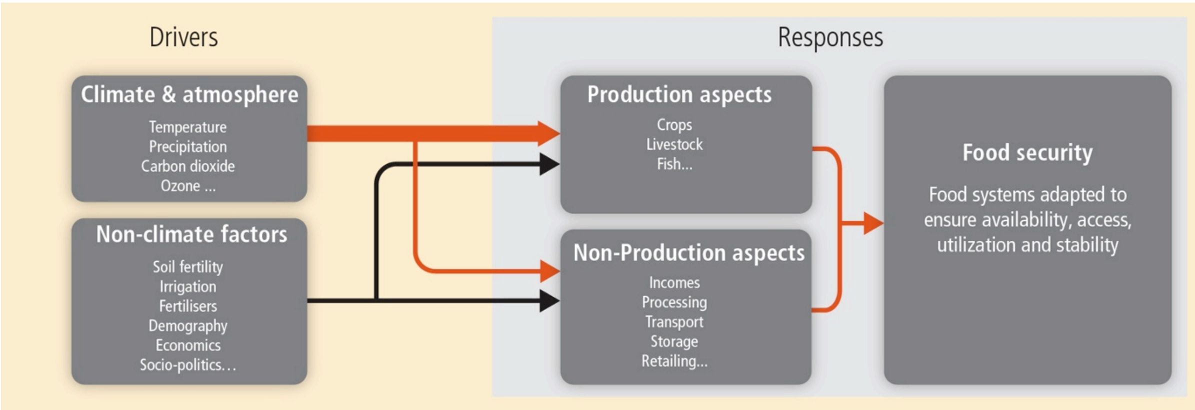

Figure 7-1: Main issues of the chapter. Drivers are divided into climate and non-climate elements, affecting production and non-production elements of food systems, thereafter combining to provide food security. The thickness of the red lines is indicative of the relative availability of refereed publications on the two elements.

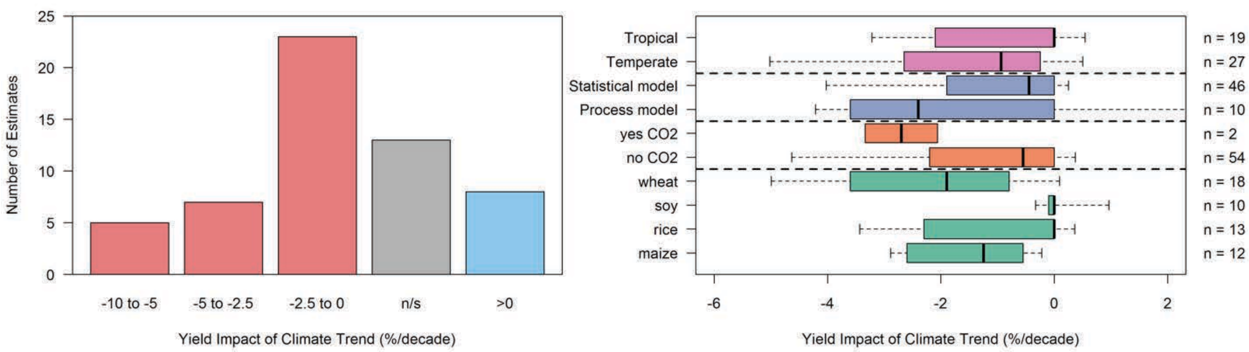

Figure 7-2: Summary of estimates of the impact of recent climate trends on yields for four major crops. Studies were taken from the peer-reviewed literature and used different methods (i.e., physiological process-based crop models or statistical models), spatial scales (stations, provinces, countries, or global), and time periods (median length of 29 years). Some included effects of positive CO_2 trends (7.3.2.1.2) but most did not. (a) shows number of estimates with different level of impact (% yield per decade), (b) shows boxplot of estimates separated by temperate vs. tropical regions, modelling approach (process-based vs. statistical), whether CO_2 effects were included, and crop. Boxplots indicate the median (vertical line), 25th-75th percentiles (box), and 10th-90th percentiles (whiskers) for estimated impacts in each category, and n indicates the number of estimates. Studies were for China (Tao *et al.*, 2006; Tao *et al.*, 2008; Wang *et al.*, 2008; You *et al.*, 2009; Chen *et al.*, 2010; Tao *et al.*, 2012), India (Pathak *et al.*,2003; Auffhammer *et al.*, 2012), United States (Kucharik and Serbin, 2008), Mexico (Lobell *et al.*, 2005), France (Brisson *et al.*, 2010; Licker *et al.*, 2013) Scotland (Gregory and Marshall, 2012), Australia (Ludwig *et al.*, 2009), Russia (Licker *et al.*, 2013), and some studies for multiple countries or global aggregates (Lobell and Field, 2007; Welch *et al.*, 2010; Lobell *et al.*, 2011). Values from all studies were converted to percentage yield change per decade. Each study received equal weighting as insufficient information was available to judge the uncertainties of each estimate. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

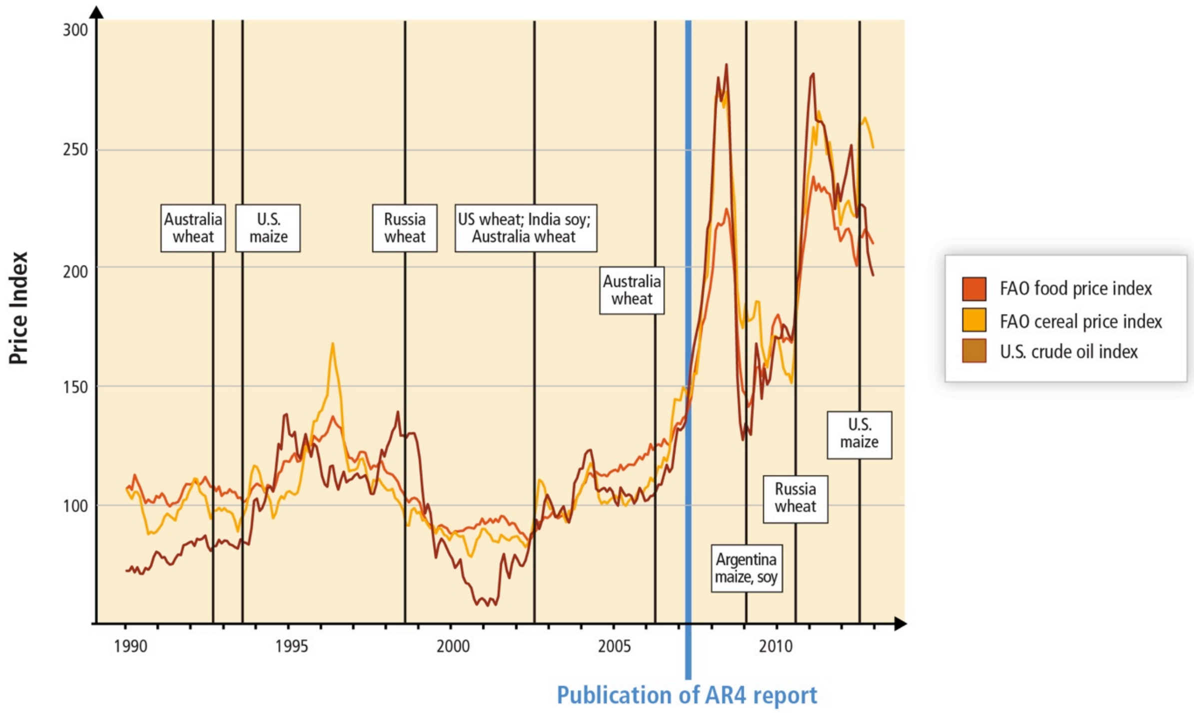

Figure 7-3: Since the AR4 report, international food prices have reversed historical downward trend. Plot shows history of FAO food and cereal price index (composite measures of food prices), with vertical lines indicating events when a top 5 producer of a crop had yields 25% below trend line (indicative of a seasonal climate extreme). Australia is included despite not being a top five producer, because it is an important exporter and the drops were 40% or more below trend line. Prices may have become more sensitive to weather-related supply shortfalls in recent years. At the same time, food prices are increasingly associated with the price of crude oil (blue line), making attribution of price changes to climate difficult. Thus, there is clear evidence since AR4 that prices can rise rapidly, but the role of weather in these increases remains unclear. All indices are expressed as percentage of 2002-2004 averages. Food price and crop yield data from FAO (http://www.fao.org/worldfoodsituation/foodpricesindex and http://faostat.fao.org/) and oil price data from http://www.eia.gov.

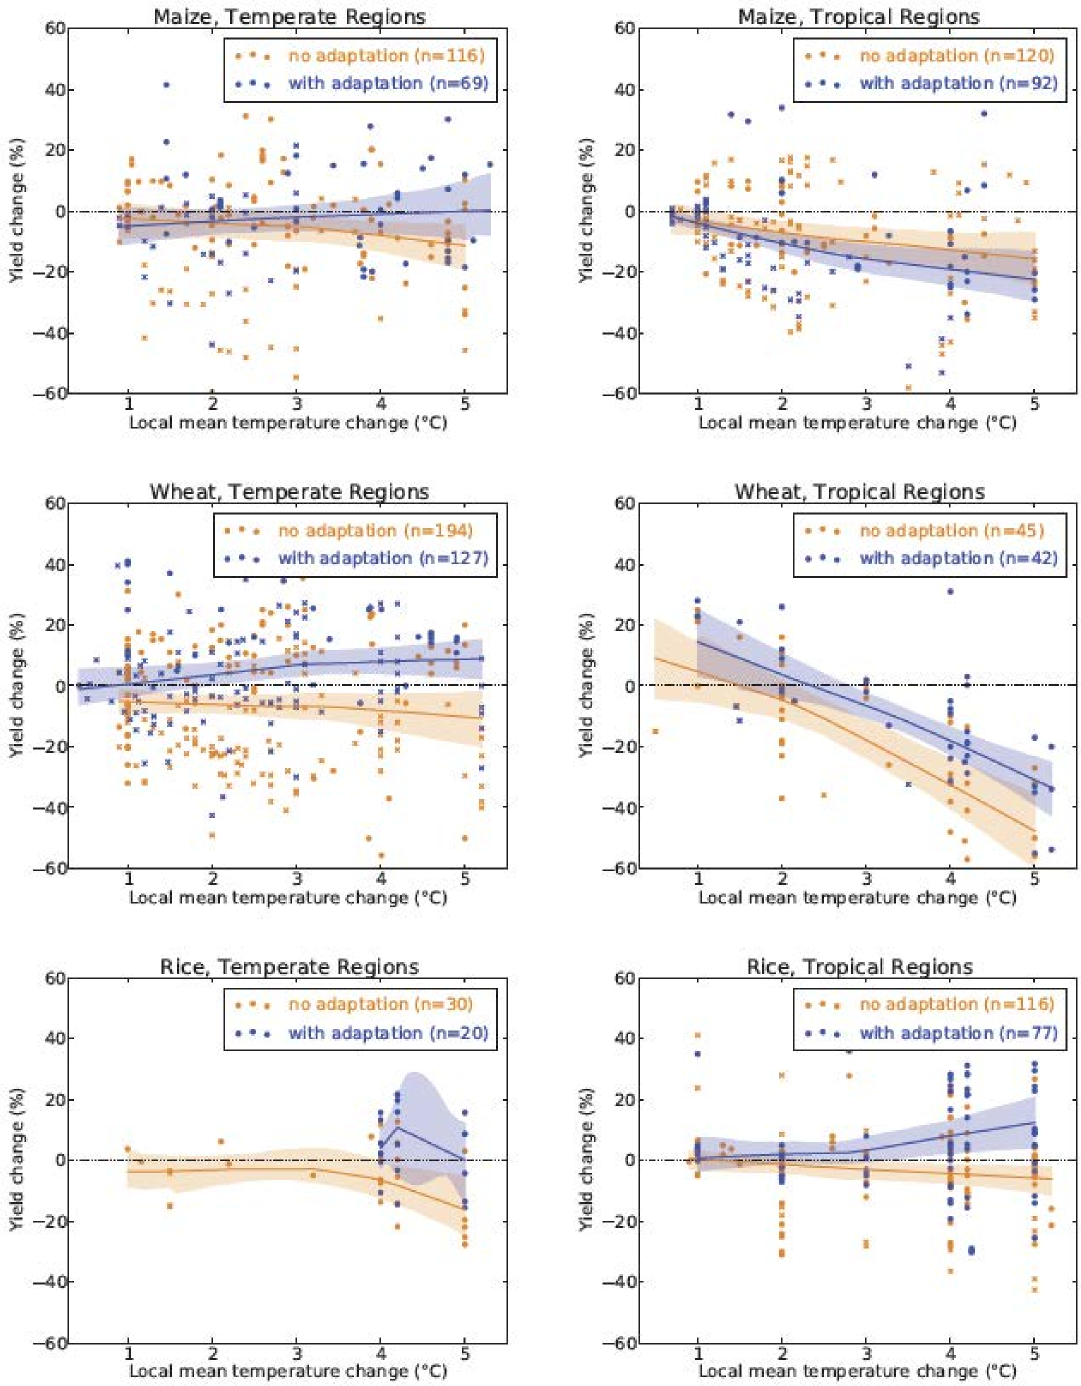

Figure 7-4: Percentage simulated yield change as a function of local temperature change temperature for the three major crops and for temperate and tropical regions. Dots indicate where a known change in atmospheric CO_2 was used in the study; remaining data are indicated by x. Note that differences in yield value between these symbols do not measure the CO_2 fertilisation effect, since changes in other factors such as precipitation may be different between studies. Non-parameteric regressions (LOESS, span=1 and degree=1) of subsets of these data were made 500 times. These bootstrap samples are indicated by shaded bands at the 95% confidence interval. Regressions are separated according to the presence (blue) or absence (red) of simple agronomic adaptation (Table 7-2). In the case of tropical maize the central regression for absence of adaptation is slightly higher than that with adaptation. This is due to asymmetry in the data – not all studies compare adaptated and non-adapted crops. Figure 7-8 presents a pair-wise adaptation comparison. Note that four of the 1048 datapoints across all six panels are outside the yield change

range shown. These were omitted for clarity. Some of the studies have associated temporal baselines, with centre-points typically between 1970 and 2005. Note that local warming in cropping regions generally exceeds global mean warming (Figure 21-3). Data are taken from a review of literature: Abou-Hadid (2006); Abraha & Savage (2006); Aggarwal & Mall (2002); Alexandrov (1999); Alexandrov & Hoogenboom (2000); Alexandrov et al. (2002); Arndt et al. (2011); Brassard & Singh 2008); Brassard & Singh (2007); Butt et al. (2005); Byjesh et al. (2010); Chhetri et al. (2010); Chipanshi et al. (2003); Matthews & Wasmann (2003); Moya et al. (1998); Osborne et al. (2013); Piao et al. (2010); Porter & Semenov (2005); Reyenga et al. (1999); Rosenzweig et al. (1994); Rowhani et al. (2011); Sands & Edmond (2005); Schlenker & Roberts (2009); Shuang-He et al. (2011); Southworth et al. (2000); Tan et al. (2010); Tao & Zhang (2010); Tao & Zhang (2011); Tubiello et al. (2000); Thomson et al. (2005); Thornton et al. (2009); Thornton et al. (2011); Thornton et al. (2010); Tingem & Rivington (2009); Tingem et al. (2008); Walker & Schulze (2008); Winters et al. (1998); Xiao et al. (2005); Xiong et al. (2007); Yates & Strzepek (1998); Zhang & Liu (2005); Zhao et al. (2005). **[Illustration to be redrawn to conform to IPCC publication specifications.]**

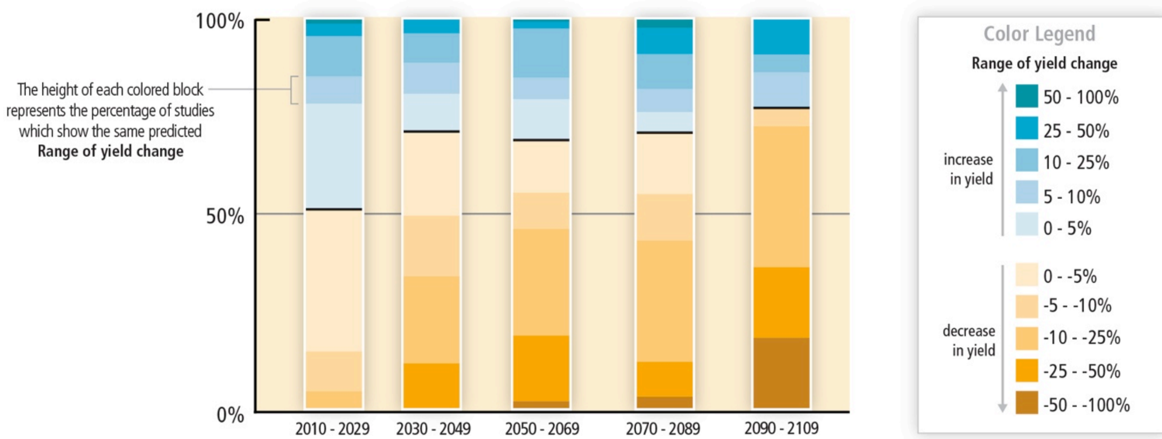

Figure 7-5: Projected changes in crop yield as a function of time. The y-axis indicates percentage of studies and the colours denote percentage change in crop yield. The sum of absolute bar heights in each time period equals 100%. Data are plotted according to the 20-year period in which the centre point of the projection period falls. Data taken from Abraha & Savage, 2006; Alexandrov & Hoogenboom, 2000; Arndt et al., 2011; Berg et al., 2012; Brassard & Singh, 2008; Brassard & Singh, 2007; Butt et al., 2005; Calzadilla et al., 2009; Chhetri et al., 2010; Ciscar et al., 2011; Deryng et al., 2011; Giannakopoulos et al., 2009; Hermans et al., 2010; Iqbal et al., 2011; Izaurralde et al, 2005; Kim et al., 2010; Lal, 2011; Li et al., 2011; Lobell et al., 2008; Moriondo et al., 2010; Muller et al., 2010; Osborne et al., 2013; Peltonen-Sainio et al., 2011; Piao et al., 2010; Ringler et al., 2010; Rowhani et al., 2011; Schlenker & Roberts, 2009 ;Shuang-He et al., 2011; Southworth et al., 2000; Tan et al., 2010; Tao & Zhang, 2010; Tao & Zhang, 2011; Tao et al., 2009; Thornton et al., 2009; Thornton et al., 2011; Thornton et al., 2010; Tingem & Rivington, 2009 Tingem et al., 2008; Walker & Schulze, 2008; Wang et al., 2011; Xiong et al., 2009; Xiong et al., 2007.

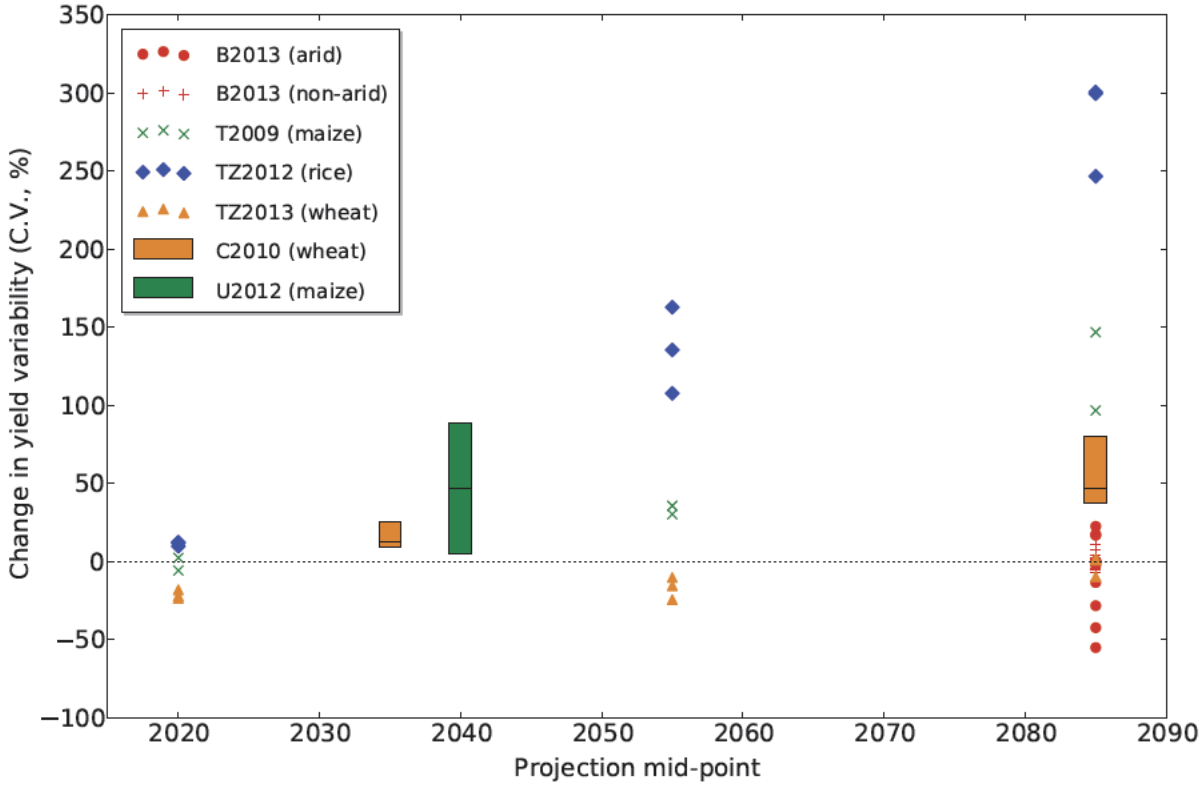

Figure 7-6: Projected percentage change in coefficient of variation (CV) of yield for wheat (gold), maize (green), rice (blue) and C_4 crops (red) taken from C2010 (Challinor et al., 2010), B2013 (Berg et al., 2013), T2009 (Tao et al., 2009), TZ2013 (Tao and Zhang, 2010), TZ2012 (Tao and Zhang, 2011) and U2012 (Urban et al., 2012). U2012 and C2012 plot multiple data points: U2012 shows the range (mean plus and minus one standard deviation) of percentage changes in CV. For C2012 paired CV changes were not available, so the box shows changes in the mean CV, the mean CV plus one standard deviation, and the mean CV minus one standard deviation. 81 datapoints are plotted in the figure, although the underlying data consist of many thousands of crop model simulations. The studies used a range of scenarios (SRES A1B, A2, A1F1 and B1). B2013 is a global study of the tropics, U2012 is for US maize, and the remaining studies are for China.

[Illustration to be redrawn to conform to IPCC publication specifications.]

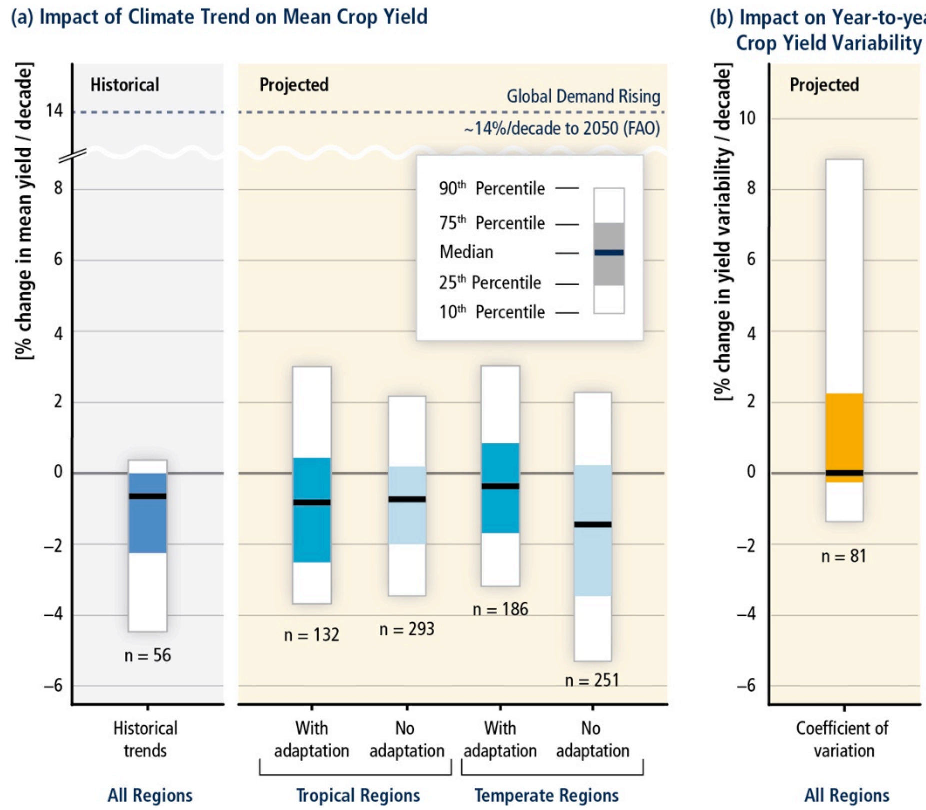

Figure 7-7: Boxplot summary of studies that quantify impact of climate and CO_2 changes on crop yields, including historical and projected impacts, mean and variability of yields, and for all available crops in temperate and tropical regions. All impacts are expressed as average impact per decade (a 10% total impact from a 50 year period of climate change would be represented as 2% per decade). References for historical impacts are given in Figure 7-2, for projected mean yields in Figure 7-5, and for yield variability in Figure 7-6. N indicates the number of estimates, with some studies providing multiple estimates. In general, decreases in mean yields and increases in yield variability are considered negative outcomes for food security. Also indicated on figure is the expected increase in crop demand of 14% per decade (Alexandratos and Bruinsma, 2012), which represents a target for productivity improvements to keep pace with demand.

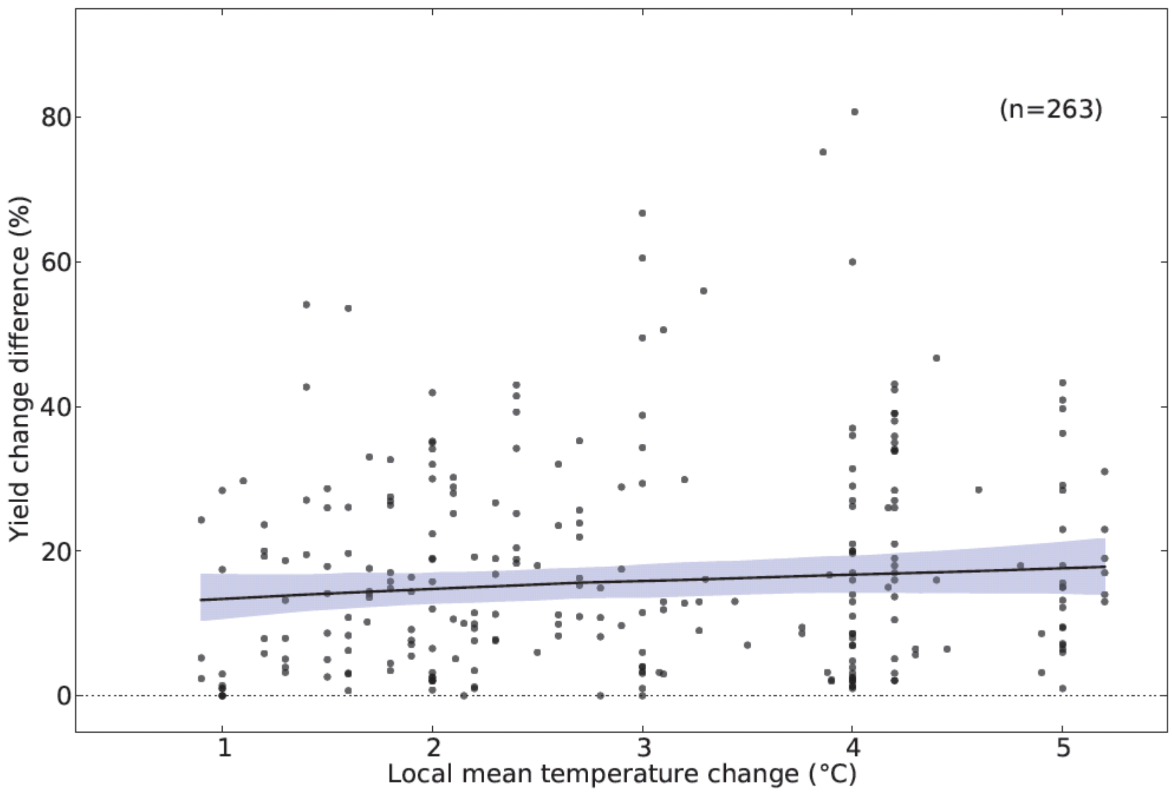

Figure 7-8: Simulated yield benefit from adaptation calculated as the difference between the yield change from baseline (%) for paired non-adapted and adapted cases as affected by temperature and aggregated across all crops. The shaded bands at the 95% confidence interval are calculated as for Fig 7.4. Data points (n=31) where assessed benefit of management changes are negative are not included as farmers are unlikely to intentionally adopt these. Data sources are the same as for Table 7-2 and only studies that examine both a 'no adaptation' and an 'adaptation' scenario are used so as to avoid the issues arising from un-paired studies documented in Fig7.4 for tropical maize. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

Frequently Asked Questions
8.1: Do experiences with disaster risk reduction in urban areas provide useful lessons for climate-change adaptation?
8.2: As cities develop economically, do they become better adapted to climate change?
8.3: Does climate change cause urban problems by driving migration from rural to urban areas?
8.4: Shouldn't urban adaptation plans wait until there is more certainty about local climate change impacts?

Executive Summary

Urban climate adaptation can build resilience and enable sustainable development. (8.1, 8.2, 8.3)

Action in urban centres is essential to successful global climate change adaptation. Urban areas hold more than half the world's population and most of its built assets and economic activities. They also house a high proportion of the population and economic activities most at risk from climate change, and a high proportion of global greenhouse gas emissions are generated by urban-based activities and residents **(***medium confidence based on high agreement, medium evidence*) (8.1).

Much of key and emerging global climate risks are concentrated in urban areas. Rapid urbanization and rapid growth of large cities in low- and middle-income countries have been accompanied by the rapid growth of highly vulnerable urban communities living in informal settlements, many of which are on land at high risk from extreme weather (*medium confidence, based on high agreement, medium evidence)* (8.2, 8.3, Table 8-2 and 8-3).

Cities are composed of complex inter-dependent systems that can be leveraged to support climate change adaptation via effective city governments supported by cooperative multi-level governance. This can enable synergies with infrastructure investment and maintenance, land-use management, livelihood creation and ecosystem services protection (*medium confidence based on medium agreement, limited evidence*) (8.3, 8.4).

Urban adaptation action that delivers mitigation co-benefits is a powerful, resource-efficient means to address climate change and to realize sustainable development goals (medium confidence based on *high agreement, medium evidence*) (8.4).

Urban climate change risks, vulnerabilities, and impacts are increasing across the world in urban centres of all sizes, economic conditions and site characteristics. (8.2)

Urban climate change-related risks are increasing (including rising sea levels and storm surges, heat stress, extreme precipitation, inland and coastal flooding, landslides, drought, increased aridity, water scarcity and air pollution) **with widespread negative impacts on people** (and their health, livelihoods and assets) **and on local and national economies and ecosystems** (*very high confidence based on high agreement, high evidence*). These risks are amplified for those who live in informal settlements and in hazardous areas and either lack essential infrastructure and services or where there is inadequate provision for adaptation (8.2, Table 8-2).

Climate change will have profound impacts on a broad spectrum of infrastructure systems (water and energy supply, sanitation and drainage, transport and telecommunication)**, services** (including health care and emergency services), **the built environment and ecosystem services.** These interact with other social, economic and environmental stressors exacerbating and compounding risks to individual and household well-being (*medium confidence based on high agreement, medium evidence*) (8.2).

Cities and city regions are sufficiently dense and of a spatial scale that they influence their local micro-climate. Climate change will interact with these conditions in a variety of ways, some of which will exacerbate the level of climate risk (*high confidence, based on high agreement, high evidence*) (8.2).

Urban climate adaptation provides opportunities for both incremental and transformative development. (8.3, 8.4)

Urban adaptation provides opportunities for incremental and transformative adjustments to development trajectories towards resilience and sustainable development via effective multi-level urban risk governance, alignment of policies and incentives, strengthened local government and community adaptation capacity, synergies with the private sector and appropriate financing and institutional development. Opportunities to do so are high in many rapidly growing cities where institutions and infrastructure are being developed, though there is limited evidence of this being realised in practice (*medium confidence, based on high agreement, limited evidence*) (8.4).

Urban adaptation can enhance economic comparative advantage, reducing risks to enterprises and to households and communities (*medium confidence based on high agreement, based on medium evidence*) (8.3).

City-based disaster risk management with a central focus on risk reduction is a strong foundation on which to address increasing exposure and vulnerability and thus to build adaptation. Closer integration of disaster risk management and climate change adaptation along with the incorporation of both into local, sub-national, national and international development policies can provide benefits at all scales *(high confidence, based on high agreement, medium evidence)* (8.3).

Ecosystem-based adaptation is a key contributor to urban resilience (*medium confidence, based on high agreement (among practitioners), medium evidence*) (8. 3).

Effective urban food-security related adaptation measures (especially social safety nets but also including urban and peri-urban agriculture, local markets and green roofs) **can reduce climate vulnerability especially for low-income urban dwellers** (*medium confidence based* on *medium agreement, medium evidence*) (8.3).

Good quality, affordable, well-located housing provides a strong base for city-wide climate change adaptation minimising current exposure and loss. Possibilities for building stock adaptation rest with owners and public, private and civil society organisations (*high confidence, based on high agreement, robust evidence*) (8.3, 8.4)

Reducing basic service deficits and building resilient infrastructure systems (water supply, sanitation, storm and waste water drains, electricity, transport and telecommunications, health care, education and emergency response) **can significantly reduce hazard exposure and vulnerability to climate change, especially for those who are most at risk or vulnerable** *(very high confidence, based on high agreement, robust evidence)* (8.3).
3.8 For most key climate change associated hazards in urban areas, risk levels increase from the present (with current adaptation) to the near-term but high adaptation can reduce these risk levels significantly. It is less able to do so for the longer-term, especially under a global mean temperature increase of 4°C (Tables 8-3 and 8-6**).**

Implementing effective urban adaptation is possible and can be accelerated. (8.4)

Urban governments are at the heart of successful urban climate adaptation because so much adaptation depends on local assessments and integrating adaptation into local investments, policies and regulatory frameworks (*high confidence*) (8.4).

Well governed cities with universal provision of infrastructure and services have a strong base for building climate resilience if processes of planning, design and allocation of human, capital, and material resources are responsive to emerging climate risks (*medium confidence, based on high agreement, medium evidence*) (8.4).

Building human and institutional capacity for adaptation in local governments, including scope for reflecting on incremental and transformative adaptation pathways, accelerates implementation and improves urban adaptation outcomes (*high confidence based on high agreement, medium evidence*) (8.4).

Coordinated support from higher levels of governments, the private sector and civil society and horizontal learning through networks of cities and practitioners benefits urban adaptation (*medium confidence based on medium agreement, medium evidence*) (8.4).

Leadership within local governments and also across all scales is important in driving successful adaptation and in promoting and sustaining a broad base of support for the urban adaptation agenda *(medium confidence based on high agreement, medium evidence)* (8.4).

Addressing political interests, mobilising institutional support for climate adaptation and ensuring voice and influence to those most at risk are important strategic adaptation concerns (*medium confidence based on medium agreement, limited evidence*) (8.4).

Enabling the capacity of low-income groups and vulnerable communities, and their partnership with local governments, can be an effective urban adaptation strategy (*medium evidence based on high confidence, limited evidence*) (8.3, 8.4).

Urban centres around the world face severe constraints to raising and allocating resources to implement adaptation. In most low-and middle-income country cities, infrastructure backlogs, lack of appropriate mandates and lack of financial and human resources severely constrain adaptation action. Small urban centres often lack economies of scale for adaptation investments and local capacity to act, as they have relatively low national and international profiles (*medium confidence based on high agreement*, *medium evidence)* (8.3, 8.4).

International financial institutions provide limited financial support for adaptation in urban areas. There is limited current commitment to finance urban adaptation from different levels of government and international agencies (*medium confidence based* on *high agreement, limited evidence*) (8.4).

A scientific evidence base in each urban centre is essential for effective adaptation action. This includes local risk and vulnerability assessments and information and data with which to consider current and future risk, adaptation and development options (*medium confidence based on high agreement, medium evidence)* (8.4).

Dealing with the uncertainty associated with climate change projections and **balancing them** with actions to address **current vulnerabilities and adaptation costs helps to assist implementation** in urban areas (*medium confidence based on medium agreement, medium evidence)* (8.2, 8.4).

8.1. Introduction

8.1.1. Key Issues

Adaptation to climate change depends centrally on what is done in urban centres – which now house more than half the world's population and concentrate most of its assets and economic activities (United Nations, 2012; World Bank, 2008). As 8.4 emphasizes, this will require responses by all levels of government as well as individuals and communities, the private sector and civil society. The serious impacts of extreme weather on many urban centres each year demonstrate some of the risks and vulnerabilities to be addressed (IFRC, 2010; United Nations, 2009). Climate change will usually add to these and other risks and vulnerabilities. Urban policies also have major implications for mitigation, especially for future levels of greenhouse gas emissions and for delivering co-benefits, as discussed in WGIII. This chapter focuses on the possibilities for governments, enterprises and populations to adapt urban centres to the direct and indirect impacts of climate change.

The level of funding needed for sound urban adaptation could exceed the capacities of local and national governments and international agencies (Brugmann, 2012; Parry *et al.*, 2009). Much of the investment will have to come from individuals and households, communities and firms through their decisions to address adaptation and resilience (see Agrawala and Fankhauser, 2008; Fankhauser and Soare, 2013). This might suggest little role for governments, especially local governments. But whether these small scale decisions by households, communities and firms do contribute to adaptation depends in large part on what local governments do, encourage, support and prevent – as well as their contribution to providing required infrastructure and services. An important part of this is the provision by local governments of appropriate regulatory frameworks and the application of building standards, to ensure that the choices made by individuals, households and firms support adaptation and prevent maladaptation. For instance, land use planning and management have important roles in ensuring sufficient land for housing that avoids dangerous sites and protects key ecological services and systems (UN-Habitat, 2011a).

In reviewing adaptation needs and options for urban areas, the documentation reviewed for this Chapter points to two key conclusions. The first is how much the adaptive capacity of any city depends on: the quality of provision and coverage of infrastructure and services; the capacities for investments and land-use management; and the degree to which buildings and infrastructure meet health and safety standards. This capacity provides a foundation for city resilience on which adaptation can be built. There is little of this foundation in most urban centres in low-income and many in middle-income nations. The second conclusion is the importance of city and municipal governments acting now to incorporate climate change adaptation into their development plans and policies and infrastructure investments. This includes not only building that foundation of resilience (and its institutional, governance and financial underpinnings) but also mobilizing new resources, adjusting building and land-use regulations and continuously developing the local capacity to respond. This is not to diminish the key roles of other actors. But it will fall to city and municipal government to provide the scaffolding and regulatory framework within which other stakeholders contribute and collaborate. Thus, adaptation in urban areas depends upon the competence and capacity of local governments and a locally-rooted iterative process of learning about changing risks and opportunities, identifying and evaluating options, making decisions, and revising strategies in collaboration with a range of actors.

8.1.2. Scope of the Chapter

This chapter focuses on what we know about the potential impact of climate change on urban centres and their populations and enterprises (8.2), what measures are being taken to adapt to these changes (and protect vulnerable groups) (8.3) and what institutional and governance changes can underpin adaptation (8.4). Both this and Chapter 9 highlight the multiple linkages between rural and urban areas that have relevance for adaptation. This chapter also overlaps with Chapter 10, especially in regard to infrastructure, although this chapter focuses on urban infrastructure and in particular the infrastructure that comes within the responsibilities or jurisdiction of urban governments.

This chapter draws its urban statistics from the United Nations Population Division (see United Nations, 2012). Urban centres vary from those with few thousand (or in some nations a few hundred) inhabitants to metropolitan areas with more than 20 million inhabitants. There is no international agreement – and considerable national variation – in how urban areas are defined (see United Nations, 2012). The main differences are in how settlements with a few hundred up to 20,000 inhabitants are classified; depending on the country, some, most or all of these may be classified as urban or rural. There are also differences in how urban boundaries are set. In some places, they encompass the urban built up area or the central urban core; in others, they go well beyond the built up area and include large areas devoted to agriculture (Satterthwaite, 2007).

The issue here is whether provision for adaptation includes ‘rural’ populations living around urban centres and within urban jurisdictions. In addition, it is common for part of the workforce in larger urban centres to live outside the urban centre and to commute – and this may include many that live in settlements designated as rural. There is also no agreed definition for what constitutes a city – although the term city implies an urban centre with some economic, political or cultural importance and would not be applied to most small urban centres.

8.1.3. Context – An Urbanizing World

In 2008, for the first time, more than half the world’s population was living in urban centres and the proportion continues to grow (United Nations, 2012). Three quarters of the world’s urban population and most of its largest cities are now in low- and middle-income nations. A comparison of Figures 8.1 and 8.2 highlights the increase in the number of large cities from 1950 to what is projected for 2025. UN projections suggest that almost all the increase in the world's population up to 2050 will be in urban centres in what are currently low- and middle-income nations (see Table 8-1). Most of the GDP of most nations and globally is generated in urban centres and most new investments have concentrated there (Satterthwaite *et al.*, 2010; World Bank, 2008). Clearly, just in terms of the population, economic activities, assets and climate risk they increasingly concentrate, adapting urban areas to climate change requires serious attention.

[INSERT TABLE 8-1 HERE

[INSERT FIGURE 8-2 HERE
Figure 8-2: Global and regional maps showing the location of urban agglomerations with 750,000 plus inhabitants projected for 2025. Source: Derived from statistics in United Nations, 2012.]

Most urbanization is underpinned by an economic logic. All wealthy nations are predominantly urbanized and rapid urbanization in low- and middle-income nations is usually associated with rapid economic growth (Satterthwaite *et al.*, 2010; World Bank, 2008). Most of the world's largest cities are in its largest economies (*ibid*). If rapid urbanization and rapid city population growth is associated with economic success, it suggests that more resources should be available there to support adaptation. But as discussed in 8.3, this is rarely the case. In most urban centres in low- and middle-income nations including many successful cities, local governments have been unable to manage their economic and physical expansion and there are large deficits in provision for infrastructure and services that are relevant to climate change adaptation. Around one in seven people in the world live in poor quality, overcrowded accommodation in urban areas with inadequate provision (or none) for basic infrastructure and services, mostly in informal settlements (Mitlin and Satterthwaite, 2013; UN-Habitat, 2003a). Much of the health risk and vulnerability to climate change is concentrated in these settlements (Mitlin and Satterthwaite, 2013). So this chapter is concerned not only with an adaptation deficit for but also with a development deficit that is relevant to this risk and vulnerability.

Many aspects of urban change in recent decades have been so rapid that they have overwhelmed government capacity to manage them. Among the 611 cities with over 750,000 inhabitants in 2010, 47 had populations that had grown more than twenty fold since 1960; in 120, the growth was more than tenfold (statistics in this paragraph are drawn from data in United Nations, 2012). The increasing concentration of the world's urban population and its largest cities outside the highest income nations represents an important change. Over the 19th and 20th centuries, most of the world's urban population and most of its largest cities were in its most prosperous nations. Now, urban areas in low- and middle-income nations have close to two-fifths of the world's total population, close to three-quarters of its urban population, and most of its large cities. In 2011, of the 23 'mega-cities' (with populations over 10 million), only 5 were in high-income nations (two in Japan, two in USA, one in France). Of the remaining 18, four were in China, three in India and two in Brazil. But over three fifths of the world's urban population is in urban centres with less than 1 million inhabitants and it is here that much of the growth in urban population is occurring.

Underlying these population statistics are large and complex economic, social, political and demographic changes, including the multiplication in the size of the world's economy and the shift in economic activities and employment structures from agriculture to industry and services (and within services to information production and exchange) (Satterthwaite, 2007). One of the most significant changes has been the growth in the size and importance of cities whose economies increased and changed as a result of globalization (Sassen, 2012). Another is the number of large cities that are now centres of large extended metropolitan regions.

One of the challenges for this chapter is to convey the very large differences in adaptive capacity between urban centres. There are tens of thousands of urban centres worldwide with very large and measureable differences in population, area, economic output, human development, quality and coverage of infrastructure and services, ecological footprint and greenhouse gas emissions. The differences in adaptive capacity are far less easy to quantify. Table 8-2 illustrates differences in adaptive capacity and factors that influence it. It indicates how each urban centre falls within a spectrum in at least four key factors that influence adaptation: local government capacity; the proportion of residents served with risk-reducing infrastructure and services; the proportion living in housing built to appropriate health and safety standards; and the levels of risk from climate change's direct and indirect impacts. This chapter and Table 8-2 also draw on detailed case studies to illustrate this diversity – New York (Solecki, 2012), Durban (Roberts and O'Donoghue, 2013) and Dar es Salaam (Kiunsi, 2013). In 8.5, there are tables of current and indicative future climate risks for Dar es Salaam, Durban, London and New York.

[INSERT TABLE 8-2 HERE
Table 8-2: The large spectrum in the capacity of urban centers to adapt to climate change.]

Many attributes of urban centres can be measured and compared. As noted above, populations vary from a few hundred to more than 20 million. Areas vary from less than one to thousands of square kilometres. Average life expectancy at birth varies from over 80 years to under 40 years, and under-five mortality rates vary by a factor of 20 or more (Mitlin and Satterthwaite, 2013). Average per capita incomes vary by a factor of at least 300; so too does the funding available to local governments per person (UCLG, 2010). Greenhouse gas emissions per person (in tonnes of carbon dioxide equivalent) vary by more than 100 (Dodman, 2009; Hoornweg *et al.*, 2011).

There are large differences between urban centres in the extent to which their economies are dependent on climate-sensitive resources (including commercial agriculture, water and tourism).There are also large variations in the scale and nature of impacts from extreme weather. As Table 8-2 suggests, there are urban indicators relevant for assessing the resilience to climate change impacts that urban areas have acquired (including the proportion of the population with water piped to their homes, sewers, drains, health care and emergency services); it is more of a challenge to find indicators for the climate change related risks and for the quality and capacity of government.

Recent analyses of disaster impacts show that a high proportion of the world's population most affected by extreme weather events is concentrated in urban centres (IFRC, 2010; United Nations, 2009; United Nations, 2011). As shown in Table 8-2, a high proportion of these urban centres lack both local governments with the capacity to reduce disaster risk, and much of the necessary infrastructure. Their low-income households may require particular assistance due to greater exposure to hazards, lower adaptive capacity, more limited access to infrastructure or insurance, and fewer possibilities to relocate to safer accommodation, compared to wealthier residents.

All successful urban centres have had to adapt to environmental conditions and available resources, although local resource constraints have often been overcome by drawing on resources and using sinks from 'distant elsewheres' (McGranahan, 2007; Rees, 1992); this includes importing goods that are resource intensive and whose fabrication involves large greenhouse gas emissions. The growth of urban population over the last century has also caused a very large anthropogenic transformation of terrestrial biomes. Urban centres cover only a small proportion of the world's land surface – according to Schneider *et al.* (2009) only 0.51 per cent of the total land area; only in Western Europe do they cover more than 1 per cent. However, their physical and ecological footprints are much larger. The net ecological impact of urban centres includes the decline in the share of wild and semi-natural areas from about 70 per cent to less than 50 per cent of land area, largely to accommodate crop and pastoral land to support human consumption. It has led not only to a decrease in biodiversity but to fragmentation in much of the remaining natural areas and a threat to the ecological services that support both rural and urban areas. Future projections (Seto *et al.*, 2012) suggest that if current trends continue, urban land cover will increase by 1.2 million square kilometres by 2030, nearly tripling global urban land area between 2000 and 2030. This would mean a "considerable loss of habitats in key biodiversity hotspots", destroying the green infrastructure that is key in helping areas adapt to climate change impacts (*ibid.*, p. 16083) as well as increasing the exposure of population and assets to higher risk levels.

Many of the challenges and opportunities for urban adaptation relate to the central features of city life – the concentration of people, buildings, economic activities and social and cultural institutions (Romero-Lankao and Dodman, 2011). Agglomeration economies are usually discussed in relation to the advantages for enterprises locating in a particular city. But the concentrations of people, enterprises and institutions in urban areas also provide potential agglomeration economies in lower unit costs for piped water, sewers, drains and a range of services (solid waste collection, schools, health care, emergency services, policing) and in the greater capacity for people, communities and institutions to respond collectively (Hardoy *et al.*, 2001). At the same time, the advantages that come with these concentrations of people and activities are also accompanied by particular challenges – for instance, the management of storm and surface run-off and measures to reduce heat islands. Large cities concentrate demand and the need for ecological services and natural resources (water, food and biomass), energy and electricity, and many city enterprises rely on lifeline infrastructure and supply chains that can be disrupted by climate change (see 8.3.3, also United Nations, 2013).

Thus, the increasing concentration of the world's population in urban centres means greater opportunities for adaptation but more concentrated risk if they are not acted on. Many urban governments lack the capacity to do so, especially those in low- and lower-middle income nations. The result is large deficiencies in infrastructure and services. Urban centres in high-income nations, although much better served, may also face particular challenges – for instance, aging infrastructure and the need to adapt energy systems, building stock, infrastructure and services to the altered risk set that climate change will bring (see Zimmerman and Faris (2010) and Solecki (2012) for discussions of this for New York). Many studies have shown that working with a range of government and civil society institutions at local and supra-local levels increases the effectiveness of urban adaptation efforts; support and enabling frameworks from higher levels of government were also found to be helpful (see 8.4 and many of the studies listed in Box 8-1).

8.1.4. Vulnerability and Resilience

For each of the direct and indirect impacts of climate change, there are groups of urban dwellers that face higher risks (illness, injury, mortality, damage to or loss of homes and assets, disruption to incomes) (Hardoy and Pandiella, 2009; Mitlin and Satterthwaite, 2013). Age may be a factor (for instance infants and elderly people are more sensitive to particular hazards such as heat stress) or health status (those with particular diseases, injuries or disabilities may be more sensitive to these impacts). Or it may be that they live in buildings or in locations facing greater risks – for instance on coasts or by rivers with increased flood risks – or that they lack coping capacities. Women may face higher risks in their work and constraints on adaptation if they face discrimination in access to labour markets, resources, finance, services and influence (see Cross-chapter box on gender and other sources of marginalization). These are often termed vulnerable groups – although, to state the obvious, they are only vulnerable to direct climate change impacts to the extent that the hazard actually poses a risk. Remove people's exposure to the hazard (e.g. provide drains that prevent flooding) and there is limited or no impact. Infants may face serious health risks when water supplies are contaminated by flooding, but rapid and effective treatment for diarrhoea and quickly re-establishing availability of drinking quality water greatly reduces impacts (Bartlett, 2008). Adaptations by individuals, households, communities, private enterprises or government service providers can all reduce risks.

Adaptation in a particular area or settlement may have clear benefits for the inhabitants there, but can also have knock-on effects on the wellbeing of inhabitants in other areas. Diverting a river course or building an embankment to protect new development may prevent flooding in one location, but may cause or increase flooding somewhere else (see Alam and Rabbani, 2007 for Dhaka; Revi, 2005 for Mumbai).

Assessments of vulnerability to climate change draws on assessments in other contexts – including the vulnerability of low-income groups to stresses and shocks (see, for instance, Chambers, 1989 and Pryer, 2003) and to disasters (see Cannon, 1994; Manyena, 2006). The term is generally used in relation to an inability to cope with external changes including avoiding harm when exposed to a hazard. This includes people's inability to avoid the hazard (exposure), anticipate it and take measures to avoid it or limit its impact, cope with it and recover from it (Hardoy and Pandiella, 2009). Vulnerable groups may be identified on the basis of any of these four factors. The definition of resilience used in this Report when applied to urban centres means the ability of urban centres (and their populations, enterprises and governments) and the systems on which they depend to anticipate, reduce, accommodate or recover from the effects of a hazardous event in a timely and efficient manner (see the glossary).

The term vulnerability is also applied to sectors, including food processing, tourism, water, energy and mobility infrastructure and their cross-linkages, for instance, the dependency of perishable commodities on efficient transport. Much tourism is sensitive to climate change, which can damage key tourist assets such as coral reefs and beaches or make particular locations less attractive to tourists because of more extreme weather. The term is also applied to natural systems/ecosystems (e.g. mangroves, coastal wetlands, urban tree canopy). If the adaptive capacity of these systems is increased, they can also provide natural protection from the impacts of climate change in urban areas (see for instance 8.2.4.5 and 8.3.3.7 for more details).

8.1.4.1. Differentials in Risk and Vulnerability within and between Urban Centres

In urban centres where virtually all buildings meet health and safety standards, where land-use planning prevents developments on sites at risk and where there is universal provision for infrastructure and basic services, the exposure differentials between high- and low-income groups to climate-related risk are quite low. Having a low-income and few assets in such urban centres does not necessarily imply greater vulnerability to climate change (Mitlin and Satterthwaite, 2013). But typically, the larger the deficit in infrastructure and service provision, the larger the differentials in exposure to most climate change impacts between income groups. Low-income groups in low- and middle-income nations are often disproportionately vulnerable because of poor quality and insecure housing, inadequate infrastructure and lack of provision for health care, emergency services and disaster risk reduction (*ibid.,* IFRC, 2010; IPCC, 2012; UN-Habitat, 2011a; United Nations, 2009). Most deaths from disasters are concentrated in low- and middle-income countries – including over 95 per cent of deaths from natural disasters between 1970 and 2008 (IPCC, 2012). More than 95 per cent of the deaths from storms and floods registered on the EM-DAT from 2000 to September 2013 were in low- and middle-income nations.[1]

[FOOTNOTE 1: These are drawn from data in the The International Disaster Database EM DAT accessed on 16 September 2013.]

An analysis of annual fatalities from tropical cyclones showed these to be heavily concentrated in low-income nations even though there was high exposure in many upper-middle and high-income nations (and these nations had larger economic losses) (United Nations, 2009). These analyses do not separate rural and urban populations – but there is a growing body of evidence that most urban deaths from extreme weather events are in low-income and lower-middle income countries (*ibid.*, IFRC, 2010). Analyses of risks across many cities usually show the cities at highest risk from extreme weather or particular kinds of such weather (e.g., floods) to be primarily in high-income countries (see Hallegatte *et al.*, 2013; Munich Re, 2004). But this is because these analyses are based on estimates of economic costs or economic losses. If they were based instead on deaths and injuries, the ranking would change fundamentally (see also Balica *et al.*, 2012). The official statistics on disaster deaths are also known to considerably under-state total deaths, in part because many deaths go unrecorded, in part because of the criteria that a disaster event has to meet to be included (one of the following criteria must be fulfilled: ten or more people reported killed; 100 or more people reported affected; declaration of a state of emergency; or call for international assistance) (United Nations, 2009).

There are dramatic examples of extreme weather events in high-income countries with very large impacts, including high mortality. But the analyses in United Nations (2009) and IFRC (2010), and the reports of deaths from extreme weather in many of the case studies listed in Box 8-1, suggest that most extreme weather disaster deaths in urban centres are in low- and lower-middle income nations, and that risks are concentrated in informal settlements. As noted by IPCC (2012), the occupants of these settlements are typically more exposed to climate events with limited or no hazard-reducing infrastructure, low-quality housing and limited capacity to cope.

Where provision for adequate housing, infrastructure and services is most lacking, the capacity of individuals, households and community organizations to anticipate, cope and recover from the direct and indirect losses and impact of disasters (of which climate-related events are a sub-set) becomes increasingly important (see 8.4). The effectiveness of early warning systems, the speed of response and the effectiveness of post-disaster response is especially important to those who are more sensitive and have less coping capacity. The effectiveness of such responses depends on an understanding of the specific vulnerabilities, needs and priorities of different income-groups, age groups and groups that face discrimination, including that faced by women and by particular social or ethnic groups (UN-Habitat, 2011a).

8.1.4.2. Understanding Resilience for Urban Centres in Relation to Climate Change

In relation to disasters, resilience is usually considered to be the opposite of vulnerability, but vulnerability is often discussed in relation to particular population groups while resilience is more often discussed in relation to the systemic capacity to protect them and reduce the impact of particular hazards through infrastructure or climate-risk sensitive land-use management. In recent years, a literature has emerged discussing resilience to climate change for urban centres and what contributes to it (see Brown *et al.*, 2012; da Silva *et al.*, 2012; Leichenko, 2011; Moench *et al.*, 2011; Muller, 2007; Pelling, 2011a). Addressing resilience for cities is more than identifying and acting on specific climate change impacts. It looks at the performance of each city's complex and interconnected infrastructure and institutional systems including interdependence between multiple sectors, levels and risks in a dynamic physical, economic, institutional and socio-political environment (Gasper *et al.*, 2011; Kirshen *et al.*, 2008). When resilience is considered for cities, certain systemic characteristics are highlighted – for instance flexibility, redundancy, responsiveness, capacity to learn and safe failure (Brown *et al.*, 2012; da Silva *et al.*, 2012; Moench *et al.*, 2011; Tyler *et al.*, 2010), as well as take account of the multiple inter-dependencies between different sectors (see 8.2).

When a specific city is being considered, the level and forms of resilience are often related to specific local factors, services and institutions – for instance, for each district in a city, will the storm and surface drains cope with the next heavy rainfall? During hot days, will measures to help those at risk from heat stress reach all high-risk groups? (see the cross-chapter box on heat stress and heat waves for more details). Here, resilience is not only the ability to recover from the impact but the ability to avoid or minimize the need to recover and the capacity to withstand unexpected or unpredicted changes (United Nations, 2011). An important aspect of resilience is the functioning of institutions to make this possible and the necessary knowledge base (da Silva *et al.*, 2012).The emerging literature on the resilience of cities to climate change also highlights the need to focus on resource availabilities and sinks beyond the urban boundaries. It may also require coordinated actions by institutions in other jurisdictions or higher levels of government (for instance watershed management upstream of a city to reduce flood risks; see Brown *et al.* (2012), Ramachandraiah (2011). There are also the slow onset impacts that pose particular challenges and that may also be outside the jurisdiction of urban governments – for instance, the impact of drought on agriculture, which can raise food prices and reduce rural incomes and demand for urban services.

Resilience to extreme weather for urban dwellers is strongly influenced by factors mentioned already - the quality of buildings, the effectiveness of land-use planning and the quality and coverage of key infrastructure and services. It is also influenced by the effectiveness of early warning systems and public response measures (IFRC, 2010; UN-Habitat, 2011a) and by the proportion of households with savings and insurance and able to afford safe, healthy homes. Safety nets for those with insufficient incomes are also important, along with the administrative capacity to ensure these reach those in need. Urban governments have importance for most of this, although their capacity to provide usually depends on the revenue raising powers and legislative and financial support from higher levels of government. These in turn are driven in part by political pressure from urban dwellers and innovation by city governments. Private companies or non-profit institutions may provide some of these but the framework for provision and quality control is provided by local government or local offices or national or provincial government.

Cities in high-income nations and many in middle-income nations have become more resilient to extreme weather (and other possible catalysts for disasters) through a range of measures responding to risks and to the political processes that demand such responses (IFRC, 2010; Satterthwaite, 2013; UN-Habitat, 2011a). The universal provision of piped water, sewers, drains, health care and emergency services and standards set and enforced on housing quality and infrastructure were not a response to climate change but what was built over the last 100-150 years in response to the needs and demands of residents. This has produced what can be termed accumulated resilience in the built environment to extreme weather and built the capacity of local governments to act on risk reduction (see for instance Hardoy and Ruete (2013) on Rosario, Argentina). In addition, it helped build the institutions, finances and governance systems that can support climate change adaptation (Satterthwaite, 2013). Building and infrastructure standards can be adjusted as required (if there is infrastructure in place that can be adjusted - for instance by increasing capacity for storm and surface water drainage systems). Existing levels of service provision can be modified to take into account new risks or risk levels, as can city planning and land-use management (for instance, by keeping city expansion away from areas facing higher risk levels). Private sector investments can support these kinds of adjustments (for instance, changing insurance premiums and coverage) (IFRC, 2010; UN-Habitat, 2011a; United Nations, 2013). All of these provide the foundation on which to build adaptive capacity to withstand climate-change related direct and indirect impacts.

Whether this will happen depends on the willingness of urban governments to take this on, the demands of local inhabitants and their capacity to organize and press for change, and the capacity for learning and cooperation within local institutions. Obviously, it also depends on global agreements that slow and stop the increases in risk from GHG emissions and other drivers of climate change. Many cities with accumulated resilience may still not be equipped to respond to the changed hazards and risks associated with climate change (IPCC, 2012). The issue here becomes whether the institutions and political pressures that built the accumulated resilience are able to shift to *resilience building as a directed process* – and to respond dynamically and effectively to evolving and changing climate-related risks (and the evolving and changing knowledge bases that supports this).

For urban centres with little accumulated resilience, resilience as a process is also important, both to help reduce over time the (often very large) deficiencies in most or all the infrastructure, services and regulatory frameworks that provide resilience in high-income nations, and to build resilience to climate change impacts (see Table 8-2). For around a third of the world's urban population, this has to be done in a context of limited incomes and assets and poor living conditions and little current coping capacity to stresses or shocks (IPCC, 2012; United Nations, 2009). Just an increase in the price of food staples, a drop in income or a new cost, like medicine for a sick family member, can quickly mean inadequate food, hunger and reduced capacity to work (Mitlin and Satterthwaite, 2013).

This implies the need for a specific perspective on how climate change adaptation must be supported. It highlights the intimate relationship between resilience to climate change impacts and the quality of governance, especially local governance. The government's capacity and willingness to listen to, work with, support and serve those who lack resilience is fundamental (IPCC, 2012). This is demonstrated by the many successful partnerships between local government and grassroots organizations formed by residents of informal settlements that have built or improved homes and neighborhoods (see 8.4).

Thus, resilience can be considered in relation to individuals/households, communities and urban centres. In each of these, it includes the capacity to undertake anticipatory adaptation - action that avoids or reduces a climate change impact, for instance by living in a safe location, having a safe house, having risk reducing infrastructure. It also includes reactive adaptation to cope with the impact of an event, to 'bounce back' to the previous state (Shaw and Theobald, 2011). For urban centres, 'bouncing back' includes the government capacity to rapidly restore key services and repair infrastructure. Ideally, for climate change adaptation, responses by urban populations, enterprises and governments should allow 'bounce forward' to a more resilient state. This is discussed in disaster risk reduction and is termed 'building-back better' (Lyons, 2009). This is part of the shift from resilience to transformative adaptation shown in Table 8-2 where urban centres have integrated their development, disaster risk reduction and adaptation policies and investments within an understanding of the need for mitigation and sustainable ecological footprints (see also Manyena *et al.*, 2011; Pelling and Dill, 2010; Shaw and Theobald, 2011).

8.1.5. Conclusions from the Fourth Assessment (AR4) and New Issues Raised by this Chapter

AR4's chapter on Industries, Settlements and Human Society (Wilbanks *et al.*, 2007) notes that variability in environmental conditions has always been a given, but that when change is more extreme, persistent or rapid than has been experienced in the past, especially if it is not foreseen and capacities for adaptation are limited, the risks will increase [7.1.1]. The chapter also noted that, except for abrupt extreme events, climate change impacts are not currently dominant issues for urban centres [7.1.3]. Their importance lies in their interaction with other stressors, which may include rapid population growth, political instability, poverty and inequality, ineffective local governments, jurisdictional fragmentation and aging or inadequate infrastructure [7.2]. Key challenges identified for turning attention to adaptation include the difficulties of estimating and projecting the magnitudes of climate risk in particular places and sectors with precision and a weak knowledge base on the costs of adaptation (issues that are still challenges today).

Wilbanks *et al.* (2007) describe how the interactions between urbanization and climate change have led to concentrations of urban populations in low-income nations with weak adaptive capacity. They also describe the interactions between climate change and a globalized economy with long supply chains, resulting in impacts spreading from directly affected areas and sectors to other areas and sectors through complex linkages [7.2]. Many impacts will be unanticipated and overall effects are poorly estimated when only direct impacts are considered. Key global vulnerabilities include interregional trade and migration patterns. This Chapter also describes how climate change impacts and most vulnerabilities are influenced by local contexts, including geographic location, the climate sensitivity of enterprises located there, development pathways and population groups unable to avoid dangerous sites and homes [7.3; 7.4.3]. Key risks are most often related to climate phenomena that exceed thresholds for adaptation (e.g. extreme weather or abrupt changes) and limited resources or institutional capacities to reduce risk and cope (for instance, with increased demands on water and energy supplies and often on health care and emergency response systems).

Individual adaptation may not produce systemic adaptation. In addition, adaptation of systems may not benefit all individuals or households, because of the different vulnerability of particular groups and places [7.6.6]. Adaptation will be well served by a greater awareness of threats and alternatives beyond historical experience and current access to finance. Technological innovation for climate adaptation comes largely from industry and services that are motivated by market signals, which may not be well matched with adaptation needs and residual uncertainties. Many are incremental adjustments to current business activities.

For the types of infrastructure most at risk – including most transport, drainage and electricity transmission systems and many water supply abstraction and treatment works, reserve margins can be increased and back-up capacity developed [7.6.4]. Adaptation of infrastructure and building stock often depends on changes in the institutions and governance framework e.g. in planning regulations and building codes. Climate change has become one of many changes to be understood and planned for by local managers and decision makers [7.6.7]. For instance, planning guidance and risk management by insurers will have roles in locational choice for industry.

Since AR4, a much larger and more diverse literature has accrued on current and potential climate change risks for urban populations and centres (see 8.2). The literature on urban ‘adaptation’ and on building resilience at city and regional scales has also expanded, (see 8.3 and 8.4) including work on urban centres in low- and middle-income nations (see Box 8-1). Far more city governments have published documents on adaptation. There is more engagement with urban adaptation by some professions, including architects, engineers, urban planners and disaster risk reduction specialists (see da Silva, 2012; Engineering the Future, 2011; Engineers Canada, 2008; UN-Habitat, 2011a; United Nations, 2009). There are also assessments and books that focus specifically in climate change and cities with a strong focus on adaptation (see Bicknell *et al.*, 2009; Bulkeley, 2013; Cartwright *et al.*, 2012; Rosenzweig *et al.*, 2011; UN-Habitat, 2011a; Willems *et al.*, 2012).

This makes a concise and comprehensive summary more difficult. But it has also allowed for more clarity on what contributes to resilience in urban centres and systems. Specifically, there is now:

- a more detailed understanding of key urban climate processes, including drivers of climate change, and improved analytical and down-scaled integrated assessment models at regional and city scale;
- a more detailed understanding on the governance of adaptation in urban centres and the adaptation responses being considered or taken. This includes a large and important grey literature produced by or for city governments and some international agencies and in many high-income and some middle-income nations, support for this from higher levels of government;
- more nuanced understanding of the many ways in which poverty and discrimination exacerbates vulnerability to climate impacts (see also Chapter 13);
- more detailed studies on particular built environment responses to promote adaptation (see for instance the growth in the literature on green and white roofs);
- more case studies of community-based adaptation and its potential contributions and limitations;

- more consideration of the role of ecosystem services and of green (land) and blue (water) infrastructure in adaptation;
- more consideration of the financing, enabling and supporting of adaptation for households and enterprises;
- more on learning from innovation in disaster risk reduction;
- a greater appreciation of the inter-dependencies between different infrastructure networks and of the importance of 'hard' infrastructure and of the institutions that plan and manage it;
- more examples of city governments and their networks contributing to national and global discussions of climate change adaptation (and mitigation), including establishing voluntary commitments (see for instance the Durban Adaptation Charter for local governments) and engaging with the Conference of Parties.

A range of key uncertainties and research priorities emerge from the literature reviewed in this Chapter:

- the limits to understanding and predicting impacts of climate change at a fine grained geographic and sectoral scale
- inadequate knowledge on the vulnerabilities of urban citizens, enterprises and centres to the direct impacts of climate change, to second and third order impacts and to the interdependence between systems;
- inadequate knowledge on the vulnerability of the built environment, buildings, building components, building materials and the construction industry to the direct and indirect impacts of climate change and of the most effective responses for new-build and for retrofitting;
- inadequate knowledge on the adaptation potentials for each urban centre (and its government) and their costs, and on the limits on what adaptation can achieve (informed by a new literature on loss and damage);
- serious limitations on geophysical, biological and socio-economic data needed for adaptation at all geographic scales, including data on nature-society links and local (fine-scale) contexts (see WMO, 2008) and hazards;
- uncertainties about trends in societal, economic and technological change with or without climate change including the social and political underpinnings of effective adaptation;
- understanding the different impacts and adaptation responses for rapid and slow onset disasters;
- developing the metrics for measuring and monitoring success in adaptation in each urban centre:
  - human deaths and injuries from extreme weather
  - number of permanently or temporarily displaced people and others directly and indirectly affected
  - impacts on properties, measured in terms of numbers of buildings damaged or destroyed
  - impacts on infrastructure, services and lifelines
  - impacts on ecosystem services
  - impacts on crops and agricultural systems and on disease vectors
  - impacts on psychological well-being and sense of security
  - financial or economic loss (including insurance loss)
  - impacts on individual, household and community coping capacities and need for external assistance.

8.2. Urbanization Processes, Climate Change Risks, and Impacts

8.2.1. Introduction

This section assesses the connections between urbanization and climate change in relation to patterns and conditions of climate risk, impact, and vulnerability. The focus is on urbanization's local, regional and global environmental consequences and the processes that may lead to increased risk exposure, constrain people in high-risk livelihoods and residences, and generate vulnerabilities in critical infrastructure and services. Understanding urbanization and associated risk and vulnerability distributions is critical for an effective response to climate change threats and their impacts (Bicknell *et al.*, 2009; Bulkeley, 2010; Romero-Lankao and Qin, 2011; Solnit, 2009; Vale and Campanella, 2005). It is also critical for the promotion of sustainable urban habitats and the transition to increased urban resilience. There is a particular interest here in the ability of cities to respond to environmental crises, and the resilience and sustainability of cities (Solecki *et al.*, 2011; Solecki, 2012).

The section assesses the direct impacts of climate change on urban populations and urban systems. Together, with shifts in urbanization, these direct impacts change the profile of societal risk and vulnerability. Both can alter transition pathways that lead towards greater resilience and sustainable practices and the basis of how such practices are managed within a community. Understanding and acting on the connections between climate change and urbanization are also crucial since changes in one can affect the other. We investigate a range of direct impacts including those on physical and ecological systems, social and economic systems, and coupled human-natural systems. Where relevant to understanding, cascading impacts (where systems are tightly coupled) and secondary (indirect) impacts also are noted.

8.2.2. Urbanization – Conditions, Processes, and Systems within Cities

8.2.2.1. Magnitude and Connections to Climate Change

The spatial, temporal, and sustainability-related qualities of urbanization are important for understanding the shifting, complex interactions between climate change and urban growth. Given the significant and usually rising levels of urbanization (see 8.1.3), a growing proportion of the world's population will be exposed to the direct impacts of climate change in urban areas (de Sherbinin *et al.*, 2007; Revi, 2008; UN-Habitat, 2011a). Urban centres in Africa, Asia, Latin America with less than a million inhabitants are where most population growth is expected (United Nations, 2012) but these smaller centres are "often institutionally weak and unable to promote effective mitigation and adaptation actions".(Romero-Lankao and Dodman, 2011, p. 114).

Urbanization alters local environments via a series of physical phenomena that can result in local environmental stresses. These include urban heat islands (higher temperatures, particularly at night, in comparison to outlying rural locations) and local flooding that can be exacerbated by climate change. It is critical to understand the interplay between the urbanization process, current local environmental change and accelerating climate change. For example, in the past, long-term trends in surface air temperature in urban centres have been found to be associated with the intensity of urbanization (Chen *et al.*, 2011; Fujibe, 2008; Fujibe, 2011; He *et al.*, 2007; Iqbal and Quamar, 2011; Jung, 2008; Kalnay *et al.*, 2006; Kolokotroni *et al.*, 2010; Ren *et al.*, 2007; Rim, 2009; Sajjad *et al.*, 2009; Santos and Leite, 2009; Stone, 2007; Tayanç *et al.*, 2009). Climate change can influence these microclimate and localized regional climate dynamics. For example, urbanization (micro scale to meso scale) can strengthen and/or increase the range of the local urban heat island (UHI) altering small scale processes, such as a land-sea breeze effect, katabatic winds, etc., and modifying synoptic scale meteorology (e.g., changes in the position of high pressure systems in relation to UHI events). Climate modeling exercises indicate an 'urban effect' that leads locally to higher temperatures. Building material properties are influential in creating different urban climate temperature regimes, which can alter energy demand for climate control systems in buildings (Jackson *et al.*, 2010).

The dense nature of many large cities has a pronounced influence on anthropogenic heat emissions and surface roughness, linked to the level of wealth, energy consumption and micro and regional climate conditions. Anthropogenic heat fluxes for large cities can be very high: a global analysis indicates up to 50-500 W m^{-2} (Allen *et al.*, 2011; Flanner, 2009) in London (Iamarino *et al.*, 2012) and in Singapore (Quah and Roth, 2012) with values locally reaching 1500 W m^{-2} in Tokyo (Ichinose *et al.*, 1999). Strong seasonal, diurnal and meteorological variability in temperature also influence the level of significance of urbanization-related changes on specific cities.

The large spatial extent and significant amount of built environment of megacities (10 million or more inhabitants) can have significant impacts on the local and regional energy balance and associated weather, climate, and related environmental qualities such as air quality. Grimmond (2011) found increasing evidence that cities can influence weather (e.g., rainfall, lightning) through complex urban land use–weather–climate directional feedbacks (see also Ohashi and Kida, 2002). Spatially massive urban centres also can affect downwind locations by raising temperature and negatively impacting air quality (Bohnenstengel *et al.*, 2011). Megacity impact on air flows has been modeled for New York and Tokyo (Holt and Pullen, 2007; Holt *et al.*, 2009; Thompson *et al.*, 2007). Megacity-coastal interactions may impact the hydrological cycle and pollutant removal processes through the development of fog, clouds, and precipitation in cities and adjoining coastal areas (Ohashi and Kida, 2002; Shepherd *et al.*, 2002). Other modeling efforts define building density and design and the scale of urban development as important local determinants of the influence of urbanization on local temperature shifts (Oleson, 2012; Trusilova *et al.*, 2008).

8.2.2.2. Spatiality and Temporal Dimensions

Spatial settlement patterns are a critical factor in the interactions among urbanization, climate-related risks, and vulnerability. One aspect is density, ranging from concentrated to dispersed, with most planned urban settlements decreasing in population density with distance from the core (Seto *et al.*, 2012; Solecki and Leichenko, 2006). In cities with large fringe and unplanned settlements, this pattern can be reversed. In both cases, urban growth is experienced through horizontal expansion and sprawl (United Nations, 2012), fostering extensive networks of critical infrastructure, which are frequently vulnerable to climate change (Rosenzweig *et al.*, 2011; Solecki *et al.*, 2011). Rapid urban population growth in the last decade also has been increasingly marked by growth in vertical density (high-rise living, and working), especially in Asia. Higher density living offers opportunities for resource conservation but also challenges for planning and urban management (see 8.3.3.).

Urbanization is associated with changing dimensions of migration and materials flows into and out of cities and also within them (Grimm *et al.*, 2008). The level of increase (or in some cases decrease) of these conditions creates a dynamic quality of risk in cities. Rapidly changing cities must try to manage this growth through housing and infrastructure development while simultaneously understanding the relative impact of climate change. For example in sub-Saharan Africa, the combination of relatively high population growth rates and increasing levels of urbanization brings a rise in exposure to climate change impacts (Parnell and Walawege, 2011). The conflation of local environmental change resulting from urbanization with climate change shifts makes the identification and implementation of effective adaptation strategies more difficult. Water shortages, for instance, already a chronic concern for many cities in low and middle-income nations, typically worsen as the population and demand continue to grow (Muller, 2007). Climate change-related reductions or uncertainties in supply combine with this existing instability to create the conditions for greater management and governance crises (Gober, 2010; Milly *et al.*, 2008).

8.2.2.3. Urbanization and Ecological Sustainability

The urbanization-climate change connection has important implications for ecological sustainability. Climate change can accelerate ecological pressures in cities, as well as interact with existing urban environmental, economic, and political stresses (Leichenko, 2011; Wilbanks and Kates, 2010). This is an especially important in a world where transgressions of key planetary boundaries such as climate change and biodiversity may take humanity out of the globe's "safe operating" space (Rockström *et al.*, 2009, p. 1) into an unsafe and unpredictable future. A study by Trusilova *et al.* (2008) analyses the urbanization-induced disturbances of the carbon cycle in Europe through the land use change, local climate modification, and atmospheric pollution. This study shows that urban effects spread far beyond the city's boundaries and trigger complex feedback/responses in the biosphere (Trusilova *et al.*, 2008). Urbanization changes land use cover, generally reduces the amount of ecologically intact land and causes fragmentation of the remaining land, which reduces habitat value for species and increases the likelihood of further ecological degradation.

The linkage between urbanization, ecological sustainability and climate change is well illustrated by the example of New Orleans. This city's geophysical vulnerability is shaped by its low-lying location, accelerating subsidence, rising sea levels, and heightened intensity and frequency of hurricanes - a combination of natural phenomena exacerbated by "settlement decisions, canal development, loss of barrier wetlands, extraction of oil and natural gas, and the design, construction, and failure of protective structures and rainfall storage" (Wilbanks and Kates, 2010 p. 726; see also Ernstson et al., 2010). For cities in arid regions, already struggling with water shortages often in the context of rising demand, climate change may further reduce water availability because of shifts in precipitation and/or evaporation (Gober, 2010).

8.2.2.4. Regional Differences and Context-Specific Risks

Case studies and regional reviews assessing urban vulnerabilities to climate change have revealed diverse physical and societal challenges and large differences in levels of adaptive capacity (Hunt and Watkiss, 2011; Rosenzweig *et* *al.*, 2011). Research on African cities (Castán Broto *et al.*, 2013; Kithiia, 2011; Simon, 2010) has highlighted the lack of capacity and awareness of climate change, and often extremely high levels of vulnerability among the continent's large and rapidly growing urban poor populations. Other reviews have considered cities in Latin America (Hardoy and Romero-Lankao, 2011; Luque *et al.*, 2013), North America (Zimmerman and Faris, 2011), Europe (Carter, 2011), and Asia (Alam and Rabbani, 2007; Birkmann *et al.*, 2010; Kovats and Akhtar, 2008; Liu and Deng, 2011; Revi, 2008). The global distribution of urban risks is highly context-specific, dynamic, and uneven among and within regions. Absolute exposure to extreme events over the next few decades will be concentrated in large cities and countries with urban populations in low-lying coastal areas, as in many Asian nations (McGranahan *et al.*, 2007). Settlements located in river flood plains also are prone to flooding during extreme or persistent precipitation/severe storm conditions.

Many cities include dangerous sites, such as steep slopes, low lands adjacent to unprotected riverbanks and ocean shorelines, and have structures that do not meet building codes (Hardoy *et al.*, 2001; Pelling, 2003). Context specific risks and associated vulnerability also relates to the socio-economic status of residents. Women, children, health-compromised people and the elderly in informal settlements are generally most vulnerable to climate change impacts. Poor access to infrastructure and transport, low incomes, limited assets and dangerous locations can combine to put them at high risk from disasters (Moser and Satterthwaite, 2009).

8.2.3. Climate Change and Variability Impacts - Primary (Direct) and Secondary (Indirect) Impacts

Climate change will lead to increased frequency, intensity and/or duration of extreme weather events such as heavy rainfall, warm spells and heat events, drought, intense storm surges and associated sea-level rise (see Hunt and Watkiss, 2011; IPCC, 2007; IPCC, 2012; Romero-Lankao and Dodman, 2011; Rosenzweig *et al.*, 2011). Several urban aspects of these changes are described below.

8.2.3.1. Urban Temperature Variation: Means and Extremes

The three maps in Figure 8-3 show where the world's largest urban agglomerations are concentrated in relation to changes in observed and projected temperature. 8.3a shows the location of the largest urban agglomerations in 2010 against the backdrop of the observed history of climate-induced temperature rise (1901-2012). The dot for each urban agglomeration is colour-coded according to its population growth rate between 1970 and 2010. Those that had the most rapid population growth rates for these four decades are strongly clustered in Asia (especially in China and India) and in Latin America and sub-Saharan Africa (with many on the coast). This map highlights the temperature rise of over 1 degree C in areas in North and Central Asia, Western Africa, South America and parts of North America, indicating the potential differential exposure of large cities to climate risk.

[INSERT FIGURE 8-3 HERE
Figure 8-3: Large urban agglomerations and temperature change. Sources: Maps drawn from IPCC, 2013; urban agglomeration population and population growth data from United Nations, 2012.]

8-3b shows the location of the largest urban agglomerations according to projected populations for 2025 within the world map showing projected temperature changes for the mid-21st century, using Representative Concentration Pathway (RCP) 2.6. This is a scenario with strong mitigation. Projected populations for urban agglomerations were not made up to 2050 because there is no reliable basis for making these. Each urban agglomeration's future population is much influenced by its economic performance and by social, demographic, economic and political changes that cannot be predicted so far into the future. Assuming that almost all the large urban agglomerations in 2025 will still be large urban agglomerations in 2050, 8-3b suggests that a number of large urban agglomerations in almost all continents, will be exposed to a temperature rise of over 1.5 degree (over pre-industrial levels) by mid-century, using the RCP 2.6 scenario (IPCC, 2013).

8-3c shows a similar map showing projected temperature changes for the mid-21st century but using the RCP 8.5 scenario. This scenario, based on unchanged current GHG emission trends by mid-century, shows that the bulk of the world's population living in the largest urban agglomerations (based on their 2025 populations) will be exposed to a minimum 2 degree temperature rise over pre-industrial levels, excluding urban heat island effects. By late-century, under the RCP 2.6 scenario, a number of the urban agglomerations that were among the largest in 2025 will be exposed to temperature rise of up to 2.5 degrees over pre-industrial levels (excluding urban heat island effects), especially in the high latitudes. This implies that mean temperature rise in some cities could be over 4 degrees C. The RCP 8.5 scenario by late-century (with unchanged current GHG emission trends), shows that the bulk of the world's population living in large urban agglomerations will be exposed to a minimum 2.5 degree temperature rise. Some cities in high latitudes experience a mean 3.5 degree rise, or over 5 degrees when combined with UHI effects. Peak seasonal temperatures could be even higher. Temperature increases of 6-8 degrees in the Arctic and temperature rise in Antarctica would contribute to sea-level rise that would impact coastal cities across the world.

Increased frequency of hot days and warm spells will exacerbate urban heat island effects, causing heat-related health problems (Hajat *et al.*, 2010) and, possibly, increased air pollution (Blake *et al.*, 2011; Campbell-Lendrum and Corvalan, 2007), as well as an increase in energy demand for warm season cooling (Lemonsu *et al.*, 2013). Conversely, widespread reduction in periods of very cold weather will mean a decline in heating demands (Mideksa and Kallbekken, 2010) and potential reduction in mortality from cold waves.

Climate change will modify urban heat islands (UHI) in cities. Recent studies with physically based models (Früh *et al.*, 2011; McCarthy *et al.*, 2010; Oleson, 2012) show mixed signals, with reductions in UHI in many areas of the world and increases in some in response to climate change simulations. London's annual number of nights with heat islands stronger than 4ºC has increased by 4 days per decade since the late 1950s; meanwhile, the average nocturnal heat island intensity rose by approximately 0.1ºC per decade over the same period (Wilby, 2007). Projections suggest that by 2050, London's nocturnal UHI in August could rise another 0.5°C, representing a 40 per cent increase in the number of nights with intense UHI episodes (*ibid*). However, McCarthy *et al.* (2011), looking specifically at London and Manchester, found 0.1ºC or less (Tmin) increase in expected UHI by the 2050s. Future projections of UHI under global warming conditions were also conducted for Tokyo where a potential increase of the urban heat island intensity of 0.5º C was defined (Adachi et al 2012). Adachi et al. (2012) model an increase in UHI from 1.0º C to 1.5º C by the 2070s. In addition to the greater UHI intensity, air temperature in August is projected to increase about 2ºC by the 2070s according to an average of 5 Global Climate Models (GCM) under the SRES A1b scenario (note: range of uncertainty in GCMs is about 2ºC).

Climate change in New York City is expected to increase extended heat waves, thus exacerbating existing UHI conditions (Rosenzweig *et al.*, 2009). Increased night time minimum temperatures are associated with increased cooling demand and health-related stresses. For cities in India, the implications of future climate for connections between urbanization and the development of UHI, have been defined (Mohan *et al.*, 2011a; Mohan *et al.*, 2011b; Mohan *et al.*, 2012). Overall, the current trend of increasingly frequent extreme events is expected to increase with climate change (Manton, 2010). The comparison of the annual mean minimum temperatures of two stations in Delhi (Safdarjung and Palam) since the 1970s show night temperature trends synchronizing with the city's pace of expansion (Mohan *et al.*, 2011a).

8.2.3.2. Drought and Water Scarcity: Means and Extremes

Drought can have many effects in urban areas, including increases in water shortages, electricity shortages (where hydropower is a source), water-related diseases (though use of contaminated water), and food prices and food insecurity from reduced supplies. These may all contribute to negative economic impacts and increased rural to urban migration (Farley *et al.*, 2011; Herrfahrdt-Pähle, 2010; Vairavamoorthy *et al.*, 2008). An estimated 150 million people currently live in cities with perennial water shortage, defined as less than 100 litres per person per day of sustainable surface and groundwater flow within their urban extent. Averages across all climate change scenarios, noting the role of demographic growth, suggest a large increase in this number, possibly up to 1 billion by 2050 (McDonald *et al.*, 2011).

8.2.3.3. Coastal Flooding, Sea Level Rise, and Storm Surge

Sea-level rise represents one of the primary shifts in urban climate change risks, given the increasing concentration of urban populations in coastal locations and within low-elevation zones (McGranahan *et al.*, 2007). The new IPCC estimates for global mean sea level rise are for between 26 and 98 cm by 2100; this is higher than the 18-59 cm projected in AR4 (IPCC, 2013). Rising sea levels, the associated coastal and riverbank erosion, or flooding in conjunction with storm surge could have widespread effects on populations, property and coastal vegetation and ecosystems, and present threats to commerce, business, and livelihoods (Carbognin *et al.*, 2010; Dossou and Gléhouenou-Dossou, 2007; El Banna and Frihy, 2009; Hanson *et al.*, 2011; Nicholls, 2004; Pavri, 2010; Zanchettin *et al.*, 2007). This is well illustrated by several large-scale recent disasters including Hurricane Sandy in the New York metropolitan region. Lowland areas in coastal cities such as Lagos, Mombasa, or Mumbai are usually more at risk of flooding, especially where there is less provision for drainage (Adelekan, 2010; Awuor *et al.*, 2008; Revi, 2008). Structures on infilled soils in the lowlands of Lagos and Mumbai are more exposed to risks of flood hazards than similar structures built on consolidated materials (*ibid.)* Many near coastal cities such as Dhaka have sites at risk from both riverine and coastal storm surge (Mehrotra *et al.*, 2011a).

Cities with extensive port facilities and large scale petro-chemical and energy-related industries are especially vulnerable to risks from increased flooding (Hallegatte *et al.*, 2013). Hanson *et al.* (2011) estimate the change in flooding by the 2070s in the exposure of large port cities to coastal flooding with scenarios of socio-economic growth, sea level rise and heightened storm surge, and subsidence. They find that with a 0.5 meter rise in sea-level, the population at risk could more than triple while asset exposure is expected to increase more than ten-fold. The "top-20" cities identified for both population and asset exposure to coastal flooding in both the current and 2070 rankings are spread across low, middle, and high-income nations, but are concentrated in Asian deltaic cities. They include: Mumbai, Guangzhou, Shanghai, Miami, Ho Chi Minh City, Kolkata, New York, Osaka-Kobe, Alexandria, Tokyo, Tianjin, Bangkok, Dhaka, and Hai Phong. Using asset exposure as the metric, cities in high-income nations and in China figure prominently: Miami, New York City, Tokyo and New Orleans as well as Guangzhou, Shanghai and Tianjin. Detailed site specific studies can define the local level of sea level rise and other local factors such as harbour development, dredging and erosion, groundwater withdrawal and subsidence and other factors.

8.2.3.4. Inland Flooding, Hydrological and Geo-Hydrological Hazards at Urban Scale

Exposure to climate related hazards will vary with differences in the geomorphologic characteristics of cities (Luino and Castaldini, 2011). Heavy rainfall and storm surges would impact urban areas through flooding which in turn can lead to the destruction of properties and public infrastructure, contamination of water sources, water logging, loss of business and livelihood options and increase in water borne and water-related diseases, as noted in wide range of studies (Adelekan, 2010; de Sherbinin *et al.*, 2007; Dossou and Gléhouenou-Dossou, 2007; Douglas *et al.*, 2008; Hardoy and Pandiella, 2009; Kovats and Akhtar, 2008; Nie *et al.*, 2009; Revi, 2008; Roberts, 2008; Sharma and Tomar, 2010; Shepherd *et al.*, 2011). Case studies of inland cities have considered the elevated risk of flooding due to climate change, as in Kampala (Lwasa, 2010) and travel disruptions in Portland (Chang *et al.*, 2010). There have been significant research attempts to improve modelling of the frequency and condition of extreme precipitation events and resulting flooding (Nelson *et al.*, 2008; Olsson *et al.*, 2009; Onof and Arnbjerg-Nielsen, 2009; Ranger *et al.*, 2011; Sen, 2009).

The review on the world-wide impacts of climate change on rainfall extremes and urban drainage by Willems *et al.* (2012) has shown that typical increases in rainfall intensity at small urban hydrology scales range from 10% to 60% from control periods in the recent past (typically 1961-1990) up to 2100. These changes in extreme short-duration rainfall events may have significant impacts for urban drainage systems and pluvial flooding. Results so far indicate more problems with sewer sub charging, sewer flooding and more frequent combined sewer overflow (CSO) spills. Extreme rainfall changes in the range of 10-60% may lead to changes in flood and CSO frequencies and volumes in the range 0-400% depending on system characteristics. This is because floods and overflows, when runoff or sewer flow thresholds are exceeded, can react to rainfall (changes) in a highly non-linear way (Arnbjerg-Nielsen *et al.*, 2013; Willems *et al.*, 2012; Willems and Vrac, 2011; Willems, 2013).

8.2.3.5. Emerging Human Health, Disease, and Epidemiology Issues in Cities

WHO/WMO (2012) and Barata *et al.* (2011) note that climate change may affect the future social and environmental determinants of health, including clean air, safe drinking water, sufficient food and secure shelter. There is good evidence that temperature extremes (heat and cold) affect health, particularly mortality rates (see 11.2.2). Increased warming and physiological stress on human comfort level is predicted in a variety of cities in sub-tropical, semi-arid, and temperate sites (Blazejczyk *et al.*, 2012; Thorsson *et al.*, 2011); see also Figure 8-3. For more discussion on cities and impacts of increased warming in specific regions, see the regional chapters (Chapters 21-30).

Recent studies have illustrated the impact of heat stress on urban populations in low- and middle-income countries (see for instance Burkart *et al.* (2011) for Bangladesh and Egondi *et al.* (2012) for children in Nairobi's informal settlements). Hot days are known to have significant impacts on health that can be exacerbated by both drought conditions and high humidity. Studies in high-income countries show the elderly more vulnerable to heat-related mortality (see Oudin Åström *et al.* (2011) for a review of this). In urban settings where child mortality is high, extreme temperatures have been shown to have an impact on mortality (e.g., Egondi *et al.*, 2012). People in some occupations are more at risk, as they are exposed to higher temperatures for long durations (see Hoa *et al.*, 2013) and low-income households are more at risk when heat waves disrupt or limit income-earning opportunities (see Kovats and Akhtar, 2008, see also 11.2.7 for more detailed discussion of occupational heat stress).

Climate change has implications for urban air quality (Athanassiadou *et al.*, 2010), air pollution, and health policy (see Chapter 11 of WGI AR5). The impacts on urban air quality in particular urban areas are highly uncertain and may include increases and decreases of certain pollutants (Jacob and Winner, 2009; Weaver *et al.*, 2009). Urban air quality in most cities already is compromised by localized air pollution from transport and industry, and often commercial and residential sources. Emerging literature shows strong evidence that climate change will generally increase ozone in the US and Europe, but that the pattern of that change is not clear, with some areas increasing and some decreasing (Katragkou *et al.*, 2011; Lam *et al.*, 2011). The effects on particulate matter (PM) are also unclear, as are the effects on ozone and PM outside of the US and Europe (Dawson *et al.*, 2013).

The incidence of asthma exacerbation may be affected by climate-change related increases in ground level ozone exposures (Barata *et al.*, 2011; Gamble *et al.*, 2009; Kinney, 2008; O'Neill and Ebi, 2009; Reid *et al.*, 2009); other pollutants may also be affected, particularly in cities with PM10 and ozone levels far above WHO guidelines (WHO, 2011). Climate change may change the distribution, quantity, and quality of pollen in urban areas, as well as the timing and duration of pollen seasons. WHO/WMO (2012) notes that diarrhoeal diseases, malnutrition, malaria and dengue are climate-sensitive and in the absence of appropriate adaptation, could be adversely affected by climate change (see chapter 11).

8.2.4. Urban Sectors: Exposure and Sensitivity

This section assesses how the observed and forecast direct impacts of climate change influence the exposure of city residents, buildings, infrastructure, and systems to risk. It considers key affected sectors and populations and possible interrelations. Direct impacts include all costs and losses attributed to the impact of hazard events, but exclude systemic impacts, for example on urban economies through price fluctuations following a disaster or the impact of disaster losses on production chains (see UN-ECLAC, 1991). Both the temporal and spatial scale of the shifts in climate risk across cities and urbanizing sites in the next few decades are considered. In addition, we analyze the change in the scale and character of risks in cities, as climate extremes, means and long-term trends (e.g., sea-level rise) change.

Climate change will have profound impacts on a broad spectrum of city functions, infrastructure and services and will interact with and may exacerbate many existing stresses. These impacts can occur both *in situ* and through long-distance connections with other cities and rural sites of resource production and extraction (Seto *et al.*, 2012; Wackernagel *et al.*, 2006). The interaction between climate change and existing environmental stresses can lead to a range of synergies, challenges, and opportunities for adaptation with complex interlinkages and often highly uncertain or non-linear processes (Ernstson *et al.*, 2010). For example, the 2007 floods in the city of Villahermosa, which covered two thirds of Tabasco State in Mexico, had serious consequences for the city's economic base, with damages and losses equivalent to 30 per cent of the state's annual GDP (CEPAL, 2008). The flood that struck the Chao Phraya River in 2011 caused a high loss of life and damages to many companies and several industrial estates in Bangkok (estimated local damage and loss was 3.5 trillion Yen), but it also disrupted global scale industrial supply chains (Komori *et al.*, 2012). Urban centres serving prosperous agricultural regions are particularly sensitive to climate change if water supply or particular crops are at risk. In Naivasha, Kenya, drought threatens high-value export-oriented horticulture (Simon, 2010). Urban centres that serve as major tourism destinations may suffer when the weather becomes stormy or excessively hot and lead to a loss of revenue. Recent assessments have projected the rising population and asset exposure in large port cities (see 8.2.3.3, also Hanson *et al.*, 2011; Munich Re, 2004), alongside case studies in Copenhagen (Hallegatte *et al.*, 2011b) and Mumbai (Ranger *et al.*, 2011). By 2070, the exposed assets in cities such as Ningbo (China), Dhaka (Bangladesh) and Kolkata (India) may increase by more than 60-fold (Hanson *et al.*, 2011).

Infrastructure will similarly be affected by systemic and cascading climate risks (Hunt and Watkiss, 2011). Climate stresses, particularly extreme events, will have effects across interconnected urban systems, within and across multiple sectors (Gasper *et al.*, 2011). The cascading effects are especially evident in the water, sanitation, energy, transport, and communications sectors, due to the often tightly coupled character of urban infrastructure systems (see Rosenzweig and Solecki (2010) for a discussion of this for New York City). The U.S. National Climate Assessment effort has looked at the impacts of climate change on infrastructure, considering the water, land, and energy nexus, as well as on a large number of industries (Skaggs *et al.*, 2012; Wilbanks *et al.*, 2012). These systemic cascades can have both direct and indirect economic impacts (Hallegatte *et al.*, 2011b; Ranger *et al.*, 2011), which can extend from the built environment to urban public health (Frumkin *et al.*, 2008; Keim, 2008). A critical element is the impact for infrastructure investments with long operational lives, in some cases 100 years or more (Hallegatte and Dumas, 2009). In low- and most middle-income cities, very large additional investment is needed to address deficits in infrastructure and services; without this investment, making the short to long-term trade-off to improve resilience is difficult (Dodman and Satterthwaite, 2009). This is an opportunity for 'climate smart' infrastructure planning that considers how to combine pro-poor development and climate change adaptation and mitigation. This is a more difficult task for cities such as New York with dense aging infrastructure and materials that "may not be able to withstand the projected strains and stresses from a changing climate" (Zimmerman and Faris, 2010, p. 63). These cities also have the opportunity, when replacing aging infrastructure, to integrate climate considerations into the new infrastructure decision-making processes.

8.2.4.1. Water Supply, Wastewater, and Sanitation

Water and sanitation systems affect household well-being and health, as well as influencing urban economic activities, energy demands and the rural-urban water balance (Gober, 2010). Climate change will impact residential water demand and supply and its management (O'Hara and Georgakakos, 2008). Among the projected impacts are altered precipitation and runoff patterns in cities, sea level rise and resulting saline ingress, constraints in water availability and quality, and heightened uncertainty in long-term planning and investment in water and waste water systems (Fane and Turner, 2010; Major *et al.*, 2011; Muller, 2007). Local government departments and utilities responsible for water supply and waste water management must confront these new climatic patterns and major uncertainties in availabilities and learn to respond to dynamic and evolving sets of constraints (Milly *et al.*, 2008).

Climate change will increase the risk and vulnerability of urban populations to reductions in groundwater and aquifer quality (e.g., Praskievicz and Chang, 2009; Taylor and Stefan, 2009), subsidence and increased salinity intrusion. High levels of groundwater extraction have led to serious subsidence problems in cities such as Bangkok (Babel *et al.*, 2006) and Mexico City (Romero-Lankao, 2010), which damage buildings, fracture pipes and can increase flood risks (see also Jha *et al.*, 2012). This problem can be compounded in coastal cities when saline intrusion reduces ground water quality and erodes structures.

In many rapidly developing cities, the impact of climate change on water supplies will interact with growing population, growing demand and economic pressures, potentially heightening water stress and negative impacts on the natural resource base, with effects for water quality and quantity. Caribbean nations, for example, with their expanding middle-class urban population, face sharply raised demands for water, and the associated challenges of managing runoff, storm water, and solid wastes. Projected reductions in rainfall amounts at specific times in particular locations would aggravate such water stresses (Cashman *et al.*, 2010).

In Shanghai, climate change is expected to bring decreased water availability as well as flooding, groundwater salinization and coastal subsidence. The city's population of 17 million is projected to continue expanding, often within areas that are "likely increasingly flood-prone" (de Sherbinin *et al.*, 2007, p. 60). Groundwater depletion has contributed to land subsidence in these already vulnerable areas, reinforcing the water stresses and risks of erosion (*ibid.*). In several large Andean cities, including Lima, La Paz, and Quito, declining volumes of glacial melt water have been observed, with expected further declines (Buytaert *et al.*, 2010; Chevallier *et al.*, 2011).

Several studies estimate how climate change will alter relationships among water users, exacerbating tensions and conflicts between the various end-users (residential, commercial, industrial, agricultural, and infrastructural) (Roy *et al.*, 2012; Tidwell *et al.*, 2012). In small and mid-sized African cities, the effect of flooding on well water quality is a growing concern (Cissé *et al.*, 2011). Floods, droughts and heavy rainfall have also impacted agriculture and urban food sources, and can exacerbate food and water scarcity in urban areas (Gasper *et al.*, 2011). But not all water systems are projected to experience negative impacts. Chicago's Metropolitan Water Reclamation District (MWRD) found that reduced precipitation due to climate change would decrease pumping and general operations costs, since sewers will contain less rainwater in drier seasons (Hayhoe *et al.*, 2010).

Wastewater and sanitation systems will be increasingly overburdened during extreme precipitation events if attention is not paid to maintenance, the limited capacity of drainage systems in old cities, or lack of provision for drainage in most unplanned settlements and in many urban centres (Howard *et al.*, 2010; Mitlin and Satterthwaite, 2013; Wong and Brown, 2009). In the city of La Ceiba, Honduras, stakeholders concluded that urban drainage and improved management of the Rio Cangrejal watershed were top priorities for protection against projected climate change impacts; the city lacks a stormwater drainage system but experiences regular flooding (Smith *et al.*, 2011).

Flooding is often made worse by uncontrolled city development that builds over natural drainage channels and flood plains or by a failure to maintain drainage channels (often blocked by solid wastes where waste collection is inadequate). These problems are most evident in cities where there are no drains or sewers to help cope with heavy precipitation (see Douglas *et al.*, 2008) and no service to collect solid wastes (in many cities in low-income nations, less than half the population has regular solid waste collection – see Hoornweg and Bhada-Tata (2012). Many cities in high-income nations also face challenges. An analysis of three cities in Washington State, assessing future streamflows and peak discharges, concluded that "concern over present (drainage) design standards is warranted" (Rosenberg *et al.*, 2010, p. 347). Climate change was identified as a key driver affecting Britain's future sewer systems. According to the model used, the volume of sewage released to the environment by combined sewage overflow spills and flooding was projected to increase by 40 per cent (Tait *et al.*, 2008).

8.2.4.2. Energy Supply

Energy exerts a major influence on economic development, health, and quality of life. Any climate change-related disruption or unreliability in power or fuel supplies can have far-reaching consequences, affecting urban businesses, infrastructure, services (including healthcare and emergency services) and residents, as well as water treatment and supply, rail-based public transport, and road traffic management (Finland Safety Investigations Authority, 2011; Halsnæs and Garg, 2011; Hammer *et al.*, 2011; Jollands *et al.*, 2007).

Past experiences with power outages indicate some of the knock-on effects (Chang *et al.*, 2007). New York City's blackout of 2003 lasted 28 hours and halted mass transport, surface vehicles due to signaling outages, and water supply (Rosenzweig and Solecki, 2010). A review of climate change impacts on the electricity sector (Mideksa and Kallbekken, 2010) projects reductions in the efficiency of water cooling for large electricity generating facilities, changes in hydropower and wind power potential, and changing demand for heating or cooling in the US and

Europe. Low-income households in Chittagong use candles or kerosene lamps during frequent power outages; this was found to disturb children's studies, increase expenses, and overheat homes (Rahman *et al.*, 2010).

Climate change will alter patterns of urban energy consumption, particularly with respect to the energy needed for cooling or heating (for a review, see Mideksa and Kallbekken, 2010). Climate change will bring increases in air conditioning demand and in turn heightened electricity demand (Radhi (2009), see also Hayhoe *et al.* (2010) for a discussion of this in relation to Chicago). In temperate and more northern regions, winter temperature increases may decrease energy demand (Mideksa and Kallbekken, 2010). In most cases within individual cities, potential increases in summertime electricity demand from climate change will exceed reductions in winter energy demand reductions (Hammer *et al.*, 2011). Less is known about the demand side impacts in low and lower-middle-income nations, where large sections the urban population still lack access to electricity (Johansson *et al.*, 2012; Satterthwaite and Sverdlik, 2012). Most of these nations are expected, as noted, to have increased mean temperatures or rising frequency of heat waves (IPCC, 2007).

Many cities' economies will be affected if water scarcity and variability interrupt hydropower supplies. For instance, reductions in hydroelectric generation will have impacts on the economies of many urban centres in Brazil as well as in neighbouring countries (de Lucena *et al.*, 2010; de Lucena *et al.*, 2009; Schaeffer *et al.*, 2011). Cities in sub-Saharan Africa often rely on hydropower for their electricity, and failures in supplies can lead "to a more general 'urban failure' " (Muller, 2007, p. 106). Laube *et al.* (2006) discuss water shortages in Ghana following low precipitation periods, and the potential for competition between hydropower and water provision, including to downstream urban centres. Declining water levels in the Hoover Dam have raised the possibility that Los Angeles will lose a major power source, and that Las Vegas will face a severe decline in drinking water availability (Gober, 2010).

Summer heat waves, with spikes in demand for air conditioning, can result in brownouts or blackouts (Mideksa and Kallbekken, 2010; Mirasgedis *et al.*, 2007). Cities in the temperate regions of Australia already experience regular blackouts on hot summer days, largely due to residential air-conditioner use (Maller and Strengers, 2011). Research in Boston suggested that rising energy demands in hotter summers have meant a "disproportional impact on (the) elderly and poor, increased energy expenditures; loss of productivity and quality of life" (Kirshen *et al.*, 2008, p. 241). Any increase in the frequency or intensity of storms may disrupt electricity distribution systems because of the collapse of power lines and other infrastructure (Rosenzweig *et al.*, 2011, see also Chapter 10).

8.2.4.3. Transportation and Telecommunications

Climate change-related extreme events will affect urban transportation and telecommunication infrastructure, including a variety of capital stock, such as bridges and tunnels, roads, railways, pipelines, and port facilities, data sensors, and wire and wireless networks (Hallegatte *et al.*, 2011a; Jacob *et al.*, 2011; Koetse and Rietveld, 2009; Major *et al.*, 2011). In the Gulf Coast region of the United States, 27 percent of major roads, 9 percent of rail lines, and 72 percent of ports are at or below 122 cm (4 ft) in elevation. With a storm surge of 7 m (23 ft), more than half the area's major highways, almost half the rail miles, 29 airports, and virtually all the ports are subject to flooding (Savonis *et al*, 2008). Assessing possible disruptions of transport networks within cities and urban systems is critical. Loss of telecommunication access during extreme weather events can inhibit disaster response and recovery efforts because of its critical role in providing logistical support for such activity (Jacob *et al.*, 2011).

Ports are central to international trade and climate change poses substantial challenges related to exposed locations in coastal zones, low-lying areas and deltas; long lifespans of key infrastructure and interdependencies with trade, shipping and inland transport services that are also vulnerable (Asariotis and Benamara, 2012; Oh and Reuveny, 2010). Hurricane Sandy crippled the New York region, leading to a week-long shut-down of one of the largest container ports in the U.S. (Hallegatte *et al.*, 2013).

Large sections of the urban population in low- and middle-income nations live in settlements without all-weather roads and paths that allow for emergency vehicle access and rapid evacuation. For instance, in Chittagong, Bangladesh, extremely narrow roads limit emergency access to most of informal neighbourhoods, exacerbating health and fire risks (Rahman *et al.*, 2010). In Lagos's informal settlements, a 2006 resident survey ranked roads second to drainage in terms of needed facilities (Adelekan, 2010). Evacuations in low-income areas may also be hampered by hazardous locations, absence of public transport and inadequate governance. Following the 2003 and 2006 floods in Santa Fe, Argentina, the lack of information and official evacuation mechanisms prevented timely responses; some residents also chose to stay in their homes to protect their possessions from looters (Hardoy and Pandiella, 2009).

Low-income urban residents can also be profoundly affected during and after extreme weather events that damage critical public transit links, prevent access to work, and heighten exposure to health risks. Interviews in Georgetown, Guyana, found that the limited transport access of low-income households during floods made them more prone to losing time from work or school, compared to wealthier households. Poorer households rarely owned cars, and wading barefoot through floodwaters exposed them to waterborne pathogens (Linnekamp *et al.*, 2011). Some studies find urban women walk or use public transport more than men (World Bank, 2010c); hence, the gendered impact of transport disruptions may merit greater consideration (see Levy, 2013; UN-Habitat, 2011a).

The literature on urban transport and climate change focuses more on mitigation, with less attention to vulnerability, impacts, and adaptation (Hunt and Watkiss, 2011). Existing studies on impacts are often limited to the short-term demand side, particularly in passenger transport (Koetse and Rietveld, 2009). However, climate change creates several challenges for transport systems. The daily functioning of most transport systems is already sensitive to fluctuations in precipitation, temperature, winds, visibility, and for coastal cities, rising sea levels with the associated risks of flooding and damages (Love *et al.*, 2010). Transport is highly vulnerable to climate variability and change, and the economic importance of transport systems has increased with the rise of just-in-time delivery methods, heightening the risk of losses due to extreme weather (Gasper *et al.*, 2011).

In addition to adapting road transport, cities should ensure bridges, railway cuttings, and other hard infrastructure are resilient to climate change over their service lifespan (Jaroszweski *et al.*, 2010). Few studies have examined the effects of climate change on railways, but rail system failures are known to be related to high temperatures, icing, and storms (Koetse and Rietveld, 2009); see Dobney *et al.* (2008) for future heat related delays in UK railways; also Palin *et al.* (2013) offers a broad discussion of climate change effects on the UK rail network. Very few studies have examined the vulnerability of air and seaborne transport and infrastructure, but climate change could mean more and lengthier weather-related delays and disruption (Becker *et al.*, 2012; Eurocontrol, 2008).

Loss of sea ice can benefit some cities by increasing opportunities for developing road networks or ports. However, it may be costly to adapt road, air and water transport networks to the known environmental risks associated with such redevelopment (Larsen *et al.*, 2008). For industries and communities in Northern Canada, reduced freshwater-ice levels creates longer shipping seasons and could also promote new seaports in marine environments. But thawing of permafrost can also result in instability and major damage to roads, infrastructure, and buildings in and around northern cities and towns, and inland towns will require sizable investments to replace winter ice roads with land-based roads (Prowse *et al.*, 2009).

The direct impacts of extreme weather on transport are more easily assessed than the indirect impacts or possible knock-on effects between systems. Studies have often examined the direct impacts of flooding on transport infrastructure, but the indirect costs of delays, detours, and trip cancellation may also be substantial (Koetse and Rietveld, 2009). Mumbai's 2005 floods caused injuries, deaths and property damage but also serious indirect impacts as most city services were shut down for five days without contact via rail, road or air (Revi, 2005). Transport and other urban infrastructure networks are often interdependent and located in close proximity to one another, yet only a few assessments have considered the joint impacts (Hayhoe *et al.*, 2010; Kirshen *et al.*, 2008).

Transportation systems are critical for effective disaster response – for example, where populations have to be evacuated prior to an approaching storm or where provision is urgently needed for food, water and emergency services to affected populations.

Key elements in cities' communications systems may have to be strengthened – for instance to avoid masts toppling due to strong winds and electrical support facilities that need to be moved or protected against flooding (Zimmerman and Faris, 2010, p. 74). New York City's dispersed communications network faces several climate-related risks. Electrical support facilities can be flooded; cell phone towers can topple in strong winds or become corroded as sea levels rise (Zimmerman and Faris, 2010). In Alaska, telecommunications towers are settling due to warming permafrost (Larsen *et al.*, 2008). Emergencies may generate a demand for communications that exceeds systems' capacities. During the extreme rainfall event in 2005, Mumbai's telecommunications networks ceased to function due to a mix of overload, shut down of the power system and lack of diesel supplies for generators (Revi, 2005).

8.2.4.4. Built Environment, and Recreation and Heritage Sites

Housing ideally provides its occupants with a comfortable, healthy and secure living environment and protects them from injuries, losses, damage and displacement (Haines *et al.*, 2013). For many low-income households, livelihoods also depend on home-based enterprises, and housing is key to protecting their assets and preventing disruption of their incomes. Decent housing has particular importance for vulnerable groups, including infants and young children (Bartlett, 2008), older residents or those with disabilities or chronic health conditions.

Urban housing is often the major part of the infrastructure affected by disasters, according to Jacobs and Williams (2011). Extreme events like cyclones and floods inflict a heavy toll, particularly on structures built with informal building materials and outside of safety standards (United Nations, 2011). Dhaka's 1998 floods damaged 30 percent of the city's units; of these, more than two-thirds were owned by the lower-middle classes and the poorest (Alam and Rabbani, 2007). Adelekan (2012) shows that a relatively modest increase in wind speeds during storms caused widespread damage in central Ibadan. Relative to the preceding decade, the period from 1998 to 2008 showed higher mean maximum wind gusts and more frequent windstorms with peak gusts greater than 48 knots, and the impacts were severe in part because of the high concentration of residents in damaged buildings. Increased climate variability, warmer temperatures, precipitation shifts, and increased humidity will accelerate the deterioration and weathering of stone and metal structures in many cities (Bonazza *et al.*, 2009; Grossi *et al.*, 2007; Smith *et al.*, 2008; Stewart *et al.*, 2011; Thornbush and Viles, 2007).

Recreational sites such as parks and playgrounds will also be affected. In New York City, these are defined as critical infrastructure and are often located in low elevation areas subject to storm surge flooding (Rosenzweig and Solecki, 2010). Little research has examined the effects upon urban tourism in particular (Gasper *et al.*, 2011).
The increased risks that climate change brings to the built environment (Spennemann and Look, 1998; Wilby, 2007) also apply to built heritage. This has led to the Venice Declaration on Building Resilience at the Local Level Towards Protected Cultural Heritage and Climate Change Adaptation Strategies, which brings together UNESCO, UN-HABITAT, EC and individual city mayors. An example is Saint-Louis in Senegal, a coastal city and World Heritage Site on the mouth of the Senegal river, which has frequent floods and large areas at risk from river and coastal flooding. There are initiatives to reduce flooding risks and relocate families from locations most at risk, but the local authority has very limited investment capacity (Diagne, 2007; Silver *et al.*, 2013).

8.2.4.5. Green Infrastructure and Ecosystem Services

Climate change will alter ecosystem functions affected by changes in temperature and precipitation regimes, evaporation, humidity, soil moisture levels, vegetation growth rates (and allergen levels), water tables and aquifer levels, and air quality. It will also accentuate the value of ecosystems services and green infrastructure for adaptation. "Green infrastructure" refers to interventions to preserve the functionality of existing green landscapes (including parks, forests, wetlands or green belts), and to transform the built environment through phytoremediation and water-management techniques and by introducing productive landscapes (Foster *et al.*, 2011b; La Greca *et al.*, 2011; Zhang *et al.*, 2011). These can influence the effectiveness of pervious surfaces used in storm water management, green/white/blue roofs, coastal marshes used for flood protection, urban agriculture and overall biomass production. Mombasa will experience more variable rainfall as a result of climate change, making the expansion of green infrastructure more difficult (Kithiia and Lyth, 2011). Trees in British cities will be increasingly prone to heat stress and attacks by pests, including new non-native pathogens and pests that can survive under warmer or wetter conditions (Tubby and Webber, 2010). Urban coastal wetlands will be inundated with sea level rise. In New York City, remnant coastal wetlands will be lost to sea-level rise because bulk heading and intensive coastal development will prevent their natural movement inland (Gaffin *et al.*, 2012).

8.2.4.6. Health and Social Services

The effects of climate change will also be evident across urban public services including health and social care provision, education, police and emergency services (Barata *et al.*, 2011, see also Chapter 11). Most urban centres in low-income nations and many in middle-income nations lack adequate social and public service provision (Bartlett, 2008; UN-Habitat, 2003a) while higher-income cities are only beginning to consider climate change in their health or disaster management plans (Brody *et al.*, 2010). Although there are few studies on adapting education, police, or other key services, a growing public health literature has discussed multi-sectoral adaptation strategies (Huang *et al.*, 2011). Cities' existing public health measures provide a foundation for adapting to climate change, such as heat warning systems or disease surveillance (Bedsworth, 2009; McMichael *et al.*, 2008). Negative climate impacts have been highlighted on some of the most vulnerable in society– including children (Ebi and Paulson, 2010; Sheffield and Landrigan, 2011; Watt and Chamberlain, 2011); the elderly (Oven *et al.*, 2012; White-Newsome *et al.*, 2011) and the severely disadvantaged (Ramin and Svoboda, 2009) (see Chapter 11).

8.2.5. Urban Transition to Resilience and Sustainability

The question of how to promote increased resilience and enhanced sustainability in urban areas (as illustrated in Table 8-2) has become a central research topic and policy consideration. It is well recognized that climate change risks affect this process by heightening uncertainties and altering longstanding patterns of environmental risk in cities, many of which continue to face other significant stressors such as rapid population growth, increased pollution, resource demands and concentrated poverty (Mehrotra *et al.*, 2011a; Wilbanks and Kates, 2010). This section discusses how climate change increasingly affects municipal decision-making frames and alters local conceptions of cities as vehicles for economic growth, for political change, for meeting livelihoods and basic needs as well as larger-scale goals of resilience and sustainability.

In recent years, different models of urban environmental transition have been introduced to illustrate the connections between health hazards and environmental impacts as cities and neighbourhoods develop – for example, shifts from a "sanitary city" focused on public health and basic service provision to a "sustainable city" focused on long-term planning, resource efficiency and ecosystem services (McGranahan, 2007). The latter includes consideration of a city's use of global and local sinks for wastes that lie outside its boundaries *(ibid.*, Wilson, 2012). Within these models, key variables have been identified that make cities vulnerable to climate change (e.g., extensive infrastructure networks, high density population in exposed or other sensitive sites).

There is the opportunity to promote societal transition that enhances resiliency and adaptive capacity in the face of accelerated climate change (Ernstson *et al.*, 2010; Gusdorf *et al.*, 2008; Mdluli and Vogel, 2010; Pelling and Manuel-Navarrete, 2011; Pelling, 2011a; Tompkins *et al.*, 2010). Transition in this context can take place at a broad scale, but can also often occur with incremental changes, potentially precipitating regime level shifts (Pelling and Manuel-Navarrete, 2011). Although such shifts also can happen as a result of discrete regime failure (Pelling, 2011a), this is less common. Such transformational changes have been observed in a variety of urban disaster contexts. Most often they follow urban earthquake events (e.g., in Nicaragua, Guatemala, Turkey) but are also associated with flooding in Bangladesh (Pelling, 2011a). Disasters can enable regime level change at moments in history where competing approaches to development have political voice, an organizational base that articulates competing analysis of the causes of the disaster and weak systemic counter response (*ibid.)*.

Climate change may exacerbate existing social and economic stressors in cities with the potential to affect urban livelihoods, engender political or social upheaval, or generate other negative impacts upon human security (Bunce *et al.*, 2010; Siddiqi, 2011; Simon and Leck, 2010) – see regional chapters for this report for more details). Climate change could potentially contribute to violent conflicts and spur migration from highly vulnerable sites in cities or increasingly environmentally stressed locales (Adamo, 2010; de Sherbinin *et al.*, 2011; Reuveny, 2007). But there is considerable uncertainty regarding projections. Migration may represent an important household strategy to adapt by diversifying income-sources and livelihoods (Tacoli, 2009). Although climate change can significantly disrupt livelihoods, outcomes will depend upon particular social structures, state institutions, and other broader determinants of human security (Barnett and Adger, 2007). In sum, “dwindling resources in an uncertain political, economic and social context are capable of generating conflict and instability, and the causal mechanisms are often indirect” between climate and conflict (Beniston, 2010, p. 567).

Different management solutions to climate change also have implications for equity (Pelling *et al.*, 2012). For example, the privatization of urban water supply and sanitation systems can advantage specific groups over others. Conversely, community-based solutions that also build social capital can be a component in generating urban resilience. However, even these solutions may exacerbate inequality at the city level, with only those local areas with strong levels of social capital being able to benefit most from community led action or garner support from international and national partners (Pelling *et al.*, 2012; UN-Habitat, 2007).

Table 8-3 serves as the link between Section 8.2 (which focuses on climate change risks and impacts) and Section 8.3 (which focuses on adaptation). It summarizes key risks from climate change to urban areas and the potential to reduce risk through adaptation for the present, near-term (2030-2040) and long-term (2080-2100). Table 8-6 has comparable summaries of key risks and potential for adaptation for Dar es Salaam, Durban, London and New York City. For the long-term, under a global mean temperature increase of 2°C above preindustrial levels, many key risks increase from the near term. High adaptation can reduce these risk levels, although for most key risks not as much as high adaptation in the near term. For the long term under a temperature increase of 4°C above preindustrial levels, almost all key risks are ‘very high’ and with many of them remain very high with high adaptation.

[INSERT TABLE 8-3 HERE
Table 8-3: Urban areas: current and indicative future climate risks. Key risks are identified based on an assessment of the literature and expert judgments by chapter 8 authors, with the evaluation of evidence and agreement presented in supporting chapter sections. Each key risk is characterized as very low to very high. For the near-term era of committed climate change (2030-2040), projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options (2080-2100), risk levels are presented for global mean temperature increases of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state.]

8.3. Adapting Urban Areas

8.3.1. Introduction

Since the Fourth Assessment, the literature on urban climate change adaptation has increased significantly, especially in three aspects:

- the examination of risks and vulnerabilities for particular cities;
- the definition of ‘resilience’ and identification of opportunities to strengthen resilience at all scales;
- documentation produced by or for particular city governments on adaptation.

There is less on local government decisions to include adaptation in plans and investment programmes, but see (2012) and (2008; 2010)for exceptions. As described below, studies have also examined how to link adaptation and city development plans and adaptation measures for key sectors.

It has been suggested that “the complexities and uncertainties associated with climate change pose by far the greatest challenges that planners have ever been asked to handle” (Susskind, 2010, p. 219). Municipal and higher-level adaptation plans will need to take into account uncertainty about future climates and extremes. These will need to consider direct and indirect economic costs, including the trade-off of inaction and locking into ill-adapted infrastructure versus investment in adaptation when climate change is less than anticipated (Hallegatte *et al.*, 2007a). Several U.S. studies have considered the cost on inaction for specific states (Backus *et al.*, 2012; Niemi *et al.*, 2009a; Niemi *et al.*, 2009b; Niemi *et al.*, 2009c; Repetto, 2011a; Repetto, 2011b; Repetto, 2012a; Repetto, 2012b; Repetto, 2012c; Repetto, 2012d; Wilbanks *et al.*, 2012).

While local governments are the fulcrum of urban adaptation planning, challenges include inadequate resources and technical capacities and a lack of data on climate-related risks and vulnerabilities. Existing climate models are not downscaled to the city level. Data on climate change risks are infrequently collected and often fragmented across city government departments (Hardoy and Pandiella, 2009). Many proposed adaptation measures respond to specific local or regional hazard risks that may not be directly climate-related (Bulkeley, 2010). To encourage local dialogue in adaptation planning, urban climate data need to be integrated geographically, across time-scales, and consider the range of regional benefits and costs of climate policy (Ruth, 2010).

8.3.2. Development Plans and Pathways

As AR4 emphasized, many of the forces shaping greenhouse gas emissions also underlie development pathways – including the scale, nature and location of investment in infrastructure (Wilbanks *et al.*, 2007). These influence the form and geography of urban development as well as the scale and location of climate-related risks to urban buildings, enterprises and populations. Local, provincial and national government share responsibility for encouraging new investments and migration flows away from high risk sites through climate sensitive disaster risk management, urban planning and zoning and infrastructure investments. But the priority given to economic growth usually means this is rarely implemented with vigour (Douglass, 2002; Reed *et al.*, 2013).

8.3.2.1. Adaptation and Development Planning

Urban adaptation is becoming important to some national and regional governments and many city governments. In high-income countries, interactions and division of responsibility between national and local level have been examined (see, for instance, Massetti *et al.* (2007) for Italy and Juhola and Westerhoff (2011) for Italy and Finland); also local adaptation implementation through subsidies and flexible schemes in different contexts and the transfer of authority and resources to city level (for the Netherlands, see Gupta *et al.*, 2007). New decision making strategies for local governments consider the complexity and dynamics of evolving socio-ecological systems (Kennedy *et al.*, 2011), for instance, adaptation plans and responses in Sydney to cope with sea level rise and storms (Hebert and Taplin, 2006) and adaptation planning in California (Bedsworth and Hanak, 2010).

The literature on urban adaptation in low and middle-income nations has grown since AR4 (see Box 8-1 for publications since 2007). A 2011 review (Hunt and Watkiss, 2011) could draw on eight case studies in Asia, five in Africa, four in South America – as well as cases from Europe, Northern America and Australasia.

_____ START BOX 8-1 HERE _____

Box 8-1. Recent Literature on Urban Adaptation in Low- and Middle-Income Nations

Among the papers and books considering climate change adaptation in urban areas since 2007 are those on Cape Town (Cartwright *et al.*, 2012; Mukheibir and Ziervogel, 2007; Ziervogel *et al.*, 2010), Durban (Cartwright *et al.*, 2013; Roberts and O'Donoghue, 2013; Roberts, 2008; Roberts, 2010; Roberts *et al.*, 2012), and other urban centres in Africa (Adelekan, 2012; Castán Broto *et al.*, 2013; Douglas *et al.*, 2008; Kithiia and Lyth, 2011; Kiunsi, 2013; Lwasa, 2010; Silver *et al.*, 2013; Wang *et al.*, 2009; World Bank, 2011); urban centres in Bangladesh (Alam and Rabbani, 2007; Banks *et al.*, 2011; Haque *et al.*, 2012; Jabeen *et al.*, 2010; Roy *et al.*, 2013); India (Revi, 2008; Saroch *et al.*, 2011; Sharma and Tomar, 2010); Pakistan (Khan *et al.*, 2008); Philippines (Button et al 2013); and Latin America (Hardoy and Ruete, 2013; Hardoy and Velásquez Barreto, 2014; Hardoy and Pandiella, 2009; Hardoy and Romero Lankao, 2011; Luque *et al.*, 2013; Romero-Lankao, 2007; Romero-Lankao, 2010). In China, discussions of division of responsibility between national and local levels include (Li, 2013; Liu and Deng, 2011; Teng and Gu, 2007).

Other papers or books discussing urban adaptation in low- and middle nations include (Agrawala and van Aalst, 2008; Ayers, 2009; Bartlett, 2008; Bicknell *et al.*, 2009; Bulkeley and Castan Broto, 2013; Bulkeley and Tuts, 2013;

de Sherbinin *et al.*, 2007; Kovats and Akhtar, 2008; Manuel-Navarrete *et al.*, 2011; McGranahan *et al.*, 2007; Moench *et al.*, 2011; Moser *et al.*, 2010; Rosenzweig *et al.*, 2011; Tanner *et al.*, 2009; UN-Habitat, 2011a; World Bank, 2010b).

_____ END BOX 8-1 HERE _____

Four issues can be highlighted around urban adaptation:

- low and middle-income nations have most of the world's current and future urban population;
- key development issues of poverty and social inequality may be aggravated by climate change;
- human agency among low-income inhabitants and organizations is important in building local responses;
- well-functioning multilevel governance helps in developing adaptation strategies (Sánchez-Rodríguez, 2009).

Although few publications suggest specific operational strategies, they do stress the importance of the link between climate adaptation and development – urban infrastructure and other development deficits can contribute to adaptation deficits. Manuel-Navarrete *et al.* (2011) explore this interplay in the Mexican Caribbean where hurricane exposure and vulnerability are influenced by political decisions and contingent development paths. Few reports exist on multidimensional approaches to operational adapation. There are some examples of adaptation integrated with development interventions and addressing structural drivers of social and urban vulnerability – for instance Climate Action Plans of Mexico City, Cartagena and San Andrés de Tumaco (Sánchez-Rodríguez, 2009).

Despite growing acceptance of its importance, there are reasons for the general lack of attention to urban adaptation. First, national climate change policies usually give little attention to urban adaptation compared to sectors like agriculture. The ministries or agencies responsible for these policies often have little involvement in urban and little influence on those whose cooperation is essential e.g. for social policies, public works and local government (Hardoy and Pandiella, 2007; Ojima, 2009; Roberts, 2010). Social policies and priorities influence the social and spatial distribution of climate-related risk and vulnerability – for instance, provision for health care, emergency services and safety nets - yet few agencies recognize their potential role in reducing risk and vulnerability.

A second factor is the initial focus for many cities on mitigation rather than adaptation (with commitments made to lowering greenhouse gas emissions), in part because of the focus of international support. Local decision-makers frequently view climate change as a marginal issue, but adaptation usually ranks lower than mitigation on the agenda (Bulkeley, 2010; Simon, 2010). Mexico City focuses on mitigation, but adaptation is still a vague concept (GDF, 2006; GDF, 2008) seen more, for instance, as a capacity to cope with floods through early warning systems than through comprehensive, long-term measures like watershed management to reduce the speed and volume of flood waters. There is still little literature on adaptation for Brazilian cities (Ojima, 2009; Soares, 2009). In Sao Paulo, adaptation is limited to broad declarations about necessary actions, even as the city gets hit by floods, landslides and water scarcity (Martins and da Costa Ferreira, 2011; Nobre *et al.*, 2010; Puppim de Oliveira, 2009).The pressure on national and local governments to act is lessened by the scant public awareness of the importance of climate change adaptation (Nagy *et al.*, 2007), and a "knowledge gap" between policymakers and scientists (Sánchez-Rodríguez, 2011). However, as 8.4 describes, interest in urban adaptation is growing, encouraged by the increasing engagement of transnational municipal networks and donor agencies (Bulkeley, 2013).

8.3.2.2. Disaster Risk Reduction and its Contribution to Climate Change Adapation

The growing concentration of people and activities in urban centres and the increasing number and scale of cities can generate new patterns of disaster hazard, exposure and vulnerability, as evident in the rising number of localized disasters in urban areas in many low- and middle-income nations associated with extreme weather (storms, flooding, fires and landslides) (Douglas *et al.*, 2008; United Nations, 2009; United Nations, 2011). This is relevant to climate change adaptation, given the increasing frequency and intensity of potentially hazardous weather events associated with climate change. Extreme weather events have also helped raise awareness of citizens and local governments of local risks and vulnerabilities.

Exposure to weather-related risk in growing urban areas increases when local governments fail to address their responsibilities by expanding or upgrading infrastructure and services and reducing risk through building standards and appropriate land-use management (United Nations, 2009; United Nations, 2011). This is typical in countries with low per capita GDPs and weak local governance (i.e., in the first two categories of Table 8-2), and can be exacerbated by rapid urban population growth. Urbanization accompanied by more capable and accountable local governments can reduce disaster risk, as evident in the declines in mortality from extreme weather (and other) disasters in many middle- and all high-income nations (United Nations, 2011). The most urbanized nations generally have the lowest mortality to these events (United Nations, 2009).

Local government investment is usually a small proportion of total investment in and around an urban centre, but has particular importance in risk reduction. Urban governments have explicit responsibilities for many assets which may be risk prone, often including schools, hospitals, clinics, water supplies, sanitation and drainage, communications and local roads and bridges (IFRC, 2010). Even where private provision for these assets is significant, local government usually coordinates such provision and has a significant planning and regulation role, ensuring buildings and infrastructure meet needed standards and guiding development away from high-risk areas.

From the late 1980s, some Latin American cities took a new approach to disaster risk, involving three processes:

- detailed analyses of local disaster records, including smaller events than those in international databases;
- recognition that most disasters were the result of local failures to assess and act on risk;
- recognition of the central roles of local governments in disaster risk reduction, supported national and local civil defence organizations, working with civil society and settlements most at risk (IFRC, 2010; United Nations, 2009).

This led to institutional and legislative changes at national or regional level (Gavidia, 2006; IFRC, 2010). In Colombia, a national law supports disaster risk reduction and a National System for Prevention and Response to Disasters, shifting the main responsibility for action to municipal administrations. In Nicaragua, the National System for Disaster Prevention, Mitigation and Response (SINAPRED), works with local government to integrate disaster mitigation and risk reduction into local development processes (von Hesse *et al.*, 2008). Other initiatives in Central and South America include the influence of La Red (IFRC, 2010), the DIPECHO project, “Developing Resilient Cities” and UNDP and GOAL in Central America. In growing numbers of cities in Asia (Shaw and Sharma, 2011) and Africa (Pelling and Wisner, 2009), experiences with community-driven ‘slum’ or informal settlement upgrading has led to a recognition of its potential to reduce risk and vulnerability to extreme weather events, most effectively when supported by local government and civil defence response agencies (Archer and Boonyabancha, 2011; Boonyabancha, 2005; Carcellar *et al.*, 2011).

The Homeless People’s Federation of the Philippines developed a series of effective responses following major disasters, including community-rooted data gathering (assessing destruction and victims’ immediate needs); trust and contact building; support for savings; registering community organizations; and identifying needs, including building materials loans for repairs. The effectiveness of these measures is much enhanced with local government support (Carcellar *et al.*, 2011) and these experiences have helped inform community-based adaptation (see 8.4).

International networks supporting innovation in disaster risk reduction and/or climate change adaptation and inter-city learning include La Red in Latin America that has been operating for 3 decades (IFRC, 2010) and the cities programme of the Asian Disaster Preparedness Centre (ADPC). As donor interest has grown in supporting disaster risk management as a vehicle for climate change adaptation, a number of urban resilience programmes have developed including ACCCRN – the Asian Cities Climate Change Resilience Network (Brown *et al.*, 2012), the UNISDR - United Nations International Strategy for Disaster Reduction Making Cities Resilient network (Johnson and Blackburn, 2014), the ICLEI – Local Governments for Sustainability city adaptation network and UN-Habitat’s Cities and Climate Change Initiative.

Despite growing international support for urban disaster risk management, local governments have difficulty accessing the resources to make real change (von Hesse *et al.*, 2008). Local government risk reduction investments are not seen as priorities and have to compete for scarce resources with what are judged to be more pressing needs. Effective policies are often tied to the terms of particular mayors or political parties (Hardoy *et al.*, 2011; Mansilla *et* *al.*, 2008). In most cases, risk reduction is not integrated into development plans or all relevant local government departments. Manizales, Colombia, is an exception: risk reduction has long been seen as part of local development and collective interests take precedence over party political interests (Hardoy and Velásquez Barreto, 2014).

Disaster risk management is increasingly positioned as a frontline sector for integrating climate change adaptation into everyday decision-making and practices (IPCC, 2012), as seen in the plans of municipalities such as Tegucigalpa and Montevideo (Aragón-Durand, 2011). Where it is taken seriously, it offers real opportunities for synergy as the long-range nature of climate change concerns and its policy visibility can enhance local support for disaster risk management. There is considerable scope in international frameworks and national responsibilities for better coordination to make urban disaster risk management climate resilient (Aragón-Durand, 2008; IPCC, 2012).

8.3.3. Adapting Key Sectors

8.3.3.1. Adapting the Economic Base of Urban Centres

Section 8.2 described how climate change can change the comparative advantages of cities and regions – for instance by influencing climate sensitive resources, water availability and flooding risks. Many case studies show how extreme weather can impede economic activities, damaging industrial infrastructure and disrupting ports and supply chains (see 8.2.3.4). Vugrin and Turnquist (2012) discuss design for resilience in distribution networks such as electric power, gas, water, food production and manufacturing supply chains. This requires absorptive capacity (to withstand extreme weather), adaptive capacity (e.g. service provision through alternative paths) and restorative capacity (quick and cheap recovery).

When urban centres fail to adapt to risks, it may discourage new investment and lead enterprises to move or expand to safer locations. Multinational corporations and many national businesses are adept at changing location in response to changing opportunities and risks, including high insurance costs. Disasters can change perceptions of risk. Businesses may adapt to avoid impacts in their own facilities but be affected by impacts to utilities and other businesses or to their workforce and the services they use (schools, hospitals) (da Silva, 2012; Hallegatte *et al.*, 2011a). Limited local capacity to reconstruct means increased vulnerability to future extreme events and less new investment weakens the economic base (Benson and Clay, 2004; Hallegatte *et al.*, 2007b; Hallegatte *et al.*, 2011a). Past experience in the U.S. and Europe show the difficulties city governments can face in attracting new investment when a city or region's main activity weakens. If climate change forces changes to economic structure and business models, transitions may be hard to manage (Berger, 2003). Specific adaptation policies may make the transition more rapid and less painful. For instance, adaptation is generally cheaper and easier in greenfield sites – as low-risk sites are chosen, trunk infrastructure to appropriate standards is installed and building and land-use regulations enforced. Retrofitting existing infrastructure and industries is generally more expensive (McGranahan *et al.*, 2007).

Within and around urban centres, local governments may require several strategies to strengthen resilience including selective relocation, better land use planning and revised building regulations to retrofit or flood-proof structures (Hanson *et al.*, 2011). Synergies can be encouraged where land-use management around a city supports rural livelihoods, and protects ecosystem services (see 8.3.3.7). There may be opportunities for proactive adaptation outside larger cities where much of the future urban growth will occur. Manizales, Colombia, which has long had innovative environmental and disaster risk reduction policies has begun incorporating climate change and environmental management into its local development agenda, including the establishment of city climate monitoring systems (Hardoy and Velásquez Barreto, 2014). But most smaller urban centres are institutionally weaker and may lack the investment capacity and critical infrastructure.

Adapting the urban economic base may require short- and long-term strategies to assist vulnerable sectors and households. The consequences of climate change for urban livelihoods may be particularly profound for low-income households who generally lack assets or insurance to help them cope with shocks (Moser and Satterthwaite, 2009). The informal sector is a significant part of the economy for most urban centres, providing employment for large numbers. But the effects of extreme weather on the informal economy are rarely considered, as in 2003 floods in Santa Fe, Argentina (Hardoy and Pandiella, 2009). In Kelurahan Pabean Pekalongan in Central Java, batik production, the primary livelihood, is being disrupted by increasingly frequent floods (UN-Habitat, 2011b). Cash transfers and safety nets are being considered to help low-income groups cope with the short-term impacts of climate change (Sanchez and Poschen, 2009), as well as climate variability. But these will not address all the risks they face or support collective or public investments in risk-reducing infrastructure and services.

There is a growing discussion of the importance of support for a 'green economy' with green infrastructure to help shift nations' economic and employment base towards lower carbon, more resilient, more sustainable patterns that respect regional and global ecological and resource limits. For urban centres, this means highlighting new (or adapted) business opportunities that limit anthropogenic climate change, resource depletion and environmental degradation. Sometimes social inclusivity and eco-efficiency are included as mutually reinforcing principles (e.g. Allen and Clouth, 2012). The literature has begun to explore the changes needed in production systems (especially in carbon intensity, waste generation and management), buildings, transport systems, electricity generation (including incorporating solar and wind) and consumption patterns of wealthier groups (Hammer *et al.*, 2011; UN-Habitat, 2012a; UN-Habitat, 2012b; UN-Habitat, 2012c; UN-Habitat, 2012d; World Economic Forum, 2013). As yet, there is too little detailed discussion of how a green economy can be fostered in relation to particular cities or in regard to the incentives and regulations that can shift private investment to this.

The 'waste economy' in cities in low- and middle-income nations is important to the green economy, providing livelihoods (Hardoy *et al.*, 2001; Hasan *et al.*, 2002; Medina, 2007) and contributing to waste reduction and GHG emission reduction (Ayers and Huq, 2009). In Brazil's main cities, over half a million people are engaged in waste picking and recycling (Fergutz *et al.*, 2011); in Lima an estimated 17,000 and in Cairo, 40,000 (Scheinberg *et al.*, 2011). The ways city governments choose to work with (or ignore) those in this waste economy have obvious implications for employment and for resource use.

For some cities, there is documentation of the adaptation costs to protect or enhance the economic base. Hallegatte *et al.* (2013) assess present and future flood losses in the world's 136 largest coastal cities and show that the estimated costs of adaptation are far below the estimate of losses in the absence of adaptation. The paper also highlights the differences in the cities most at risk, depending on whether the ranking is by economic average annual losses or by such losses as a proportion of each city's GDP. In the first, it is mainly cities in high-income nations, in the second, mainly prosperous cities in middle-income nations.

Mombasa may have to redesign and reconstruct the city's ports, protect cement industries and oil refineries and relocate some industries inland, all requiring major capital investments (Awuor *et al.*, 2008). Adaptation can help protect many parts of Rio de Janeiro's diverse economy (including manufacturing, oil refineries, shipyards and tourism) and the large populations living in informal settlements (favelas) on land at risk of landslides (de Sherbinin *et al.*, 2007). Defences needed to safeguard coastal industries and residential areas could threaten Rio's beach tourist industry and cause further erosion to other unprotected areas. As in most cities, making Rio's economic base more resilient to climate change means resolving such trade-offs, and dialogue among local stakeholders (Ruth, 2010).

As yet, there is little evidence that cities' adaptive capacities influence private sector investments. But private investment is influenced by the quality and availability of infrastructure and services that are an essential part of adaptive capacity. Many cities in Asian high growth economies are located in low-elevation coastal zones undergoing rapid urbanisation and economic transformation (McGranahan *et al.*, 2007). Cyclones are common in many of these coastal settlements. Rising concentrations of people, infrastructure, and industries along India's coasts, without adaptation, could mean non-linear increase in vulnerability over the next two decades (Revi, 2008). The same is true for China (McGranahan *et al.*, 2007). In most nations, urban governments find it difficult to prevent new developments on sites at risk of flooding, especially in locations attractive for housing or commerce, even when there are laws and regulations in place to prevent this (see Olcina Cantos *et al.* (2010) for an example in Alicante in Spain).

There are few economic assessments of climate change risks in West African coastal cities. Many cities or districts and their industries, infrastructure and tourism will be a challenge to protect, as in Cotonou (Dossou and Gléhouenou-Dossou, 2007), Lagos (Douglas *et al.*, 2008) and Dakar (Wang *et al.*, 2009).These and other important economic centres in the Gulf of Guinea (including Abidjan and Port Harcourt) have large areas close to mean sea level and highly vulnerable to erosion and rising sea levels. Rapid construction, destruction of mangrove swamps and inadequate refuse collection compound the risks (Simon, 2010).

8.3.3.2. Adapting Food and Biomass for Urban Populations

Many urban dwellers in low- and middle-income countries suffer hunger, while a larger number face food and nutrition insecurity (Ahmed *et al.*, 2007; Cohen and Garrett, 2010; Crush *et al.*, 2012; Montgomery *et al.*, 2003) due more to their low incomes than to overall food shortages (Cohen and Garrett, 2010; Crush *et al.*, 2012). For these low-income urban households, food expenditures generally represent more than half of total expenditures (Cohen and Garrett, 2010), putting them at particular risk from real increases in long-term food prices or temporary spikes associated with disasters.

Climate change impacts can have far-reaching influences on food security and safety, but these “will crucially depend on the future policy environment for the poor” (Schmidhuber and Tubiello, 2007, p. 708, see also Douglas, 2009). Agriculture has managed to keep up with rising demands worldwide, despite rapid population growth, the reduction in agricultural workers that accompanies urbanisation, and dietary shifts that are more carbon- and often land- intensive (Satterthwaite *et al.*, 2010). But food security may be eroded by competing pressures for water or bio-fuels. In addition, there may be tensions between managing land-use to reduce flood risk and food and energy policies (Wilby and Keenan, 2012). Adapting urban food systems represents a major challenge and will necessitate radical changes in food production, storage and processing (and in reducing waste), in transport/the supply chain and in access (Godfray *et al.*, 2010). Both supply and demand side constraints must be considered. Climate-change related constraints on agricultural production affect urban consumers through reduced supplies or higher prices; falling production and farmer incomes reduces their demand for urban goods and services; disruption to urban centres can mean disruption to the markets, services or remittance flows on which agricultural producers rely (Tacoli, 2003). Thus, strengthening urban food security needs to take account of complex rural-urban linkages (Revi, 2008) and responses must bridge rural and urban boundaries.

Urban centres that are seriously impacted by extreme weather face serious challenges in ensuring that those affected have access to adequate and safe food and water supplies. Flooding, drought, or other extreme events often lead to food price shocks in cities (Bartlett, 2008) as well as spoiling or destroying food supplies for many households. After the 2004 floods in Bangladesh, Dhaka’s rice prices increased by 30 percent and vegetable prices more than doubled, with urban slum-dwellers and rural landless poor the worst affected (Douglas, 2009). When facing increased food prices, the urban poor adopt a range of strategies such as reduced consumption, fewer meals, purchasing less nutritious foods, or increasing income earning work hours, particularly for women and children (Cohen and Garrett, 2010). But these erode nutrition and health status, especially of the most vulnerable and fail to strengthen resilience, particularly in the context of more frequent disasters.

Adaptive local responses include support for urban and peri-urban agriculture, green roofs, local markets and enhanced safety nets. Food price increases may be moderated by improving the efficiency of urban markets, promoting farmers’ markets, investing in infrastructure and production technologies (Cohen and Garrett, 2010). Food security may be enhanced by support for urban agriculture and street food vendors (*ibid.*, Lee-Smith, 2010) and access to cheaper food or measures like cash transfers (e.g. Brazil’s Bolsa Familia Programme) or, for older groups, pensions (Soares *et al.*, 2010). Initially rural in focus, cash transfer programmes have expanded in urban areas, in some places reaching much of the low-income population (Johannsen *et al.*, 2009; Mitlin and Satterthwaite, 2013; Niño-Zarazúa, 2010).

8.3.3.3. Adapting Housing and Urban Settlements

The built environment in urban areas has to adapt to the range of climate change impacts outlined in 8.2, in order to protect urban populations and economies and protect among society’s most valuable assets. Knowledge and innovation are required for adapting existing and new buildings. This will be built on the bedrock of affordable housing appropriate for health and safety, built to climate-resilient standards and with the structural integrity to protect its occupants long term against extreme weather (United Nations, 2009; United Nations, 2011). The resilience of poor quality housing, often at risk from extreme weather, can be enhanced via structural retrofitting, interventions that reduce risks (for instance expanding drainage capacity to limit or remove flood risks) and non-structural interventions (including insurance). Attention to all three is more urgent where housing quality is low, where settlements are on high-risk sites and in cities where climate change impacts are greatest. Enhancing the resilience of buildings that house low-income groups will usually be expensive and may face political challenges (see Roaf *et al.*, 2009).The range of actors in the housing sector, the myriad connections to other sectors and the need to promote mitigation, adaptation as well as development goals point to the importance of well-coordinated strategies that can support resilience (Maller and Strengers, 2011).

There have been studies in increasing numbers of cities to identify measures to adapt housing (and other buildings) and discussions on revising standards, although it is difficult to set standards with uncertain forecasts and scenarios and evolving risks (Engineers Canada, 2008). There is less evidence of the action plans, budget commitments and regulation changes to implement them. Measures identified in a Bangkok assessment included flood-proofing homes, building elevated basements, and moving power-supply boxes upstairs, along with keeping enough food, water, fuel, and other supplies for 72 hours; it also pointed to regulatory changes to bolster resilience including land use restrictions in floodplains and other at-risk sites and revised safety and fire codes for buildings and other structures (BMA and UNEP, 2009). Cape Town's climate change framework (2006) proposed housing interventions including regulations for building informal housing, in part to reduce the need for emergency response and anticipate projected climate change. Regulations in New York and Boston are being updated to address climate-related risks (Boston, 2011; City of New York, 2011). London and Melbourne's adaptation plans both consider strategies combining green infrastructure and housing interventions (GLA, 2010; UN-Habitat, 2011a).

Housing and other buildings and extreme heat: More attention is being paid to extreme heat in particular cities (for instance, Chicago 2008; Chicago 2010; City of Toronto 2013; Tomlinson *et al.* (2011) for Birmingham, Matzarakis and Endler (2010) for Freiberg, GLA (2010) for London, and Giguère (2009) for Quebec); also in regard to low-income housing in Athens (see Sakka *et al.*, 2012).

Attention is required to buildings that provide protection from hot days and to populations more vulnerable to extreme heat, including those who work outside (see cross-chapter box on heat stress and heat waves). In locations with large daily variations in temperature, the response can include upgrading homes with limited ventilation and low thermal mass. Chicago's 2008 Climate Action Plan discussed the need for innovative cooling ideas for property owners (Chicago, 2008, p. 52). Air conditioning and other forms of mechanical cooling are too expensive, unavailable for the many urban households with no electricity, and mal-adaptive when electricity generation contributes to greenhouse gas emissions. Residents' vulnerabilities may be exacerbated if electricity supplies are unreliable; blackouts tend to occur on the hottest days when demand is highest (Maller and Strengers, 2011, p. 3). The literature on adaptations for extreme heat focuses on high-income nations and more attention is required to this in urban centres in low- and middle-income nations.

Passive cooling can be used in both new-build and retrofitted structures to reduce solar and internal heat gains, while enhancing natural ventilation or improving insulation (Hacker and Holmes, 2007; Roberts, 2008a; Roberts, 2008b). Passive designs, using super-insulation, ventilation, and other measures to ensure energy is not required for most of the year, as in the Beddington Zero Energy Development (BedZED) in London (Chance, 2009) or Germany's Passive Haus standard (Rees 2009) have set precedents for mitigating household emissions but they can simultaneously contribute to adaptation. Thermal mass can be used for cooling, "because it introduces a time-delay between changes in the outside temperature and the building's thermal response necessary to deal with the high daytime temperatures" (Hacker and Holmes, 2007, p. 103). Structures in southern Europe already use solar shading, ventilation, and thermal mass to promote enhanced cooling (*ibid.*). Simulations for London (under UKCIP02 Medium-High emissions scenarios) suggest that passive designs are an "eminently viable option for the UK, at least over the next 50 years or so" (*ibid.*, p. 111). There are several obstacles though: opening windows may be hampered by security concerns or noise pollution (Hacker and Holmes, 2007). Modern windows may not ventilate well, and site restrictions and cost can impede the use of passive cooling in refurbishing existing buildings (Roberts, 2008a).

Housing and disaster-preparedness measures: When populations are displaced or temporarily evacuated, provision for emergency shelters and services have to be able to respond, especially for vulnerable residents. For instance, after Cyclone Larry in Queensland (in 2006) and New South Wales' coastal flooding (in 2007), officials recalled the strains faced in shelters and the coordination difficulties with emergency health workers, police, insurance, and other agencies (Jacobs and Williams, 2011). This points to the range of social support, structural strategies, and interagency efforts that local authorities may develop to adapt to climate change. For many urban centres, there is also the issue of how to move populations at risk, which presents many challenges (Roaf *et al.*, 2009).

Urban centres facing extreme heat require plans that provide early warning for citizens, inform them of measures they can take and ensure adequate water provision, back up electricity, emergency healthcare, and other public services focused on vulnerable residents, especially infants and the elderly in hospitals and residential facilities (Brown and Walker, 2008; Hajat *et al.*, 2010) or living alone. Public buildings with cooling may also be required. Cities with responses to hot days for those most at risk are mainly from high-income nations. Several hundred million urban dwellers in low- and middle-income nations have no access to electricity (Johansson *et al.*, 2012) or mechanical devices that help with cooling.

8.3.3.4. Adapting Urban Water, Storm, and Waste Systems

It is challenging to summarize key adaptation strategies from the highly heterogeneous mix of urban areas across the globe. In high-income and some middle-income nations, virtually all the urban population is served by drinking quality water piped to the home 24 hours a day, by systems of sanitation that minimize risks of faecal contamination and by storm and surface drainage. Many urban centres in such nations may face serious climate change-related challenges for water, but do not have to address the fact that much of their population lacks piped water, toilets or storm drains. They can also bill users for much of the funds required for water provision and management.

At the other extreme are a very large number of urban centres with large deficits in provision for water, sanitation and drainage and with weak, under-resourced institutions (UN-Habitat, 2003b; UNEP, 2012). Around a billion people live in informal settlements where providers responsible for water and sanitation are often unwilling to invest or not allowed to do so (Mitlin and Satterthwaite, 2013). New York City can develop a ten billion dollar plan to assure adequate water supplies (Solecki, 2012); many cities in sub-Saharan Africa not only have very large deficits in piped water, sewers and drains but very limited investment capacities (see, for instance, Kiunsi (2013) for Dar es Salaam).

Some studies have sought to estimate the costs of adapting urban water and sanitation systems, pointing to the need for significant investments (Arnell, 2009). Muller (2007) suggests that $1-2.7 billion is required annually in sub-Saharan African cities to adapt existing water infrastructure; this does not include the cost of addressing deficient infrastructure. Another $1-2.6 billion a year is required to adapt new developments (including water storage, waste-water treatment and electricity generation).

Adapting urban water supply systems: For cities with climate change adaptation plans, water and waste water management are usually important components (see, for instance, Helsinki Region Environmental Services Authority, 2012). Major *et al.* (2011) list a range of cities that have begun to adapt water systems and other infrastructure including Boston, London, Halifax (Canada), New York, Seattle and Toronto. The US Government has developed a guide for adaptation strategies for water utilities (US EPA, 2013). But developing such measures is not yet common place.

Supply-side approaches to seasonal water shortages are frequently advocated. An analysis of 21 draft Water Resources Management Plans in the UK found that agencies usually favoured reservoirs and other supply-side measures to adapt to climate change, although authors suggest that demand-side interventions may also be needed (Charlton and Arnell, 2011). To expand its reservoir capacity after 1998 floods exposed existing infrastructure, Rotterdam developed plans combining adaptation and urban renewal goals, mixing economic activities with water-based adaptive designs, including 'water retention squares' and green roofs; floating houses; and networks of channels (Van der Brugge and De Graaf, 2010). Seattle has used demand-side strategies to cut water consumption including aggressive conservation measures, system savings and price increases (Vano *et al.*, 2010).

In Mexico City, a number of measures in the water sector have been proposed many times since the 1950s but not acted on, including a decrease in water use and the restoration and management of urban and rural micro-basins (Romero-Lankao, 2010). Adaptation measures have been conceived as too general and lacking institutional commitment. In Durban, where the water sector is revenue earning and seen as critical to development, the importance of climate change adaptation was recognized as a priority (Roberts, 2010). In Cape Town, which faces profound challenges in ensuring future supplies, water management studies identified the need to consider climate change and population and economic growth (Mukheibir and Ziervogel, 2007). During the 2005 drought, the local authority substantially increased water tariffs, considered a most effective way to promote efficient water usage (Mukheibir, 2008). Other measures may include water restrictions; reuse of grey water; consumer education; or technological solutions such as low-flow systems or dual flush toilets (*ibid*).

In Phoenix, Arizona, a rapidly expanding desert city projected to reach 11 million people by 2050, most peripheral growth depends on groundwater (Bolin *et al.*, 2010). Simulations explored how water usage may be reduced to achieve safe yield while accommodating future growth. Reducing current high use may be achieved through urban densification, increased water prices and water conservation measures *(ibid).* Gober *et al.* (2010) agree that stringent demand and supply policies can forestall "even the worst climate conditions and accommodate future population growth, but would require dramatic changes to the Phoenix water supply system" *(ibid,* p. 370). Here and in other cities in Arizona, supply side management including active management of groundwater and groundwater storage is combined with extensive demand side measures (Colby and Jacobs, 2007).

In Quito, where reduced freshwater supplies are projected with glacier retreat and other climate-related changes, local government has formulated a range of adaptation plans, including encouraging a culture of rational water use, reducing water losses and developing mechanisms to reduce water conflicts (Hardoy and Pandiella, 2009). However, community participation in planning and implementation has not been considered (*ibid.*). Participatory water planning has occurred elsewhere in Latin America: stakeholders in Hermosillo, Mexico, identified and prioritized specific adaptations such as rainwater harvesting and water-saving technologies (Eakin *et al.*, 2007).

Several cities actively encourage rainwater harvesting while others are considering its potential. Since 2004, in New South Wales, Australia, homeowners have been required to ensure that newly built houses use 40% less potable water than an established benchmark level of consumption, through water-saving measures like water-efficient shower heads, dual-flush toilets, rainwater tanks and grey water treatment systems (Warner, 2009). Many low-income Caribbean households rely on rainwater collection systems for domestic use. Extending existing communal collection and distribution systems would require community financing or governmental interventions, as well as overcoming resistance from higher-income residents (Cashman *et al.*, 2010). Rainwater harvesting has been promoted in several cities in India (Shaban and Sharma, 2007).

Waste and storm water management: More attention has been given to adaptations to help ensure sufficient water supplies than to increasing the capacity of sewer and drainage systems, or adapting them to allow for the impacts of heavier rainfall or sea-level rise. We noted earlier the very large deficiencies in provision for drainage for urban centres in low- and many middle-income nations.

In St. Maarten, Netherlands Antilles, the government, after a storm water modelling study, is developing a flood warning system and considering such institutional adaptations as a new decision-support framework, centralised GIS for infrastructure planning and public education, along with structural measures like draining areas with a high groundwater table (Vojinovic and Van Teeffelen, 2007). City management in Toronto, Canada, has prioritised an upgrade of storm water and wastewater systems (Kessler, 2011). Deak and Bucht (2011) analyse past hydrological structures in Lund, Sweden and use the concept of indigenous blue infrastructure to question current storm water management in the urban core. Cities in California have a range of flood management methods but Hanak and Lund (2012) suggest that they will also require forward-looking reservoir operation planning and floodplain mapping, less restrictive rules for raising local funds, and improved public information on flood risks.

Willems and Arnbjerg-Nielsen (2013) suggest that climate change adaptation for urban drainage systems requires a re-evaluation of the technical solutions implemented over the last 150 years. The objective is cities that interact with water (including storms) in a healthy, environmentally friendly, and cost-efficient way. This includes the incorporation of roads and parks into the active drainage system and the use of blue and green storm water infrastructure (see section 3.3.3.7). These authors also note that this implies changing roles for water scientists, water managers and water engineers as well as for water users, property owners, insurers, city planners and politicians (*ibid.*, also Willems *et al.* 2012). Many governments in the last 20 years have developed integrated water resource management (UNEP, 2012) with linkages between provisions for water, sanitation and drainage and other sectors, and a recognition of the need to work with a range of partners, consider broader development goals, identify tensions or trade-offs (Willems and Arnbjerg-Nielsen, 2013) and implement low-regret anticipatory solutions. For cities, this often includes management of groundwater use and water catchment in areas outside their jurisdiction and thus collaboration with other local governments (WMO, 2008). Most examples of this are in high-income nations (for an exception, see Bhat *et al.*, 2013).

Urban water systems usually depend on reliable electricity supplies and can be energy intensive – for instance, in conveying or treating water from distant or low-quality sources. Integrated planning (for instance, in concert with energy conservation, water catchment management and green infrastructure strategies) can minimize conflicts, support local industries, and ensure equitable access to water in cities.

8.3.3.5. Adapting Electric Power and Energy Systems

The heavy dependence of urban economies, infrastructure, services and residents on electricity and fossil fuels means far-reaching consequences if supplies are disrupted or unreliable (see 8.2.4.2). With mitigation concerns dominating the literature and urban energy policy discussions, there is less focus on adaptation issues (Carmin *et al.*, 2009; Mdluli and Vogel, 2010). The UNFCCC's estimates for investment to address climate change (UNFCCC, 2007) did not include the costs of adapting the energy sector (Fankhauser, 2010). Key issues relating to energy sector adaptation, including generation and distribution, are usually national or regional and are discussed in Chapter 10. But urban governments' and residents' responses are also important. Research has suggested that "private autonomous measures will dominate the adaptation response as people adjust their buildings, [or] change space-cooling and -heating preferences..." (Hammer *et al.*, 2011, p. 27). A few cities have adaptation initiatives underway for energy systems; others have begun to consider the steps needed (*ibid.*). Some relevant local urban concerns are the extent of the need for autonomous provision or back-up generating capacity, and the functioning of emergency services when energy supplies are disrupted or unreliable. The interrelations between energy and other sectors suggest the need for an integrated approach in understanding vulnerability and shaping appropriate responses (Gasper *et al.*, 2011).

Despite growing concern about the potential impact of climate change and extreme weather events for the oil industry in Canada, US and Mexico and how hurricanes, floods and sea level rise will disrupt oil, gas and petrochemical installations (Levina *et al.*, 2007; Savonis *et al.*, 2008), few adaptation studies have been undertaken.

8.3.3.6. Adapting Transport and Telecommunications Systems

Urban centres depend on transport and telecommunications systems for daily functioning and for vital regional, national and international supply chains. For instance, 80 percent of the food consumed in London is imported (Best Foot Forward, 2002). The Great Lakes–St. Lawrence route in the USA supports 60,000 jobs and US$ 3 billion worth annual movement of goods (Ruth, 2010). Most large and successful cities have also spread spatially, and well-functioning transport systems support the decentralization of the workforce and businesses. Many cities, for instance, depend on underground electric rail systems which require protection from the considerable risk from flooding – such as New York and London (Eichhorst, 2009). Adapting all these systems to the impacts of climate change (including hot days, storms and sea-level rise) poses many challenges (Mehrotra *et al.*, 2011b).

Transport systems: Four different aspects to adaptation strategies for transport can be highlighted: maintain and manage, strengthen and protect, enhance redundancy and, where needed, relocation. Cities that have developed adaptation plans usually include attention to more resilient transport systems (UN-Habitat, 2011a). Melbourne's adaptation plan notes that intense storms and wind may lead to blocked roads and disrupt traffic lights, trains, and trams and that these disruptions can be exacerbated by such compounding factors as power disruptions and emergency situations (Melbourne, 2009). Adaptation will require transport planners to take a whole-of-life approach to managing infrastructure, and constantly update risk assessments (Love *et al.*, 2010). Coordination at national, regional, and local levels is important for implementing adaptation strategies in the transport sector, since climate change impacts are widespread and extend across scales (Regmi and Hanaoka, 2011). Interdisciplinary approaches can include changing meteorological hazards as well as social and political values and the governance framework for more resilient transport systems (Jaroszweski *et al.*, 2010).

Adapting roads: Climate change may increase the costs of maintaining and repairing road transport networks (see Hayhoe *et al.* (2010) for discussion of changing conditions in Chicago). In Durban, revised road construction standards may be needed (Roberts, 2008). Coastal road adaptation may require strengthening barriers and designing roads or realigning them to higher locations to cope with sea-level rise (Regmi and Hanaoka, 2011).

Transport planners are beginning to reassess maintenance costs and traditional materials – for instance stiffer binding materials to cope with rising temperatures; softer bitumen for colder regions (Regmi and Hanaoka, 2011). But cost considerations may impede their use. The Chicago Department of Transportation decided not to use more permeable, adaptive road materials because of higher cost, although costs may fall with greater economies of scale as demand rises for such materials (Hayhoe *et al.*, 2010). Road maintenance costs vary widely, depending on local context, and future climate scenarios. In Hamilton, New Zealand, increases in rainfall in spring (within one scenario) or winter (in another) would increase road repair costs while decreases in rainfall in other seasons could decrease them; results depend upon the scenario and further investigation was recommended (Jollands *et al.*, 2007).

Adapting surface and underground railways: Underground transport systems are specific to cities and of great importance to the functioning of many major cities. They may have "particular vulnerabilities related to extreme events, with uniquely fashioned adaptation responses" (Hunt and Watkiss, 2011, p. 14). Heat impacts are often significant, as these systems gradually warm due to engine heat, braking systems, and increased passenger loads. To cope with increasing frequency of hot days, substantial investments in ventilation or cooling may be necessary (Love *et al.*, 2010). For New York City's subways, the system's age, fragmented ownership, overcapacity and in some cases floodplain location may augment the challenge of adaptation (Zimmerman and Faris, 2010, pp. 69-70). Storm surge flooding from Hurricane Sandy flooded eight under-river subway tunnels, severely impacting mobility and economic activity (Blake *et al.*, 2012).

Rail systems that struggle to cope with existing climate variability may require considerable investment to withstand higher temperatures and more extreme events (see Baker *et al.*, 2010). Railway systems may be more vulnerable to climate variability than the road system, which can more easily redirect traffic (Lindgren *et al.*, 2009). The costs of delays and lost trips due to extreme weather events, analysed in Boston (Kirshen *et al.*, 2008) and Portland (Chang *et al.*, 2010), were found to be small relative to the damage to infrastructure and other property. Floodplain restoration, use of porous pavements, and detention ponds may help address the projected increased flooding in Portland (*ibid.*).

In flood-prone cities, transport systems may require more stringent construction standards, design parameters, or relocation. Much of central Mumbai is built on landfill areas and prone to flooding, but they contain the main train stations and train lines as well as large populations and a large part of the city's economy. Rising sea levels may cause shifts at the sub-surface level of landfill areas and structural instabilities (de Sherbinin *et al.*, 2007).

Ports: 8.2 outlined the many ways in which ports can be impacted by climate change and the investments required to take account of these. Many ports remain largely unaware of the potential threats of climate change, or are slow to consider appropriate adaptation measures (Becker *et al.*, 2012). Rotterdam's Climate Proof Programme includes as key components flood safety and accessibility for ships and passengers (Rotterdam Climate Initiative, 2010; Vellinga and De Jong, 2012). A climate risk study for the Port of Muelles el Bosque (Cartagena, Colombia) analyzed projected changes in sea level rise, storm surge height, precipitation, temperature and wind patterns and their direct and indirect effects on port assets and operations, surrounding environment and communities, and on the trade of goods transported through the port and this helped catalyze adaptation investments (Stenek *et al.*, 2011).

There are also the deficits in basic infrastructure noted in 8.2 that inhibit adaptation including the lack of all-weather roads and paths in informal settlements that constrain rapid evacuation and limit access for emergency vehicles.

Telecommunications: A wide range of components and sub-systems for telecommunications systems that are within cities may need adaptation to the impacts of climate change – including telephone poles and exchanges, cables, mobile telephone masts and data centres (Chapman *et al.*, 2013; Engineering the Future, 2011).

8.3.3.7. Green Infrastructure and Ecosystem Services within Urban Adaptation

Ecosystem based adaptation has relevance for many chapters (see the cross-chapter box on Ecosystem-based Adaptation CC-EA). Ecosystem-based adaptation in urban areas as part of the climate change adaptation strategy seeks to move beyond a focus on street trees and parks to a more detailed understanding of the ecology of indigenous ecosystems, and how biodiversity and ecosystem services can reduce the vulnerability of ecosystems and people. Strategies to achieve biodiversity goals (developing corridors for species migration, enlarging core conservation areas, identifying areas for improved matrix management to enhance ecological viability) can have adaptation co-benefits. Recognizing that the adaptation deficit is both in the lack of conventional infrastructure and the loss of ecological infrastructure, the approach includes an interest in how ecosystem restoration and conservation can contribute to food security, urban development, water purification, waste water treatment climate change adaptation and mitigation (Roberts *et al.*, 2012). The growing attention to ecosystem services includes adaptations in urban, peri-urban and rural areas which use opportunities for the management, conservation and restoration of ecosystems to provide services and increase resilience to climate extremes. They can also deliver co-benefits (e.g. purifying water, absorbing runoff for flood control, cleansing air, moderating temperature, preventing coastal erosion) while helping contribute to food security and carbon sequestration (Foster *et al.*, 2011b; GLA, 2011; Newman, 2010; Roberts *et al.*, 2012; see also City of New York, 2011; Helsinki Region Environmental Services Authority, 2012; Institute for Sustainable Communities, 2010; Oliveira *et al.*, 2011; Tallis *et al.*, 2011; Wilson *et al.*, 2011). These approaches are particularly important in low- and many middle-income countries where livelihoods for some urban residents and much of the peri-urban population depend on natural resources. But there are considerable knowledge gaps in determining the limits or thresholds to adaptation of various ecosystems and where and how ecosystem based adaptation is best integrated with other adaptation measures. There is also some indication that the costs of ecosystem based adaptation in urban contexts might be higher than expected, in large part because costs are higher for land acquisition and ecosystem management (Cartwright *et al.*, 2013; Roberts *et al.*, 2012).

Box 8-2 describes how ecosystem-based adaptation is being developed in Durban. Another example is addressing flood risk through catchment management that includes community-based partnerships supported by full cost accounting and payment for ecosystem services – rather than the more conventional canalisation of rivers (Kithiia and Lyth, 2011; Roberts *et al.*, 2012).

_____ START BOX 8-2 HERE _____

Box 8-2. Ecosystem-based Adaptation in Durban

Durban has adopted an ecosystem-based adaptation approach as part of its climate adaptation strategy. This required a series of steps:

- A better understanding of the impacts of climate change on local biodiversity and the management Durban’s open space. The projected warmer and wetter conditions seem to favour invasive and woody plant species.
- Improved local research capacity that includes generating relevant local data.
- Reducing the vulnerability of indigenous ecosystems as a short term precautionary measure.

- Enhancing protected areas owned by local government and developing land-use management interventions and agreements to protect privately-owned land areas critical to biodiversity and ecosystem services. This can be supported by government incentives and regulation to stop development on environmentally sensitive properties, the removal of perverse incentives and support for affected landowners.
- The promotion of local initiatives that contribute jobs and promote skills and environmental education within ecosystem management and restoration programmes. Durban has initiated a large scale Community Reforestation Programme where community level 'tree-preneurs' produce indigenous seedlings and help plant and manage the restored forest areas as part of a larger strategy to enhance biodiversity refuges and water quality, river flow regulation, flood mitigation, sediment control and improved visual amenity. Advantages include employment creation, improved food security and educational opportunities.

Source: (Roberts *et al.*, 2012)

_____ END BOX 8-2 HERE _____

Although much of the early innovation in ecosystem services and green infrastructure was geared to address water shortages or flooding, its importance for climate change adaptation is increasingly recognized.

Green spaces in cities are beneficial for absorbing rainfall and moderating high temperatures. Urban forests and trees can provide shading, evaporative cooling and rainwater interception, storage and infiltration services for cities (Pramova *et al.*, 2012). Increasing tree cover is proposed as a way to reduce UHI. Cooling effects are especially high in large parks or areas of woodland but the land these are on face competition from developers, as well as management challenges *(ibid).* The rapid and often unregulated expansion of cities in low- and middle-income nations may also have left a much lower proportion of the urbanized area as parks and other green spaces.

There is also lack of detailed knowledge on the climatic effects of specific urban plants and vegetation structures (Mathey *et al.*, 2011) and on other important aspects such as the influence of green areas in local circulation patterns and impact on urban fluxes and urban metabolism (Chrysoulakis *et al.*, 2013). In addition, green infrastructure projects may select plant material for particular purposes that do not support habitat values or large ecosystem function and greater ecosystem services.

Some city governments have focused on green infrastructure within built up areas. In the USA, Portland and Philadelphia have encouraged green roofs, porous pavements and disconnection of downspouts) to reduce storm water at much lower cost than increasing storm water capacity (Foster *et al.*, 2011b). Some cities have invested in green infrastructure linked to both regeneration and climate change adaptation. The Green Grid for East London seeks to create "a network of interlinked, multi-purpose open spaces" to support the wider regeneration of the sub-region, enhancing the potential of existing and new green spaces to connect people and places, absorb and store water, cool the vicinity and provide a mosaic of habitats for wildlife (GLA, 2008, p. 80). New York has a well-established programme to protect and enhance its water supply through watershed protection. This includes city ownership of crucial natural areas and working with land owners and communities to balance protection of drinking water with facilitating local economic development and improving waste water treatment. There is also an ambitious green infrastructure plan, including porous pavements and streets, green and blue roofs and other measures to control stormwater. The programme is costly, compared to constructing and operating a filtration plant, but is the most cost-effective choice for New York (Bloomberg and Holloway, 2010; Foster *et al.*, 2011b).

The coastal city of Quy Nhon in Vietnam is reducing flood risks by restoring a 150-hectare zone of mangroves (Brown *et al.*, 2012). Singapore has used several anticipatory plans and projects to enhance green infrastructure including its Streetscape Greenery Master Plan, constructed wetlands or drains and community gardens (Newman, 2010). Authorities in England and the Netherlands are recognising the linkages between spatial planning and biodiversity, but without much direct response to climate change adaptation. Barriers to action include short-term planning horizons, uncertainty of climate change impacts, and problems of creating habitats due to inadequate resources, ecological challenges, or limited authority and data (Wilson and Piper, 2008).

In Mombasa, the Bamburi Cement Company rehabilitated 220 hectares of quarry land (Kithiia and Lyth, 2011). The resulting Haller Park attracts over 150,000 visitors per year, and has the potential to create adaptation co-benefits. Cape Town has initiated community partnerships to conserve biodiversity, including the Cape Flats Nature project with the para-statal South African National Biodiversity Institute. Participating schools and organisations explore ecosystem services (such as flood mitigation and wetland restoration), and the project facilitates "champion forums" to support conservation efforts (Ernstson *et al.*, 2010, p. 539).

Dedicated green areas within urban environments compete for space with other city-based needs and developer priorities. The role of strategic urban planning in mediating among competing demands is potentially useful for the governance of adaptation as demonstrated in London, Toronto, and Rotterdam (Mees and Driessen, 2011). The experience in Durban (see Box 8-2) also faces many challenges (Roberts *et al.*, 2012), including an assumption that ecosystem based adaptation is an easy alternative to the constraints that limit the implementation and effectiveness of "hard engineering" solutions (*ibid.*, Kithiia and Lyth, 2011). Experience in Durban shows that implementing an ecologically functional and well-managed, diverse network of bio-infrastructure requires data collection, expertise and resources, and to have direct and immediate co-benefits for local communities and ensure integration across institutional and political boundaries. There are substantial knowledge gaps such as determining where the limits or thresholds lie; many ecosystems have been degraded to the point where their capacity to provide useful services may be drastically reduced (TEEB, 2010).

Burley *et al.* (2012)'s review of the wetlands of South East Queensland, Australia indicates that adaptations focused on wetland and biodiversity conservation may impact urban form in coastal areas. A study of changes in tree species composition, diversity and distribution across old and newly established urban parks in Bangalore, India, aims to find ways to increase ecological benefits from these biodiversity hotspots (Nagendra and Gopal, 2011). When Leipzig applied a new approach to evaluating the impacts on local climate of current land uses and proposed planning policies, using evapotranspiration and land surface emissivity as indicators, green areas and water surfaces were found to have cooling effects, as expected, but some policies increased local temperatures (Schwarz *et al.*, 2011).

Some aspects of mitigating climate change in urban areas requires a dense urban form to maximize agglomeration economies in more efficient resource use and waste reduction and to reduce urban expansion, reliance on motorized transport and building energy use. But adaptation may require an urban form that favours green infrastructure and open space for storm water management, species migration and urban cooling (Hamin and Gurran, 2009; Mees and Driessen, 2011). Higher densities can prevent the maintenance of ecologically viable systems with high biodiversity and exacerbate the urban heat island, in turn generating the need for more cooling, increasing energy use and further escalating the urban heat island effect. This is the "density conundrum" (Hamin and Gurran, 2009, p. 242) at what point are densities too high to maintain ecologically viable systems with high biodiversity, especially given that urbanization has already compromised the ability of ecosystems to buffer urban development from hazards? This situation will be further exacerbated by new hazards (e.g. floods, fires) to which systems are or will be exposed as the result of climate change (Depietri *et al.*, 2012).

Green and white roofs: Green and white roofs, introduced in a range of cities, have the potential to create synergies between mitigation and adaptation. Rooftop vegetation helps decrease solar heat gain while cooling the air above the building (Gill *et al.*, 2007) thus improving the building's energy performance (Mees and Driessen, 2011; Parizotto and Lamberts, 2011). It can reduce cooling demand and often the use of air conditioning with its local contribution to heat gain and its implications for greenhouse gas emissions (Jo *et al.*, 2010; Zinzi and Agnoli, 2012). Rooftop vegetation can also retain water during storms, reducing stormwater run-off (Palla *et al.*, 2011; Schroll *et al.*, 2011; Voyde *et al.*, 2010) and promoting local biodiversity and food production. Studies have compared the performance of living roofs across different plant cover types, levels of soil water, and climatic conditions (see, e.g., Jim, 2012; Simmons *et al.*, 2008). Hodo-Abalo *et al.* (2012) confirm that a dense foliage green roof has a greater cooling effect on buildings in Togolese hot-humid climate conditions. Several field experiments combined with simulated modelling of impacts in the US also confirm the positive thermal behaviour of green roofs compared to alternative roof coverings (for example, Getter *et al.*, 2011; Scherba *et al.*, 2011; Susca *et al.*, 2011). Durban has a pilot green roof project on a municipal building; indigenous plants are being identified for the project and rooftop food production is being investigated (Roberts, 2010). New York's lack of space for street-level planting helped encourage the adoption of living roofs (Corburn, 2009). Under its Skyrise Greenery project, Singapore has provided subsidies and handbooks for rooftop and wall greening initiatives (Newman, 2010). Based on field tests in the UK, Castleton *et al.* (2010) find that older buildings with poor insulation benefit more from green roofs than newer structures built to higher insulation standards. Wilkinson and Reed (2009) suggest that the overshadowing caused by buildings in city centres may mean lower potential for green roof retrofits compared to installations in suburban areas and smaller towns with lower rise buildings. Benvenuti and Bacci (2010) highlight the availability of water as the main limiting factor in the realisation of green roofs.

A recent meta-analysis suggests that green roofs and parks may have limited effects on cooling. Findings on green roofs were mixed; some studies, but not all, showed lower temperatures above green sections. An urban park was found to be about 1◦C cooler than a non-green site and larger parks had a greater cooling effect. Yet studies were mainly observational, lacking rigorous experimental designs. It remains unclear whether there is a simple linear relationship between a park's size and its cooling impact (Bowler *et al.*, 2010) .

Cool roofs or white reflective roofs use bright surfaces to reflect short-wave solar radiation, which lowers the surface temperature of buildings compared to conventional (black) roofs with bituminous membrane (Saber *et al.*, 2012). There is also some work on roads and pavements with increased reflectivity (Foster *et al.*, 2011b) . Some studies have quantified the cooling benefits from white roofs in various urban settings - in Hyderabad (Xu *et al.*, 2012), in Sicily (Romeo and Zinzi, 2011) and in the North American climate (Saber et al. 2012). Comparisons between green and white roofs have also been undertaken. Ismail *et al.* (2011) investigated their cooling potential on a single-storey building in Malaysia and Zinzi and Agnoli (2012) explored the difference in a Mediterranean climate. Results suggest that local conditions play a dominant role in determining the best treatment. Hamdan *et al.* (2012), for instance, found a layer of clay on top of the roof as the most efficient for passive cooling purposes in Jordan, compared to two different types of reflective roofs.

8.3.3.8. Adapting Public Services and Other Public Responses

As city risk and vulnerability assessments become more common and detailed, they provide a basis for assessing how policies and services can adapt. Many sections of 8.2 noted health impacts that can arise or be exacerbated by climate change that will increase demands on health care systems – including those linked to air pollution, extreme weather, food or water contamination and climate sensitive disease vectors. For air quality, additional research is still needed to understand the complex links between weather and pollutants in the context of climate change (Harlan and Ruddell, 2011). Important synergies can be achieved through combining mitigation and adaptation strategies to improve air quality, reduce private transport and promote healthier lifestyles *(ibid.,* also Bloomberg and Aggarwala, 2008).

In responding to disasters, health care and emergency services (including ambulance, police and fire fighting) will have increased workloads while also ensuring that their systems can adapt. Their effectiveness can be enhanced by good working relationships with other key government sectors and with civil protection services including the army and the Red Cross/Red Crescent national societies. For cities without a robust early warning system or an emergency response network, adapting to climate change may require significant improvements in staffing, resources, and preparedness plans, for example, the data and personnel to deal with vulnerable residents during heat waves. Particular attention may be required to provide emergency services for informal settlements lacking adequate roads or infrastructure and when needed, evacuation plans for all those that have to move. There is little evidence of consideration to changes in services in response to climate change in the city case studies listed in Box 8-1.

Enhanced emergency medical services may help cope with extreme events while health officials can also improve surveillance, forecast the health risks and benefits of adaptation strategies, and support public education campaigns. Public health systems may need to increase attention to disease vector control (e.g. screening windows, eliminating breeding grounds for the mosquitoes that are vectors for malaria and dengue) and bolster food hygiene measures linking to increased flooding and temperatures. The costs of adapting health care systems may be considerable – for instance, modifying buildings and equipment, training staff, setting up comprehensive surveillance and monitoring systems that can capture the health risks of climate change, as well as other risks.

Schools and day-care centres may need risk and vulnerability assessments. School buildings can be designed and built to serve as safe shelters during floods or storms to which those at risk can move temporarily – although it is also important after a disaster to quickly re-establish functioning schools both for the benefit of children and their parents (Bartlett, 2008).

8.4. Putting Urban Adaptation in Place: Governance, Planning, and Management

This section discusses what we have learnt about introducing adaptation strategies into the decision-processes of urban governments, households, communities and the private sector. Many aspects of adaptation can only be implemented through what urban governments do, encourage, allow, support and control. This necessarily involves overlapping responsibilities and authority across other levels of government as well (Blanco *et al.*, 2011; Corfee-Morlot *et al.*, 2011; Dietz *et al.*, 2003; Kehew *et al.*, 2013; McCarney *et al.*, 2011; Ostrom, 2009). Approaches include new urban policies and incentives for action, as well as ensuring that existing policies reduce risk and vulnerability (Bicknell *et al.*, 2009; Brugmann, 2012; Urwin and Jordan, 2008). Transformation should be considered where fundamental change to economic, regulatory or environmental systems is seen as the most appropriate mechanism for reducing risk and where maintaining existing systems offers little scope for adaptation (Pelling and Manuel-Navarrete, 2011) for instance resettlement or abandonment of previously developed land.

City governments that have developed adaptation policies recognize the value of an iterative process responsive to new information, analyses or frameworks (National Research Council, 2010). In a range of cities, it has proved useful to have a unit responsible for this within city government, drawing together relevant data, informing key politicians and civil servants, encouraging engagement by different sectors and departments and consulting with key stakeholders (Brown *et al.*, 2012; Roberts, 2010).

The capacity of local authorities to work effectively, alone or with other levels, is constrained by limited funding and technical expertise, institutional mechanisms and lack of information and leadership (see Carmin *et al.*, 2013; Gupta *et al.*, 2007). Established development priorities and planning practices in functions like land-use, construction or infrastructure provision may not be aligned with the goals or practice of adaptation (Garschagen, 2013; Ostrom, 2009; Pelling, 2011a). Many national governments face comparable constraints and still do not recognize the importance of local governments in adaptation (OECD, 2010). Local adaptive capacity can benefit from disaster risk reduction (Schipper and Pelling, 2006; UNISDR, 2008). New national legislation and institutions on disaster risk reduction have helped in some cases to strengthen and support local government capacity (see 8.3.2.2), but as with other forms of adaptation, they require budgetary support and an increase in local professional capacities to be effective locally (Johnson, 2011).

8.4.1. Urban Governance and Enabling Frameworks, Conditions, and Tools for Learning

Enabling conditions and frameworks to support urban adaptation are grounded in institutional structures, values and local competence, interest, awareness and analytical capacity (Birkmann *et al.*, 2010; Moser and Luers, 2008). Preconditions for sound adaptation decision-making relate to principles of good urban government (what government does) and governance (how they work with other institutions and actors including the private sector and civil society) (Bulkeley *et al.*, 2011; Garschagen and Kraas, 2011; OECD, 2010). This includes science-policy deliberative practice and vulnerability assessment (Adger *et al.*, 2009; Corfee-Morlot *et al.*, 2011; Kehew, 2009; Moser, 2009; National Research Council, 2007; National Research Council, 2008; National Research Council, 2009; Renn, 2008). Civil society has important roles, for instance through community risk assessment, and the incorporation of local knowledge, preferences and norms (Fazey *et al.*, 2010; Krishnamurthy *et al.*, 2011; Shaw *et al.*, 2009; Tompkins *et al.*, 2008; van Aalst *et al.*, 2008). Human behaviour, values and social norms have a role and can evolve through dialogue and understanding (Dietz *et al.*, 2003; Moser, 2006; Ostrom, 2009) and engagement with stakeholders over time is key to effective adaptation (Bulkeley *et al.*, 2011; Kehew *et al.*, 2013). This has to allow consideration of dominant development trajectories and alternatives that can be approached by transformative adaptation. The capacity to act within urban settings varies with the organisational context for development (see 8.1

and Table 8-2), including the level of decentralization (Blanco *et al.*, 2011; Corfee-Morlot *et al.*, 2011; McCarney *et al.*, 2011).

8.4.1.1. Multi-Level Governance and the Unique Role of Urban Governments

A framework for urban governance emerges from the challenges that climate change brings to multilevel risk governance. Figure 8-4 summarises key actors and their relationships. Here, knowledge, policy and action are produced through the interaction, across scales, of three kinds of actors (based upon Corfee-Morlot *et al.*, 2011):

- knowledge producers (academic science, community, business and NGO produced research);
- knowledge actors or users (most important here is local government often in collaboration with partners);
- knowledge filters who can mediate between knowledge production and action (the media, lobby groups and boundary organisations that help in translation) (Ashley *et al.*, 2012; Carvalho and Burgess, 2005; Leiserowitz, 2006).

[INSERT FIGURE 8-4 HERE
Figure 8-4: The co-production of knowledge and policy for adaptation, mitigation, and development in urban systems. Source: Adapted from Corfee-Morlot *et al*., 2011.]

Urban governments, provided with authority for relevant policy decisions, are central to this process (Blanco *et al.*, 2011; Corfee-Morlot *et al.*, 2011; Kehew *et al.*, 2013; McCarney, 2012). Good practice also hinges in part upon the credibility, legitimacy and salience of science-policy processes, a strong local evidence base of historical and projected data on climate change, and on-going, open processes to support dialogue between government, civil society and expert advisors (Cash and Moser, 2000; Cash *et al.*, 2006; Kehew *et al.*, 2013; National Research Council, 2007; Preston *et al.*, 2011b; see also Ch.2). Timely and salient communication is important where a key role is played by the media, lobby groups and boundary organisations that "translate" scientific or expert information for local communities and sometimes also help to shape the questions of scientific inquiry (Gieryn, 1999; Jasanoff, 1998; Moser, 2006; Moser and Dilling, 2007; Moser and Luers, 2008). Good governance facilitates the mediation of policy and decision processes across these different actors, spheres of influence, sources of information and resources, to co-produce knowledge and support learning and action over time.

While urban governments have authority for many relevant adaptation decisions, they can be enabled, bounded or constrained by national, sub-national or supra-national laws, policies and funding and land use and infrastructure planning decisions (Arup/C40, 2012; Brown, 2011; Carter, 2011; Kehew *et al.*, 2013; Martins and da Costa Ferreira, 2011; OECD, 2010). This includes establishing formal mandates for urban adaptation action, without which adaptation becomes optional or discretionary, dependent on local-level interest and resources, and particularly vulnerable to leadership change. Where mandates for adaptation exist, they have been important in driving local level action (Kazmierczak and Carter, 2010). New mandates (formal or informal) may also require institutional changes (Kazmierczak and Carter, 2010; Lowe *et al.*, 2009; Roberts, 2008).

The level of complexity is raised in large metropolitan areas, especially when they are growing rapidly. Action has to be coordinated and harmonized across multiple urban jurisdictions; often dozens of them (e.g. Mexico City, Sao Paulo, London and Buenos Aires) and occasionally hundreds (e.g. Abidjan and Tokyo) (McCarney *et al.*, 2011; McCarney, 2012), for instance to implement flood protection of contiguous land areas (Hallegatte *et al.*, 2011b). Although there is some evidence of innovative responses at sub-national levels to plan for extreme weather events and climate change, limited capacity and experience at local government level suggests the need for support from higher levels of government (EEA, 2012; Gurran *et al.*, 2012; Norman and Nakanishi, 2011).

Policies and incentives need to be aligned to work coherently across multiple levels of government to define and deliver effective urban adaptation. This often involves institutions at different levels with different scopes of authority (Bulkeley and Kern, 2006; Cash *et al.*, 2006; Corfee-Morlot *et al.*, 2011; EEA, 2012; Kern and Gotelind, 2009; Mukheibir and Ziervogel, 2007; Urwin and Jordan, 2008; Young, 2002). Water authorities, for instance, may operate at water-basin level, representing both national and local interests while operating independently of urban authorities. Failing to ensure consistent alignment and integration in risk management can lock in outcomes that raise the vulnerability of urban populations, infrastructure and natural systems even where pro-active adaptation policies exist (Benzie *et al.*, 2011; OECD, 2009; Urwin and Jordan, 2008). Local government capacity is important, as well as the institutions that facilitate coordination across multiple, nested, poly-centric authorities with potential to mainstream adaptation measures and tailor national goals and policies to local circumstances and preferences. Horizontal coordination and networking across actors and institutions in different municipalities and metropolitan areas can accelerate learning and action (Aall *et al.*, 2007; Lowe *et al.*, 2009; Schroeder and Bulkeley, 2009).

Consultation and awareness-raising can help avoid the kind of public backlash that occurred when the French government sought to ban urban development and require strategic retreat in areas of risk to coastal flooding after the 2010 storm Xynthia (Laurent, 2010; Przyluski and Hallegatte, 2012). There can also be vested interests and trade-offs where near-term development conflicts with longer-term adaptation and resilience goals. Public engagement, openness and transparency can help ensure democratic debate to balance public interests and longer-term goals against the short-term benefits of unconstrained development. Urban governments are uniquely situated to understand local contexts, raise local awareness, respond to citizens' and civil society pressures and work to build an inclusive policy space (Brunner *et al.*, 2005; Brunner, 1996; Cash and Moser, 2000; Grindle and Thomas, 1991; Healey, 2006). Urban governments can also promote understanding of climate change risk and help to create a common vision for the future (Corfee-Morlot *et al.*, 2011; Moser, 2006; Moser and Dilling, 2007; Ostrom, 2009). The fact that preferences are more homogenous within smaller units (Ostrom, 2009) provides opportunities for leadership and innovation that may not exist at higher levels of governance. Urban governments, so often responsible for a substantial share of urban infrastructure (Arup/C40, 2012; Hall *et al.*, 2012), are also central to the interface between climate change and development, including provision for essential infrastructure and services (Bulkeley and Kern, 2006; Bulkeley, 2010). Urban planning structures, processes and plans can integrate and mainstream adaptation plans and risk management into urban and sectoral planning with a clear time frame, mandate and resources for implementation (Agrawala and Fankhauser, 2008; Bicknell *et al.*, 2009; Brugmann, 2012), even if functional authority is at national or sub-national regional levels (Hall *et al.*, 2012). Many urban governments show growing awareness and analytical capacity in adaptation planning but there is less evidence in implementation and influence on key sectors (Roberts, 2010).

Local government decisions can be driven by short-term priorities of economic growth and competitiveness (Moser and Luers, 2008) and addressing climate change can mean taking a longer-term perspective (Leichenko, 2011; Pelling, 2011a; Romero-Lankao and Qin, 2011; Viguié and Hallegatte, 2012). Tension also exists between economic growth and the needs of the large, often growing, numbers of ill-served urban poor (Bicknell *et al.*, 2009) whose resilience to climate change will depend on infrastructure and services. The challenges in low- and middle-income countries are exacerbated by relative inattention from international donors to urban policy and development concerns, as they have historically worked through national government planning processes, which may not capture the needs of urban populations (Mitlin and Satterthwaite, 2013). Donors may also prefer visible physical infrastructure projects over local institution and capacity building investments. Most national governments in high-income countries also have yet to fully embrace local adaptation initiatives (McCarney *et al.*, 2011).

8.4.1.2. Mainstreaming Adaptation into Municipal Planning

Mainstreaming adaptation into urban planning and land-use management and legal and regulatory frameworks is key to successful adaptation (Kehew *et al.*, 2013; Lowe *et al.*, 2009). It can help planners rethink traditional approaches to land use and infrastructure design based on past trends, and move towards more forward looking risk-based design for a range of future climate conditions (Kennedy and Corfee-Morlot, 2013; Kithiia, 2010; Solecki *et al.*, 2011), as well as reducing administrative cost by building resilience through existing policy channels (Benzie *et al.*, 2011; Blanco *et al.*, 2011; Urwin and Jordan, 2008). Mainstreaming through local government policies and planning ensures that investments and actions by businesses and households contribute to adaptation (Brown, 2011; Kazmierczak and Carter, 2010; Mees and Driessen, 2011; Sussman *et al.*, 2010). But this must avoid overloading already complex and inadequate planning systems with unrealistic new requirements (Kithiia, 2010; Roberts, 2008); particularly in many low- and middle-income countries, these systems are already stressed by lack of information, institutional constraints and resource limitations.

Mainstreaming may best be initiated by encouraging pilot projects and supporting experimentation by key sectors within local government. Assigning responsibility to specific departments can make the adaptation (and mitigation) message easier to understand by local governments and other stakeholders and the associated responsibilities and actions clearer and simpler to identify and assign (Roberts and O'Donoghue, 2013; Roberts, 2010; UN-Habitat, 2011a). Pilot projects and sectoral approaches ground adaptation in practical reality (Brown *et al.*, 2012; Roberts, 2010; Tyler *et al.*, 2010; UN-Habitat, 2011a). As actors in each sector in local government come to understand their roles and responsibilities, the basis for integration and cross-sectoral coordination is formed.

The literature suggests that opportunities to mainstream climate change into urban planning and development are still largely missed (Sánchez-Rodríguez, 2009). The planning agenda can already be full (Measham *et al.*, 2011). Challenges in information, institutional fragmentation and resources (Sánchez-Rodríguez, 2009; Wilson *et al.*, 2011) make it difficult to introduce the additional layer of climate change planning (Kithiia, 2010; Roberts, 2008) which may also be seen merely as “add-ons” (Kithiia and Dowling, 2010, p. 474).

Other challenges also limit progress – for instance the lack of leadership and of focal points on urban adaptation (see 8.4.3.4 for more detail). In times of economic hardship (e.g. the current recession), local authorities with already limited resources may prioritise conventional economic and development goals over ‘environmental’ issues including climate change adaptation (Shaw and Theobald, 2011; Solecki, 2012). A further challenge is getting the timely evaluation of emerging adaptation measures (Hedger *et al.*, 2008; Preston *et al.*, 2011).

Experience with adaptation programmes show they are often more cross-sectoral, cross-institutional and complex; they operate across a range of scales and timelines, are rooted in local contexts, involve many stakeholders and include high levels of uncertainty (Roberts and O'Donoghue, 2013; Roberts *et al.*, 2012). Standardised guidelines for action are less relevant and urban adaptation practitioners have identified instead the need for “clarity, creativity, and courage” (ICLEI Oceania, 2008, p. 62). In all instances, where progress on adaptation planning is observed, local leadership is a central factor (Carmin *et al.*, 2009; Carmin *et al.*, 2013; Measham *et al.*, 2011).

8.4.1.3. Delivering Co-Benefits

Important opportunities also exist to combine adaptation and mitigation goals in urban housing policies (and the energy sources they draw on), infrastructure investments and land use decisions - especially in high- and middle-income countries (Satterthwaite, 2011). Co-benefits for mitigation and for transformation require a reconsideration of dominant development pathways and of possible alternatives both within and beyond the urban core, influencing, for instance, local environments along with water-basin management and coastal defence regimes (OECD, 2010; Urwin and Jordan, 2008). Examples of positive and negative interactions between urban adaptation and mitigation strategies suggest that these strategies will need to be assessed and managed to achieve co-benefits (Kennedy and Corfee-Morlot, 2013; Viguié and Hallegatte, 2012). Viguié and Hallegatte (2012) demonstrate that despite trade-offs, careful planning can yield adaptation-mitigation co-benefits across greenbelt policies, flood zoning and transportation policies. Local governments may be able to address both adaptation and mitigation using pre-existing tools and policies such as building standards, transport infrastructure planning, and other urban planning tools (Hallegatte *et al.*, 2011a). It may be possible to avoid or limit trade-offs by developing institutional links between the different policy areas at the level of local planning (Kennedy and Corfee-Morlot, 2013; Swart and Raes, 2007; Viguié and Hallegatte, 2012).

Adaptation can produce development co-benefits in urban areas including safer, healthier, more comfortable urban homes and environments and reduced vulnerability for low-income groups to disruptions in their incomes and livelihoods (Anguelovski and Carmin, 2011; Bicknell *et al.*, 2009; Burch, 2010; Clapp *et al.*, 2010; Hallegatte *et al.*, 2011a; Kousky and Schneider, 2003; Roberts, 2010). Local development co-benefits may be particularly important to highlight in low and middle-income countries, where lack of policy buy-in accompanies limited local capacity (UN-Habitat, 2011a) and where current climate change challenges appear marginal compared with development deficits (Kithiia and Dowling, 2010; Kiunsi, 2013; Roberts, 2008). Urban authorities in India can see adaptation as a priority if it also addresses development and environmental health concerns (Sharma and Tomar, 2010).

Development and climate change adaptation are often seen as separate challenges in a sub-national planning context. A review in OECD countries showed only Japan and South Korea championing climate action as integral to sub-national development planning, although Finland and Sweden have innovative sub-national climate policies and action programmes funded by central government (OECD, 2010). For most OECD countries, urban development and adaptation are tackled separately. Yet policy research finds that successful adaptation is rooted within and harmonised with such development priorities as poverty reduction, food security and disaster risk reduction (Bicknell *et al.*, 2009; Measham *et al.*, 2011; Moser and Luers, 2008).

8.4.1.4. Urban Vulnerability and Risk Assessment Practices: Understanding Science, Development, and Policy Interactions

A critical aspect of urban climate risk governance is the integration of scientific knowledge into decision-making, building on exchange between scientists, policy-makers and those at risk (Government of South Africa, 2010; National Research Council, 2009; Rosenzweig and Solecki, 2010; Vescovi *et al.*, 2007). International policy advisory agencies with an interest in urban adaptation can augment this (ICLEI, 2010; Sonover *et al.*, 2007) , but will depend upon local capacity and engagement to produce, access and use climate change information and processes (Carmin *et al.*, 2013; Hallegatte *et al.*, 2011a). Local and regional boundary organisations can be influential in making scientific and technical information more salient to decision-makers (Bourque *et al.*, 2009; Corfee-Morlot *et al.*, 2011). In many instances, key boundary functions are carried out by nearby academic or research communities and these can also be a source of leadership for urban adaptation (Government of South Africa, 2010; Sánchez-Rodríguez, 2009).

Even where detailed vulnerability or risk assessments exist, their influence may be limited if decision-makers do not access and use this information. Urban master plans or strategic plans with a time horizon of ten or more years can incorporate climate risks and vulnerabilities, but assessments must be available to influence such plans. Moser and Tribbia (2006), exploring how decision makers access and use information, find that resource managers tend to rely more on informal sources (maps or in-house experts, media and internet) than on scientific journals. This reinforces the point made earlier in regard to producers of scientific and information and knowledge actors to needing to work closely with decision makers in the production and communication of scientific information (Cash *et al.*, 2003; Cash *et al.*, 2006; Corfee-Morlot *et al.*, 2011; Moser, 2006).

8.4.1.5. Assessment Tools: Risk Screening, Vulnerability Mapping, and Urban Integrated Assessment

Assessments of risk and vulnerability to the direct and indirect impacts of climate change are often the first step in getting government attention, especially when put in the context of development policy objectives (Hallegatte *et al.*, 2011a; Mehrotra *et al.*, 2011a, see also 8.2). Including risk management information in infrastructure design at the planning or design phase can mean lower retrofit costs later on (Baker, 2012; World Bank, 2012). A variety of planning and assessment tools can be helpful, including impact assessment, environmental audits, vulnerability mapping, disaster risk assessment and management tools, local agenda 21 plans, urban integrated assessment as part of public investment planning and as used by community organisations (Baker, 2012; Haughton, 1999; UN-Habitat, 2007). Governments can ensure that up-to-date climate information is available to the private sector to support adaptation (Agrawala *et al.*, 2011, see also 8.4.2.3). Some of these tools provide entry points and a means for participatory engagement, but often give little consideration to adaptation (Gurran *et al.*, 2012). More reliable, specific and downscaled projections of climate change and tools for risk screening and management can help engage relevant public sector actors and the interest of businesses and consumers (AGF, 2010a; UNEP, 2011).

Local climate change risk assessments, vulnerability and risk mapping can identify vulnerable populations and locations at risk and provide a tool for urban adaptation decisions (Hallegatte *et al.*, 2011a; Kienberger *et al.*, 2013; Livengood and Kunte, 2012; Ranger *et al.*, 2009). The LOCATE methodology (Local Options for Communities to Adapt and Technologies to Enhance Capacity), which integrates hazard and vulnerability mapping to inform choices about which populations, infrastructure and areas to prioritise for action (Annecke, 2010) is being tested in eight

African countries; in each, an NGO is working with communities on across-project design and implementation, monitoring, evaluation and learning.

Tools that organize and rank information on vulnerability in different locations often aim to identify relative and absolute differences in risk and resilience capacity (Hahn *et al.*, 2009; Manuel-Navarrete *et al.*, 2011; Milman and Short, 2008; Posey, 2009). They vary from quick screenings to a fuller risk analyses and evaluations of adaptation options (Hammill and Tanner, 2011). Preston *et al.* (2011), noting the wide variety of functions and methods in 45 vulnerability mapping studies, suggest that effectiveness is guided by identifying clear goals, robust technical methods and engagement of the appropriate user communities. Halsnæs and Trærup (2009) recommend the use of a limited set of indicators, engagement with representatives of local development policy objectives, and a stepwise approach to address climate change impacts, development linkages, and economic, social and environmental dimensions. Methods for application across scale (Kienberger *et al.*, 2013), considering the urban environment as a system, allow for better understanding of interconnections between root causes, risk production, cascading impacts and vulnerabilities (da Silva *et al.*, 2012; Kirshen *et al.*, 2008; United Nations, 2011).

Downscaling of climate scenarios, systems models and urban integrated assessment modelling at local scales integrate information in a forward-looking framework to support urban policy assessment (e.g. Dawson *et al.*, 2009; Hall *et al.*, 2010; Hallegatte *et al.*, 2011a; van Vuuren *et al.*, 2007; Viguié and Hallegatte, 2012; Walsh *et al.*, 2011). Integrated assessment modelling considers the driving forces of urban vulnerability and climate change impacts alongside possible policy responses and their outcomes. By integrating knowledge, this provides a tool for policy-makers to examine and better understand synergies and trade-offs across policy strategies (Dawson *et al.*, 2009; Viguié and Hallegatte, 2012). These modelling frameworks take time to build and to be incorporated into decision-making processes. While early results are promising, they also highlight the difficulty of producing tools that can be easily used by local governments (e.g. see also Hall *et al.*, 2012; Walsh *et al.*, 2013; Walsh *et al.*, 2011).

Despite growing attention, useful assessment of climate change at urban spatial scales is generally lacking (Hunt and Watkiss, 2011). A small number of cities, largely in high-income countries, have quantified local climate change risks; even fewer have quantified possible costs under different scenarios. Some exceptions exist – Durban has developed a benefit-cost model for adaptation options (Cartwright *et al.*, 2013), and there have been urban climate risk assessments in low- or middle-income developing countries as part of targeted development cooperation programmes, supported by external partners (World Bank, 2011; World Bank, 2013). Sea level rise and coastal flood risk, health and water resources are among the most studied sectors; energy, transport and built infrastructure get far less attention *(ibid.*, Hunt and Watkiss, 2011; Roy *et al.*, 2012). Science and climate change information is increasingly available, but socio-economic drivers of vulnerability and impacts, and opportunities and barriers to adaptation are less well studied and understood (Measham *et al.*, 2011; Romero-Lankao and Qin, 2011).

8.4.2. Engaging Citizens, Civil Society, the Private Sector, and Other Actors and Partners

8.4.2.1. Engaging Stakeholders in Urban Planning and Building Decision Processes for Learning

A common vision of a future resilient, safe and healthy city can be the first step to achieving it (Corfee-Morlot *et al.*, 2011; Moser, 2006; Moser and Dilling, 2007; UN-Habitat, 2011a). Participatory processes figure prominently in cities that have been leaders in urban adaptation (Brown *et al.*, 2012; Carmin *et al.*, 2012b; Rosenzweig and Solecki, 2010); see also below). The conceptual literature agrees that participatory decision-making is essential where uncertainty and complexity characterise scientific understanding of policy problems (Funtowicz and Ravetz, 1993; Liberatore and Funtowicz, 2003). Many have argued that the institutional features of the risk management decision-making process – participatory inclusiveness, equity, awareness raising, deliberation, argument and persuasion – will determine the legitimacy and effectiveness of action (Corfee-Morlot *et al.*, 2011; Dietz *et al.*, 2003; Lim *et al.*, 2004; Mukheibir and Ziervogel, 2007). Yet the review of 45 vulnerability mapping exercises found that only 40 percent included stakeholder participation, raising questions about the legitimacy and salience of contemporary approaches (Preston *et al.*, 2011). It also highlights the challenge local governments face to garner resources, including technical expertise and institutional capacity, to organise and use participatory processes to strengthen rather than delay adaptation decision-making (Carmin *et al.*, 2013).

In many urban settings, civil society and the private sector already have significant and positive roles in support of adaptation planning and decisions. Some studies show that despite limited information, adaptation at urban scale is moving ahead, particularly through initial planning and awareness-raising (Anguelovski and Carmin, 2011; Hunt and Watkiss, 2011; Lowe *et al.*, 2009). Experience in a handful of cities– e.g. Cape Town, Durban, London, New York –shows that a wide number and variety of engaged stakeholders at early stages in a risk assessment creates political support and momentum for follow-up research and adaptation planning (Anguelovski and Carmin, 2011; Hunt and Watkiss, 2011; Rosenzweig and Solecki, 2010). In informal settlements with little or no formal infrastructure and services, stakeholder engagement is a means for participatory community risk assessment, where local adaptive capacity is built in part through local knowledge (Kiunsi, 2013; Livengood and Kunte, 2012). Over time, institutional mechanisms can be built that support innovation, collaboration and learning within and across sectors to advance urban adaptation action, but it takes time and resources (Anguelovski and Carmin, 2011; Burch, 2010; Mukheibir and Ziervogel, 2007; Roberts, 2010).

8.4.2.2. Supporting Household and Community-Based Adaptation

In well-governed cities, community groups and local governments are mutually supportive, providing information, capacity and resources in maintaining local environmental health and public safety, which in turn can support adaptation. Where local government has not yet formulated an adaptation strategy, community groups can raise political visibility for climate risks and provide front-line coping (Granberg and Elander, 2007; Wilson, 2006), and also begin to address gender disparities in urban risks (Björnberg and Hansson, 2013).

The full range of infrastructure and services needed for resilience is generally affordable only in middle- and upper-income residential developments in low- and lower-middle income countries. In most cities and neighbourhoods, where infrastructure coverage is incomplete and household incomes limited, community organisations – or community-based adaptation - offer a rich resource of adaptive capacity to cope and to prepare for future risk. A range of studies document the depth of knowledge and capacities held by local populations around reducing exposure and vulnerability (Anguelovski and Carmin, 2011; Dodman and Mitlin, 2011; Livengood and Kunte, 2012). For a high proportion of the households that live in informal urban settlements, household and community-based adaptation is their only means of responding to risk. They are well used to coping with environmental hazards (Adelekan, 2010; Jabeen *et al.*, 2010; Kiunsi, 2013; Livengood and Kunte, 2012; Wamsler, 2007). Some seek to modify hazards or reduce exposure, for example through ventilation and roof coverings to reduce high temperatures; barriers to prevent floodwater entering homes; keeping food stores on top of high furniture; and moving temporarily to safer locations (Douglas *et al.*, 2008). A study in Korail, one of Dhaka's largest informal settlements, showed the range of household responses to flood risk (see Figure 8-5). These include barriers across door fronts, increasing the height of furniture, building floors or shelves above the flood line and using portable cookers (Jabeen *et al.*, 2010). Provision for ventilation, creepers or other material on roofs and false ceilings helped to keep down temperatures. These are important near-term adaptations, and there are similar responses in many informal settlements (see for instance Adelekan, 2010; Kiunsi, 2013), but they do not generate capacity to adapt to future risk.

[INSERT FIGURE 8-5 HERE
Figure 8-5: Household adaptation - a cross section of a shelter in an informal settlement in Dhaka (Korail) showing measures to cope with flooding and high temperatures. CI: Corrugated iron. Source: Jabeen *et al*., 2010.]

There are multiple constraints on action for low-income households. Even where there are early warnings, a lack of trust in the security of their property and the right to return, along with fears for personal safety in shelters, are deterrents against evacuation (Hardoy *et al.*, 2011; Jabeen *et al.*, 2010). Tenants and those with the least secure tenure are often amongst the most vulnerable and exposed to hazards but also are usually unwilling to invest in improving the housing they live in and less willing to invest in community initiatives. Community-based responses are often reactive, addressing current more than future risks, though they may embody alternative development values and support local transformation. Shifting the burden of adaptation to the community level alone is unlikely to bring success. There are limits to what community action can do in urban areas. For instance, communities may build and maintain local water sources, toilets and washing facilities or construct or improve drainage (see for instance the programmes in cities in Pakistan described in Hasan, 2006) but they cannot provide the network infrastructure on which these depend (e.g. the water, sewer and drainage mains and water treatment) nor can they improve city-region governance (Bicknell *et al.*, 2009). Work on cities in the Caribbean and Latin America indicates the need for supportive links to community networks and/or local government for community-level adaptation to be effective (Mitlin, 2012; Pelling, 2011b).

There is some recognition that strengthening the asset base of low-income households helps increase their resilience to stresses and shocks, including those related to climate change (Moser and Satterthwaite, 2009). It has become more common for local governments to work with community-based organizations in upgrading their homes and settlements in disaster risk reduction (IFRC, 2010; Pelling, 2011b; United Nations, 2009; United Nations, 2011), and community-based adaptation is building on these experiences and capacities (Archer and Boonyabancha, 2011; Carcellar *et al.*, 2011). Communities can have close relationships with formal state and market institutions, shaping subsequent adaptive capacity for members. Most housing and infrastructure upgrading programmes mean that those living in low-income settlements become incorporated into 'the formal' city and this often means an increased expectation on the state to reduce vulnerability, including long-term and strategic adaptation investments through access to schools, health care, infrastructure and safety nets (Almansi, 2009; Boonyabancha, 2005; Ferguson and Navarrete, 2003; Fernandes, 2007; Imparato and Ruster, 2003; UN Millennium Project, 2005). There can still be obstacles. Where climate change or disaster risk is seen as distant or low probability, the immediate pressures of poverty tend to dominate local agendas (Banks *et al.*, 2011). In many informal settlements, the issue of land tenure is also difficult to resolve and impedes upgrading programmes (Almansi, 2009; Boonyabancha, 2005; Boonyabancha, 2009) and thus local-level adaptation action.

In a growing number of cities, residents' organizations supported by grassroots leaders and local NGOs are mapping and enumerating their informal settlements with eventual support and recognition from city governments (Patel and Baptist, 2012). This provides the data and maps needed to plan the installation or upgrading of infrastructure and services. Some of these enumerations also collect data on risks and vulnerabilities to extreme weather and other hazards (Carcellar *et al.*, 2011; Livengood and Kunte, 2012; Pelling, 2011b; UN-Habitat, 2007). For example, community surveys in the Philippines identified at-risk communities under bridges, in landslide-prone areas, on coastal shorelines and river banks, near open dumpsites and in flood-prone locations (Carcellar *et al.*, 2011). This mapping raises awareness among inhabitants of the risks they face, as well as getting their engagement in planning risk reduction and making early warning systems and emergency evacuation effective (Pelling, 2011b). Table 8-4 illustrates the contemporary limits of community-based action across key sites of coping and adaptation – highlighting where strategic partnerships, especially with a supportive municipal government, have key advantages.

[INSERT TABLE 8-4 HERE
Table 8-4: The possibilities and limitations of focused activity for community groups on climate change coping and adaptation.]

IFRC (2010) identifies three broad requirements for successful urban community-based disaster risk reduction that can be extended to assess coping and adaptive capacity: the motivation and partnership of stakeholders; community ownership, with flexibility in project design; and sufficient time, funding and management capacity. The effectiveness of community-based action also depends on how representative and inclusive the community leaders and organizations are (Appadurai, 2001; Banks, 2008; Houtzager and Acharya, 2011; Mitlin, 2012; Wamsler, 2007); their capacity to generate pressure for larger changes within government; and the relations between community organizations and government (Boonyabancha and Mitlin, 2012). Community-based adaptation can support transformation where it engages with key development agendas to reduce poverty and vulnerability (Sabates-Wheeler *et al.*, 2008), and can address local inequalities and adverse power relations at district, city, national and transnational levels (Mohan and Stokke, 2000). But urban governance regimes are often resistant to change and civil society organizations can be marginalized or co-opted, reducing the scope for transformative adaptation (Pelling and Manuel-Navarrete, 2011).

8.4.2.3. Private Sector Engagement and the Insurance Sector

Cities are attractive to private enterprises because so much business activity, private investment and demand are concentrated there. Private enterprises generally favour cities with functioning city infrastructure and a wide range of services. As noted earlier, much investment for sound adaptation will need to come from households and firms of all sizes (Agrawala and Fankhauser, 2008; Bowen and Rydge, 2011). Brugmann (2012) argues that effective adaptation depends on catalysing market-based investments. Beyond acting to protect their own interests, businesses are stakeholders in urban decision making, positioned to exploit new opportunities that arise from climate change (Chapter 14, also Khattri *et al.*, 2010). Private service providers and professional associations - including architects, engineers and urban planners – can influence the pace and quality of adaptation efforts where an understanding of climate change is part of professional training and knowledge (McBain *et al.*, 2010). Even when considering more political issues around the support of adaptation efforts (AGF, 2010b; AGF, 2010c), most studies conclude that the need for adaptation investments will far exceed available funds from public budgets (see Ch. 15; also Agrawala and Fankhauser, 2008; Hedger, 2011; World Bank, 2010d).

For markets to favour urban adaptation, the private sector will need to see financial justification for involvement, for example to ensure business continuity. A survey of companies on the most serious risks they faced (Aon, 2013) ranked weather/natural disasters 16th and climate change 38th although some higher ranked risks such as commodity prices (8th) or distribution/supply chain failure (14th) may be associated with climate change. Risk rankings differed by region (in Asia Pacific weather/natural disasters were 8th) and by sector (for agribusiness, weather/natural disasters were 2nd). Failure of climate change adaptation (as "governments and business fail to enforce or enact effective measures to protect populations and transition businesses impacted by climate change") was listed by World Economic Forum (2013, p. 46) as one of the most likely environmental risks over the next ten years and with having a high impact if the risk was to occur. Private sector actors may not be well positioned to consider the big adaptation questions, including changes in land use, development and infrastructure planning (Redclift *et al.*, 2011). For example, in Cancun, Mexico, close relationships between government and the corporate sector and the push for lucrative development have perpetuated an urban development model that generates climate change risk by increasing the hazard exposure of capital intensive, large-scale coastal development (Manuel-Navarrete *et al.*, 2011). Without transformative change in urban development planning, private sector investments in adaptation will remain limited, such as designing buildings to withstand hurricanes but not tackling where development occurs. In the Cancun case, most investment comes from the state, for example in beach replenishment and policies for rapid disaster recovery (Manuel-Navarrete *et al.*, 2011).

The Private Sector Initiative of the UNFCCC Nairobi Work Programme offers support for businesses to integrate climate change science into their business planning, including in urban infrastructure and technology developments (http://unfccc.int/adaptation/nairobi_work_programme/private_sector_initiative/items/6547.php). This shows that both public and private (including civil society) actors can have a role in providing regional data and projections of socio-economic trends, climate change, urban water supply and management practices, land use and building trends, and hazard mapping (UNEP, 2011). A review shows anecdotal evidence of large businesses investing in vulnerability assessments, yet few beginning to invest in adaptation (Agrawala *et al.*, 2011). While some private sector actors take action against climate change risks, many postpone upfront investments for longer-term benefits against uncertain risks. Eakin *et al.* (2010) and Chu and Schroeder (2010) suggest that the private sector becomes more prominent when local governments and civil society action is limited, but this raises the issue of what incentives are required, especially in regard to low-income countries and communities.

Particularly in wealthier countries and communities, insurance markets can share and spread financial risk from climate change, for example, to help limit damages and manage risks in urban flood-prone areas (Rosenzweig and Solecki, 2010; see also Ch. 10 and 14). Risk-differentiated property insurance premiums can incentivise individuals and businesses to invest in adaption and retrofitting property or to avoid building in high-risk areas (Fankhauser *et al.*, 2008; Mills, 2012; Mills, 2007). Relevant insurance instruments include health and life insurance for individuals; property and possession insurance for home and commercial property owners; and micro insurance or micro finance mechanisms to support those in low-income urban communities that are not covered by commercial insurance (see Box 8-3). Catastrophe bonds may be developed to cover some urban climate risks, but experience to date suggests they are quite narrowly written for specific events in specific locations, not providing the broad protection necessary to limit catastrophic risk in a changing climate and urban context (Brugmann, 2012; Keogh *et al.*, 2011). Multicat Mexico 2009 is a catastrophe bond used to reinsure the Natural Disaster Fund covering the Mexican territory against hurricanes and earthquakes. This provides resources to mitigate losses up to US$ 50 million for hurricanes (Aragón-Durand, 2012). The insurance industry can also help shape urban adaptation initiatives, collaborating with building owners, developers and governments to inform and encourage action.

Private investment or standard insurance markets will not protect low-income urban dwellers (Hallegatte *et al.*, 2010; Ranger *et al.*, 2009). For example, around half of Mumbai's population live in informal settlements mostly without protective infrastructure and at increasing risk of flooding under most climate change scenarios (Hallegatte *et al.*, 2010; McFarlane, 2008; Ranger *et al.*, 2011). This population (and most of those living in informal settlements in oither cities) will not be served by insurance because of the low ability to pay, high risks and the high transaction costs for companies of administering many small policies. Low-income groups rely instead on local solidarity and government assistance when disaster hits (Hallegatte *et al.*, 2010). In addition, where risk levels exceed certain thresholds, insurers will abandon coverage or set premiums unaffordable to those at risk. Insurance reduces the net risk and loss potential in urban areas, but can also increase inequality in security within neighbourhoods or across cities unless coupled with government action to help manage risk in low-income communities (da Silva, 2010).

In many informal settlements, informal savings groups give members (mostly women) quick access to emergency loans (Mitlin, 2008). Where access to formal banking is limited, but social capital is high, those living in informal settlements have also pooled their savings for collective investments that reduce risk in their settlements or allow them to negotiate land and support for new homes (d'Cruz and Mudimu, 2013; Manda, 2007; Satterthwaite and Mitlin, 2014).

_____ START BOX 8-3 HERE _____

Box 8-3. Microfinance for Urban Adaptation

Microfinance schemes may contribute to pro-poor, urban adaptation through a variety of different instruments including micro-credit, micro-insurance and micro-savings to help households and small entrepreneurs without access to formal insurance or commercial credit markets. These have been applied mostly in rural areas, usually benefitting those with some property (and thus not the poorest of rural populations). As Hammill *et al.* (2008, p. 117) state: "*The value MFS holds for climate change adaptation is in its outreach to vulnerable populations through a combination of direct and indirect financial support, and through the long-term nature of its services that help families build assets and coping mechanisms over time, especially through savings and increasingly through micro insurance – products and sharing of knowledge and information to influence behaviours.*" Although typically more costly than commercial loans, micro-finance can support entrepreneurial undertakings by those unable to get bank loans, help diversify local economies and empower women in particular, which can in turn contribute to adaptive capacity in a local context (Agrawala and Carraro, 2010; Moser *et al.*, 2010). Microfinance also provides a means for donors to deliver support to low-income groups without creating an on-going dependence on aid. But there is a need to target it well to avoid encouraging growth in areas prone to climate risk (Agrawala and Carraro, 2010; Hammill *et al.*, 2008). A limitation of micro-finance for adaptation is that it typically provides credit to individuals, so it is not easily used to finance collective investments - for instance improving drainage - and it can be a route to indebtedness during disaster recovery. There has been some experience of pooling savings, e.g. in low-income communities to set up City Development Funds in Asia, from which they can draw loans for disaster rehabilitation among other things (Archer, 2012). Von Ritter and Black-Layne (2013) explore the possible role for microfinance and crowd funding to support local climate change action e.g. finance small decentralised energy solutions or "climate-proof" homes; they also suggest the new Green Climate Fund could support such activity through its private sector window.

_____ END BOX 8-3 HERE _____

For the private sector to fulfil its potential to facilitate urban adaptation, public policy may need to establish enabling conditions in markets (see also 8.3), for example, targeting payment for provision of ecosystem services to deliver urban adaptation benefits that otherwise fall outside the market system. Such services include storm buffering and flood protection by paying for mangrove protection in coastal zones or urban green space along river-ways (Fankhauser *et al.*, 2008; Roberts *et al.*, 2012). In building construction, well-documented examples of market failure exist. Private investment in weather proofing new construction and retrofitting existing stock, may fail to occur without regulatory intervention. This is an area where municipal governments often have authority to act. Public policy and funding is also needed to protect the poorest and most vulnerable households, and to ensure or enable action by the private sector. This may include filling gaps in insurance markets (Fankhauser *et al.*, 2008; IPCC, 2012; Mills, 2007; UN-Habitat, 2011c), helping provide information about risks particularly where this is highly uncertain and encouraging pro-active engagement by the private sector, as in the UK where vulnerability assessment is required for infrastructure investments (Agrawala *et al.*, 2011). There are examples of urban governments leading by example, requiring the integration of adaptation considerations into public operations and infrastructure investments through procurement requirements, which in turn affects private sector providers. Thus, even where markets exist and are well-functioning, all levels of government may need to engage the private sector in adaptation. Public-private initiatives also have a role providing educational and skill development resources to ensure that the professional networks of private service providers are trained in the latest decision tools, assessment methods and practices (da Silva, 2012; McBain *et al.*, 2010). Where markets do not exist or do not function well, there will be an even larger role for policy and public investments to support urban adaptation.

8.4.2.4. Philanthropic Engagement and other Civil Society Partnerships

Philanthropic and other civil society support for urban adaptation is gaining momentum at all levels. The most diverse and numerous are local actions undertaken by community-based organisations, as described above. Philanthropic organisations demonstrate the enabling role that can be played by international civil society to support urban adaptation, particularly in cities and communities in low- and lower-middle income countries. The coming together of grassroots civil society organisations to form international collaborations and networks can also strengthen the framing role of civil society while retaining local accountability and focus to support adaptation. Some examples include:

- Rockefeller Foundation’s support for the Asian Cities Climate Change Resilience Network (ACCCRN) (Brown *et al.*, 2012; Moench *et al.*, 2011)
- The Asian Coalition for Community Action Program managed by the Asian Coalition for Housing Rights
- The Asian Disaster Reduction and Response Network (ADRRN)
- Philippines Homeless People’s Federation, working with local governments to identify and help those most at risk to natural disasters (Carcellar *et al.*, 2011)
- Shack/Slum Dwellers International (SDI), a network of community-based organizations and federations of the urban poor in 33 countries in Africa, Asia, and Latin America and their local support NGOs.

Many disaster events are small and local but taken together, have a widespread and cumulative impact on the development prospects of low-income households and communities, underscoring the need for enhanced civil society engagement and coordination (United Nations, 2009). Civil society organisations are well placed to address the local conditions and some of the structural root causes of vulnerability, necessary for successful urban adaptation. For example, the scale and range of recent disaster events in Asian cities suggest a growing need for new support mechanisms to facilitate action among local stakeholders – one that should include local government as well as local civil society organisations (Shaw and Izumi, 2011). Where urban civil society is well coordinated and has legitimacy, it can offer alternative models for urban governance and adapting to climate change to assist local governments (Mitlin, 2012). Elsewhere ad-hoc coalitions of civil society actors, or even uncoordinated activity in some cities, provide a de facto delivery mechanism for accessing basic infrastructure and rights as part of development and disaster response (Pelling, 2003), although the lack of coordination limits the scale and scope of adaptive capacity. Many civil society initiatives have developed models of infrastructure delivery that are not centered on urban adaptation but have relevance for it, in part through activities designed to reduce disaster risk and increase management capacity (see Hasan, 2006).

8.4.2.5. University Partnerships and Research Initiatives

Since AR4, interest in urban aspects of adaptation has grown in the research community and its funders, as is evident in the number of conferences on this topic, both within social and behavioural sciences and in engineering and city planning sciences. More professional societies are considering their roles and responsibilities. Some cities are tapping into relevant networks; for instance the Urban Climate Change Research Network (UCCRN) brings together researchers and city planners to exchange knowledge and build a coalition of awareness and policy (Rosenzweig *et al.*, 2010). Other examples include London's use of scenarios generated by UK Climate Impact Programme by University of Oxford's Environmental Change Institute (Carmin *et al.*, 2013); the Urbanization and Global Environmental Change Programme (UGEC) of the International Human Dimensions Programme on Global Environmental Change, the Earth System Science Partnership (ESSP) a pioneer in promoting social science and knowledge exchange; the Land-Ocean Interactions in the Coastal Zone programme; Integrated Research on Disaster Risk (IRDR) co-sponsored by the International Council for Science (ICSU), the International Social Science Council (ISSC), and the United Nations International Strategy for Disaster Reduction (UNISDR) and the research on urban adaptation in Africa supported by the International Development Research Centre (IDRC).

Individual academic institutes have also begun to support urban adaptation efforts. The Urban Observatory in Manila has become a regional hub for climate change science and urban adaptation; the Universiti Kebangsaan in Malaysia hosts a Malaysian Network for Research on Climate, Environment and Development (MyCLIMATE) focused on awareness and capacity in industry and civil society (Shaw and Izumi, 2011); the Climate and Disaster Resilience Initiative (Kyoto University, CITYNET and UNISDR) works with city managers and practitioners (Shaw and IEDM Team, 2009); Latin American networks such as FLACSO (Facultad Latinoamericana de Ciencias Sociales) provide leadership across the region in disaster risk reduction, management and climate change adaptation. Individual centers have also become more engaged in urban adaptation, for instance, UNAM (Universidad Nacional Autónoma de México) in Mexico and the International Centre for Climate Change and Development (ICCCAD) in Dhaka (Anguelovski and Carmin, 2011; Mehrotra *et al.*, 2009). There remains a challenge to reform university curricula to include urban adaptation and mitigation.

8.4.2.6. City Networks and Urban Adaptation Learning Partnerships

Opportunities for accelerating learning and action may stem from horizontal coordination and networking across actors, professions and institutions in different municipalities and metropolitan areas. The growing interest in urban adaptation is also seen in the growth of transnational networks and coalitions working across organisational boundaries to influence outcomes, both nationally and internationally (Bulkeley and Betsill, 2005; Bulkeley and Moser, 2007; Rosenzweig *et al.*, 2010) and providing an institutional foundation to concerted effort and collaboration at city level (Aall *et al.*, 2007; Kern and Gotelind, 2009; Romero-Lankao, 2007). ICLEI's Cities for Climate Protection has been extensively analyzed in the literature (Aall *et al.*, 2007; Betsill and Bulkeley, 2004; Betsill and Bulkeley, 2006; Lindseth, 2004) with a broad conclusion that they are influencing decision-making and offer an effective means of sharing experience and learning. Other examples include the Climate Alliance, the C-40 Large Cities Climate Leadership Group and the Urban Leaders Adaptation Initiative in the US (OECD, 2010). The United Cities and Local Governments (UCLG) network, representing local governments within the United Nations, also has a growing interest in adaptation. The Asian Cities Climate Change Resilience Network (ACCCRN), mentioned above, also encourages inter-city learning for officials and local researchers (Brown *et al.*, 2012). The Making Cities Resilient network, supported by the UN International Strategy for Disaster Risk Reduction (UNISDR) promotes a ten-point priority agenda for city governments, building on good risk reduction practices (UNISDR, 2008; see also Johnson and Blackburn, 2014). Another example of the influence of city networks is the signing of the Durban Adaptation Charter in December 2011 by 107 mayors representing over 950 local governments at COP17 (Roberts and O'Donoghue, 2013), signalling their intention to begin addressing climate change adaptation in a more concerted and structured way (Rosenzweig *et al.*, 2010). The initial focus of some city networks was on mitigation but attention and leadership on adaptation is growing (as in the US Urban Leaders Adaptation Initiative - Foster *et al.*, 2011a).

8.4.3. Resources for Urban Adaptation and their Management

Resources for urban adaptation action can come from public and private sectors, domestic and international. Table 8-5 summarizes the main funding sources and financial instruments. In high-income countries, local governments are responsible for an estimated 70 percent of public spending in urban areas and roughly 50 percent of public spending on environment infrastructure, often in partnership with other levels of government (OECD, 2010). The scale and source of funds contributing to adaptation varies widely by location and depends in part on the extent of to which local authorities can tax residents, property owners and businesses. A survey of 468 cities conducted by Carmin *et al.* (2012a) found that most (60%) are not receiving any financial support for their adaptation actions. Of the small percentage of cities receiving funding, the most common source of support is from national governments (24%). A smaller number of cities (9%) reported funding from sub-national governments while others (8%) reported support from private foundations and non-profit organizations; only 2-4% of the cities reported receiving financial support from international (bilateral and multilateral) financial institutions such as multilateral development banks and this varied widely by region (Carmin *et al.*, 2012a). Some of the environmental innovation in Latin America over the last 20 years is associated with decentralization that has strengthened fiscal bases for cities, along with more, elected mayors and more accountable city governments (Cabannes, 2004; Campbell, 2003); Latin American cities have also reported multilateral development banks as the most prevalent source of funding for adaptation representing about 21% of funding to date (Carmin *et al.*, 2012a). In Africa and Asia, a high proportion of urban governments still have very limited investment capacities as most of their revenues go to salaries and other recurrent expenditures (UCLG, 2011). UCLG data points to the large difference in annual expenditure per person by local governments, ranging from over US$6,000 in some high-income nations to less than US$20 in most low-income nations (UCLG, 2010).

[INSERT TABLE 8-5 HERE
Table 8-5: Main sources of funding and financial instruments for urban adaptation.]

As Table 8-5 indicates, large cities with strong economies and administrative capacity can best attract external funding (including transfers from higher levels of government) and raise internal funding for adaptation. Less prosperous and smaller urban centers and cities with fragmented governance structures or administrations lacking in capability have worse prospects. A key issue is 'unfunded mandates' – responsibilities assigned to cities with no increase in funding and capacity (UCLG, 2011)– and this can happen with new responsibilities around climate change (Kehew *et al.*, 2012; Tavares and Santos, 2013). Funding regimes and supportive legal frameworks need to integrate urban climate change risk management and adaptation into development.

8.4.3.1. Domestic Financing: Tapping into National or Sub-national Regional Sources of Funding and Support

For adaptation specifically, domestic public funding is one of the most significant and sustainable sources in many countries. Initiatives to green local fiscal policies are spreading, including congestion charges on motor vehicles and value-capture land taxes that make the cost of environmental externalities visible, and/or the benefits of infrastructure and services to property owners (e.g. transport, water and wastewater services). Such measures can promote private investment in risk management while mobilising local revenue sources. Local fiscal incentives can lead to mal-adaptation where urban government budgets and actions are financed by land sales, which in turn promote urban sprawl or development in areas at risk (Drejza *et al.*, 2011; Merk *et al.*, 2012). Greening local fiscal policies will need to identify and address these kinds of concerns.

Grants, loans and other revenue transfers from national or regional (sub-national) governments are also important sources, for instance to compensate local governments for the spillover environmental benefits of their expenditures (Hedger and Bird, 2011; Hedger, 2011; OECD, 2010). An example is municipal funding in Brazil, where the allocation of tax revenues is based on ecosystem management performance (see Box 8-3).

_____ START BOX 8-4 HERE _____

Box 8-4. Environmental Indicators in Allocating Tax Shares to Local Governments in Brazil

In Brazil, part of the revenues from a value-added state government tax (ICMS) must be redistributed among municipalities. Three-quarters is defined by the federal constitution with the remaining 25% allocated by each state government. The state of Paraná introduced the ecological ICMS (ICMS-E) in 1992 against the background of state-induced land-use restrictions (protected areas) for several municipalities, which prevented them from developing land but provided no compensation. For example, 90% of the Piraquara municipality was designated as a protected watershed, supplying the Curitiba metropolitan region with water (May *et al.*, 2002).

States have different systems in place, but there are many commonalities. Revenues are allocated based on the proportion of a municipality's area set aside for protection, and protected areas are weighted according to different categories of conservation management (higher for biological reserves, for instance, than for areas of tourist interest). Paraná and some other states evaluate the protected areas based on physical and biological quality (fauna and flora), quality of water resources, physical representativeness and quality of planning, implementation and maintenance.

The ICMS-E, built on existing institutions and administrative procedures, has had very low transaction costs (Ring, 2008). Evaluations show it has been associated with improved environmental management and the creation of new protected areas (May *et al.*, 2002). It has also improved relations with the surrounding inhabitants as they start to see these areas as an opportunity to generate revenue, rather than an obstacle to development.

Source: Adapted from OECD, 2010.

_____ END BOX 8-4 HERE _____

Other innovative financial mechanisms for urban adaptation include revolving funds and the energy services company ("ESCO") model (OECD, 2010). Revolving funds can be developed from a variety of revenue streams such as Clean Development Mechanism projects (Puppim de Oliveira, 2009), and savings from energy efficiency investments in municipal buildings to feed public funds for investments that yield adaptation benefits. Local governments in high- and some middle-income countries may also have direct access to bond markets or loans from national (or regional) development banks or financial institutions (Merk *et al.*, 2012; OECD, 2010). Local access to capital markets can be facilitated through risk-sharing mechanisms or guarantees provided by development banks e.g. the German government's Development Bank KfW provides low-interest loans to local banks which then finance energy-efficient renovations in residential and commercial buildings (OECD, 2010; Pfliegner *et al.*, 2012).

A key challenge is determining how far adaptation funding should be geared to target associated policy realms. The very high costs of extreme weather events in many urban areas, and the fact that climate change usually increases these risks, indicates the need for increased funding and attention from national budgets for risk reduction, early warning and evacuation procedures within urban areas, alongside other adaptation measures (Hallegatte and Corfee-Morlot, 2011; World Bank, 2010a; World Bank, 2010e). The urban funding gap may be particularly wide for "soft" rather than "hard" infrastructure investments, yet both can be a motor for resilience.

8.4.3.2. Multilateral Humanitarian and Disaster Management Assistance

The international humanitarian community is increasingly active in urban contexts, with relevance for adaptation capacity (IFRC, 2010). Non-climate related disasters (including earthquakes and tsunamis) provide a learning opportunity, and the sector is beginning to review experience and develop appropriate tools and guidelines for urban contexts (e.g., ALNAP, 2012). In 2009, humanitarian groups formed a reference group on meeting humanitarian challenges in urban areas, setting a two-year action plan in 2010, and developing a database of urban-specific aid tools, the Urban Humanitarian Response Portal (http://www.urban-response.org/). Policies sensitive to the needs of internally displaced urban populations are a big challenge for the sector, especially where the resident population is chronically poor (Crawford *et al.*, 2010; Zetter and Deikun, 2010); so too are appropriate responses to increased urban food insecurity (Battersby, 2013).

The systematic programming of climate change adaptation into multilateral humanitarian, disaster response and management funding within development cooperation is in its infancy. Urban dimensions are under-developed although this is changing (see IFRC, 2010; United Nations, 2009; United Nations, 2011). The World Bank's Global Facility for Disaster Reduction and Recovery (GFDRR) explicitly includes adaptation to climate change. Its Country Programmes for Disaster Risk Management and Climate Change Adaptation 2009-2011, and more recently 2014-2016, seek to deepen engagement in some priority countries (GFDRR, 2009; GFDRR, 2013; World Bank, 2013). The GFDRR, with UNISDR, has also advocated for more integrated policy and advisory services at the technical level (see Mitchell *et al.*, 2010). A 2009-11 survey of reports from 82 governments on disaster risk reduction and urban and climate change issues, found some progress in both areas (Figure 8-6, United Nations, 2011).

[INSERT FIGURE 8-6 HERE
Figure 8-6: Progress reported by 82 governments in addressing some key aspects of disaster risk reduction by countries' average per capita income. Source: United Nations, 2011.]

Despite progress, many urban governments lack the capacity to address disaster risk reduction and management. Almost 60 percent of the countries surveyed by the UN (80 percent of lower-middle income countries) reported that local governments have legal responsibility for disaster risk management, but only about a third had dedicated budget allocations, mostly in upper-middle and high-income countries (United Nations, 2011). Figure 8-6 highlights attention to investments in drainage infrastructure, but much less in urban and land-use planning in lower-middle and low-income countries. Progress in integrating climate change policies into disaster risk reduction was reported by over two thirds of governments in high, upper-middle and lower-middle income countries but under half of low-income countries.

8.4.3.3. International Financing and Donor Assistance for Urban Adaptation

The limited data available show attention to urban areas in the growing levels of international development financing available to support adaptation (e.g., OECD, 2013; World Bank, 2013). Development finance is a key source of support for adaptation in many low- and middle-income countries, but many vulnerable cities and municipalities are poorly positioned to access available funding (ICLEI, 2010; Paulais and Pigey, 2010), for their often very large deficits in risk-reducing infrastructure and services. In some local governments, international programmes offer the main source of institutional and financial support for mitigation and adaptation work at local level, but this can raise the danger of a "donor-driven model" (where the funding agency's agenda do not coincide with local priorities); experience shows that without strong and lasting local ownership, programmes are unsustainable once support is withdrawn (Hedger, 2011; OECD, 2012). More international funding for adaptation and mitigation is being committed, largely as Official Development Assistance (ODA), and governments are broadly on track delivering on their international promises (see for instance the Cancun Agreements) to scale up international climate finance (Buchner *et al.*, 2012; Clapp *et al.*, 2012). Less in evidence are sound institutional arrangements to make this support available to urban governments. SREX calls for arrangements that will allow adaptive urban management systems to evolve with changing social and environmental dynamics (IPCC, 2012) but international channels for development finance have yet to adjust to this call to action.

Recent data suggest that a small share of total flows of climate-related ODA targets adaptation (OECD, 2012; UNEP, 2011), and some this is supporting urban adaptation (e.g. see OECD, 2013; World Bank, 2013). OECD estimates bilateral ODA commitments targeting climate change to be in the range of US$11 – 20 billion per year on average in 2010-2011 for both adaptation and mitigation; of this roughly 20-40% targets adaptation (OECD, 2013). One in-depth assessment of five major donors, covering concessional and non-concessional finance, estimated adaptation to be 30% of their climate change portfolio, mostly targeted to water and sanitation (about 75%) (UNEP, 2011). The rest were for other relevant sectors (i.e. transport, policy loans, disaster risk reduction), but with energy and health largely overlooked (UNEP, 2011), see also Atteridge *et al.* (2010). Despite growing attention to climate change, many bilateral agencies have historically had very limited engagement with urban initiatives (Mitlin and

Satterthwaite, 2013). Some authors also note the difficulty in distinguishing adaptation from development finance, which limits the accuracy of such estimates (Buchner *et al.*, 2012; Tirpak *et al.*, 2010).

Despite the uncertainties in tracking adaptation ODA, OECD statistics (OECD, 2013) show that there is some attention to urban issues today.[2] Urban adaptation is estimated to represent about 20% of bilateral climate adaptation portfolios, equivalent to US$0.65 – 1.6 billion per year (on average over 2010- 2011). Slightly more than half of this goes to projects in urban centres with between 10,000 and 500,000 inhabitants while the rest goes to large cities with 500,000 or more inhabitants. The major sectors are water (about 38%, considering projects that had adaptation as principal or significant) and sanitation (another 6%) (OECD, 2013). The largest providers of urban adaptation ODA in these years were Japan (an average of $683 million a year in commitments), Germany ($333 million), France ($111 million) and South Korea, European Union Institutions, Spain and Denmark (between $48 and $80 million). The largest recipients were Vietnam ($232 million), Bangladesh ($146 million), China ($100 million) and the Philippines, Peru, Indonesia and Kenya ($52-76 million).

[FOOTNOTE 2: Data and information as found in the OECD DAC-CRS 2013, www.oecd.org/dac/stats/rioconventions.htm [last accessed: 7 September 2013]. These estimates derive from data and project descriptions in the OECD DAC-Creditor Reporting System. It is based on a project-by-project review of qualitative information in the 2013 version of the database describing official development finance from bilateral agencies and the EU institutions. This sub-set of “urban” adaptation activities describes those projects that identify the geography of benificiaries as urban and which include a verifiable location (e.g. metropolitan Lima); data were organized by key characteristic of each urban location (i.e.population size and recipient country). Only urban areas with populations of 10,000 or more are included here. Projects are marked with climate adaptation “Rio marker”; this data set includes all projects marked as targeting climate adaptation, either as a principal objective as well as those with it as a significant objective.]

Around 70 percent of urban adaptation aid is dedicated to “hard” infrastructure while about 10% goes to “soft” measures to support capacity building related to urban infrastructure planning and adaptation. So OECD data suggest that urban adaptation is a recent but significant objective in climate aid activities but it is still only a small part of overall ODA portfolios (OECD, 2013).

Conventional channels for development finance appear to have the biggest role in adaptation financing in low- and middle-income countries, though new vertical funds are also emerging. The proliferation of multiple, single purpose funding mechanisms runs contrary to long-standing harmonization principles of sound development cooperation (Hedger, 2011; OECD, 2012). This more complex funding architecture makes it difficult for smaller actors like local authorities to access sources for timely adaptation investments.

Development assistance can be better targeted if reconciled with bottom-up, locally-based planning processes that take climate risks into account, and programmes aiming to be mainstreamed into urban development over time (Brugmann, 2012). Research shows the lack of well-defined priorities in partner countries, combined with a donor tendency to “control” funds for short-term results and a large variety of different funding instruments results in fragmented delivery systems and unclear outcomes (Brown and Peskett, 2011). Even where climate strategies exist to guide action – as in Bangladesh, an “early mover” on adaptation planning – the plan is often not costed nor sequenced, making it an inadequate framework for finance delivery (Hedger, 2011). A key to improving effectiveness of international public finance will be building the capacity for country-led planning processes identifying priority actions for targeting adaptation funds. National Adaptation Plans of Action (NAPAs) have become a principal way of organising adaptation priorities in Least Developed Countries, but the majority of plans do not explicitly include urban projects and do not reflect local government perspectives (UN-Habitat, 2011c).

A number of authors conclude that international development finance is failing to tackle urban adaptation financing needs (ICLEI, 2011; Parry *et al.*, 2009; Paulais and Pigey, 2010; UN-Habitat, 2011c). Some suggest that national governments could set up funds supported by international finance (governmental, philanthropic or both) and on which urban governments and community-based organisations can draw (Paulais and Pigey, 2010; Satterthwaite and Mitlin, 2014). In some middle-income countries, such as Indonesia, a more effective and sustainable strategy than a focus on external funding may be national policy reforms and incentives to steer investment to priority needs

(Brown and Peskett, 2011). There is also a need to mobilise domestic public and private investment to ensure delivery of adaptation at national and urban levels (Hedger and Bird, 2011; Hedger, 2011; OECD, 2012). Accessing all these sources of development finance for urban adaptation will require institutional mechanisms to support multilevel planning and risk governance (Carmin *et al.*, 2013; Corfee-Morlot *et al.*, 2011).

8.4.3.4. Institutional Capacity and Leadership, Staffing, and Skill Development

Leadership is critical for generating interest in urban adaptation, championing awareness and institutional change to bring action (Anguelovski and Carmin, 2011; Carmin *et al.*, 2012a). Creating a climate change and environmental focal point or office in a city can help coordinate climate action across government departments or agencies (Anguelovski and Carmin, 2011; Brown *et al.*, 2012; Hunt and Watkiss, 2011; OECD, 2011; Roberts, 2008; Roberts, 2010). Yet there may be downsides when this function is housed in the environmental line department – see Durban (Roberts, 2008), Boston (Boston, 2011), and Sydney (Measham *et al.*, 2011) - since they are typically among the weakest parts of city government with limited influence (Roberts, 2010).

Although there is growing evidence of urban adaptation leadership (Anguelovski and Carmin, 2011; Foster *et al.*, 2011b; Lowe *et al.*, 2009), there are also important political constraints at the local level. Powerful vested interests may oppose attention to adaptation and promote development on sites at risk. As noted earlier, concerns about employment and competitiveness make it difficult for local governments to focus on the more distant implications of climate change. This is especially so during periods of economic hardship (Shaw and Theobald, 2011; Solecki, 2012). A key step forward is institutionalising different types of behaviour and norms.

Beyond goal setting and planning, the literature also suggests the need for regulatory frameworks to require relevant behaviour and investment. Governments can institute small changes, such as job descriptions that require actions and provide incentives to act in new ways (e.g. for line managers and sector policymakers) or by providing training and clear guidance to staff (Carmin *et al.*, 2013; Moser, 2006; Tavares and Santos, 2013). Budgetary transparency and metrics to measure progress on adaptation can also help to institutionalize changes in planning and policy practice (OECD, 2012).

8.4.3.5. Monitoring and Evaluation to Assess Progress

Adaptation leaders and funding institutions need tools for monitoring and evaluating urban adaptation actions to justify investments but these are not well developed yet nor widely implemented in urban areas (Kazmierczak and Carter, 2010). This requires indicators that show if adaptation is taking place, at what pace, and in what locations. Relevant evaluation criteria include cost, feasibility, efficacy, co-benefits (direct and indirect), and institutional considerations (Jacob *et al.*, 2010). Assessment methods can capture outcomes of adaptation decisions, or the decision-making processes themselves – ideally both. Monitoring is challenging for adaptation, especially urban, given the lack of standard metrics, the differences in local contexts and the often localized nature of adaptation (Lamhauge *et al.*, 2012; Spearman and McGray, 2012).

City authorities, NGOs and researchers have begun to design adaptation monitoring and evaluation frameworks. Box 8-5 presents the experience of New York City. Development of standard tools offers scope for international benchmarking and coordination across scales of assessment, for example by associating local indicators of resilience with those in the Hyogo Framework for Action (that prioritize disaster risk reduction) and the post-2015 development agenda (IFRC, 2011).

_____ START BOX 8-5 HERE _____

Box 8-5. Adaptation Monitoring: Experience from New York City

The adaptation monitoring approach developed for New York City has four indicator elements: (1) physical climate change variables; (2) risk exposure, vulnerability and impacts; (3) adaptation measures; and (4) new research in each of these categories. Examples of indicators arising from these categories include: the percentage of building permits issued in a given year in current Federal Emergency Management Agency (FEMA) coastal flood zones, and in projected 2080 coastal flood zones; a tally of building permits with measures to reduce precipitation runoff; an index based on insurance data that measures the insurer's perception of the city's infrastructure-coping capacity; an index that measures the rating of city-issued bonds or infrastructure operators for capital projects with climate change risk exposure; the detailed trend of weather-related emergency/disaster losses (whether insured or uninsured, relative to the total asset volume); and the number of days with major telecommunication outages (wireless versus wired), correlated with weather-related power outages. Data criteria were decided through a scientist-stakeholder consensus with designated groups to evaluate prospective indicators and their values. This case study shows the need for interdisciplinary, longitudinal data collection and analysis systems along with an inclusive, transparent process for stakeholder engagement to interpret the data (Jacob *et al.*, 2010).

_____ END BOX 8-5 HERE _____

Monitoring and evaluation focusing on the effectiveness of donor aid on climate adaptation is a growing area of research (Chaum *et al.*, 2011; Lamhauge *et al.*, 2012; Spearman and McGray, 2012). Recent work shows the urgent need for consistent and internationally harmonised data collection to support monitoring. This is a concern for both adaptation and wider disaster risk reduction spending, suggesting a systemic challenge to the architecture of international finance (Kellett and Sparks, 2012). Steps are being made through multi-site assessment programmes, in some instances including treatment of urban issues. For example, the World Bank recently included an adaptive capacity index as part of an analysis of risk and adaptation options for five cities in Latin America and the Caribbean. The methodology was previously applied in Guyana, where it demonstrated a gap between national and city level adaptive capacity (Pelling and Zaidi, 2013).

Monitoring also needs to consider the delivery and use in cities of international climate finance to ensure that funds are being effectively directed (Chaum *et al.*, 2011; Hedger, 2011). This is especially important for cities at an early stage of planning, implementing and monitoring of adaptation, as they can learn from one another's experiences. There is some evidence that international agencies overburden partner organizations and countries (including in some cases city authorities) with monitoring requirements; with limited local capacities, this can detract from further programme design and implementation.

8.5. Annex: Climate Risks for Dar es Salaam, Durban, London, and New York City

This annex has four city profiles of current and indicative future climate risks: Dar es Salaam, Durban, London and New York. Each summarizes the present, near-term (2030-2040) and long-term (2080-2100) climate risks and the potential for risk reduction through adaptation. As noted earlier, data should not be compared between cities but trends in adaptive capacity and impact can be drawn out.

[INSERT TABLE 8-6 HERE
Table 8-6: Current and Indicative future climate risks for Dar es Salaam, Durban, London, and New York City.]

Frequently Asked Questions

FAQ 8.1: Do experiences with disaster risk reduction in urban areas provide useful lessons for climate-change adaptation? *[to be inserted in Section 8.3.2.2]*
There is a long experience with urban governments implementing disaster risk reduction that is underpinned by locally-driven identification of key hazards, risks and vulnerabilities to disasters and that identifies what should be done to reduce or remove disaster risk. Its importance is that it encourages local governments to act before a disaster – for instance for risks from flooding, to reduce exposure and risk as well as being prepared for emergency responses prior to the flood (eg temporary evacuation from places at risk of flooding) and rapid response and building back afterwards. In some nations, national governments have set up legislative frameworks to strengthen and support local government capacities for this (see 8.3.2.2). This is a valuable foundation for assessing and acting

on climate-change related hazards, risks and vulnerabilities, especially those linked to extreme weather. Urban governments with effective capacities for disaster risk reduction (with the needed integration of different sectors) have institutional and financial capacities that are important for adaption. But while disaster risk reduction is informed by careful analyses of existing hazards and past disasters (including return periods), climate change adaptation needs to take account of how hazards, risks and vulnerabilities will or might change over time. Disaster risk reduction also covers disasters resulting from hazards not linked to climate or to climate change such as earthquakes.

FAQ 8.2: As cities develop economically, do they become better adapted to climate change?
[to be inserted in Section 8.3.3.1]
Cities and nations with successful economies can mobilize more resources for climate change adaptation. But adaptation also needs specific policies to ensure provision for good quality risk-reducing infrastructure and services that reach all of the city's population and the institutional and financial capacity to provide, and manage these and expand them when needed. Poverty reduction can also support adaptation by increasing individual, household and community resilience to stresses and shocks for low-income groups and enhancing their capacities to adapt. These provides a foundation for building climate change resilience but additional knowledge, resources, capacity and skills are generally required, especially to build resilience to changes beyond the ranges of what have been experienced in the past.

FAQ 8.3: Does climate change cause urban problems by driving migration from rural to urban areas?
[to be inserted in Section 8.3.3.2]
The movement of rural dwellers to live and work in urban areas is mostly in response to the concentration of new investments and employment opportunities in urban areas. All high-income nations are predominantly urban and increasing urbanization levels are strongly associated with economic growth. Economic success brings an increasing proportion of GDP and of the workforce in industry and services, most of which are in urban areas. While rapid population growth in any urban centre provides major challenges for its local government, the need here is to develop the capacity of local governments to manage this with climate change adaptation in mind. Rural development and adaptation that protects rural dwellers and their livelihoods and resources has high importance as stressed in other chapters – but this will not necessarily slow migration flows to urban areas, although it will help limit rural disasters and those who move to urban areas in response to these.

FAQ 8.4: Shouldn't urban adaptation plans wait until there is more certainty about local climate change impacts? *[to be inserted in Section 8.4.1.5]*
More reliable, locally specific and downscaled projections of climate change impacts and tools for risk screening and management are needed. But local risk and vulnerability assessments that include attention to those risks that climate change will or may increase provide a basis for incorporating adaptation into development now, including supporting policy revisions and more effective emergency plans. In addition, much infrastructure and most buildings have a lifespan of many decades so investments made now need to consider what changes in risks could take place during their lifetime. The incorporation of climate change adaptation into each urban centre's development planning, infrastructure investments and land-use management is well served by an iterative process within each locality of learning about changing risks and uncertainties that informs an assessment of policy options and decisions.

Cross-Chapter Box

Box CC-UR. Urban-Rural Interactions –
Context for Climate Change Vulnerability, Impacts, and Adaptation

[John Morton (UK), William Solecki (USA), Purnamita Dasgupta (India), David Dodman (Jamaica), Marta G. Rivera-Ferre (Spain)]

Rural areas and urban areas have always been interconnected and interdependent, but recent decades have seen new forms of these interconnections: a tendency for rural-urban boundaries to become less well-defined, and new types of land-use and economic activity on those boundaries. These conditions have important implications for understanding climate change impacts, vulnerabilities, and opportunities for adaptation. This box examines three critical implications of these interactions:

1) Climate extremes in rural areas resulting in urban impacts – teleconnections of resources and migration streams mean that climate extremes in non-urban locations with associated shifts in water supply, rural agricultural potential, and the habitability of rural areas will have downstream impacts in cities;
2) Events specific to the rural-urban interface – given the highly integrated nature of rural-urban interface areas and overarching demand to accommodate both rural and urban demands in these settings, there is a set of impacts, vulnerabilities and opportunities for adaptation specific to these locations. These impacts include loss of local agricultural production, economic marginalization resulting from being neither rural or urban, and stress on human health; and,
3) Integrated infrastructure and service disruption – as urban demands often take preference, interdependent rural and urban resource systems place nearby rural areas at risk, because during conditions of climate stress, rural areas more often suffer resource shortages or other disruptions in order to sustain resources to cities. For example, under conditions of resource stress associated with climate risk (e.g., droughts) urban areas are at an advantage because of political, social, economic requirements to maintain service supply to cities to the detriment of relatively marginal rural sites and settlements.

Urban areas historically have been dependent on the lands just beyond their boundaries for most of their critical resources including water, food, and energy. While in many contexts, the connections between urban settlements and surrounding rural areas are still present, long distance, teleconnected, large-scale supply chains have been developed particularly with respect to energy resources and food supply (Güneralp et al., 2013). Extreme event disruptions in distant resource areas or to the supply chain and relevant infrastructure can negatively impact the urban areas dependent on these materials (Wilbanks et al., 2012). During the summer of 2012, for instance, an extended drought period in the central United States led to significantly reduced river levels on the Mississippi River which led to interruptions of barge traffic and delay of commodity flows to cities throughout the country. Urban water supply is also vulnerable to droughts in predominantly rural areas. In the case of Bulawayo, Zimbabwe, periodic urban water shortages over the last few decades have been triggered by rural droughts (Mkandla et al., 2005).

A further teleconnection between rural and urban-areas is rural-urban migration. There have been cases where migration and urbanization patterns have been to attributed to climate change or its proxies such as in parts of Africa (Morton 1989, Barrios et al., 2006). However, as recognized by Black *et al.* (2011), life in rural areas across the world typically involves complex patterns of rural-urban and rural-rural migration, subject to economic, political, social and demographic drivers, patterns which are modified or exacerbated by climate events and trends rather than solely caused by them.

Globally, an increased blending of urban and rural qualities has occurred. Simon *et al*. (2006:4) assert that the simple dichotomy between 'rural' and 'urban' has "long ceased to have much meaning in practice or for policy-making purposes in many parts of the global South". One approach to reconciling this is through the increasing application of the concept of "peri-urban areas" (Simon *et al*., 2006; Simon, 2008). These areas can be seen as rural locations that have "become more urban in character" (Webster 2002: 5); as sites where households pursue a wider range of income-generating activities while still residing in what appear to be "largely rural landscapes" (Learner and Eakin 2010: 1); or as locations in which rural and urban land uses coexist, whether in contiguous or fragmented units (Bowyer-Bower, 2006). The inhabitants of "core" urban areas within cities have also increasingly turned to agriculture, with production of staple foods, higher-value crops and livestock (Bryld, 2003; Devendra et al., 2005; Lerner and Eakin, 2010; Lerner et al., 2013). Bryld (2003) sees this as driven by rural-urban migration and by structural adjustment (e.g. withdrawal of food price controls and food subsidies). Lerner and Eakin (2011, also Lerner et al., 2013) explored reasons why people produce food in urban environments, despite high opportunity costs of land and labour: buffering of risk from insecure urban labour markets; response to consumer demand; and the meeting of cultural needs.

Livelihoods and areas on the rural-urban interface suffer highly specific forms of vulnerability to disasters, including climate-related disasters. These may be summarised as specifically combining: urban vulnerabilities of population concentration, dependence on infrastructure, and social diversity limiting social support with rural traits of distance, isolation and invisibility to policy-makers (Pelling and Mustafa, 2010). Increased connectivity can also encourage land expropriation to enable commercial land development (Pelling and Mustafa, 2010). Vulnerability may arise from the co-existence of rural and urban perspectives, which may give rise to conflicts between different social / interest groups and economic activities (Darly and Torre 2013, Masuda and Garvin 2008, Solona-Solona 2010).

Additional vulnerability of peri-urban areas is on account of the re-constituted institutional arrangements and their structural constraints (Iaquinta and Drescher 2000). Rapid declines in traditional informal institutions and forms of collective action, and their imperfect replacement with formal state and market institutions, may also increase vulnerability (Pelling and Mustafa, 2010).

Peri-urban areas and livelihoods have low visibility to policy-makers at both local and national levels, and may suffer from a lack of necessary services, and inappropriate and uncoordinated policies. In Tanzania and Malawi, national policies of agricultural extension to farmer groups for example, do not reach peri-urban farmers (Liwenda et al., 2012). In peri-urban areas around Mexico City (Eakin et al., 2013), management of the substantial risk of flooding is led *de facto* by agricultural and water agencies, in the absence of capacity within peri-urban municipalities and despite clear evidence that urban encroachment is a key driver of flood risk. In developed country contexts suburban areas, suburban-exurban fringe areas often are overlooked in the policy arena that traditionally focuses on rural development and agricultural production, or urban growth and services (Hanlon et al., 2011). The environmental function of urban agriculture, in particular, in protection against flooding, will increase in the context of climate change. (Aubry et al., 2012).

However, peri-urban areas and mixed livelihoods more generally on rural-urban interfaces, also exhibit specific factors that increase their resilience to climate shocks (Pelling and Mustafa, 2010). Increased transport connectivity in peri-urban areas can reduce disaster risk by providing a greater diversity of livelihood options and improving access to education. The expansion of local labour markets and wage labour in these areas can strengthen adaptive capacity through providing new livelihood opportunities (Pelling and Mustafa, 2010). Maintaining mixed portfolios of agricultural and non-agricultural livelihoods also spreads risk (Lerner et al., 2013).

In high-income countries, practices attempting to enhance the ecosystem services and localized agriculture more typically associated with lower density areas have been encouraged. In many situations these practices are focused increasingly on climate adaptation and mitigating the impacts of climate extremes such as those associated with heating and the urban heat island effect, or wetland restoration efforts to limit the impact of storm surge wave action (Verburg et al., 2012).

The dramatic growth of urban areas also implies that rural areas and communities are increasingly politically and economically marginalized within national contexts, resulting in potential infrastructure and service disruptions for such sites. Existing rural-urban conflicts for the management of natural resources (Castro and Nielsen, 2003) such as water (Celio et al., 2011) or land-use conversion in rural areas (e.g. wind farms in rural Catalonia (Zografos and Martínez-Alier, 2009); industrial coastal areas in Sweden (Stepanova and Bruckmeier, 2013); or conversion of rice land into industrial, residential and recreational uses in the Philippines (Kelly, 1998) or Spain have been documented, and it is expected that stress from climate change impacts on land and natural resources will exacerbate these tensions. For instance, climate induced reductions in water availability may be more of a concern than population growth or increased per-capita use for securing continued supplies of water to large cities (Darrel Jenerette and Larsen, 2006), both of which requires an innovative approach to address such conflicts (Pearson et al., 2010).

Oceania	1.1	1.0	0.8	0.7	0.7	0.6

*Chapter 26 on North America includes Mexico; in the above statistics, Mexico is included in Latin America and the Caribbean.

Table 8-2: The large spectrum in the capacity of urban centers to adapt to climate change. One of the challenges for this chapter is to convey the very large differences in adaptive capacity between urban centres. This table seeks to illustrate differences in adaptive capacity and the factors that influence it. For a more detailed assessment of adaptation potentials and challenges for specific cities, see the Tables for Dar es Salaam, Durban, London, and New York in Section 8.5.

Indicator Clusters	**Very little adaptive capacity or resilience/ 'bounce-back' capacity**	**Some adaptive capacity and resilience/ 'bounce-back' capacity**	**Adequate capacity for adaptation and resilience/ 'bounce-back' but needs to be acted on**	**Climate resilience and capacity to bounce forward**	**Transformative adaptation**
The proportion of the population served with risk-reducing infrastructure (paved roads, storm and surface drainage, piped water ….) and services relevant to resilience (including health care, emergency services, policing/rule of law) and the institutions needed for such provision	0-30% of the urban centre's population served; most of those unserved or inadequately served living in informal settlements	30-80% of the urban centre's population served; most of those unserved or inadequately served living in informal settlements	80-100% of the urban centre's population served; most of those unserved or inadequately served living in informal settlements	Most/all of the urban centre's population with these and with an active adaptation policy identifying current and probable future risks and with an institutional structure to encourage and support action by all sectors and agencies. In many cities, also upgrade ageing infrastructure	Urban centres that have integrated their development and adaptation policies and investments within an understanding of the need for mitigation and sustainable ecological footprints
The proportion of the population living in legal housing built with permanent materials (meeting health and safety standards)				Active programme to improve conditions, infrastructure and services to informal settlements and low-income areas. Identify and act on areas with higher/increasing risks. Revise building standards.	Land use planning and management successfully providing safe land for housing, avoiding areas at risk and taking account of mitigation
Proportion of urban centres covered	Most urban centres in low-income and many in middle-income nations	Many urban centres in many low-income nations; most urban centres in most middle-income nations	Virtually all urban centres in high-income nations, many in middle-income nations	A small proportion of cities in high-income and upper-middle income nations	Some innovative city governments thinking of this and taking some initial steps
Estimated number of people living in such urban centres	One billion	1.5 billion	1 billion	Very small	
Infrastructure deficit	Much of the built up area lacking infrastructure	Most or all the built up area with infrastructure (paved roads, covered drains, piped water…..)			
Local government investment capacity	Very little or no local investment capacity	Substantial local investment capacity			
Occurrence of disasters from extreme weather*	Very common	Uncommon (mostly due to risk-reducing infrastructure, services and good quality buildings available to almost all the population)			

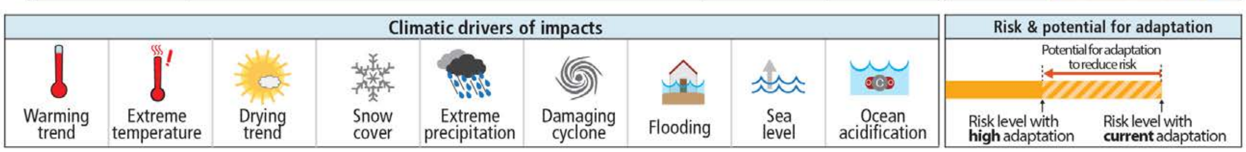
Indicator Clusters	**Very little adaptive capacity or resilience/ 'bounce-back' capacity**	**Some adaptive capacity and resilience/ 'bounce-back' capacity**	**Adequate capacity for adaptation and resilience/ 'bounce-back' but needs to be acted on**	**Climate resilience and capacity to bounce forward**	**Transformative adaptation**
Examples	Dar es Salaam, Dhaka	Nairobi, Mumbai	Most cities in high-income nations	Cities such as New York; London, Durban and Manizales with some progress	
Implications for climate change adaptation	Very limited capacity to adapt. Very large deficits in infrastructure and in institutional capacity. Very large numbers exposed to risk if these are also in locations with high levels of risk from climate change	Some capacity to adapt, especially if this can be combined with development but difficult to get city governments to act. Particular problems for those urban centres in locations with high levels of risk from climate change	Strong basis for adaptation but needs to be acted on and to influence city government and many of its sectoral agencies.	City government that is managing land-use changes as well as having adaptation integrated into all sectors	City government with capacity to influence and work with neighbouring local government units. Also with land-use changes managed to protect eco-system services and support mitigation
NB: For cities that are made up of different local government areas, it would be possible to apply the above at an intra-city or intra-metropolitan scale. For instance, for many large Latin American, Asian and African cities, there are local government areas that would fit in each of the first three categories					

* See text in regard to disasters and extensive risk (United Nations, 2011).

Sources: This table was constructed to provide a synthesis of key issues, so it draws on all the sources cited in this chapter. However, it draws in particular on Solecki (2012), Kiunsi (2013), and Roberts and O'Donoghue (2013).

Table 8-3: Urban areas: current and indicative future climate risks. Key risks are identified based on an assessment of the literature and expert judgments by chapter 8 authors, with the evaluation of evidence and agreement presented in supporting chapter sections. Each key risk is characterized as very low to very high. For the near-term era of committed climate change (2030-2040), projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options (2080-2100), risk levels are presented for global mean temperature increases of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Modal Urban (*medium confidence*)	Climate change will have profound impacts on urban infrastructure systems and services, the built environment and ecosystem services and hence on urban economies and populations. This could exacerbate existing social, economic and environmental drivers of risk, especially for vulnerable groups who lack essential services. An appropriate urban governance frame and coordinated urban adaptation focused on the built environment, improved infrastructure and services and risk reduction, has significant potential for reducing key climate risks in the medium term and especially in the long term.		8.2, 8.3, 8.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Coastal zones systems (*medium confidence*)	Coastal cities with extensive port facilities and large scale industries are vulnerable to increased flood exposure. High growth cities located on low-lying coastal areas are also at greater risk. There is possibility of non-linear increase in coastal vulnerability over the next two decades.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Terrestrial ecosystems & ecological infrastructure (*medium confidence*)	Ecosystem services will be impacted by altered ecosystem functions such as temperature and precipitation regimes, evaporation, humidity and soil moisture levels, indicating close links with sustainable water management. Knowledge gaps exist with respect to thresholds to adaptation of various ecosystems.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Water supply systems (*high confidence*)	Adaptation response requires changes to network infrastructure as well as demand side management, to ensure sufficient water supplies, increased capacities to manage reduced freshwater availability, flood risk reduction and water quality.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Waste water system (*high confidence*)	Managing waste water flows improves water supply and ecosystem services. Reducing vulnerability of infrastructure may be easier in new areas, well-funded local bodies or as part of scheduled interventions.		8.2, 8.3, 8.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Green built infrastructure (*medium confidence*)	Green infrastructure not utilised sufficiently in most cities. Climate change impacts can bring attention to the dual benefits of green infrastructure for climate change mitigation and impact management.		8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Energy systems (*high confidence*)	Most urban centres are energy intensive, with energy related climate policies focused only on mitigation measures. A few cities have adaptation initiatives underway for critical energy systems. There is great potential for non-adapted, centralised energy systems to magnify and cascade impacts to national or transboundary consequences from localised extreme events.		8.2, 8.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Food systems and security (*high confidence*)	Urban food sources are dependent upon local, regional and often global supplies. Climatic drivers can exacerbate food insecurity, especially of the urban poor. Enhanced social safety nets can support adaptation measures. Urban and peri-urban agriculture, local markets and green roofs hold good prospects as adaptive measures, but are under-utilised in rapidly growing cities.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Transportation systems (*medium confidence*)	A difficult sector to adapt due to large existing stock, especially in developed country cities leading to potentially large secondary economic impacts with regional and potentially global consequences for trade and business. Emergency response requires well-functioning transport infrastructure.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Communication systems (*medium confidence*)	Resilient communication systems are a critical component of emergency response, and therefore adaptation. The rise of decentralised and networked mobile communications offer great potential for real-time and easily accessed information dissemination and communication systems, information quality control is a key element in realising the potential of communications systems for early warning and adaptation.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Urban risks associated with housing (*high confidence*)	Poor quality, inappropriately located housing is often most vulnerable to extreme events. Adaptation options include enforcement of building regulations and upgrading. Some city studies show the potential to adapt housing and promote mitigation, adaptation, and development goals simultaneously. Rapidly growing cities, or those rebuilding after a disaster, especially have the opportunities to increase resilience, but this is rarely realized. Without adaptation, risks of economic losses from extreme events are substantial in cities with high-value infrastructure and housing assets, with broader economic effects possible.		8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Human health (*high confidence*)	Health is a higher order risk impacted by key developmental issues including water supply,water and air quality, waste management, housing quality, sanitation, food security and provision of health care servicesand insurance. Certain groups of people are particularly vulnerable, such as the elderly, the chronically ill, the poor and the very young, and require targeted social care interventions. Longer term developmental improvements need considerable financial resources and coherent intergovernmental action, limiting prospects for near-term adaptation.		8.2, 8.3, 8.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Human security & Emergency response (*medium confidence*)	Security is linked to key developmental issues such as income, housing, health care, education and food security. Moderate prospects as city governments can enhance emergency response services, to significantly reduce vulnerability for those who are most at risk. Where security and emergency forces have limited public trust, and especially with regard to gender issues,scope for supporting adaptation and risk management is considerably constrained.		8.3, 8.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Key economic sectors and services (*medium confidence*)	Large diversity across cities in terms of key economic sectors and adaptive capacity to disruptions in city services. Cities reliant on climate-sensitive tourism or agriculture may require economic diversification. Good prospects for advancing co-benefits through 'green' and 'waste' economy.		8.2, 8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Livelihoods (*medium confidence*)	Informal economy is more vulnerable, and often less adaptive in the short term. Social protection measures, in the specific context of urban livelihoods, are required.		8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Poverty & Access to basic services (*high confidence*)	Reducing basic service deficit could reduce hazard exposure, especially of the poor and vulnerable, alongside upgrading of informal settlements, improved housing conditions and enabling the agency of low income communities. Significant prospects where adaptation is already being implemented as part of human development or social protection.		8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high

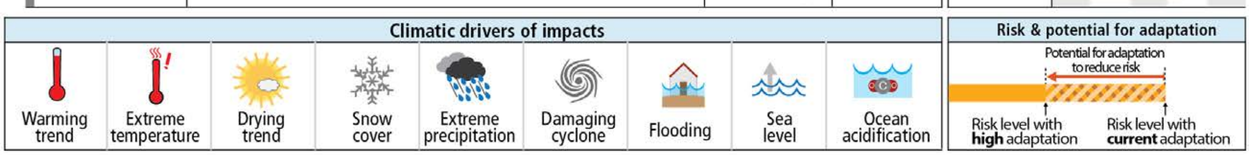


Table 8-4: The possibilities and limitations of focused activity for community groups on climate change coping and adaptation.

Capacity/Focus of Action	Coping (drawing on existing resources to reduce vulnerability and hazardousness and contain impacts from current and expected risk)	Adaptation (using existing resources and especially information to reorganize future asset profiles and entitlements to better position the household in the light of anticipated future risk, and to prepare for surprises)
Physical – buildings and critical community-level infrastructure	**Often possible to improve these although tenants will have little motivation to do so**	**Limits in how much risk reduction is possible within settlement (i.e. without trunk infrastructure to connect to)**
Physical – land and environment	**Local hazard reduction through drain cleaning, slope stabilization etc. is a common focus of community-based action (although there are less incentives where the majority of residents are short-term tenants or threatened with eviction)**	**External input required to design local hazard reduction works in ways that will consider the impacts of climate change 20 years or more in the future**
Social – health, education	**Many examples of community based action to improve local health and education access and outcomes, often with strong NGO and/or local government support**	**Health care and education are amenable to supporting adaptation by providing long-term investments in capacity building. They are rarely framed in climate change adaptation terms**
Economic – local livelihoods	**Livelihoods routinely assessed as part of household assessments of coping capacity in urban areas. More rarely is there a local livelihood focus for community based coping**	**Livelihoods and wider economic entitlements are key to individual adaptive profiles, but are seldom considered as part of urban community based adaptation programmes**
Institutional – community organization	**Local community strengthening is a common goal of interventions aimed at building coping capacity. Risk mapping, early warning, risk awareness, community health promotion and shelter training are common foci increasingly applied to urban communities. Local savings groups may have important roles**	**Local community strengthening is a core element of planning for adaptation but there are few assessments of the medium/long-term sustainability of outcomes. Where these have been undertaken, close ties to wider civil society networks or supportive local government is evident for community organizations and actions to persist**
Institutional – external influence	**It is unusual for coping programmes to include an element of external advocacy aimed at changing policy or practices in local government**	**Despite being core to determining future adaptation, there are very few examples of urban community based adaptation projects that include a targeted focus or parallel activity aimed at shifting priorities and practices in local government and beyond to support community capacity building**

Key: green = many cases of activity, amber = few cases of activity, red = very few cases of activity

Table 8-5: Main sources of funding and financial instruments for urban adaptation.

Sources of funding	Types	Instruments	What can be funded (with some examples of funds)	Urban capacity required to access funding
Local – public	Local revenue raising policies: taxes, fees and charges, or use of local bond markets	♦ Local taxes (eg on property, land value capture, sales, businesses, personal income, vehicles….) ♦ User charges (eg for water, sewers, public transport, refuse collection) ♦ Other charges or fees (eg parking, licenses)	♦ Urban infrastructure and services ♦ Urban adaptation programmes and planning processes ♦ Urban capacity building	Cities with well-functioning administrative and institutional capacity and adequate funding from local revenue generation and inter-governmental transfers
Local – public-private	Public-Private-Partnerships (PPP) contracts and concessions	♦ Concessions and private finance initiatives to build, operate and/or maintain key infrastructure ♦ Energy performance contracting	♦ Medium to large-scale infrastructure with strong private goods (to allow rents for private sector)	Cities with strong capacity for legal oversight and management
Local or national - Private or Public	National or local financial markets	♦ Commercial loans, ♦ Private bonds ♦ Municipal bonds	♦ Basic physical infrastructure (need for collateral)	Well-functioning local or national financial markets that city governments can access
National - public	National (or state/provincial) revenue transfers or incentive mechanisms	♦ Revenue transfers from central or regional government ♦ Payment for ecosystem services or other incentive measures	♦ Urban Payment for Environmental Services in Brazil ♦ Sweden's KLIMP Climate Investment programme	Cities with good relations with national governments, strong administrative capacity to design and implement policies and plans
International – private	Market-based investment	♦ Foreign Direct Investment, Joint Ventures	♦ Industrial infrastructure ♦ Power generation infrastructure	Cities with strong national enabling conditions and policies for investment
International sources	Grants, concessional financing (e.g. Adaptation Fund)	♦ Grants, concessional loans and loan guarantees through bilateral and multilateral development assistance ♦ Philanthropic grants	♦ Urban capacity building ♦ Urban infrastructure adaptation planning	Typically requires strong multi-level governance – cities with good relations with national governments. Cities with low levels of administrative and financial market capacity

Table 8-6: Current and Indicative future climate risks for Dar es Salaam, Durban, London, and New York City.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Dar es Salaam					
Coastal zones systems (*medium confidence*)	Construction of coastal protection structures such as sea walls and groynes to minimize coastal erosion and land inundation in Dar es Salaam. Medium prospects due to high costs.		8.3.3.3, 8.3.3.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Terrestrial ecosystems & ecological infrastructure (*low confidence*)	Demarcation and protection of green areas, provision of more drainage systems and protection of urban wetlands and ground water resources. Low prospects due to poor development control including land-use management.		8.3.3.7, Table 8-2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Water supply systems (*high confidence*)	Improvement in Dar es Salaam's water resources management and increased coverage and efficiency in water supply systems. Medium prospects as some of these measures are already being implemented.		8.2.4.1, 8.3.3.4, Table 8-2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Waste water system (*high confidence*)	Increase in spatial coverage of sewerage and improvement of on-site excreta disposal systems. Low prospects for extending sewer coverage; higher prospects for expanding onsite disposal systems.		8.2.4.1, 8.3.3.4, Table 8.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Energy systems (*very high confidence*)	Reduced dependence on hydropower as the main source of energy by replacing it with natural gas. Very high prospects as the country has vast resources of natural gas.		8.2.4.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Food systems and security (*high confidence*)	Urban and peri-urban agriculture and new adaptation policies to take into account impacts of climate change on food costs and supply chain. . Enhanced social safety nets can support adaptation measures.		8.3.3.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Transportation and communication systems (*medium confidence*)	New design standards in context of climate change and enforcement of development controls. Low prospects as climate change issues are yet to be mainstreamed in the sector.		8.2.4.3, 8.3.3.6	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
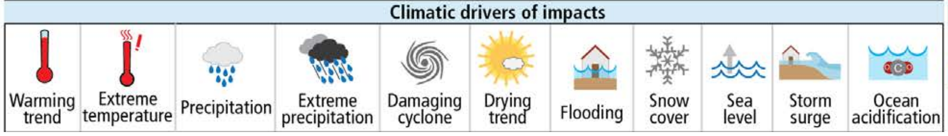
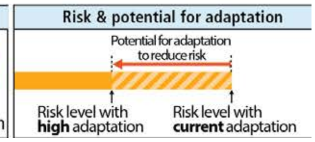
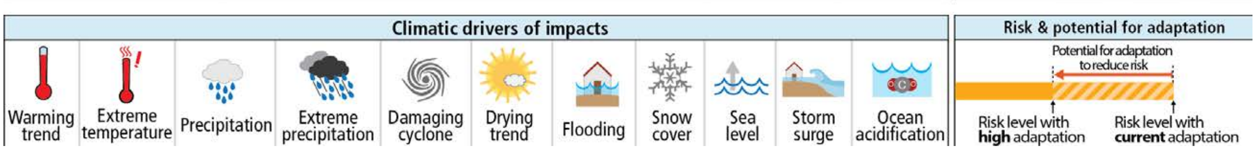
Climatic drivers of impacts



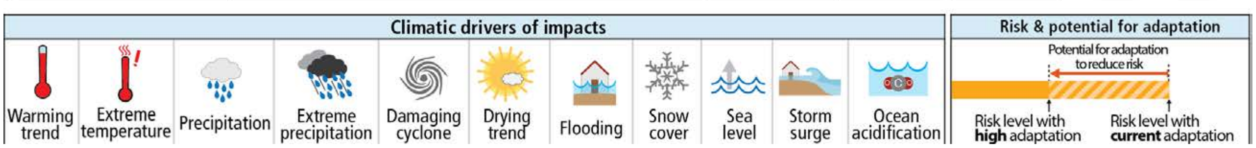
Risk & potential for adaptation



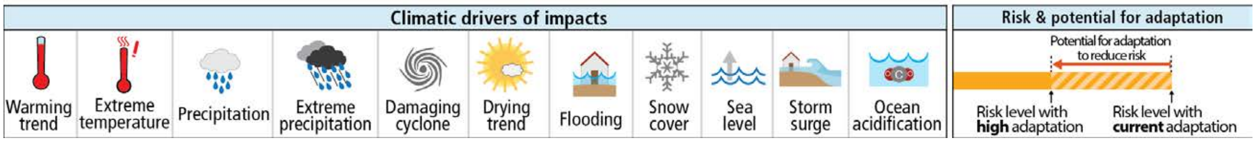
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Dar es Salaam (continued)					
Housing (*high confidence*)	Climate change adaptation plans, new building codes, effective development control and upgrading of informal settlements. High prospects as some of these measure are already being taken into account.		8.2.4.4, 8.3.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Human health (*medium confidence*)	Improvement of water supply, solid waste management, housing conditions, land use planning and food security and provision of health insurance. Medium prospects as these are key development issues that require a lot of financial resources.		8.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Key economic sectors and services (*medium confidence*)	Improvement of storm water infrastructure and transport networks. Use of natural gas as main source for power generation, relocating of key economic activities and infrastructure along coastal buffer areas. A mixture of high and low prospects due to availability of natural gas and high requirements of financial resources.		8.3.3.1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Poverty & Access to basic services (*high confidence*)	Formalizing informal economic sector, upgrading of informal settlements, improving of housing conditions and empowering local communities in tackling problems related to climate change. High prospects as this is already being implemented as a development issue.		8.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Durban					
Coastal zones systems (*medium confidence*)	Maintaining and restoring Durban's coastal ecosystems. Use of coastal protection structures such geofabric sand bags, retaining walls, groynes and a beach nourishment scheme to minimize coastal erosion and infrastructure damage. Use of a development setback line and in some instances strategic retreat to protect infrastructure. High prospects as systems for coastal protection exist and are being improved, but may be overwhelmed by the increase in severity and frequency of storm surges over time.		8.3.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Terrestrial ecosystems and ecological infrastructure (*medium confidence*)	Design and implementation of a fine scale systematic conservation plan to protect a representative and persistent system of local biodiversity and related ecosystem services. Remove non-climate threats e.g. by managing alien invasive species. Medium prospects due to lack of human and financial resources to protect and manage system and poor enforcement of contraventions.		8.3.3.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Water supply systems (*high confidence*)	Demand and supply side management required. Reduce non-revenue water losses. Use of ecological infrastructure to improve level of assurance. Medium prospects as measures are already being implemented or considered.		8.3.3.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Waste water system (*high confidence*)	Increase in spatial coverage of Durban's waterborne sewerage system and use of appropriate alternative services in areas too costly to serve with water-borne systems. Recycling of waste water to potable standards. Medium prospects as measures are already being implemented or investigated.		8.3.3.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Durban (continued)					
Energy systems (*medium confidence*)	No integration of energy policy with adaptation policy or practice. Need to avoid maladaptation e.g. increased electricity use for cooling in response to rising temperatures. Low prospects as institutional structures not yet in place to drive this integration.		8.3.3.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Food systems and security (*high confidence*)	Need to change planting dates and to provide increased crop irrigation. Need to take into account the impacts of climate change on the full food supply chain. Low prospects as climate change not yet considered a serious threat.		8.3.3.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Transportation and communications systems (*medium confidence*)	New design standards in context of climate change and enforcement of development control. Medium prospects as climate change issues are beginning to be considered in the transportation sector.		8.3.3.6	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Housing (*high confidence*)	New building codes, effective development control, upgrading of informal settlements and retrofitting of existing housing stock. Changes in stormwater policy, preparation of master drainage plans, use of attenuation facilities and calculation of new floodlines. Promotion of higher densities to reduce pressure on ecological infrastructure. Medium prospects as measures are already being implemented or being investigated.		8.3.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Human health (*high confidence*)	Improvement of basic services, housing conditions, land use planning and food security. Extend coverage of primary health care and health insurance. Maintain and extend vector control. Ensure ability to deal with the impacts of large scale disasters through inter-sectoral co-ordination. Low to medium prospects due to limited human and financial resources.		8.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Key economic sectors and services (*medium confidence*)	Durban is a logistics, manufacturing and tourist centre. Need to protect and properly locate vulnerable infrastructure in coastal areas – particularly port-related infrastructure. High prospects because of the national economic significance of the port and petro-chemical sectors and local economic significance of tourism.		8.3.3.1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Poverty and access to basic services (*high confidence*)	Formalizing informal economic sector, upgrading informal settlements, provision of interim services to informal settlements, improving housing conditions and increasing the adaptive capacity of local communities (especially through ecosystem based adaptation). Use of climate change adaptation interventions to create employment opportunities. Medium prospects because of the scale of the problem and related costs.		Box 8-2, 8.3.3.7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
London					
River/coastal zones systems (*high confidence*)	London is currently well protected from tidal flooding and has utilised an 'adaptation pathways' approach to ensure it identifies and delivers a flexible long-term tidal flood risk management plan to maintain a high standard of protection through the century.		8.3.3.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
London (continued)					
Terrestrial ecosystems & ecological infrastructure (*medium confidence*)	Adaptation is compromised primarily by habitat fragmentation and can be exacerbated, especially in wetland habitats, by invasive species. The city is taking an approach which promotes the multifunctional benefits of ecologically-designed urban green spaces to benefit adaptation with restoring ecological function.	Warming trend; Precipitation	8.3.3.7	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Water supply systems (*high confidence*)	London faces increasing water security issues during droughts created by higher relative per capita consumption, ageing infrastructure, a rapidly growing population and projected diminishing resources. Resilience is being increased through programmes to reduce consumption and increase the diversity of supply.	Precipitation; Extreme precipitation	8.3.3.4	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Waste water system (*high confidence*)	Much of London is served by a combined rain and foul water drainage system that regularly overflows into the River Thames. Population growth, urban creep and projected more intense rainfall will further challenge the system. The city is working with the relevant drainage partners to manage this increasing risk through a combination of grey and green infrastructure.	Extreme precipitation; Flooding	8.3.3.4	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Energy systems (*medium confidence*)	The city's energy security is threatened by a reduction in national generation capacity and the resilience of local distribution systems not matching the increasing demand. The city is responding through increasing energy efficiency and local energy production to improve resilience. Some concern over amplifications effects of energy system failure during heat or cold shocks.	Extreme temperature; Precipitation	8.3.3.5	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Food systems and security (*low confidence*)	London's food supply is globalised and access is strongly influenced by global food prices relative to income, as well as regional and national agricultural productivity.	Warming trend; Drying trend	8.3.3.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Transportation and communication systems (*medium confidence*)	London is served by a complex communications and public transport network, which whilst vulnerable in parts has sufficient redundancy to be resilient at the strategic level. Detailed risk assessments are informing an investment programme in the transport network that will deliver increasing resilience to climate impacts.	Warming trend; Precipitation; Snow cover	8.3.3.6	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Housing (*high confidence*)	London has an extensive historic housing stock that demonstrates poor thermal performance in summer and winter, poor water efficiency and significant numbers of which are at risk of flooding. There is improving integration between mitigation and adaptation policy implementation at the regional level, but insufficient funding and levers to implement widespread adaptation.	Warming trend; Extreme precipitation	8.3.3.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Human health (*high confidence*)	Health observations systems and care delivered through the National Health Service respond well but need to integrate better with social care provision to be more proactive, especially for vulnerable groups such as the elderly.	Warming trend	8.2.2.1, 8.2.3.1	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
London (continued)					
Key economic sectors and services (*medium confidence*)	London's economy is dominated by service sector activities, particularly finance and including global businesses that expose it to failure in external markets that may be associated with climate change impacts or management. Business continuity is routinely integrated into business plans. Failure of essential infrastructure, including transport and energy networks has short-term impacts.	Extreme temperature; Extreme precipitation	8.3.3.1	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Poverty & access to basic services (*high confidence*)	A significant proportion of the population struggles to pay their energy and water bills. Pockets of deprivation create areas of high vulnerability to climate risks, compounded by low levels of community capacity / social networks.	Extreme temperature; Extreme precipitation	8.3.3.8	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
New York City					
Coastal zones systems (*very high confidence*)	New York City is highly vulnerable to coastal storm events and sea level rise associated flooding. Integration of infrastructure and policy changes with opportunity to enhance ecosystem service services is possible.	Damaging cyclone; Storm surge	8.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Terrestrial ecosystems & ecological infrastructure (*high confidence*)	Promotion of ecosystem restoration efforts consistent with the current degraded state of most of NYC's ecosystem function. A need exists for continued land use protection of the City's water supply region.	Extreme temperature; Extreme precipitation; Flooding	8.2.4.5; 8.3.3.4	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Water supply systems (*medium confidence*)	New York City maintains an extremely extensive and resilient water supply infrastructure. Long term adaptation could potentially include heightened drought management and interagency coordination with other water supply demand entities in region.	Drying trend	8.3.3.4, 8.3.3.7	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Waste water system (*medium confidence*)	NYC maintains an extremely extensive and resilient wastewater infrastructure. Gray and green infrastructure adaptation to limit effects of extreme precipitation events and combined sewer overflows will be necessary.	Extreme precipitation; Storm surge; Flooding	8.2.3.3, 8.2.4.1	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Energy systems (*medium confidence*)	NYC is served by an extensive energy generation and distribution system most of which is operated by private companies or semi-public authorities. Peak load demand adaptation especially for cooling demand will be necessary, as will adaptation for distribution disruptions associated with extreme events including ice storm events and coastal storm surge.	Extreme temperature; Snow cover; Storm surge	8.2.4, 8.2.4.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Food systems and security (*medium confidence*)	NYC is connected to a regional, national, and global food distribution system. Adaptation will be necessary to ensure that food processing and distribution systems within the City can be resilient in the face of potential extreme event impacts.	Storm surge; Flooding	8.3.3.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high

Climatic drivers of impacts

Warming trend | Extreme temperature | Precipitation | Extreme precipitation | Damaging cyclone | Drying trend | Flooding | Snow cover | Sea level | Storm surge | Ocean acidification

Risk & potential for adaptation

Potential for adaptation to reduce risk

Risk level with **high** adaptation — Risk level with **current** adaptation

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
New York City (continued)					
Transportation systems (*high confidence*)	NYC is served by a complex and redundant transportation and communications infrastructure. Numerous vulnerabilities to extreme events are present which result in short term disruption. Long term SLR and increased flood frequency can result in increased disruption and will require adaptation strategies.		8.2.2.2, 8.3.3.6	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Housing (*high confidence*)	NYC includes approximately 1 million buildings and similar structures. These maintain a broad range of vulnerabilities to climate change particularly associated with flooding and extreme heat events. Adaptation strategies could include retrofit construction practices especially in coastal zone locations or areas affected by urban heat island conditions.		8.1.3, 8.2.4, 8.3.3.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Human health (*high confidence*)	Great diversity of health conditions of the 8.3 plus million residents are associated with a wide range of human health vulnerabilities to climate change. The very young, aged, and otherwise health- compromised face heightened risk and require adaptation strategies, particularly focused on heat stress and disease.		8.2.3.1	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Key economic sectors and services (*medium confidence*)	NYC has a diverse economic base focused on the service related industries with regional, national, and global connections. Adaptation will be necessary to limit vulnerability and enhance resilience in the face of large scale extreme events such as Hurricane Sandy.		8.3.3.1	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Poverty & Access to basic services (*medium confidence*)	NYC has an extensive public service provision capacity. Adaptation will be necessary to ensure that more frequent or more intense extreme events will not limit this capacity.		8.3.3.8	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Frequently Asked Questions

Executive Summary

Rural areas still account for almost half the world's population, and about 70% of the developing world's poor people. [9.1.1] There is a lack of clear definition of what constitutes rural areas, and definitions that do exist depend on definitions of the urban. [9.1.2] Across the world, the importance of peri-urban areas and new forms of rural-urban interactions are increasing (*high agreement, limited evidence*). [9.1.3] Rural areas, viewed as a dynamic, spatial category, remain important for assessing the impacts of climate change and the prospects for adaptation. [9.1.1]

Climate change in rural areas will take place in the context of many important economic, social and land-use trends (*very high confidence*). In different regions, absolute rural populations have peaked or will peak in the next few decades. [9.3.1] The proportion of the rural population depending on agriculture is extremely varied across regions, but declining everywhere. Poverty rates in rural areas are higher than overall poverty rates, but also falling more sharply, and the proportions of population in extreme poverty accounted for by rural people are also falling: in both cases with the exception of sub-Saharan Africa, where these rates are rising [Fig 9-2]. Accelerating globalization, through migration, labour linkages, regional and international trade, and new information and communication technologies, is bringing about economic transformation in rural areas of both developing and developed countries. [9.3.1]

Rural people in developing countries are subject to multiple non-climate stressors, including under-investment in agriculture (though there are signs this is improving), problems with land and natural resource policy, and processes of environmental degradation (*very high confidence*). In developing countries, the levels and distribution of rural poverty are affected in complex and interacting ways by processes of commercialization and diversification, food policies, and policies on land tenure. In developed countries, there are important shifts towards multiple uses of rural areas, especially leisure uses, and new rural policies based on the collaboration of multiple stakeholders, the targeting of multiple sectors and a change from subsidy-based to investment-based policy. [9.3.1, Table 9-3]

Impacts of climate change on the rural economic base and livelihoods, land-use and regional interconnections are at the latter stages of complex causal chains (*high confidence*). These flow through changing patterns of extreme events and/or effects of climate change on biophysical processes in agriculture and less-managed ecosystems. [9.3.3] This increases both the uncertainty associated with detection and attribution of current impacts [9.3.2], and with projections of specific future impacts. [9.3.3]

Structural features of farm households and communities affect their vulnerability to climate change in complex ways (*high confidence*). There is *low agreement* on some of the key factors associated with vulnerability or resilience in rural areas [9.3.5.1], including rainfed as opposed to irrigated agriculture [9.3.5.1.1], small-scale and family-managed farms, and integration into world markets. [9.3.5.1.2]. There is *high agreement* on the importance for resilience of access to land and natural resources, flexible local institutions [9.3.5.1.3], and knowledge and information [9.3.5.1.6], and on the association of gender inequalities with vulnerability. [9.3.5.1.5] Specific livelihood niches such as pastoralism, mountain farming systems, and artisanal fisheries are vulnerable and at high risk of adverse impacts (*high confidence*), partly due to neglect, misunderstanding or inappropriate policy towards them on the part of governments. [9.3.5.2]

Cases in the literature of observed impacts on rural areas often suffer from methodological problems of attribution, but evidence for observed impacts, both of extreme events and other categories, is increasing (*medium confidence*). Impacts attributable to climate change include some direct impacts of droughts, storms, and other extreme events on infrastructure and health (*low confidence* globally, but *medium confidence* in certain regions), as well as longer-term declining yields of major crops, from which impacts on income and livelihoods can be inferred with *low confidence*. There is *high confidence* in geographically-specific impacts, such as glacier melt in the Andes. [9.3.2]

Major impacts of climate change in rural areas will be felt through impacts on water supply, food security [9.3.3.1] and agricultural incomes [9.3.4.1] (*high confidence*). Shifts in agricultural production, of food and non-food crops, are projected for many areas of the world (*high confidence*). [9.3.3.1] Price rises, which may be induced by climate shocks as well as other factors [9.3.3.3.2], have a disproportionate impact on the welfare of the poor in rural areas, such as female headed households and those with limited access to modern agricultural inputs, infrastructure and education. [9.3.3.1] The time scale for impacts varies across regions and sectors, and by the nature of the specific climatic impact.

Climate change will impact international trade volumes in both physical and value terms (*medium agreement, limited evidence*). Importing food can help countries adjust to climate-change induced domestic productivity shocks while short-term food deficits in low-income countries may have to be met through food aid. Options exist for adaptations within international agricultural trade (*medium confidence*). Deepening agricultural markets and improving the predictability and the reliability of the world trading system through trade reform, as well as investing in additional supply capacity of small-scale farms in developing countries, could result in reduced market volatility and manage food supply shortages caused by climate change. [9.3.3.3.2]

Migration patterns will be driven by multiple factors of which climate change is only one (*high confidence*). [9.3.3.3.1] Given these multiple drivers of migration (economic, social, political, demographic and environmental) and the complex interactions which mediate migratory decision-making by individuals or households, establishment of a relation between climate change and intra-rural and rural-to-urban migration, observed or projected, remains a major challenge.

Climate policies, such as increasing energy supply from renewable resources, encouraging cultivation of biofuels, or payments under REDD, will have significant secondary impacts, both positive (increasing employment opportunities) and negative (landscape changes, increasing conflicts for scarce resources), in some rural areas (*medium confidence*). [9.3.3.4] There is a need to understand how implementation of these policies will impact on rural livelihoods. These secondary impacts, and trade-offs between mitigation and adaptation in rural areas, have implications for governance, including the need to promote participation of rural stakeholders.

Most studies using valuation methodologies conclude that climate change impacts will be substantial, especially for developing countries, due to their economic dependence on agriculture and natural resources, low adaptive capacities, and geographical locations (*very high confidence*). [9.3.4] Valuation of climate impacts needs to draw upon both monetary and non-monetary indicators. The valuation of non-marketed ecosystem services

[9.3.4.5] and the limitations of economic valuation models which aggregate across multiple contexts [9.3.4] pose challenges for valuing impacts in rural areas (*high confidence*).

There is a growing body of literature on adaptation practices in both developed and developing country rural areas [9.4.1], including documentation of practical experience in agriculture, water, forestry and biodiversity and, to a lesser extent, fisheries [9.4.3] (*very high confidence*). Public policies supporting decision-making for adaptation exist in developed and, increasingly, in developing countries, and there are also examples of private adaptations led by individuals, companies and NGOs (*high confidence*). [9.4.2] Constraints on adaptation come from lack of access to credit, land, water, technology, markets, knowledge and information, and perceptions of the need to change; and are particularly pronounced in developing countries *(high confidence)*. [9.4.4] Gender and institutions affect access to adaptation options and the presence of barriers to adaptation (*very high confidence).* [9.4.4]

9.1. Introduction

9.1.1. Rationale for the Chapter

This chapter assesses the impacts of climate change on, and the prospects for adaptation in, rural areas. Rural areas include diverse patterns of settlement, infrastructure and livelihoods, and relate in complex ways with urban areas. The chapter shows that rural areas experience specific vulnerabilities to climate change, both through their dependence on natural resources and weather-dependent activities, and through their relative lack of access to information, decision-making, investment and services. Adaptation strategies will need to address these vulnerabilities. Some of the key starting points, which affect the scope and coverage of literature assessed in this chapter, will be as follows.

- Rural areas, even after significant demographic shifts, still account for 3.3 billion people or almost half (47.9%) of the world's total population (UN-DESA Population Division 2012).
- The overwhelming majority of the world's rural population (3.1 billion people, or 91.7% of the world's rural population, or 44.0% of the world's total population) live in less developed or least developed countries (UN-DESA Population Division 2012).
- Rural dwellers also account for about 70% of the developing world's poor people. IFAD (2010) states that around 70% of the extreme poor in developing countries lived in rural areas in 2005. Ravallion *et al*. (2007) using 2002 data and poverty lines of $US1.08 or $US2.15, in each case with urban poverty lines adjusted upwards to recognize additional non-food spending, give a figure of around 75% of people, under either poverty line, being rural.
- Rural areas are a spatial category, associated with certain patterns of human activity, but with those associations being subject to continuous change.
- Rural areas are largely defined in contradistinction to urban areas, but that distinction is increasingly seen as problematic.
- Rural populations have, and will have, a variety of income sources and occupations, within which agriculture and the exploitation of natural resources have privileged, but not necessarily predominant, positions.

The chapter will complement the treatment of issues also dealt with in Chapter 7 "Food Production Systems and Food Security" and Chapter 4 "Terrestrial and Inland Water Systems", but will primarily look at how biophysical impacts of climate change on agriculture and on less-managed ecosystems translate into impacts on human systems, and in this regard will complement sections of Chapter 12 "Human Security", Chapter 13 "Poverty and Livelihoods", and other sectoral and regional chapters. The important impacts of climate change on human health are covered in Chapter 11. In accordance with the proportion of the rural population found in developing countries, literature on these countries is given prominence, but issues of impact, vulnerability and adapatation in developed countries are also assessed.

9.1.2. Definitions of the Rural

"Rural" refers generally to areas of open country and small settlements, but the definition of "rural areas" in both policy-oriented and scholarly literature are terms often taken for granted or left undefined, in a process of definition which is often fraught with difficulties (IFAD, 2010). Ultimately, in developing countries as well as developed countries, the rural is defined as the inverse or the residual of the urban (Lerner and Eakin, 2010). Human settlements in fact exist along a continuum from 'rural' to 'urban', with 'large villages', 'small towns' and 'small urban centres' not clearly fitting into one or the other. The variations in definitions from country-to-country can best be described through several examples (from both developed and developing countries of different sizes) shown in Table 9-1.

[INSERT TABLE 9-1 HERE
Table 9-1: Definitions of the "rural" and the "urban" in selected countries.]

Researchers have increasingly recognized that the simple dichotomy between 'rural' and 'urban' has is extremely problematic (Simon et al., 2006:4). Additional categories such as "peri-urban areas" (Simon et al., 2006; Simon, 2008; Webster 2002; Lerner and Eakin 2010; Bowyer-Bower, 2006), and *desakota* (Desakota Study Team 2008; McGee 1991; Moench and Gyawali 2008), allow more nuanced analysis of the permeable boundaries of rural and urban areas and the diversified economic systems that exist across the urban-rural spectrum – see Box CC-UR.

While remaining aware of issues of definition, this chapter will in general assess literature on rural areas using whatever definitions of the rural are used in that literature. Global statistics collated by international organizations and cited here are generally aggregations of national statistics compiled under each national definition.

9.2. Findings of Recent Assessments

The Fourth Assessment Report (AR4) of the IPCC contains no specific chapter on "rural areas". Material on rural areas and rural people is found throughout the AR4, but rural areas are approached from specific viewpoints and through specific disciplines. Table 9-2 summarizes key findings on rural areas from AR4 (particularly Easterling *et al*., 2007 on agriculture, Wilbanks *et al.*, 2007 on industry, settlement and society, and Klein *et al.* 2007 on links between adaptation and mitigation), and relevant findings from the International Assessment of Agricultural Knowledge, Science and Technology for Development (McIntyre *et al.*, 2009). All these sources stress uncertainty, the importance of non-climate trends, complexity and context-specificity, in any findings on rural areas and climate change.

[INSERT TABLE 9-2 HERE
Table 9-2: Relevant findings on rural areas from the IPCC Fourth Assessment Report and the International Assessment of Agricultural Science and Technology for Development.]

9.3. Assessing Impacts, Vulnerabilities, and Risks

9.3.1. Current and Future Economic, Social, and Land-Use Trends in Rural Areas

Climate change in rural areas will take place against the background of the trends in demography, economics and governance which are shaping those areas. While there are major points of contact between the important trends in developing and developed countries, and the analytical approaches used to discuss them, it is easier to discuss trends separately for the two groups of countries. In particular there is a close association in developing countries between rural areas and poverty. Table 9-3 summarizes and compares the most important trends across the two groups of countries. Figure 9-1, Table 9-4, and Figure 9-2 focus on two specific trends in developing countries: demographic trends and trends in poverty indicators.

[INSERT TABLE 9-3 HERE
Table 9-3: Major demographic, poverty-related, economic, governance, and environmental trends in rural areas of developed and developing countries.]

Source: Adapted from IFAD (2010).]

9.3.2. Observed Impacts

Documentation of observed impacts of climate change on rural areas involves major questions of detection and attribution (see chapter 18). Whilst having potential, there are complications with using traditional knowledge and farmer perceptions to detect climate trends (Box 18-4, Rao *et al.*, 2011). Implied equivalence between local perceptions of climate change, local decadal trends, extreme events and global change is common, and often used without systematic discussion of the challenges (Ensor and Berger, 2009; Paavola, 2008; Castro *et al.*, 2012). This is not a problem in the context of detailed social-scientific analysis of vulnerability, adaptive capacity and their determinants, but becomes more problematic to use as evidence for observed impact. Detection and attribution of extreme events to climate change is no less challenging (Seneviratne *et al.* 2012). Exposure to non-climate trends and shocks further complicates the issue (Nielsen and Reenberg, 2010, Section 3.2.7).

The impacts of climate change on patterns of settlement, livelihoods and incomes in rural areas will be the result of multi-step causal chains of impact. Typically, those chains will be of two sorts. One sort will involve extreme events, such as floods and storms, as they impact on rural infrastructure and cause direct loss of life. The other sort will involve impacts on agriculture or on ecosystems on which rural people depend. These impacts may themselves stem from extreme events, from changing patterns of extremes due to climate change, or from changes in mean conditions. The detection and attribution of extreme events is discussed by the IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (Seneviratne *et al.*, 2012). The detection and attribution of impacts on ecosystems and on agriculture are dealt with in Chapters 4 and 7 of this report. Both exercises are complex.

Seneviratne *et al.* (2012) give a detailed and critical assessment of the detection and attribution of observed patterns of extreme events, which shows greatly varying levels of confidence in the attribution to climate change of global and regional trends, and that "attribution of single extreme events to anthropogenic climate change is challenging" (2012:112). They state that it is *likely* there has been a worldwide increase in extreme high-water events during the late 20th century, with a *likely* anthropogenic influence on it. They have *medium confidence* in detecting trends towards more intense and frequent droughts in some parts of the world (Southern Europe and West Africa) since 1950. They note that opposite trends exist elsewhere, and that there is *low confidence* in any trend in drought in, for example, East Africa. WG I AR5 Chapter 2 similarly ascribes *low confidence* in a global observed trend in drought in the later 20th century, with a *likely* increase in frequency and intensity of drought in the Mediterranean and West Africa and a likely decrease in central North America. Lyon and DeWitt (2012) see a "recent and abrupt decline in the East African long rains" since 1999. Seneviratne *et al.* (2012) assign *low confidence* to any observed long-term increases in tropical cyclone activity, as does WGI AR5 Chapter 2, and to attribution of any changes in cyclone activity to anthropogenic influence. WGI AR5 Chapter 2 states that an observed increase in the frequency and intensity of North Atlantic cyclones is virtually certain. It also describes varying regional trends towards heavy precipitation events, *very likely* in central North America. Section 3.2.7 ascribes *medium confidence* to observed increased likelihood of flooding at the scale of some regions.

Handmer *et al.* (2012) discuss both observed and projected impacts of extreme events on human systems and ecosystems, with numerous examples of diverse, widespread negative impacts (see also Chapter 18). Important categories of extreme events causing negative impacts in rural areas include tropical storms and droughts: Hurricane Stan in October 2005 affected nearly 600,000 people on the Chiapas coast as a consequence of flooding and sudden river overflows (Saldaña-Zorrilla, 2008). Droughts in rural areas produce severe economic stresses, including employment reduction and migration (Gray and Mueller, 2012). Agricultural livelihoods are affected by droughts. Ericksen *et al.* (2012) review a variety of livestock mortality rates for recent droughts in the Horn of Africa, ranging up to 80% of livestock in Southern Kenya in 2009.

Climate change impacts on agriculture and ecosystems run through rising temperature and changes in rainfall variability and seasonality as well as through extreme events. Changes in temperature caused reduction in global yields of maize and wheat by 3.8 and 5.5% respectively from 1980 to 2008 relative to a counterfactual without climate change, which offset in some countries some of the gains from improved agricultural technology (Lobell et al., 2011, section 7.2.1.1). Badjeck *et al.* (2010) discuss current and future impacts on fisherfolk across the world. Many local-level studies are subject to the attribution problems mentioned above, but Wellard *et al.* (2012) cautiously note a convergence of climate data with the perceptions of farmers and officials to the effect that over the last 30 years the rainfall in Malawi has become less predictable, that the rainy season is arriving later in the year causing delays in planting of the main crops, and that damaging dry spells during the rainy season have become more likely.

Glacial retreat in Latin America is one of the best evidenced current impacts on rural areas (see Section 27.3.1.1). In highland Peru there have been rapid observed declines since 1962 in glacier area and dry-season stream flow, on which local livelihoods depend, which accord well with local perceptions of changes that are necessitating adaptation (Orlove, 2009). Other studies of the area focus both on observed changes in water availability and on glacial lake outburst floods, which are attributable to climate change (Bury *et al.*, 2011; Carey, 2010, Carey *et al.* 2012). There is also a rich specialized literature on the impacts of shrinking sea-ice and changing seasonal patterns of ice formation and melt on indigenous peoples in the Arctic (Ford, 2009; Beaumier and Ford, 2010, Section 28.2.5.1.7).

Migration associated with weather-related extremes or longer-term climate trends is discussed in Chapter 12, Table 12-3, with empirical examples of migrations linked to droughts, coastal storms, floods and sea level rise. The Asian Development Bank (ADB, 2012) gives a figure of 42 million people displaced by extreme weather events in Asia and the Pacific over 2010-2011. Attribution of migration to climate change is extremely complex, as recognized by Black *et al.* (2011a), because life in rural areas across the world typically involves complex patterns of rural-urban and rural-rural migration, subject to economic, political, social and demographic drivers, patterns which are modified or exacerbated by climate events and trends rather than solely caused by them (see also Section 12.4.1).

9.3.3. Future Impacts

This section will examine the major impacts of climate change identified or projected for rural areas, under the headings of: economic base and livelihoods; infrastructure; spatial and regional interconnections, including migration, trade, investment and knowledge; and second-order impacts of climate policy. Section 9.3.4, assesses literature on impact through a different and specific lens, that of economic valuation. The biophysical impacts of climate change on food crops are dealt with primarily in Chapter 7; but also here and in section 9.3.4 insofar as they affect rural economies. Biophysical impacts on non-food cash crops, are discussed below. As with the observed impacts in section 9.3.2, the future impacts of climate change described here, and quantified in section 9.3.4, are at the latter stages of complex causal chains that flow through changing patterns of extreme events and/or effects of climate change on biophysical processes in agriculture and less-managed ecosystems. Lal *et al.* (2011) show the regional specificity of projected socio-economic impacts across the rural United States, with different regions affected through agriculture, water stress and energy costs. Anderson *et al.* (2010) discuss the complexity of projected impacts across dryland regions of developing countries. These considerations increase the uncertainty associated with any particular impact on the economic base, on land-use or on regional interconnections.

9.3.3.1. Economic Base and Livelihoods

9.3.3.1.1. General considerations

Climate change will affect rural livelihoods, or "the capabilities, assets (stores, resources, claims and access) and activities required for a means of living" (Chambers and Conway, 1992). Many, though by no means all, rural livelihoods are dependent on natural resources (e.g. agriculture, fishing and forestry), and their availability will vary in a changing climate. This will have effects on human security and wellbeing (Kumssa and Jones, 2010, see also Chapter 12). Climate change impacts on smallholder and subsistence farmers will be compounded by environmental and physical processes affecting production at a landscape, watershed or community level; and other impacts, including those on human health and on non-agricultural livelihoods (Morton, 2007) and also trade and food prices (Anderson *et al*,. 2010). Despite the growing importance of non-farm livelihoods in rural areas worldwide (Ellis, 2000; Reardon *et al*., 2007), and households pursuing interdependent agricultural and non-agricultural livelihoods in peri-urban areas as a risk management strategy (Lerner and Eakin, 2010; Lerner *et al.*, 2013), there is a relative scarcity of literature on the interactions of these with climate variability and climate change.

Climate variability and change interacts with, and sometimes compounds, existing livelihood pressures in rural areas, such as economic policy, globalization, environmental degradation and HIV/AIDS, as has been shown in Tanzania (Hamisi *et al.*, 2012), Ghana (Westerhoff and Smit, 2009), South Africa (O'Brien *et al*., 2009; Ziervogel and Taylor, 2008; Reid and Vogel, 2006), Malawi (Casale *et al.*, 2010), Kenya, (Oluoko-Odingoa, 2011), Senegal (Mbow *et al*., 2008) and India (O'Brien *et al.*, 2004). Economic heterogeneity of farm households within communities, in terms of farm and household size, crop choices and input use, will be important in determining impacts (Claessens *et al.* (2012), as will social relations within households that affect production (Morton, 2007).

Projected impacts on yields and production of food crops are assessed in Section 7.4.1 and Figure 7-7. Local warming in excess of 1°C is projected to have negative impacts in both temperate and tropical regions without adaptation (though individual locations may benefit). There is *medium confidence* in large negative impacts of local increases of 3-4°C, on productivity, production and food security, globally and particularly in tropical countries, that go beyond adaptive capacity. The impacts of climate change on the agricultural sector in Africa, dominated by smallholder farming and very largely rainfed are considered to be very significant to economies and livelihoods (Müller *et al.*, 2011; Kotir, 2011; Collier et al., 2008; Hassan, 2010). These results emerge across a range of scenarios. Several other studies also map declines in net revenues from crops and the associated links with food security and poverty (Molua, 2009; Thurlow et al., 2009; Reid et al., 2008; Thurlow and Wobst, 2003).

Post-harvest aspects of agriculture – storage on-farm and commercially, handling and transport – have been relatively neglected in discussions of climate change, but will be affected by changes in temperature, rainfall, humidity, and by extreme events. Many adaptation opportunities are already understood by postharvest service providers, but getting postharvest knowledge into use at scale is a significant challenge (Stathers *et al.*, 2013, also Tefera, 2012). Future impacts on production and storage will affect prices. Food crises in Africa triggered by moderate declines in agricultural production have been exacerbated by "exchange entitlement failures" – food price spikes and asset price collapses (Devereux, 2009). Rising food prices negatively affect many rural people who are net food buyers (see Table 7-1), and the poorest of the poor in rural areas - female-headed households (which tend to be poorer than male-headed households) and those who have limited access to land, modern agricultural inputs, infrastructure and education (Ruel *et al.*, 2009).

The remainder of this section will discuss issues around climate impacts on agricultural livelihoods, other than food crop production: water as an input to agriculture, non-food crops, livestock and fisheries.

9.3.3.1.2. Water

Water supply will be impacted through climate change (Ch 3). In rural areas groundwater extraction and irrigation water availability is crucial for agricultural livelihoods but is typically not included in modelled projections of future crop yields, as discussed by Lobell and Field (2012). At the same time, non-climate trends including population growth and lack of adequate regulatory frameworks will greatly affect demand for water by agriculture and other, competing, uses, as discussed by Macdonald, 2010 for the Southwestern USA, by Juana et al., 2008 for South Africa, and multiple authors for the Middle East (Chenoweth *et al.*, 2011; Rochdane *et al.*, 2012; Iglesias *et al.*, 2010; Hanafi *et al.*, 2012, Sowers *et al.*, 2011; Verner, 2012: 166).

At the continental level in Africa, analysis of existing rainfall and recharge studies suggests that climate change will not lead to widespread catastrophic failure of improved rural groundwater supplies, but it could affect a population of up to 90 million people, as they live in rural areas where annual rainfall is between 200 and 500mm per year, and where decreases in annual rainfall, changes in intensity or seasonal variations may cause problems for groundwater supply (Macdonald *et al*., 2009). At higher resolution groundwater resources are threatened (e.g. in South Africa, Knüppe, 2011), and multiple water crises are expected to result from the increasing demand, further affecting people in rural areas (Nkem *et al*., 2011). Climate change is expected to impact water resources in the Asian region in a major way. Immerzeel *et al*. (2010) in a study of the Indus, Ganges, Brahmaputra, Yangtze and Yellow River basins conclude that different river basins would experience different impacts on water availability and food security due to climate change. They further argue that the Brahmaputra and Indus basins would be more susceptible to changes in water availability affecting the food security of 60 million people. In Southern Europe, declines in rainfall and meltwater from glacial ice and snow would increase the costs of production and living (Falloon and Betts, 2010). Drought could threaten biodiversity and traditional ecosystems particularly in Southern Europe with problems exacerbated by declining water quality. Decline in economic activity may increase rural depopulation and harm the development of rural communities in Southern Europe (Westhoek *et al*., 2006).

9.3.3.1.3. Non-food crops and high-value food crops

Non-food crops and high-value food crops, such as cotton, wine grapes, beverage crops and other cash crops, which represent an important source of livelihood in many rural areas, have received less attention than staple food crops when assessing the impacts of climate change. Literature on biofuels such as jatropha focuses on the impacts of biofuels on climate change rather than on the effects of climate on yields and other relevant variables in these agricultural systems. Where crops have dual use as food and biofuel (for example oilseeds, sugarcane, sugar beet, maize and wheat) impacts can be inferred from studies that focus on their use for food.

The findings of Easterling *et al.*, (2007), that cotton yields would decrease as changes in temperature and precipitation overcome potential benefits of increasing carbon dioxide have been corroborated in other findings, such as those of Haim *et al.* (2008: 433) that cotton cultivation in Israel will decline by 52% and 38% by 2070-2100 under the A2 and B2 scenarios, and that the net revenue will also decrease by 240% and 173% in both scenarios. Few systematic assessments have been done on other fibre crops such as jute, kenaf, and flax.

Climate change impacts on wine grapes have been extensively studied and documented. Climate impacts such as increasing number of hot days and decreasing frost risk may benefit some varieties. Lobell *et al*. (2006) assess the impacts of climate change on yields of six perennial crops in California by 2099, and report that the production of wine grapes will experience relatively small changes compared to other commodities during the concerned period. The uncertainty analysis shows the yield variations are limited within 10% although Gatto *et al*. (2009) argue that the revenue of the industry in Napa, California could decline by 2034. Jones *et al*. (2005) indicate that future climate change will exceed climatic thresholds affecting ripening for existing varieties grown at the margins of their climatic limits. Warmer conditions could also lead to more poleward locations becoming more conducive to grape growing and wine production.

Lobell and Field (2012) model impacts on 20 perennial crops in California under the A2 and B1 scenarios; of the four crops with the most reliable models cherry yields are projected to decline by nearly 20%, strawberries and table grapes to experience smaller declines, and almonds a slight positive trend. These projections do not incorporate adaptation options, nor possible decline in irrigation water supply, which would limit production. Yields of several cash crops in the Middle East such as olives, apples and pistachios may decline if winter temperatures are too high (Verner, 2012).

The case of tropical beverage crops, in particular coffee, is discussed in Box 9-1, and projected changes in area suitable for all three tropical beverage crops are set out in Table 9-5.

____ START BOX 9-1 HERE ____

Box 9-1. Impacts of Climate Change on Tropical Beverage Crops

The major traded beverage crops coffee, tea and cocoa support the livelihoods of several million small-scale producers in over 60 countries of the tropics of Africa, Asia and Latin America. Coffee production has long been recognized as sensitive to climate variability with global production and prices sensitive to occasional frosts in Brazil – the world's largest producer (Varangis *et al.*, 2003). Likewise the livelihoods of millions of small producers are dependent both on stability of production and stability in world prices. During the last crash in coffee prices from 2000-2003 poverty levels in the coffee growing regions of Nicaragua increased, while they fell in the rest of the country (World Bank, 2003); subsequently during the drought associated with El Nino in 2005 coffee productivity fell to between a third and half of normal similarly leading to severely reduced income for small producers (Haggar, 2009).

Gay *et al.* (2006), analysing the effects of recent climate change on coffee producing areas in Veracruz, Mexico, have developed econometric models of the relationship between coffee productivity and fluctuations in temperature and precipitation, which gave an R-squared of 0.69 against historical data. Extrapolating the historical tendencies in temperature and precipitation to 2020 and applying their econometric model they predict that coffee production is *likely* to decline by 34%, and this decline in production takes producers from making net profits of on average around US$200 per acre, to less than $20 per acre. This has led to a series of studies projecting the effects of climate change on the distribution of Arabica coffee growing areas of the coming decades summarized below and in Table 9-5.

For Brazil, Assad *et al.* (2004) and Pinto *et al.* (2007) have mapped the changes in area suitable for coffee production in the four main coffee producing states. A 3^{o}C increase in temperature and 15% increase in rainfall (taken from the general prediction of climate change for Southern Brazil in the IPCC Third Assessment Report of 2001) would lead to major changes in the distribution of coffee producing zones. In the main coffee producing states of Minas Gerais and Sao Paulo the potential area for production would decline from 70-75% of the states to 20-25%, production in Gioas would be eliminated, but the area would only be reduced by 10% in Parana. New areas suitable for production in Santa Catarina and Rio Grande do Sul will only partially compensate the loss of area in other states (Pinto and Assad, 2008). The economic impacts of a rise in temperature of 3^{o}C would cause a 60% decline in coffee production in the state of Sao Paulo equal to nearly US$300 million income (Pinto *et al.*, 2007).

Models developed by CIAT predict the distribution of coffee under the A2a climate scenario using a statistical downscaling of the climate change data from 20 different GCM models used in the IPCC Fourth Assessment. They use WorldClim data to characterize the current distribution of coffee using 19 climatic variables and then use the climate data downscaled to 1, 5 and 10 km resolution to map where those conditions may occur in the future (2020 or 2050). This method has been applied to coffee distribution in Kenya (CIAT 2010), Central America and Mexico (Laderach *et al.*, 2010, Glenn *et al* 2013), tea production in Kenya (CIAT, 2011a) and Uganda (CIAT, 2011b), and cocoa production in Ghana and Ivory Coast (CIAT, 2011c) (Table 9-5). The suitability for coffee crops in Costa Rica, Nicaragua and El Salvador will be reduced by 40% (Glenn *et al.*, 2013) while the loss of climatic niches in Colombia will force the migration of coffee crops towards higher altitudes by mid-century (Ramirez-Villegas *et al.*, 2012). In the same way, increases in temperature will affect tea production, in particular at low altitudes (Wijeratne, et al., 2007). Only one similar study has been done for Robusta coffee (Simonett, 2002), in Uganda, which shows similarly drastic changes in both distribution and total area suitable for coffee production.

Effects are also expected on the incidence of pests and diseases in these crops. Increased generations under climate change for the coffee nematode have been predicted for Brazil (Ghini *et al*., 2008). Jaramillo *et al.* (2011) conclude that Coffee Berry Borer (*Hypothenemus hampei*) distribution in East Africa has expanded due to rising temperatures, and predicts (based on A2A and B2B scenarios of HADCM3 model) that it will spread to affect the main coffee producing areas of Ethiopia, Kenya, Uganda, Rwanda and Burundi by 2050.

At a minimum climate change will cause considerable changes in the distribution of these crops disrupting the livelihoods of millions of small-holder producers. In many cases the area suitable for production would decrease considerably with increases of temperature of only 2-2.5ºC. Although some local areas may experience improved conditions for coffee production, e.g. high altitude areas of Guatemala, the overall predictions are for a reduction in area suitable for coffee production by 2050 in all countries studied (Laderach *et al.* 2010).

[INSERT TABLE 9-5 HERE
Table 9-5: Projected changes in areas suitable for production of tropical beverage crops by 2050.]

9.3.3.1.4. Livestock

The impacts of climate change on livestock – which form a part of a variety of farming systems (Devendra *et al.* 2005) – are seen by Thornton *et al.* (2009), as a neglected research area complicated by other drivers of change, rapid change in livestock systems, spatial heterogeneity and social inequality between livestock-keepers. They review various pathways of impact on livestock. Impacts through drought will be significant, as will heat stress, particularly of *Bos taurus* cattle. Impacts through animal health and disease will be even harder to predict than other categories of impact (Thornton *et al.*, 2009). Franco *et al.* (2011) reveal significant declines in forage for ranching in California under SRES scenarios B1 and A2.

Pastoralists, who are dependent on livestock grazed in arid, semi-arid or mountainous areas, represent a specific case, display very specific combinations of adaptive capacity, especially through mobility, and vulnerability, as discussed in 9.3.5 below. Ericksen *et al.* (2012), with particular reference to East Africa, discuss possibilities of loss of rangeland productivity, changes in rangeland composition towards browse species, and changes in herd dynamics through more frequent droughts as possible impacts. In the Middle East, rangelands will be under substantial climate stress which may reduce their carrying capacity, in light of the growing demand for meat products and the region's growing livestock population (Verner, 2012: 166). Little *et al.* (2001) discuss impacts of floods, directly and through disease, on pastoral herds. Similarly in the Ferlo Region in Northern Senegal, modest reduction in rainfall of 15% in combination with a 20% increase in rainfall variability could have considerable effects on livestock stocking density and profits, reducing the optimal stocking density by 30%, based on six GCMs (Hein *et al.* 2009).

As extensive livestock production is associated with semi-arid areas marginal for cropping, some authors project shifts toward livestock production under climate change. Modeled data from across Africa on the net income per unit of land from crops and different livestock species, show that farmers are more likely to keep livestock, compared to crop cultivation, as temperatures increase and as precipitation decreases. Within livestock production, beef production will decline and sheep and goat production increase (Seo and Mendelsohn, 2007a). Large-scale commercial beef cattle farmers are most vulnerable to climate change, particularly since they are less likely to have diversified (Seo and Mendelsohn, 2007b). Kabubo-Mariara (2009) shows for non-pastoral areas of Kenya the non-linear relationship of livestock production to climate change, whereby increased mean precipitation of 1% could reduce revenues from livestock by 6%. Jones and Thornton (2009) identify major transition zones across Africa where increased probability of drought up to 2050 will create conditions for shifts from cropping to livestock.

9.3.3.1.5. Fisheries

Impacts of climate change on aquatic ecosystems will have adverse consequences for the world's 36 million fisherfolk, through multiple pathways including changes in fish stock distribution and abundance, and destruction of fishing gear and infrastructure in storms and severe weather events (Badjeck *et al*., 2010; 5.4.3.3, 6.4.1.1, 7.4.2, 30.6.2.1). An indicator approach (assessing climate change impacts together with the high share of fisheries as a source of income) showed that economies with the highest vulnerability of capture fisheries to climate change were in Central and Western Africa (e.g. Malawi, Guinea, Senegal, and Uganda), Peru and Colombia in north-western South America, and four tropical Asian countries (Bangladesh, Cambodia, Pakistan, and Yemen) (Allison *et al*., 2009). In China, Japan and South Korea changes in climate and social systems could have a negative impact on fisheries adversely affecting livelihoods and food security of the region (Kim, 2010).

9.3.3.2. Infrastructure

Assessments of the impacts of climate change on infrastructure take a general or urban perspective and do not focus on rural areas, though rural impacts can be inferred. River flooding and sea level rise will produce temporary loss of land and land activities, and damage to transportation infrastructure particularly on coastal areas (Kirshen *et al*., 2008), with specific evidence from North America (Hess *et al.*, 2008). Flooding events may cause sediment transport and damage roads and bridges (Nearing *et al.*, 2004) as well as to affect reservoir storing capacity. Importantly, in rural areas usually there are few alternatives once a road is blocked and that may increase vulnerability of rural areas when facing extreme hydroclimatological events that impact transportation infrastructure (NRC, 2008). Climate change will affect the operation of existing water infrastructures (Kundzewicz *et al.*, 2008). Some documented impacts on dams, reservoirs and irrigation infrastructure are: reduction of sediment load due to reductions in flows (associated with lower precipitation), positively affecting infrastructure operation (Wang et al., 2007); impacts of climate variability and change on storage capacity that creates further vulnerability (Lane *et al.*, 1999); and failures in the reliability of water allocation systems (based on water use rights) due to reductions of streamflows under future climate scenarios (Meza *et al.*, 2012).

In Arctic Canada and Alaska, infrastructure built for very cold weather will deteriorate as the air and ground warm. Larsen *et al.* (2008) estimate, using the AOGCM model inter-comparison project and an A1B scenario, increases in public infrastructure costs of 10-20 percent through 2030 and 10% through 2080 for Alaska, amounting to several billion dollars, much of it to be spent outside of urban centers. Lemmen *et al.* (2008) reports that foundation fixes alone in the largely rural Northwest Territories could cost up to CAN$420 million, and that nearly all of Northern Canada's extensive winter road network, which supplies rural communities and supports extractive industries which bring billions of dollars to the Canadian economy annually, is at risk (Furgal and Prowse 2008) from a 2-4℃ change in ground surface temperatures, which would imply a cost of replacement with all-weather roadways of CAN$85,000/km, over several decades.

9.3.3.3. Spatial and Regional Interconnections

In both developing and developed countries, rural areas have been increasingly integrated with the rest of world. The main channels through which this rapid integration process takes place are migration (permanent and cyclical), commuting, transfer of public and private remittances, regional and international trade, inflow of investment and diffusion of knowledge through new information and communication technologies (IFAD, 2010), as well as the spatial intermingling of rural and urban economic activities (see Box CC-UR).

9.3.3.3.1. Migration

It is difficult to establish a causal relationship between environmental degradation and migration (see Section 12.4.1). Many authors argue that migration will increase during times of environmental stress (e.g. Afifi, 2011; Gray and Mueller, 2012; Kniveton *et al*., 2011; Brown and Crawford, 2008), and will lead to an increase in abandonment of settlements (McLeman, 2011). Climate variability has been associated with rural-urban migration (Mertz *et al.*, 2011; Parnell and Walawege, 2011). Another body of literature argues that migration rates are no higher under conditions of environmental or climate stress (Black *et al.*, 2011a and b; van der Geest, 2011; van der Geest and de Jeu, 2008; Tacoli, 2009; McLeman and Hunter, 2010; Gemenne, 2011; Foresight, 2011; Cohen, 2004; Brown, 2008). For Tacoli (2009) the current alarmist predictions of massive flows of so-called “environmental refugees” or “environmental migrants”, are not supported by past experiences of responses to droughts and extreme weather events and predictions for future migration flows are tentative at best. Analogies with past migration experiences are used frequently in such studies (McLeman and Hunter 2010). For example, in Ghana the causality of migration was established to be relatively clear in the case of sudden-onset environmental perturbations such as floods, whereas in case of slow-onset environmental deterioration, there was usually a set of overlapping causes - political and socioeconomic factors – which come into play (van der Geest, 2011). Similarly, a recent survey by Mertz *et al*. (2010) has argued that climate factors played a limited role in past adaptation options of Sahelian farmers. Given the multiple drivers of migration (Black *et al.*, 2011a and b) and the complex interactions which mediate migratory decision-making by individual or households (Raleigh, 2008; McLeman and Smit, 2006; Kniveton *et al.*, 2011; Black *et al.*, 2011a and b), the projection of the effects of climate change on intra-rural and rural-to-urban migration remains a major challenge.

9.3.3.3.2. Trade

Agricultural exports accounted for around one sixth of world agricultural production in 2012, while this proportion was higher for some commodities such as oilseeds, sugar and fish (OECD-FAO, 2013). Global agricultural exports grew at an average annual rate of 9% in 2000-2005 and 11% in 2005-2011 (WTO, 2013: 63-72). Apart from a major price hike and high price volatility since 2007-2008, several structural and cyclical factors – such as droughts in major producers, expansion of area under biofuel crop production, financial speculation, export restrictions – have led to volatility and unpredictability in the trading environment (Chapter 7 this report, FAO, 2008; Cooke and Robles, 2009; Abbott 2008, Timmer, 2010; Schmidhuber and Matuschke, 2010; Karapinar and Haberli, 2010; Wright, B.D. 2011; Headey , 2011; Anderson and Nelgen, 2012; Nazlioglu, 2013). In the absence of extensive literature and reliable data on within-country trade, this section focuses on international trade in the specific context of climate change.

There is *medium agreement* and *limited evidence* that climate change will affect trade patterns and it will increase international trade volumes in both physical and value terms by altering the comparative advantage of countries and regions, and given its potential impacts on agricultural prices (Nelson et al., 2009b; 2010; 2013b; Tamiotti et al., 2009). For example, simulation based results from variants of the NCAR and CSIRO climate models (A2 scenario) suggest that climate change might lead to increases in export volumes (of rice, wheat, maize, millet, sorghum, and other grains) from developed to developing countries by 0.9 million mt to 39.9 million mt by 2050. Higher export volumes are expected if future scenarios consider CO_2 fertilization effects as they produce lower world prices than scenarios without CO_2 effects. Many regions including South Asia, East Asia and Pacific, Middle East, North Africa and Sub-Saharan Africa are projected to increase their imports substantially over this period. (Nelson *et al*., 2009b; 2010).

The recent literature highlights the potential role of trade in adaptation to climate impacts on global crop yields, while cautioning policy makers about the possible negative consequences of increased trade (Verburg *et al*., 2009; Lotze-Campen *et al*. 2010; Schmitz *et al.*, 2012; Huang *et al.*, 2011). Importing food might help countries adjust to climate-change induced domestic productivity shocks and mitigate related welfare losses (Tamiotti *et al.*, 2009; Reimer and Li, 2009). Countries might also capitalize on new export opportunities arising from higher achievable yields, for example in Argentina (Asseng *et al.*, 2013) or increasing heterogeneity of climate impacts on yields in neighbouring countries, for example in Tanzania (Ahmed *et al.*, 2012). Increased trade would lower the cost of food and thus help alleviate food insecurity, however if it is driven by an expansion of agricultural areas (especially to marginal land and to forests), it would also lead to negative environmental consequences in the form of loss of biodiversity, deforestation and additional carbon emissions (Verburg *et al.*, 2009; Schmitz *et al.*, 2012; Lotze-Campen *et al.*, 2010).

If climate change affects crop yields negatively, and results in increased frequency of extreme events (Chapter 3, IPCC, 2012), especially in low-income developing countries, the consequent short-term food deficits might need to be supplied, fully or partly, through food aid (Alderman, 2010). Hence food aid agencies, such as the United Nations World Food Programme, might face additional operational challenges (Barrett and Maxwell, 2006; Harvey *et al.*, 2010). Local or regional procurement of food aid, targeted distribution of food and safety net programs through direct income transfers could be part of an overall strategy to address climate-induced shocks to food security (see also Chapter 7) (Alderman, 2010; Harvey *et al.*, 2010).

The potential impacts of climate change on agricultural trade and the role that trade could play in adaptation will inevitably depend on countries' trade policies. There is *medium agreement* and *medium evidence* that deepening agricultural markets through trade reform, improved market access, avoiding export controls and developing institutional mechanisms to improve the predictability and the reliability of the world trading system as well as investing in additional supply capacity of small-scale farms in developing countries could help reduce market volatility and offset supply shortages which might be caused by climate change (Reimer and Li, 2009; Tanaka and Hosoe, 2011; Karapinar, 2011, 2012; Ahmed *et al.*, 2012, UNEP, 2009; Tamiotti et al., 2009).

9.3.3.3.3. Investment

Climate change may also affect investment patterns in rural areas. On the one hand, countries, regions and sectors that are expected to be affected adversely by climate change may have difficulty attracting investment. On the other hand, ecological zones that will become favourable due to climate change are expected to see increasing inflow of investment. The recent price hikes in agricultural commodities have led to new initiatives of foreign direct investment (FDI) in large-scale crop production (Anseeuw *et al.*, 2012; World Bank, 2010b), with capital-endowed countries with high food imports investing in large production projects in low-income countries endowed with low-cost labour forces, land and water resources. Climate change will lead to similar investment patterns. However, there is a risk that these new investments might not be integrated into local structures and that local populations will become increasingly vulnerable as they lose access to vital assets such as land and water (Anseeuw *et al.*, 2012).

9.3.3.3.4. Knowledge

Rural areas are increasingly exposed to diffusion of knowledge through migration, trade and investment flows, technology transfers, and improved communication and transport facilities (IFAD, 2010), although differentials on knowledge access and diffusion (e.g. access to high speed internet) between rural and urban areas remain, even in high-income countries. Future impacts of climate change on these channels of integration will affect the pace and intensity of knowledge transfers. If trade, migration and investment flows will be intensified as a result of climate change, this will have a positive impact on knowledge transfer both from and to rural areas.

Traditional Knowledge (TK) developed to adapt to past climate variability and change, can both be affected by climate change and used and transformed in adaptation (Nyong, *et al.*, 2007). Ettenger (2012) discusses how seasonal hunting camps among the Cree of Northern Quebec that were the occasion for intergenerational knowledge transfer have been disrupted by changing bird migrations, while new technologies such as the internet, GPS and satellite phones have been integrated into livelihood strategies. Climate-change induced migration can threaten TK transfer (Valdivia *et al.*, 2010; Gilles *et al.*, 2013). Disaster management by central government may undermine decentralization efforts, disfavouring TK transfer (Dekens, 2008).

9.3.3.4. Second-Order Impacts of Climate Policy

Policy responses for mitigation and adaptation affect rural people, their livelihoods and environments. Working towards increasing energy supply from renewable resources may result in landscape changes (Dockerty *et al.*, 2006; Prados 2010); increasing employment opportunities (del Río and Burguillo, 2008); or increasing conflicts for scarce resources, such as water (Gold and Bass, 2010; Blair *et al.*, 2011; McIntyre and Duane, 2011; Phadke, 2011).

Planning applications for wind energy schemes in the UK have been subject to local opposition when they are perceived as having negative impacts on rural landscape qualities (van der Horst, 2007, Jones and Eiser, 2010, Wolsink 2007). Governance of energy distribution is thus an important issue (Vermeylen, 2010; Devine-Wright, 2011). Steps towards energy self-sufficiency can reinforce rural autonomy in isolated rural communities, including indigenous groups (Love and Garwood, 2011).

Social responses to such changes are expected (Molnar, 2010). The promotion of biofuel crops has been an extremely controversial issue during the last decade, as they have potential socioeconomic impacts related to their asserted ability to act as stimulus for rural economies, promote changes in land ownership and affect food security (German *et al.*, 2011). Delucchi (2010) concludes that biofuels produced from intensive agriculture will aggravate stresses on water supplies, water quality and land use, and impact rural areas (through land-use change) and agriculture (see also Box CC-WE). Concerns about the impact of biofuel production on food security relates to increases in food prices, land concentration (and landgrabs), and competition for water (Eide, 2008; Müller *et al*., 2008, (German *et al.*, 2011)). Gurgel *et al*. (2007), who modeled potential production and implications of a global biofuels industry by the end of the century under a reference scenario and a high-mitigation scenario, recognized the need for a high land conversion rate to achieve moderate objectives. Delucchi (2010) suggests developing biofuels programs with low inputs of fossil fuels and chemicals, that do not require irrigation, and on land with little or no economic or ecological opportunity cost (Plevin *et al.*, 2010). This implies analysing each case in its context, including production for both local and global markets, and factoring in concerns for social, cultural, and economic costs of biofuel production (i.e. impact of biofuel production on indigenous livelihoods and culture).

International mechanisms for emission reduction through forest and land management have been developed under the global initiative REDD, now REDD+. These mechanisms are designed to use market tools (e.g. payment for ecosystem services) to reduce emissions, while providing social co-benefits following the principles of effectiveness, efficiency and equity (Hoang *et al.*, 2013; Hall, 2012; Brown *et al.*, 2008b). However, there have been many criticisms that the rural poor are excluded from participation (Hall, 2012; van Noordwijk *et al.*, 2010; Sikor *et al.*, 2010; Campbell, 2009); and that community participation can undermine a general decentralization of forest management (Phelps *et al.*, 2010).

9.3.4. Valuation of Climate Impacts

This section assesses studies that have adopted various economic methods for valuation of impacts of climate change on rural areas. This is a difficult task and should reflect the significance of the ecological service categories for different stakeholders, including women (Kennet 2009) and minority groups, and ideally the valuations of unit changes in the levels of those services across management options. Valuations can be made at individual or communal levels (Farber *et al.*, 2006) and often involve complexities with regard to the use of social discount rates for comparing intergenerational effects over varying time horizons (Dasgupta, 2011). Different understandings of value, and different philosophical approaches to address it may exist (Spangenberg and Settele, 2010; Kosoy and Corbera, 2010; Weisbach and Sunstein, 2008), which makes it more difficult to agree on valuation methodologies. The impacts of climate change are expected to be unequally distributed across the globe, with developing countries at a disadvantage, given their geographical position, low adaptive capacities (Stern, 2007; World Bank, 2010a) and the significance of agriculture and natural resources to the economies and people (World Bank, 2010a; Collier *et al.*, 2008). Both direct and indirect impacts have been projected, such as lower agricultural productivity, increase in prices for major crops, and rise in poverty (Hertel *et al.*, 2010), which have implications for rural areas and rural communities. This section discusses the valuation of impacts with reference to agriculture, fisheries and livestock, water resources, mining, extreme weather events and sea level rise, recreation, tourism and forestry. There are various channels through which changes in economic values may occur in rural areas, such as through changes in profitability, crop and land values and loss of livelihoods of specific communities through changes in fisheries and tourism values. Losses and gains in health status and nutrition, and wider economy-wide impacts such as changes in job availability and urbanization also impact economic values that accrue to rural communities, the opportunities and the constraints that rural communities experience and changes that rural landscapes undergo. Since rural areas are included, but not exclusively dealt with in calculations of economy wide GDP losses due to climate change impacts, these are not dealt with separately in this chapter. Studies on the health impacts of climate change for the most part do not distinguish between rural and urban areas, although there are specific vulnerabilities that communities in rural areas face arising from a variety of factors such as remoteness, lack of access to services and dependence on certain occupations such as farming which are dealt with in chapter 11, section 11.3. The impact on availability of fresh water resources is another major area of concern for the developing regions in particular. Climate change can adversely impact poverty through multiple channels (Section 10.9 and Chapter 13).

Viewing impacts regionally, despite the ongoing debates around the uncertainty and limitations of valuation studies, scholars generally agree that some African countries could experience relatively high losses compared to countries in other regions (World Bank, 2010a; Watkiss *et al*., 2010; Collier *et al.*, 2008). These conclusions emerge across a range of climate scenarios and models used by researchers. For instance, Watkiss *et al.* (2010) use the FUND model for a business-as-usual scenario and a scenario of mitigation to 450ppm and 2℃ global mean temperature increase as generated by using the PAGE2002 model, while the World Bank uses a range of country specific models for calculating costs. Global costs including adaptation costs are calculated for an approximately 2℃ warmer world by 2050 for Mozambique, Ethiopia, Ghana, Bolivia, Vietnam, Samoa and Bangladesh. Overall negative consequences are seen for Africa and Asia, due to changes in rainfall patterns and increases in temperature (Müller *et al*., 2011). Though climate change and climate variability would impact a range of sectors, water and agriculture are expected to be the two most sensitive to climatic changes in Asia (Cruz *et al*., 2007; Chapter 3) and for droughts in particular for Australia (Nelson *et al.*, 2007; Meinke and Stone 2005). In Latin American and Caribbean countries, higher temperatures and changes in precipitation patterns associated with climate change affect the process of land degradation, compromising extensive agricultural areas. Research on climate change impacts in rural North America has largely focused on the effects on agricultural production and on indigenous populations, many of whom rely directly on natural resources. Developed countries in Europe will be less affected than the developing world (Tol *et al.*, 2004), with most of the climate sensitive sectors located in rural areas.

Valuation and costing of climate impacts draw upon both monetary and non-monetary metrics. Most studies use models that estimate aggregated costs or benefits from impacts to entire economies, or to a few sectors, expressed in relation to a country's gross domestic product (GDP) (Stage, 2010; Watkiss, 2011). Values which are aggregated across sectors generalize across multiple contexts and could mask particular circumstances that could be significant to specific locations, while expressing outcomes in aggregated GDP terms. This is a matter of concern for economies in Africa and Asia, where subsistence production continues to play a key role in rural livelihoods. Valuation of non marketed ecosystem services poses further methodological and empirical concerns (Dasgupta, 2008; Dasgupta, 2009; Watkiss, 2011; Stage, 2010). Würtenberger *et al.* (2006) developed a methodology to estimate environmental and socio-economic impacts of agricultural trade regarding virtual land use, and Adger *et al.* (2011) use qualitative methodologies to consider non-market metrics of risk, focusing on place and identity based principles of justice, which recognizes individual and community identity in decision-making.

Integrated assessment models and cost-benefit tools have been criticized: for being inadequate to assess intergenerational events, or processes with high levels of uncertainty and irreversibility; for not considering equity concerns and power structures; for assigning monetary values on the basis of incomplete information or assuming speculative judgements regarding the monetary value of, e.g. natural resources (Ackerman et al. 2009; Kuik *et al.*, 2008); and for not recognising incommensurability (Aldred 2012). In recent years, various perspectives for valuing the economic impacts of climate change have come into focus including the feminist (Nelson 2008; Power 2009), deliberative (Zografos and Howarth 2010) or behavioural economics-based (Brekke and Johansson-Stenman 2008; Gowdy 2008), and the integration of economics with moral and political philosophy (Dietz *et al.*, 2008). Some common characteristics of these new approaches include interdisciplinarity, acknowledging the diversity of views and maintaining complexity in models. Research in this area although relatively recent, shows promise. Illustrative regional and sub-regional estimates for the value of agricultural and non-agricultural impacts of climate change, as available in the literature, are presented here.

9.3.4.1. Agriculture

Changes in agricultural production will have corresponding impacts on incomes and wellbeing of rural peoples. The largest known economic impact of climate change is upon agriculture because of the size and sensitivity of the sector, particularly in the developing world and to a lesser extent in parts of the developed world. A large number of studies to evaluate the impacts on the agricultural sector and its ramifications for communities have been conducted at various scales, ranging from micro level farm models to large scale regional and country level climate cum socio-economic scenario modeling exercises. Some of these also report values for associated economic losses.

Since models are simplifications of complex real world phenomena, different models tend to highlight different aspects of impacts and their consequent economic values. For instance, in estimating economic losses the Ricardian method has been used widely to study climate change impacts (with adaptation inbuilt) in agriculture. However, often such analysis does not incorporate features like technological progress, relative price changes, agricultural policy and other dynamic characteristics. Similarly on the bio-physical impacts side, changes in the El Niño/Southern Oscillation (ENSO) statistics may also have serious economic implications for the agricultural sector in certain countries such as in Latin America and Australia (Kokic *et al.*, 2007). However, ENSO responses differ strongly across climate models, and at the current stage of understanding do not allow conclusions to be drawn on how global warming will affect the Tropical Pacific climate system (Latif and Keenlyside, 2009). A sample of the available studies is provided in Table 9-5.

[INSERT TABLE 9-6 HERE
Table 9-6: Illustrative sample of studies on economic value and changes in value from climate change for the agriculture sector.]

9.3.4.2. Other Rural Sectors: Water, Fisheries, Livestock, Mining

The changes in valuation of water resources due to climate change arise from expected impacts on populations dependent on these water resources and these will be felt in several parts of the world (Sections 3.4.9, 3.5 and 3.8, Chapter 3, AR5). Monetary estimates of losses due to impacts on water resources are not generalizable. Among alternative approaches to value water resources, use of the water footprint tool (Hoekstra and Mekonnen, 2012) which measures human utilization of water by a nation and the concept of virtual water has been suggested for informing policy-makers in water-scarce countries, such as Egypt.

Analysis of intergenerational valuation has provided some interesting results in valuation of marine fisheries (Ainsworth and Sumaila 2005). For fisheries in rural coastal areas, some of the challenges faced include the valuation of environmental externalities such as breeding habitats, or mangroves, that might be lost due to climate change or other forces (Hall 2011). It has also been argued that the true worth of livelihoods dependent on fisheries in developing countries, where these constitute part of a diversified livelihood or subsistence strategy, requires a different set of metrics from those used in the developed world (Mills *et al.*, 2011). Climate change can also have significant impacts on livestock production (Section 9.3.3.1).

A relatively less researched area which may impact the livelihoods of rural communities is mining (Section 26.11.1.2). Economic viability of mining enterprises as well as communities dependent on them is vulnerable to climate change. Pearce *et al.* (2011) highlight concerns for Canada, where mining is a rural activity with few other available economic activities while Damigos (2012) finds economic losses for mining in the Mediterranean region and Greece in particular. Current and past infrastructure for mines was built under a no-climate change presumption and economic and ecological vulnerabilities as a result are substantial, and industry actors are unprepared to deal with this. There is little research in impacts on mining sectors in the US and Mexico. Changes in the energy and water sector present a complex mix of risks and opportunities for primary extraction and processing industries. Site management, transport of supplies and resources to and from mines, exploration activities and their associated costs are would determine the extent of loss, along with the importance of the sector in the local economy (Backus et al 2012).

9.3.4.3. Extreme Weather Events, Sea-Level Rise

The climate change related extreme events that may cause changes in economic values in rural areas include heat waves and droughts, storms, inundation and flooding (Stern 2007; Handmer *et al.*, 2012; Section 3.4.9, Chapter 3, AR5). A detailed discussion on the costs of climate extremes and disasters is set out by Handmer *et al.*, 2012. Costs can be of two kinds: losses or damage costs and costs of adaptation. While some of the costs lend themselves to monetary valuation (such as infrastructure costs) others cannot be easily estimated such as the value of lives lost and the value of eco system services lost (for discussion on the methodologies for valuing costs refer to Handmer *et al.*, 2012: Section 4.5.3).

Damage costs of floods and droughts (Section 10.3.1, chapter 10, AR5) and from sea-level rise in Europe (Swiss Re, 2009) demonstrate the cost implications for rural communities in the developed regions of the world. Studies mapping the adverse impacts in UK and Europe show a range of sectors that are impacted in rural areas particularly due to drought in Europe and flooding in UK, the worst effect being on summer crops in Mediterranean regions (Giannakopoulos *et al.*, 2009). Longer term adaptation could reduce the severity of losses but could include displacement of agricultural and forestry production from Southern Europe to the North. The UK Government's Foresight Programme (2004) estimates that global warming of 3 to 4 ºC could increase flood damage costs from 0.1% up to 0.4% of GDP. Much of the investment in flood defences and coastal protection would be in rural coastal areas.

Several studies from the developing countries provide evidence on the substantial costs rural communities in particular face in these countries. Salinity and salt water intrusion have implications for rural livelihoods as they impact both fisheries and agriculture (Section 5.5.3; Chapter 5). Sea-level rise also leads to wetland loss and coastal erosion. A few illustrations of the range of impacts of relevance for the rural economy are provided here. Loss of agricultural land and changes in the saline-freshwater interface is estimated to impact the economies of Africa adversely (SEI, 2009, S. Dasgupta *et al.*, 2009). Ahmed *et al.* (2009) suggest that climate volatility from increase in extreme events, increases poverty in developing countries, particularly Bangladesh, Mexico, Indonesia and countries in Africa. They also find that on simulating the effect of climate extremes on poverty in Mexico using the A2 scenario as generated by a CMIP3 multi-model dataset, rural poverty increases by 43-52% following a single climate shock due to climate extremes. Studying extreme events, Boyd and Ibarrarán (2009) use a CGE model to simulate the effects of persistent droughts on the Mexican economy and find declines in production of 10-20% across a variety of agricultural sectors between 2005 and 2026. Scenario-based stakeholder engagement has been tested for coastal management planning under climate change threats (Tompkins *et al*., 2008) and to determine impacts and responses of extreme-events in coastal areas (Toth and Hizsnyik, 2008).

9.3.4.4. Recreation and Tourism; Forestry

Studies assessing the changes in economic value of recreation and tourism due to climate change are relatively fewer in number (coastal tourism is discussed in Section 5.4.4.2; Chapter 5). Both sensitivity to climate variability and climate change have been considered in the literature. While some studies locate an increase in values for certain regions others estimate shifts in tourism and losses (Bigano *et al.*, 2007; Hamilton *et al*., 2005; Beniston, 2010), methodological challenges and contrasting findings for the short and long run pose problems in generalizing findings (economic values for recreation and tourism are discussed in Section 10.6). Change in economic values will impact rural communities (Lal *et al.*, 2011), with the linkages between biodiversity, tourism and rural livelihoods and rural landscapes being an established one both for developing and developed countries (Nyaupane and Poulde 2011, Scott *et al*., 2007, Hein *et al*., 2009, Wolfsegger et al 2008, Collins 2008).

It has been argued that climate change would have adverse impacts on various ecosystems, including forests and biodiversity in many regions of the world (Stern, 2007; Eliasch, 2008; Ogawa-Onishi *et al.*, 2010; ADB, 2009; Tran *et al.*, 2010; Preston *et al*., 2006) and these will have implications for rural livelihoods and economies (Chopra and Dasgupta, 2008; Safranyik and Wilson, 2006; Kurz *et al*., 2008; Walton, 2010, Fleischer and Sternberg 2006). However, monetary valuation of changes in non-marketed ecosystem services due to climate change continues to pose a challenge to researchers. To overcome some of the limitations, multicriteria analysis has been used for forest management (Fürstenau *et al*., 2007).

9.3.5. Key Vulnerabilities and Risks

9.3.5.1. Drivers of Vulnerability and Risk

Discussions on climate vulnerability in rural areas must recognize competing conceptualizations and terminologies of vulnerability, particularly those of "starting point" and "end-point" vulnerability (O'Brien *et al.*, 2007). The focus here is on starting point vulnerability, or contextual vulnerability (see Glossary and Chapter 19) while we consider risk to be the probability of adverse impact resulting from exposure and vulnerability (see Chapter 19). These distinctions are important, because, they can result in contradictory findings regarding vulnerability in rural areas, and the policy prescriptions derived therein are also different.

There is *low agreement,* but *medium evidence* on the direction in which some key factors may affect vulnerability or resilience in rural areas, including rain-fed as opposed to irrigated agriculture, small-scale and family-managed farms, integration into world markets, and diversification. Brouwer *et al.* (2007), contrary to expectations, found that vulnerability to flooding in Bangladesh in terms of damage suffered was lower for households that fully depended on natural resources than those who did not. Osbahr *et al.* (2008) found that diversification in rural areas does not always reduce vulnerability and can increase inequity within communities if it is not accompanied by reciprocity. There is *high agreement, robust evidence* on the importance for resilience of drivers such as access to land and natural resources, flexible local institutions and knowledge and information, and the association of gender and vulnerability (see Box CC-GC, and Chapter 13).

The most commonly used approaches to analyzing causes of vulnerability use the concepts of entitlements or livelihoods in evaluating the multi-scale factors shaping people's assets, as well as their adaptive capacity to hazards and stressors. Although vulnerability is experienced locally, its causes and solutions occur at different social, geographic, and temporal scales, and are seen as context-dependent (Ribot, 2010). Non-climate factors affecting vulnerability in rural areas at both individual and community levels (Eakin and Wehbe, 2009) include the following:

- Physical geography, e.g. desert or semi-desert conditions (Lioubimtseva and Henebry, 2009), remoteness (Horton *et al.*, 2010), level of dependence on climate conditions (Brondizio and Moran 2008; Sietz *et al.*, 2012)
- Economic constraints and poverty (Ahmed *et al.*, 2011; Macdonald *et al.*, 2009; Mertz *et al.*, 2009a; Sietz *et al.*, 2011)
- Gender inequalities (Nelson *et al.*, 2002)
- Social, economic and institutional shocks and trends (e.g. urbanization, industrialization, prevalence of female-headed households, landlessness, short-time policy horizons, low literacy, high share of agriculture in GDP), as well as demographic changes, HIV/AIDS, access and availability of food, density of social networks, memories of past climate variations, knowledge and long-term residence in the region (Macdonald *et al.*, 2009; Mougou *et al.*, 2011; Ruel *et al.*, 2010; Sallu *et al.*, 2010; Simelton *et al.*, 2009; Mertz *et al.*, 2009a; Parks and Roberts, 2006; Gbetibouo *et al.*, 2010b; Ahmed *et al.*, 2011; Cooper *et al.*, 2008; Brondizio and Moran, 2008; Seto 2011).

This section focuses on the following drivers of vulnerability to climate change: water, market orientation and farm scale, institutions and access to resources, gender, migration and access to information and knowledge.

9.3.5.1.1. Access to water

Reducing vulnerability requires a reduction of the multiple non-climate-related pressures on freshwater resources (e.g. water pollution, high water withdrawals) together with improvement of water supply and sanitation in developing countries (Kundzewicz *et al*., 2008). Water supply will be adversely affected by climate change, but vulnerability of populations will also be determined by other elements, such as the role of institutions in facilitating the access to water, or people's demand, which in turn is influenced by local cultural norms (Wutich *et al.*, 2012) and perceptions of vulnerability which may differ between men and women (Larson *et al.*, 2011). Improvements in technologies can reduce the perception of water scarcity and increase water demand without reductions in underlying vulnerability (El-Sadek, 2010; Sowers *et al.*, 2011). Where appropriate water management institutions exist and are effective, their role in improving rural livelihoods has been demonstrated, for example in Tanzania's Great Ruaha basin (Kashaigili *et al.*, 2009).

Past research has tended to agree that rain-fed agriculture is more vulnerable to climate change (Bellon *et al.*, 2011) and that irrigation is needed to decrease that vulnerability (Gbetibouo *et al.*, 2010a). More recent findings suggest that this is context-dependent and irrigation has been found to increase vulnerability in certain cases (Lioubimtseva and Henebry, 2009; Eakin, 2005). Cooper *et al.* (2008) concluded that in rainfed Sub-Saharan Africa the focus should be on improving productivity of rain-fed agriculture instead of irrigation as irrigation schemes are also being threatened by drought, and Ahmed *et al.* (2011) emphasize the role of drought-tolerant crops.

9.3.5.1.2. Market orientation and farm scale

Some authors argue that opening markets to international trade increases vulnerability of small farmers and poor people. However, linkages among international, regional and local markets are not clear, including how global prices affect regional and local prices in the long term (Ulimwengu *et al.*, 2009). Market integration is seen as reducing the capacity of indigenous or smallholder systems for dealing with climate risk in Bolivia (Valdivia *et al.*, 2010), Honduras (McSweeney and Coomes, 2011), Mexico (Eakin, 2005), Mozambique (Eriksen and Silva, 2009; Silva *et al.*, 2010), and in the Sahel (Fraser *et al.*, 2011) by variously accelerating socio-economic stratification and reducing crop diversity. On the other hand distance from large markets is seen as increasing vulnerability of rainfed mixed crop/livestock areas in sub-Saharan Africa (Jones and Thornton 2009) and the Peruvian Altiplano (Sietz *et al.*, 2011). Each case needs to be analysed within its complexity, considering interactions among all the factors that can affect vulnerability (Rivera-Ferre *et al.*, 2013a).

Regarding the scale of farms, some authors suggest that small-scale farming increases the vulnerability of communities in rural areas (Bellon *et al.*, 2011; Gbetibouo *et al.*, 2010b) although their resilience capacity (stemming from factors such as indigenous knowledge, family labour, livelihood diversification) should not be underestimated. Brondizio and Moran (2008) indicate that small farmers are less vulnerable than large, monocrop farmers when climatic variations make an area inappropriate for a particular crop, because they tend to cultivate multiple crops and work with on-farm biodiversity. However, they recognize that small farmers tend to suffer from technological limitations, low access to extension services, and market disadvantages.

9.3.5.1.3. Institutions, access to resources, and governance

Institutions and networks can affect vulnerability to climate change: through distribution of climate risks between social groups; by determining the incentive structures for adaptation responses; and by mediating external interventions (e.g. finances, knowledge and information, skills training) into local contexts (Ribot, 2010; Agrawal and Perrin, 2008). Institutions can decrease vulnerability (Anderson *et al.* 2010) or increase it (Eakin, 2005) Governance structures and communication flows as shown in a Swiss mountain region vulnerable to climate change (Ingold *et al.*, 2010) and the knowledge and perceptions of decision-makers are also important. Romsdahl *et al.*(2013) show that local government decision-makers in the US Great Plains resist seeing climate change as within their responsibilities, which has contributed to low levels of planning for either adaptation or mitigation, and thus to greater vulnerability, but that a reframing of issues around current resource management priorities could allow proactive planning.

Lack of access to assets, of which land is an important one, is accepted to be an important factor increasing vulnerability in rural people (McSweeney and Coomes 2011). The breakdown of traditional land tenure systems increases vulnerability, particularly for those who experience poorer land access as a result (Fraser *et al.*, 2011;

Dougill *et al.*, 2010; Brouwer *et al.*, 2007). Those that benefit, for example wealthier farmers who increased their landholding after privatization in Botswana, remain less vulnerable (Dougill *et al.* 2010).

9.3.5.1.4. Migration

The relationship of vulnerability to migration is complex. Areas of out-migration can experience reduced vulnerability if migrants send remittances, or increased vulnerability if the burden of work, usually for women, also increases. The decline in transmission of traditional knowledge through social networks can also increase vulnerability (Valdivia *et al.*, 2010). Furthermore, those places receiving migrants can experience an excessive demographic growth, which increases pressure over scarce resources, as is being experienced in the semi-arid tropics (Cooper *et al.*, 2008; Obioha, 2008). Brondizio and Moran (2008) found that in-migration in the Amazon brought people with knowledge that is ill-adapted to the local environment (see chapter 12.4)

9.3.5.1.5. Gender

Box CC-GC sets out the general issues on climate change and gender-related inequalities. These are of special relevance to rural areas, particularly, but not solely in the developing world (Alston, 2011; Vincent *et al.*, 2010; Nelson and Stathers 2009) (*high agreement, robust evidence*). Access to land shows strong differences between men and women, as do labour markets (FAO, 2010), and access to non-farm entrepreneurship (Rijkers and Costa, 2012). Less than 20% of the world's landholders are women, but women still play a disproportionate role in agriculture. On average women make up around 43% of the agricultural labour force in developing countries; in South Asia almost 70% of employed women work in agriculture, and more than 60% in sub-Saharan Africa (FAO, 2011; FAO, 2010). Climate change also increases vulnerability through male out-migration that increases the work to women (Chindarkar, 2012); cropping and livestock changes that affect gender division of labour (Lambrou and Paina, 2006); increased difficulty in accessing resources (fuelwood and water) (Tandon, 2007) and increased conflicts over natural resources (Omolo, 2011). Women are generally, though not in every context, more vulnerable to the impacts of extreme events, such as floods and tropical cyclones (Neumayer and Plümper, 2007).

9.3.5.1.6. Knowledge and information

Lack of access to information and knowledge of rural people can also interact with all the above mentioned drivers to mediate vulnerability. Shared knowledge and lessons learned from previous climatic stresses provide vital entry points for social learning and enhanced adaptive capacity (Tschakert, 2007). But while some authors emphasize the need for local responses and indigenous knowledge to reduce vulnerability (Valdivia *et al.*, 2010), and call for an integration of local knowledge into climate policies (Nyong *et al.*, 2007; Brugger and Crimmins 2012), Bellon *et al.* (2011) state that local knowledge is too local, and in some contexts gathering information from further away is important.

Access to information alone is not a guarantee of success. Coles and Scott (2009) found that in Arizona, despite ample access to weather forecasting, ranchers did not rely on such information, implying that changes are required to make more attractive information to users, as well as to understand prevailing local cultures and norms.
It is also important how knowledge is produced, managed, and disseminated within the formal institutional structure to address vulnerability issues. A local case-study in Sweden shows that limited co-operation between local sector organizations, lack of local co-ordination, and an absence of methods and traditions to build institutional knowledge present barriers to manage vulnerability (Glaas *et al.*, 2010). In Benin, as elsewhere in Africa, there is a lack of co-ordination between climate policies and the policies and practices which govern agricultural research and extension, while good practice at project level has been insufficiently harnessed to foster collective learning of farmers and other agricultural stakeholders, and thus adaptation to climate change (Moumouni and Idrissou 2013a and 2013b). For institutional learning, knowledge transfer, and more reliable assessments of local vulnerabilities, local institutional structure must be flexible, establishing communication mechanisms between public authorities, other knowledge producers, and civil society (Glaas *et al.*, 2010).

9.3.5.2. Outcomes

The outcome of vulnerability is the result of, and interaction of, the driving forces that determine vulnerability in a given sector, social group, etc. This section analyses how different drivers may affect specific vulnerable groups in rural areas, particularly pastoralists, mountain farmers and artisanal fisherfolk. Box 9-2 takes a specific economic sector important in rural areas, and demonstrates the interplay of vulnerability and exposure.

_____ START BOX 9-2 HERE _____

Box 9-2. Tourism and Rural Areas

The three major market segments of tourism most likely to be affected by climate change are rural-based, namely, coastal tourism, nature-based tourism and winter sports tourism (Scott *et al.*, 2012). Tourism is a significant rural land use in many parts of the world, yet compared to other economic sectors in rural areas, the impacts of climate change are typically under-researched. In the Caribbean, for example, tourism has overtaken agriculture in terms of economic importance, with several regional states (including the Bahamas, the Cayman Islands and St Lucia) receiving more than 60 percent of their GDP from this industry (Meyer, 2006). Coastal environments elsewhere in the world are also characterized by dependence on rural tourism, and are known to be vulnerable to cyclones and sea level rise (Klint *et al.*, 2012a; Payet, 2007).

Terrestrial natural resource-based tourism is also a significant foreign exchange earner in many countries. In sub-Saharan Africa, between 25 and 40% of mammal species in national parks are likely to become endangered by 2080, assuming no species migration (and 10-20% with the opportunity for migration) (Thuiller *et al.*, 2006). There are also many rural environments viewed as “iconic” or having cultural significance that are vulnerable to climate change. In South Africa, for example, the Cape Floral (fynbos) ecosystem has a high level of species endemism which will be vulnerable to the projected increase in dry conditions (Midgley *et al*., 2002; Boko *et al*., 2007). The projected increase in climate change-related hazards, such as glacial lake outbursts, landslides, debris flows and floods, may affect trekking in the Nepali Himalayas (Nyaupane and Chhetri, 2009).

The development of tourism has, in many cases, increased levels of exposure to climate change impacts. In the Caribbean, for example, tourism has led to considerable coastal development in the region (Potter, 2000), which may exacerbate vulnerability to sea-level rise. In many cases, the carbon emissions resulting from participating in rural tourism threaten the very survival of the areas being visited. This is often the case for very remote locations, for example polar bear tourism in Canada (Dawson *et al.*, 2010), dive tourism in Vanuatu (Klint *et al.*, 2012b). Although on aggregate resource consumption of tourists and locals has been shown to be similar in developed county contexts (e.g. in Italy – Patterson *et al*., 2007); in many developing countries resource use by tourists is much higher than that of locals (e.g. in Nepal - Nepal, 2008).

Despite the potential impacts of climate change on rural tourism, there is *low evidence* of significant concern, which impedes adaptive responses. Surveys in both the upper Norrland area of northern Sweden and New Zealand showed that climate change is not perceived to pose a major threat in the short term, relative to other business risks perceived by small business owners and tourism operators (Brouder and Landmark, 2011; Hall, 2006).

That said, there is evidence that, with planned adaptation, tourism can flourish in rural areas under climate change. In the Costa Brava region of Spain, for example, although the increasing temperatures and reduced water availability is projected to negatively impact tourism in the current high seasons, there is scope to shift to the current shoulder seasons, namely April, May, September and October (Ribas *et al.*, 2010). Recognition of the opportunities for adaptation has also necessitated reassessment of the extent of the potential impacts of climate change on the tourism industry in rural areas. With the availability of snowmaking as a (costly and uncertain) adaptation in the eastern North American ski industry, only four out of fourteen ski areas are at risk before 2029, but ten out of fourteen in the period 2070-2099 (Scott *et al.*, 2006).

_____ END BOX 9-2 HERE _____

9.3.5.2.1. Pastoralists

Pastoralists have developed successful strategies for responding to climate variability, especially "strategic mobility" in pursuit of high-quality grazing (Krätli *et al.* 2013), in combination with shorter-term coping strategies (Morton, 2006), for example in Sub-Saharan Africa (Davies and Bennett, 2007; Kristjanson et al. 2010) or Inner Mongolia (Wang and Zhang 2012). However, mobility, a key component for community resilience, is declining , increasing the vulnerability of people in arid and semiarid regions (Lioubimtseva and Henebry, 2009; Fraser *et al.*, 2011). The lack of other alternatives in certain marginal areas where animals are the only secure assets can lead to overstocking and overgrazing, and thus, to increased vulnerability of pastoralism (Cooper *et al.*, 2008).

This is "induced vulnerability" (Krätli *et al.*, 2013), arising from a range of social, economic, environmental and political pressures external to pastoralism that bring about encroachment on rangelands, inappropriate land policy, undermining of pastoral culture and values, and economic policies promoting uniformity and competition over diversity and complementarity. Other authors list as constituents of increased vulnerability: population growth; increased conflict over natural resources; changed market conditions and access to services under liberalization; concentration of political power in national centres; and perceptions that pastoralists are backward (Dougill *et al.*, 2010; Rivera-Ferre and López-i-Gelats, 2012; Smucker and Wisner, 2008; Dong *et al*,. 2011). These in turn can be seen as results of what Reynolds *et al.*, (2007) conceptualize as two key features of dryland populations: remoteness, and distance from the centres and priorities of decision-makers or "distant voice". However Dong *et al.* (2011) and Sietz *et al.* (2011) stress the geographic differentiation of pastoral systems (and more broadly of dryland systems).

9.3.5.2.2. Mountain farmers

Mountain ecosystems have been identified as extremely vulnerable to climate change (Fischlin et al. 2007), and thus populations have a high exposure to climate change. A detailed understanding of climate change impacts in mountain areas is difficult because of physical inaccessibility and scarcity of resources for research in mountain states and regions (Singh *et al.*, 2011), as well as more generic uncertainties relating to climate projection. Mountain dwellers, as pastoralists in drylands, are adapted to live in steep and harsh and variable conditions, and thus have a variety of strategies to adapt and foster resilience to changing climatic conditions. However, to develop their strategies they need to overcome other drivers that can affect their vulnerability in different contexts. For instance, in most developed countries, mountains are becoming depopulated (Gellrich *et al.*, 2007; López-i-Gelats, 2013; Gehrig-Fasel *et al.*, 2007) given the extreme climatic conditions, their remoteness and subsequent isolation, while in developing countries (e.g. tropical mountain areas) there is a trend towards increasing population (Lama and Devkota, 2009; Huber *et al.*, 2005). The impacts of the projected warming on mountain farming, as well as their adaptation strategies, differ spatially because the socioeconomic role of mountains varies significantly between industrialized and industrializing or non-industrialized countries (Nogués-Bravo *et al.*, 2007). Mountain grasslands in developed countries are usually managed via a sub-exploitation model that involves the intensive use of the most productive areas and the abandonment of those regions where production is economically less viable (López-i-Gelats *et al.*, 2011). In contrast, mountain grasslands in developing countries remain centres of fodder and livestock production. Thus, two general trends are identified in world mountain grasslands, while temperate grasslands tend to suffer from conversion to agriculture, and land abandonment where livestock raising is less feasible (Gellrich *et al.*, 2008); in tropical grasslands the main cause of degradation is overgrazing, linked to processes of demographic growth. Land privatization, loss of grazing rights, or changes in land use (e.g., development of infrastructure) also affect mountain farmers both in developed and developing countries (Tyler *et al.*, 2007; Xu *et al.*, 2008).

9.3.5.2.3. Artisanal fisherfolk

Small coastal and riparian rural communities face several drivers that increase their vulnerability, which remain largely ignored by mainstream fisheries policy analysts; for example, the potential impact of demographic, health and disease trends, or of wider development policy trends (Hall, 2011), pressure from other resources (e.g. water, agriculture, coastal defense), unbalanced property-rights; lack of adequate health systems, potable water, or sewage and drainage (Badjeck *et al.*, 2010). The most important drivers affecting small-scale fisheries can be grouped into: international trade and globalization of markets; technology; climate and environment; health and disease; demography; development patterns and aquaculture; for instance, freshwater fisheries are threatened by increasing irrigation, while vulnerability of coastal fisheries increases with mangrove loss to aquaculture facilities in response to growing markets for prawns (Hall, 2011). Another difficulty faced by fisheries-based livelihoods is the neglect of governments and researchers, which is more focussed on industrial fishing to the neglect of artisanal fishing (Mills *et al.*, 2011).

9.4. Adaptation and Managing Risks

9.4.1. Framing Adaptation

AR4 stated with very high confidence that adaptation to climate change was already taking place, but on a limited basis, and more so in developed than developing countries. Since then, the documentation of adaptation in developing countries has grown *(high confidence*). Adaptation is progressive, and is distinguished from coping as it reduces vulnerability in the cast of re-exposure to the same hazard (Vincent *et al*., 2013): it can therefore be identified even without high confidence that a local hazard or climate trend is attributable to global climate change – indeed many cases of adaptation are primarily driven by other stressors, but have the result of aiding adaptation to climate change (Berrang-Ford *et al.*, 2011).

Many adaptations do build on examples of responses to past variability in resource availability, and it has been suggested that the ability to cope with current climate variability is a prerequisite for adapting to future change (Cooper *et al*., 2008). At the same time, however, it cannot be assumed that past response strategies will be sufficient to deal with the range of projected climate change. In some cases, existing coping strategies may increase vulnerability to future climate change, by prioritising short–term resource availability (O’Brien *et al.*, 2007; Adepetu and Berthe, 2007). In Malawi, for example, forest resources are used for coping (gathering wild food and firewood to sell), but this process reduces the natural resource base and increases vulnerability to future flooding through reduced land cover and increased overland flow (Fisher *et al*., 2010). In developing countries, there is *high confidence* that adaptation could be linked to other development initiatives aiming for poverty reduction or improvement of rural areas (Nielsen *et al*., 2012; Hassan, 2010; Eriksen and O’Brien, 2007, section 13.4). For more information on the integration of adaptation and development in climate-resilient development pathways, see Chapter 20. In Ethiopia, for example, “low regrets” measures to respond to current variability are important to shift the trajectory from disaster-focused to longer-term vulnerability reduction (Conway and Schipper, 2011).

9.4.2. Decision-Making for Adaptation

Decision-making for adaptation takes place at a variety of levels, and can be public or private. International mechanisms variously support adaptation decision-making at all levels (see sections 14.4, 15.2). At the national and local levels, law and policies can enable planned adaptation (Stuart-Hill and Schulze, 2010). A longer history of evidence for public policies to support adaptation exists from developed countries, although increasingly developing countries are also introducing such policies (for more information see section 15.2; and Box 25-2 for information on Australia’s water policy and management, section 26.9.1 for information on federal adaptation policies in the USA and Canada). At local level, some progress towards adaptation planning has been observed, particularly in developed countries. In Australia, for example, Western Australia, South Australia and Victoria have mandatory State planning benchmarks for 2100 (see Box 25-1), and in the Great Plains of the US, some jurisdictions have developed plans on either climate adaptation or climate mitigation, although so far less than 20% have done so (Romsdahl *et al.*, 2013).

At the local level, many adaptations are examples of private decisions for adaptation, undertaken by NGOs (primarily in developing countries, often in the form of community-based adaptation), and companies and individuals. Public and private decision-making for adaptation is not always mutually exclusive: one example of where policy can support private adaptation is in the provision of index-based insurance schemes (Suarez and Linnerooth-Bayer, 2010; Linnerooth-Bayer and Mechler, 2007), which have variously been trialed in India, Africa and South America (Patt *et al*., 2010; Patt *et al*., 2009; for a case study on index-based weather insurance in Africa see Box 22-1). However, national policies and laws are not always mutually-supportive of private actions (Stringer *et al.*, 2009).

There is now *high confidence* that public decision-making for adaptation can be strengthened by understanding the decision-making of rural people in context, and in particular considering examples of autonomous adaptation and the interplay between informal and formal institutions (Eakin and Patt, 2011; Naess, 2012; Adhikari and Taylor, 2012; Bryan *et al.*, 2009). Adaptation can also build upon local and indigenous knowledge for responding to weather events and a changing climate as has been observed in Samoa (Lefale, 2010 – see chapter 29), the Solomon Islands (Rasmussen *et al*., 2009 – see chapter 29), Namibia (Newsham and Thomas, 2011), Canada (Nakashima *et al*., 2011-see chapter 24), the Indo-Gangetic Plains (Rivera-Ferre *et al*., 2013b), and Australia (Green *et al*., 2010)

9.4.3. Practical Experiences of Adaptation in Rural Areas

In AR4, examples of adaptation in rural areas exhibited a bias towards developed countries (chapter 17), but since then practical examples of adaptation in rural areas have increased substantially in developing countries (*very high confidence*). These practical experiences of adaptation are found in agriculture, water, forestry and biodiversity, and fisheries.

*9.4.3.1. Agricultur*e

Agricultural societies have a history of responding to the impacts of change in exogenous factors, including (but not limited to) weather and climate (Mertz *et al.*, 2009a). They undertake a range of adjustment measures relating to their farming practices – for example, planting, harvesting and watering/fertilizing existing crops; using different varieties, diversifying crops; implementing management practices such as shading and conservation agriculture. Table 9-7 gives some examples; Box 9-3 describes adaptation initiatives in the beverage crop sector: more information on agricultural adaptation is available in Sections 23.8.2 (Europe), 24.4.3.5 (Asia), 25.7.2 (Australasia), 26.5.4 (North America), 27.3.4.2 (Central and South America).

[INSERT TABLE 9-7 HERE
Table 9-7: Examples of adaptations in the agricultural sector in different regions.]

Conservation agriculture shows promising results and can be used as an adaptation (Speranza, 2013) and for sustainable intensification of production (Pretty *et al.*, 2011), with significant yield productions observed in South Asia and southern Africa (Erenstein *et al.*, 2012). See Box 22-2 for a case study on integrating trees into annual cropping systems. Water management for agriculture is also critical in rural areas under climate change, for example the use of rainwater harvesting (Kahinda *et al.*, 2010, Vohland and Barry, 2009; Rivera-Ferre *et al.*, 2013b), and more efficient irrigation, particularly in rural drylands (Thomas, 2008).

Adaptations are also evident among small-scale livestock farmers (Rivera-Ferre and López-i-Gelats, 2012; (Kabubo-Mariara, 2009, 2008), who use many different strategies, including changing herd size and composition, grazing and feeding patterns, or diversifying their livelihoods, also they may use new varieties of fodder crops suited to the changing conditions (Salema *et al.*, 2010).

Diversified farms are more resilient than specialized ones (Seo, 2010); but rural societies also diversify their income sources beyond agriculture, which in many contexts allows them to reduce their risk exposure. Examples include the exploitation of gums and resins in Kenya (Gachathi and Eriksen, 2011).There may be some rural areas, however, where limits to agricultural adaptation are reached, and thus the only option that remains is to migrate or diversify away from farming (Mertz *et al.*, 2011). According to chapter 7, adaptation leads to lower reductions in food production with more effective adaptation (of around 15-20% compared with no adaptation), and adaptations are more successful at higher latitudes (for maize, wheat and rice) than in tropical regions. Figure 7-8 shows the varying efficiency of different crop adaptation measures, with cultivar adjustment leading to the largest percentage difference from the baseline, compared with irrigation optimization and planting date adjustment (although this shows the largest variation).

9.4.3.2. Water

As well as being an important input to agriculture, adaptation in water resources through improved management is critical in rural areas, not only at basin level but also for human settlements (Mukheibir, 2008). The extent to which adaptation measures have been implemented to date varies: in a study from Europe, Africa and Asia, European basins were most advanced (Krysanova *et al.*, 2010). In the cases of transboundary basins additional barriers exist to adaptive management measures, particularly in Africa (Goulden *et al.*, 2009), although examination of potential institutional designs has been undertaken (Huntjens *et al.*, 2012). In the Middle East and North Africa, whilst supply-side measures are advanced, little attention has been paid to the demand-side measures that will be critical in a changing climate (Sowers *et al*., 2011).

Whilst the majority of focus on adaptation concerning water relates to its availability, many rural areas in both developed and developing countries are subject to riverine or coastal flooding. In the low-lying Netherlands protection measures have been employed, including increasing river runoff, increasing storage for water (Deltacommissie, 2008; Kabat *et al.*, 2009), and small scale containment of flood risks through increasing compartmentalization (Klijn *et al.*, 2009). In the Mekong Delta in Vietnam, the government's "living with floods" program has encouraged rice farmers to shift to aquaculture, while the planned relocation of 20,000 "landless and poor households" has altered social networks and livelihoods (De Sherbinin *et al.*, 2011). See Table 9-8 for further examples.

[INSERT TABLE 9-8 HERE
Table 9-8: Examples of adaptations in the water sector observed in different regions.]

More information on adaptation in the water sector is available in sections 24.4.1.5 and 24.4.2.5 (Asia), 26.3.3 (North America), 27.3.1.2 and 27.3.2.2 (Central and South America).

9.4.3.3. Forestry and Biodiversity

Effective management is also essential for adaptation of forests and biodiversity to climate change, particularly involving (where appropriate) communities (Porter-Bolland *et al*., 2012). Forest resources have been shown to play a role in enabling livelihood adaptation during extreme events in Zambia, Mali and Tanzania, although should take place within a managed context to ensure sustainability (Robledo *et al.*, 2011). As with water resources, forests can adapt through management of forest fires, silvicultural practices, and the conservation of forest genetic resources. Ecological restoration, where required, is another effective adaptation measure that enhances biodiversity and environmental services (Benayas *et al.*, 2009) and increases the potential for carbon sequestration and promotes economic livelihoods in rural areas (Chazdon, 2008), as seen in examples of the Brazilian Atlantic Forest (Calmon *et al.*, 2011; Rodrigues *et al.*, 2011). Direct species management is important (Mawdsley *et al.*, 2009). In terms of managing protected areas, to maintain appropriate habitats a network approach may be effective (Hole *et al.*, 2011).

As the climate changes, part of adaptive management may entail modification of existing biodiversity management practices. Manipulating vegetation composition and stand structure, for example, has been proposed as an adaptation option to wildfires in Canada (Terrier et a, 2013; Girardin *et al*., 2013); for more information on wildfires see Box 26-2. In Central and South America, protected areas of restricted use reduced fire substantially, but multi-use protected areas are even more effective; and in indigenous reserves the incidence of forest fire was reduced by 16% as compared to non-protected areas (Nelson and Chomitz, 2011).

Reflecting the growing evidence for community-based management and wise use, an emerging mechanism for ecosystem-based adaptation includes payment for ecosystem services (PES) (Montagnini and Finney, 2011). The PES literature is more developed for carbon payments, CDM and REDD+, but some research suggests potential for adaptation as well (see 13.3.1.2 for an assessment of the relationship between REDD+ and poverty alleviation). Particularly developed in Central and South America (see Table 27-7 for examples of PES schemes), communities can be paid for collecting scientific data to contribute to research and monitoring protocols (Luzar *et al.*, 2011), or for actively managing natural resources, which may improve adaptive capacity in the longer term, bearing in mind with reforestation there is a time delay before payments are received (Locatelli *et al*., 2008). More indirectly, there are opportunities for PES to contribute to adaptation indirectly through natural adaptation co-benefits (for example water regulation and soil protection for reduced climate impacts in watersheds)(Pramova *et al*., 2012) and through the creation of institutional structures that may support adaptive capacity (Wertz-Kanounnikof *et al*., 2012). For further case studies on ecosystem-based adaptation see Figure 22-8 (Africa), Box CC-EA (cross-chapter), Section 14.3.2; and for a diagrammatic representation see Figure CC-EA-1. More information on adaptation for forestry and biodiversity is available in Sections 23.8.2 and 23.8.4 (Europe), 24.5.1 (Asia) and 25.7.1.2 (Australasia).

9.4.3.4. Fisheries

Adaptation in marine ecosystems is also of relevance to rural areas. As with terrestrial natural resources, evidence from the marine resources sphere shows that a transformative approach to fisheries co-management, introducing ecosystem, rights and participation principles is essential for adaptation (Andrew and Evans 2011; Charles 2011). Such an approach, involving local fishermen and allowing limited extraction of resources, favours a balance between resource conservation and livelihoods, e.g. in Brazil (Francini-Filho and Moura, 2008), and the improvement of livelihoods, as well as the cultural survival of traditional populations (Hastings, 2011; Moura *et al*., 2009)(see also section 30.6.2.1). Selective use of fishing gear is a recommended management measure, based on 15 global sites, to ensure sustainable harvesting of remaining fish stocks (Cinner *et al.*, 2009). According to section 6.4.1.1, appropriate management will have a greater impact on biological and economic conditions than climate change. Table 30-2 outlines potential adaptation options and supporting policies for fisheries and aquaculture in the Pacific Islands considering a variety of timescales. Section 7.5 gives additional examples on adaptation for aquaculture.

_____ START BOX 9-3 HERE _____

Box 9-3. Adaptation Initiatives in the Beverage Crop Sector

One of the leading initiatives to prepare small holder producers of beverage crops for adaptation to climate change is the AdapCC project which worked with coffee and tea producers in Latin America and East Africa (Schepp, 2010). This process used risk and opportunity analysis and participatory capacity building (CafeDirect/GTZ, 2010) to help farmers identify changes in management practices to both mitigate their contribution to climate change and adapt to the changes in climate they perceived to be occurring. In general the actions for adaptation were a reinforcement of principles of sustainable production, such as using tree shade. Facilitating processes of adaptation in the context of strong variability in vulnerability between different communities in the same region and even families within the same community (Baca 2011) will be a challenge, but supports the need for participatory community adaptation processes that would enable families to implement strategies appropriate to their own circumstances and capacity.

Policy recommendations to support adaptation in these sectors (Eakin *et al.*, 2011; Laderach *et al.*, 2010 Schepp, 2010; Schroth *et al.*, 2009) have prioritized the follows interventions to support adaptation:

- Community-based analysis of climate risks and opportunities as a basis for community adaptation strategies
- Improved recording and access to climate information including medium and long-term predictions
- Sustainable production techniques including soil and water conservation, shaded production systems, diversification of production systems
- Development of new varieties with broader adaptability to climate variation, higher temperatures and increased drought tolerance
- Financial support to invest in adaptation and reduce risks through climate insurance

- Organization of small producers to improve access to knowledge, financial support and coordinate implementation
- Environmental service payments and access to carbon markets to support sustainable practices
- Development of value chain strategies across all actors to support adaptation and increase resilience across the sectors.

There are possibilities for synergy between adaptation and mitigation. The sustainability standards Rainforest Alliance and Common Code for the Coffee Community are piloting climate-friendly standards for producers that aim to reduce the GHG emissions from agricultural practices, increase sequestration of carbon in soils and trees, but also prepare producers for adapting to climate change (SAN, 2011; Linne, 2011. The later consists of improved understanding of climate impacts and promoting sustainable production practices to increase resilience in the production systems.

_____ END BOX 9-3 HERE _____

9.4.4. Limits and Constraints to Rural Adaptation

The Fourth Assessment Report stated with *very high confidence* that there are substantial limits and barriers to adaptation (Adger *et al.*, 2007). Limits are typically defined (Dow *et al.*, 2013) as hard, i.e. they will not change over time, and are particularly applicable to biophysical systems (where, for example, there are critical thresholds to species and ecosystem tolerances of climate parameters and regimes). Constraints, on the other hand, are typically soft, and are more relevant to social systems, where changes in factors such as financial and physical resources, technology and infrastructure, knowledge and information and human resources may change over time. For further information, see Figure 16-1 and Sections 16.3.2 and 16.4.1. Here we focus on the soft constraints in social systems that act as barriers to implementation of practical adaptation options in rural areas.

As with risks and vulnerabilities, the literature emphasizes constraints to adaptation in rural areas in developing regions, although adaptation bottlenecks exist also in developed countries (where there has been an increase in awareness and planning for adaptation, but that has not necessarily translated into implementation – see chapter 14). Constraints to adaptation in developed regions have been observed in North America (Section 26.8.4.2) and Australasia (Section 25.4.2, Boxes 25-1, 25-2 and 25-9). Another key bottleneck comes from the fact that the need for adaptation to climate change is not the only pressing issue in rural areas in developed countries (Kiem and Austin, 2013).

There is *very high confidence* that lack of financial resources (in the form of credit) and physical resources (such as water and land) are major factors inhibiting adaptation for farmers in Africa and Asia (e.g. Ringler, 2010; Deressa *et al*., 2009; Bryan *et al*., 2009; Hassan and Nhemachena, 2008). A multinomial logit analysis of climate adaptation responses suggested that access to water, credit, extension services and off-farm income and employment opportunities, tenure security, farmers' asset base and farming experience are key to enhancing farmers' adaptive capacity (Gbetibouo *et al.*, 2010).

Rural households’ lack of access to technologies and infrastructure (e.g. markets) is also a major barrier to adaptation for certain production systems (*high agreement, medium evidence*). According to a study of adoption of improved, high yield maize in Zambia, production and price risks could render input use unprofitable and prevent rural households from benefiting from technological change crucial for adaptation (Langyintuo and Mungoma, 2008). The severe 1997 drought in the Central Plateau of Burkina Faso highlighted that household with a larger resources base took the advantage of distress sales and high prices of agricultural commodities (Roncoli *et al.*, 2001). A nationally representative rural household survey in Mozambique from 2005 shows that, overall, using an improved technology (improved maize seeds, improved granaries, tractor mechanization, and animal traction) did not have a statistically significant impact on household income. However when distinguishing between households using improved technologies, especially improved maize seeds and tractors, and those who do not, households who had better market access had significantly higher income (Cunguara and Darnhofer, 2011). A multinomial choice model fitted to data from a cross-sectional survey of over 8000 farms from 11 African countries showed that better access to markets, extension and credit services, technology and farm assets (labour, land and capital) are critical for helping African farmers adapt to climate change. Hence education, markets, credit and information about adaptation to climate change, including technological and institutional methods are important (Hassan and Nhemachena, 2008).

Although access to credit, water, technologies and markets are barriers, more fundamental is access to knowledge and information (*very high confidence)*. Since adaptation strategies involve dealing with uncertainty, whether stakeholders have access to information for decision making and how they perceive and utilize this information affects their adaptation choices (Ringer, 2010; Bryan *et al*., 2009; Deressa *et al*., 2009; Sheate *et al.*, 2008; Patt and Schröter, 2008; Dockerty *et al.*, 2006). Relevant information includes that on agricultural technologies that can be used in adaptation, but in developing countries agricultural research and extension systems are not integrated with climate planning to deliver this, as discussed by Moumouni and Idrissou (2013a) for Benin. There is now an important literature on dissemination of short-term or seasonal weather forecasts to farmers in developing countries, as detailed in Box 9-4.

Access to information is affected by human resources, or social characteristics (*high agreement, medium evidence*). These include culture, gender, age, governance and institutions (Jones and Boyd, 2011; Nielsen and Reenberg, 2010; Deressa *et al*., 2009; Goulden *et al*., 2009). A growing body of literature investigates the socio-cognitive, psychological and cultural barriers to adaptation. Section 2.2.1.2 explains how culture and psychology affect decision-making; Section 16.2 also discusses how the framing of adaptation depends on perception of risk and values. For planned adaptation to be successful, or autonomous adaptation to occur, actors need to be convinced of the magnitude of risks of climate change (Patt and Schröter, 2008).

_____ START BOX 9-4 HERE _____

Box 9-4. Factors Influencing Uptake and Utility of Climate Forecasts in Rural Africa

The IPCC SREX report identified the use of forecasts as a risk management measure (IPCC, 2012). So far the uptake of weather and climate information has been suboptimal (Vogel and O'Brien, 2006). In Africa annual climate information (e.g. seasonal forecasts) is more used than climate change scenarios for agricultural development (Ziervogel and Zermoglio, 2009), although attempts to use longer term climate projections for crop forecasting and livestock farming have been examined (Challinor, 2009; Boone *et al.*, 2004). The potential for improved prediction and effective timely dissemination of such information has been noted in different sectors, including water managers (Ziervogel *et al*., 2010a) and disaster planners (Tall *et al.*, 2012), as well as farmers (both arable and pastoral)(Archer *et al*., 2007; Klopper *et al*., 2006, Bryan *et al*., 2009).

Extensive research has taken place to assess factors influencing uptake and utility of climate forecasts, including mapping of dissemination through stakeholder networks (Ziervogel and Downing, 2004), and user needs (Ziervogel, 2004). Such studies have shown that various factors affect dissemination and use: including stakeholder involvement in the process (usually higher when participatory processes had taken place) (Peterson *et al.*, 2010; Roncoli et al, 2009); effects of user wealth, risk aversion, and presentational parameters, such as the position of forecast parameter categories, and the size of probability categories (Millner and Washington, 2011), and the legitimacy, salience, access, understanding and capacity to respond (Hansen *et al*., 2011). Gender differences have been observed in preferred dissemination channels (Archer, 2003; Naab and Korenteng, 2012).

There are promising signs for the integration of scientific-based seasonal forecasts with indigenous knowledge systems (Ziervogel *et al*., 2010b; Speranza *et al.*, 2010). Ensuring improved validity and utility of seasonal forecasts will require collaboration of researchers, data providers, policy developers and extension workers (Coe and Stern, 2011), as well as with end users. Additional opportunities to benefit rural communities come from expanding the use of seasonal forecast information for coordinating input and credit supply, food crisis management, trade and agricultural insurance (Hansen *et al*., 2011). For more information on climate information and services, and the history, politics and practice of this area, see section 2.4.1.

_____ END BOX 9-4 HERE _____

9.5. Key Conclusions and Research Gaps

9.5.1. Key Conclusions

This chapter has assessed impacts of climate change, vulnerability to climate change and prospects for adaptation to climate change in the rural areas of the world. Rural areas are distinctive and important in the context of climate change because:

- They account for nearly half of the world's population, even with rapid urbanization
- They account for well over half of the world's poor and extremely poor people
- Economic activity and livelihoods in rural areas are closely linked to natural resources and thus particularly sensitive to climate variability and climate change
- Conversely, it is in rural areas that long-established adaptations to climate variability exist and can form a basis under certain conditions for adaptations to climate change.

Rural areas are both hard to define – there is no internationally valid definition, and definitions that do exist depend on definitions of the urban (see Table 9-1). They are also extremely diverse, existing in nearly every country of the world, across low-, middle- and high income- countries, although 90% of the world's rural population lives in low- and middle-income countries, which receive particular attention in this chapter. Rural areas are undergoing important and rapid changes in terms of their demography, economic profile and governance (see Table 9-3); some specific to developing countries, some to high-income counties and some generic. Many of these changes are in the direction of economic and livelihood diversification away from agriculture and natural resources. Others are in the direction of increased rural-urban interdependencies and less well-defined boundaries between the rural and the urban.

Many of the non-climate factors characterizing rural areas and populations within them, especially in low- and middle-income countries, are cited as factors increasing vulnerability to climate change. There is *high agreement* on the importance for resilience of access to land and natural resources, flexible local institutions, and knowledge and information, and the association of gender inequalities with vulnerability. There are *low levels of agreement* on some of the key factors associated with vulnerability or resilience in rural areas, including rainfed as opposed to irrigated agriculture, small-scale and family-managed farms, and integration into world markets. Specific livelihood niches such as pastoralism and artisanal fisheries are vulnerable and at high risk of adverse impacts (*high confidence*), partly due to neglect, misunderstanding or inappropriate policy towards them on the part of governments (9.3.5).

Against this background, discussion of impacts of climate change will be complex. The impacts of climate change on patterns of settlement, livelihoods and incomes in rural areas will be the result of multi-step causal chains of impact, starting either with increased frequency of extreme events or with more gradual manifestations of climate change, and working through impacts on agriculture, ecosystems or infrastructure. This increases the uncertainty associated with any particular projected impact. Biophysical impacts on food production are discussed in Chapter 7: this is supplemented here by an assessment of impacts on the production of non-food crops on which many millions of rural people depend, illustrated in particular by coffee, tea and cocoa (Box 9-1). Literature on the downstream impacts on incomes and livelihoods of changes in agricultural production (including livestock and fisheries) is also assessed.

Despite methodological problems in attribution, around the difficulties of attributing extreme events to climate change, the status of local knowledge, and the action of non-climate shocks and trends, evidence for observed impacts, both of extreme events and other categories, is increasing. Impacts on income and livelihoods can be inferred from biophysical impacts, but with *low confidence*. There is *high confidence* in geographically-specific impacts such as glacier melt in the Andes (9.3.2).

Major impacts of climate change in rural areas will be felt through impacts on agricultural production and therefore through agricultural incomes. In some regions shifts in agricultural production, of food and non-food crops, are *likely* to take place, not only as a result of changes in temperature and rainfall, but also through changes in availability of irrigation water, which are not necessarily factored into crop yield projections based on crop models

(9.3.3.1). There are also *likely* to be impacts on rural infrastructure both in developing and developed countries (9.3.3.2).

The interconnections between rural and urban areas will be affected in complex ways. Climate change will impact international trade volumes in both volume and value terms (*medium agreement, limited evidence).* Options exist for adaptations within international agricultural trade (*medium confidence)* to reduce market volatility and manage food supply shortages caused by climate change. Migration patterns will be driven by multiple factors of which climate change is only one (*high confidence*) and establishment of a relation between climate change and intra-rural and rural-to-urban migration, observed or projected, remains a major challenge (9.3.3.3).

Climate policies, such as increasing energy supply from renewable resources, encouraging cultivation of biofuels, or payments under REDD, will have significant secondary impacts, both positive (increasing employment opportunities) and negative (landscape changes, increasing conflicts for scarce resources), in some rural areas (*medium confidence*). These secondary impacts, and trade-offs between mitigation and adaptation in rural areas, have implications for governance, including the need to promote participation of rural stakeholders (9.3.3.4).

Most studies on valuation highlight that climate change impacts will be significant especially for the developing regions, due to their economic dependence on agriculture and natural resources, low adaptive capacities, and geographical locations (*very high confidence*). In rural areas especially, valuation of climate impacts needs to draw upon both monetary and non-monetary indicators.The valuation of non-marketed ecosystem services and the limitations of economic valuation models which aggregate across multiple contexts pose challenges for valuing impacts in rural areas and require interdisciplinarity and innovative approaches (9.3.4).

There is a growing body of literature on successful adaptation in rural areas and constraints upon it, including both documentation of practical experience, and discussion of preconditions (9.3.4). In developing countries adaptation can be linked to other development initiatives aiming for poverty reduction or improvement of rural areas, and “low regrets” measures to respond to current variability can shift the trajectory from disaster-focused to longer-term vulnerability reduction. Prevailing constraints, such as low levels of educational attainment, environmental degradation, gender inequalities, and isolation from decision-making create additional vulnerabilities which undermine rural societies’ ability to cope with climate risks (*high confidence*). The supply of information and opportunities for learning will be a key issue.

9.5.2. Research Gaps

There is a major continuing need for research on climate change in rural areas, which takes in their nature as areas with shifting combinations of human activity, in which agriculture (food crops, non-food crops and livestock) is important but not necessarily predominant. Such research will need to be developed, and extended to rural areas and diverse categories of rural people throughout the world.

Integrated research is needed on changes in land-use and trade-offs between land-uses under climate change, including non-agricultural land-uses such as conservation, and tourism. It should examine the trade-offs and synergies between adaptation and mitigation in rural areas, the impact of climate policies on rural livelihoods, and the appropriate structures for governance of natural resources at a landscape level for both developed and developing countries.

Research is required on the valuation and costing of climate change impacts, which takes note of the complexity and specificity of rural areas, with special emphasis on non-marketed ecosystem services and specific populations that have not as yet been studied.

More research is needed on vulnerability, to identify the most vulnerable areas, populations and social categories, but it should include research on methodological questions such as conceptualizations of vulnerability, assessment tools, spatial scales for analysis, and the relations between short-term support for adaptation, policy contexts and development trajectories, and long-term resilience or vulnerability.

A relevant area will be that of improving understanding of rural-urban linkages, their evolution and their management under climate change, including the respective roles of climate and other factors in rural-urban migration.

Research is needed on practical adaptation options, not only for agriculture but for non-agricultural livelihoods. Adaptation research must also look at adaptations to institutions, to better enable them to address lack of access to credit, markets, information, risk-sharing tools and property rights. Research must be open to participatory and action-research approaches which build on both local and scientific knowledge, and foster learning for adaptation and resilience among rural people.

Frequently Asked Questions

FAQ 9.1: What is distinctive about rural areas in the context of climate change impacts, vulnerability and adaptation? *[to be placed in Section 9.1.2]*
Nearly half of the world's population, approximately 3.3 billion people, lives in rural areas, and 90% of those people live in developing countries. Rural areas in developing countries are characterized by a dependence on agriculture and natural resources, high prevalence of poverty, isolation and marginality, neglect by policy-makers, and lower human development. These features are also present to a lesser degree in rural areas of developed countries, where there are also a closer interdependencies between rural and urban areas (such as commuting), and where there are also newer forms of land-use such as tourism and recreational activities (although these also generally depend on natural resources.

The distinctive characteristics of rural areas make them uniquely vulnerable to the impacts of climate change because:

- Greater dependence on agriculture and natural resources makes them highly sensitive to climate variability, extreme climate events and climate change
- Existing vulnerabilities caused by poverty, lower levels of education, isolation and neglect by policy makers, can all aggravate climate change impacts in many ways.

Conversely, rural people in many parts of the world have, over long timescales, adapted to climate variability, or at least learned to cope with it. They have done so through farming practices and use of wild natural resources (often referred to as indigenous knowledge or similar terms), as well as through diversification of livelihoods and through informal institutions for risk-sharing and risk management. Similar adaptations and coping strategies can, given supportive policies and institutions, form the basis for adaptation to climate change, although the effectiveness of such approaches will depend on the severity and speed of climate change impacts.

FAQ 9.2: What will be the major climate change impacts in rural areas across the world?
[to be placed in Section 9.3.3.4]
The impacts of climate change on patterns of settlement, livelihoods and incomes in rural areas will be complex and will depend on many intervening factors, so they are hard to project. These chains of impact may originate with extreme events such as floods and storms, some categories of which, in some areas, are projected with high confidence to increase under climate change. Such extreme events will directly affect rural infrastructure and may cause loss of life. Other chains of impact will run through agriculture and the other ecosystems (rangelands, fisheries, wildlife areas) on which rural people depend. Impacts on agriculture and ecosystems may themselves stem from extreme events like heat waves or droughts, from other forms of climate variability, or from changes in mean climate conditions like generally higher temperatures. All climate-related impacts will be mediated by the vulnerability of rural people living in poverty, isolation, or with lower literacy etc., but also by factors that give rural communities resilience to climate change, such as indigenous knowledge, and networks of mutual support.

Given the strong dependence in rural areas on natural resources, the impacts of climate change on agriculture, forestry and fishing, and thus on rural livelihoods and incomes, are likely to be especially serious. Secondary (manufacturing) industries in these areas, and the livelihoods and incomes that are based on them will in turn be substantially affected. Infrastructure (e.g. roads, buildings, dams and irrigation systems) will be affected by extreme events associated with climate change. These climate impacts may contribute to migration away from rural areas, though rural migration already exists in many different forms for many non-climate-related reasons. Some rural areas will also experience secondary impacts of climate policies – the ways in which governments and others try to reduce net greenhouse gas emissions such as encouraging the cultivation of biofuels or discouraging deforestation. These secondary impacts may be either positive (increasing employment opportunities) or negative (landscape changes, increasing conflicts for scarce resources).

FAQ 9.3: What will be the major ways in which rural people adapt to climate change?
[to be placed in Section 9.4.4]
Rural people will in some cases adapt to climate change using their own knowledge, resources and networks. In other cases governments and other outside actors will have to assist rural people, or plan and execute adaptation on a scale that individual rural households and communities cannot. Examples of rural adaptations will include modifying farming and fishing practices, introducing new species, varieties and production techniques, managing water in different ways, diversification of livelihoods, modifying infrastructure, and using or establishing risk sharing mechanisms, both formal and informal. Adaptation will also include changes in institutional and governance structures for rural areas.

Box CC-GC. Gender and Climate Change

[Jon Barnett (Australia), Marta G. Rivera Ferre (Spain), Petra Tschakert (U.S.A.), Katharine Vincent (South Africa), Alistair Woodward (New Zealand)]

Gender, along with socio-demographic factors of age, wealth and class, is critical to the ways in which climate change is experienced. There are significant gender dimensions to impacts, adaptation and vulnerability. This issue was raised in WGII AR4 and SREX reports (Adger *et al.*, 2007; IPCC, 2012), but for the AR5 there are significant new findings, based on multiple lines of evidence on how climate change is differentiated by gender, and how climate change contributes to perpetuating existing gender inequalities. This new research has been undertaken in every region of the world (e.g. Brouwer *et al.*, 2007; Nightingale, 2009; Buechler, 2009; Nelson and Stathers, 2009; Dankelman, 2010; MacGregor, 2010; Alston, 2011; Arora-Jonsson, 2011; Resureccion, 2011; Omolo, 2011).

Gender dimensions of vulnerability derive from differential access to the social and environmental resources required for adaptation. In many rural economies and resource-based livelihood systems, it is well established that women have poorer access than men to financial resources, land, education, health and other basic rights. Further drivers of gender inequality stem from social exclusion from decision-making processes and labour markets, making women in particular less able to cope with and adapt to climate change impacts (Rijkers and Costa, 2012; Djoudi and Brockhaus, 2011; Paavola, 2008). These gender inequalities manifest themselves in gendered livelihood impacts and feminisation of responsibilities: whilst both men and women experience increases in productive roles, only women experience increased reproductive roles (Resureccion, 2011; 9.3.5.1.5, Box 13-1). A study in Australia, for example, showed how more regular occurrence of drought has put women under increasing pressure to earn off-farm income, and contribute to more on-farm labor (Alston, 2011). Studies in Tanzania and Malawi demonstrate how women experience food and nutrition insecurity since food is preferentially distributed among other family members (Nelson and Stathers, 2009; Kakota *et al.*, 2011).

AR4 assessed a body of literature that focused on women's relatively higher vulnerability to weather-related disasters in terms of number of deaths (Adger *et al.*, 2007). Additional literature published since that time adds nuances by showing how socially-constructed gender differences affect exposure to extreme events, leading to differential patterns of mortality for both men and women (*high confidence*) [11.3.3, Table 12-3]. Statistical evidence of patterns of male and female mortality from recorded extreme events in 141 countries between 1981-2002 found that disasters kill women at an earlier age than men (Neumayer and Plümper, 2007) [Box 13-1]. Reasons for gendered differences in mortality include various socially- and culturally-determined gender roles. Studies in Bangladesh, for example, show that women do not learn to swim and so are vulnerable when exposed to flooding (Röhr, 2006) and that, in Nicaragua, the construction of gender roles means that middle-class women are expected to stay in the house, even during floods and in risk-prone areas (Bradshaw, 2010). While the differential vulnerability of women to extreme events has long been understood, there is now increasing evidence to show how gender roles for men can affect their vulnerability. In particular, men are often expected to be brave and heroic, and engage in risky life-saving behaviors that increase their likelihood of mortality [Box 13-1]. In Hai Lang district, Vietnam, for example, more men died than women due to their involvement in search and rescue and protection of fields during flooding (Campbell *et al.*, 2009). Women and girls are more likely to become victims of domestic violence after a disaster, particularly when they are living in emergency accommodation, which has been documented in the U.S. and Australia (Jenkins and Phillips, 2008; Anastario *et al.*, 2009; Alston, 2011; Whittenbury, 2013; Box 13-1).

Heat stress exhibits gendered differences, reflecting both physiological and social factors (11.3.3). The majority of studies in European countries show women to be more at risk, but their usually higher physiological vulnerability can be offset in some circumstances by relatively lower social vulnerability (if they are well connected in supportive social networks, for example). During the Paris heat wave, unmarried men were at greater risk than unmarried women, and in Chicago elderly men were at greatest risk, thought to reflect their lack of connectedness in social support networks which led to higher social vulnerability (Kovats and Hajat, 2008). A multi-city study showed geographical variations in the relationship between sex and mortality due to heat stress: in Mexico City, women had a higher risk of mortality than men, although the reverse was true in Santiago and Sao Paulo (Bell *et al.*, 2008).

Recognizing gender differences in vulnerability and adaptation can enable gender-sensitive responses that reduce the vulnerability of women and men (Alston, 2013). Evaluations of adaptation investments demonstrate that those approaches that are not sensitive to gender dimensions and other drivers of social inequalities risk reinforcing existing vulnerabilities (Figueiredo and Perkins, 2012; Arora-Jonsson, 2011; Vincent *et al.*, 2010). Government-supported interventions to improve production through cash-cropping and non-farm enterprises in rural economies, for example, typically advantage men over women since cash generation is seen as a male activity in rural areas (Gladwin *et al.*, 2001;13.3.1). In contrast, rainwater and conservation-based adaptation initiatives may require additional labor which women cannot necessarily afford to provide (Baiphethi *et al.*, 2008). Encouraging gender-equitable access to education and strengthening of social capital are among the best means of improving adaptation of rural women farmers (Below *et al.*, 2012; Goulden *et al.*, 2009; Vincent *et al.*, 2010) and could be used to complement existing initiatives mentioned above that benefit men. Rights-based approaches to development can inform adaptation efforts as they focus on addressing the ways in which institutional practices shape access to resources and control over decision-making processes, including through the social construction of gender and its intersection with other factors that shape inequalities and vulnerabilities (Tschakert, 2013; Bee *et al.*, 2013; Tschakert and Machado, 2012; see also 22.4.3 and Table 22-5).

Box CC-UR. Urban-Rural Interactions –
Context for Climate Change Vulnerability, Impacts, and Adaptation

[John Morton (UK), William Solecki (USA), Purnamita Dasgupta (India), David Dodman (Jamaica), Marta G. Rivera-Ferre (Spain)]

Rural areas and urban areas have always been interconnected and interdependent, but recent decades have seen new forms of these interconnections: a tendency for rural-urban boundaries to become less well-defined, and new types of land-use and economic activity on those boundaries. These conditions have important implications for understanding climate change impacts, vulnerabilities, and opportunities for adaptation. This box examines three critical implications of these interactions:

1) Climate extremes in rural areas resulting in urban impacts – teleconnections of resources and migration streams mean that climate extremes in non-urban locations with associated shifts in water supply, rural agricultural potential, and the habitability of rural areas will have downstream impacts in cities;
2) Events specific to the rural-urban interface – given the highly integrated nature of rural-urban interface areas and overarching demand to accommodate both rural and urban demands in these settings, there is a set of impacts, vulnerabilities and opportunities for adaptation specific to these locations. These impacts include loss of local agricultural production, economic marginalization resulting from being neither rural or urban, and stress on human health; and,
3) Integrated infrastructure and service disruption – as urban demands often take preference, interdependent rural and urban resource systems place nearby rural areas at risk, because during conditions of climate stress, rural areas more often suffer resource shortages or other disruptions in order to sustain resources to cities. For example, under conditions of resource stress associated with climate risk (e.g., droughts) urban areas are at an advantage because of political, social, economic requirements to maintain service supply to cities to the detriment of relatively marginal rural sites and settlements.

Urban areas historically have been dependent on the lands just beyond their boundaries for most of their critical resources including water, food, and energy. While in many contexts, the connections between urban settlements and surrounding rural areas are still present, long distance, teleconnected, large-scale supply chains have been developed particularly with respect to energy resources and food supply (Güneralp et al., 2013). Extreme event disruptions in distant resource areas or to the supply chain and relevant infrastructure can negatively impact the urban areas dependent on these materials (Wilbanks et al., 2012). During the summer of 2012, for instance, an extended drought period in the central United States led to significantly reduced river levels on the Mississippi River which led to interruptions of barge traffic and delay of commodity flows to cities throughout the country. Urban water supply is also vulnerable to droughts in predominantly rural areas. In the case of Bulawayo, Zimbabwe, periodic urban water shortages over the last few decades have been triggered by rural droughts (Mkandla et al., 2005).

A further teleconnection between rural and urban-areas is rural-urban migration. There have been cases where migration and urbanization patterns have been to attributed to climate change or its proxies such as in parts of Africa (Morton 1989, Barrios et al., 2006). However, as recognized by Black *et al.* (2011), life in rural areas across the world typically involves complex patterns of rural-urban and rural-rural migration, subject to economic, political, social and demographic drivers, patterns which are modified or exacerbated by climate events and trends rather than solely caused by them.

Globally, an increased blending of urban and rural qualities has occurred. Simon *et al*. (2006:4) assert that the simple dichotomy between ‘rural’ and ‘urban’ has “long ceased to have much meaning in practice or for policy-making purposes in many parts of the global South”. One approach to reconciling this is through the increasing application of the concept of “peri-urban areas” (Simon *et al*., 2006; Simon, 2008). These areas can be seen as rural locations that have “become more urban in character” (Webster 2002: 5); as sites where households pursue a wider range of income-generating activities while still residing in what appear to be “largely rural landscapes” (Learner and Eakin 2010: 1); or as locations in which rural and urban land uses coexist, whether in contiguous or fragmented units (Bowyer-Bower, 2006). The inhabitants of “core” urban areas within cities have also increasingly turned to agriculture, with production of staple foods, higher-value crops and livestock (Bryld, 2003; Devendra et al., 2005; Lerner and Eakin, 2010; Lerner et al., 2013). Bryld (2003) sees this as driven by rural-urban migration and by structural adjustment (e.g. withdrawal of food price controls and food subsidies). Lerner and Eakin (2011, also

Lerner et al., 2013) explored reasons why people produce food in urban environments, despite high opportunity costs of land and labour: buffering of risk from insecure urban labour markets; response to consumer demand; and the meeting of cultural needs.

Livelihoods and areas on the rural-urban interface suffer highly specific forms of vulnerability to disasters, including climate-related disasters. These may be summarised as specifically combining: urban vulnerabilities of population concentration, dependence on infrastructure, and social diversity limiting social support with rural traits of distance, isolation and invisibility to policy-makers (Pelling and Mustafa, 2010). Increased connectivity can also encourage land expropriation to enable commercial land development (Pelling and Mustafa, 2010). Vulnerability may arise from the co-existence of rural and urban perspectives, which may give rise to conflicts between different social /interest groups and economic activities (Darly and Torre 2013, Masuda and Garvin 2008, Solona-Solona 2010).

Additional vulnerability of peri-urban areas is on account of the re-constituted institutional arrangements and their structural constraints (Iaquinta and Drescher 2000). Rapid declines in traditional informal institutions and forms of collective action, and their imperfect replacement with formal state and market institutions, may also increase vulnerability (Pelling and Mustafa, 2010).

Peri-urban areas and livelihoods have low visibility to policy-makers at both local and national levels, and may suffer from a lack of necessary services, and inappropriate and uncoordinated policies. In Tanzania and Malawi, national policies of agricultural extension to farmer groups for example, do not reach peri-urban farmers (Liwenda et al., 2012). In peri-urban areas around Mexico City (Eakin et al., 2013), management of the substantial risk of flooding is led *de facto* by agricultural and water agencies, in the absence of capacity within peri-urban municipalities and despite clear evidence that urban encroachment is a key driver of flood risk. In developed country contexts suburban areas, suburban-exurban fringe areas often are overlooked in the policy arena that traditionally focuses on rural development and agricultural production, or urban growth and services (Hanlon et al., 2011). The environmental function of urban agriculture, in particular, in protection against flooding, will increase in the context of climate change. (Aubry et al., 2012).

However, peri-urban areas and mixed livelihoods more generally on rural-urban interfaces, also exhibit specific factors that increase their resilience to climate shocks (Pelling and Mustafa, 2010). Increased transport connectivity in peri-urban areas can reduce disaster risk by providing a greater diversity of livelihood options and improving access to education. The expansion of local labour markets and wage labour in these areas can strengthen adaptive capacity through providing new livelihood opportunities (Pelling and Mustafa, 2010). Maintaining mixed portfolios of agricultural and non-agricultural livelihoods also spreads risk (Lerner et al., 2013).

In high-income countries, practices attempting to enhance the ecosystem services and localized agriculture more typically associated with lower density areas have been encouraged. In many situations these practices are focused increasingly on climate adaptation and mitigating the impacts of climate extremes such as those associated with heating and the urban heat island effect, or wetland restoration efforts to limit the impact of storm surge wave action (Verburg et al., 2012).

The dramatic growth of urban areas also implies that rural areas and communities are increasingly politically and economically marginalized within national contexts, resulting in potential infrastructure and service disruptions for such sites. Existing rural-urban conflicts for the management of natural resources (Castro and Nielsen, 2003) such as water (Celio et al., 2011) or land-use conversion in rural areas (e.g. wind farms in rural Catalonia (Zografos and Martínez-Alier, 2009); industrial coastal areas in Sweden (Stepanova and Bruckmeier, 2013); or conversion of rice land into industrial, residential and recreational uses in the Philippines (Kelly, 1998) or Spain have been documented, and it is expected that stress from climate change impacts on land and natural resources will exacerbate these tensions. For instance, climate induced reductions in water availability may be more of a concern than population growth or increased per-capita use for securing continued supplies of water to large cities (Darrel Jenerette and Larsen, 2006), both of which requires an innovative approach to address such conflicts (Pearson et al., 2010).

Table 9-1: Definitions of the "rural" and the "urban" in selected countries.

Indicative examples of urban and rural definitions	
Country	**Definitions**
Australia	**Major Urban Areas**: population of over 100,000 **Other Urban Areas**: population of 1,000-99,999 **Rural Areas**: includes small towns with a population of 200-999 (Australian Bureau of Statistics, 2013)
China	**Major Urban Areas**: population of over 10,000 **Medium Urban Areas**: population of 3,000-9,999 **Small Urban Areas**: population of less than 3,000 **Major Villages**: population of 1,000-3,000 **Medium Villages**: population of 300-1,000 **Small Villages**: population of less than 300 (Ministry of Construction, 1993)
India	**Urban Areas**: population of 5,000 or more; or where at least 75% of the male working population is non-agricultural; or having a density of population of at least 400 people / km^2 (Government of India, 2012). It is implied that all non-urban areas are rural.
Jamaica	A **place** is considered to be **urban** if: it has a population of more than 2,000 people and provides a certain set of amenities and facilities that are deemed to indicate "modern living" (Statistical Institute of Jamaica, 2012). It is implied that all non-urban areas are rural.
United States of America	**Rural Areas**: all territory outside of defined urbanized areas and urban clusters, that is open country and settlements with fewer than 2,500 residents; with population densities as high as 386 people / km^2 (Womach, 2005)

Table 9-2: Relevant findings on rural areas from the IPCC Fourth Assessment Report and the International Assessment of Agricultural Science and Technology for Development.

Importance of non-climate trends	Source
The significance of climate change needs to be considered in the multi-causal context of its interactions with other non-climate sources of change and stress (e.g. water scarcity, governance structures, institutional and jurisdictional fragmentation, limited revenue streams for public sector roles, resource constraints, or inflexible land use patterns)	W 7.4.2 I 6.7.5
Different development paths may increase or decrease vulnerabilities to climate-change impacts	W 7.7
Neglect by policy-makers and under-investment in infrastructure and services has negatively affected rural areas	I 1.3.4.
Policy neglect specifically disfavours rural women	I 1.3.4.
Assessment of climate change impacts on agriculture has to be undertaken against a background of demographic and economic trends in rural areas	E 5.3.2
Global numbers of people at risk from hunger will be affected by climate change, but more by socioeconomic trends as captured in the difference between the SRES scenarios	E 5.6.5
Specific characteristics of smallholder agriculture	
Subsistence and smallholder livelihood systems suffer from a number of non-climate stressors, but are also characterized for having certain resilience factors (efficiencies associated with the use of family labour, livelihood diversity to spread risks)	E 5.3.2
Traditional knowledge on agriculture and natural resources is an important resilience factor	I 2.1.2, 3.2.2, 3.2.3 E 5.3.2 CC4
The combination of stressors and resilience factors gives rise to complex and locally specific impacts, resistant to modelling	E 5.4.7 W 7.2, 7.4, 7.5
Impacts on agriculture and agricultural trade	
In low-latitude regions, temperature increases of 1-2°C are likely to have negative impacts on yields of major cereals. Further warming has increasingly negative impacts in all regions	E 5.4.2
Increases in global mean temperatures (GMTs) of 2-3°C might lead to a small rise or decline (10-15%) in food (cereals) prices, while GMT increases in the range of 5.5°C or more might result in an increase in food prices of, on average, 30%	E 5.6.1
Forestry	
Loss of forest resources through climate change may affect 1.2 billion poor and forest-dependent people, including through impacts on Non-Timber Forest Products.	E 5.4.5
Valuation	
Robust valuation of climate change impact on human settlements is difficult, and social and environmental costs are poorly captured by monetary metrics: non-monetary valuation methods should be explored	W 7.4.3, 7.5, I 8.2.5
Adaptation	
The need and the capacity to adapt vary considerably from region to region, and from farmer to farmer	I 1.3.3
Adaptation actions can be effective in achieving their specific goals, but they may have other (positive or negative) effects, including resource competition	I 6.7.5
Diversification of agricultural and non-agricultural livelihood strategies is an important adaptation trend, but requires institutional support and access to resources	E 5.5.1, 5.5.2
The effectiveness of adaptation efforts is likely to vary significantly between and within regions, depending on geographic location, vulnerability to current climate extremes, level of economic diversification and wealth, and institutional capacity	I 6.8
Multi-stakeholder processes are increasingly important with respect to climate change adaptation	I 7.5.3
Links between adaptation and mitigation	
Mitigation and adaptation policies are in many cases, and certainly for agriculture, closely linked	K 18.4.3, 18.7.1 E 5.4.1, 5.4.2, 5.6.5 W 7.1, 7.7

Sources: W = Wilbanks *et al.* 2007; E = Easterling *et al.* 2007; I = McIntyre *et al.* 2009; K = Klein *et al.* 2007, CC4 = Cross-Chapter Case Study C4 “Indigenous knowledge for adaptation to climate change” in AR4 (Parry *et al*. 2007).

Table 9-3: Major demographic, poverty-related, economic, governance, and environmental trends in rural areas of developed and developing countries.

	Developed countries	**Developing countries**
Demographic Trends	Rural population accounts for 22.3% of the total population (or about 276 million people) (UN-DESA Population Division, 2012). Rural areas account for 75% of land area in OECD countries (OECD 2006). Rural population has peaked (absolute numbers) in Europe and North America. Rural depopulation in some places, but also counter-urbanization with people moving from urban to rural areas elsewhere.	Rural population accounts for 50.3% of the total population (or about 2.5 billion people) in less developed countries (excluding LDCs), 71.5% (or about 608 million people) in the LDCs (UN-DESA Population Division, 2012) Rural population has already peaked in Latin America and Caribbean, East and South East Asia; expected to peak around 2025 in Middle East, North Africa, South and Central Asia; around 2045 in sub-Saharan Africa.
Dependence on agriculture	Agriculture accounts for only 13% of rural employment in the EU (2006), and less than 10% on average across developed countries; however, has a strong indirect influence on rural economies. Increased competition as a result of economic globalization has resulted in agriculture no longer being the main pillar of the rural economy in Europe. Economic policies are primary drivers with social re-composition and economic restructuring taking place.(Marsden, 1999, Lopez-i-Gelats, *et al.*, 2009)	Proportion of rural population engaged in agriculture declining in all regions (Figure 9-2). Agriculture still provides jobs for 1.3 billion smallholders and landless workers (World Bank, 2008). Non-agricultural including labour-based and migration-based livelihoods increasingly existing alongside (and complementing) farm-based livelihoods. Agricultural initiatives and growth still important for adaptation and for small holders in Africa and Asia; (Osbahr *et al.*, 2008; Collier *et al.*, 2008; Kotir, 2011)
Poverty and Inequality	Per capita GDP in rural areas of OECD countries is only 83% of national average (but significant variation within and between countries): driven by out-migration, aging, lower educational attainment, lower productivity of labour, low levels of public services.(OECD, 2006)	Rates of poverty (percentage of population living on less than US $ 2/day) and extreme poverty (percentage of population living on less than US $ 1.25/day) falling in rural areas in most parts of the world; but rural poverty and rural extreme poverty rising in sub-Saharan Africa. Recent price hikes and volatility exacerbated hunger and malnutrition among rural households many of which are net-food buyers (FAOSTATS, 2013). Hunger and malnutrition prevalent among rural children in South Asia and Sub-Saharan Africa (UN, 2010; IFAD, 2010; World Bank, 2007).Figure 9-2 and Table 9-3

Table 9-3 (continued)

Economic, Policy, Governance Trends	Shift from agricultural (production) to leisure (consumption) activities; focus on broader amenity values of rural landscapes for recreation, tourism, and forests, ecosystem services. (Bunce, 2008; OECD, 2006; Rounsevell *et. al.*, 2006) Agricultural subsidies under pressure from international trade negotiations and domestic budgetary constraints. As a result of recent price hikes, domestic price support has been lowered in OECD countries. New policy approach in OECD countries that focuses on investments and targets a range of rural economic sectors and environmental services.	Interconnectedness and economic openness in rural areas have encouraged shifts to commercial agriculture, livelihoods diversification and aid knowledge transfers (section 9.3.3). Interlinkages between land tenure, food security and biofuel policies impact rural poverty (see Chapter 7, section 7.1 and 7.3.2 for further details) Decentralization of governance and emergence of rural civil society. Movements towards land reform in some parts of Asia (Kumar, 2010). Emergence of economies in transition, characterised in places by co-existence of leading and lagging regions; political and democratic decentralization expanding leading to increasing complexity of policy (World Bank, 2007).
Environmental Degradation	Different socio-economic scenarios have varying impacts on land use and agricultural biodiversity (Reidsma *et al.*, 2006).	Resource degradation, environmentally fragile lands subject to overuse and population pressures, exacerbate social and environmental challenges. Multiple stressors increase risk, reduce resilience and exacerbate vulnerability among rural communities from extreme events and climate change impacts (Chapter 13, Section 13.2.6).
Rural-Urban Linkages and Transformations	Changes in land-use and land-cover patterns at urban-rural fringe affected by new residential development, local government planning decisions, and environmental regulations (Brown *et al.*, 2008).	Stronger rural-urban linkages through migration, commuting, transfer of public and private remittances, regional and international trade, inflow of investment and diffusion of knowledge (through new information and communication technologies) (IFAD, 2010). Continued out-migration to urban areas by the semi-skilled and low-skilled, reducing the size of rural workforce (IFAD, 2010). Trend for migration to small and medium-sized towns (Sall *et al.*, 2010). Increased volumes of agricultural trade, growing by 5% on average (annually) between 2000-2008 (WTO, 2009). New initiatives of foreign direct investment (FDI) in agriculture in the form of large-scale land acquisitions in developing countries (Anseeuw *et al.*, 2012; World Bank, 2010).

Table 9-4: Poverty indicators for rural areas of developing countries.

	Incidence of poverty (%)		**Incidence of rural poverty (%)**		**Incidence of extreme poverty (%)**		**Incidence of extreme rural poverty (%)**		**Rural people as % of those in extreme poverty**	
	1988	2008	1988	2008	1988	2008	1988	2008	1988	2008
Developing World	69.1	51.2	83.2	80.9	45.1	27.0	54.0	34.2	80.5	71.6

* The incidence of extreme poverty and poverty is defined as percentage of people living on less than US$1.25 per day and less than US$2 per day, respectively.
Source: adapted from IFAD, 2010.

Table 9-5: Projected changes in areas suitable for production of tropical beverage crops by 2050.

Crop	**Countries**	**Change in climate to 2050**	**Change in total area by 2050**	**Change in distribution by 2050**
Coffee	Guatemala, Costa Rica, Nicaragua, El Salvador, Honduras, Mexico[5]	2.0-2.5ºC increase in temperature 5-10% decline in total rainfall	Between 38 and 89% decline in area suitable for production	Minimum altitude suitable for production rises from 600 to 1000 m.a.s.l.
	Kenya[1]	2.3ºC increase in temperature Rainfall increase from 1405mm to 1575 mm	Substantial decline in suitability of western highlands, some decline in area optimal for production in eastern highlands	Minimum altitude for production rise from 1000 to 1400 m.a.sl.
Tea	Kenya[2]	2.3ºC increase in temperature Rainfall increase from 1655mm to 1732 mm	Majority of western highlands loose suitability, while looses are compensated by gains at higher altitude in eastern highlands	Optimum altitude for production change from 1500-2100 m.a.s.l. to 2000-2300 m.a.s.l.
	Uganda[4]	2.3ºC increase in temperature Rainfall increase from 1334mm to 1394 mm	Considerable reduction in suitability for production across all areas	Optimal altitude change from 1450-1650 m.a.s.l. to 1550-1650 m.a.s.l.
Cocoa	Ghana, Ivory Coast[4]	2.1ºC increase in temperature No change in total rainfall	Considerable reduction in area suitable for production; almost total elimination in Ivory Coast	Optimal altitude changes from 100-250 m.a.s.l. to 450-500 m.a.s.l.

Sources: [1]CIAT, 2010; [2]CIAT 2011a [3]CIAT, 2011b; [4]Laderach *et al*. 2013; [5]Glenn *et al*. 2013. Projections use the A2 scenario, the projection methodology is described in Box 9-1.

Table 9-6: Illustrative sample of studies on economic value and changes in value from climate change impacts in the agriculture sector.

Findings and Estimates	**Study : Author /s**	**Country / Region and Model/ Scenario**
Annual economic loss in rice production: $ 54.17 million	Vaghefi *et al.*, 2011	Malaysia (2 degrees C rise in temperature)
GDP reduction from loss of agricultural productivity by 2080: 1.4%; welfare loss 1.7%	Zhai and Zhuang, 2009	South East Asian countries : Thailand, Vietnam, Philippines, Singapore, Malaysia, Indonesia(dynamic CGE)
Decline in foodgrain production between 2030-2050 by up to 18%	Dasgupta *et al*., 2013	India (AIB Scenario)
Annually spending for coping with adverse agricultural impacts between 2010-2050: $4.2 - $ 5 billion	ADB and IFPRI, 2009	Asia(various scenario based estimates)
Decline in farmland values for each degree Celsius of warming: 4-6000 pesos	Mendelsohn *et al.*, 2010	Mexico (Ricardian Analysis)
Fall in crop land values for rural communities: 13%	Mendelsohn *et al.*, 2007	U.S. A. (10% average increase in temperature)
Mixed effects with some improved profits Adverse impacts on farming	Mendelsohn and Reinsborough, 2007	Canada (increasing precipitation) U.S.A. (increasing temperature)
Crop losses under drought: CAN$ 7-171 per hectare	Wittrock *et al.*, 2011	Canada (Canadian Global Model 2)
Annual Agricultural losses upto $3billion Flooding increases losses	Franco *et al.*, 2011	California (B1 – low emissions and A2 – medium emissions scenarios)
Damages to agriculture, hydropower and infrastructure (including coastal areas) by 2050: $7.6 billion	World Bank, 2010a	Mozambique (Dynamic CGE model)
Decline in GDP from agriculture and linked sectors: 10% from benchmark levels	Mideksa, 2010	Ethiopia (Cline, CGCM2 and PCM)
By 2100: Total losses of $48.2 billion to gains of $ 90 billion In 2020 for 1.6% warmer and 3.7% dryer climate: net farm revenues decline by upto 25%	Dinar *et al.*, 2008	11 African countries (Ricardian analysis; various climate scenarios)
Decline in daily per capita calorie availability by upto 10% in 2050	Nelson *et al.*, 2009	Developing countries (A2 scenario; CSIRO and NCAR models)
Losses in gross value of production upto 25% (Guatemala, followed by other countries)	ECLAC, 2010a, b	Guatemala, Belize, Costa Rica, Honduras (SRES A2 and B2; Regional climate models)
Loss in incomes of farmers by: 2020: 14% 2060: 20%	Seo and Mendelsohn, 2008	South America (SRES A1; Canadian Climate Centre)
Annual damages between: 1 – 39%	Sanghi and Mendelsohn, 2008	Brazil (Climate predictions from 14 GCMs)
Varying impacts across regions; Declining agricultural crop productivity in some	Falloon and Betts, 2010	Southern Europe (IPCC AR4 climate projections; qualitative assessment)
Large variation in impacts on crops in Europe by 2050, mostly negative	Olesen *et al.*, 2011	Most affected : Hungary, Serbia, Bulgaria, Romania (Expert evaluation; climate predictions from RCMs)

Table 9-7: Examples of adaptations in the agricultural sector in different regions.

Agricultural adaptations	**Where it has been observed and source**
Modifying planting, harvesting and fertilizing practices for crops	Anchioreta in Brazil (Bonatti *et al*., 2012), semi-arid mountain regions of Bolivia (PNCC, 2007), Chile (Meza and Silva, 2009), maize and wheat crops in Argentina (Magrin et al., 2009)South Africa and Ethiopia (Bryan *et al.,* 2009), composting and coralling of livestock to collect waste in northern Burkina Faso (Barbier *et al*., 2009), Sahelian region of Mali (Adepetu and Berthe, 2007), in North West Province, Limpopo Province and KwaZulu Natal, South Africa (Thomas *et al.*, 2007)
Changing amount or area of land under cultivation	Moving winter wheat northwards and expanding rice crops (Lin *et al.*, 2005), South Africa (Bryan *et al*., 2009), expansion of fields in northern Burkina Faso (Barbier *et al.*, 2009), increase in the size of plots in the Sahelian region of Mali (Adepetu and Berthe, 2007)
Using different varieties (e.g. early maturing, drought-resistant)	Early maturing cultivars in South Brazil (Walter et al, 2010), North America (Coles and Scott, 2009), drought-tolerant in Asia (Thomas, 2008; Zhao *et al.*, 2010), South Africa and Ethiopia (Bryan *et al.*, 2009), Ghana (Gyampoh *et al*., 2008), northern Burkina Faso (Barbier *et al*., 2009), Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), in North West Province, Limpopo Province and KwaZulu Natal, South Africa (Thomas *et al*, 2007)
Diversifying crops and/or animal species	Crops in Peruvian Andes (Lin, 2011), South America (Montenegro and Ragrab, 2010), northeastern Mexico (Eakin and Appendini, 2008; Eakin and Bojorquez-Tapia, 2008), Tasmania, Australia (Smart, 2010), in KwaZulu Natal, South Africa (Thomas *et al*., 2007); cows by goats and camels in Kenya (Rivera-Ferre and López-i-Gelats , 2012)
Commercialisation of agriculture	Income generation from natural resources (e.g. fuelwood) in the Limpopo River Basin, Botswana (Dube and Sekhela, 2007), Ghana (Gyampoh *et a.l*, 2008), Limpopo Province, South Africa (Thomas *et al.*, 2007)
Water control mechanisms (including irrigation and water allocation rights)	Improved rice harvests in monsoonal Asia (Hatcho et al., 2010); adaptation for quinoa (Bolivian Altiplano), tomatoes (central Brazil) and cotton (northern Argentina (Geerts and Raes, 2009); for rice in northeast China (Lin et al, 2005); small water harvesting pits (known as zai) in improved yields and incomes due to improved soil moisture in Ethiopia (Amede*et al*., 2011;Bryan *et al*, 2009) and Burkina Faso (Hertsgaard, 2011, Barbier*et al*, 2009), in South Africa (Bryan et al, 2009), amongst rural women farmers in the Eastern Cape, South Africa (Bryan *et al*, 2009), Ghana (Gyampoh et al, 2008), dry season vegetable production through irrigation in northern Burkina Faso to enable two crop cycles (Barbier et al, 2009), Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), in Limpopo Province, South Africa (Thomas et al, 2007)
Shading and wind breaks	For coffee in Brazil, Costa Rica and Colombia (Camargo, 2010), Ethiopia (Bryan *et al,* 2009)
Conservation agriculture (e.g. soil protection, agroforestry)	Honduras, Nicaragua and Guatemala (Holt-Gimenez, 2002), Burkina Faso (Hertsgaard, 2011, Barbier *et al.*, 2009),Ethiopia (Bryan *et al*, 2009), Sahelian region of Mali (Adepetu and Berthe, 2007)
Modifying grazing patterns for herds	Arctic (Bartsch *et al.*, 2010), East Africa (Eriksen and Lind, 2009) and southern Africa (O'Farrell *et al*., 2009), moving livestock to less densely populated pastures in northern Burkina Faso (Barbier *et al*., 2009) and the Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), in North West Province, Limpopo Province and KwaZulu Natal, South Africa (Thomas *et al.*, 2007)
Providing supplemental feeding for herds/ storage of animal feed	Arctic (Forbes and Kumpula, 2009), South Africa (Bryan *et al.*, 2009), use of sorghum and hay residue for feeding livestock in northern Burkina Faso (Barbier *et al*., 2009), Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007), cutting fodder for livestock in Limpopo Province, South Africa (Thomas *et al.*, 2007)
Ensuring optimal herd size	Changing size of European reindeer herds to match pasture availability (Rees *et al.*, 2008), (, culling of livestock in Northern Nigeria (Adepetu and Berthe, 2007), selling of livestock northern Burkina Faso (Barbier *et al*., 2009) and the Sahelian region of Mali and Nigeria (Adepetu and Berthe, 2007)
Developing new crop and livestock varieties (e.g. biotechnology and breeding)	Brazil and Argentina (Marshall, 2012; Urcola *et al*., 2010), Northern Nigeria (Adepetu and Berthe, 2007)

Table 9-8: Examples of adaptations in the water sector observed in different regions.

Type	Example	Where it has been observed and source
Supply-side mechanisms	Dams	Proposed in the Volta River in Ghana (van de Giesen *et al.*, 2010).
	Reservoirs	Asia (Tyler and Fajber, 2009), particularly in areas where water stress is an issue of distribution rather than absolute shortage (Biemans *et al*., 2011; Rivera-Ferre *et al*. 2013)
	Groundwater pumping	Arid and semi-arid South America (Burte *et al.*, 2011; Döll, 2009; Kundzewicz and Döll, 2009; Zagonari, 2010)
	Groundwater recharge	Potential identified in India (Sukhija, 2008)
	Irrigation (often using water-saving technology)	Asia (Ngoundo *et al.*, 2007; Tischbein *et al.*, 2011)
	Fog interception practices	South America (Holder, 2006; Klemm *et al.*, 2012)
	Water capture	Bolivia (PNCC, 2007)
Demand-side mechanisms	Improved management, e.g. through efficiency	Asia (Kranz et al, 2010), South America (Bell *et al.*, 2011; Geerts *et al.*, 2010; Montenegro and Ragab, 2010; Van Oel *et al.*, 2010); Pampas Argentina (Quiroga and Gaggioli, 2011)
	Policies	Murray-Darling Basin Authority (MDBA) established to address over-allocation of water resources (Connell and Grafton, 2011; MDBA, 2011) See also box 26-3 on Australia's water policies;
	Reviewing allocation rights	Indogangetic Plains (Rivera-Ferre *et al.*, 2013b); Australia's MDBA reviewed the "exceptional circumstances" concept in drought policy (Productivity Commission, 2009);

Executive Summary

This chapter assesses the implications of climate change on economic activity in key economic sectors and services, on economic welfare, and on economic development.

For most economic sectors, the impact of climate change will be small relative to the impacts of other drivers (*high agreement, medium evidence*). Changes in population, age, income, technology, relative prices, lifestyle, regulation, governance and many other aspects of socio-economic development will have an impact on the supply and demand of economic goods and services that is large relative to the impact of climate change [10.10].

Climate change will reduce energy demand for heating and increase energy demand for cooling in the residential and commercial sectors (*high agreement, robust evidence*); the balance of the two depends on the geographic, socioeconomic and technological conditions. Increasing income will allow people to regulate indoor temperatures to a comfort level that leads to fast growing energy demand for air conditioning even in the absence of climate change in warm regions with low income levels at present. Energy demand will be influenced by changes in demographics (upwards by increasing population and decreasing average household size), lifestyles (upwards by larger floor area of dwellings), the design and heat insulation properties of the housing stock, the energy efficiency of heating/cooling devices and the abundance and energy efficiency of other electric household appliances. The relative importance of these drivers varies across regions and will change over time. [10.2]

Climate change will affect different energy sources and technologies differently, depending on the resources (water flow, wind, insolation), the technological processes (cooling) or the locations (coastal regions, floodplains) involved (*high agreement, robust evidence*). Gradual changes in various climate attributes (temperature, precipitation, windiness, cloudiness, etc.) and possible changes in the frequency and intensity of extreme weather events will progressively affect operation over time. Climate-induced changes in the availability and temperature of water for cooling are the main concern for thermal and nuclear power plants. Several options are available to cope with reduced water availability but at higher cost; however, decreased efficiency of thermal conversion remains a primary concern. Similarly, already available or newly developed technological solutions allow firms to reduce the vulnerability of new structures and enhance the climate suitability of existing energy installations. [10.2]

Climate change may influence the integrity and reliability of pipelines and electricity grids (*medium agreement, medium evidence*). Pipelines and electric transmission lines have been designed and operated for over a century in diverse and often extreme climatic conditions on land from hot deserts to permafrost areas and increasingly at sea. Due to the private nature and high economic value to the energy sector, they have been designed to higher tolerance levels than most transportation infrastructure. Climate change may require changes in design standards for the construction and operation of pipelines and power transmission and distribution lines. Adopting existing technology from other geographical and climatic conditions may reduce the cost of adapting new infrastructure as well as the cost of retrofitting existing pipelines and grids to the changing climate, sea-level and weather conditions which is likely to become more intense over time. [10.2]

Climate change will have impacts, positive and negative and varying in scale and intensity, on water supply infrastructure and water demand (*high agreement, robust evidence*), but the economic implications are not well understood. Economic impacts include flooding, scarcity and cross sectoral competition. Flooding can have major economic costs, both in term of impacts (capital destruction, disruption) and adaptation (construction, defensive investment). Water scarcity and competition for water, driven by institutional, economic or social factors, may mean that water is not available in sufficient quantity or quality for some uses or locations. [10.3]

Climate change may negatively affect transport infrastructure (*high agreement, limited evidence*). Transport infrastructure malfunctions if the weather is outside the design range, which would happen more frequently as the climate continues to change. All infrastructure is vulnerable to freeze-thaw cycles. Paved roads are particularly vulnerable to temperature extremes; unpaved roads and bridges to precipitation extremes. Transport infrastructure on ice or permafrost is especially vulnerable. [10.4]

Climate change will affect tourism resorts, particularly ski resorts, beach resorts, and nature resorts (*high agreement, robust evidence*) and tourists may spend their holidays at higher altitudes and latitudes (*high agreement, medium evidence*). The economic implications of climate-change-induced changes in tourism demand and supply entail gains for countries closer to the poles and higher up the mountains and losses for other countries. The demand for outdoor recreation is affected by weather and climate, and impacts will vary geographically and seasonally. [10.6]

Climate change will affect insurance systems (*high agreement, robust evidence*). More frequent and/or intensive weather disasters as projected for some regions/hazards will increase losses and loss variability in various regions and challenge insurance systems to offer affordable coverage while raising more risk-based capital, particularly in low- and middle-income countries. Economic-vulnerability reduction through insurance has proven effective. Large-scale public-private risk prevention initiatives and government insurance of the non-diversifiable portion of risk offer example mechanisms for adaptation. Commercial reinsurance and risk-linked securitization markets also have a role in ensuring financially resilient insurance and risk transfer systems. [10.7]

Climate change will affect the health sector (*high agreement, medium evidence*) through increases in the frequency, intensity, and extent of extreme weather events as well as increasing demands for health care services and facilities, including public health programs, disease prevention activities, health care personnel, infrastructure, and supplies related to treatment of infectious deceases and temperature related events. [10.8]

Well-functioning markets provide an additional mechanism for adaptation and thus tend to reduce negative impacts and increase positive ones for any specific sector or country (*high agreement, medium evidence*). The impacts of climate on one sector of the economy of one country in turn affect other sectors and other countries though product and input markets. Markets increase overall welfare, but not necessarily welfare in every sector and country. [10.9]

The impacts of climate change may decrease productivity and economic growth, but the magnitude of this effect is not well understood (*high agreement, limited evidence*). Climate could be one of the causes why some countries are trapped in poverty, and climate change may make it harder to escape poverty. [10.9]

Globally aggregated economic impacts of global warming are a small fraction of income up until 3°C [10.9.2, *medium evidence, high agreement*]. A global mean average temperature rise of 2.5C may lead to global aggregated economic losses between 0.2 and 2.0% of income (*medium evidence, medium agreement*) and losses increase with greater warming. Little is known about aggregate economics impacts above 3°C. Impact estimates are incomplete and depend on a large number of assumptions, many of which are disputable. Aggregate impacts hide large differences between and within countries. **The incremental impact of emitting a tonne of carbon dioxide lies between a few dollars and several hundreds of dollars per tonne of carbon [10.9.3, *robust evidence, medium agreement*]. Estimates vary strongly with the assumed discount rate.** The uncertainty about the marginal impacts is large, and more so for lower discount rates. [10.9]

Not all key economic sectors and services have been subject to detailed research. Few studies have evaluated the possible impacts of climate change on mining, manufacturing or services (apart from health, insurance and tourism). Further research, collection and access to more detailed economic data and the advancement of analytic methods and tools will be required to further assess the potential impacts of climate on key economic systems and sectors. [10.5, 10.8, 10.10]

10.1. Introduction and Context

This chapter discusses the implications of climate change on key economic sectors and services; e.g., economic activity. Other chapters discuss impacts from a physical, chemical, biological, or social perspective. Economic impacts cannot be isolated; and therefore, there are a large number of cross-references to other chapters in this chapter. In some cases, particularly agriculture, the discussion of the economic impacts is integrated with the other impacts.

Focusing on the potential impact of climate change on economic activity, this chapter addresses questions such as: how does climate change affect the demand for a particular good or service? What is the impact on its supply? How do supply and demand interact in the market? What are the effects on producers and consumers? What is the effect on the overall economy, and on welfare?

An inclusive approach was taken, discussing all sectors of the economy. Appendix A shows the list of sectors according to the International Standard Industrial Classification. This assessment reflects the breadth and depth of the state of knowledge across these sectors; many of which have not been evaluated in the literature. We extensively discuss five sectors: Energy (10.2), water (10.3), transport (10.4), tourism (10.6), and insurance (10.7). Other primary and secondary sectors are discussed in 10.5, and 10.8 is devoted to other service sectors. Food and agriculture is addressed in Chapter 7. Sections 10.2 through 10.8 discuss individual sectors in isolation. Markets are connected, however. Section 10.9 therefore assesses the implications of changes in any one sector on the rest of the economy. It also discusses the effect of the impacts of climate change on economic growth and development. Chapter 19 assesses the impact of climate change on economic welfare – that is, the sum of changes in consumer and producer surplus, including for goods and services not traded within the formal economy. This is not attempted here. The focus is on economic activity. Section 10.10 discusses whether there may be vulnerable sectors that have yet to be studied.

Previous assessment reports by the IPCC did not have a chapter on “key economic sectors and services”. Instead, the material assembled here was spread over a number of chapters. AR4 is referred to in the context of the sections below. In some cases, however, the literature is so new that previous IPCC reports did not discuss these impacts at any length.

10.2. Energy

Studies conducted since AR4 and assessed here confirm the main insights about the impacts of climate change on energy demand as reported in the SAR (Acosta *et al.*, 1995) and reinforced by the TAR (Scott *et al.*, 2001) and AR4 (Wilbanks *et al.*, 2007): ceteris paribus, in a warming world, energy demand for heating will decline and energy demand for cooling will increase; the balance of the two depends on the geographic, socioeconomic and technological conditions. The relative importance of temperature changes among the drivers of energy demand varies across regions and will change over time. Earlier IPCC assessments did not write much about energy supply, but an increasing number of studies now explore its vulnerability, impacts and the adaptation options (Ebinger and Vergara, 2011; Troccoli, 2010; USGCRP, 2009). The energy sector will be transformed by climate policy (IPCC WG3 AR5 Chapter 7) but impacts of climate changes too will be important for secure and reliable energy supply.

10.2.1. Energy Demand

Most studies conducted since AR4 explore the impacts of climate change on residential energy demand, particularly electricity (Mideksa and Kallbekken, 2010). Some studies encompass the commercial sector as well but very few deal with industry and agriculture. In addition to a few global studies based on global energy or integrated assessment models, the new studies tend to focus on specific countries or regions (Olonscheck *et al.*, 2011; Zachariadis, 2010), rely on improved methods (more advanced statistical techniques) (de Cian *et al.*, 2013) and data (both historical and regional climate projections), and many of them explicitly include non-climatic drivers of energy demand (e.g., sources). A few studies consider changes in demand together with changes in climate-dependent energy sources, like hydropower (Hamlet *et al.*, 2010).

Sorting the assessed studies according to the present climate (represented by mean annual temperature based on 1971-2000 climatology) and current income (represented by GDP per capita in 2009), the general patterns are as follows. In countries and regions with already high incomes, climate related changes in energy demand will be primarily driven by increasing temperatures. In countries/regions with high incomes and warm climates, increasing temperatures will be associated with heavier use of air conditioning. In countries/regions with high incomes and temperate and cold climates, increasing temperatures will result in lower demands for various energy forms (electricity, gas, coal, oil). Increasing incomes will play a marginal role in these countries and regions. In contrast, changes in income will be the main driver of increasing demand for energy (mainly electricity for air conditioning and transportation fuels) in present-day low-income countries in warm climates. Neither indicator is ideal because country-level mean annual temperatures for large countries can hide large regional differences and average incomes may conceal large disparities, but they help cluster the national and regional studies in the search for general finding.

At the global scale, energy demand for residential air conditioning in summer is projected to increase rapidly in the 21st century under the reference climate change scenario (medium population and economic growth globally, but faster economic growth in developing countries; no mitigation policies in addition to those in place in 2008) by the TIMER/IMAGE model (Isaac and Van Vuuren, 2009). The increase is from nearly 300 TWh in 2000, to about 4,000 TWh in 2050 and more than 10,000 TWh in 2100, about 75% of which is due to increasing income in emerging market countries and 25% is due to climate change. Energy demand for heating in winter increases too, but much less rapidly, since in most regions with the highest need for heating, incomes are already high enough for people to heat their homes to the desired comfort level (except in some poor households). In these regions, energy demand for heating will decrease.

These general patterns and especially the quantitative results of the projected shifts in energy and electricity demand can be modified by many other factors. In addition to changes in temperatures and incomes, the actual energy demand will be influenced by changes in demographics (upwards by increasing population and decreasing average household size, mixed effects from urbanization), lifestyles (upwards by larger floor area of dwellings), building codes and regulations for the design and insulation of the housing stock, the energy efficiency of heating/cooling devices, the abundance and energy efficiency of other electric household appliances, the price of energy, etc.

10.2.2. Energy Supply

Changes in various climate attributes (temperature, precipitation, windiness, cloudiness, etc.) will affect different energy sources and technologies differently. Gradual climate change (CC) will progressively affect the operation of energy installations and infrastructure over time. Possible changes in the frequency and intensity of extreme weather events (EWEs) as a result of CC represent a different kind of hazard forthem.. (EWEs are weather events that are rare at a particular place and time of the year; usually defined as rare or rarer than the 10^{th} and 90^{th} percentile of a probability density function estimated from observations – see the Glossary in this report). (Rummukainen, 2013) and (Mika, 2013) summarize recent trends and prospects relevant for the energy sector. This section assesses the most important impacts and adaptation options in both categories. Table 10-1 provides an overview.

[INSERT TABLE 10-1 HERE
Table 10-1: Main projected impacts of climate change and extreme weather events on energy supply and the related adaptation options.]

Currently, thermal power plants provide about 80% of global electricity and their share is projected to remain high in most mitigation scenarios (IEA, 2010a). Thermal power plants can be designed to operate under diverse climatic conditions from the cold Arctic to the hot tropical regions and are normally well adapted to the prevailing conditions. However, they might face new challenges and will need to respond by hard (design or structural methods) or soft (operating procedures) measures as a result of climate change.

A general impact of CC on thermal power generation (including combined heat and power) is the decreasing efficiency of thermal conversion as a result of rising temperature that cannot be offset per se. Yet there is much room to improve the efficiency of currently operating subcritical steam power plants (IEA, 2010b). As new materials allow higher operating temperatures in coal-fired power plants (Gibbons, 2012), supercritical and ultra-supercritical steam-cycle plants (operating at much higher pressure and temperature conditions than conventional power plants) will reach even higher efficiency that can more than compensate the efficiency losses due to higher temperatures. Yet in the absence of CC, these efficiency gains from improved technology would reduce the costs of energy, so there is still a net economic loss due to CC. Another problem facing thermal power generation in many regions is the decreasing volume and increasing temperature of water for cooling, leading to reduced power generation, operation at reduced capacity and even temporary shutdown of power plants (Hoffmann *et al.*, 2010; IEA, 2012; Ott and Richter, 2008; Sieber, 2013). Both problems will be exacerbated if CO_2 capture and handling equipment is added to fossil-fired power plants: energy efficiency declines by 8-14 % and water requirement per MWh electricity generated can double (IPCC, 2005). Using partial equilibrium river basin models, (Hurd *et al.*, 2004; Strzepek *et al.*, 2013) estimate USA welfare loses due to thermal cooling water changes at $622 million per year up to 2100, a 6.5 % welfare loss in the energy sector. (Van Vliet *et al.*, 2012) find that the southeastern United States, Europe, eastern China, southern Africa and southern Australia could potentially be affected by reduced water available for thermoelectric power and drinking water, inducing changes to dry or hybrid cooling (with concomitant loss in electric output), or plant shut downs, with associated impacts on local and regional economic activity.

Adaptation possibilities range from relatively simple and low-cost options like exploiting non-traditional water sources and re-using process water to measures like installing dry cooling towers, heat pipe exchangers and regenerative cooling (De Bruin *et al.*, 2009; Ott and Richter, 2008), all which increase costs. Water use regulation, heat discharge restrictions and occasional exemptions might be an institutional adaptation (Eisenack and Stecker, 2012). While it is easier to plan for changing climatic conditions and select the site and the conforming cost-efficient cooling technology for new builds, response options are more limited for existing power plants, especially for those towards the end of their economic lifetime.

CC impacts on thermal efficiency and cooling water availability affect nuclear power plants as well but the safety regulations are stricter than for fossil-fired plants (Williams and Toth, 2013). A range of alternative cooling options are available to deal with water deficiency, ranging from re-using wastewater and recovering evaporated water (Feeley III *et al.*, 2008) to installing dry cooling (EPA, 2001).

The implications of EWEs for nuclear plants can be severe if not properly addressed. Reliable interconnection (onsite power and instrumentation connections) of intact key components (reactor vessel, cooling equipment, control instruments, back-up generators) is indispensable for the safe operation and/or shutdown of a nuclear reactor. For most of the existing global nuclear fleet, a reliable connection to the grid for power to run cooling systems and control instruments in emergency situations is another crucial item (IAEA, 2011). Several EWEs can damage the components or disrupt their interconnections. Preventive and protective measures include technical and engineering solutions (circuit insulation, shielding, flood protection) and adjusting operation to extreme conditions (reduced capacity, shutdown) (Williams and Toth, 2013).

Hydropower is by far the largest of renewable energy sources in the current electricity mix. It is projected to remain important in the future, irrespective of the climate change mitigation targets in many countries (IEA, 2010a; IEA, 2010b). The resource base of hydropower is the hydrologic cycle driven by prevailing climate and topology. The former makes the resource base and hence hydropower generation highly dependent on future changes in climate and related changes in extreme weather events (Ebinger and Vergara, 2011; Mukheibir, 2013).

Assessing the impacts of climate change on hydropower generation is a highly complex. A series of non-linear and region-specific changes in mean annual and seasonal precipitation and temperatures, the resulting evapotranspiration losses, shifts in the share of precipitation falling as snow and the timing of its release from high elevation, and the climate response of glaciers make resource estimates difficult (see Chapters 2 and 3) while regional changes in water demand due to changes in population, economic activities (especially irrigation demand for agriculture) present competition for water resources that are hard to project (see Section 10.3). Further complications stem from the possibly increasing need to combine hydropower generation with changing flood control and ecological (minimum dependable flow) objectives induced by changing climate regimes. For hydropower locations, adaption to climate change to maintain output has been reported; in Ethiopia, (Block and Strzepek, 2012) report that capital expenditures through 2050 may either decrease by ~3% under extreme wet scenarios, or increase by up to 4% under a severe dry scenario. In the Zambezi river basin, hydropower may fall by 10% by 2030, and by 35% by 2050 under the driest scenario (Strzepek *et al.*, 2012). Lower generation is *likely* in the upstream powerstations of the Zambezi basin and increases are *likely* downstream (Fant *et al.*, 2012).

Focusing on the possible impacts of CC on hydroelectricity and the adaptation options in the sector in response to the changes in the amount, the seasonal and inter-annual variations of available water, and in other demands, the conclusion from the literature is that the overall impacts of CC and EWEs on hydropower generation by 2050 is expected to be slightly positive in most regions (e.g., in Asia, by 0.27%) and negative in some (e.g., in Europe, by -0.16%), with diverging patterns across regions, watersheds within regions and even river basins within watersheds (IPCC, 2011). Adaptation responses and planning tools for long-term hydrogeneration may need to be enhanced to cope with slow but persistent shifts in water availability. Short-term management models may need to be enhanced to deal with the impacts of EWEs. A series of hard (raising dam walls, adding bypass channels) and soft (adjusting water release) measures are available to protect the related infrastructure (dams, channels, turbines, etc.) and optimize incomes by timing generation when electricity prices are high (Mukheibir, 2013).

Solar energy is expected to increase from its currently small share in the global energy balance across a wide range of mitigation scenarios (IEA, 2008; IEA, 2009; IEA, 2010a; IEA, 2010b). The three main types of technologies for harnessing energy from insolation include thermal heating (TH) (by flat plate, evacuated tube and unglazed collectors), photovoltaic (PV) cells (crystalline silicon and thin film technologies) and concentrating solar power (CSP) (power tower and power trough producing heat to drive a steam turbine for generating electricity). The increasing body of literature exploring the vulnerability and adaptation options of solar technologies to CC and EWEs is reviewed by (Patt *et al.*, 2013).

All types of solar energy are sensitive to changes in climatic attributes that directly or indirectly influence the amount of insolation reaching them. If cloudiness increases under climate change (see Chapters 11 and 12 of the WGI report), the intensity of solar radiation and hence the output of heat or electricity would be reduced. Efficiency losses in cloudy conditions are less for technologies that can operate with diffuse light (evacuated tube collectors for TH, PV collectors with rough surface). Since diffuse light cannot be concentrated, CSP output would cease under cloudy conditions but the easy and relatively inexpensive possibility to store heat reduces this vulnerability if sufficient volume of heat storage is installed (Khosla, 2008; Richter *et al.*, 2009).

The exposure of sensitive material to harsh weather conditions is another source of vulnerability for all types of solar technologies. Windstorms can damage the mounting structures directly and the conversion units by flying debris, whereby technologies with smaller surface areas are less vulnerable. Hail can also cause material damage and thus reduced output and increased need for repair. Depending on regional conditions, strong wind can deposit sand and dust on the collectors' surface, reducing efficiency and increasing the need for cleaning.

CC and EWE hazards per se do not pose any particular constraints for the future deployment of solar technologies. Technological development continues in all three solar technologies towards new designs, models and materials. An objective of these development efforts is to make the next generation of solar technologies less vulnerable to existing physical challenges, changing climatic conditions and the impacts of EWEs. Technological development also results in a diverse portfolio of models to choose from according to the climatic and weather characteristics of the deployment site. These development efforts can be integrated in addressing the key challenge for solar technologies today: reducing the costs.

Harnessing wind energy for power generation is an important part of the climate change mitigation portfolio in many countries. Assessing the possible impacts of CC and EWEs and identifying possible adaptation responses for wind energy is complicated by the complex dynamics characterizing this generation source. Relevant attributes of climate are expected to change; the technology is evolving (blade design, other components); see (Barlas and Van Kuik, 2010; Kong *et al.*, 2005); there is an increasing deployment offshore and a transition to larger turbines (Garvey, 2010) and to larger sites (multi megawatt arrays) (Barthelmie *et al.*, 2008).

The key question concerning the impacts of a changing climate regime on wind power is related to the resource base: how climate change will rearrange the temporal (inter- and intra-annual variability) and spatial (geographical distribution) characteristics of the wind resource. In the next few decades, wind resources (measured in terms of multi-annual wind power densities) are estimated to remain within the ±50% of the mean values over the past 20 years in Europe and North America (Pryor and Barthelmie, 2010). The wide range of the estimates results from the circulation and flow regimes in different General Circulation Models (GCMs) and regional climate models (RCMs) (Bengtsson *et al.*, 2006; Pryor and Barthelmie, 2010). A set of four GCM-RCM combinations for the period 2041-2062 indicates that average annual mean energy density will be within ±25% of the 1979-2000 values in all 50 km grid cells over the contiguous USA (Pryor and Barthelmie, 2013; Pryor *et al.*, 2011). Yet, little is known about changes in the inter-annual, seasonal or diurnal variability of wind resources.

Wind turbines already operate in diverse climatic and weather conditions. As shown in Table 10-1, siting, design and engineering solutions are available to cope with various impacts of gradual changes in relevant climate attributes over the coming decades. The requirements to withstand extreme loading conditions resulting from climate change are within the safety margins prescribed in the design standards, although load from combinations of extreme events may exceed the design thresholds (Pryor and Barthelmie, 2013). In summary, the wind energy sector does not face insurmountable challenges resulting from climate change.

In the coal fuel cycle, vulnerability in mining depends on the mining method. Surface mining might be particularly affected by high precipitation extremes and related floods and erosion, and temperature extremes, especially extreme cold that might encumber extraction for some time, whereas impacts on coal cleaning and operation of underground mines will probably be less severe (Ekman, 2013). Changes in drainage and run-off regulation for on-site coal storage as well as in coal handling might be required due to the increased moisture content of coal and more energy might be required for coal drying before transportation (CCSP, 2007). At the back end of the fuel cycle, the management of fly-ash, bottom ash and boiler slag may need to be modified in response to changes in some EWE patterns like wind, precipitation and floods. Impacts on biomass-based energy sources are discussed in Chapter 7 of this report.

Climate and weather related hazards in the oil and gas sector include tropical cyclones with potentially severe effects on off-shore platforms and on-shore infrastructure as well, leading to more frequent production interruptions and evacuation (Cruz and Krausmann, 2013). Gradual changes in air temperature and precipitation are projected to generate risk and opportunities for the oil and gas industry. For example, new areas for oil and gas exploration could open in the Arctic, potentially increasing the technically recoverable resource base (Cruz and Krausmann, 2013). Reduced sea ice thickness and coverage might open new shipping routes, thus reducing shipping costs, while ice scour and ice pack loading on marine structures would increase. However, most changes involve increased risks, such as thawing permafrost would increase construction costs on unstable ground relative to ice-based construction, while thaw subsidence would trigger increased maintenance costs. Sea level rise and coastal erosion would degrade coastal barriers, damage facilities and trigger relocation (Dell and Pasteris, 2010).

10.2.3. Transport and Transmission of Energy

Primary energy sources (coal, oil, gas, uranium), secondary energy forms (electricity, hydrogen, warm water) and waste products (CO_2, coal ash, radioactive waste) are transported in diverse ways to distances ranging from a few to thousands of kilometres. The transport of energy-related materials by ships (ocean and inland waters), rail and road are exposed to the same impacts of climate change as the rest of the transport sector (see Section 10.4). This subsection deals only with transport modes that are unique to the energy sector (power grid) or predominantly used by it (pipelines). Table 10-2 provides an overview of the impacts of CC and EWEs on energy transmission, together with the options to reduce vulnerability.

[INSERT TABLE 10-2 HERE
Table 10-2: Main impacts of climate change and extreme weather events on pipelines and the electricity grid.]

Pipelines play a central role in the energy sector by transporting oil and gas from the wells to processing and distributing centres to distances from a few hundred to thousands of kilometres. With the potential spread of CO_2 capture and storage (CCS) technology, another important function will be to deliver CO_2 from the capture site (typically fossil power plants) to the storage site onshore or offshore. Pipelines have been operated for over a century in diverse climatic conditions on land from hot deserts to permafrost areas and increasingly at sea. This implies that technological solutions are available for the construction and operation of pipelines under diverse geographical and climatic conditions. Yet adjustments may be needed in existing pipelines and improvements in the design and deployment of new ones in response to the changing climate and weather conditions.

In addition to reduced line-heating and dilution needs due to reduced viscosity of liquid fuels under warmer temperatures, pipelines will be mainly affected by secondary impacts of climate change: sea-level rise in coastal regions, melting permafrost in cold regions, floods washing away infrastructure, landslides triggered by heavy rainfall and bushfires caused by heat waves or extreme temperatures in hot regions. A proposed way to reduce vulnerability to these events is to amend land zoning codes, risk based design and construction standards for new pipelines, and structural upgrades to existing infrastructure (Antonioni *et al.*, 2009; Cruz and Krausmann, 2013).

Due to the very function of the electricity grid to transmit power from generation units to consumers, the bulk of its components (overhead lines, substations, transformers) are located outdoors and exposed to EWE. The power industry has developed numerous technical solutions and related standards to protect assets and provide reliable electricity supply under existing climate and weather conditions worldwide. However, these assets and the reliability of supply may be vulnerable to changes in the frequency and intensity of EWEs under changing climate conditions (DOE, 2013).

Higher average temperatures increase transmission efficiency and reduce current carrying capacity, but this effect is relatively small compared to the physical and monetary damages that can be caused by EWEs (Ward, 2013). Historically, high wind conditions, including storms, hurricanes and tornados, have been the most frequent cause of grid disruptions (mainly due to damages to the distribution networks); and, more than half of the damage was caused by trees (Reed, 2008). Other impacts include freezing precipitation, ice and winter storms, wildfires caused by higher temperatures, less precipitation and increased tree death caused by pests. If the frequency and power of high wind conditions, as well as extreme precipitation events, will increase in the future, vegetation management along existing power lines, rerouting new transmission lines along roads or across open fields or moving them underground might help reduce related risks. An important institutional option is to redefine technical standards to provide incentives for grid operators to implement appropriate adaptation measures. Such measures are cheaper to implement as part of the maintenance-renewal cycle than as independent retrofit measures.

The economic importance of a reliable transmission and distribution network is highlighted by the fact that the damage to customers tends to be much higher than the price of electricity not delivered (lost production, electricity enabled commerce, service delivery, food spoilage, lost or restricted water availability). Losses can be minimized through efficient rationing of electricity (de Nooij *et al.*, 2009) if generation is the limiting factor. Designing and building climate-resilient infrastructure will depend on technical standards, market governance, and the type and degree of liberalization and deregulation of grid services.

10.2.4. Macroeconomic Impacts

Most economic research related to climate change impacts on the energy sector has focused on mitigation rather than the economic implications of climate change itself. Table 10-3 summarizes the recent studies on the economic implications of climate change and extreme weather impacts in the energy sector.

[INSERT TABLE 10-3 HERE
Table 10-3: Economy-wide implications of impacts of climate change and extreme weather on the energy sector.]

Assessing across a broad array of studies that focus on different regions and regional divisions, examine different climate change impacts, include a different mix of sectors, model different timeframes, make different assumptions about adaptation, and employ different types of models with different output metrics leads to the overall conclusion that the macroeconomic impact of climate change on energy demand is *likely* to be minimal in developed countries (Aaheim *et al.*, 2009; Bosello *et al.*, 2007a; Bosello *et al.*, 2009; Eboli *et al.*, 2010a; Eboli *et al.*, 2010a; Jochem *et al.*, 2009; Jochem *et al.*, 2009).

The current literature sheds less light on the implications for developing countries and on other climate impacts in the energy sector beyond those related to changes in energy demand. Europe is the focus of most of the literature so far. Only two studies focus on developing countries: Mexico and Brazil (Boyd and Ibarraran, 2009; de Lucena *et al.*, 2010). Asia and Africa are not well represented, appearing as aggregated regions in only three global studies (Bosello *et al.*, 2007a; Bosello *et al.*, 2009; Eboli *et al.*, 2010a; Eboli *et al.*, 2010b). The limited results indicate that developing countries *likely* face a greater negative GDP impact with respect to climate change implications for the energy sector than developed countries, largely because of higher expected temperature changes (Aaheim *et al.*, 2009; Boyd and Ibarraran, 2009; Eboli *et al.*, 2010a; Eboli *et al.*, 2010b).

Despite the considerable number of potential climate change and extreme weather phenomena – higher mean temperatures, changes in rainfall patterns, changes in wind patterns, changes in cloud cover and average insolation, lightning, high winds, hail, sand storms and dust, extreme cold, extreme heat, floods, drought, fire, and sea-level rise – and their potential impacts on electricity generation and transmission systems, fuel infrastructure and transport systems, and energy demand (Williams, 2013) – the range of impacts modeled in the literature (Table 10-3) is quite limited. Most studies consider changing energy demand (specifically, changes in electricity and fuel consumption for space heating/cooling) resulting from rising temperatures as the only or primary climate change impact. These studies draw upon recent literature refining the relationship between climate change and energy demand: the demand for natural gas and oil in residential and commercial sectors tends to decline with climate change because of less need for space heating, and demand for electricity tends to increase because of greater need for space cooling (Eskeland and Mideksa, 2010; Gabrielsen *et al.*, 2005; Kirkinen *et al.*, 2005; Mansur *et al.*, 2005; Mideksa and Kallbekken, 2010; Rübbelke and Vögele, 2010).

Studies using a computable general equilibrium (CGE) model that consider only climate impacts in the energy sector find that the effect on GDP in 2050 is in the range of -0.3% to 0.03% (Bosello *et al.*, 2007a) and -1.3% to -0.6% (Jochem *et al.*, 2009). These findings are largely consistent despite the fact that (Bosello *et al.*, 2007a; Bosello *et al.*, 2009) are global studies that model only the change in demand due to rising temperatures, whereas (Jochem *et al.*, 2009) focus on the EU and model the change in demand plus six other climate impacts.

Studies using CGE models that examine the aggregate changes in GDP brought on by climate impacts in energy and several other sectors have also primarily found similar shifts in GDP. (Aaheim *et al.*, 2009) conclude that in 2100 in cooler regions in the EU, GDP changes by -1% to -0.25% and in warmer regions changes by -3% to -0.5%. (Boyd and Ibarraran, 2009) project a -3% change in GDP in 2026 for Mexico, consistent with the warmer regions modeled by (Aaheim *et al.*, 2009). Roughly consistent with each other, (Aaheim *et al.*, 2009; Eboli *et al.*, 2010a; Eboli *et al.*, 2010b) find GDP impacts for the predominantly cooler regions of Japan, the EU, EEFSU, and Rest of Annex I as having a "significant positive impact", while the predominantly warmer regions of the USA, EEx (China/India, Middle East/Most of Africa/Mexico/parts of Latin America), and the Rest of the World have a "significantly negative impact." (Jorgenson *et al.*, 2004) find that overall GDP impacts are -0.6% to 0.7% in 2050 for the United States, which stands in contrast to (Eboli *et al.*, 2010a; Eboli *et al.*, 2010b) with a "significantly negative impact" in the United States.

Several CGE studies attempt to evaluate how adaptation changes in the energy sector impact GDP but do not examine specific adaptation options since CGE models lack the necessary technological detail. They make general assumptions about the effectiveness of adaptation policy in reducing climate impacts. (Jorgenson *et al.*, 2004) find that pessimistic assumptions about adaptation imply a 0.6% reduction in GDP in 2050 but optimistic assumptions lead to a 0.7% gain in GDP. (Aaheim *et al.*, 2009) conclude that adaptation can mitigate the costs of climate change by 80% to 85%, and (Boyd and Ibarraran, 2009) find that adaptation can shift a 3% GDP loss in 2026 in Mexico to a gain in GDP of 0.33%.

Partial equilibrium models, by their nature, do not have a full macroeconomic representation and therefore rarely report changes in GDP. Instead, these models focus on details in the energy sector, such as price and quantity effects for fuels and electricity (and the mix of generation). For example, (Rübbelke and Vögele, 2013) conclude that the short-term effects of climate-related problems affecting water cooling and hydropower production can have negative distributional effects. (de Lucena *et al.*, 2010) find that rising temperature and changing precipitation lead to the need for an additional 153 – 162 TWh per year by 2035 with a capital investment of $48 to $51 billion.

(Golombek *et al.*, 2011) report a 1% increase in the price of electricity for Western Europe in 2030 stemming from rising temperatures that affect demand and thermal efficiency of supply, as well as water inflow. (UNDP, 2011) finds between a 0.06% and 1.74% increase in electricity system costs for Macedonia resulting from temperature changes. (Gabrielsen *et al.*, 2005) conclude that for Nordic countries in 2040, as a result of rising temperatures that affect demand, changes in water inflow, and changes in wind speeds, the price of electricity will decline by 1%. (Koch *et al.*, 2012) conclude that thermal plant outages in Berlin resulting from heat wave-driven water temperatures that exceed regulatory limits can amount to a cumulative cost of $80 million over the period 2010 through 2050 for 2850 MW of capacity. Assuming an 80% capacity factor, the premium for high water temperatures in Berlin is $0.1 per MWh. The magnitude of change in electricity price is small in each of the previously mentioned studies that evaluate gradual temperature increases.

In contrast, studies that consider shorter-term heat waves and water shortages find considerably higher price impacts. (Bye *et al.*, 2008) consider a hypothetical water shortage scenario – 25% lower inflow over 2 years – in Nordic countries and conclude that the price of electricity can double over a 2 year period and then return to normal as water flow returns. (McDermott and Nilsen, 2013) find more generally that electricity prices in Germany increase by 1% for every degree that water temperatures rise above 25°C and by 1% for every 1% that river levels fall. (DOE, 2009) also finds that a drought scenario can lead to average monthly electricity prices that are 8.1% (November) to 24.1% (July) higher. (Pechan and Eisenack, 2013) find that an equivalent of the 2006 German heat wave can result in an increase in electricity prices of 11% or even 24% (affected plants running at minimum output) and 50% (affected plants at zero output).

10.2.5. Summary

The balance of evidence emerging from the literature assessed in this section suggests that climate change per se will *likely* increase the demand for energy in most regions of the world. At the same time, increasing temperature will decrease the thermal efficiency of fossil, nuclear, biomass, and solar power generation technologies (Mideksa and Kallbekken, 2010). However, gradual temperature-induced impacts on energy supply will probably make a relatively small contribution to the cost of energy and electricity. Acute heat waves and droughts can have a much greater, albeit short-term, impact on electricity prices. Additionally, many other potential climate impacts on energy supply are possible but have not been fully studied, leading to cost estimates to date, based only on temperature change, that underestimate the full cost of climate change on energy supply. Pre-existing subsidies may distort signals for adaptation. CC impacts on energy supply will be part of an evolving picture dominated by technological development in the pursuit for safer, cheaper and more reliable energy sources and technologies as well as mitigation and adaptation response pathways.

Given the limitations in the literature, sweeping conclusions about results may be premature on macroeconomic implications. However, some narrow conclusions are possible. The change in GDP due to temperature-induced changes in energy demand – even if combined with other climate impacts – range from -3% to 1.2%. (Jochem *et al.*, 2009) is the most detailed and comprehensive study, and report only a 1.3% drop in GDP in 2050 in Europe due to at least seven climate impacts in the energy sector. The GDP impact in warmer regions tends to be greater than in cooler regions, which benefit from less need for space cooling. Energy related economic impact for developing countries is anticipated to be negative, and positive in developed countries. Adaptation within the energy sector can lower the cost of climate change, but these results may be driven largely by assumption since specific policies have not been modeled in these macroeconomic impact studies. Results from some of the partial equilibrium models suggests that CGE modeling studies, which largely focus on changes in energy demand, may be neglecting some potentially costly impacts from extreme weather events like drought (see, e.g., Box CC-WE), which, if modeled, may lead to greater GDP losses than reported thus far in the literature.

Much research is still needed to understand the implications of climate change and extreme weather on the energy sector and to identify cost-effective adaptation options. The best understood area is the implications of climate on energy demand. A comprehensive evaluation of a full range of supply-side climate change impacts and adaptation options for all aspects of energy infrastructure is needed. This information will lead improved assessment of climate impacts due to the use of better, empirically-based assumptions about the relationship of climate impacts and the economy, as well as about the effectiveness of adaptation options.

10.3. Water Services

This section focuses on economic aspects of climate change in water-intensive sectors and infrastructure to provide water services. The climate change impacts on biophysical water system, including the engineering aspects of water infrastructure, are assessed in Chapter 3. There is limited set of studies published in this area and conclusions are limited by the scope of information to date.

10.3.1. Water Infrastructure and Economy-wide Impacts

Between the 1950s and the 1990s, the annual economic losses from large extreme events, including floods and droughts, increased tenfold, with developing countries being hardest hit (Kabat *et al.*, 2003). Over the past few decades, flood damage constitutes about a third of the economic losses inflicted by natural hazards worldwide (Munich Re, 2005). The economic losses associated with floods worldwide have increased by a factor of five between the periods 1950-1980 and 1996-2005 (Kron and Berz, 2007). In 1990-1996 alone, there were six major floods throughout the world in which the number of fatalities exceeded 1,000, and 22 floods with losses exceeding US$1 billion each (Kabat *et al.*, 2003). Although these increases are primarily due to several non-climatic drivers, climatic factors are also partly responsible (Kundzewicz *et al.*, 2007). SREX Chapter 4 provides a comprehensive look at the impacts of extreme events on water supply (IPCC, 2012) and flooding at wide range of spatial scales.

Most of the studies examining the economic impacts of climate change on the water sector have been carried out at the local, national, or river-basin scale; and, the global distribution of such studies is skewed towards developed countries (Chen *et al.*, 2001; Choi and Fisher, 2003; Hall *et al.*, 2005; Hurd and Rouhi-Rad, 2013; Middelkoop *et al.*, 2001; Schreider *et al.*, 2000). In other studies, the economic impacts of climate variability on floods and droughts in developing countries were reported as substantial. These studies address climate variability; climate change may impact both mean and variability of the hydro-climatic system. The floods associated with the 1997-1998 El Niño and the drought associated with the 1998-2000 La Niña, show a cost to Kenya of 11% and 16% of GDP, respectively (Mogaka *et al.*, 2006). Floods and droughts are estimated to cost Kenya about 2.4% of GDP annually at mid-century, and water resources degradation a further 0.5% (Mogaka *et al.*, 2006). For Ethiopia, economy-wide models incorporating hydrological variability show a drop in projected GDP growth by up to 38% compared to when hydrological variability is not included (World Bank, 2006). Syria is projected to experience reduction in economy-wide growth and incomes of urban households (Breisinger *et al.*, 2013). However, it is not hydrological variability per se that causes the problem, but rather a lack of the necessary capacity, infrastructure, and institutions to mitigate the impacts (Grey and Sadoff, 2007). Similarly, future flood damages will depend not only on changes in the climate regime, but also on settlement patterns, land use decisions, flood forecasting quality, warning and response systems, and other adaptive measures (Changnon, 2005; Pielke and Downton, 2000; Ward *et al.*, 2008). In many developing countries, water related impacts are *likely* to be more pronounced with climate change (Chapter 3) and associated economic costs can be expected to be more substantial in the future, holding all other factors constant.

Climate change could increase the annual cost of flooding in the UK almost 15-fold by the 2080s under high emission scenarios. If climate change increased European flood losses by a similar magnitude, annual costs could increase by up to $120-150 billion, for the same high emission scenarios (ABI, 2005). (Feyen *et al.*, 2012) project average annual damage in the EU to increase to $18-28 billion by 2100 depending on the scenario, compared to $8.5 billion today. Continental US mean annual flood damages may increase by $5 billion and $12 billion in 2050 and 2100, respectively (Wobus *et al.*, 2013). (Ntelekos *et al.*, 2010) estimate a range of $7-19 billion, depending on the economic growth rate and the emissions scenarios. (Dasgupta *et al.*, 2010) report that by 2050 Bangladesh will face incremental cost to flood protection (against both sea and river floods) of $2.6 billion initial costs and $54 million annual recurring costs. (Ward *et al.*, 2008) found that the average annual costs to adapt to a 1in 50 year river flood to range from $3.5 to $6.0 billion per year for low- to upper-middle-income countries over the period 2010–50 for the A2 scenario.

10.3.2. Municipal and Industrial Water Supply

Municipal and industrial water supply economic systems are also impacted through changes in precipitation patterns and quantities. These impacts are evaluated as current costs of building in resiliency to the system to adapt to anticipated future changes. For example, the costs of adaptation to maintain supply and quality of water for municipal and industrial uses have been reported for the Assabet River near Boston (Kirshen *et al.*, 2006), Toronto (Dore and Burton, 2001) and Quito (Vergara *et al.*, 2007). Initial analysis indicates that adapatation measures may be beneficial for water infrastructure with an economic and engineering life of more than 25 years. (Nassopoulos *et al.*, 2012) suggest that neglecting to account for future climate change while designing water supply reservoirs can cost 0.2 to 2.8% of the net present value, based on analysis for Greece. For sub-Saharan Africa, adapting urban water infrastructure (storage facilities, wastewater, and additional supply infrastructure) to a 30% reduction in runoff could be $2-5 billion per year (Muller, 2007). Climate change impacts on the Berg River in South Africa are estimated to account for 15% revenue loss for the water supply provider (Callaway *et al.*, 2012). For the OECD, the cost of adaption in the water supply sector is 1-2% of base costs and would save $6-12 billion per year (Hughes *et al.*, 2010). U.S. impacts are estimated to be less than 1% of municipal and industrial welfare (Hurd *et al.*, 2004; Strzepek *et al.*, 2013). In Colorado, a 30% decrease in annual runoff will result in a 12% treatment cost increase and a 22% rise in residential costs (Towler *et al.*, 2011).

(Ward *et al.*, 2010) estimate the costs of adaptation to climate change to ensure enough raw water to meet future industrial and municipal water demand for each country to 2050. Increased demand is assumed to be met through a combination of increased reservoir yield and alternative backstop measures. The global adaptation costs are estimated to be US$12B/yr (0.04-0.06% of GDP), on top of US$73B/yr to meet the needs of development, with 83-90% in developing countries. The highest costs are in Sub Saharan Africa, and may be as high as 16% of the global total. Adding adaptive measures to water infrastructure adds 10-20% to the total costs of developing countries meeting the water related millennium goals (Ward *et al.*, 2010).

10.3.3. Wastewater and Urban Stormwater

More frequent heavy rainfall events may overload the capacity of sewer systems and water and wastewater treatment plants more often, and increased occurrences of low flows will lead to higher pollutant concentrations. It is projected for USA in 2100 that national wastewater treatment costs will increase by $0.6-8 billion per year (Henderson *et al.*, 2013). The annual costs of urban stormwater system adaptation , averaged costs over17 climate models simulating the A2 emissions scenario, is $3.0 billion per year in low- to upper-middle-income nations over the period 2010–50 (Hughes *et al.*, 2010). Adaptation costs estimates (for a 10-year, 24-hour storm in 2100) for various locations in the USA are relatively low; e.g., $135 million for Los Angeles, $7 million for Boston and $40 million for Chicago (Neumann *et al.*, 2013). Adapting bridges to altered urban floods could cost $140-250 billion in the USA through the 21st century (Wright *et al.*, 2012).

10.3.4. Inland Navigation

See 10.4.4.

10.3.5. Irrigation

Climate change impacts on the economics of irrigation reflect the anticipated change in temperature, precipitation, and agricultural demand and practices. Assessments of surface, ground and grey water irrigation supplies are addressed in Chapter 3; implications for food production are covered in Chapter 7. By 2080, the global annual costs of additional irrigation water withdrawals for currently existing irrigated land are estimated at $24-27 billion (Fischer *et al.*, 2007). The global cost of improved irrigation efficiency to maintain yields is $1.5-2.0 billion dollar per year for the A2 scenario in developing countries in 2050 (Nelson *et al.*, 2009). Adaptation to maintain agricultural production in Ethiopia would be best achieved by better soil water management with the application of integrated irrigation and drainage systems, improved irrigation efficiency and research related to on-farm practices; adaptation costs range from $68 million per year for the dry scenario dominated by irrigation, to $71 million per year under the wet scenario dominated by drainage (Strzepek *et al.*, 2010).

10.3.6. Nature Conservation

Climate change is expected to worsen many forms of water pollution, including the load of sediments, nutrients, dissolved organic carbon, pathogens, pesticides, and salt, as well as thermal pollution, increased precipitation intensity, and low flow periods (Kundzewicz *et al.*, 2007). Future water demands for nature conservation will be different than today’s (see Chapter 4). There is no published assessment of the economic implications.

10.3.7. Recreation and Tourism

Tourism and recreation use substantial amounts of water but the implications of climate-change-induced changes in tourism and recreation on water demand have yet to be quantified. See Section 10.6.

10.3.8. Water Management and Allocation

Water scarcity and competition for water, driven by institutional, economic or social factors, may mean that water assumed to be available for a sector is not and thus economic analyses at the sectoral level are crucial, inter-sectoral and economy-wide assessments are needed for comprehensive economic impacts of water services. Changes in water availability, demand and quality due to climate change would impact water management and allocation decisions. Traditionally, water managers and users have relied on historical experience when planning water supplies and distribution (Adger *et al.*, 2007; UNFCCC, 2007). Under a changing climate, existing allocations may no longer be appropriate. (Arndt *et al.*, 2012) examine the implications of alternative development paths and water allocations to suggest climate-smart development strategies in Africa; under stress situations, allocations of water to energy-generation and irrigation may have economy-wide welfare implications. Water resource related climate change impacts on the USA economy measured as cumulative undiscounted welfare changes over the 21st century range from plus (2000US$) $3 trillion for wet scenarios to minus $13 trillion under dry scenarios (Henderson *et al.*, 2013).

10.3.9. Summary

Globally, greenhouse gas induced increases in flooding and droughts may have substantial economic impacts (capital destruction, sectoral disruption) while estimates of adaptation costs (construction, defensive investment) range from relatively modest to relative high levels (see Box CC-WE).

10.4. Transport

The impact of climate change and sea level rise (SLR) on transport has received qualitative, but limited quantitative, focus in the published literature. The impact depends greatly on the climatic zone the infrastructure is in and how climate change will be manifest. There are three major zones:

Geographic Zone	Changes in Climate Expected to Impact Vulnerability
Freezing/Frost Zone	Permafrost, freeze-thaw cycles, precipitation, flooding, SLR and storms (coastal)
Temperate Zone	Precipitation intensity, flooding, maximum daily precipitation, SLR and storms (coastal)
Tropical Zone	Precipitation intensity, flooding, maximum daily precipitation, SLR and storms (coastal)

As detailed below, several studies have explored the potential impacts of climate change on the transport sector, focusing for example on safety or disruptions of service. Quantitative, economic analyses of the impact on physical infrastructure include (Chinowsky *et al.*, 2010; Chinowsky *et al.*, 2011; Hunt and Watkiss, 2010; Larsen *et al.*, 2008) and on wider economic implications (Arndt *et al.*, 2012).

Adaptation options for each sub-sector of transport infrastructure have been studied. Existing literature includes (Chinowsky *et al.*, 2011; Savonis *et al.*, 2008) with proposed strategies ranging from technical to political, including focus on upgraded design specifications during new construction, retrofitting structures, and modified land-use planning in coastal area. Adaptation and resiliency to extreme events is of particular interest as they may have a cascading impact, in that the loss of critical infrastructure assets will negatively affect the recovery and resiliency of a community (Kirshen *et al.*, 2008a; Kirshen *et al.*, 2008b).

10.4.1. Roads

Studies on the direct effects of climate change on road networks are primarily focused on qualitative predictions and surveys concerning impacts on road durability (Eisenack *et al.*, 2012; Koetse and Rietveld, 2009; Ryley and Chapman, 2012; TRB, 2008); with some studies of the quantitative effects (Chinowsky *et al.*, 2013; Nemry and Demirel, 2012). Noted impacts from changes in precipitation and temperature include changes in required road maintenance. These quantitative studies focus on specific impacts such as maintenance in an effort to quantify the long-term costs that need to be assumed by national and regional road agencies. Examples of the metrics used include kilometers of roads lost over time, redistribution requirements of transport funds and benefits from adaptation on long-term maintenance. Chapter 8 addresses the indirect effects of climate change on roads in the areas of congestion and safety. As an example, increases in heavy precipitation events will negatively affect driving safety through decreased driver visibility and changing surface conditions (Qiu and Nixon, 2008).

Paved road degradation is directly related to heat stress that can lead to softening of the pavement as temperatures exceed design thresholds (Lavin, 2003) and an increase in the number of freeze-thaw cycles impacts both the base and pavement surface (FHWA, 2006). The melting of permafrost in northern climates, as well as increased precipitation and flooding, threaten the integrity of road base and sub-bases (Qin *et al.*, 2005). Drainage presents a specific problem for urban areas that experience rainfall above their built capacity and will influence new design standards and costs for urban transport (CCTF, 2008; Hunt and Watkiss, 2010; Lemmen and Warren, 2010). Increased fire danger from droughts could also pose a threat to roads.

Unpaved roads are vulnerable to a number of climate-based factors especially to increasingly intense precipitation, leading to wash out and disruption of service (Chinowsky and Arndt, 2012). Increased precipitation may agricultural areas may have negative economic impacts in addition to the direct impact on infrastructure. In cold climates, temporary winter roads are susceptible to warming and associated lower connectivity of rural areas and reduced economic activity in Northern climates (Mills and Andrey, 2002). Warming could imply that ice roads can no longer be maintained.

Bridges form a core component of any nation's infrastructure. However, highway bridges that cross water, ubiquitous to most highway networks, are exposed to climate changes via flood events and associated changes in long-term flow regimes. The potential disruptions that could occur due to the loss of or damage to these bridges are numerous. Estimates in the United States range from $140 to $250 billion to address adaptation requirements for bridge infrastructure over the next 50 years (Wright *et al.*, 2012). Similarly, European estimates range from $350-500 million per year to adapt bridge infrastructure (Nemry and Demirel, 2012). Once again, the potential cascading effects of these failures will affect the economic conditions of multiple sectors.

10.4.2. Rail

Rail beds are susceptible to increases in precipitation, flooding and subsidence, sea level rise, extreme events and incidence of freeze-thaw cycles (Nemry and Demirel, 2012). In Northern climates, the melting of permafrost (URS, 2010) may lead to ground settlement, undermining stability (Larsen *et al.*, 2008). Increased temperatures pose a threat to rail through thermal expansion. In urban areas, increased temperatures pose a threat to underground transport systems that will see a burden on increased need for cooling systems (Hunt and Watkiss, 2010). For example, $290 million has been allocated to finding a workable solution for increasing the capacity of London's underground cooling system (Arkell and Darch, 2006). The complexity of addressing rail infrastructure is increased through differences in design specifications, multiple types of rail and materials used, and uncertainty about the changes in future temperatures.

10.4.3. Pipeline

Increases in precipitation and temperature affect pipelines through scouring of base areas and unearthing of buried pipelines (URS, 2010), compromised stability of bases built on permafrost, and increases in necessary maintenance (TRB, 2008; URS, 2010). Temperature increase can result in thermal expansion of the pipelines, causing cracking at material connection points. In tropical areas, increased precipitation may lead to landslides that can compromise pipeline infrastructure (Sweeney *et al.*, 2005). There has been no economic assessment of the impacts.

10.4.4. Shipping

Impacts of inland navigation vary widely due to projected rise or fall in water levels. Overall, the effects on inland navigation are projected to be negative, and are region-specific.

Increased frequency of flood periods will stop ship traffic on the Rhine more often; longer periods of low flow will also increase the average annual number of days during which inland navigation is hampered or stagnates due to limited load carrying capacity of the river; channel improvements can only partly alleviate these problems (Middelkoop *et al.*, 2001). Economic impact could be substantial given the value of navigation on the Rhine (Krekt *et al.*, 2011). See Chapter 23 for more detail.

Virtually all scenarios of future climate change project reduced Great Lakes water levels and connecting channel flows, mainly because of increased evaporation resulting from higher temperatures. The potential economic impact may result in reductions in vessel cargo capacities and increases in shipping costs. The lower water levels predicted as a result of a doubling of the atmospheric carbon dioxide could increase annual transportation costs by 29%, while more moderate climate change could result in a 13 percent increase in annual shipping costs. The impacts vary across commodities and routes (Millerd, 2010).

Warming leads to increased ice-free navigation and longer shipping season, but also to lower water levels from reduced runoff (Lemmen and Warren, 2010). In cold regions, increased days of ice-free navigation and a longer shipping season could impact shipping and reduce transportation costs (Koetse and Rietveld, 2009; TRB, 2008; UNCTAD, 2009; UNECE and UNCTAD, 2010), although movement in ice waters as the Canada Arctic sea more become more difficult (Stewart *et al.*, 2007; Wilson *et al.*, 2004).

Ports will be affected by climate changes including higher temperatures, sea level rise, increasingly severe storms, and increased precipitation (Becker *et al.*, 2011; Nursey-Bray and Miller, 2012). However, (the need to prioritize) adaptation of ports has been overshadowed by a focus on potential impacts. Training of port personnel is needed to begin the adaptation process. Over $3 trillion in port infrastructure assets in 136 of the world's largest port cities are vulnerable to weather events (Potter *et al.*, 2008; UNCTAD, 2009; UNECE and UNCTAD, 2010).

Increased storminess in certain routes may raise cost of shipping through additional safety measures or longer routes that are less storm-prone (UNCTAD, 2009; UNECE and UNCTAD, 2010). Transport costs would increase or new routes sought if storms disrupt supply chains by destroying port infrastructure connecting road or rail (Becker *et al.*, 2011). Increased storminess may also affect passage through lock systems (Potter *et al.*, 2008; UNCTAD, 2009). Increased storminess may increase maintenance costs for ships and ports and result in more frequent weather-related delays.

10.4.5. Air

Hotter air is less dense. In summer months, especially at airports located at high altitudes, this may result in limitations for freight capacity, safety, and weather-related delays, unless runways are lengthened (Pejovic *et al.*, 2009; TRB, 2008). (Chapman, 2007) suggests that technological innovations will negate the challenges posed by extreme temperatures.

Increased storminess at airports, particularly those located in coastal regions, may increase the number of weather-related delays and cancellations (Lemmen and Warren, 2010; Pejovic *et al.*, 2009) and increase maintenance and repair costs (Gusmao, 2010). Clear-air turbulence will increase in the Atlantic corridor leading to longer and bumpier trips (Williams and Joshi, 2013). The impact of climate change on airport pavement is very similar to paved roads (DOT, 2002; Fortier *et al.*, 2007). The effect of temperature and increase precipitation intensity on airports imposes a risk to the entire facility if pavements are not adapted to these increases (Pejovic *et al.*, 2009).

10.5. Other Primary and Secondary Economic Activities

This section assesses the impact of climate change on primary (agriculture, mining) and secondary economic activities (manufacturing, construction), unless they are discussed elsewhere in the chapter or the report.

10.5.1. Primary Economic Activities

Primary economic activities (e.g. agriculture, forestry, fishing, mining) are particularly sensitive to the consequences of climate change because of their immediate dependence on the natural environment. In some regions, these activities dominate the economy.

10.5.1.1. Crop and Animal Production

Chapters 7 and 9 assess the impact of climate change on agriculture, including the effects on (international) markets for crops.

10.5.1.2. Forestry and Logging

Chapter 4 assesses the biophysical impact of climate change on forestry. Including adaptation in forest management, climate change will accelerate tree growth. This will reduce prices to the benefit of consumers everywhere. Low to mid latitude producers will benefit too as they switch to short-rotation forest plantations. Mid to high latitude producers will be hurt by lower prices while their productivity increases only modestly (*Adaptation of Forests and*

*People to Climate Change -- A Global Assessment Report.*2009; Lee and Lyon, 2004; Perez-Garcia *et al.*, 2002; Sohngen and Mendelsohn, 1997; Sohngen and Mendelsohn, 1998; Sohngen *et al.*, 2001). The value of the forest land in Europe would fall between 14 and 50 percent by 2100 (Hanewinkel *et al.*, 2013). Different trees will be affected differently (Aaheim *et al.*, 2011a; Aaheim *et al.*, 2011b). Higher biomass prices differentially impact different forest-based industries (Moiseyev *et al.*, 2011).

10.5.1.3. Fisheries and Aquaculture

Chapter 4 assesses the impact of climate change on freshwater ecosystems, and Chapter 5, 6 and 30 on marine ecosystems. These assessments include the effects on commercially valuable fish stocks, but exclude the effects on markets. Adaptation and markets will substantially change the effect of climate change on fisheries (Link and Tol, 2009; Yazdi and Fashandi, 2010).

(Allison *et al.*, 2009), using an indicator based approach, analyzed the vulnerability of capture fishery of 132 economies. They find, incongruously, that the sign and size of climate-driven change for particular fish stocks and fisheries are uncertain but are expected to lead to either increased economic hardship or missed opportunities for development in countries that depend upon fisheries but lack the capacity to adapt. A major part of the gross turnover of nine key fish and cephalopod species in the Bay of Biscay remains potentially unaffected by climate change (Floc'h *et al.*, 2008). In contrast, Iberian-Atlantic sardine biomass and profitability declines due to climate change (Garza-Gil *et al.*, 2011). The economic impact of climate change on fisheries is dominated by the impact of management regime and market (Eide and Heen, 2002; Eide, 2008; McGoodwin, 2007; McIlgorm, 2010; Merino *et al.*, 2010).

Ocean acidification has a range of impacts on the biological systems (Doney *et al.*, 2009), but the studies on the economic impacts of ocean acidification are rare (Cooley and Doney, 2009; Hilmi *et al.*, 2013). Using a partial equilibrium model, (Narita *et al.*, 2012) estimate the economic impact of ocean acidification on shellfish. By the turn of this century the aggregate cost could be over $100 billion.

10.5.1.4. Mining and Quarrying

Climate change will affect exploration, extraction, production, and shipping in the mining and quarrying industry (Pearce *et al.*, 2011). An increase in climate-related hazards (such as forest fires, flooding, windstorm) affects the viability of mining operations and potentially increases operating, transportation, and decommissioning costs. Most infrastructure was built based on presumption of a stable climate, and is thus not adapted to climate change (Ford *et al.*, 2010; Ford *et al.*, 2011; Pearce *et al.*, 2011). (Damigos, 2012) estimates the damages due to climate change under IPCC A1B scenarios for the period 2021-2050 of the extent of 0.8 billion US dollars for the Mediterranean Region. Note that other factors such as research and development might influence the viability of mining operations by lowering the cost of adaptation.

10.5.2. Secondary Economic Activities

10.5.2.1. Manufacturing

Climate change will impact manufacturing through three channels. First, climate change affects primary economic activities (see above), and this means that prices and qualities of inputs are different. Second, the supply chain is affected, or the quality of the product. The impact of climate change on energy demand is well understood (see 10.2). Using a biophysical model of the human body, (Kjellstrom *et al.*, 2009) project labour productivity to fall, particularly of manual labour in humid climates. Labour productivity losses will be accentuated by increased incidences of malaria and vector borne diseases. Note that the loss in labour productivity can be offset by the technological progress. (Hübler *et al.*, 2008) uphold the finding with a German case study, and (Hsiang, 2010) corroborate it with a statistical analysis of weather data and labour productivity in the Caribbean for 1970-2006.

Some manufacturing activity is location specific, perhaps because it is tied to an input or product market, and will thus have to cope with the current and future climate; other manufacturing has discretion over its location (and hence its climate). Third, climate change affects the demand for products. This is pronounced for manufactures that supply primary sectors (Kingwell and Farré, 2009) and construction material (see below). Unfortunately, there are only a few studies that quantify these effects (see Appendix A).

10.5.2.2. Construction and Housing

Climate and climate change affect construction in three ways. First, weather conditions are one of the key factors in construction delays and thus costs. Climate change will change the length of the building season. Additionally, precipitation affects the cost of construction through temporary flood protection (coffer) structures, slope stabilization management and dewatering of foundations. There are adaptation measures that may reduce some of the costs. (Apipattanavis *et al.*, 2010) show a reduction in the expected value of road construction delays and associated costs. Second, buildings and building materials are designed and selected to withstand a particular range of weather conditions. As climate changes, design standards will change too. Exterior building components including windows, roofing, and siding are all specified according to narrow environmental constraints. Climate change will introduce conditions that are outside the prescribed operating environment for many materials, resulting in increased failures of window seals, increased leaks in roofing materials, and reduced lifespan of timber or glass-based cladding materials. Similarly, the interior building systems that allow for proper airflow in a facility face significant issues with climate change. For example, the increases in temperature and precipitation will lead to increased humidity as well as indoor temperatures. This requires increased airflow in facilities such as hospitals, schools, and office buildings; that is, upgrades to air conditioning and fan units and perhaps further renovations that may be significant in scope and cost. Third, a change in the pattern of natural disasters will imply a change in the demand for rebuilding and repair. Unfortunately, these impacts have yet to be quantified (Hertin *et al.*, 2003). Note that the direction and magnitude of the effect on construction and housing costs will possibly vary geographically. Cost impacts due to changing precipitation and storms patterns (magnitude, frequency, and/or variation) will vary as these changes are expected to vary by region as well. Air to air heat exchangers, heat recovery ventilators, and dehumidifiers and other technologies may be useful in adapting indoor air quality.

10.6. Recreation and Tourism

Recreation and tourism is one of the largest sectors of the world economy. In 2011, it accounted for 9% of global expenditure, and employed 260 million people (WTTC, 2011). Supply of tourism services is the dominant activity in many regional economies.

Recreation and tourism encompass many activities, some of which are more sensitive to weather and climate than others: compare sunbathing to angling, gambling, business seminars, family visits, and pilgrimage. Climate change would affect the place, time and nature of these activities.

There is a large literature on the impact of climate change on tourism (Gössling *et al.*, 2012; Pang *et al.*, 2013; Scott *et al.*, 2012a). Some studies focus on the changes in the behavior of tourists, that is, the demand for recreation and tourism services (see 10.6.1). Other studies look at the implications for tourist operators and destinations, that is, the supply of recreation and tourism services (see 10.6.2). A few studies consider the interactions between changes in supply and demand (see 10.6.3).

10.6.1. Recreation and Tourism Demand

Conventionally, recreation does not involve an overnight stay whereas tourism does. That implies that recreation, unlike tourism, is done close to home. Whereas tourists, to a degree, chose the climate of their holidays, recreationists do not (although climate is a consideration in the choice where to live). Tourists would adapt to climate change by changing the region, timing and activities of their holidays; recreationists would adapt only timing and activities (Becken and Hay, 2007).

10.6.1.1. Recreation

There has been no research on systematic differences of recreational behaviour due to differences in climate at large spatial scales. The impact of climate change on recreation is therefore largely unknown. The economic impact is probably limited, as people will tend to change the composition rather than the level of their time and money spent on recreation. For instance, (Shaw and Loomis, 2008) argue that climate change would increase boating, golfing and beach recreation at the expense of skiing.

There are case studies that indicate the impact of climate change on recreation. (Buckley and Foushee, 2012) find that a trend toward earlier visits to US national parks between 1979 and 2008. They argue this is due to climate change, but do not rigorously test this hypothesis nor control for other explanations. (Whitehead *et al.*, 2009) find a substantial decrease in the recreational value of sea shore fishing in North Carolina due to sea level rise. (Daugherty *et al.*, 2011) conclude that climate change will make it more difficult to guarantee adequate water levels for boating and angling in artificial reservoirs. (Pouta *et al.*, 2009) project a reduction in cross-country skiing in Finland, particularly among women, the lower classes, and urban dwellers. (Shih *et al.*, 2009) find that weather affects the demand for ski lift trips. (Hamilton *et al.*, 2007) highlight the importance of “backyard snow” to induce potential skiers to visit ski slopes. One could expect people to adopt other ways of enjoying themselves but such alternatives were excluded from these studies. There are positive effects too (Richardson and Loomis, 2005). (Scott and Jones, 2006; Scott and Jones, 2007) foresee an increase in golf in Canada due to climate change, (Kulshreshtha, 2011) sees positive impacts on recreation on the Canadian Prairies, and (Coombes *et al.*, 2009) predict an increase in beach tourism in East Anglia. (Graff Zivin and Neidell, 2010) find that people recreate indoors when the weather is inclement. (Scott *et al.*, 2007) estimate the relationship between visitors to Waterton Lakes National Park and *weather* variables for eight years of monthly observations; and use this to project an increase in visitor numbers due to *climate change*. A survey among current visitors indicates that a deterioration of the quality of nature would reduce visitor numbers. (Jones *et al.*, 2006) study the impact of climate change on three festivals in Ottawa. They argue for heat wave preparedness for Canada Day, find that skating on natural ice may become impossible for Winterlude, and that the dates of the Tulip Festival may need to be shifted to reflect changing phenology.

10.6.1.2. Tourism

Climate (Becken and Hay, 2007; WTO and UNEP, 2008) and weather (Day *et al.*, 2013; Falk, 2013; Førland *et al.*, 2012; Rossello, 2011; Rosselló-Nadal *et al.*, 2010; Álvarez-Díaz and Rosselló-Nadal, 2010) are important factors in tourist destination choice, and the tourist sector is susceptible to extreme weather (Forster *et al.*, 2012; Forster *et al.*, 2012; Hamzah *et al.*, 2012; Tsai *et al.*, 2012). (Eijgelaar *et al.*, 2010), for instance, argues that so-called “last chance tourism” is a strong pull for tourists to visit Antarctica to admire the glaciers while they still can. (Farbotko, 2010; Prideaux and Mcnamara, 2012) use a similar mechanism to explain the rise in popularity of Tuvalu as a destination choice. (Huebner, 2012) find no impact of future climate change on current travel choices. (Taylor and Ortiz, 2009) show that domestic tourists in the UK often respond to past weather; the hot summer of 2003 had a positive impact on revenues of the tourist sector. (Denstadli *et al.*, 2011) find that tourists in the Arctic do not object to the weather in the Arctic; (Gössling *et al.*, 2006) reaches the same conclusion for tourists on Zanzibar; and (Moreno, 2010) for tourists in the Mediterranean.

There are a number of biometeorological studies of the impact of climate change on tourism. (Yu *et al.*, 2009a) find that Alaska has become more attractive over the last 50 years, and Florida less attractive to tourists. (Yu *et al.*, 2009b) conclude that the climate for sightseeing has improved in Alaska, while the climate for skiing has deteriorated. (Matzarakis *et al.*, 2010) construct a composite index of temperature, humidity, wind speed and cloud cover, and use this to map tourism potential. (Lin and Matzarakis, 2008; Lin and Matzarakis, 2011) apply the index to Taiwan POC and Eastern China. (Endler and Matzarakis, 2010a; Endler and Matzarakis, 2010b; Endler and Matzarakis, 2011) use an index to study the Black Forest in Germany in detail, highlighting the differences between summer and winter tourism, and between high and low altitudes (Endler *et al.*, 2010). (Matzarakis and Endler, 2010; Zaninović and Matzarakis, 2009) use this method to study Freiburg and Hvar. (Matzarakis *et al.*, 2007) project this potential into the future, finding that the Mediterranean will probably become less attractive to tourists. (Amelung and Moreno, 2012; Amengual *et al.*, 2012; Giannakopoulos *et al.*, 2011; Hein *et al.*, 2009; Perch-Nielsen *et al.*, 2009) reach the same conclusion, but also point out that Mediterranean tourism may shift from summer to the other seasons. (Giannakopoulos *et al.*, 2011) notes that coastal areas in Greece may be affected more than inland areas because, although temperature would be lower, humidity would be higher. (Moreno and Amelung, 2009), on the other hand, conclude that climate change will not have a major impact (before 2050) on beach tourism in the Mediterranean because sunbathers like it hot (Moreno, 2010; Rutty and Scott, 2010). (Amelung *et al.*, 2007) use a weather index for a global study of the impact of climate change on tourism, finding shifts from equator to pole, summer to spring and autumn, and low to high altitudes. (Perch-Nielsen, 2010) combines a meteorological indicator of exposure with indicators of sensitivity and adaptive capacity, and uses this to rank the vulnerability of beach tourism in 51 countries. India stands out as the most vulnerable, and Cyprus as the least vulnerable.

The main criticism of most biometeorological studies is that the predicted gradients and changes in tourism attractiveness have rarely been tested to observations of tourist behaviour. (De Freitas *et al.*, 2008) validate their proposed meteorological index to survey data. (Moreno *et al.*, 2008) and (Ibarra, 2011) use beach occupancy to test meteorological indices for beach tourism. (Gómez-Martín, 2006) tests meteorological indices against visitor numbers and occupancy rates. All four studies find that weather and climate affects tourists, but in a different way than typically assumed by biometeorologists.

(Maddison, 2001) estimates a statistical model of the holiday destinations of British tourists, (Lise and Tol, 2002) for Dutch tourists, (Bujosa and Rosselló, 2012) for Spanish tourists in Spain, and (Bigano *et al.*, 2006) for international tourists from 45 countries. These models control for as many other variables as possible; their focus on the average tourist may be misleading, and their representation of climate may be oversimplified (Gössling and Hall, 2006). Tourists have a clear preference for the climate that is currently found in Southern France, Northern Italy and Northern Spain. People from hot climates care more about the climate in which they spend their holidays than people from cool climates. Whereas (Bigano *et al.*, 2006) find regularity in *revealed* preferences, (Scott *et al.*, 2008b) find pronounced differences in *stated* preferences between types of people.

(Bigano *et al.*, 2007; Hamilton *et al.*, 2005a; Hamilton *et al.*, 2005b) construct a simulation model of domestic and international tourism and climate change (but not sea level rise), considering the simultaneous change in the attractiveness of all potential holiday destinations (Dawson and Scott, 2013); (Hamilton and Tol, 2007) downscale these national results to the regions of selected countries. Two main findings emerge. First, climate change would drive tourists to higher latitudes and altitudes. International tourist arrivals would fall, relative to the scenario without warming, in hotter countries, and rise in colder countries. Tourists from Northwestern Europe, the main origin worldwide of international travelers at present, would be more inclined to spend the holiday in their home country, so that the total number of international tourists falls. Second, the impact of climate change is dominated by the impact of population growth and, particularly, economic growth. In the worst affected countries, climate change slows down, but nowhere reverses, growth in the tourism sector.

10.6.2. Recreation and Tourism Supply

Studies on the supply side often focus on ski tourism. Warming is expected to raise the altitude of snow-reliable ski resorts, and fewer resorts will be snow-reliable (Hendrikx *et al.*, 2012; Hendrikx *et al.*, 2013; Steger *et al.*, 2012)(Dawson *et al.*, 2009). Snowmobiling will be negatively affected too (Scott *et al.*, 2008a)(Mcboyle *et al.*, 2007). Artificial snow-making cannot fully offset the loss in natural snowfall (Elsasser and Bürki, 2002; Scott *et al.*, 2006)(Hoffmann *et al.*, 2009), particularly in lower areas (Schmidt *et al.*, 2012)(Morrison and Pickering, 2012; Wolfsegger *et al.*, 2008), and water scarcity and the costs of snowmaking will be increasingly large problems (Matzarakis *et al.*, 2012)(Scott *et al.*, 2003)(Scott *et al.*, 2007)(Hendrikx and Hreinsson, 2012)(Steiger and Mayer, 2008)(Pons-Pons *et al.*, 2012); skiers prefer natural over artificial snow (Pickering *et al.*, 2010). Tourism alternatives to skiing or non-tourism alternatives need to be considered as a source of economic development (Hill *et al.*, 2010)(Scott and McBoyle, 2007)(Bicknell and Mcmanus, 2006)(Pickering and Buckley, 2010)(Moen and Fredman, 2007)(Tervo, 2008)(Serquet and Rebetez, 2011)(Landauer *et al.*, 2012)(Matzarakis *et al.*, 2012)(Bourdeau, 2009)(Steiger, 2010)(Potocka and Zajadacz, 2009). Other socio-economic trends dominate the impact of climate change (Steiger, 2012)(Hopkins *et al.*, 2012).

Other studies consider beach tourism. (Scott *et al.*, 2012b) highlight the vulnerability of coastal tourism facilities to sea level rise. (Hamilton, 2007) finds that tourists are averse to artificial coastlines, so that hard protection measures against sea level rise would reduce the attractiveness of an area. (Raymond and Brown, 2011) survey tourists on the Southern Fleurieu Peninsula. They conclude that tourists who are there for relaxation worry about climate change, particularly sea level rise, while tourists who are there to enjoy nature (inland) do not share that concern. (Becken, 2005) finds that tourist operators have adapted to weather events, and argues that this helps them to adapt to climate change. (Belle and Bramwell, 2005) find that tourist operators on Barbados are averse to public adaptation policies. (Uyarra *et al.*, 2005) find that tourists on Barbados would consider holidaying elsewhere if there is severe beach erosion. (Buzinde *et al.*, 2010a; Buzinde *et al.*, 2010b) find that there is a discrepancy between the marketing of destinations as pristine and the observations of tourists, at least for Mexican beach resorts subject to erosion. They conclude that tourists have a mixed response to environmental change, contrary to the officials' view that tourists respond negatively. (Jopp *et al.*, 2013) find that an increase in tourism in the shoulder season may offset losses in the peak season in Victoria.

Some studies focus on nature tourism. (Cavan *et al.*, 2006) find that climate change may have a negative effect on the visitor economy of the Scottish uplands as natural beauty deteriorates through increased wild fires. (Saarinen and Tervo, 2006) interviewed nature-based tourism operators in Finland, and found that about half of them do not believe that climate change is real, and that few have considered adaptation options. (Nyaupane and Chhetri, 2009) argue that climate change would increase weather hazards in the Himalayas and that this would endanger tourists. (Uyarra *et al.*, 2005) find that tourists on Bonaire would not return if coral were bleached. (Hall, 2006) finds that small tourist operators in New Zealand do not give high priority to climate change, unless they were personally affected by extreme weather in recent times. The interviewed operators generally think that adaptation is a sufficient response to climate change for the tourism sector. (Klint *et al.*, 2012) find that tourist operators in Vanuatu give low priority to adaptation to climate change and (Jiang *et al.*, 2012) find Fiji poorly prepared. (Saarinen *et al.*, 2012) find that tourist operators in Botswana think that climate change would not affect them. (Wang *et al.*, 2010) note that glacier tourism is particularly vulnerable to climate change, highlighting the Baishiu Glacier in China. (Brander *et al.*, 2012) estimate the economic impacts of ocean acidification on coral reefs under four IPCC marker scenarios using value transfer function approach and find that the annual economic impacts increase rapidly overtime, though it remains a small fraction of total income.

While the case studies reviewed above provide rich detail, it is hard to draw overarching conclusions. A few studies consider all aspects of the impact of climate change for particular countries or regions (Ren Guoyu, 1996)(Harrison *et al.*, 1999). In France, the Riviera may benefit because it is slightly cooler than the competing coastal resorts in Italy and Spain; the Atlantic Coast, although warming, would not become more attractive because of increased rainfall; it is not probable that the increase in summer tourism in the mountains would offset the decrease in winter tourism (Ceron and Dubois, 2005). In the Great Lakes regions, there is a reduced tourism potential in winter but increased opportunities in summer (Dawson and Scott, 2010). Tourist operators in Australia find the uncertainty about climate change too large for early investment in adaptation (Turton *et al.*, 2010).

10.6.3. Market Impacts

There are only two papers that consider the economic impacts of rather stylized climate-change-induced changes in tourism supply and demand. Both studies use a global computable general equilibrium model, assessing the effects on the tourism sector as well as all other markets. (Berrittella *et al.*, 2006) consider the consumption pattern of tourists and their destination choice. They find that the economic impact is qualitatively the same as the impact on tourist flows (discussed above): Colder countries benefit from an expanded tourism sector, and warmer countries lose. They also find a drop in global welfare, because of the redistribution of tourism supply from warmer (and poorer) to colder (and richer) countries. (Bigano *et al.*, 2008) extend the analysis with the implications of sea level rise. The impact on tourism is limited because coastal facilities used by tourists typically are sufficiently valuable to be protected against sea level rise. The economic impacts on the tourism sector are reinforced by the economic impacts on the coastal zone; the welfare losses due to the impact of climate change on tourism are larger than the welfare losses due to sea level rise.

10.7. Insurance and Financial Services

10.7.1. Main Results on insurance of AR4 and SREX

More intense or frequent weather-related disaster would affect property insurance, of which coverage is expanding with economic growth (WG II, 7.4.2.2.4). Insurability can be preserved through risk-reducing measures. Adaptation to climate change can be incentivized through risk-commensurate insurance premiums. Improved risk management would further financial resilience (WG II, 7.4.2.2.4, 7.6.3). Insurance is linked to disaster risk reduction and climate change adaptation, because it enables recovery, reduces vulnerability and provides knowledge and incentives for reducing risk (IPCC, 2012).

10.7.2. Fundamentals of Insurance Covering Weather Hazards

Insurance is organized either through private markets, publicly or public-private partnerships. It internalizes catastrophe risk costs prior to catastrophic events, reducing the economic impact of weather-related and other disasters to individuals, enterprises,and governments, thus stabilizing income and consumption, and decreasing societal vulnerability (Melecky and Raddatz, 2011) (17.5.1). Insurance is based on the law of large numbers: the larger the portfolio of uncorrelated and relatively small risks, the more accurately the average loss per policy can be predicted and charged accordingly, allowing for a lower premium than with a smaller ensemble. Besides spreading risk over a diversified insured population, insurance spreads risk over time. However, weather-related disasters such as floods simultaneously affect many, and thus violate the principle of uncorrelated risks. Consequently, large losses are much more probable, the loss variance is greater, and the tail risk is higher (Kousky and Cooke, 2012). If insurance coverage is to be maintained, insurers would need more risk-based capital to indemnify catastrophic losses and remain financially solvent. This coverage is purchased in the reinsurance and capital markets. The capital costs account for a substantial portion of premiums and the affordability and viability of weather insurance are subjects of ongoing research given future climate change (Charpentier, 2008); (Maynard and Ranger, 2012); (Clarke and Grenham, 2012).

Increasing volatility and burden of losses in many regions are expected to fundamentally impact the industry, leading insurers to adapt their business to the changing risk (Herweijer *et al.*, 2009); (Phelan *et al.*, 2011); (Mills, 2012); (Paudel, 2012), including the use of short-term contracts to adapt to changing cirumstances (Botzen *et al.*, 2010a).

10.7.3. Observed and Projected Insured Losses from Weather Hazards

Direct and insured losses from weather-related disasters have increased substantially in recent decades both globally and regionally (IPCC, 2012); (Bouwer *et al.*, 2007); (Swiss Re, 2013c); (Munich Re, 2013); (Crompton and McAneney, 2008); (Smith and Katz, 2013). Global insured weather-related losses in the period 1980-2008 increased by US$^{2008}1.4bn per year on average (Barthel and Neumayer, 2012). As a rule, insured loss figures are more accurate than direct economic loss estimates, because insurance payouts are closely monitored. Often they are the basis for estimates of direct overall losses (Kron *et al.*, 2012); (Smith and Katz, 2013). Economic growth, including greater concentrations of people and wealth in periled areas and rising insurance penetration, is the most important driver of increasing losses.

Growth induced changes in past losses are removed by normalizing to current levels of destructible wealth. So far, only one study analyzes normalized global weather-related insured losses (Barthel and Neumayer, 2012), but the period is too short (1990-2008) to support a meaningful analysis oftrends. A few studies focus on specific perils and regions, in particular Australia, USA and Europe. Trends were detected for the USA and Germany, but not for Australia and Spain (Table 10-4). Such trends can be influenced by changing damage sensitivities, adaptive measures, different normalization, and changes in insurance – besides changing hazards (Barthel and Neumayer, 2012); (Crompton and McAneney, 2008); (Bouwer, 2011); (IPCC, 2012). Prevention measures such as flood control structures, or improved building standards, would offset an increase in hazard (Kunreuther *et al.*, 2009); (Kunreuther *et al.*, 2012). Given such confounding factors, it can be challenging to estimate to what degree developments in losses convey a climate signal (Kron, 2012); (IPCC, 2012). Nonetheless, normalized direct natural disaster losses have already been demonstrated to properly reflect climate variability on various time scales (Pielke and Landsea, 1999); (Welker and Faust, 2013).

Studies analyzing changes in climate variables and insured losses in parallel are still rare. Variability and mean level of thunderstorm-related insured losses in the USA in the period 1970-2009 have substantially increased, while meteorological thunderstorm forcing has risen in parallel (Sander *et al.*, 2013). The number of days that a regional insurer in southwest Germany sustains hail losses displays an upward trend since 1986, while meteorological severe storm indicators also show upward trends (Kunz *et al.*, 2009). Although more studies find increases of large hail in Europe, general data and monitoring issues hindered assessing more than low confidence in observed meteorological trends (WG1-2.6.2.4). (Corti *et al.*, 2009) found an increase in modeled and partly observed insured subsidence losses in France over the period 1961-2002, consistent with a *likely* increase in dryness in Mediterranean regions (WG1-2.6.2.3). The observed rise in US normalized insured flood losses (Barthel and Neumayer, 2012) may partly correspond to *very likely* increased heavy precipitation events in central North America (WG1-2.6.2.1), while the evidence for climate driven changes in river floods is not compelling (WG1-2.6.2.2). Declining anthropogenic aerosol emissions may partly explain the recent upswing in hurricane hazard and losses (WG1-14.6; WG1-2.6.3; Table 10-4). Apart from detection, loss trends have not been conclusively attributed to anthropogenic climate change; most such claims are not based on scientific attribution methods.

[INSERT TABLE 10-4 HERE
Table 10-4: Observed normalized insured losses from weather hazards (trends significant at the 10% level are indicated as a trend).]

Many GCM-based projection studies agree that extreme winter storm wind speeds fall in the Mediterranean and increase in west, central, and northern Europe (WG1-14.6.2.2). Loss ratios, i.e. insured loss divided by insured value, follow the same pattern (Schwierz *et al.*, 2010); (Donat *et al.*, 2011); (Pinto *et al.*, 2012) (Table 10-5). Return periods per loss level are projected to shorten in large parts of Europe, indicating more frequent high losses (Pinto *et al.*, 2012) (Table 10-5). Projected overall losses and fatalities develop accordingly (IPCC, 2012); (Narita *et al.*, 2010). Across three modeling approaches calibrated to German insurance data, the 25-year loss is projected (A1B) to change by –10% to +18% (2011-2040), +5% to +41% (2041-2070), and +45% to +58% (2071-2100) against 1971-2000, keeping exposures and damage sensitivities constant (Held *et al.*, 2013). Although it is *unlikely* that the North Atlantic response to climate change is just a simple poleward shift of the stormtrack, overall confidence in the magnitude of regional storm track changes is low (WG1-14.6.3).

[INSERT TABLE 10-5 HERE
Table 10-5: Climate change projections of insured losses and/or insurance prices.]

Direct losses and fatalities from flooding will increase with climate change in various locations in the absence of adequate adaptation, given *very likely* wide-spread increases in heavy precipitation (WG1-12.4.5.4; 11.3.2.5.2) (IPCC, 2012). This is selectively reflected in studies projecting mean annual insured heavy rainfall and flood losses will rise with climate change in the UK, the Netherlands, Germany, southern Norway and the Canadian province of Ontario (Table 10-5).

Direct losses and fatalities from tropical cyclones will increase with exposure and may increase with the frequency of very intense cyclones in some basins (WG1-14.6); (IPCC, 2012); (Nordhaus, 2010); (Peduzzi *et al.*, 2012). (Ranger and Niehoerster, 2012), (Kunreuther *et al.*, 2012), and (Raible *et al.*, 2012) found insured hurricane losses change in opposite directions across a range of dynamical and statistical model projections, whereas a high-resolution approach tends to support a long-term increase (Emanuel, 2011). Here, increased probabilities of upward shifted accumulated loss might be detectable by 2025 at earliest, whereas a significant loss trend might emerge much later (Emanuel, 2011); (Crompton *et al.*, 2011). Insured typhoon-related property losses in China are projected to increase (Dailey *et al.*, 2009). Averaged across four GCMs, (Mendelsohn *et al.*, 2012) project rising direct losses for Central America, the Caribbean, North America, and East Asia. (Narita *et al.*, 2009) report an increase in damages and fatalities in all parts of the world.

Hailstorm insurance losses in the Netherlands (Botzen *et al.*, 2010b) and Germany (Gerstengarbe *et al.*, 2013) are projected to increase, consistent with more severe thunderstorms (WG1-12.4.5.5). Paddy rice insurance payouts in Japan are projected to decrease (Iizumi *et al.*, 2008) (Table 10-5).

Rising insured wealth will increase both losses and premium income, not necessarily altering the ratio of both. Such automatic compensation is not effective for changing hazards. Hence, projected ratios of losses to premiums or sums insured (while assuming constant insured property) are an approximation of the climate change impact (Donat *et al.*, 2011). Additional impact factors such as future economic growth (Aerts and Botzen, 2011) or changing vulnerability are rarely projected.

10.7.4. Fundamental Supply-Side Challenges and Sensitivities

10.7.4.1. High-Income Countries

The provision of weather hazard insurance is contingent on an insurer’s ability to find a balance between affordability of the premiums and costs that have to be covered by the revenue. Costs include, the expected level of losses, expenses for risk assessment, product development, marketing, operating, and claims processing. Moreover, the revenue must provide a return on shareholders’ equity and allow for the purchase of external capital to cover large losses (Charpentier, 2008); (Kunreuther *et al.*, 2009).

The balance between affordability and profitability is sensitive to climate change. Increases in large weather-related losses may corrode an insurer’s solvency if it fails to adjust its risk management, or is hampered in doing so by price regulation (Grace and Klein, 2009). Additionally, misguided incentives for development in hazard-prone areas, as with the US National Flood Insurance Program (Kousky and Cooke, 2012)); (Michel-Kerjan, 2010); (GAO, 2011), can aggravate the situation (Table 10-6).

[INSERT TABLE 10-6 HERE
Table 10-6: Fundamental supply-side challenges and sensitivities.]

The additional uncertainty induced by climate change translates into a need for more risk capital (Charpentier, 2008); (Kunreuther *et al.*, 2009); (Grace and Klein, 2009). This raises insurance premiums and affects the economy (Table 10-6). Health and life insurance may also be affected through the health impacts of climate change (Hecht, 2008). Liability insurance, too, may be susceptible to climate change. So far, no damages have been awarded for greenhouse gas emissions as such, but litigation where damages are sought is pending (Mills, 2009); (Heintz *et al.*, 2009); (Patton, 2011). Defense cost coverage under liability insurance in such cases depends on the specific contractual wording (Supreme Court of Virginia, U.S.A., 2012)) (Table 10-6).

10.7.4.2. Middle- and Low-Income Countries

Middle- and low-income countries account for a small share of worldwide non-life insurance: approximately 14% of premiums in 2012 (Swiss Re, 2013b). In high-income countries, some 35% of direct natural disaster losses have been covered by insurance in the period 1980-2011, about 5% in middle-income countries, and less than 1% in low-income countries (Wirtz *et al.*, 2013). For instance, only about 1% of direct overall losses in the 2010 floods in Pakistan were insured (Munich Re., 2011).

The small share of insurance in risk financing in middle and low income countries may be insufficient because other options, such as external credit or donor assistance, can be unreliable and late. This leaves a financial gap in the months immediately following an EWE, often exacerbated by overstretched public finances. Pre-disaster financing instruments such as insurance or trigger-based risk-transfer products have proven to be effective means of providing prompt liquidity for households, businesses, and governments (Ghesquiere and Mahul, 2007); (Linnerooth-Bayer *et al.*, 2011); (Melecky and Raddatz, 2011; von Peter *et al.*, 2012); (IPCC, 2012); Table 10-6). These may become more important if disaster incidence increases with climate change (IPCC, 2012); (Collier *et al.*, 2009); (Hochrainer *et al.*, 2010).

It is challenging to increase catastrophe insurance coverage because of low business volumes, high transaction costs, and high reinsurance premiums following large disasters. Small-scale insurance schemes in middle- and low-income countries may find it difficult to obtain sufficient risk capital (Cummins and Mahul, 2009); (Mahul and Stutley, 2010).

Microinsurance schemes, keeping transaction costs at the lowest operable level, mainly provide health and life insuracne to households and small enterprises in low-income markets. Supply of property insurance suffers from correlated weather risks, although weather-related agricultural damages are covered. Such weather coverage is growing, typically with government and NGO assistance or cross-subsidies from local insurers (Linnerooth-Bayer *et al.*, 2011; Qureshi and Reinhard, 2011). These schemes may be particularly sensitive to a rise in disaster risk due to climate change (Collier *et al.*, 2009); (Leblois and Quirion, 2011); (Clarke and Grenham, 2012).

Adverse selection is another challenge: clients do not always disclose their true risk, e.g. a floodplain site, to the insurer so as to benefit from lower rates. Lower-risk participants may be charged too high premiums and leave the scheme, thus increasing overall risk; and in low-income countries, where data to establish homogenous risk groups are not available, this can cause disaster insurance markets to fail. Moral hazard is another issue, where the insured adopt more risky behavior than anticipated by the insurer, particularly in the absence of proper monitoring (Barnett *et al.*, 2008); (Mahul and Stutley, 2010).

10.7.5. Products and Systems Responding to Changes in Weather Risks

10.7.5.1. High-Income Countries

A rise in weather-related disaster risk may drive the need for more risk-based capital to cover the losses. There are several options that sustain insurability. Reducing vulnerability often makes sense even if expected climate change impacts will not materialize. Theoretically, risk-based premiums incentivize policyholders to reduce their vulnerability (IPCC, 2012); (Hecht, 2008); (Kunreuther *et al.*, 2009) (Table 10-7). Premium discounts for loss-prevention can further promote this (Ward *et al.*, 2008); (Kunreuther *et al.*, 2009) (Table 10-7). Moral hazard can be reduced by involving the policyholder in the payment of losses, e.g. via deductibles or upper limits of insurance coverage (Botzen and van den Bergh, 2009); (Botzen *et al.*, 2009). Coordinated efforts of insurers and governments on damage prevention decrease risk (Ward *et al.*, 2008); (Reinhold *et al.*, 2012). For example, new building standards in Florida reduced mean damage per house by 42% in the period 1996-2004 relative to pre-1996; risks can be further reduced, and premium discounts contingent on building standard are offered (Kunreuther *et al.*, 2009); (Kunreuther *et al.*, 2012). However, risk-based premiums required to incentivize vulnerability reduction are often hampered (see also 15.4.4, 17.5.1). Price regulation, subsidies, competitive pressures, and bundling of perils in one product (implying cross-subsidies) have fostered underpricing. Also, availability of sufficient on-site risk information limits price adequacy, e.g. for flood insurance (Maynard and Ranger, 2012).

[INSERT TABLE 10-7 HERE
Table 10-7: Products and systems responding to changes in weather risks.]

Most commercial risk-assessment models only incipiently factor in changes in weather hazards, mainly to reflect higher hurricane frequencies (Seo and Mahul, 2009), assuming unchanging conditions for other weather hazards. Ignoring changing hazard conditions results in biased estimates of expected loss, loss variability and risk capital requirements (Charpentier, 2008); (Herweijer *et al.*, 2009) (10.7.3). Other confounding factors, e.g. systemic economic impact, in recent large losses have been addressed (Muir-Wood and Grossi, 2008) (Table 10-7). For example, geospatial risk-assessment tools, e.g. flood-recurrence zoning with premium differentiation, counteract adverse selection (Kunreuther *et al.*, 2009); (Mahul and Stutley, 2010). Some insurers have offered weather alert systems to clients (Niesing, 2004). Further, credit rating agencies and Solvency II insurance regulations in Europe contribute to enhanced disaster resilience (Michel-Kerjan and Morlaye, 2008); (Kunreuther *et al.*, 2009); (Grace and Klein, 2009). Finally, insurers and researchers have projected climate change driven losses to allow for adaptation of the industry (10.7.3).

Reinsurers are key to the supply of disaster risk capital. They operate globally to diversify the regional risks of hurricanes and other disasters. Access to reinsurance enhances risk diversification of insurers. Periodic shortages in reinsurance capacity following major disasters have moderated over the last two decades because of easier new capital inflow (Cummins and Mahul, 2009).

Global diversification potential of large losses has fallen over recent decades because of increasing dependence between major insurance markets. For instance, the floods in Thailand in 2011 disrupted industrial hubs and global supply chains (Courbage *et al.*, 2012). This process may continue with climate change (Sherement and Lucas, 2009); (Kousky and Cooke, 2012). However, global diversification potential can be increased by developing insurance markets in middle- and low-income countries (Cummins and Mahul, 2009).

Very large loss events, say in excess of US$ 100bn, may make additional capacity desirable. These disasters can be diversified in the financial securitization market (IPCC, 2012). Natural catastrophe risks are not correlated with capital market risks and hence are attractive to institutional investors. For instance, a catastrophe bond assures the investor above-market returns as long as a parametric index (e.g., wind-based) does not exceed a threshold, but pays the insurer’s loss otherwise. The catastrophe bond market reached critical mass after the hurricanes of 2004 and 2005, with some US$ 11bn of risk capital in effect by June 2011 (Cummins, 2012); (Cummins and Weiss, 2009); (Michel-Kerjan and Morlaye, 2008); (Kunreuther and Michel-Kerjan, 2009) (Table 10-7).

10.7.5.2. Middle- and Low-Income Countries

Index-based weather insurance is often considered well-suited to the agricultural sector in developing countries (Collier *et al.*, 2009); (IPCC, 2012). Payouts depend on a physical trigger, e.g. cumulative rainfall at a nearby weather station, instead of the policyholder’s condition. Thus, they can be timely; costly loss assessments and moral hazard are avoided, and adverse selection reduced (Barnett *et al.*, 2008). Risk-based premiums can encourage adaptive responses (Mahul and Stutley, 2010) (Table 10-7). However, basis risk, where losses occur but no payout is triggered, provokes distrust. Misunderstanding and scaling up of pilots pose further difficulties (Patt *et al.*, 2010); (Leblois and Quirion, 2011); (Clarke and Grenham, 2012). Suggested improvements include area-yield indices and coverage at aggregate levels to reduce basis risk, and a cooperative design (Clarke and Grenham, 2012); (Biener and Eling, 2012) (Table 10-7). Application of indemnity-based insurance and index-based concepts depend on the insured’s characteristics and the market setting ((Herbold, 2013a); (Swiss Re, 2013a)). Insurance-linked services can strengthen farmers’ resilience by seasonal-forecast-based agricultural guidance (*AgroClima. Informática Avanzada SA de CV.*2013).

Improved building standards at high-risk sites in the Caribbean ubstantially reduce damages from tropical cyclones and increase benefits twofold over costs over a twenty year period, assuming scenarios of changing hazard inferred from past decades (Ou-Yang *et al.*, 2013); (Michel-Kerjan *et al.*, 2013). Insurance coverage linked to credit for retrofitting could improve adaptation (Mechler *et al.*, 2006).

Sovereign insurance is deemed appropriate in developing countries suffering from post-disaster financing gaps (see 10.7.4). Current schemes include government disaster reserve funds (FONDEN, Mexico) and pools of developing states’ sovereign risks (e.g., CCRIF, Caribbean) (IPCC, 2012). In both cases, peak risk is transferred to reinsurance and catastrophe bonds (Table 10-7).

10.7.6. Governance, Public-Private Partnerships, and Insurance Market Regulation

10.7.6.1. High-Income Countries

Theory favors an arrangement where individual risk is insured, but the non-diversifiable component of risk (that may rise with climate change) is public (Borch, 1962); (Kunreuther *et al.*, 2009). Accordingly, many high-income states have public-private arrangements involving government intervention on peak risk (Aakre *et al.*, 2010); (Bruggeman *et al.*, 2010); (Schwarze *et al.*, 2011); (Paudel, 2012), or even public statutory insurance systems (Quinto, 2011) (Table 10-8). Expected post-disaster relief has been shown to counteract insurance uptake (Raschky *et al.*, 2013). The pro-adaptive, risk-reducing features of insurance are more effective if the price reflects the risk and the pool of insureds is larger, e.g. through bundled perils (Bruggeman *et al.*, 2010); (Paudel, 2012). People who cannot afford premiums can be covered by vouchers, leaving the price signal undistorted, or by subsidies (Kunreuther *et al.*, 2009); (Aakre *et al.*, 2010) (Table 10-8). Insurance regulation ensures availability, affordability, and solvency, but often adopts only short- to medium-term views. Because of climate change, the role of regulators has changed to include risk-adequate pricing, risk education, and risk-reduction in the long term (Hecht, 2008); (Grace and Klein, 2009); (Mills, 2009).

[INSERT TABLE 10-8 HERE
Table 10-8: Governance, public-private partnerships, and insurance market regulation.]

10.7.6.2. Middle- and Low-Income Countries

A key element of risk financing is the transfer of private risks to an insurance system. This reduces the governments' burden and uncertainty due to weather disasters (Ghesquiere and Mahul, 2007); (Melecky and Raddatz, 2011). Interest in public-private partnerships may evolve, e.g. between government, farmers, rural banks and insurers, in order to expedite agricultural development and resilience, e.g. by means of subsidies for start-up costs and peak risk (Collier *et al.*, 2009); (Mahul and Stutley, 2010) (Table 10-8). Previously implemented systems have suffered from adverse selection and moral hazard (Makki and Somwaru, 2001); (Glauber, 2004), suggesting an improved design is needed. For instance, group policies that foster mutual monitoring, programs or legislative actions that encourage purchase of insurance may increase participation rates. Further, insurance pools can diversify weather risks across larger regions, reduce premiums and improve access to external risk capital (Mendoza, 2009); (Hochrainer and Mechler, 2011); (Biener and Eling, 2012); (IPCC, 2012).

In least developed countries, domestic insurance markets are rare. Climate change-related disaster risk management was proposed for inclusion in the adaptation regime of the UNFCCC. Besides prevention, insurance is a central element in these concepts, partly funded from an UNFCCC adaptation fund according to the principles of "equity and […] common but differentiated responsibilities and respective capabilities" (UNFCCC Art.3.1); (Warner and Spiegel, 2009); (Linnerooth-Bayer *et al.*, 2009); (IPCC, 2012) (Table 10-8).

For insurance systems in developing markets, challenges include adequate public-privated partnership framing, improved risk assessment, with sufficient detail and appropriate dynamics, development of markets and regulation, and scaling-up of successful schemes. Regulatory requirements for risk-based capital, and access to reinsurance and securitization markets further contribute to a resilient insurance system.

10.7.7. Financial Services

The financial industry apart from insurance is vulnerable to both slow-onset changes and to more frequent and/or intensive weather-related disasters. Equity investors potentially face a higher exposure than debt investors, due to exit conditions and a focus on longer-term returns in equity markets, but ultimately the impact on debt investors depends on the exposure of credit collateral to climate change (Stenek *et al.*, 2010). In the short-to medium term, the financial sector is better sheltered from climate change due to high capital mobility, an ability to hedge against a range of business risks, an aptitude for the development of new products to cater for changing demand in particular with respect to risk transfers and invest in growing markets (Oliver Wyman, 2007); (Whalley and Yuan, 2009). In the longer-term, some risks associated with climate change will be more difficult to diversify in particular for financial institutions with local reach.

There are few papers on the impact of climate change on the financial sector (other than insurance). Surveys agree with earlier views (AR3, WGII, 8.4.) that climate change is perceived as a material threat by few bankers and asset managers. There is growing awareness of climate change impacts, as illustrated by increasing membership of sector initiatives such as the Carbon Disclosure Project, the UN Principles for Responsible Investment or the Global Reporting Initiative, potentially influencing the responsiveness of the sector to climate change (Brimble and Stewart, 2009). However, only a few financial institutions have systematically factored in climate change into their risk management and analytical framework (Cogan, 2008); (Furrer *et al.*, 2012).

While direct physical impact (i.e. damage to financial infrastructure) is not seen to be a material issue, this may change in the future in light of the exposure of major financial centres to rising sea levels and the reliance on complex IT infrastructure. Moreover, there is an increasing share of equity allocated to infrastructure and real estate that is more long-term oriented and could face higher maintenance and adaptation requirements (Stenek *et al.*, 2010); (Mercer, 2011).

Indirect impacts may become material over the next few decades, for example, value losses of assets/loan portfolios as a result of physical damage. Regulatory and reputational effects, together with liability and litigation risks linked to climate change are of concern too (Cogan, 2008); (Mercer, 2011); (Furrer *et al.*, 2012). However, legitimacy concerns linked to climate change (as reflected by clients) are insufficient, overshadowed by the financial crisis, or mitigated by the size and influence of the financial sector (Brimble and Stewart, 2009).

It is difficult to quantify how significant the impact of climate change will be for the industry. While it is not probable that climate change alone will affect the liquidity or financial capacity of an institution, the financial performance of both equity and debt markets could be weakened by a variety of factors including changes in market conditions through climate driven price variations, higher capital and operating expenditure or aggravation of country risk but also regulatory drivers, e.g. higher capital reserve requirements to cover higher on-and off-balance-sheet exposures (Stenek *et al.*, 2010).

10.7.8. Summary

More frequent or more severe extreme weather events, and increased uncertainty about such hazards, would lead to higher insurance premiums and reduced cover in several regions, to the detriment of the insured, and perhaps to reduced profitability of insurers, and to the detriment of their shareholders. Improvements in risk management, product innovation, financial innovation and better regulation would partially alleviate these impacts.

10.8. Services Other than Tourism and Insurance

Other service sectors of the economy include waste management, wholesale and retail trade, engineering, government, education, defense and health. Contributions to the economy vary substantially by country; however, overall worldwide economic activity related to government accounts for approximately 30% of global expenditures.

10.8.1. Sectors Other than Health

The literature on the impact of climate change on other sectors of the economy is sparse (see Appendix A). Few studies have evaluated the possible impacts of climate change, and particularly the economic impacts, on these sectors. (Tamiotti *et al.*, 2009) conducted a qualitative assessment of climate and trade. (Travers and Payne, 1998) and (Subak *et al.*, 2000) find that weather affects retail, mostly through transfers in the economy. (Sabbioni *et al.*,

2009) note that climate change may require a greater effort to protect cultural heritage. Chapter 12 discusses the impact of climate change on violent conflict, which has implications for military expenditures.

10.8.2. Health

Climate change-related alterations in weather patterns, particularly extreme weather and climate events, have the potential to affect the health sector through impacts on infrastructure and the delivery of health care services from changing demand. Increased demands for services put additional burdens on public health and health care personnel and supplies, with potential economic consequences. For example, hydrologic disasters (floods and wet mass movements) in 2011 were associated with 20% (140 million) of all reported disaster deaths and 19% of total damages (Guha - Sapir *et al.*, 2012).

Health care facilities are priority infrastructure that can be damaged by weather and climate events, compromising critical resources required for patient treatment; physical damage and destruction of equipment and buildings; and possibly requiring evacuation of critical care patients, with attendant risks for the patients (Carthey *et al.*, 2009). Adverse impacts on transportation (such as flooded roads) can further affect access and evacuation. The ability of health care facilities to properly care for the affected and for those with ongoing health issues requiring medication or treatment may be compromised by very large events that affect multiple health care facilities. Areas projected to experience increases in extreme events could consider additional “surge capacity” to manage such events without interruption of service (Banks *et al.*, 2007; Hess *et al.*, 2009).

Although the proportion of individuals seeking medical treatment during a disaster is typically a small subset of the total number of those affected, the additional burden on health care facilities can be significant (Hess *et al.*, 2009). Six weather and climate events that struck the US between 2000 and 2009 were estimated to have increased health care costs by US$740 million, reflecting more than 760,000 encounters with the health care system (Knowlton *et al.*, 2011). Hospitalizations, with attendant costs, can increase from cases of heat stress, heat stroke, and acerbations of cardiorespiratory diseases and other health conditions during heatwaves (e.g. (Astrom *et al.*, 2013; Lin *et al.*, 2012), and from the adverse health impacts of other extreme events (Chapter 11.4.1; 11.4.2). For example, one trauma center in the U.S. found a 5% increase in hourly admissions for each approximately 5°C increase in temperature (Rising *et al.*, 2006). Individuals looking for an air-conditioned location during high ambient temperatures can further increase hospital visits (Carthey *et al.*, 2009).

Climate change is projected to increase the burden of major worldwide causes of childhood mortality, including malnutrition, diarrheal diseases, and malaria (Chapter 11.5.1; 11.5.2; 11.6.1). Any increase in health burdens or risks would increase the demands for public health services (e.g. surveillance and control programs) and the demands for health care and relevant supplies (e.g. antimalarials, insecticide treated bednets, oral rehydration). Studies estimating the costs of additional cases of climate-sensitive health outcomes focus on the costs of treatment, typically omitting the costs of providing additional health services, implementing new policies, and health actions in other sectors (Hutton, 2011). Because most climate change-related cases of adverse health outcomes are projected to occur in low-income countries, treatment costs will primarily be borne by families where governments provide limited health care (WHO, 2004). Time off from work to care for sick children could affect productivity.

Public and private health expenditures account for approximately 10% of global GDP (http://data.worldbank.org/indicator/SH.XPD.TOTL.ZS). A systematic analysis of developing country government expenditures on health from domestic sources estimated that from 1995 to 2006, public financing of health in constant US$ increased nearly 100%; this was a product of rising GDP, slight decreases in the share of GDP spent by government, and increases in the share of government spending on health (Lu *et al.*, 2010). The results varied by region, with shares of government expenditures on health increasing in many regions but decreasing in many sub-Saharan African countries. Development assistance for health rose from about US$8 billion (in constant 2007 US$) in 1995 to nearly $19 billion in 2005 (Ravishankar *et al.*, 2009). Domestic government spending on health was negatively affected by development assistance to governments and positively effect when assistance was to the non-governmental sector (Lu *et al.*, 2010).

Estimates of the costs of treating future cases of adverse health outcomes from climate change are in the range of billions of US$ annually (Ebi, 2008; Pandey, 2010). An estimate of the worldwide costs in 2030 of additional cases of malnutrition, diarrheal disease, and malaria due to climate change, assuming no population or economic growth, emissions reductions resulting in stabilization at 750 ppm CO_2 equivalent in 2210, and current costs of treatment in developing countries, estimated treatment costs without adaptation could be $4-12 billion worldwide, depending on assumptions of the sensitivity of these health outcomes to climate change (Ebi, 2008). The costs for additional infrastructure and health care workers were not estimated, nor were the costs of additional public health services, such as surveillance and monitoring. The costs were estimated to be unevenly distributed, with most of the costs borne by developing countries, particularly in South East Asia and Africa, to address the projected approximately 3-5% increase in the number of cases of diarrheal disease and malaria from the 2002 baseline (Markandya and Chaibai, 2009). The prevalence of these diseases have since declined (http://apps.who.int/gho/data/node.main.14?lang=en; Chapter 11.1.1), although there is considerable uncertainty in mortality data from many low-income countries because of the low proportion of deaths covered by vital registration programs (Byass *et al.*, 2013).

A second global estimate assumed UN population projections, strong economic growth, updated projections of the current health burden of diarrheal diseases and malaria, two climate scenarios, and updated estimates of the costs of malaria treatment (Pandey, 2010). In 2010, the average annual adaptation costs for treating diarrheal disease and malaria were estimated to be $3-5 billion, with the costs expected to decline over time with improvement in basic health services. Over the period 2010-2050, the average annual costs were estimated to be around $2 billion, with most of the costs related to treating diarrheal disease; the largest burden is expected to be in Sub-Saharan Africa. The differences in costs from (Ebi, 2008) are primarily due to a reduction in the baseline burden of disease and lower costs for malaria treatment.

(Watkiss and Hunt, 2012) estimated the health impacts of climate change in Europe in 2071-2100 using physical and monetary metrics, taking socioeconomic change into consideration. Temperature-related mortality during winter and summer due to climate change included positive and negative effects, with welfare costs (and benefits) of up to $130 billion annually, with impacts unevenly distributed across countries. Assumptions about acclimatization influenced the size of the health impacts. The welfare costs for salmonellosis were estimated at potentially several hundred million Euro annually, and those for the mental health impacts associated with coastal flooding due to climate change were up to approximately $2 billion annually.

Estimated additional health care costs for climate change-related cases of malaria are similar in Southern Africa (van Rensburg and Blignaut, 2002). Ranges for (low-high) additional cost scenarios for the prevention and treatment of malaria in South Africa in 2025 were estimated to be approximately $280 - $3,764 million. Estimates for Botswana and Namibia are $9- $124 million and $13- $177 million, respectively. The high cost scenario for Namibia is about 4.6% of GDP. The climate change-related malaria inpatient and outpatient treatments costs at the end of the century (2080-2100) in 25 African countries[1] indicated that even marginal changes in temperature and precipitation could affect the number of malaria cases, with increases in most countries and decreases in others (Egbendewe-Mondzozo et al. 2011). The end of century treatment costs as a proportion of annual 2000 health expenditures per 1,000 people would increase in the vast majority of countries, with increases of more than 20% in inpatient treatment costs for Burundi, Cote D'Ivoire, Malawi, Rwanda, and Sudan.

[FOOTNOTE 1: Algeria, Benin, Botswana, Burkina, Burundi, Central African Republic, Chad, Cote D'Ivoire, Djibouti, Egypt, Ethiopia, Ghana, Guinea, Malawi, Mali, Mauritania, Morocco, Niger, Rwanda, South Africa, Sudan, Togo, Uganda, Tanzania, Zimbabwe.]

The costs of treating cases of cholera in Tanzania due to climate change in 2030 were estimated to be in the range of 0.32 – 1.4 % of GDP (Trærup *et al.*, 2011), and there would be costs for treating additional cases of diarrhea and malaria in India in 2030, depending on the emission scenario (Ramakrishnan, 2011).

(Bosello *et al.*, 2006) used a computable general equilibrium model to study the economic impacts of climate-change-induced changes in mortality and morbidity due to cardiovascular and respiratory diseases, malaria, diarrhea, schistosomiasis, and dengue fever. They considered the effects on labor productivity and demand for health care, and found that health and welfare impacts have the same sign. The economy-wide health impacts were greater than simple aggregation of the costs of the individual health outcomes. Increased health problems were associated with an expansion of the public sector at the expense of the private sector.

Estimates of the impacts of climate change on worker productivity, assuming current work practices, primarily through heat stress, indicate that productivity has already declined during the hottest and wettest seasons in parts of Africa and Asia, with more than half of afternoon hours projected to be lost to the need for rest breaks in 2050 in South East Asia and up to a 20% loss in global productivity in 2100 under RCP4.5 (Chapter 11.6.2; (Dunne *et al.*, 2013; Kjellstrom *et al.*, 2013; Kjellstrom *et al.*, 2009). Alternate workpractices may offer some relief from a health perspective, but would *likely* lead to significantly decreased productivity (Chapter 11).

10.9. Impacts on Markets and Development

Prior sections of this chapter present the direct impacts of climate change on the economy sector by sector. There are, however, also indirect impacts, from the one sector on the rest of the economy (10.9.1) and on economic growth and development (10.9.2).

10.9.1. Effects of Markets

There are three channels through which economic impact diffuse. First, outputs of one sector are used as inputs to other sectors. For example, a change in crop yields would affect the food-processing industry. Second, products compete for the consumers' finite budget. If, for example, food becomes more expensive, consumer would shift to cheaper food but also spend less money on other goods and services. Third, sectors compete for the primary factors of production (labor, capital, land, water). If, besides more fertilizers and irrigation, more labor is needed in agriculture to offset a drop in crop yields, less labor is available to produce other goods and services. Firms and households react to changes in relative prices, domestically and internationally. Ignoring these effects would lead to biased estimates of the impacts of climate change.

General equilibrium analysis describes how climate change impacts in one sector propagate to the rest of the economy, how impacts in one country influence other countries, and how macroeconomic conditions affect each impact (Ginsburgh and Keyzer, 1997). General equilibrium models can provide a comprehensive and internally consistent analysis of the medium-term impact of climate change on economic activity and welfare. However, these models necessarily make a number of simplifying assumptions, particularly with regard to the rationality of consumers and producers and the absence of market imperfections. Other types of economic models have yet to be applied to the estimation of indirect economic effects of climate change.

Computable general equilibrium models have long been used to study the wider economic implications of changes in crop yields (Kane *et al.*, 1992). (Yates and Strzepek, 1998) show for instance that the impact of a reduced flow of the Nile on the economy of Egypt is much more severe without international trade than with, because trade would allow Egypt to focus on water-extensive production for export and import its food.

Older studies focused on the impact of climate change on patterns of specialization and trade, food prices, food security and welfare (Darwin and Kennedy, 2000; Darwin, 2004; Kane *et al.*, 1992; Reilly *et al.*, 1994; Winters *et al.*, 1998; Yates and Strzepek, 1998). This has been extended to land use (Lee, 2009; Ronneberger *et al.*, 2009), water use (Calzadilla *et al.*, 2011; Kane *et al.*, 1992), and multiple stresses (Reilly *et al.*, 2007). General equilibrium models have also been used to estimate the value of improved weather forecasts (Arndt and Bacou, 2000), a form of adaptation to climate change. Computable general equilibrium analysis has also been used to study selected impacts other than agriculture, notably sea level rise (Bosello *et al.*, 2007b; Darwin and Tol, 2001), tourism (Berrittella *et al.*, 2006; Bigano *et al.*, 2008), human health (Bosello *et al.*, 2006) and energy (see 10.2).

(Bigano *et al.*, 2008) study the joint, global impact on tourism and coasts in the 21st century, finding that changes in tourist demand dominate the welfare impacts of sea level rise. (Kemfert, 2002) and (Eboli *et al.*, 2010a; Eboli *et al.*, 2010b) estimate the joint, global effect on the world economy(Eboli *et al.*, 2010b) of a range of climate change impacts in the 21st century, but conflate general equilibrium and growth effects. (Aaheim *et al.*, 2010) analyze the economic effects of impacts of climate change on agriculture, forestry, fishery, energy demand, hydropower production, and tourism on the Iberian Peninsula. They find positive impacts on output in some sectors (agriculture, electricity) negative impacts in other sectors (forestry, transport) and negligible ones in others (manufacturing, services). (Ciscar *et al.*, 2011) study the combined impact on agriculture, coasts, river floods and tourism in the current European economy. They find an average welfare loss of 0.2-1.0% (depending on the SRES scenario) but there are large regional differences with losses in Southern Europe and gains in Northern Europe.

The following initial conclusions emerge. First, markets matter. Impacts are transmitted across locations—with local, regional and global impacts-- and across multiple sectors of the economy. For instance, landlocked countries are affected by sea level rise because their agricultural land increases in value as other countries face erosion and floods. Second, consumers and producers are often affected differently. The price increases induced by a reduction in production may leave producers better off while hurting consumers. Third, the distribution of the direct impacts can be very different than the distribution of the indirect effects. For instance, a loss of production may be advantageous to an individual company or country if the competition loses more. Fourth, a loss of productivity or productive assets in one sector leads to further losses in the rest of the economy. Fifth, markets offer options for adaptation, particularly possibilities for substitution. This changes the size, and sometimes the sign of the impact estimate.

10.9.2. Aggregate Impacts

Since AR4, four new estimates of the global aggregate impact on human welfare of moderate climate change were published (Bosello *et al.*, 2012; Maddison and Rehdanz, 2011; Roson and van der Mensbrugghe, 2012), including two estimates for warming greater than 3°C. Estimates agree on the size of the impact (small relative to economic growth) but disagree on the sign (Figure 10-1). Climate change may be beneficial for moderate climate change but turn negative for greater warming. Impacts worsen for larger warming, and estimates diverge. The new estimates have slightly widened the uncertainty about the economic impacts of climate.

Welfare impacts have been estimated with different methods, ranging from expert elicitation to econometric studies and simulation models. Different studies include different aspects of the impacts of climate change, but no estimate is complete; most experts speculate that excluded impacts are on balance negative (Füssel, 2010; Tol, 2008; Yohe, 2008). Estimates across the studies reflect different assumptions about intersectoral, interregional and intertemporal interactions, about adaptation, and about the monetary values of impacts. Aggregate estimates of costs mask significant differences in impacts across sectors, regions, countries and populations. Relative to their income, economic impacts are higher for poorer people.

[INSERT FIGURE 10-1 HERE
Figure 10-1: Estimates of the total impact of climate change plotted against the assumed climate change (proxied by the increase in the global mean surface air temperature); studies published since IPCC AR5 are highlighted as diamonds; see Table 10.B.1.]

10.9.3. Social Cost of Carbon

The social cost of carbon (SCC) monetizes the expected welfare impacts of a marginal increase in carbon dioxide emissions in a given year (i.e., the welfare loss associated with an additional tonne of CO_2 emitted), aggregated across space, time, and probability (Tol, 2011). Figure 10-2 shows estimates published before AR4 and since, using the kernel density estimator by (Tol, 2013), extending the data with new estimates by (Anthoff and Tol, 2013b; Hope and Hope, 2013; Hope, 2013; Interagency Working Group on the Social Cost of Carbon, 2013). Central estimates of the social cost of carbon have fallen slightly for all pure rates of time preference and the uncertainty has tightened, particularly for studies that use a pure rate of time preference of zero. See Table 10-9. For comparison, the EU ETS price in July 2013 was about $21/tC.

[INSERT TABLE 10-9 HERE
Table 10-9: Selected statistical characteristics of the social cost of carbon: average (Avg) and standard deviation (SD), both in dollar per tonne of carbon, and number of estimates (N; number of studies in brackets).]

Uncertainty in SCC estimates is high due to the uncertainty in underlying total damage estimates (see 10.9.2), uncertainty about future emissions, future climate change, future vulnerability and future valuation. The spread in estimates is also high due to disagreement regarding the appropriate framework for aggregating impacts over time (discounting), regions (equity weighing), and states of the world (risk aversion).

Quantitative analyses have shown that SCC estimates can vary by at least ~2x depending on assumptions about future demographic conditions (Interagency Working Group on the Social Cost of Carbon, 2010), at least ~3x due to the incorporation of uncertainty (Kopp *et al.*, 2012), and at least ~4x due to differences in discounting (Tol, 2011) or alternative damage functions (Ackerman and Stanton, 2012).

Concerns have been raised that the uncertainty about climate change is so large that the SCC would be unbounded (Weitzman, 2009), but this result is sensitive to assumptions about the utility function (Buchholz and Schymura, 2012; Millner, 2013; Nordhaus, 2011) and disappears when climate policy is formulated as balancing the risks of climate change against those of mitigation policy (Anthoff and Tol, 2013a; Hwang *et al.*, 2013).

[INSERT FIGURE 10-2 HERE

10.9.4. Effects on Growth

10.9.4.1. The Rate of Economic Growth

Climate change will also affect economic growth and development, but our understanding is limited. (Fankhauser and Tol, 2005) investigate four standard models of economic growth and three transmission mechanisms: economic production, capital depreciation, and the labor force. They find that, in three models, the fall in economic output is slightly larger than the direct impact on markets while in the 4th model (which emphasizes human capital accumulation) indirect impacts are 1.5 times as large. The difference can be understood as follows. In the three models, the impacts of climate change crowd out consumption and investment in physical capital, while in the fourth model investment in human capital is also crowded out; lower investment implies slower growth. (Hallegatte, 2005) reaches a similar conclusion. (Hallegatte and Thery, 2007; Hallegatte and Ghil, 2008; Hallegatte and Dumas, 2009) highlight that the impact of climate change through natural hazards on economic growth can be amplified by market imperfections and the business cycle. Additionally, (Eboli *et al.*, 2010a; Eboli *et al.*, 2010b) use a multi-sector, multi-region growth model, and find that the impact of climate change would lead to a 0.3% reduction of global GDP in 2050. Regional impacts are more pronounced, ranging from -1.0% in developing countries to +0.4% in Australia and Canada. In contrast, (Garnaut, 2008) finds -2.1% for Australia; the difference is mainly due to impacts on infrastructure (cf. Section 10.4). Sectoral results are varied too, with output changes ranging from +0.5% for power generation (to meet increased demand to air conditioning) to -0.7% for natural gas (as demand for space heating falls).

Using a biophysical model of the human body's ability to do work, (Kjellstrom *et al.*, 2009) find that by the end of the century climate change may reduce labor productivity by 11-27% in the humid (sub)tropics (depending on the SRES scenario; see Chapter 11 for further discussion). Assuming an output elasticity of labor of 0.8, this would reduce economic output in the affected sectors (involving heavy manual labor without air conditioning) by 8-22%. Although structural changes in the economy may well reduce the dependence on manual labor and air conditioning would be an effective adaptation, even the ameliorated impact would have a substantial, but as yet unquantified, impact on economic growth.

There are also statistical analyses of the relationship between climate and economic growth. (Barrios *et al.*, 2010) find that the decline in rainfall in the 20th century partly explains the economies of Sub-Saharan Africa have grown more slowly than those of other developing regions. (Brown *et al.*, 2011) corroborate this. (Dell *et al.*, 2012) find that, in the second half of the 20th century, anomalously hot weather slowed down economic growth in poor countries, in both the agricultural and the industrial sectors. (Dell *et al.*, 2009) find that one degree of warming would reduce income by 1.2% in the short run, and by 0.5% in the long run. The difference is due to adaptation. (Horowitz, 2009) finds a much larger effect: a 3.8% drop in income in the long run for one degree of warming. The impact of natural disasters on economic growth in the long-term is disputed, with studies reporting positive effects (Skidmore and Toya, 2002), negative effects (Raddatz, 2009), and no discernible effects (Cavallo *et al.*, 2013).

10.9.4.2. Poverty Traps

Poverty is concentrated in the tropics and subtropics. This has led some analysts to the conclusion that a tropical climate is one in a complex of causes of poverty (which itself is a cause of poverty). We here focus on national economies, while Chapter 13 discusses groups of people in poverty. (Gallup *et al.*, 1999) emphasize the link between climate, disease, and poverty while (Masters and McMillan, 2001) focus on climate, agricultural pests, and poverty. Other studies (Acemoglu *et al.*, 2001; Acemoglu *et al.*, 2002; Easterly and Levine, 2003) argue that climatic influence on development disappears if differences in human institutions (the rule of law, education, etc) are accounted for. However, (Van der Vliert, 2008) demonstrates that climate affects human culture and thus institutions, but this has yet to be explored in the economic growth literature. (Brown *et al.*, 2011) find that weather affects economic growth in Sub-Saharan Africa – particularly, drought decelerates growth. (Jones and Olken, 2010) find that exports from poor countries fall during hot years. (Bloom *et al.*, 2003) find limited support for an impact of climate (rather than weather) on past growth in a single-equilibrium model, but strong support in a multiple-equilibrium model: Hot and wet conditions and large variability in rainfall reduce long-term growth in poor countries (but not in hot ones) and increase the probability of being poor.

(Galor and Weil, 1996) speculate about the existence of a climate-health-poverty trap. (Bonds *et al.*, 2010; Bretschger and Valente, 2011; Gollin and Zimmermann, 2012; Ikefuji and Horii, 2012; Strulik, 2008) posit theoretical models and offer limited empirical support, while (Tang *et al.*, 2009) offers more rigorous empirical evidence. This is further supported by yet-to-be-published analyses (Gollin and Zimmermann, 2008; Ikefuji *et al.*, 2010). Climate-related diseases such as malaria and diarrhea impair children's cognitive and physical development. This contributes to poverty in their later life so that there are limited means to protect their own children against these diseases. Furthermore, high infant mortality may induce parents to have many children so that the investment in education is spread thin. An increase in infant and child mortality and morbidity due to climate change could thus trap more people in poverty.

(Ikefuji and Horii, 2012; Zimmerman and Carter, 2003) build a model in which the risk of natural disasters causes a poverty trap: At higher risk levels, households prefer assets with a safe but low return. (Carter *et al.*, 2007) find empirical support for this model at the household level, but (van den Berg, 2010) concludes the natural disaster itself has no discernible impact on investment choices. At the macro-economic level, natural disasters disproportionally affect the growth rate of poor countries (Noy, 2009).

(Devitt and Tol, 2012) construct a model with a conflict-poverty trap, and show that climate change may exacerbate this. (Bougheas *et al.*, 1999; Bougheas *et al.*, 2000) show that more expensive infrastructure, for example because of frequent repairs after natural disasters, slows down economic growth and that there is a threshold infrastructure cost above which trade and specialization do not occur, suggesting another mechanism through which climate could cause a poverty trap. The implications of climate change have yet to be assessed.

10.9.5. Summary

In sum, estimates of the aggregate economic impact of climate change are relative small but with a large downside risk. Estimates of the incremental damage per tonne of carbon dioxide emitted vary by two orders of magnitude, with the assumed discount rate the main driver of the differences between estimates. The literature on the impact of climate and climate change on economic growth and development has yet to reach firm conclusions. There is agreement that climate change would slow economic growth, by a little according to some studies and by a lot according to other studies. Different economies will be affected differently. Some studies suggest that climate change may trap more people in poverty.

10.10. Summary; Research Needs and Priorities

Table 10-10 summarizes the main findings. For each of the sectors discussed above, it gives the main climate drivers, the relationship between climate and impact (limited to less than linear, linear, and more than linear), the sign of the impacts (where needed split by economic actor), drivers other than climate change, and the relative importance of climate change.

[INSERT TABLE 10-10 HERE
Table 10-10: Summary of findings.]

Evaluating the economic aspects of the impacts has emerged as an active research area. Initial work has developed in a few key economic sectors and through economy wide economic assessments. Data, tools and methods continue to evolve to address additional sectors and more complex interactions among the sectors in the economic systems and a changing climate.

Based on a comprehensive assessment across economic sectors, few key sectors have been subject to detailed research. Multiple aspects of energy impacts have been assessed, but others remain to be evaluated, particularly economic impact assessments of adaptation both on existing and future infrastructure, but also the costs and benefits for future systems under differing climatic conditions. Studies focused on the impacts of climate change on the energy sector indicate both potential benefits and detrimental impacts across developed and developing countries. In energy supply, the deployment of extraction, transport and processing infrastructure, power plants and other installations are expected to proceed rapidly in developing countries in the coming decades to satisfy fast growing demand for energy. Designing newly deployed facilities with a view to projected changes in climate attributes and extreme weather patterns would require targeted inquiries into the impacts of climate change on the energy related resource base, conversion and transport technologies.

The economics of climate change impacts on transportation systems and their role in overall economic activity have yet to be well understood. For water related sectors, improved estimation of flood damages to economic sectors, research on economic impacts of ecosystems, rivers, lakes and wetlands, ecosystems service, and tourism and recreation are needed. Economic assessments of adaptation strategies such as water savings technologies, particularly for semi-arid and arid developing countries, are also needed. Further, detailed studies are needed of the integrated impact of climate change on all water-dependent economic sectors, as existing studies do not examine competitiveness between water uses among sectors and economic productivity.

Although both tourism and recreation are sensitive to climate change, the literature on tourism is far more extensive. Current studies either have a rudimentary representation of the effect of weather and climate but a detailed representation of substitution between holiday destination and activities, or a detailed representation of the immediate impact of climate change but a rudimentary representation of alternatives to the affected destinations or activities.

Considerable research has been developed related to climate change impacts on insurance; however, only limited research is available on observed and projected changes in insured climate-related losses. To advance such research, climate science and risk research communities need to be better integrated. Additionally, only few quantitative projection studies exist on regional markets including scenarios of changing hazard properties, exposure, vulnerability and adaption status, regulation, and availability of risk-based capital to indemnify disaster losses. Little research is available on the implications of climate change for banking/investment activities, in particular regarding the direct exposure of financial infrastructure. But also indirect effects through value losses in loan portfolios and assets as a result of physical damage and regulatory/reputational effects, together with liability and litigation risks, are underinvestigated.

Little literature exists on potential climate impacts on other economic sectors, such as mining, manufacturing, and services (apart from health, insurance and tourism); in particular assessments of whether these sectors are indeed sensitive to climate and climate change.

The spillover effects of the impacts of climate change in one sector on other markets are understood in principle, but the number of quantitative studies is too few to place much confidence in the numerical results. Similarly, the impact of climate and climate change on economic growth and development is not well understood, with some studies pointing to a small or negligible effect and other studies arguing for a large or dominant effect. A limited set of studies have evaluated the aggregate economic impact of climate change up to 3°C annual mean temperature rise, while only one study has evaluated larger temperature scenarios; suggesting considerable new analysis is warranted to improved confidence in the conclusions and investigation of a broader suite of RCPs.

Frequently Asked Questions

FAQ 10.1: Why are key economic sectors vulnerable to climate change? *[to be placed after Section 10.1]*
Many key economic sectors are affected by long-term changes in temperature, precipitation, sea level rise, and extreme events, all of which are impacts of climate change. For example, energy is used to keep buildings warm in winter and cool in summer. Changes in temperature would thus affect energy demand. Climate change also affects energy supply through the cooling of thermal plants, through wind, solar and water resources for power, and through transport and transmission infrastructure. Water demand increases with temperature but falls with rising carbon dioxide concentrations as carbon dioxide fertilization improves the water use efficiency plant respiration. Water supply depends on precipitation patterns and temperature, and water infrastructure is vulnerable to extreme weather, while transport infrastructure is designed to withstand a particular range of weather conditions, and climate change would expose this infrastructure to weather outside historical design criteria. Recreation and tourism are weather-dependent. As holidays are typically planned in advance, tourism depends on the *expected* weather and will thus be affected by climate change. Health care systems are also impacted, as climate change affects a number of diseases and thus the demand for and supply of health care.

FAQ 10.2: How does climate change impact insurance and financial services? *[to be placed in Section 10.7]*
Insurance buys financial security against, among other perils, weather hazards. Climate change, including changed weather variability, is anticipated to increase losses and loss variability in various regions through more frequent and/or intensive weather disasters. This will challenge insurance systems to offer coverage for premiums that are still affordable, while at the same time requiring more risk-based capital. Adequate insurance coverage will be challenging in low and middle-income countries. Other financial service activities can be affected depending on the exposure of invested assets/loan portfolios to climate change. This exposure includes not only physical damage but also regulatory/reputational effects, liability and litigation risks.

FAQ 10.3: Are other economic sectors vulnerable to climate change too? *[to be placed in Section 10.8]*
Economic activities such as agriculture, forestry, fisheries and mining are exposed to the weather and thus vulnerable to climate change. Other economic activities, such as manufacturing and services, largely take place in controlled environments and are not really exposed to climate change. However, markets connect sectors so that the impacts of climate change spill over from one activity to all others. The impact of climate change on economic development and growth also affects all sectors.

Cross-Chapter Box

Box CC-WE: The Water-Energy-Food/Feed/Fiber Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Kenneth M. Strzepek (UNU / USA), Blanca Elena Jimenez Cisneros (Mexico), Andy Reisinger (New Zealand), FerencToth (IAEA / Hungary), Taikan Oki (Japan)]

Water, energy, and food/feed/fiber are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure WE-1. The depth and intensity of those linkages vary enormously between countries, regions and production systems. Energy technologies (e.g. biofuels, hydropower, thermal power plants), transportation fuels and modes, and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops and forages) may require significant amounts of water (Sections 3.7.2, 7.3.2, 10.2, 10.3.4, 22.3.3, 25.7.2; Allan, 2003; King and Weber 2008; McMahon and Price, 2011; Macknick *et al*., 2012a). In irrigated agriculture, climate, irrigating procedure, crop choice and yields determine water requirements per unit of produced crop. In areas where water (and wastewater) must be pumped and/or treated, energy must be provided (Asano et al., 2006; Khan and Hanjra, 2009; USEPA, 2010; Gerten et al., 2011). While food production, refrigeration, transport and processing require large amounts of energy (Pelletier et al., 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (Section 7.3.2, Box 25-10; Diffenbaugh et al., 2012; Skaggs et al., 2012) *(robust evidence, high agreement)*. Food and crop wastes, and wastewater, may be used as sources of energy, saving not only the consumption of conventional non-renewable fuels used in their traditional processes, but also the consumption of the water and energy employed for processing or treatment and disposal (Schievano et al., 2009; Sung et al., 2010; Olson, 2012). Examples of this can be found in several countries across all income ranges. For example, sugar cane by-products are increasingly used to produce electricity or for cogeneration (McKendry, 2002; Kim and Dale 2004) for economic benefits, and increasingly as an option for greenhouse gas mitigation.

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change. The interlinkages of supply/demand, quality and quantity of water, energy and food/feed/fiber with changing climatic conditions have implications for both adaptation and mitigation strategies.]

Most energy production methods require significant amounts of water, either directly (e.g., crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Sections 10.2.2 10.3.4, 25.7.4; van Vliet et al., 2012; Davies et al., 2013) *(robust evidence, high agreement)*. Water for biofuels, for example, under the IEA Alternative Policy Scenario, which has biofuels production increasing to 71 EJ in 2030, has been reported by Gerbens-Leenes et al. (2012) to drive global consumptive irrigation water use from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water is also required for mining (Section 25.7.3), processing, and residue disposal of fossil and nuclear fuels or their byproducts. Water for energy currently ranges from a few percent in most developing countries to more than 50% of freshwater withdrawals in some developed countries, depending on the country (Kenny et al., 2009; WEC, 2010). Future water requirements will depend on electricity demand growth, the portfolio of generation technologies and water management options employed (WEC, 2010; Sattler et al., 2012) *(medium evidence, high agreement)*. Future water availability for energy production will change due to climate change (Sections 3.4, 3.5.1, 3.5.2.2) *(robust evidence, high agreement).*

Water may require significant amounts of energy for lifting, transport and distribution and for its treatment either to use it or to depollute it. Wastewater and even excess rainfall in cities requires energy to be treated or disposed. Some non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced potable water from ground/surface water sources vs. desalinated seawater (Box 25-2, Tables 25-6 and 25-7; Macknick et al., 2012b; Plappally and Lienhard, 2012). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user; Döll et al., 2012) is generally more energy intensive than surface water. In India, for example, 19% of total electricity use in 2012 was for agricultural purposes (Central Statistics Office, 2013), with a large share for groundwater pumping. Pumping from greater depth increases energy demand significantly– electricity use (kWhr/m^3 of water) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard, 2012).

The reuse of appropriate wastewater for irrigation (reclaiming both water and energy-intense nutrients) may increase agricultural yields, save energy, and prevent soil erosion (Smit and Nasr, 1992; Jimenez, 1996; Wichelns et al., 2007; Raschid-Sally and Jayakody, 2008) *(medium confidence)*. More energy efficient treatment methods enable poor quality ("black") wastewater to be treated to quality levels suitable for discharge into water courses, avoiding additional fresh water and associated energy demands (Keraita et al, 2008). If properly treated to retain nutrients, such treated water may increase soil productivity, contributing to increased crop yields/food security in regions unable to afford high power bills or expensive fertilizer (Oron, 1996; Lazarova and Bahri, 2005; Redwood and Huibers, 2008; Jimenez, 2009) *(high confidence)*.

Linkages among water, energy, food/feed/fiber and climate are also strongly related to land use and management (Section 4.4.4, Box 25-10) *(robust evidence, high agreement)*. Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and compromises food security (Sections 3.7.2, 4.4.4). On the other hand, afforestation activities to sequester carbon have important co-benefits of reducing soil erosion and providing additional (even if only temporary) habitat (see Box 25-10) but may reduce renewable water resources. Water abstraction for energy, food or biofuel production or carbon sequestration can also compete with minimal environmental flows needed to maintain riverine habitats and wetlands, implying a potential conflict between economic and other valuations and uses of water (Sections 25.4.3 and 25.6.2, Box 25-10) *(medium evidence, high agreement)*. Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water and climate (McCornick et al., 2008; Bazilian et al., 2011; Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy and water demand, bioproductivity and other factors (see Figure WE-1 and Wise et al., 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this report.

The interconnectivity of food/fiber, water, land use, energy and climate change, including the perhaps not yet well understood cross-sector impacts, are increasingly important in assessing the implications for adaptation/mitigation policy decisions. Fuel-food-land use-water-GHG mitigation strategy interactions, particularly related to bioresources for food/feed, power, or fuel, suggest that combined assessment of water, land type and use requirements, energy requirements and potential uses and GHG impacts often epitomize the interlinkages. For example, mitigation scenarios described in the IPCC Special Report on Renewable Energy Sources and Climate Change Mitigation (IPCC, 2011) indicate up to 300EJ of biomass primary energy by 2050 under increasingly stringent mitigation scenarios. Such high levels of biomass production, in the absence of technology and process/management/operations change, would have significant implications for land use, water and energy, as well as food production and pricing. Consideration of the interlinkages of energy, food/feed/fiber, water, land use and climate change is increasingly recognized as critical to effective climate resilient pathway decision making *(medium evidence, high agreement)*, although tools to support local- and regional-scale assessments and decision-support remain very limited.
