Table 18-1: Observed changes in ocean system properties and their effects, with confidence levels for the detection of the effect of climate change and an assessment of the magnitude of its role.]

There has been a substantial increase in the number of studies documenting significant changes in marine species and processes since the AR4. A new meta-analysis using a database of long-term observations from peer-reviewed studies of biological systems, with nearly half of the time series extending prior to 1960, shows that more than 80% of observed responses are consistent with regional climate change (see 30.4, Box CC-MB). Poloczanska *et al*. (2013) argue that the high consistency of marine species' responses across geographic regions (coastal to open ocean, polar to tropical), taxonomic groups (phytoplankton to top predators), and types of responses (distribution, phenology, abundance) reported in their analysis support the detection of a widespread impact of climate change on marine populations and ecosystems (see 30.4 and 30.5 for more detail). Table 18-2 gives examples of the manifestation of climate change on marine species and ecosystems.

[INSERT TABLE 18-2 HERE
Table 18-2: Observed changes in marine species and ecosystems, with confidence levels for the detection of the effect of climate change and an assessment of the magnitude of its role (see also 6.2, 6.3, 30.4, Box CC-MB).]

18.3.4.2. Observed Climate Change Effects across Ocean Regions

Climate change has affected physical properties across the ocean, with regional variations (Table 30-1; Figures 30-2 to 30-5; WGI AR5 Chapter 3). Confidence in the detection and attribution of these impacts also varies regionally, reflecting differences in system understanding, data availability, influence of long term natural variability and the impact of factors unrelated to climate change. The attribution of changes in heat content to climate change is less certain regionally than globally, but warming has been detected with *high confidence* in all basins except Eastern boundary upwelling systems (Table 30-1, Figure 30-2), Recent research shows declining oxygen levels *(medium confidence*, 30.3.2.3) and deep penetration of warming in some regions. Regional estimates of CO_2 uptake are in line with global estimates, and ocean acidification has been detected with *high confidence* in most regions (WGI AR5 Chapter 3.8.2, 30.3.2.2).

The high latitude spring bloom systems of the Northern Hemisphere show strong warming and associated effects (see above). In the North Pacific, the Bering Sea has undergone major changes in recent decades as a result of climate variability, climate change and fishing impacts (Litzow *et al.*, 2008; Mueter and Litzow, 2008; Jin *et al.*, 2009; Hunt *et al.*, 2010). Loss of sea ice has led to the retreat of the cold pool in the Bering Sea, and northward expansion of productivity.

Marginal seas such as the East China Sea are also warming rapidly, with subsequent impacts such as declining primary productivity and fisheries yields as well as other ecological changes (30.5.4.1). However, other human pressures including over-fishing, habitat alteration, and nutrient loading are important contributing factors and it is difficult to disentangle these from the impacts of climate change.

Semi-enclosed seas such as the Black and Baltic Seas and the Arabian / Persian Gulf show differing patterns of change over the past decades (30.5.3.1). Expansions of hypoxic zones in the Baltic and Black Seas have been detected. Although there is *high confidence* that climate change has had a role, its magnitude is difficult to assess in light of other contributing factors. Coral reefs in the Arabian / Persian Gulf and Red Seas appear to have experienced widespread bleaching in 1996 and 1998 associated with elevated temperature with *high confidence* that climate change has played a major role.

Warming of the Mediterranean has been associated with mass mortality events as well as invasions and spread of new warm water species, resulting in the 'tropicalisation' of fauna with *high confidence* in a major role for climate change (30.5.3.1.5). In many tropical regions and the subtropical gyres of the Pacific, Indian, and Atlantic, periodic heat stress related to climate change has combined with other local stresses to cause mass coral bleaching and mortality (see also Box CC-CR, 30.5).

In other regions, such as the California Current upwelling system, there is *very high confidence* in both the detection and attribution of ecological changes associated with climate change, but separating the effects of ENSO and the PDO from that of anthropogenic climate change is not possible.

In overall terms, attributing observed local and regional changes in marine species and ecosystems to climate change remains an important question for on-going research (Stock *et al.*, 2010).

Box 18-3. Differences in Detection and Attribution of Ecosystem Change on Land and in the Ocean

Marine and terrestrial ecosystems differ in fundamental ways. Gradients in turbulence, light, pressure and nutrients uniquely drive fundamental characteristics of organisms and ecosystems in the ocean. While the critical factor for transporting nutrients to marine primary producers is ocean mixing driven by wind, water is the primary mode for transporting nutrients to land plants. In addition to these characteristics, marine ecosystems are often more technically difficult and costly to explore than terrestrial equivalents, which explains the low number and shorter scientific studies of marine ecosystems (Hoegh-Guldberg and Bruno, 2010). The latter has restricted the extent to which changes within the Ocean can be detected and attributed.

Impacts of climate change in terrestrial and marine systems differ significantly for the same types of measures, e.g., species phenology and range shifts, leading to differences in expert's interpretations of the data and possibly divergent levels of confidence in detection and attribution. There are also fundamental differences in exposure of organisms to recent warming, their biological responses and our ability to detect change through observations. Changes in temperature of ocean systems have generally been less than those of terrestrial ecosystems over the last four decades (Burrows *et al.*, 2011). Furthermore, despite higher variability the horizontal spatial gradient of temperature change (°C km^{-1}) is generally much higher in terrestrial ecosystems than in marine ecosystems. All else being equal, the net result is that species have generally needed to move much shorter distances in terrestrial ecosystems to stay within their preferred climates, also due to the influence of the topography such as mountain ranges (Burrows *et al.*, 2011), although many marine species can potentially exploit strong vertical thermal gradients to attenuate the need for range shifts in response to warming.

Species and ecosystems may respond very differently to these climate signals in ways that influence the ability to detect change. For example, a comparison of ectotherm species (i.e., species that do not actively regulate their body temperatures such as reptiles and fish) indicates that marine species' ranges have tracked recent warming at both their poleward and equatorial range limits, while many other terrestrial species' ranges have only tracked warming at their poleward range limits (Sunday *et al.*, 2012). Biological processes influencing phenological shifts may also differ substantially between systems. For example, the effect of climate on the timing of flowering of terrestrial plants at high latitudes is only moderately influenced by confounding effects, whereas the timing of phytoplankton blooms in high latitude marine systems is highly dependant on ocean temperature and associated stratification and changes in nutrient availability.

18.4. Detection and Attribution of Observed Climate Change Impacts in Human and Managed Systems

Observed impacts on human systems have received considerably less attention in previous IPCC reports and the scientific literature, compared to observed impacts on natural systems. Human systems' "normal state in the absence of climate change" is almost never stationary. Confounders other than climate change have been and continue to drive the normal evolution of these systems with climate often playing a relatively minor role. Further, monitoring in many of the systems have been and continue to be inadequate. It is therefore difficult to detect and attribute the signal of climate change in the majority of human systems, food production systems constituting one noteworthy exception. There is emerging literature estimating the sensitivity to climate of many sectors within the human system (see Box 18-4), yet climate impacts are often not detectable over the impacts from non-climate confounders.

For some human systems, the clearest situations where a climate signal had a detectable and sometimes attributable impact are during extreme weather events. Impacts of extreme events, and single event attribution are therefore discussed in a separate section below, and the discussion is expanded to include responses to extreme weather for some sectors. Overall, the literature has made significant progress for certain sectors, such as food systems, since AR4. The following sections provide a synthesis of findings with regard to food systems, economic systems, human health, human security and human livelihoods and poverty, which are documented in greater detail in Chapters 7, 9, 10, 11, 12 and 13. They also incorporate evidence from regional chapters and further available literature, especially for the discussion of extreme events, human security, and observed changes in indigenous communities.

_____ START BOX 18-4 HERE _____

Box 18-4. The Role of Sensitivity to Climate and Adaptation for Impact Models in Human Systems

Impacts of climate change on a measurable attribute of a human system only occur if a) the attribute is sensitive to climate and b) a change in climate has occurred. Many studies now attempt to quantify both climate sensitivity of various systems and observed changes in climate.

Assessment of the sensitivity of an outcome such as crop yields, heat related mortality or migration,to climate relies on observed climate variability either across space (e.g., Schlenker *et al.*, 2005), time (e.g., Mann and Emanuel, 2012), or space and time (e.g., Dell *et al.*, 2012). While there are many studies using climate variability across space, the lack of long observational weather time series required for exploring climate variability across space and time have limited the opportunities for study. A number of studies have instead estimated the sensitivity of outcomes to short run fluctuations (e.g., weather) in order to project the future impacts of climate change (Deschênes and Greenstone, 2007; Deschênes and Greenstone, 2011), or attribute impacts for the past (Auffhammer *et al.*, 2006). The issue with impact studies using a weather based sensitivity measure is that they cannot provide estimates of impacts based on the sensitivity to climate. For example, farmers may respond to an unusually hot summer, which is a weather event, by applying more irrigation water. However, in the long run farmers may respond to a warmer climate by switching crops, changing irrigation technology or abandoning farming altogether. The two sensitivities and resulting magnitudes of attributable impacts due to a change in weather versus a change in climate are therefore different. In order to detect and attribute a change in a system to climate change, one needs to combine a measure of sensitivity of the outcome to climate with climate observations under climate change.

_____ END BOX 18-4 HERE _____

18.4.1. Food Production Systems

Detection and attribution of climate change impacts in food systems is challenging, given that the behavior of the system in the absence of climate change is driven by a large number of other factors (7.2.1). For cropping systems, these confounders include, but are not limited to, cultivar improvement and increased use of synthetic fertilizers, herbicides, and irrigation. These confounders are often not well measured in terms of their distribution across space and time. Further, it is difficult to quantify or model the exact relationship between these confounders and outcomes of interest (e.g., crop yield or pasture productivity). In addition, the role of farmers' behavior in response to climate change requires significant assumptions and has been shown to change over time (7.2.1). The discussion below is limited to crop systems and fisheries, as literature is scarce on observed impacts for other important sources of food.

18.4.1.1. Agricultural Crops

A significant number of studies have provided impact estimates of observed changes in climate on cropping systems over the past few decades (e.g., Auffhammer *et al.*, 2006; Kucharik and Serbin, 2008; Ludwig *et al.*, 2009; Lobell *et al.*, 2011; Tao *et al.*, 2012, see also Figure 7-2). Over the past several decades, observed climate trends have adversely affected wheat and maize production for many regions, as well as the total global production of these crops (*medium confidence* in a minor role of climate change in overall production). Climate change impacts on rice and soybean yields over this time period have been small in major production regions and globally (*medium confidence,* Figure 7-2). In some mid latitude regions, such as the United Kindom and Northeast China, warming has benefitted crop production during recent decades (*high confidence* in a minor role of climate change; 7.2.1.1, Jaggard *et al.*, 2007; Chen *et al.*, 2011). At the continental or global scale, observed trends in some climatic variables, including mean summer temperatures, attributed to anthropogenic activity (see 7.2.1.1; WGI AR5 10.3.1; Table 10-1) have had significant negative impacts on trends in yields for certain crops (Lobell and Field, 2007; You *et al.*, 2009; Lobell *et al.*, 2011).

Attributable trends have been found not only in the seasonal averages of climate variables, but also for extremes (WGI AR5 Chapter 10.6). Extreme rainfall events are widely recognized as important to cropping systems (Rosenzweig *et al.*, 2002), and global scale changes in the patterns of rainfall extremes have been attributed to anthropogenic activity (Min *et al.*, 2011). High nighttime temperatures are harmful to most crops, particularly for rice yield (Peng *et al.*, 2004; Wassmann *et al.*, 2009; Welch *et al.*, 2010) and quality (Okada *et al.*, 2009). Daytime extreme heat is also damaging and sometimes lethal to crops (Porter and Gawith, 1999; Schlenker and Roberts, 2009). At the global scale, trends in annual maximum daytime temperatures have been attributed to greenhouse gas emissions (Zwiers *et al.*, 2011), and similar observation have been made for the occurrence of very hot nights (WGI AR5 Chapter 10.6.1.1, Seneviratne *et al.*, 2012).

Changing atmospheric conditions are affecting crops both positively and negatively. It is *virtually certain* that the increase in atmospheric CO_2 concentrations since preindustrial times has improved water use efficiency and yields most notably in C_3 crops. These effects are however of relatively minor importance when explaining total yield trends (Amthor, 2001; McGrath and Lobell, 2011). Emissions of CO_2 have been associated with tropospheric ozone (O_3) precursors (Morgan *et al.*, 2006; Mills *et al.*, 2007, 7.3.2.1.2). O_3 suppresses global output of major crops, with reductions estimated at roughly 10% for wheat and soy and 3-5% for maize and rice (Van Dingenen *et al.*, 2009). Detected impacts are most significant for India and China, but can also be found for soybean production in the United States in recent decades (Fishman *et al.*, 2010; Christidis *et al.*, 2011).

18.4.1.2. Fisheries

Many new studies focus on the relationship between the dynamics of marine fish stocks and climate, suggesting a sensitivity to climate of these stocks and on the fisheries that exploit them (Hollowed *et al.*, 2001; Roessig *et al.*, 2004; Shriver *et al.*, 2006; Brander, 2007). Some fisheries and aquaculture do not show evidence of climate change impacts (e.g. aquaculture in the UK and Ireland, Callaway *et al.*, 2012), while many others do with both positive and negative changes (see also 18.3.4, 30.6.2.1, 7.2.1.1).

There is *high confidence* in the detection of a climate change impact on the spatial distributions of marine fishes (Perry *et al.*, 2005) and in the timing of events like spawning and migration (Sydeman and Bograd, 2009), with *high confidence* of a major role of climate change (see 18.3.4, CC-MB, 30.4). This distributional shift is reflected in the species composition of harvest, with the relative share of warm water species increasing (Cheung *et al.*, 2013). The impacts of ocean warming and acidification on fish stocks vary from region to region (30.6.2.1). To date, the role of climate change in change in fish stocks and fishery yields is, in most cases, minor (*high confidence*) in relation to other factors such as harvesting, habitat modification, technological development, and pollution (Brander, 2010).

18.4.2. Economic Impacts, Key Economic Sectors, and Services

18.4.2.1. Economic Growth

In low income countries, careful tracking of incomes and temperatures over an extended period, taking into account important confounders, shows that higher annual temperatures as well as higher temperatures averaged over 15 year periods result in substantially lower economic growth (Dell *et al.*, 2012). This effect is not limited to the level of per capita income, but also to its rate of growth. Declining rainfall over the 20^{th} century partly explains the slower growth of Sub-Saharan economies relative to those of other developing regions (Barrios *et al.*, 2006; Brown *et al.*, 2011). Dell *et al*. (2009) find that 1° C of warming reduces income by 1.2% in the short run, and by 0.5% in the long run. The difference is argued to be due to adaptation. Horowitz (2009) finds a much larger effect: a 3.8% drop in income in the long run for 1° C of warming. One proposed mechanism for this is the impact of heat stress on workers in the workplace (Dash and Kjellström, 2011; Dunne *et al.*, 2013). Temperature shocks have negatively affected the growth of developing countries' exports, for which 1° C of warming in a given year reduced the growth rate of its exports by 2.0-5.7% (Jones and Olken, 2010). The export sectors most affected are agricultural and light manufacturing exports.

18.4.2.2. Energy Systems

Energy production and consumption is growing rapidly globally, with much of the growth taking place in low income and emerging economies. Various parts of the energy sector are known to be sensitive to climate change (cf. Ebinger and Vegara, 2011). Higher temperatures raise the demand for cooling and lower the demand for heating. Cooling demand is largest in the summer and in some areas peak loads during the summer months have increased, this peak being highly correlated with summer maximum temperatures (Franco and Sanstad, 2008). There are also opposing effects of warmer winters and summers on electricity and gas demand. Statistical studies have confirmed this U-shaped relationship of energy and electricity demand in temperature for the United States and elsewhere (Isaac and van Vuuren, 2009; Akpinar-Ferrand and Singh, 2010; Deschênes and Greenstone, 2011). On the supply side, sensitivity to climatic factors such as ambient temperature, wind speeds, or snow and ice is well-known for many energy technologies and part of the transmission infrastructure (see 10.2.2, 10.2.3), however, there are no studies available that discuss observed effects of climate change on the energy sector.

18.4.2.3. Tourism

Tourism is a climate sensitive economic sector and ample research has been performed to understand its sensitivity to climate change and impacts of (future) climate change on tourism, yet few studies have focused on detection and attribution of observed impacts (cf. Scott *et al.*, 2008, see also 10.6). A comparatively well-studied area is the sensitivity of the winter sports industry in lower lying areas to climate. For example, the increase in investment in artificial snow machines in the European Alps can be attributed with *high confidence* to a general decrease of snow depth, snow cover duration and snow fall days since the end of the 1980s for low-elevation mountain stations (Durand *et al.*, 2009; Valt and Cianfarra, 2010; Voigt *et al.*, 2011), which in turn has been attributed to anomalous higher winter temperatures over the past 20 years (Marty, 2008). Variability in precipitation, shrinking glaciers and milder winters have been shown to negatively affect visitor numbers in winter sports areas in Europe and North America (Becken and Hay, 2007). Another indirect effect of climate change that has been reported is a rise in popularity of destinations that are perceived to be at risk from climate change (e.g., Eijgelaar *et al*. (2010) for Antarctic glaciers, or Farbotko (2010) for Tuvalu).

18.4.3. Impacts of Extreme Weather Events

The impacts of extreme weather events depend on the frequency and intensity of the events, as well as exposure and vulnerability of society and assets. The last several decades have seen changes in the frequency and intensity of extreme weather events including extreme temperature, droughts, heavy rainfall, and tropical and extratropical cyclones with *low* to *very high confidence*, depending on the type of extreme event (IPCC, 2012, WGI AR5 Chapter 2). However, the impacts of extreme weather events also depend on the vulnerability and exposure of systems. It is possible that climate change can affect vulnerability and exposure, but typically both are primarily influenced by non-climate confounders, most notably economic development.

18.4.3.1. Economic Losses due to Extreme Weather Events

Extreme weather events can result in economic impacts related to damage to private and public assets as well as the temporary disruption of economic and social activities, long-term impacts and impacts beyond the areas affected. Some economic and especially social impacts are not readily monetizable and are thus excluded from most economic assessments (Handmer *et al.*, 2012, their chapter 4.5.1, 4.5.3).

Economic costs of extreme weather events have increased over the period 1960-2000 *(high confidence),* with insured losses increasing more rapidly than overall losses (10.7.3, Handmer *et al.*, 2012, their chapter 4.5.3.3, 4.5.4.1). This is also reflected by an increase in the frequency of extreme weather-related disasters over the same period (Neumayer and Barthel, 2011). Recent studies from Mexico and Colombia highlight both variability and positive trends in disaster frequency, (unadjusted) losses and other damage metrics (Saldaña-Zorrilla and Sandberg, 2009; Marulanda *et al.*, 2010; Rodriguez-Oreggia *et al.*, 2013). However, the greatest contributor to increased cost is rising exposure associated with population growth and growing value of assets (*high confidence;* Bouwer *et al.*, 2007; Bouwer, 2011; Barthel and Neumayer, 2012; Handmer *et al.*, 2012, their Chapter 4.2.2, Box 4.2 and 4.5.3.3).

To account for changes over time in the value of exposed assets, many studies attempt to normalize monetary losses by an overall measure of changes in asset value. A majority of studies have found no detectable trend in normalized losses (Bouwer, 2011). Studies on insured losses that in general meet higher data quality standards than data on overall losses due to thoroughly monitored payouts, have focused on developed countries including Australia, Germany, Spain, the US, (Changnon, 2007; Changnon, 2008; Changnon, 2009a; Changnon, 2009b; Barredo *et al.*, 2012; Barthel and Neumayer, 2012; Sander *et al.*, 2013, see also 10.7.3). Studies of normalized losses from extreme winds associated with hurricanes in the US (Miller *et al.*, 2008; Pielke Jr *et al.*, 2008; Schmidt *et al.*, 2010; Bouwer and Botzen, 2011) and the Caribbean (Pielke Jr *et al.*, 2003), tornadoes in the US (Brooks and Doswell, 2002; Boruff *et al.*, 2003; Simmons *et al.*, 2013) and wind storms in Europe (Barredo, 2010) have failed to detect trends consistent with anthropogenic climate change, although some studies were able to find signals in loss records related to climate variability, such as damage and loss of life due to wildfires in Australia related to El Niño Southern Oscillation and Indian Ocean dipole phenomena (Crompton *et al.*, 2010), or typhoon loss variability in the Western North Pacific (Welker and Faust, 2013). Effects of adaptation measures (disaster risk prevention) on disaster loss changes over time cannot be excluded as research is currently not able to control for this factor (Neumayer and Barthel, 2011).

In conclusion, although there is *limited evidence* of a trend in the economic impacts of extreme weather events that is consistent with a change driven by observed climate change, climate change cannot be excluded as at least one of the drivers involved in changes of normalized losses over time in some regions and for some hazards.

18.4.3.2. Detection and Attribution of the Impacts of Single Extreme Weather Events to Climate Change

Although most studies on the relationship between climate change and extreme weather events have focused on changes over time in their frequency and intensity, a few studies have focused on the contribution of climate change to specific events (WGI AR5 Chapter 10.6.2). Assessing the contribution of climate change to a specific event poses particular challenges, both in terms of methodology and communication of results (Allen, 2011; Curry, 2011; Hulme *et al.*, 2011; Trenberth, 2011). Only a few studies have attempted to evaluate the role of climate change in the impacts of individual extreme weather events. For instance, Pall *et al.* (2011) and Kay *et al.* (2011), using observational constraints on climate and hydrologic model simulations, concluded that greenhouse gas emissions have increased the probability of occurrence of a comparable flooding event in autumn 2000 over the UK.

In highly temperature-sensitive regions, such as high mountains, several extreme impact events of recent decades can be qualitatively attributed to effects of long-term warming *(high confidence)*, namely glacier lake outburst floods due to glacier recession and subsequent formation of unstable lakes (Evans and Clague, 1994; Carey, 2005; Bajracharya and Mool, 2009), debris flows from recently deglaciated areas, and rock fall and avalanches following the loss of mechanical support accompanying glacier retreat (Haeberli and Beniston, 1998; Oppikofer *et al.*, 2008; Huggel *et al.*, 2012b; Stoffel and Huggel, 2012, see also 18.3.1.3). Multi-step approaches can be used to evaluate the contributions of anthropogenic emissions to recent damaging extreme events (Hegerl *et al.*, 2010).

Irrespective of whether a specific event can be attributed in part to climate change, there is ample evidence of the severity of related impacts on people and various assets. Both low- and high-income countries have been strongly impacted by extreme weather events in recent years, but the impacts relative to economic strength have been higher in low-income countries (Handmer *et al.*, 2012). Similarly, at the national scale, poor or elderly people have been disproportionately affected, as documented for Hurricane Katrina in the US in 2005 (Elliott and Pais, 2006; Bullard and Wright, 2010) or the 2003 European heat wave (Fouillet *et al.*, 2008). Exacerbating effects of extreme weather events are mostly of non-climatic nature, including increasing exposure and urbanization, land-use changes including deforestation, or vulnerable infrastructure. Table 18-3 lists a selection of recent weather-related disasters, and lists various factors contributing to long-term changes in the risk of damage, including recent climate change.

[INSERT TABLE 18-3 HERE
Table 18-3: Illustrative selection of recent disasters related to extreme weather events, with description of the impact event, the associated climate hazard, recent climate trends relating to the weather event, and recent trends relating to the consequences of such a weather event.]

18.4.4. Human Health

IPCC AR4 (Confalonieri *et al.*, 2007) concluded that there was *weak to moderate evidence* of effects of recent observed climate change on three main categories of health exposure (ranging from *low* to *medium confidence*): vectors of human infectious diseases (changes in distribution), allergenic pollen (changes in phenology), and extreme heat exposures (trend in increased frequency of very hot days and heat wave events). Overall, there was a lack of evidence for observed effects of climate change on human health outcomes, and this generally remains the case (see Chapter 11). Evaluation of the detection and attribution of impacts on health outcomes requires disentangling the roles of changes in exposures (e.g. patterns), control measures (e.g. vaccination, drug resistance), population structures (e.g. population aging), and reporting practices.

The most direct potential health impact of climate change is through exposure to higher temperatures, as the association between very hot days and increases in mortality is very robust (11.4.1). Recent decades have seen a shift toward more frequent hot extremes and less frequent cold extremes (*high confidence;* Seneviratne *et al.*, 2012, WGI Table 2.13). However, the translation of this trend in hazard to a trend in exposure is complicated by changes in social, environmental, and behavioral factors (e.g., Carson *et al.*, 2006, Table 18-3) and interseasonal mortality relationships (Rocklöv *et al.*, 2009; Ha *et al.*, 2011). Climate change has contributed to a shift from cold-related mortality to heat-related mortality during recent decades in Australia (*medium confidence;* Bennett *et al.*, 2013). In a similar shift in England and Wales, a contribution from anthropogenic climate change has been detected (*medium confidence;* Christidis *et al.*, 2010).

For pollen production, changes in phenology have been consistently observed in mid to high latitudes with, for example, earlier onset in Finland (e.g., Yli-Panula *et al.*, 2009) and Spain (D'Amato *et al.*, 2007; García-Mozo *et al.*, 2010, see also 4.3) over the past few decades. In North America, the pollen season of ragweed (*Ambrosia* spp.) has been extended by 13-27 days since 1995 at latitudes above 44 °N (Ziska *et al.*, 2011). Allergic sensitization of humans has changed over a 25 year period in Italy, but the attribution to observed warming remains unclear (Ariano *et al.*, 2010).

There is *limited evidence* regarding the role of observed warming in changes in tick-borne disease in mid to high latitudes. While patterns of changes in tick borne encephalitis (TBE) incidence in the Czech Republic match those expected from observed warming (Kriz *et al.*, 2012), the upsurge of TBE in the 1980-90s in Central and Eastern Europe generally has been attributed to socio-economic factors (human behavior) rather than temperature (Šumilo *et al.*, 2008; Šumilo *et al.*, 2009). Changes in the latitudinal and altitudinal distribution of ticks in Europe and North America are consistent with observed warming trends (e.g., Gray *et al.*, 2009; Ogden *et al.*, 2010), but there is no evidence so far of any associated changes in the distribution of human cases of tick-borne diseases. There is *limited evidence* of a change in the distribution of rodent-borne infections in the US (plague and tularaemia) consistent with observed warming (Nakazawa *et al.*, 2007). Specifically, a northward shift of the southern edge of the distributions of the diseases (based on human case data for period 1965-2003) was observed. There was no change detected in the northern edge of the distributions though.

Globally, the dominant trend concerning malaria has been a contraction of the geographical range and a decrease in endemicity over the past century due to changes in land cover, behaviour, and health care (Gething *et al.*, 2010). Given that the mosquito vector is climate-sensitive, however, there may be specific locations where climate change matches the influence of these other factors. In the Kericho region of Kenya, both increasing incidence and warming have been observed over several decades (Omumbo *et al.*, 2011). Modelling suggests that the gradual warming is inducing an amplified non-linear response in malaria incidence (Alonso *et al.*, 2011). A detailed review concluded that decadal temperature changes have played at least a minor role in these malaria trends in the East African highlands (*low confidence;*Chaves and Koenraadt, 2010).

18.4.5. Human Security

A small number of studies have examined the connection between the collapse of civilizations and large-scale climate disruptions such as severe or prolonged drought. However, both the detection of a climate change effect and an assessment of the importance of its role can only be made with *low confidence* due to limitations on both historical understanding and data. Some studies have suggested that levels of warfare in Europe and Asia were relatively high during the Little Ice Age (Parker, 2008; Brook, 2010; Tol and Wagner, 2010; White, 2011; Zhang *et al.*, 2011), but for the same reasons the detection of the effect of climate change and an assessment of its importance can only be made with *low confidence*. There is no evidence of a climate change effect on inter-state conflict in the post-WW II period.

Most recent research in this area has focused on the relationship between interannual climate variability in temperature, precipitation, and other climate variables and civil conflict, with most studies focusing on Africa (Hsiang *et al.*, 2013, see also 12.5). A number of studies have identified statistical relationships (Miguel *et al.*, 2004; Hendrix and Glaser, 2007; Hsiang *et al.*, 2011), but the results have been challenged (Buhaug *et al.*, 2010; Theisen *et al.*, 2011; Buhaug and Theisen, 2012; Slettebak, 2012) on both technical and substantive grounds. The issue is further complicated by the focus on interannual variability – rather than climate change – and civil conflict. While a plausible argument could be made that climate change has increased interannual variability and has, therefore, contributed positively to the rate of civil conflict, this argument has not been tested in the literature. For these reasons, neither the detection of an effect of climate change on civil conflict nor an assessment of the magnitude of such an effect can currently be made with a degree of confidence.

Several studies have examined links between climate variability and small-scale communal violence (Adano *et al.*, 2012; Butler and Gates, 2012; Hendrix and Salehyan, 2012; Raleigh and Kniveton, 2012; Theisen, 2012). As with larger-scale civil conflict, this work has focused on climate variability rather than on climate change, so neither the detection of the effect of climate change nor an assessment of its magnitude can currently made with a degree of confidence.

Finally, efforts have been made to establish a link between high temperatures and violent crime (Anderson, 1987; Field, 1992; Anderson, 2001; Rotton and Cohn, 2001; Butke and Sheridan, 2010; Breetzke and Cohn, 2012; Gamble and Hess, 2012). However, the findings remain controversial with other studies identifying non-climate factors as explaining variations in the rate of violent crime (Kawachi *et al.*, 1999; Fajnzylber *et al.*, 2002; Neumayer, 2003; Cole and Gramajo, 2009). Again, the focus in this work has been on weather rather than climate and, in light of this and the equivocal nature of the results, neither the detection of a climate change effect nor an assessment of its magnitude can currently be made with a degree of confidence.

The impact of future climate change on human displacement and migration has been identified as an emerging risk (19.4.2.1). The social, economic, and environmental factors underlying migration are complex and varied (see e.g. Black *et al.*, 2011) and it has not been possible to detect the effect of observed climate change nor assess its magnitude with any degree of confidence (see also 12.4.1.1). Migration in response to climate-related events has been identified in sub-Saharan Africa (Marchiori *et al.*, 2012), with evidence from North America a subject of disagreement (Auffhammer and Vincent, 2012; Feng *et al.*, 2012; Feng and Oppenheimer, 2012).

18.4.6. Livelihoods and Poverty

The vulnerability of the world's poor to climate change, and more general the sensitivity of many livelihood aspects to climate variability has been shown in this and earlier IPCC reports (see Chapter 13). However available research about climate related effects on livelihood and poverty has focused on impacts of climate extremes or year to year climate variability rather than long term climatic trends, resulting in a paucity of evidence on observed impacts of climate change on livelihoods and poverty. Moreover, detection of changes in livelihood aspects is often difficult due to a lack of observations (13.2.1), while multiple confounding factors and lack of both adequate climate data and system understanding preclude attribution (Nielsen and Reenberg, 2010).

Table 18-4 summarizes examples of impacts on livelihoods related to climatic trends, climate variability and extreme weather events. Impacted natural assets include land, water, fish stocks and livestock (Osbahr *et al.*, 2008; Bunce *et al.*, 2010). There is growing concern about negative effects of climate change and ocean acidification on marine and coastal fisheries, and the livelihoods of fisherfolks (Cooley and Doney, 2009; Badjeck *et al.*, 2010), however there are no studies evaluating observed impacts.

[INSERT TABLE 18-4 HERE
Table 18-4: Cases of regional livelihood impacts associated with weather- and climate related extreme events, inter-annual climate variability or climate change (see also Table 18-3; 13.2.1.1).]

Climate related impacts disproportionately affect poor populations, thus increasing social and economic inequalities, both in urban and rural areas, and in low-, middle- and high-income countries (13.1.4; 13.2.1). Evidence for poor people in high-income nations being disproportionately affected by extreme weather events comes, for instance, from 2005 US Hurricane Katrina (Elliott and Pais, 2006; Bullard and Wright, 2010, see also 13.2.5.1) or severe drought in Australia (Alston, 2011). Glacial lake outburst floods in the Peruvian Andes also affected different populations depending on their degree of exposure, level of vulnerability, race, ethnicity, and socio-economic class (Carey, 2010; Carey *et al.*, 2012b). Due to gender specific roles within the household, communities, and wider socio-political and institutional networks, a gender bias has been found in observations of impacts of extreme weather events and climate variability (Carr, 2008; Arora-Jonsson, 2011; Nightingale, 2011, see also Box 13-1).

Poor people living in hazard exposed areas in Africa and Latin America were increasingly affected by floods and landslides in the 1990s and 2000s *(high confidence)*, however most of this trend was due to increased urbanization in such areas (Douglas *et al.*, 2008; Hardoy and Pandiella, 2009). There is evidence of a decline in average precipitation in West Africa since 1960 (Lacombe *et al.*, 2012) including repeated droughts (Dietz *et al.*, 2004; Armah *et al.*, 2011), which in some cases has been partly attributed to anthropogenic climate forcing (Held *et al.*, 2005; Jenkins *et al.*, 2005; Biasutti and Giannini, 2006). However, there is only *limited evidence* of changes in poverty among affected small-holder and subsistence farmers that can be attributed to climate drivers such as rainfall decline and droughts (13.2.1).

Livelihoods of indigenous people in the Arctic have been identified as among the most severely affected by climate change, including food security aspects, traditional travel and hunting, and cultural values and references (Hovelsrud *et al.*, 2008; Ford *et al.*, 2009; Ford, 2009a; Ford, 2009b; Beaumier and Ford, 2010; Pearce *et al.*, 2010; Olsen *et al.*, 2011; Eira, 2012; Crate, 2013, see also Box 18-5, Table 18-9). Impacts of rising temperatures, increased variability, and weather extremes on crops and livestock of indigenous people in highlands were reported from Tibet (Byg and Salick, 2009) and the Andes of Bolivia (McDowell and Hess, 2012).

_____ START BOX 18-5 HERE _____

Box 18-5. Detection, Attribution, and Traditional Ecological Knowledge

Indigenous and local peoples often possess detailed knowledge of climate change that is derived from observations of environmental conditions over many generations. Consequently, there is increasing interest in merging this traditional ecological knowledge (TEK)—also referred to as indigenous knowledge - with the natural and social sciences in order to better understand and detect climate change impacts (Huntington *et al.*, 2004; Parry *et al.*, 2007; Salick and Ross, 2009; Green and Raygorodetsky, 2010; Ford *et al.*, 2011; Diemberger *et al.*, 2012). TEK, however, does not simply augment the sciences, but rather stands on its own as a valued knowledge system that can, together with or independently of the natural sciences, produce useful knowledge for climate change detection or adaptation (Agrawal, 1995; Cruikshank, 2001; Hulme, 2008; Berkes, 2009; Byg and Salick, 2009; Maclean and Cullen, 2009; Wohling, 2009; Ziervogel and Opere, 2010; Ford *et al.*, 2011; Herman-Mercer *et al.*, 2011).

Cases in which TEK and scientific studies both detect the same phenomenon offer a higher level of confidence about climate change impacts and environmental change (Huntington *et al.*, 2004; Laidler, 2006; Krupnik and Ray, 2007; Salick and Ross, 2009; Gamble *et al.*, 2010; Green and Raygorodetsky, 2010; Alexander *et al.*, 2011; Cullen-Unsworth *et al.*, 2012). Evidence is available in particular from Nordic and Mountain peoples, e.g from Peru's Cordillera Blanca mountains (Bury *et al.*, 2010; Carey, 2010; Baraer *et al.*, 2012; Carey *et al.*, 2012b), Tibet (Byg and Salick, 2009), and Canada (Nichols *et al.*, 2004; Laidler, 2006; Krupnik and Ray, 2007; Ford *et al.*, 2009; Aporta *et al.*, 2011). TEK can also inspire scientists to study new issues in the detection of climate change impacts.

In one case, experienced Inuit weather forecasters in Baker Lake, Nunavut, Canada, reported that it had become increasingly difficult for them to predict weather, suggesting an increase of weather variability and anomalies in recent years. To test Inuit observations, scientists analyzing hourly temperature data over a 50 year period confirmed that afternoon temperatures fluctuated much more during springtime during the last 20 years—precisely when Inuit forecasters noted unpredictability—than they had during the previous 30 years (Weatherhead *et al.*, 2010).

Despite frequent confluence between TEK and scientific observations, there are sometimes discrepancies between them, indicating uncertainty in the identification of climate change impacts. They can arise because TEK and scientific studies frequently focus on different and distinct scales that make comparison difficult. Local knowledge may fail to detect regional environmental changes while scientific regional or global scale analyses may miss local variation (Wohling, 2009; Gamble *et al.*, 2010). Furthermore, TEK based observations and related interpretations necessarily need to be viewed within the context of the respective cultural, social, and political backgrounds (Agrawal, 1995). Therefore, a direct translation of TEK into a natural science perspective is often not feasible.

_____ END BOX 18-5 HERE _____

18.5. Detection and Attribution of Observed Climate Impacts across Regions

Since the AR4, significant new knowledge about detected impacts of recent climate change has been gained from all continents and oceans of the world, assessed in the Chapters 22-30 of this report. The tables in this section (18-5, 18-6, 18-7, 18-8, 18-9) summarize impacts in major natural and human systems, at the local to continental scale, for which assessment of the role of climate as one driver has been possible. The following paragraphs provide a summary of recent climate changes in these regions along with notes about particular challenges in the regional assessments.

For much of *Africa*, knowledge about recent climate change is limited, due to weak climate monitoring, and gaps in coverage that continue to exist. On the other hand, the low natural temperature variability over the continent allows earlier detection of warming signals. Thus there is *medium to high confidence* in regional warming, with *low to high confidence* in attribution to anthropogenic emissions. A main regional feature has been the drying of the Sahel during the decades following 1970, but that trend has halted during the most recent decade (Hoerling *et al.*, 2006; Giannini *et al.*, 2008; Greene *et al.*, 2009; Seneviratne *et al.*, 2012). African natural and human systems present challenges for the potential detection and attribution of responses to climate change. Given the weak spatial and temporal variations in temperature, there is smaller scope for migrational and phenological responses to anthropogenic climate change than in other parts of the world. High quality monitoring is relatively sparse in time and space, and is often unsuitable for detecting changes across margins and borders where responses to climate change are most expected. The dearth of studies examining attribution questions means it is currently difficult to estimate the degree to which studies are selectively published based on results, and thus to determine whether each attribution study is only indicative of local reasons for concern or if it is more generally representative of a broader domain.

Amongst all continents, *Europe* has the longest tradition in climate monitoring. Warming has been occurring across the continent in all seasons, with an associated decreasing frequency of cold extremes and increasing frequency of hot extremes (Seneviratne *et al.*, 2012). The Mediterranean basin has been getting drier, while northern areas have been getting wetter (23.2.2.1), with a general increase in the frequency of extreme wet events everywhere (Seneviratne *et al.*, 2012).

Asia spans a particularly wide range of climate types. Warming has been observed throughout the continent with northern areas amongst the fastest warming on the planet. Precipitation trends vary geographically, with a but weaker Indian monsoon (WGI AR5 Chapter 14.2.2.1), and contrasting increasing and drying trends over coastal and inland China (24.3.1).

Warming has occurred in *Australasia* during the past century, with hot extremes becoming more frequent and cold extremes becoming less frequent (25.2, Table 25-1). Winters in southern areas of Australia have become drier in the past few decades and the northwest has become wetter, and precipitation increased over the south and west of both islands of New Zealand. While there have been no significant trends in drought frequency over Australia, regional warming may have increased their hydrological intensity; and fire weather increased since 1973 in Australia (Table 25-1, Clarke *et al.*, 2012).

North America spans a wide range of climate types and observed climate changes. While the northwest has been amongst the fastest warming regions on the planet, the southeast of the USA has experienced slight cooling (26.2.2.1). Hot extremes have been becoming more frequent while cold extremes and frost days have been becoming less frequent over the past several decades. Trends in precipitation over western parts of the continent are strongly influenced by the variability of the El Niño Southern Oscillation, with a matching drying and decreasing snowpack. The intensity of precipitation events has been increasing over most of the continent, but trends in dryness are spatially heterogeneous (26.2.2.1). Intense tropical storms have increased in the North Atlantic over the past several decades (WGI AR5 Chapter 2.6.3).

Most of *Central and South America* has warmed over the past half century, except for a slight cooling over a western coastal strip (27.2.1). Precipitation over much of Central and South America is strongly influenced by the El Niño Southern Oscillation, with accompanying long-term variability. There has been a reduction in the number of dry summer months in the southern half of the continent, while trends over the Amazon are sensitive to the selection of time period (27.2.1). More frequent and severe droughts in the Amazon have been linked to warming (Marengo *et al.*, 2011a).

The areas of largest observed warming are all *Polar:* the northwest of North America, northern Asia, and the Antarctic Peninsula. The nature of Polar regions means that warming can lead to large changes in other aspects of the climate system, in particular the observed decrease in summer sea ice cover, earlier thaw, earlier spring runoff, and thawing of permafrost (28.2).

Despite the widely accepted high vulnerability of many *small islands* to climate change, there are only few formal studies on observed impacts. Detection of climate change impacts in small islands is challenging due to the strong presence of other anthropogenic drivers of local environmental change. Attribution is further challenged by the strong influence of natural variability compared to incremental changes of climate drivers, and the lack of long term monitoring, high quality data.

18.6. Synthesis: Emerging Patterns of Observed Impacts of Climate Change

18.6.1. Approach

The AR4 precursor of the current chapter (Rosenzweig *et al.*, 2007) provided a geographically distributed empirical analysis of correlations across numerous detailed and localized studies of changing systems (more elaborated later in Rosenzweig *et al.*, 2008). Rather than expand that approach, this synthesis organizes the findings on detection and attribution of observed impacts of climate change aiming at covering the full disciplinary, sectoral and geographic diversity of impacts, drawn directly from sectoral and regional assessments in this report.

A key motivation for the effort in assessing these observed changes is the possibility that observed impacts could constitute indications of future expected changes. Observed losses in glacial volume, for example, lend important additional plausibility to model-based expectations that sustained warming could result in additional ice loss. Such extrapolation faces important limitations, however. First, due to the complex nonlinear behavior of most natural and human systems, it cannot always be assumed that past impacts scale linearly to future impacts. Likewise, absence of past impacts cannot constitute evidence against the possibility of future impacts. Nonetheless, detection and attribution of observed impacts may serve as part of the foundation for a climatic risk analysis. In order to do so, the total body of observed impacts needs to undergo a synthetic assessment pointing towards any conceivable risks.

Virtually all observed impacts of climate change are of regional nature (18.5); however the occurrence of similar impacts in many regions of the world emerges more strongly with every IPCC assessment. The global pattern emerging from the sum of observed regional impacts is therefore analysed in section 18.6.2. The current body of observations provides improved evidence of major impacts in natural and human systems which have ‘cascading’ consequences for other systems – key examples for these are synthesized in section 18.6.3. Finally, section 18.6.4 aims to establish current conditions concerning the risk analysis model formulated earlier by the IPCC through the establishment of a limited number of “Reasons for Concern” (RFC) – the risk analysis itself is part of Chapter 19 of this report.

18.6.2. The Global Pattern of Regional Impacts

The global pattern of observed climate change differs strongly for the different climate variables. Broadly, more warming has occurred at higher latitudes than in the Tropics, while the pattern of rainfall changes is highly complex (WGI AR5 Chapter 2). Taken together, this provides a heterogenous pattern of climate change across the globe. In addition, some natural and human systems (and the regions in which they occur) are more vulnerable to changing climate than others. Crucially, observational records are of highly heterogenous nature: not only do low-income countries report fewer impacts than high-income countries, but there is also a significant shortage of observations from remote areas such as the deep Sea or sparsely populated mountains and deserts. Taken together, it is therefore natural to expect an uneven distribution of detected impacts (Figure 18-3).

The outstanding finding about the global pattern of observed impacts is that, on all continents and across major ocean regions, significant impacts have now been observed. Many of these concern systems affected directly by warming (the cryosphere, marine systems), but a growing number of observed impacts have been shown to be the result of a combination of changing temperature and precipitation (agricultural and hydrological systems).

The global distribution of observed impacts shown in Figure 18-3 demonstrates that analyses can now detect impacts in systems strongly influenced by confounding factors and hence where climate change plays only a minor role. The most outstanding examples for this are agricultural systems where impacts now emerge in a number of places. An identified minor role of climate for some impact does not imply that this role is less important. New studies now identify more clearly such roles even when they are masked by stronger confounding factors such as environmental degradation or improved technology. Examples for such studies include, assessments of mangrove degradation, caused by both warming and pollution (Giri *et al.*, 2011), or changes in Inuit livelihoods, influenced by both warming and social changes (Ford *et al.*, 2009). Enhanced research efforts would probably add additional observations of impacts with a minor, but important, role of climate to the global map.

[INSERT FIGURE 18-3 HERE
Figure 18-3: Global patterns of observed climate change impacts. Each colored symbol in the top panels indicates a class of systems for which climate change has played a major role in observed changes in at least one measure of that class across the respective region, and the range of confidence in attribution. Regional-scale impacts where climate change has played a minor role are shown by colored open symbols in a box in the respective region. Localized impacts are indicated with symbols on the map, placed in the approximate area of their occurrence. Impacts on physical (blue), biological (green) and human (red) systems are differentiated by color. This map represents a graphical synthesis of Tables 18-5, 18-6, 18-7, 18-8 and 18-9.]

18.6.3. Cascading Impacts

Many impacts of climate change are direct cause-effect relationships, such as reduction of glacier volume following higher temperatures. Others may be mediated through impacts on intermediary systems (e.g., Johnson *et al.*, 2011). Enhanced evidence of observed impacts of climate change, and improved research methodologies now allow attribution of effects at various stages along the causal impact chain (Figure 18-4). Within the cryosphere, changes in atmospheric and ocean properties of the climate have driven changes in the cryosphere on the land surface, the land subsurface, and the ocean surface. These changes have in turn led to changes in multiple aspects of hydrology and ecosystems, and in some regions (e.g., the Arctic) changes in these systems have impacted human livelihoods (Xu *et al.*, 2009). Within most ocean regions, warming has lead to a number of observed impacts on biota, some of which are mediated through the effect of warming on the ocean’s thermal stratification or on sea ice. Impacts tend to propagate up the food chain, eventually affecting large mammals, birds, reptiles and humans. In forests and woodlands, climate change impacts on trees have been transmitted through pests, fire, and drought, while impacts on forests have also been observed to affect the forest fauna. In all these cases, confidence in detection and attribution to observed climate change decreases for effects further down each impact chain.

[INSERT FIGURE 18-4 HERE
Figure 18-4: Major systems where new evidence indicates interconnected, ‘cascading’ impacts from recent climate change through several natural and human subsystems. Bracketed text indicates confidence in the detection of a climate change effect and the attribution of observed impacts to climate change. The role of climate change can be major (solid arrow) or minor (dashed arrow). Confidence is assessed in 18.3, 18.4, 18.5, and 18.6.]

18.6.4. Reasons for Concern

In order to synthesize its findings in support of a risk analysis the Third Assessment Report of the IPCC (TAR) developed the "Reasons for Concern" (RFC) concept (Smith *et al.*, 2001), which was adopted for a second time in IPCC-AR4 (IPCC, 2007), and elaborated in Smith *et al*. (2009). It is further developed in Chapter 1 of this report and employed extensively in Chapter 19 for the risk framing approach of WGII AR5. In this chapter, the goal is to establish, qualitatively, the evidence of impacts already observed that are relevant to these categories (names of categories have been adapted for consistency across Chapters 1, 18 and 19, see sections below). The broad definitions of the RFC continue to imply significant overlap; hence some observed impacts are referred to under more than one RFC.

The RFC *Risks to Unique and Threatened Systems* is concerned with the potential for increased damage to, or irreversible loss of, systems such as physical systems, ecosystems, and human livelihoods, all of which are known to be highly sensitive to temporal and/or spatial variations in climate. Figure 18-5 displays confidence levels in the current evidence derived from detection and attribution studies of such observed impacts. Changes in the three indicated main natural systems (physical systems, marine and terrestrial ecosystems) have at least *high confidence* in attribution of a major role of climate change, with regional assessments also tending to have similar confidence. There is at least *medium confidence* in attribution of a major role for at least one each of ecosystems, physical systems, and human systems.

The unique and threatened systems with strongest detection and attribution evidence cover the Arctic, warm-water coral reefs, and mountains. In the Arctic, climate change has played a major role in observed impacts on glaciers, permafrost, the tundra, marine ecosystems, and livelihoods of indigenous peoples (at least *medium confidence*), reflecting large-scale changes across both natural and human systems and across the physical and ecological subregions. Evidence for the detection and attribution of shrinkage and recession of glaciers comes from all continents, while evidence for attribution of coral bleaching spans a similarly broad area of the tropical oceans (see Figure 18-5).

[INSERT FIGURE 18-5 HERE
Figure 18-5: Confidence in detection and attribution of observed impacts on "Unique and Threatened Systems" as a result of recent climate change. Global assessments (large upper case) and regional assessments (small lower case) are discussed in 18.3.1.1, 18.3.2.4, Box 18-2, and Tables 18-2 and 18-5 through 18-9. Attribution assessments are for a minor (open font) or major (bold) role of climate change, as indicated.]

The RFC *Risks Associated with Extreme Weather Events* "tracks increases in extreme events with substantial consequences for societies and natural systems" (Smith *et al.*, 2009). Besides episodic (e.g., coral bleaching) and chronic (e.g., erosion) impacts of extreme weather events, this RFC also considers increased frequency of extreme impact events (e.g., floods), even if their climate drivers are not wholly episodic in nature. A change in the risk of impacts of extreme weather events could be caused by a change in the probability, intensity, or sequencing of the weather event itself (which are manifestations of recent climate change), or by a change in exposure, vulnerability, or the resilience of the impacted system.

Trends have been noted for extreme weather hazards. Temperature extremes have changed in most regions over the past half century, with more frequent hot events and less frequent cold events (*high confidence;* Hansen *et al.*, 2012; Seneviratne *et al.*, 2012, WGI AR5 Chapter 2.6.1; Coumou *et al.*, 2013). Some regions have also experienced increasingly frequent periods of heavy precipitation events (*medium confidence;* Min *et al.*, 2011), while other regions have experienced positive or negative trends in measures of dry spells (Seneviratne *et al.*, 2012). Current evidence does not, however, indicate sustained global trends in tropical cyclone or extratropical cyclone activity (Seneviratne *et al.*, 2012, WGI AR5 2.6.3).

Table 18-10 summarizes new evidence concerning this RFC. Generally, the strongest evidence of detected impacts related to extremes concerns warm water corals where bleaching has been linked directly to high temperature spells (Box 18-2, Baker *et al.*, 2008; Strong *et al.*, 2011). Outside of these coral reef systems, however, evidence for extreme event impacts is *limited* and mostly local. Overall, a number of trends in observed impacts on natural systems have been documented which indicate changing risks driven by changes in extreme weather (*medium confidence*), but any similar trends in human systems have not been detected against large shifts in exposure, vulnerability and resilience.

[INSERT TABLE 18-10 HERE
Table 18-10: Confidence in detection and attribution of observed trends in natural disasters related to extreme weather. The assessment is for the impacts on various systems, in attribution of those trends to climate change, and in the existence of observed trends in that extreme weather. The assessment of confidence in detection is against the specified reference behaviour, while the assessment for attribution is for the indicated minor or major role of observed climate trends. The confidence statements refer to a globally balanced assessment.]

The RFC *Risks Associated with the Distribution of Impacts* focuses on the disparities of impacts between regions, countries, and populations. The survey of recent studies presented in 18.5 indicates that, while evidence for detected impacts is still more exhaustive from Europe and North America, considerable confidence in conclusions has been developed elsewhere since the AR4, particularly in Central and South America and Australasia (Figure 18-3). It is no longer the case that higher confidence levels of detected impacts are restricted to any particular region (Figure 18-6).

The qualitative conclusion that observed impacts on human and managed systems have now been detected with at least *medium confidence* on all inhabited continents is new and noteworthy. However, the number of systems with detectable impacts is only an indicative metric of coverage, because many options exist for aggregation and disaggregation of evidence. Thus this synthesis of detection and attribution studies does not, at this time, provide evidence of differing severity of impacts between continents. Throughout its assessments, the IPCC has repeatedly noted the significant disparity between the vulnerability of countries, regions, and social groups, related to differences in adaptive capacity (e.g., Wilbanks *et al.*, 2007). Nevertheless, additional coverage of detection and attribution studies is required for broad evaluation of social disparities in impacts.

[INSERT FIGURE 18-6 HERE
Figure 18-6: Confidence in detection of observed climate change impacts in physical natural systems, biological systems, and human and managed systems across regions, and confidence in attribution of such trends to observed climate change as a major or minor driver. Based on assessments developed in Tables 18-5 - 18-9.]

The original intent of the category now labeled as *Risks Associated with Aggregate Impacts* was to assess those economic impacts, damages, and risks that are specifically driven by climate change at a globally aggregated level, using unified monetary metrics. Recognizing the limits of calibrated monetarization of impacts, the scope of this RFC has been expanded over time to also include non-monetary metrics (Smith *et al.*, 2009). Table 18-11 lists various aggregate systems of near-global extent for which the following two conditions apply: there is some form of calibrated metric for comparison of impacts across space and subsystems, and the evidence for detection and attribution of the impacts has sufficient geographical coverage to count as spatially representative sample.

Confidence in such large-scale detection is, again, highest in cryospheric systems (expressed in glacier volume or permafrost active layer thickness), but climate change has also affected ecosystems (expressed as net productivity or carbon stocks, ranging from *medium to high confidence*) and some human systems (crop yields, losses due to extreme events, ranging from *low to medium confidence*) according to the listed aggregate measures. Thus, several globally aggregated impacts of recent climate change have now been identified.

[INSERT TABLE 18-11 HERE
Table 18-11: Confidence in detection of impacts on aggregate impact measures against the specified reference behaviour and confidence in attribution of the specified role of climate change in those observed changes.]

The RFC *Risks Associated with Large-Scale Singular Events* "represents the likelihood that certain phenomena (sometimes called singularities or tipping points) would occur, any of which may be accompanied by very large impacts" (Smith *et al.*, 2009). Several studies have identified "tipping elements" in the Earth System that exhibit non-linear behavior with potentially strong feedbacks on the Earth system (Lenton *et al.*, 2008; Leadley *et al.*, 2010). For observed impacts, the concern translates into a question of the possible presence of "early warning signals" for discontinuities that may be derived from monitoring changes in some climate or natural systems (Collie *et al.*, 2004; deYoung *et al.*, 2008; Andersen *et al.*, 2009; Lenton, 2011).

For the Arctic region, new evidence indicates a biophysical regime shift is taking place, with cascading impacts on physical systems, ecosystems and human livelihoods. For Arctic marine biota, the rapid reduction of summer ice cover causes a tipping element which is now severely affecting pelagic ecosystems as well as ice-dependent mammals such as seals and polar bears (*high confidence;* Duarte *et al.*, 2012a;Table 18-2, 18-8; 28.2.2.1). On land, thawing of Arctic permafrost and shrub encroachment on the tundra have been driven by warming and prolongation of the growing season (*high confidence;* 18.3.2.4, Table 18-5, 18-7; Figure 4-4, 4.3.3.4; 24.4.2.2). Permafrost degradation has contributed to wide-spread hydrological changes including lake formation or disappearance within a few years' time (*high confidence*; Prowse and Brown, 2010; Callaghan *et al.*, 2013; Table 18-6), while increasing winter rains have had consequences for the tundra food webs (*medium confidence;* Post *et al.*, 2009; Callaghan *et al.*, 2013; Hansen *et al.*, 2013). Indigenous people throughout the Arctic are impacted by these changes (18.4.6, Eira, 2012; Crate, 2013). In summary, several indicators of the ongoing regime shift in the entire Arctic land-sea socio-ecological system can be interpreted as warning sign for a large-scale singular event (Post *et al.*, 2009; CAFF, 2010; Callaghan *et al.*, 2010; AMAP, 2011; Duarte *et al.*, 2012b; Figure 18-3, Tables 18-5, 18-7, 18-8, 18-9; 28.2).

Reef building corals are in rapid decline in many regions, and climate change is one of the major drivers (*high confidence,* Box 18-2). This irreversible loss of biodiversity has significant feedbacks within the marine biosphere, and significant consequences for regional marine ecosystems as well as the human livelihoods which depend on them (Hoegh-Guldberg and Bruno, 2010; Richardson *et al.*, 2012). The growing evidence for presently ongoing change and its attribution to warming gained since the AR4 strengthens the conclusion that increased mass bleaching of corals constitutes a strong warning signal for the singular event that would constitute the irreversible loss of an entire biome.

Dieback and degradation in the boreal forests as well as the Amazonian rainforest have also been identified as potential tipping elements in the Earth system, due to their large extent and the possible feedbacks with the carbon cycle (Lenton *et al.*, 2008; Leadley *et al.*, 2010; Marengo *et al.*, 2011b, see also 4.3.3.1). For the boreal forest, increases in tree mortality have been observed in many regions, including wide-spread dieback related to insect infestations and fire in North America (4.3.3.1; 26.4.2.1). Taken together, these may be seen as indicators of an ongoing regime shift in the boreal forest, but there is only *low confidence* in attribution to climate change (18.3.2.4; Figure 4-4). In the humid tropical forests of the Amazon basin, increased tree turnover (both mortality and growth) and enhanced drought risks have been observed during recent decades. However, the main reason for concern is the interaction between climate change, deforestation, and the high susceptibility of forests to fire, which together could produce positive feedbacks leading to degradation of forests in large areas of the Amazon (Malhi *et al.*, 2009). Currently, there is only *low confidence* in attribution of observed ecosystem changes in the Amazon to climate change. In conclusion, there is insufficient evidence from observed climate change impacts to support a climate-related warning sign of possible large-scale singular events in the boreal and Amazonian forest.

18.6.5. Conclusion

Detection and attribution studies evaluate the agreement between observations of change in a system and process understanding of its causes, whether these are due to climate change or other forces. This sets a higher bar for establishing confidence in the assessment of past changes than is generally applied to the projections of future changes, because observational evidence has important gaps, while the plausibility of future changes is established on the basis of process knowledge only. Despite this constraint, the body of evidence on observed impacts of recent climate change demonstrates increasing coverage of the Earth and its various subsystems, including human livelihoods. Increasingly, there is also evidence for complex changes in interconnected systems.

This analysis lends new qualitative support to four out of the RFC established by earlier IPCC assessments. Specifically, evidence is notable for risks to unique and threatened systems, risks stemming from extreme weather events, risks associated with globally aggregated impacts and – in terms of early warnings – risks associated with large-scale discontinuities. Only the spatial or social disparities covered under "risks associated with the distribution of impacts" are still insufficiently studied to permit a synthesis of available observations for the characterization of a global concern. While the Arctic stands out as a region with robust evidence of impacts across numerous systems, current detection and attribution literature does not address whether the severity of those impacts differs from other regions. The Arctic region, warm-water coral reef systems and mountain glaciers feature strongly in the observational evidence discussed for all the RFC, but there are also important observations from impacted hydrological systems and human systems including agriculture.

The evidence gathered since the AR4 on detection and attribution of observed impacts from climate change has reached a level at which it can inform evaluation of many of the aspects of present-day climate change risk as described by the RFC. In particular, the geographical distribution of studies is reaching the point where assessment of the global nature of impacts is possible:

- There is now *robust evidence* of observed changes in natural systems in all of the regional groupings used in this report. Climate change has played a major role in observed changes in various components of the cryosphere on all continents (*high confidence*). Climate change has also driven observed changes in terrestrial ecosystems on six continents (*high confidence*, the exception being *low confidence* in Central and South America) and on some small islands (*medium confidence*), and for marine ecosystems surrounding six continents and some small islands (*high confidence*, with evidence lacking for Africa).
- There is *new and stronger evidence* of the detection of impacts in human systems on the inhabited continents. There is at least *medium confidence* in detection of impacts on food production in all the inhabited continents except North America.
- While the current detection and attribution literature does not reveal observational evidence of geographical differences in the severity of climate change impacts between continents, it does indicate that the unique systems of the Arctic region and warm water coral reefs are undergoing rapid changes in response to observed warming in ways that are potentially irreversible.

18.7. Gaps, Research Needs, Emerging Issues

There are three broad areas relating to the detection and attribution of the impacts of climate change on natural and human systems that require more research. The first concerns the formulation of the relevant issues and further development of rigorous scientific methods for addressing them. At present, the terms detection and attribution are used in numerous different ways and, while there is no need for a single definition, more clarity about usage is important. Methods in this area are closely linked to specific formulations of these terms and there is a parallel need to develop, refine, and evaluate them in light of this. For example, statistical methods are commonly used to detect the impact of variations in climate on human and natural systems while controlling for the effect of other factors. Such detection can be valuable in helping to predict the response of systems to projections of future climate change but a positive correlation does not necessarily imply that the system has already changed in response to historical climate change. A second example is the growing use of methods that combine information from multiple systems - for example, different locations or species - to draw a conclusion about systems in general. More conceptual work is needed to develop the basis for such ecological meta-analysis and the interpretation of its results.

A second area in which more work is needed is data collection and monitoring. Globally, environmental data are still insufficient for monitoring the impacts of climate change. In addition, developed countries are typically over-represented in impact studies because of their comparable wealth in socioeconomic data. Because the level of economic development is extremely important in determining the impacts of climate change, this over-representation probably gives rise to a distorted picture of the global impacts of climate change.

Finally, this chapter has stressed the need to base detection and attribution studies on a scientific understanding of the system in question and the way in which climate change (and other factors) might affect it rather than on relatively simple correlational analysis. This is particularly important for human systems and at least some natural systems in which the combined effect of climate change and other factors is complex and historical adaptation to climate change must be expected. Further development, refinement, and evaluation of both conceptual and process-based models of the human-environment system will be essential for improved conclusions about detection and attribution.

Frequently Asked Questions

FAQ 18.1: Why are detection and attribution of climate impacts important? *[to remain at the end of the chapter]*
To respond to climate change, it is necessary to predict what its impacts on natural and human systems will be. As some of these predicted impacts are expected to already have occurred, detection and attribution provides a way of validating and refining predictions about the future. For example, one of the clearest predicted ecological impacts of climate is a poleward shift in the ranges of plant and animal species. The detection in historical data of a climate-related shift in species ranges would lend credence to this prediction and the assessment of its magnitude would provide information about the likely magnitude of future shifts.

FAQ 18.2: Why is it important to assess impacts of all climate change aspects, and not only impacts of anthropogenic climate change? *[to remain at the end of the chapter]*
Natural and human systems are affected by both natural and anthropogenic climate change, operating locally, regionally and/or globally. In order to understand the sensitivity of natural and human systems to expected future climate change, and to anticipate the outcome of adaptation policies, it is less important whether the observed changes have been caused by anthropogenic climate change or by natural climate fluctuations. In the context of this chapter, all known impacts of climate change are assessed.

FAQ 18.3: What are the main challenges in detecting climate change impacts?
[to remain at the end of the chapter]
The detection of climate change impacts addresses the question of whether a system has changed beyond its expected behavior in the absence of climate change. This requires an understanding of both the external and internal factors that affect the system. External factors that can affect natural systems include exploitation, land-use changes, and pollution. Even in the absence of changes in external factors, many natural systems exhibit substantial internal variability – such as booms and busts in wild populations – that can last for long periods. For example, to detect the impact of climate change on wild fish stocks, it is necessary to understand the effects of fishing, habitat alteration, and possibly pollution, as well as the internal stock dynamics. In the same way, human systems are affected by social and economic factors that are unrelated to climate change. For example, to detect the impact of climate change on human health, it is necessary to understand the effects of changes in public health measures such as improved sanitation.

FAQ 18.4: What are the main challenges in attributing changes in a system to climate change?
[to remain at the end of the chapter]
Whereas the detection of climate change impacts addresses the question only of whether or not a system has changed as a result of climate change, attribution addresses the magnitude of the contribution of climate change to such changes. Even when it is possible to detect the impact of climate change on a system, more detailed understanding can be needed to assess the magnitude of this impact in relation to the influences of other external factors and natural variability.

FAQ 18.5: Is it possible to attribute a single event, like a disease outbreak or the extinction of a species, to climate change? *[to remain at the end of the chapter]*
It is possible to detect trends in the frequency or characteristics of a class of a class of weather events like heat-waves. Similarly, trends in a certain kind of impact of that class of events can also be detected and attributed, although the influence of other drivers of change, such as policy decisions and increasing wealth, can make this challenging. However, any single impact event also results from the antecedent conditions of the impacted system. Thus while damage from a single extreme weather event may occur against the background of trends in many influencing factors, including climate change, there is always a contribution from random chance.

Table 18-1: Observed changes in ocean system properties and their effects, with confidence levels for the detection of the effect of climate change and an assessment of the magnitude of its role.

Process	**confidence in**		**role**	**context**	**Ref**
	detection	**attribution**			
Impacts of ocean acidification on pelagic marine biota	*low*	*very low*	minor	e.g., reduction in foraminiferan, coccolithophores and pteropod shell weight. Attribution supported by experimental evidence and physiological knowledge	[1]
Expansion of midwater hypoxic zones	*medium*	*low*	minor	oxygen minimum zones (OMZs) caused by enhanced stratification and bacterial respiration due to effects of warming	[2]
Regional and local impacts of expanding hypoxic zones	*medium*	*low*	minor	reduction of biodiversity, compression of oxygenated habitat for intolerant species, range expansion for tolerant taxa	[3]
Direct temperature effects on marine biota related to limited physiological tolerance ranges	*very high*	*high*	major	e.g., large scale latitudinal shifts of species distribution, changes in community composition; attribution supported by experimental and statistical evidence as well as physiological knowledge	[4]
Increase in net primary production at high latitudes	*medium*	*medium*	major	At higher latitudes, NPP is increasing due to sea ice decline and warming. At global scale, estimates vary regionally, and there is a discrepancy between satellite observations and open ocean time-series sites	[5]
Changes in microbial processes	*low*	*very low*	minor	limited understanding of microbial processes, drivers and interactions, and subsequently of large scale shifts in biogeochemical pathways such as oxygen production, carbon sequestration and export production and nitrogen fixation	[6]

Table 18-2: Observed changes in marine species and ecosystems, with confidence levels for the dection of the effect of climate change and an assessment of the magnitude of its role (see also 6.2, 6.3, 30.4, Box CC-MB).

Process	**confidence in**		**role**	**Context**	**Ref**
	detection	**attribution**			
Range shifts of fish and macroalgae	*high*	*high*	major	changes in species biogeographical ranges to higher latitudes or greater depths	[1]
Changes in community composition	*high*	*high*	major	due to effects of warming, hypoxia, and sea ice retreat	[1]
Changes in abundance	*high*	*medium*	major	observed in fish, corals and intertidal species	[1]
Impacts on large non-fish species, e.g. walruses, penguins, and other sea-birds	*high*	*high*	major	observed effects include changing abundance, phenology, species distribution and turtle sex ratios, and are mostly mediated through changes in resource availability including prey	[2]
Impacts on reef-building corals	*very high*	*high*	major	effects mostly attributed to warming and rising extreme temperatures, though ocean acidification may contribute	[3]
Changes in fish species richness in temperate and high latitude zones	*high*	*medium*	major	effect associated with loss of sea ice and latitudinal species shifts due to warming trends	[4]

Table 18-3: Illustrative selection of recent disasters related to extreme weather events, with description of the impact event, the associated climate hazard, recent climate trends relating to the weather event, and recent trends relating to the consequences of such a weather event.

Date and locale	**Impact event**	**Associated climate hazard**	**Trends relating to likelihood of climate hazard**	**Trends relating to consequence of climate hazard**
France, summer 2003	Approximately 15 000 excess deaths (Hémon and Jougla, 2003; Fouillet *et al.*, 2006)	Record hot days / heatwave (Hémon and Jougla, 2003; Fouillet *et al.*, 2006)	Increasingly frequent hot days and heat waves in recent decades (Perkins *et al.*, 2012; Seneviratne *et al.*, 2012) (*high confidence*)	Aging population, increasing population, trends in marital status (Hémon and Jougla, 2003; Prioux, 2005; Fouillet *et al.*, 2006; Rey *et al.*, 2006) Difficulties staffing health services, undeveloped early warning system (Lalande *et al.*, 2003; Fouillet *et al.*, 2008)
Altantic and Gulf coasts of the United States, 2005	Over 1000 deaths and over US$100 billion in damage (Beven *et al.*, 2008)	Record number of tropical storms, hurricanes, and category 5 hurricanes (Bell *et al.*, 2006)	Recent increase in frequency but no clear century-scale trends in US landfalling tropical storms or hurricanes (WGI AR5 2.6.3, Knutson *et al.*, 2010) (*high confidence*)	More population, settlement, and wealth in coastal areas (Pielke Jr *et al.*, 2008; Schmidt *et al.*, 2010) Strengthening of building codes (IntraRisk, 2002)
Mozambique, early 2007	Over 100 000 people displaced by flooding (Foley, 2007; Artur and Hilhorst, 2012)	High rainfall in upper Zambezi Basin in preceding months, passage of Cyclone Favio (Thiaw *et al.*, 2008)	Warming and decreasing rainfall leading to lower discharge of the Zambezi (Dai *et al.*, 2009) (*low confidence*) Decreasing frequency of tropical cyclones in the Mozambique Channel during past 50 years (Mavume *et al.*, 2009) (*medium confidence*)	Increased settlement of Zambezi flood plain following dam construction (Foley, 2007) Development of emergency response plans (Cosgrave *et al.*, 2007; Foley, 2007)
Colombia, October-December 2010	Floods affecting 4 million people, US$7.8 billion total damage (Hoyos *et al.*, 2013)	Wettest year since records began 40 years ago (Martinez *et al.*, 2011)	No clear trend in discharge of rivers in flood-affected areas since 1940 (Hoyos *et al.*, 2013) (*low confidence*)	Rapid urbanisation, with high concentration of residential areas in flood-prone areas (UNISDR, 2013; Álvarez-Berríos *et al.*, 2013) Increasing vulnerability of rural population over the past decades and highly fragile urban systems (e.g. water and gas) (UNISDR, 2013)
Pakistan, July-September 2010	Flooding leading to 2000 deaths, 20 million affected, total loss US$10 billion (NDMA, 2011)	Exceptionally high monsoon rainfall over northern Pakistan during July and August (Houze Jr *et al.*, 2011; Rajeevan *et al.*, 2011; Webster *et al.*, 2011)	No substantial trend in heavy rainfall event frequency in northern Pakistan in past several decades (Wang *et al.*, 2011c; Webster *et al.*, 2011) (*low confidence*)	Rapid population growth and expansion of formal and informal human settlements (Oxley, 2011) Decreased risk through development of flood and disease warning systems and disaster planning (NDMA, 2011) Increased risk from deforestation on mountainous slopes (Ali *et al.*, 2006) Recent unrest in north constrains ability of institutions to deliver basic services (WorldBank/ADB, 2010)

European Russia, July-August 2010	Burned area > 12 500 km (Müller, 2011)	Record hot days (Barriopedro *et al.*, 2011; Müller, 2011) Unusually dry June-August (Bulygina *et al.*, 2011)	Trends in temperature, precipitation, humidity, soil moisture, and snow cover toward less conducive climatic conditions for fire (Groisman *et al.*, 2007) (*medium confidence*)	Increased risk from draining of peat bogs in 1960s and earlier (GFMC, 2010; Müller, 2011) Increased risk from poorly implemented devolution of forest management and forest fire protection in 2007 to regional administrations (GFMC, 2010)
Russia, summer 2010	Grain harvest 30% lower than forecast (Wegren, 2011)	Hottest June-August in at least 130 years, unusually dry June-August (Bulygina *et al.*, 2011)	~1°C summer warming trend over last 70 years (Gruza and Mescherskaya, 2008; Bulygina *et al.*, 2011) (*very high confidence*)	Increase in grain production partially due to government support programs (Wegren, 2011)
Southeast Queensland, Australia, January 2011	Floods affecting >200 000 people, >30 000 homes flooded, damages and cost to economy of US$2.5-10 billion (Hayes and Goonetilleke, 2012)	2010 was wettest year since 1974, with landfall of tropical cyclone in December and wet start to January resulting in highest flood since 1974 (Van den Honert and McAneney, 2011; Hayes and Goonetilleke, 2012)	Decreasing frequency of intense floods since 1840 (Van den Honert and McAneney, 2011) (*medium confidence*)	Increased development in flood-prone urban areas (Van den Honert and McAneney, 2011) Lack of development of riverine flood insurance (Van den Honert and McAneney, 2011; Ma *et al.*, 2012)
Thailand, 2011	Prolonged inundation of urban and industrialized areas, manufacturing losses of about US$32 billion (WorldBank, 2012)	One of the wettest monsoon seasons on record in middle and upper Chao Phraya Basin, resulting in flooding (Komori *et al.*, 2012; Van Oldenborgh *et al.*, 2012)	No detectable change in preciptation over the basin (Van Oldenborgh *et al.*, 2012) (*low confidence*)	Economic development focused on large industrial estates built in flood plains (Chongvilaivan, 2012; Courbage *et al.*, 2012) Recent spell of political instability (Courbage *et al.*, 2012) Subsistence from groundwater pumping (Phien-Wej *et al.*, 2006)
Contiguous United States, summer 2012	Agricultural drought, with 57% of cropland and 43% of farms experiencing at least severe drought (Crutchfield, 2013)	Second warmest summer and warmest month (July) in the contiguous U.S., and one of the driest March-July periods in the central U.S. in the 118-year record (Crouch *et al.*, 2013; Kumar *et al.*, 2013)	~0.5ºC warming in summer over the last century (Menne *et al.*, 2009) (*very high confidence*) No substantial long-term trend in drought occurrence (Peterson *et al.*, 2013) (*medium confidence*)	Significant growth in area dedicated to soy and maize (FAOSTAT, 2013)

Table 18-4: Cases of regional livelihood impacts associated with weather- and climate related exevents, inter-annual climate variability or climate change (see also Table 18-3;13.2.1.1).

Impacted Population	Climate-related driver	Impact on livelihood	Reference
Small-scale farmers, Ghana	Drought (past 20-30 years)	Landscape transformation causing emotional distress, sense of loss of belonging	Tschakert *et al.* (2013)
Middle-class farmers, Australia	Drought (2000s)	Landscape transformation, income loss from agriculture, social conflict, poverty	Alston (2011)
Arctic indigenous peoples	Warming (past decades)	Changing ice and snow conditions, dwindling access to hunting grounds	28.2.4; Table 18-9; Hovelsrud *et al.* (2008); Ford (2009a); Brubaker *et al.* (2011); Arctic Council (2013); Crate (2013)
Urban populations in Maputo, Accra, Nairobi, Lagos, Kampala	Flood frequency and severity increase (1990s and 2000s)	Direct impacts on people and loss of physical assets (e.g. housing)	Douglas *et al.*(2008); Adelekan (2010)
Industry workers in India	Temperature variability and heat waves (1960s to present)	Decrease of fully workable days since 1960Limited ability to carry out physical work, health impacts	Ayyappan *et al.* (2009); Balakrishnan *et al.*(2010); Dash and Kjellström (2011)
Farmers in Subarnabad, Bangladesh	Sea-level rise (~1980s to present)	Salt water intrusion, shift from agriculture to shrimp farming, loss of agricultural livelihoods	Pouliotte *et al.* (2009)
Women farmers, Ghana	Rainfall-related climate variability (~1990s and 2000s)	Adaptation practices in agriculture produce gender inequalities	Carr (2008)
Cambodian rice farmers	Warming, rainfall-related climate variability (1980s to present)	Shift in income generation patterns between men and women	Resurreccion (2011)
Poor children in Africa and Latin America	Weather and climate-related events (1980s to present)	Food price shocks, reduced caloric intake, physical stunting, long-term effects such as reduced lifetime earnings	Alderman (2010)
Smallholder farmers in highlands of Bolivia	Locally perceived changes in temperature means and extremes, and rainfall seasonality (~1990s and 2000s)	Stress on household resources due to need to respond to increasing plant pests, switching to other crop types or livestock	McDowell and Hess (2012)

Table 18-5: Observed impacts of climate change on mountains, snow, and ice, over the past several decades, across major world regions, with descriptors for: i) the confidence in detection of a climate change impact, ii) the relative contribution of climate change to the observed change, compared to that of non-climatic drivers, iii) the main climatic driver (s) causing the impacts, iv) the reference behavior of the system in the absence of climate change, and v) the confidence in attribution of the impacts to climate change. References to related chapters in this report are given as well as key references to other IPCC reports and the scientific literature.

	Mountains, snow and ice	**conf. detect.**	**role of climate**	**climate driver**	**reference behaviour**	**conf. attrib.**
Africa	**Retreat of tropical highland glaciers in East Africa** [Table 22-3; (Mölg *et al.*, 2008; Taylor *et al.*, 2009; Mölg *et al.*, 2012)]	*very high*	major	warming, drying	no change	*high*
Europe	**Retreat of Alpine, Scandinavian and Icelandic glaciers** [WGI AR5 Chapter 4.3.3; (Bauder *et al.*, 2007; Björnsson and Pálsson, 2008; Paul and Haeberli, 2008; WGMS, 2008; Zemp *et al.*, 2009; Andreassen *et al.*, 2012; Marzeion *et al.*, 2012; Gardner *et al.*, 2013)]	*very high*	major	warming	no change	*high*
	Increase in rock slope failures in Western Alps [18.3.1.3; 23.3.1.4, (Fischer *et al.*, 2012; Huggel *et al.*, 2012a)]	*high*	major	warming	no change	*medium*
Asia	**Permafrost degradation in Siberia, Central Asia, and the Tibetan Plateau** [WGI AR5 Chapter 10.5.3; Box 3-2; 24.4.2.2; (Romanovsky *et al.*, 2010; Yang *et al.*, 2013)]	*high*	major	warming	no change	*high*

Polar Regions	**Decreasing Arctic sea ice cover in summer** [WGI AR5 Chapter 4.2.2.1; (ACIA, 2005; AMAP, 2011)]	*very high*	major	air and ocean warming, Δ ocean circulation	no change	*high*
	Reduction in ice volume in Arctic glaciers [WGI AR5 Chapter 4.3.3; (ACIA, 2005; Nuth *et al.*, 2010; AMAP, 2011; Gardner *et al.*, 2011; Moholdt *et al.*, 2012; Gardner *et al.*, 2013)]	*very high*	major	warming	no change	*high*
	Decreasing snow cover across the Arctic [28.2.3.1.2; (AMAP, 2011; Callaghan *et al.*, 2011)]	*high*	major	warming	no change	*medium*
	Widespread permafrost degradation, especially in the southern Arctic [28.2.1.1; (AMAP, 2011; Olsen *et al.*, 2011)]	*high*	major	warming	no change	*high*
	Ice mass loss along coastal Antarctica [WGI AR5 Chapter 4.2.3,4.4, 4.6; 10.5.2.1; (Gardner *et al.*, 2013; Miles *et al.*, 2013)]	*medium*	major	warming	no change	*medium*

Table 18-6: Observed impacts of climate change on rivers, lakes and soil moisture, over the past several decades, across major world regions, with descriptors for: i) the confidence in detection of a climate change impact, ii) the relative contribution of climate change to the observed change, compared to that of non-climatic drivers, iii) the main climatic driver (s) causing the impacts, iv) the reference behavior of the system in the absence of climate change, and v) the confidence in attribution of the impacts to climate change. References to related chapters in this report are given as well as key references to other IPCC reports and the scientific literature.

	Rivers, lakes and soil moisture	**conf. detect.**	**role of climate**	**climate driver**	**reference behaviour**	**conf. attrib.**
Africa	**Reduced discharge in West African rivers** (d'Orgeval and Polcher, 2008; Dai *et al.*, 2009; Di Baldassarre *et al.*, 2010)	*medium*	major	reduced precipitation	no change	*low*
	Lake surface warming and water column stratification increases in the Great Lakes and Lake Kariba [22.3.2.2; (Tierney *et al.*, 2010; Ndebele-Murisa *et al.*, 2011; Powers *et al.*, 2011)]	*high*	major	warming	no change	*high*
	Increased soil moisture drought in the Sahel since 1970, partially wetter conditions since 1990 [22.2.2.1, 22.2.3; (Hoerling *et al.*, 2006; Giannini *et al.*, 2008; Greene *et al.*, 2009; Seneviratne *et al.*, 2012)]	*medium*	major	precipitation	no change	*medium*
Europe	**Changes in the occurrence of extreme river discharges and floods** [23.2.3; (Schmocker-Fackel and Naef, 2010; Beniston *et al.*, 2011; Cutter *et al.*, 2012; Vorogushyn and Merz, 2012; Kundzewicz *et al.*, 2013)]	*low*	minor	precipitation, extreme precipitation	no change	*very low*
Asia	**Changes in water availability in many Chinese rivers** (Casassa *et al.*, 2009; Li *et al.*, 2010; Shrestha and Aryal, 2011)	*high*	minor	precipitation	changes due to land use	*low*
	Increased flow in many rivers due to shrinking glaciers in the Himalayas and Central Asia [Box 3-1;(Casassa *et al.*, 2009; Li *et al.*, 2010; Shrestha and Aryal, 2011; Zhang *et al.*, 2011)]	*high*	major	warming, snow	no change	*high*
	Earlier timing of maximum spring flood in Russian rivers [28.2.1.1; (Shiklomanov *et al.*, 2007; Tan *et al.*, 2011)]	*high*	major	warming	no change	*medium*
	Reduced soil moisture in North Central and NE China 1950-2006 [24.3.1, 24.4.1.2; (Sheffield and Wood, 2007; Wang *et al.*, 2011a; Seneviratne *et al.*, 2012)]	*medium*	major	warming, precipitation	no change	*medium*
	Surface water degradation in parts of Asia [24.4.1.2; (Prathumratana *et al.*, 2008; Delpla *et al.*, 2009; Huang *et al.*, 2009)]	*medium*	minor	warming, precipitation	changes due to land use	*medium*
Australasia	**Intensification of hydrological drought due to regional warming in South East Australia** [Table 25-1; (Nicholls, 2006; Cai *et al.*, 2009)]	*low*	minor	warming	no change	*low*
	Reduced inflow in river systems in south-western Australia (since the mid 1970s) [Table 25-1; 25.5.1; (Cai and Cowan, 2006; Nicholls, 2010)]	*high*	major	precipitation, warming	no change	*high*
North America	**Shift to earlier peak flow in snow dominated rivers in western North America** [WGI AR5 Chapter 2.6.2; (Barnett *et al.*, 2008)]	*high*	major	warming, snow	no change	*high*
	Runoff increases in the Midwestern and Northwestern US, decreases in Southern states (Georgakakos *et al.*, 2013)	*high*	minor	precipitation, warming	no change	*medium*

South and Central America	**Changes in extreme flows in Amazon River** [27.3.1.1; (Rodríguez-Morales *et al.*, 2010; Butt *et al.*, 2011; Wang *et al.*, 2011b; Espinoza *et al.*, 2013)]	*high*	major	precipitation, extreme precipitation	no change	*medium*
	Changing discharge patterns in rivers in the Western Andes; for major river basins in Colombia discharge has decreased during the last 30-40 years [27.3.1.1, Table 27-3; (Vuille *et al.*, 2008; Bradley *et al.*, 2009; Jomelli *et al.*, 2009; Poveda and Pineda, 2009; Rabatel *et al.*, 2013)]	*medium*	minor	warming	no change	*medium*
	Increased streamflow in sub-basins of the La Plata River [27.3.1.1; (Pasquini and Depetris, 2007; Krepper *et al.*, 2008; Saurral *et al.*, 2008; Conway and Mahé, 2009; Krepper and Zucarelli, 2010; Doyle and Barros, 2011)]	*high*	major	precipitation	increase due to land use	*high*
Polar Regions	**Increased river discharge for large circumpolar rivers (1997–2007)** [28.2.1.1; (Overeem and Syvitsky, 2010)]	*high*	major	warming, precipitation, snow cover	no change	*low*
	Winter minimum river flow increase in most sectors of the Arctic [28.2.1.1; (Tan *et al.*, 2011)]	*high*	major	warming, snow cover	no change	*medium*
	Increasing lake water temperatures 1985–2009, prolonged ice-free seasons [28.2.1.1; (Callaghan *et al.*, 2010; Schneider and Hook, 2010)]	*medium*	major	warming	no change	*medium*
	Thermokarst lakes disappear due to permafrost degradation in the low Arctic, new ones created in areas of formerly frozen peat [28.2.1.1; (Riordan *et al.*, 2006; Marsh *et al.*, 2008; Prowse and Brown, 2010)]	*high*	major	warming	no change	*high*
Small Islands	**Increased water scarcity in Jamaica** [(Gamble *et al.*, 2010; Jury and Winter, 2010)]	*low*	minor	precipitation	increase due to water use	*very low*

Table 18-7: Observed impacts of climate change on terrestrial ecosystems, over the past several decades, across major world regions, with descriptors for: i) the confidence in detection of a climate change impact, ii) the relative contribution of climate change to the observed change, compared to that of non-climatic drivers, iii) the main climatic driver (s) causing the impacts, iv) the reference behavior of the system in the absence of climate change, and v) the confidence in attribution of the impacts to climate change. References to related chapters in this report are given as well as key references to other IPCC reports and the scientific literature.

	Terrestrial ecosystems	**conf. detect.**	**role of climate**	**climate driver**	**reference behaviour**	**conf. attrib.**
Africa	**Tree density decreases in Sahel and semi-arid Morocco** [22.3.2.1; (Gonzalez *et al.*, 2012; Le Polain de Waroux and Lambin, 2012)]	*medium*	major	precipitation	changes due to land use	*medium*
	Range shifts of several southern plants and animals: South African bird species polewards; Madagascan reptiles and amphibians upwards; Namib aloe contracting ranges [Table 22-3,(Foden *et al.*, 2007; Raxworthy *et al.*, 2008; Hockey and Midgley, 2009; Hockey *et al.*, 2011)]	*high*	major	warming	changes due to land use	*medium*
	Wildfires increase on Mt. Kilimanjaro [Table 22-3, (Hemp, 2005)]	*medium*	major	warming, drying	no change	*low*
Europe	**Earlier greening, earlier leaf emergence and fruiting in temperate and boreal trees** [4.3.2.1; (Menzel *et al.*, 2006)]	*high*	major	warming	no change	*high*
	Increased colonization of alien plant species in Europe [4.2.4.6; Table 23-6; (Walther *et al.*, 2009)]	*medium*	major	warming	some invasion	*medium*
	Earlier arrival of migratory birds in Europe since 1970 [4.2.4.6; Table 23-6; (Møller *et al.*, 2008)]	*medium*	major	warming	no change	*medium*
	Upward shift in tree-line in Europe [18.3.2.3; Table 23-6; (Gehrig-Fasel *et al.*, 2007; Lenoir *et al.*, 2008)]	*medium*	major	warming	changes due to land use	*low*
	Increasing burnt forest areas during recent decades in Portugal and Greece [Table 23-6; (Camia and Amatulli, 2009; Hoinka *et al.*, 2009; Costa *et al.*, 2011; Koutsias *et al.*, 2012)]	*high*	major	warming, precipitation	some increase due to land use	*high*
Asia	**Changes in plant phenology and growth in many parts of Asia** (earlier greening), particularly in the North and the East [4.3.2.1; Figure 4-5; 24.4.2.2; (Ma and Zhou, 2012; Panday and Ghimire, 2012; Shrestha *et al.*, 2012; Ogawa-Onishi and Berry, 2013)]	*high*	major	warming	no change	*medium*
	Distribution shifts in many plant and animal species, particularly in the North of Asia, upwards in elevation or polewards [4.3.2.5; Figure 4-5; 24.4.2.2; (Moiseev *et al.*, 2010; Chen *et al.*, 2011; Jump *et al.*, 2012; Ogawa-Onishi and Berry, 2013)]	*high*	major	warming	no change	*medium*
	Invasion of Siberian larch forests by pine and spruce during recent decades, growth decline in Mongolian larches [24.4.2.2.; (Kharuk *et al.*, 2010; Dulamsuren *et al.*, 2011; Lloyd *et al.*, 2011)]	*medium*	major	warming	no change	*low*
	Advance of shrubs into the Siberian tundra [4.3.3.4; 24.4.2.2., 28.2.3.1; (Henry and Elmendorf, 2010; Blok *et al.*, 2011)]	*high*	major	warming	no change	*high*

Australasia	**Changes in genetics, growth, distribution and phenology of many species, in particular birds, butterflies and plants in Australia** [Table 25-3; (Chambers, 2008; Chessman, 2009; Green, 2010; Kearney *et al.*, 2010; Keatley and Hudson, 2012; Chambers *et al.*, 2013b)]	*high*	major	warming	fluctuations due to variable local climates, land use, pollution, invasive species	*high*
	Expansion of some wetlands and contraction of adjacent woodlands in SE Australia [Table 25-3; (Keith *et al.*, 2010)]	*medium*	major	precipitation, warming	no change	*low*
	Expansion of monsoon rainforest at expense of savannah and grasslands in N Australia [Table 25-3; (Banfai and Bowman, 2007; Bowman *et al.*, 2010)]	*medium*	major	precipitation, increased CO_2	no change	*medium*
	Migration of glass eels advanced by several weeks in Waikato River, New Zealand [Table 25-3; (Jellyman *et al.*, 2009)]	*medium*	major	warming	no change	*low*
North America	**Phenology changes and species distribution shifts upward in elevation and northward across multiple taxa** [26.4.1; (Parmesan and Galbraith, 2004; Parmesan, 2006; Kelly and Goulden, 2008; Moritz *et al.*, 2008; Tingley *et al.*, 2009)]	*high*	major	warming	no change	*medium*
	Increased wildfire frequency in subarctic conifer forests and tundra [28.2.3.1.4; (Mack *et al.*, 2011; Mann *et al.*, 2012)]	*high*	major	warming	no change	*medium*
	Regional increases in tree mortality and insect infestations in forests [26.4.2.1; (Van Mantgem *et al.*, 2009; Peng *et al.*, 2011)]	*medium*	minor	warming	no change	*low*
	Increase in wildfire activity, fire frequency and duration, and burnt area in boreal forest of North America [Box 26-2; (Gillett *et al.*, 2004; Westerling *et al.*, 2006; Girardin *et al.*, 2013)]	*high*	minor	warming, precipitation	changes due to land use and fire management	*medium*
South and Central America	**Increased tree mortality and forest fire in the Amazon** [4.3.3.1.3;(Phillips *et al.*, 2009)]	*medium*	minor	warming	no change	*low*
	Degrading and receding rainforest in the Amazon [18.3.2.4; 27.2.2.1, 27.3.2.1; (Etter *et al.*, 2006; Nepstad *et al.*, 2006; Oliveira *et al.*, 2007; Wassenaar *et al.*, 2007; Killeen *et al.*, 2008; Nepstad and Stickler, 2008)]	*low*	minor	warming	deforestation and land degradation	*low*
Polar Regions	**Increase in shrub cover in tundra in North America and Eurasia** [28.2.3.1.2; (Tape *et al.*, 2006; Walker *et al.*, 2006; Henry and Elmendorf, 2010; Blok *et al.*, 2011; Elmendorf *et al.*, 2012; Tape *et al.*, 2012)]	*high*	major	warming	no change	*high*
	Advance of Arctic tree-line in latitude and altitude [28.2.3.1.2; (AMAP, 2011; Hedenås *et al.*, 2011; Van Bogaert *et al.*, 2011)]	*high*	major	warming	no change	*medium*
	Loss of snow-bed ecosystems and tussock tundra [28.2.3.1.2; (Björk and Molau, 2007; Molau, 2010a; Hedenås *et al.*, 2011; Callaghan *et al.*, 2013)]	*high*	major	warming, precipitation	no change	*high*
	Impacts on tundra animals from increased ice layers in snow pack, following rain-on-snow events [28.2.3.1.3; (Callaghan *et al.*, 2013; Hansen *et al.*, 2013)]	*medium*	major	precipitation, warming	no change	*medium*

	Changes in breeding area and population size of subarctic birds, due to snowbed reduction and/or tundra shrub encroachment (Molau, 2010b; Callaghan *et al.*, 2013)	*high*	major	warming	no change	*medium*
	Increase in plant species ranges in the West Antarctic Peninsula and nearby islands over the past 50 years [28.2.3.2; (Fowbert and Smith, 1994; Parnikoza *et al.*, 2009)]	*high*	major	warming	no change	*high*
	Increasing phytoplankton productivity in Signy Island lake waters (Quayle *et al.*, 2002; Laybourn-Parry, 2003)	*high*	major	warming	no change	*high*
Small Islands	**Changes in tropical bird populations in Mauritius** [29.3.2; (Senapathi *et al.*, 2011)]	*medium*	major	precipitation	no change	*medium*
	Decline of an endemic plant in Hawai'i (Krushelnycky *et al.*, 2013)	*medium*	major	warming, precipitation	no change	*medium*
	Upward trend in tree-lines and associated fauna on high elevation islands [29.3.2; (Benning *et al.*, 2002; Jump *et al.*, 2006)]	*low*	minor	warming	no change	*low*

Table 18-8: Observed impacts of climate change on coastal and marine ecosystems, over the past several decades, across major world regions, with descriptors for: i) the confidence in detection of a climate change impact, ii) the relative contribution of climate change to the observed change, compared to that of non-climatic drivers, iii) the main climatic driver (s) causing the impacts, iv) the reference behavior of the system in the absence of climate change, and v) the confidence in attribution of the impacts to climate change. References to related chapters in this report are given as well as key references to other IPCC reports and the scientific literature.

	Coastal and marine ecosystems	**conf. detect.**	**role of climate**	**climate driver**	**reference behaviour**	**conf. attrib.**
Europe	**Northward shifts in the distributions of zooplankton, fish, seabirds and benthic invertebrates in the NE Atlantic** [Box 6-1; Table 6-2; 6.3.1;23.6.5, 30.5.1.1; (Beaugrand *et al.*, 2009; Philippart *et al.*, 2011)]	*high*	major	ocean warming	no change	*high*
	Northward and depth shift in distribution of many fish species across European seas [6.3.1; Table 6-2; 23.6.4; 23.6.5; 30.5.3.1;(Perry *et al.*, 2005; Pörtner *et al.*, 2008; Beaugrand *et al.*, 2009; Beaugrand *et al.*, 2010; Beaugrand and Kirby, 2010; Hermant *et al.*, 2010; Philippart *et al.*, 2011)]	*high*	major	ocean warming	no change	*medium*
	Phenology changes in plankton in the NE Atlantic [Box 6-1; 6.3.1; 23.6.5, 30.5.1.1; (Beaugrand *et al.*, 2002; Edwards and Richardson, 2004; Beaugrand *et al.*, 2009; Philippart *et al.*, 2011)]	*medium*	major	ocean warming	no change	*medium*
	Spread of warm water species into the Mediterreanean [23.6.5, 30.5.3.1.5; (Boero *et al.*, 2008; Lasram and Mouillot, 2009; Raitsos *et al.*, 2010)]	*high*	major	ocean warming	changes due to invasive species and human impacts	*medium*
Asia	**Coral reefs and large seaweeds decline in tropical Asian waters and in the coastal waters of Western Japan** [24.4.3.2; 30.5.1.4.3, (McLeod *et al.*, 2010; Krishnan *et al.*, 2011; Nagai *et al.*, 2011; Coles and Riegl, 2012)]	*high*	major	ocean warming	decline due to human impacts	*high*
	Northward range extension of coral reefs and predatory fish in the Japan Sea [24.4.3.2, (Yamano *et al.*, 2011; Tian *et al.*, 2012; Ogawa-Onishi and Berry, 2013)]	*medium*	major	ocean warming	no change	*medium*
	Shift from sardines to anchovies in the western North Pacific [6.3.1, 6.3.6;Table 6-2, (Takasuka *et al.*, 2007; Takasuka *et al.*, 2008)]	*medium*	major	ocean warming	fluctuations due to fisheries	*low*
	Increased coastal erosion in Arctic Asia [24.4.3.2**,** (Razumov, 2010; Forbes, 2011; Lantuit *et al.*, 2011)]	*medium*	major	permafrost degradation, ocean warming, sea ice	no change	*low*
Australasia	**Southward shifts in the distribution of marine species near Australia** [Table 25-3; (Ling *et al.*, 2009; Pitt *et al.*, 2010; Neuheimer *et al.*, 2011; Wernberg *et al.*, 2011; Wernberg *et al.*, 2011)]	*high*	major	ocean warming	changes due to short term env. fluctuations, fishing and pollution	*medium*
	Change in timing of migration of seabirds in Australia [25.6.2.1; (Chambers *et al.*, 2011; Chambers *et al.*, 2013a)]	*medium*	major	air and ocean warming	no change	*low*
	Increase in coral bleaching in the Great Barrier Reef and Western Australian Reefs [6.3.1.4, 6.3.1.5, Table 25-3; 25.6.2.1; (Cooper *et al.*, 2008; De'ath *et al.*, 2009; De'ath *et al.*, 2012; Moore *et al.*, 2012)]	*high*	major	ocean warming	pollution, physical disturbance	*high*

	Changes in coral disease patterns at Great Barrier Reef [25.6.2.1; Table 25-3; (Bruno *et al.*, 2007; Sato *et al.*, 2009; Dalton *et al.*, 2010)]	*medium*	major	ocean warming	pollution	*medium*
North America	**Northward shifts in the distributions of NW Atlantic fish species** [30.5.1.1; (Nye *et al.*, 2009; Lucey and Nye, 2010; Nye *et al.*, 2011)]	*high*	major	ocean warming	no change	*high*
	Changes in musselbeds along the west coast of the United States (Smith *et al.*, 2006; Menge *et al.*, 2008; Harley, 2011)	*high*	major	ocean warming,	no change	*high*
	Changes in migration and survival of salmon in the northeast Pacific (Table 6-2, Eliason *et al.*, 2011; Kovach *et al.*, 2012)	*high*	major	ocean warming	no change	*high*
	Increased coastal erosion in Alaska and Canada [18.3.1.1; 18.3.3.1; (Mars and Houseknecht, 2007; Forbes, 2011; Lantuit *et al.*, 2011)]	*high*	major	permafrost degradation, ocean warming, sea ice	no change	*medium*
South and Central America	**Increase in coral bleaching in the western Caribbean** [27.3.3.1; (Guzman *et al.*, 2008; Manzello *et al.*, 2008; Carilli *et al.*, 2009; Eakin *et al.*, 2010)]	*high*	major	ocean warming	pollution, physical disturbance	*high*
	Mangrove degradation on north coast of South America [27.3.3.1; (Alongi, 2008; Lampis, 2010; Polidoro *et al.*, 2010; Giri *et al.*, 2011)]	*low*	minor	ocean warming	degradation due to pollution and land use	*low*
Polar Regions	**Increased coastal erosion across the Arctic** [18.3.1.1; 18.3.3.1; 28.2.4.2; 28.3.4; (Mars and Houseknecht, 2007; Razumov, 2010; Forbes, 2011; Lantuit *et al.*, 2011)]	*medium*	major	permafrost degradation, ocean warming, sea ice	no change	*medium*
	Negative effects on non-migratory Arctic species [28.2.2.1; (Laidre *et al.*, 2008; Amstrup *et al.*, 2010; McIntyre *et al.*, 2011)]	*high*	major	atmospheric and ocean warming, circulation change, sea ice	no change	*high*
	Decreased reproductive success in Arctic seabirds [28.2.2.1.2; (Gaston *et al.*, 2009; Grémillet and Boulinier, 2009)]	*medium*	major	air and ocean warming, ocean circulation, sea ice	no change	*medium*
	Decline in Southern Ocean seals and seabirds [28.2.2.2; (Croxall *et al.*, 2002; Patterson *et al.*, 2003; Jenouvrier *et al.*, 2005; Véran *et al.*, 2007; Forcada *et al.*, 2008; Trathan *et al.*, 2011; Chambers *et al.*, 2013a)]	*high*	major	ocean warming	no change	*medium*
	Reduced thickness of foraminiferal shells in the Southern Ocean [6.3.2; 28.2.2.2; (Moy *et al.*, 2009)]	*medium*	major	ocean acification	no change	*medium*
	Reduced density of krill in the Scotia Sea (Atkinson *et al.*, 2004; Trivelpiece *et al.*, 2011)	*medium*	major	ocean warming, ocean circulation, sea ice	no change	*medium*
Small Islands	**Increased coral bleaching near many tropical small islands** [29.3.1.2; (Alling *et al.*, 2007; Bruno and Selig, 2007; Oxenford *et al.*, 2008; Sandin *et al.*, 2008)]	*high*	major	ocean warming	degradation due to fishing and pollution	*high*
	Degradation of mangroves, wetlands and seagrass around small islands [29.3.1.2; (McKee *et al.*, 2007; Gilman *et al.*, 2008; Schleupner, 2008; Krauss *et al.*, 2010; Marbà and Duarte, 2010; Rankey, 2011)]	*low*	minor	sea level rise, atmospheric and ocean warming	degradation due to other disturbances	*very low*

	Inreasing flooding and erosion [29.3.1.1; (Webb, 2006; Webb *et al.*, 2007; Yamano *et al.*, 2007; Cambers, 2009; Novelo-Casanova and Suarez, 2010; Storey and Hunter, 2010; Ballu *et al.*, 2011; Rankey, 2011; Ford, 2012; Romine *et al.*, 2013)]	*low*	minor	sea level rise	erosion due to human activities, natural erosion and accretion	*low*
	Degradation of groundwater and freshwater ecosystems due to saline intrusion [29.3.2; (White *et al.*, 2007a; White *et al.*, 2007b; Ross *et al.*, 2009; Carreira *et al.*, 2010; Terry and Falkland, 2010; White and Falkland, 2010; Goodman *et al.*, 2012)]	*low*	minor	sea level rise	degradation due to pollution, groundwater pumping	*low*

Table 18-9: Observed impacts of climate change on human and managed systems, over the past several decades, across major world regions, with descriptors for: i) the confidence in detection of a climate change impact, ii) the relative contribution of climate change to the observed change, compared to that of non-climatic drivers, iii) the main climatic driver (s) causing the impacts, iv) the reference behavior of the system in the absence of climate change, and v) the confidence in attribution of the impacts to climate change. References to related chapters in this report are given as well as key references to other IPCC reports and the scientific literature.

	Human and managed systems	**conf. detect.**	**role of climate**	**climate driver**	**reference behaviour**	**conf. attrib.**
Africa	**Adaptative responses to changing rainfall by South African farmers [**13.2.1.1; (Thomas *et al.*, 2007)]	*low*	major	precipitation	changes due to economic conditions	*very low*
	Decline in fruit-bearing trees in Sahel (Wezel and Lykke, 2006; Maranz, 2009)	*medium*	major	precipitation	no change	*low*
	Malaria increases in Kenyan highlands [11.4.4; (O'Meara *et al.*, 2010; Alonso *et al.*, 2011; Stern *et al.*, 2011)]	*low*	minor	warming	changes due to vaccination, drug resistance, demography, livelihoods	*low*
	Reduced fisheries productivity of Great Lakes and Lake Kariba [7.2.1.2; 13.2.1.1; 22.3.2.2; (Descy and Sarmento, 2008; Hecky *et al.*, 2010; Ndebele-Murisa *et al.*, 2011; Marshall, 2012)]	*low*	minor	warming	changes due to fisheries management and land use	*low*
Europe	**Shift from cold-related mortality to heat-related mortality in England and Wales** [18.4.4; 23.5.1; (Christidis *et al.*, 2010)]	*medium*	major	warming	changes due to exposure and health care	*low*
	Impacts on livelihoods of Sámi people in Northern Europe (Eira, 2012; Mathiesen *et al.*, 2013)	*medium*	major	warming	economic and sociopolitical changes	*medium*
	Stagnation of wheat yields in some countries in recent decades [23.4.1; (Brisson *et al.*, 2010; Kristensen *et al.*, 2011)]	*high*	minor	warming	increase due to improved technology	*medium*
	Positive yield impacts for some crops mainly in Northern Europe [Figure 7-2; 23.4.1, (Jaggard *et al.*, 2007; Supit *et al.*, 2010; Gregory and Marshall, 2012)]	*high*	minor	warming	increase due to improved technology	*medium*
	Spread of bluetongue virus in sheep, and of ticks across parts of Europe [23.4.2; (Arzt *et al.*, 2010; Randolph and Rogers, 2010; Van Dijk *et al.*, 2010; Guis *et al.*, 2012; Petney *et al.*, 2012)]	*high*	minor	warming	no change	*medium*
Asia	**Impacts on livelihoods of indigenous groups in Arctic Russia** [13.2.1.2; 18.4.6; Table 18-4; 28.2.4.2; (Crate, 2013)]	*medium*	major	warming, snow cover, sea ice	economic and sociopolitical changes	*low*
	Negative impacts on aggregate wheat yields in South Asia [7.2.1; Figure 7-2; (Pathak *et al.*, 2003; Auffhammer and Vincent, 2012)]	*medium*	minor	warming, precipitation	increase due to improved technology	*medium*
	Negative impacts on aggregate wheat and maize yields in China [7.2.1; Figure 7-2; (Tao *et al.*, 2006; Tao *et al.*, 2008; You *et al.*, 2009; Chen *et al.*, 2010; Tao *et al.*, 2012)	*low*	minor	warming	increase due to improved technology	*low*
	Increases in a water-borne disease in Israel (Paz *et al.*, 2007)	*low*	minor	warming	no change	*low*

Australasia	**Advance timing of wine-grape maturation in recent decades** [Table 25-3; (Webb *et al.*, 2012)]	*high*	major	warming	advance due to improved management	*medium*
	Shift in winter vs. summer human mortality in Australia [18.4.4; 25.8.11, 11.4.1; (Bennett *et al.*, 2013)]	*medium*	major	warming	changes due to exposure and health care	*low*
	Relocation or diversification of agricultural activities in Australia [25.7.2; Box 25-5; (Gaydon *et al.*, 2010; Howden *et al.*, 2010; Park *et al.*, 2012; Thorburn *et al.*, 2012)	*medium*	minor	warming	changes due to policy, markets, and short-term climate variability	*low*
Central and South America	**More vulnerable livelihood trajectories for indigenous Aymara farmers in Bolivia**, due to water shortage [13.1.4; (McDowell and Hess, 2012)]	*high*	major	warming	increasing social and economic stress	*medium*
	Increase in agricultural yields and expansion of agricultural areas in Southeastern South America [27.3.4.1; (Magrin *et al.*, 2007; Barros, 2010; Hoyos *et al.*, 2013)]	*medium*	major	precipitation increase	increase due to improved technology	*medium*
North America	**Impacts on livelihoods of indigenous groups in the Canadian Arctic** [18.4.6; Table 18-4; 28.2.4.2; (Hovelsrud *et al.*, 2008; Ford *et al.*, 2009; Beaumier and Ford, 2010; Pearce *et al.*, 2010; Brubaker *et al.*, 2011)	*medium*	major	warming, snow cover, sea ice	economic and sociopolitical changes	*medium*
Polar Regions	**Impact on livelihoods of Arctic indigenous peoples** [18.4.6; Table 18-4; 28.2.4.2; (Hovelsrud *et al.*, 2008; Ford *et al.*, 2009; Beaumier and Ford, 2010; Pearce *et al.*, 2010; Eira, 2012; Crate, 2013; Mathiesen *et al.*, 2013)]	*medium*	major	warming, snow cover, sea ice	economic and sociopolitical changes	*medium*
	Increase of shipping traffic across the Bering Strait [28.2.6.1.3; Figure 28-4; (Robards, 2013)]	*medium*	major	warming, sea ice	no change	*medium*
Small Islands	**Increased degradation of coastal fisheries due to direct effects and effects of increased coral reef bleaching** [Box CC-CR; 18.3.3.3; 18.4.1.2; 29.3.1.2; 30.6.2.1]	*low*	minor	ocean warming	coastal fisheries degraded by overfishing and pollution	*low*

Table 18-10: Confidence in detection and attribution of observed trends in natural disasters related to extreme weather. The assessment is for the impacts on various systems, in attribution of those trends to climate change, and in the existence of observed trends in that extreme weather. The assessment of confidence in detection is against the specified reference behaviour, while the assessment for attribution is for the indicated minor or major role of observed climate trends. The confidence statements refer to a globally balanced assessment.

	Impacts and impact events				**Climate/weather drivers**		**Reference**
Observed trend	**Confidence in detection**	**Reference behaviour**	**Attribution**	**Role of climate change**	**Observed trend**	**Confidence in existence of trend**	
Earlier timing and decreasing magnitude of snowmelt floods	*medium*	no change	*medium*	major	Decreasing snow pack	*high*	3.2.7; Tables 18-5 and 18-6; WGI AR5 4.5; Seneviratne *et al.* (2012)
					Increasing heavy precipitation amounts	*medium*	
Changes in flood frequency and magnitude in non-snowmelt-fed rivers	*low*	changes due to land use	*low*	minor	Trends in extreme rainfall amounts	*medium*	Min *et al.* (2011); WGI AR5 2.5.3; 2.6.2
					Increased evapotranspiration and decreased soil moisture	*medium*	
Increased coastal erosion in low and mid latitudes	*very low*	erosion due to shoreline modification and natural processes	*very low*	minor	Increasingly frequent high storm waves and surges	*high*	18.3.3.1; 5.4.2; WGI AR5 3.7.5
Increased erosion of Arctic coasts	*medium*	no change	*medium*	major	Lack of sea ice protection from wind storms	*very high*	Table 18-8; 18.3.1.1; 24.4.3.2; 28.2.4.2; 28.3.4; Forbes (2011); WGI AR5 4.2.2
Increase in high-mountain rock slope failures	*low*	no change	*low*	major	Increasingly frequent and intense heatwaves	*medium*	Huggel *et al.* (2012a); Seneviratne *et al.* (2012); Allen and Huggel (2013), WGI AR5 2.6.1, Figure 18-2
Increased coral bleaching	*very high*	changes due to pollution, physical disturbance, and fishing	*high*	major	Increasingly frequent extreme hot surface waters	*very high*	Table 18-2; Table 18-8; 5.2.4.2; 6.3.1; Box 18-2; 24.4.3.2; 27.3.3.1; 29.3.1.2; 30.3.1.1; 30.5
Increased monetary losses	*low*	changes due to exposure and wealth	*low*	minor	Increased frequency of storms	*low*	18.4.3.1; 10.7.3, Seneviratne *et al.* (2012); WGI AR5 2.6

Increased heat related mortality	*low*	changes due to exposure and health care	*very low*	minor	Increased frequency of heat waves	*medium*	11.4.1; Seneviratne *et al.* (2012);WGI AR5 2.6.1

Table 18-11: Confidence in detection of impacts on aggregate impact measures against the specified reference behaviour and confidence in attribution of the specified role of climate change in those observed changes.

Global aggregated impact	Confidence in detection	Reference behaviour	Confidence in attribution	Role of climate change	Reference
Glacier ice volume reduction	*very high*	no change	*high*	major	3.2.2; 18.3.1.1
Permafrost degradation and increase of active layer thickness	*high*	no change	*high*	major	18.3.1.1
Increase in terrestrial net primary production and carbon stocks	*high*	changes due to nitrogen deposition, afforestation, and land management	*low*	major	18.3.2.2
Negative yield impacts on global wheat and maize yields	*medium*	changes due to technology, practice, and coverage	*medium*	minor	18.4.1.1; Figure 7-2
Increase in monetary losses due to extreme weather	*low*	changes due to exposure and wealth	*low*	minor	10.7.3;18.4.3.1

	Example of Drivers	Example of Impacts	
		Direct impacts	Subsequent impacts
1 1a 1b	Emission of CO_2	Warming	 Altered crop yield Shift in species phenology
2 2a 2b	Emission of CO_2	Carbon fertilization of plants	 Increase in forestry yield Change in humidity
3	Pollution of river catchment	Fisheries collapse	
4	Plague of crop pests	Decrease in crop yield	
5	Forest fire	Aerosol Emissions	
6	El Nino event	More wildfires	
7	El Nino event	Crop Failures	

Figure 18-1: Schematic of the subject covered in this chapter. The Earth system consists of three coupled and overlapping systems. Direct drivers of the human system on the climate system are denoted with a red arrow; some of these drivers may also directly affect natural systems. These effects can in turn influence other systems (dashed red arrows). Further influences of each of the systems on each other (confounding factors) that do not involve climate drivers are represented by blue arrows. Examples of drivers and their impacts are given in the table. Adapted from Stone *et al*. (2013).

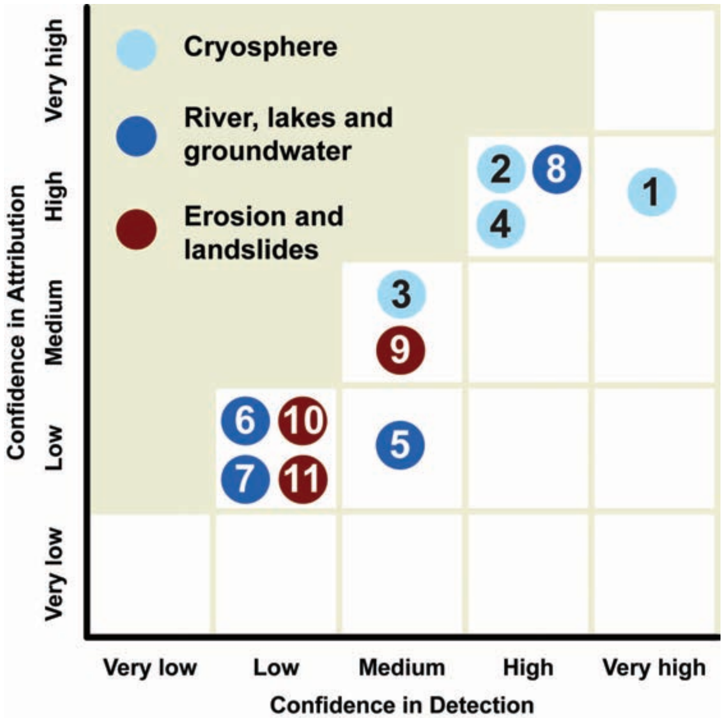

Figure 18-2: Assessment of confidence in detection of observed climate change impacts in global freshwater systems over the past several decades, with confidence in attribution of a major role of climate change, based on expert assessment contained in this section 18.3.1 and augmented by subsections of Chapter 3 as indicated. Numbered symbols refer to: Cryosphere (18.3.1.1): 1 shrinking glaciers (3.2.2), 2 changes in glacier lakes, 3 erosion and degradation of arctic coastal permafrost, 4 degradation and thaw of lowland and mountain permafrost; Rivers, lakes and groundwater (18.3.1.2): 5 groundwater storage change (3.2.4), 6 changing river flow (3.2.3), 7 changing flood frequency or intensity (3.2.3), 8 reduction in lake and river ice duration or thickness in the Northern Hemisphere; Erosion and landslides (18.3.1.3): 9 Increasing erosion (3.2.6), 10 changes in shallow landslides (3.2.6), 11 increasing frequency of high-mountain rock failures.
[Illustration to be redrawn to conform to IPCC publication specifications.]

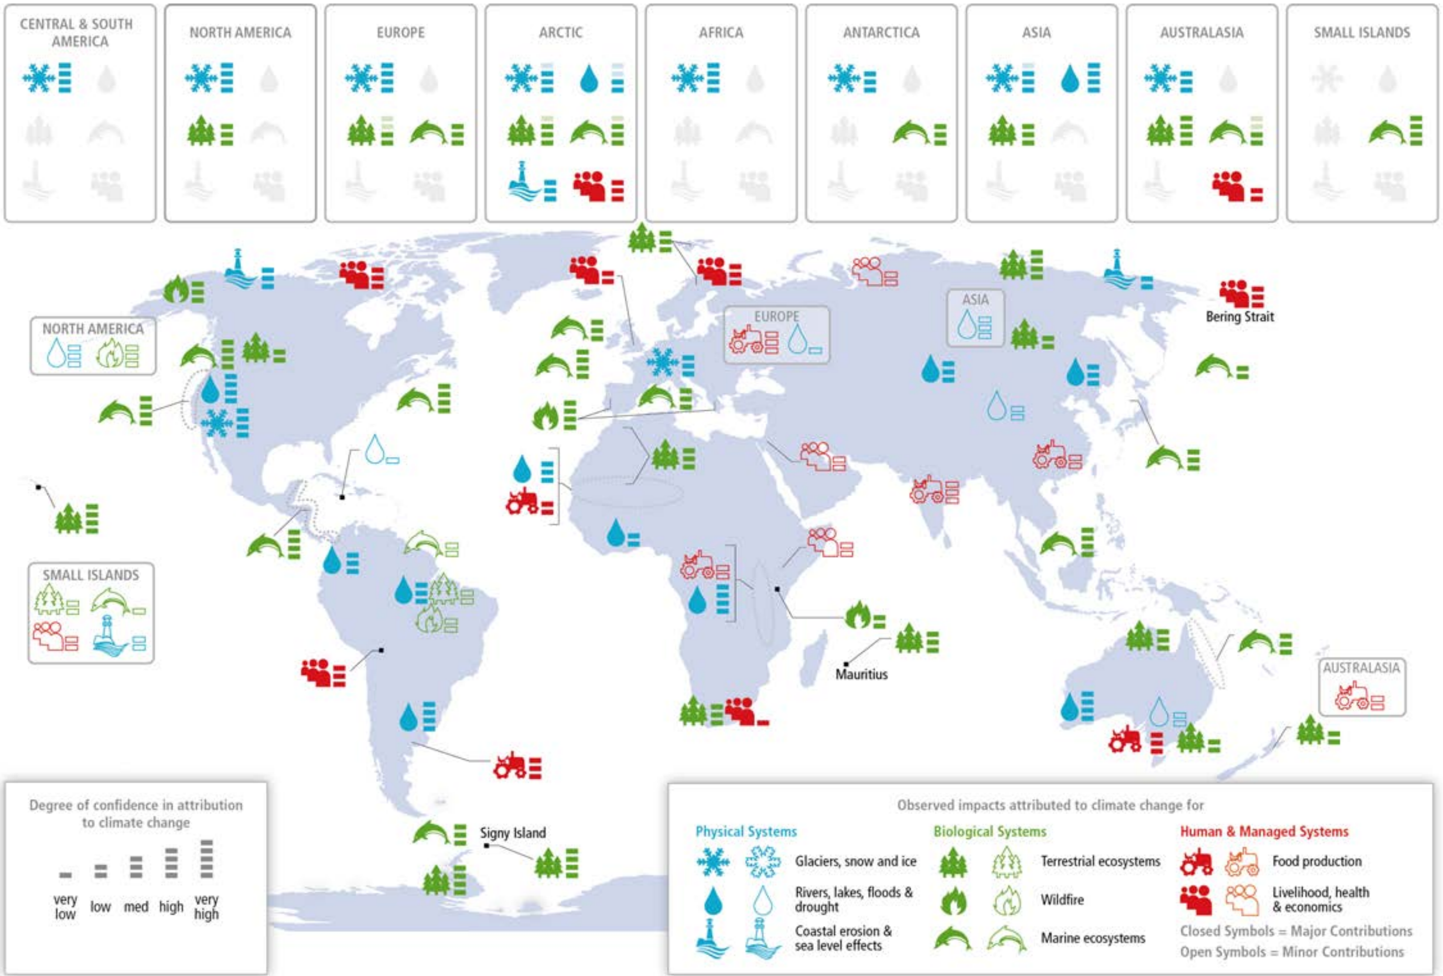

Figure 18-3: Global patterns of observed climate change impacts. Each colored symbol in the top panels indicates a class of systems for which climate change has played a major role in observed changes in at least one measure of that class across the respective region, and the range of confidence in attribution. Regional-scale impacts where climate change has played a minor role are shown by colored open symbols in a box in the respective region. Localized impacts are indicated with symbols on the map, placed in the approximate area of their occurrence. Impacts on physical (blue), biological (green) and human (red) systems are differentiated by color. This map represents a graphical synthesis of tables 18-5, 18-6, 18-7, 18-8 and 18-9.

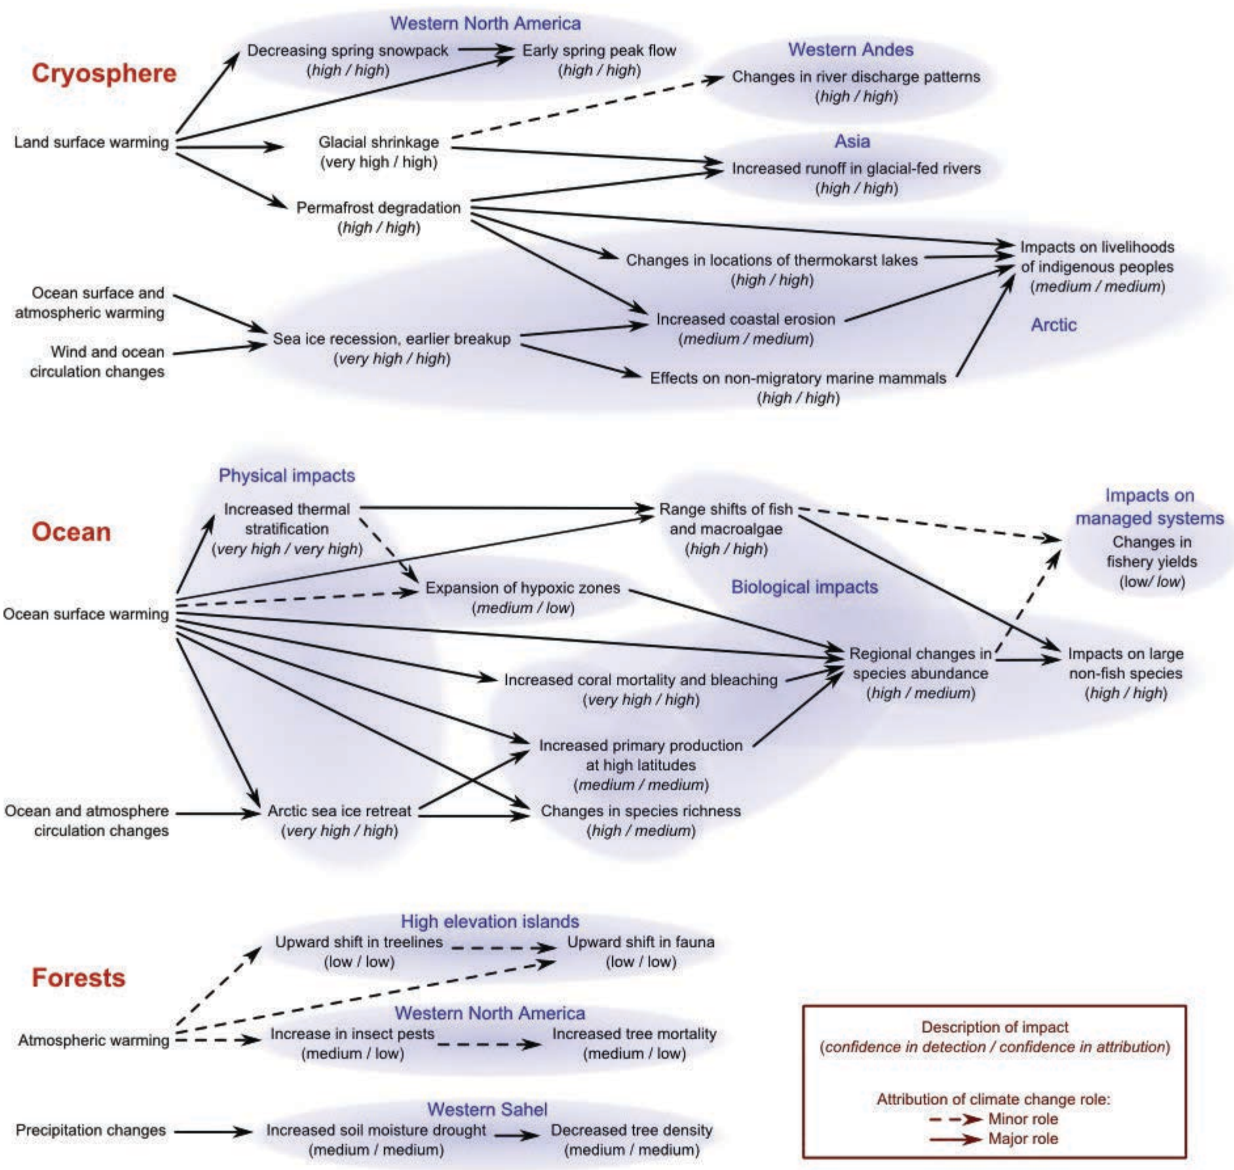

Figure 18-4: Major systems where new evidence indicates interconnected, ‘cascading’ impacts from recent climate change through several natural and human subsystems. Bracketed text indicates confidence in the detection of a climate change effect and the attribution of observed impacts to climate change. The role of climate change can be major (solid arrow) or minor (dashed arrow). Confidence is assessed in 18.3, 18.4, 18.5, and 18.6.
[Illustration to be redrawn to conform to IPCC publication specifications.]

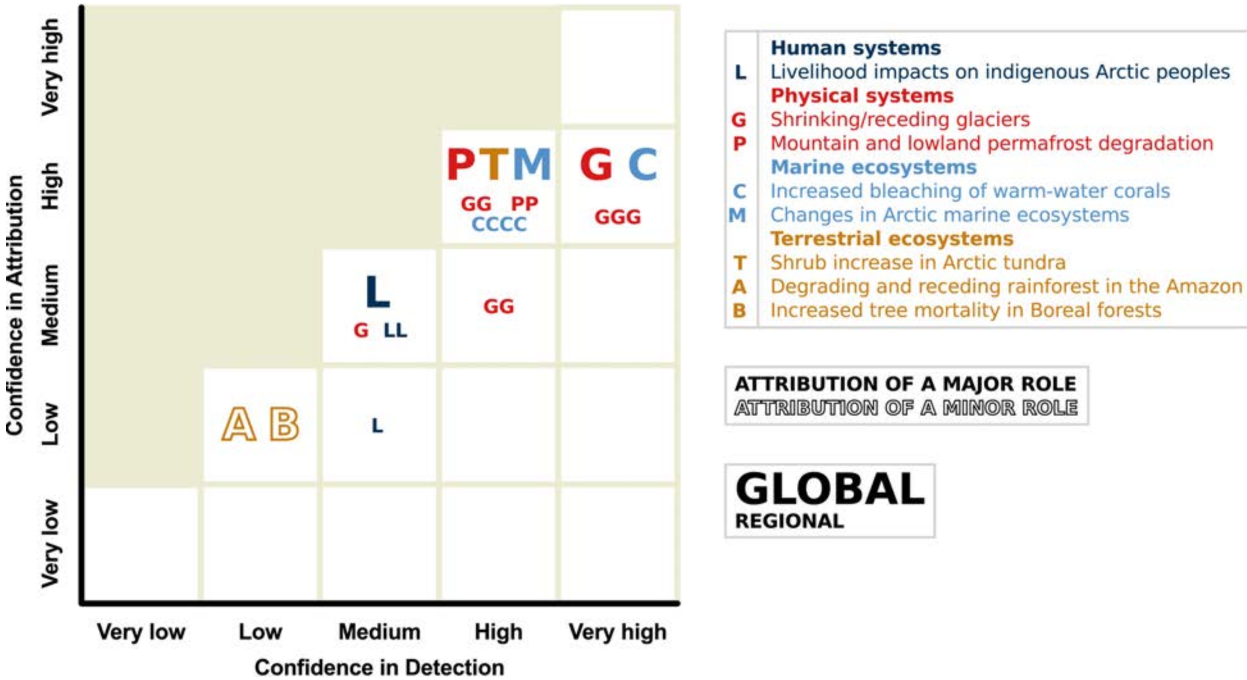

Figure 18-5: Confidence in detection and attribution of observed impacts on "Unique and Threatened Systems" as a result of recent climate change. Global assessments (large upper case) and regional assessments (small lower case) are discussed in 18.3.1.1, 18.3.2.4, Box 18-2, and Tables 18-2 and 18-5 through 18-9. Attribution assessments are for a minor (open font) or major (bold) role of climate change, as indicated.
[Illustration to be redrawn to conform to IPCC publication specifications.]

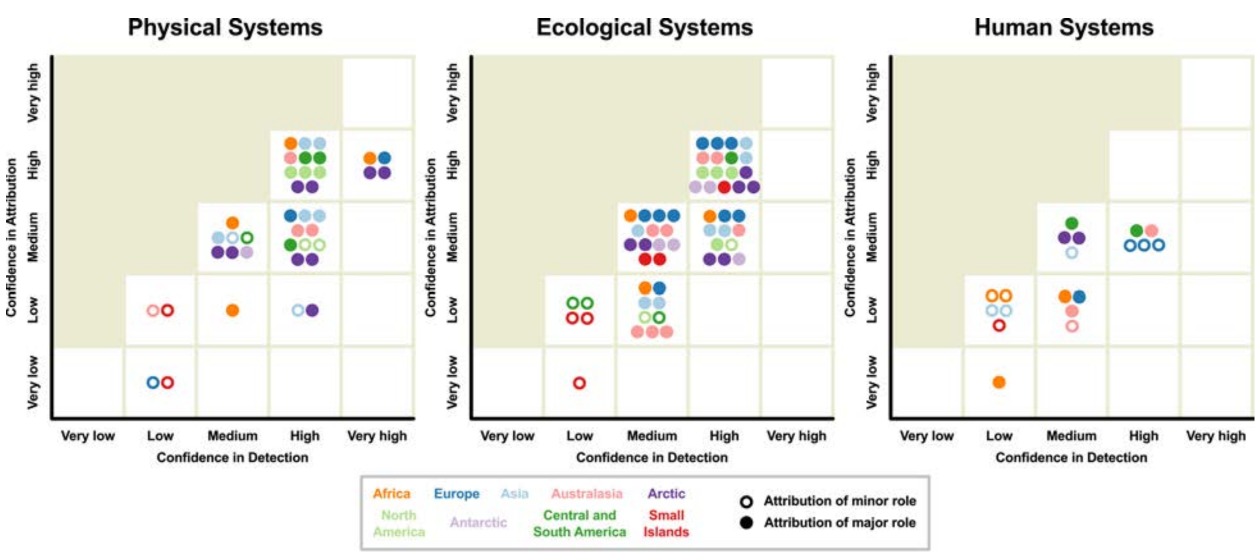

Figure 18-6: Confidence in detection of observed climate change impacts in physical natural systems, biological systems, and human and managed systems across regions, and confidence in attribution of such trends to observed climate change as a major or minor driver. Based on assessments developed in Tables 18-5 through 18-9.

Executive Summary

This chapter assesses climate-related risks in the context of Article 2 of the UN Framework Convention on Climate Change [Box 19.1]. Such risks arise from the interaction of the evolving exposure and vulnerability of human, socioeconomic and biological systems with changing physical characteristics of the climate system [19.2]. Alternative development paths influence risk by changing the likelihood of climatic events and trends (through their

effects on greenhouse gases and other emissions) and by altering vulnerability and exposure [19.2.4, Figure 19-1, Box 19-2].

Interactions of climate change impacts on one sector with changes in exposure and vulnerability, as well as adaptation and mitigation actions affecting the same or a different sector are generally not included or well integrated into projections of risk. However, their consideration leads to the identification of a variety of *emergent risks* [Box 19-2] that were not previously assessed or recognized [19.3, *high confidence*]**.** This chapter identifies several such complex-system interactions that increase vulnerability and risk synergistically. For example:

- **The risk of climate change to human systems (e.g., agriculture and water supply) is increased by the loss of ecosystem services which are supported by biodiversity** (e.g. water purification, protection from extreme weather events, preservation of soils, recycling of nutrients, and pollination of crops) [*high confidence*]. Studies since AR4 broadly confirm that a large proportion of species are at increased risk of extinction at all but the lowest levels of warming. [19.3.2.1, 19.5.1, 19.6.3.5]
- **Risks result from the management of water, land, and energy in the context of climate change.** For example, in some water stressed regions, as groundwater stores that have historically acted as buffers against impacts of climate variations and change are depleted, adverse consequences arise for human systems and ecosystems simultaneously undergoing alteration of regional groundwater resources due to climate change. The production of bioenergy crops to mitigate climate change leads to land conversion (e.g., from food crops and unmanaged ecosystems to energy crops; [*high confidence*]) and in some scenarios, reduced food security as well as additional greenhouse gas emissions over the course of decades or centuries. [19.3.2.2]
- **Climate change has the potential to adversely affect human health by increasing exposure and vulnerability to a variety of stresses.** For example the interaction of climate change with food security can exacerbate malnutrition, increasing vulnerability of individuals to a range of diseases [19.3.2.3, *high confidence*].
- **The risk of severe harm and loss due to climate change-related hazards and various vulnerabilities is particularly high in large urban and rural areas in low-lying coastal zones** (*high confidence*). These areas, many characterized by increasing populations, are exposed to multiple hazards and potential failures of critical infrastructure, generating new systemic risks. Cities in Asian megadeltas, where populations are subject to sea level rise, storm surge, coastal erosion, saline intrusion, and flooding, provide an example [19.2.3, 19.3.2.4, 19.4.2.1, 19.6.1.3.1, 19.6.2.1, 19.7.5, Table 19-4].
- **Spatial convergence of impacts in different sectors creates compound risk in many areas** (*medium confidence*). Examples include the Arctic (where thawing and sea ice loss disrupt land transportation, buildings, other infrastructure, and are projected to disrupt indigenous culture); and the environs of Micronesia, Mariana Island, and Papua New Guinea (where coral reefs are highly threatened due to exposure to concomitant sea surface temperature rise and ocean acidification) [19.3.2.4].

Emergent risks also arise from indirect, trans-boundary, and long-distance impacts of climate change. Adaptive responses and mitigation measures sometimes increase such risks [19.4, *high confidence*]. Human or ecological responses to local impacts of climate change can generate harm at distant places.

- Increasing prices of food commodities on the global market due to local climate impacts, in conjunction with other stressors, decrease food security and exacerbate food insecurity at distant locations [19.4.1].
- Climate change will bear significant consequences for human migration flows at particular times and places, creating risks as well as benefits for migrants and for sending and receiving regions and states (*high confidence*) [19.4.2.1].
- The effect of climate change on conflict and insecurity is an emergent risk because factors such as poverty and economic shocks that are associated with a higher risk of violent conflict are themselves sensitive to climate change. In numerous statistical studies, the influence of climate variability on violent conflict is large in magnitude [*medium confidence*, 19.4.2.2].
- Many species shift their ranges in response to climate change, adversely affecting ecosystem function and services while presenting new challenges to conservation efforts [19.4.2.3*; medium confidence*].
- Mitigation measures taken in one location can have long-distance or indirect impacts on biodiversity and/or human systems. For example, the development of biofuels as energy sources can increase food prices [*high confidence*] and affect distant land use practices [19.4.1, 19.4.3].

Additional risks related to particular biophysical impacts of climate change have arisen recently in the literature in sufficient detail to permit assessment [19.5, *high confidence*].

- **Risks associated with global temperature rise in excess of 4°C relative to preindustrial levels**[1] arise from the potential for adverse impacts on agricultural production worldwide, extensive loss of ecosystem functioning, extinction of a substantial proportion of the earth's species *(high confidence)*, and traversing thresholds that lead to disproportionately large earth systems responses [19.5.1].
- **Ocean acidification poses risks to marine ecosystems and the societies that depend on them.** For example, ocean acidification is *very likely* to lead to changes in coral calcification rates. Reduced coral calcification is projected to have impacts of medium to high magnitude on some ecosystem services, including tourism and the provisioning of fishing [19.5.2].
- **There is increasing evidence in the literature that high ambient CO_2 concentrations in the atmosphere will affect human health by increasing the production and allergenicity of pollen and allergenic compounds and by decreasing nutritional quality of important food crops [19.5.3].**
- **In addition to providing potential climate change abatement benefits, geoengineering poses widespread risks to society and ecosystems.** For example, in some model experiments the implementation of Solar Radiation Management [SRM] for the purpose of limiting global warming leads to ozone depletion and reduces precipitation. In addition, the failure or abrupt halting of SRM risks rapid climate change [19.5.4].

[FOOTNOTE 1: Levels of global mean temperature change are variously presented in the literature with respect to "pre-industrial" temperatures in a specified year or period, e.g., 1850-1900. Alternatively, the average temperature within a recent period, e.g., 1986-2005, is used as a baseline. In this chapter, we use both, depending on the literature being assessed. The increase above pre-industrial (1850-1900) levels for the period 1986-2005 is estimated at 0.61°C (AR5 WGI Section 11.3.6.3). For example, using these baselines, a 2°C increase above pre-industrial levels corresponds to a 1.39°C increase above 1986-2005 levels. We use other baselines on occasion depending on the literature cited and explicitly indicate where this is the case. Climate impact studies often report outcomes as a function of regional temperature change, which can differ significantly from changes in global mean temperature. In most land areas, regional warming is larger than global warming (AR5 WGI Section 10.3.1.1.2). However, given the many conventions in the literature for baseline periods, the reader is advised to check carefully and to adjust baseline levels for consistency when comparing outcomes.]

Global, regional, and local socio-economic, environmental and governance trends indicate that vulnerability and exposure of communities or social-ecological systems to climatic hazards related to extreme events are dynamic and thus vary across temporal and spatial scales [*high confidence*]. Effective risk reduction and adaptation strategies consider these dynamics and the inter-linkages between socio-economic development pathways and the vulnerability and exposure of people. Changes in poverty or socio-economic status, ethnic composition, age structure and governance had a significant influence on the outcome of past crises associated with climatic hazards [19.6.1.].

Challenges for vulnerability reduction and adaptation actions are particularly high in regions that have shown severe difficulties in governance. Studies confirm that countries that are classified as failed states and afflicted by violence are often not able to effectively reduce vulnerability. Unless governance improves in countries with severe governance failure, risk will increase as a result of climate changes interacting with increased human vulnerability [*high confidence*, 19.6.1.3.3.].

***Key risks* inform evaluation of "dangerous anthropogenic interference with the climate system," in the terminology of UNFCCC Article 2. These are potentially severe adverse consequences for humans and social-ecological systems resulting from the interaction of hazards linked to climate change and the vulnerability of exposed societies and systems. Key risks were identified in this assessment based on expert judgments made by authors of the various chapters of this report in light of criteria described here [19.2.2.2] and consolidated into the following representative list (*high confidence*).** [CC-KR; 19.2.2.2, 19.6.2.1, Table 19-4, Box 19-2; Roman numerals indicate corresponding entries in Table 19-4; Notation at end of each entry indicates corresponding Reasons for Concern, discussed below.]

(i) **Risk of death, injury, and disruption to livelihoods, food supplies, and drinking water, in addition to loss of common-pool resources, sense of place, and identity due to sea level rise,** coastal flooding and storm surges affecting high concentrations of people, economic activity, biodiversity, and critical infrastructure in low-lying coastal zones and small island developing states. [*RFC 1, 2, 3, 4, and 5*]
(ii) **Risk of food insecurity and the breakdown of food systems** linked to warming, drought and precipitation variability particularly in regions that are characterized by poorer populations in urban and rural settings. [*RFC 2, 3 and 4*]
(iii) **Risk of severe harm due to inland flooding** and the limited coping and adaptive capacities of large urban populations. [*RFC 2 and 3*]
(iv) **Risk of loss of rural livelihoods and income of rural residents due to insufficient access to drinking and irrigation water,** and reduced agricultural productivity, as well as risk of food insecurity, particularly for farmers and pastoralists with minimal capital in semi-arid regions. [*RFC 2 and 3*]
(v) **Systemic risks due to multiple interacting hazards affecting infrastructure in combination with a high dependency of people on critical services** (electricity, water supply, health and emergency services) which may break down during extreme events. [*RFC 2, 3, and 4*]
(vi) **Risk of loss of marine ecosystems and the services they provide for coastal livelihoods.** Biodiversity and coastal ecosystem services important for fishing communities in the tropics and the Arctic are especially at risk due to rising water temperature and the increase of stratification and ocean acidification. [*RFC 1, 2, 3, 4, and 5*]
(vii) **Risk of loss of terrestrial ecosystems and the services they provide for terrestrial livelihoods.** Biodiversity and terrestrial ecosystem services are important for rural and urban communities globally. These services are at risk due to rising temperatures, changes in precipitation patterns, and extreme weather events. Risks are high for communities whose livelihoods depend on provisioning services [*RFC 1, 3, and 4*].
(viii) **Risk of mortality, morbidity, and other harms during periods of extreme heat, particularly for urban populations of the elderly, infants, people with chronic diseases or compromised immune systems, and expectant mothers**. Increasing frequency and intensity of extreme heat (including exposure to the urban heat island effect and air pollution) interacts with an inability of some local organizations that provide health, emergency, and social services to adapt to new risk levels for vulnerable groups. [*RFC 2 and 3*]

Climate change risks vary substantially across plausible alternative development pathways and the relative importance of development and climate change varies by sector, region and time period; both are important to understanding possible outcomes [*high confidence*]. In some cases, there is substantial potential for adaptation to reduce risks, with development pathways playing a key role in determining challenges to adaptation, including through their effects on ecosystems and ecosystem services. [19.6.2.2]

Assessment of the Reasons for Concern framework pertinent to Article 2 of the UNFCCC has led to evaluations of risk being updated in light of the advances since the AR4. [19.6.3] (All temperature changes are relative to 1986-2005, i.e.,"recent"; Numbers are indicative of RFC designation in key risk enumeration, above.)

(1) Some **unique and threatened systems** are at risk from climate change at recent temperatures, with increasing numbers at risk of severe consequences at global mean warming of 1°C, and many species and systems with limited ability to adapt subject to very high risk at warming of 2°C, particularly Arctic sea ice and coral reef systems (*high confidence*) [19.6.3.2].

(2) Risk associated with **extreme events** accompanying climate change is moderate at recent temperatures based on the attribution of heat extremes to anthropogenic climate change, the attribution to climate change of impacts of extremes on a unique and threatened system, coral reefs (*high confidence*), and the current vulnerability of other exposed systems. Risk is high at 1°C warming based on the *magnitude* and *likelihood* and *timing* of the change in hazard from extreme events (*medium confidence*) [19.6.3.3].

(3) Risk associated with the **distribution of impacts** is generally greatest in low-latitude, less developed areas, but because vulnerability is unevenly distributed within countries, some populations in developed countries are highly vulnerable. Risk is moderate at recent temperatures because regionally differentiated impacts generally related to food production have been attributed to climate change *with medium to high confidence*. Based on risk to regional crop production and water resources in some countries, risk becomes high for warming above 2°C (*medium confidence*). [19.6.3.4]

(4) Risk associated with **global aggregate impacts** is determined by both economic and noneconomic metrics. For instance, the evidence for a link between increasing risk of long-term species extinction, a noneconomic metric, and increasing temperature is *robust*. Overall, global aggregate impacts become moderate between 1-2°C of warming based on model assessment that the global aggregate economic impact of climate change will become negative and significant in magnitude (*medium confidence*). Risk becomes high around 3°C, reflecting an increase in the *magnitude* and *likelihood* of both aggregate economic risks (*low confidence*) and risk of extensive loss of biodiversity with concomitant loss of ecosystem services (*high confidence*; 19.3.2.1; 19.5.1; 19.6.3.5).

(5) Risk associated with **large-scale singular events** becomes moderate between 0-1°C due to early warning signs that both coral reef and Arctic systems are experiencing irreversible regime shifts. Risk becomes high between 1-4°C with a disproportionate increase in risk as temperature increases between 1°C and 2°C due to the potential for commitment to a large and irreversible sea level rise from ice sheet loss (*medium confidence*). [19.6.3.6]

Impacts of climate change avoided under a range of scenarios for mitigation of greenhouse gas emissions are potentially large and increasing over the 21st century [19.7.1, *high confidence*]. Among the impacts assessed here, benefits from mitigation are most immediate for surface ocean acidification and least immediate for impacts related to sea level rise. Since mitigation reduces the rate as well as the magnitude of warming, it also increases the time available for adaptation to a particular level of climate change, potentially by several decades.

Only mitigation scenarios in the most stringent category (i.e. with 2100 CO_2e concentrations of 430-480ppm) maintain moderately healthy coral reefs (*medium confidence*). With respect to the Reasons for Concern, these scenarios constrain overall risks to Unique and Threatened Systems, and those associated with Extreme Weather Events to a moderate level for some stringent scenarios and to the lower end of the high range of risk for others. Such scenarios constrain the level of risk associated with all other Reasons for Concern to the moderate or neutral level *(high confidence)* [19.6.3.2, 19.6.3.3, 19.7.1].

The higher part of the range of greenhouse gas emission scenarios in the literature, i.e. those with 2100 CO_2e concentrations above 720 ppm create risks in the high range for all Reasons for Concern and in the very high range (reflecting inability to adapt) for Unique and Threatened Systems. Risks for Distribution of Impacts also approach the very high range *(high confidence)* [19.6.3.2, 19.6.3.4, 19.7.1].

Under any plausible scenario for mitigation and adaptation, some degree of risk from residual damages is unavoidable (*very high confidence*). For example, very few integrated assessment model-based scenarios in the literature demonstrate the feasibility of limiting warming to a maximum of 1.5°C with at least 50% likelihood [19.7.1, 19.7.2.].

The risk of crossing tipping points (critical thresholds) in the Earth system or socio-ecological systems is projected to decrease with reduced greenhouse gas emissions [19.7.3], and the risk of crossing tipping points in socio-ecological systems can also be reduced by reducing human vulnerability or by preserving ecosystem services, or both (*medium confidence*) [19.7.4]. The risk of crossing tipping points is reduced by limiting the level of climate change and/or removing concomitant stresses such as overgrazing, overfishing, and pollution, but there is *low confidence* in the level of climate change associated with such tipping points and measures to avoid them.

19.1. Purpose, Scope, and Structure of the Chapter

The objective of this chapter is to assess new literature published since the Fourth Assessment Report on emergent risks and key vulnerabilities to climate change from the perspective of the distribution of risk over geographic location, economic sector, time period, and socioeconomic characteristics of individuals and societies. Frameworks used in previous IPCC reports to assess risk in the context of Article 2 of the UN Framework Convention on Climate Change (UNFCCC) are updated and extended in light of new literature; and additional frameworks arising in recent literature are examined. A focal point of this chapter is the interaction of the changing physical characteristics of the climate system with evolving characteristics of socioeconomic and biological systems (exposure and vulnerability) to produce risk (see Figure 19-1). Given the centrality of Article 2 to this chapter, the greater emphasis is on harmful outcomes of climate change rather than potential benefits.

[INSERT FIGURE 19-1 HERE
Figure 19-1: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. The figure visualizes the different terms and concepts discussed in this chapter. It underscores that risks are a product of a complex interaction between physical hazards associated with climate change and climate variability on the one hand, and the vulnerability of a society or a social-ecological system and its exposure to climate-related hazards on the other. The definition and use of “key” and “emergent” are indicated in Box 19-2 and the Glossary. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions (although changing hazard patterns also play a role, see 19.6.1.1). Changes in both the climate system (left side) and development processes (right side) are key drivers of the different core components (vulnerability, exposure, and hazards) that constitute risk (modified version of Figure 1, IPCC 2012a).]

19.1.1. Historical Development of this Chapter

The Third and Fourth Assessment Reports (TAR and AR4, respectively) each devoted chapters to evaluating the state of knowledge relevant to Article 2 of the UNFCCC (Smith *et al.*, 2001; Schneider *et al.*, 2007; see Box 19-1). The TAR sorted and aggregated impacts discussed in the literature according to a framework called *Reasons for Concern* (RFCs), and assessed the level of risk associated with individual impacts of climate change as well as each category or “reason” as a whole, generally as a function of global mean warming. This assessment took account of the distribution of vulnerability across particular regions, countries, and sectors. AR4 furthered the discussion relevant to Article 2 by assessing new literature and developing criteria potentially useful for policy makers in the determination of *key* impacts and vulnerabilities, i.e, those meriting particular attention in respect to Article 2 (see Box 19-2 for definitions of Reasons for Concern, Key Vulnerabilities (KVs) and related terms. Some definitions go beyond those in the Glossary to provide details especially pertinent to this chapter). AR4 emphasized the differences in vulnerability between developed and developing countries but also assessed new literature describing vulnerability pertaining to various aggregations of people (such as by ethnic, cultural, age, gender, or income status) and response strategies for avoiding key impacts. The Reasons for Concern were updated and the Synthesis Report (IPCC, 2007) noted that they “remain a viable framework to consider key vulnerabilities” (AR4 WGII Section 5.2). However, their utility was limited by several factors: the lack of a time dimension (i.e., representation of impacts arising from timing and rates of climate change and climate forcing), the focus on risk only as a function of global mean temperature, lack of a clear distinction between impacts and vulnerability, and importantly, incomplete incorporation of the evolving socioeconomic context, particularly adaptation capacity, in representing impacts and vulnerability.

19.1.2. The Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)

SREX (IPCC, 2012a) provides additional insights with respect to two RFC (risks associated with extreme weather events and the distribution of impacts) and particularly the distribution of capacities to adapt to extreme events across countries, communities, and other groups, and the limitations on implementation of these capacities. SREX emphasized the role of the socioeconomic setting and development pathway (expressed through exposure and vulnerability) in determining, on the one hand, the circumstances where extreme events do or do not result in extreme impacts and disasters, and on the other hand, when non-extreme events may also result in extreme impacts and disasters.

19.1.3. New Developments in this Chapter

With these frameworks already established, and a long list of impacts and key vulnerabilities enumerated and categorized in previous assessments, the current chapter has three goals: first, to recognize and assess risks which arise out of complex interactions involving climate and socioecological systems, called *emergent risks* (see Box 19-2, Table 19-4, CC-KR). In many cases, scientific literature sufficient to permit assessment of such risks has become available largely since AR4. In this chapter, we consider only those emergent risks which are relevant to interpreting Article 2 or have the potential to become relevant (see criteria in 19.2.2) as additional understanding accumulates. For example, since AR4, sufficient literature has emerged to allow initial assessment of the potential relationship between climate change and conflict. The second goal is to reassess and reorganize the existing frameworks (based on Reasons for Concern and Key Vulnerabilities) for evaluating the literature pertinent to Article 2 of the UNFCCC in order to address the deficiencies cited in section 19.1.1, particularly in light of the advances in SREX and the current report's discussions of vulnerability and human security (see Chapters 12 and 13) and adaptation (see Chapters 14-17 and 20). From this perspective, the objective stated in Article 2 may be viewed as aiming in part to ensure human security in the face of climate change. Thirdly, this chapter will assess recent literature pertinent to additional frameworks for categorizing risk and vulnerability, particularly focusing on indirect impacts and interaction and concatenation of risk, including geographic areas of compound risk (see Section 19.3).

In order to clarify the relative roles of characteristics of the physical climate system, like increases in temperature, precipitation, or storm frequency, and characteristics of the socioeconomic and biological systems with which these interact (vulnerability and exposure) to produce risks of particular consequences (the latter term used interchangeably here with "impacts" and "outcomes"), we rely heavily on a concept used sparingly in the TAR and AR4, *key risks* (see Box 19-2). Furthermore, we emphasize recent literature pointing to the *dynamic* character of vulnerability and exposure based on their intimate relationship to development.

Section 19.2 describes the framework used here for identifying key vulnerabilities, key risks, and emergent risks. We consider a variety of types of emergent risks, including in 19.3 those arising from multiple interacting systems and stresses, and in 19.4, those arising from indirect impacts, trans-boundary impacts, and impacts occurring at a long distance from the location of the climate change which causes them. One example which illustrates all of these properties is the extent to which climate change impacts on agriculture, water resources, and sea level affect human migration flows. These shifts entail both risks of harm and potential benefits for the migrants, for the regions where they originate, and for the destination regions (see 19.4.2.1 and 12.4). Associated risks include indirect impacts, like the effect of land use changes on ecosystems occurring at the new locations of settlement, which may be near the location of the original climate impact or quite distant. Such distant, indirect effects would compound the direct consequences of climate change at the locations receiving the incoming migrants. In 19.5, we discuss other risks newly assessed here, including those arising from ocean acidification. Section 19.6 assesses key risks and vulnerabilities in light of the criteria discussed here [19.2.2] and in the context of the Reasons for Concern, and section 19.7 assesses response strategies aimed at avoiding key risks.

_____ START BOX 19-1 HERE ____

Box 19-1. Article 2 of the UNFCCC

Article 2

OBJECTIVE
The ultimate objective of this Convention and any related legal instruments that the Conference of the Parties may adopt is to achieve, in accordance with the relevant provisions of the Convention, stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time-frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner.

_____ END BOX 19-1 HERE ____

____ START BOX 19-2 HERE ____

Box 19-2. Definitions

Exposure - The presence of people, livelihoods, species or ecosystems, environmental services and resources, infrastructure, or economic, social, or cultural assets in places that could be adversely affected.

Vulnerability - The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts including sensitivity or susceptibility to harm and lack of capacity to cope and adapt.

A broad set of factors such as wealth, social status, and gender determine vulnerability and exposure to climate-related risk.

Impacts (Consequences, Outcomes) - Effects on natural and human systems. In this report, the term *impacts* is used primarily to refer to the effects on natural and human systems of extreme weather and climate events and of climate change. Impacts generally refer to effects on lives, livelihoods, health status, ecosystems, economic, social, and cultural assets, services (including environmental), and infrastructure due to the interaction of climate changes or hazardous climate events occurring within a specific time period and the vulnerability of an exposed society or system. Impacts are also referred to as *consequences* and *outcomes*. The impacts of climate change on geophysical systems, including floods, droughts, and sea level rise, are a subset of impacts called physical impacts.

Hazard - The potential occurrence of a natural or human-induced physical event or trend, or physical impact, that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, livelihoods, service provision, and environmental resources. In this report, the term *hazard* usually refers to climate-related physical events or trends or their physical impacts.

Stressors - Events and trends, often not climate-related, which have an important effect on the system exposed and can increase vulnerability to climate-related risk.

Risk - The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk is often represented as probability of occurrence of hazardous events or trends multiplied by the consequences if these events occur.

Risk = (Probability of Events or Trends) X Consequences

This report assesses climate-related risks.

Key vulnerability, key risk, key impact – A vulnerability, risk, or impact relevant to the definition and elaboration of “dangerous anthropogenic interference (DAI) with the climate system,” in the terminology of United Nations Framework Convention on Climate Change (UNFCCC) Article 2, meriting particular attention by policymakers in that context.

Key risks are potentially severe adverse consequences for humans and social-ecological systems due to the interaction of climate-related hazards with vulnerabilities of societies and systems exposed. Risks are considered “key” due to high hazard or high vulnerability of societies and systems exposed, or both.

Vulnerabilities are considered “key” if they have the potential to combine with hazardous events or trends to result in key risks. Vulnerabilities that have little influence on climate-related risk, for instance, due to lack of exposure to hazards, would not be considered key.

Key impacts are severe consequences for humans and social-ecological systems.

Extract from Chapter 19, WGII, AR4:

Many impacts, vulnerabilities and risks merit particular attention by policy-makers due to characteristics that might make them 'key'. The identification of potential key vulnerabilities is intended to provide guidance to decision-makers for identifying levels and rates of climate change that may be associated with 'dangerous anthropogenic interference' (DAI) with the climate system, in the terminology of United Nations Framework Convention on Climate Change (UNFCCC) Article 2 (see Box 19-1). Ultimately, the definition of DAI cannot be based on scientific arguments alone, but involves other judgments informed by the state of scientific knowledge.

Emergent Risk: A risk that arises from the interaction of phenomena in a complex system, for example the risk caused when geographic shifts in human population in response to climate change lead to increased vulnerability and exposure of populations in the receiving region. Many of the emergent risks discussed in this report have only recently been analyzed in the scientific literature in sufficient detail to permit assessment. In this chapter, the only emergent risks discussed are those which have the potential to become key risks once sufficient understanding accumulates.

Reasons for Concern – Elements of a classification framework, first developed in the IPCC Third Assessment Report, which aims to facilitate judgments about what level of climate change may be "dangerous" (in the language of Article 2 of the UNFCCC) by aggregating impacts, risks, and vulnerabilities.

Summary of Reasons for Concern (revised from TAR, WGII, Chapter 19; see also Chapter 1.2.3. and Chapter 18.6.4.):

"Reasons for Concern" may aid readers in making their own determination about what is a "dangerous" climate change. Each Reason for Concern is consistent with a paradigm that can be used by itself or in combination with other paradigms to help determine what level of climate change is dangerous. The reasons for concern are the relations between global mean temperature increase and:

1. Risks to unique and threatened systems
2. Risks associated with extreme weather events
3. Risks associated with the distribution of impacts
4. Risks associated with aggregate impacts
5. Risks associated with large-scale singular events

19.2. Framework for Identifying Key Vulnerabilities, Key Risks, and Emergent Risks

19.2.1. Risk and Vulnerability

Definitions and frameworks that systematize hazards, exposure, vulnerability, risk and adaptation in the context of climate change are multiple, overlapping, and often contested (see e.g. Burton *et al.*, 1983; Blaikie *et al.*, 1994; Twigg, 2001; Turner *et al.*, 2003a; Turner *et al.*, 2003b; UNISDR, 2004; Schröter, 2005; Füssel and Klein, 2006; Adger, 2006; Villagrán de León, 2006; Thomalla *et al.*, 2006; Tol and Yohe, 2006; Birkmann, 2006b; IPCC, 2007; Cutter *et al.*, 2008; Cutter and Finch, 2008; ICSU - LAC, 2010a; ICSU - LAC, 2010b; Cardona, 2011; Kienberger, 2012; IPCC, 2012a; Costa and Kropp, 2012; DEFRA, 2012; Birkmann *et al.*, 2013a). Today, key reports and most authors differentiate between hazards, vulnerability, risk and impacts (see e.g. Hutton *et al.*, 2011; IPCC, 2012a; Birkmann *et al.*, 2013a). The recent literature underscores that risks from climate change are not solely externally generated circumstances or changes in the climate system to which societies respond, but rather, the result of complex interactions among societies or communities, ecosystems, and hazards arising from climate change (Susman *et al.*, 1983; Comfort *et al.*, 1999; Birkmann *et al.*, 2011a; UNISDR, 2011; IPCC, 2012a; Birkmann *et al.*, 2013a). The differentiation of the various aspects of these interactions is an important improvement since AR4 because it exhibits the social construction of risk through the concept of vulnerability (IPCC, 2012a). This new framework, growing out of SREX, translates information more easily into a risk management approach that facilitates policy making (de Sherbinin, 2013). The following section advances this framework in the context of Article 2 of the UNFCCC.

We refer to the characteristics of climate change and its effects on geophysical systems, such as floods, droughts, deglaciation, sea level rise, increasing temperature and frequency of heat waves, as *hazards*. In contrast, *vulnerability* refers primarily to characteristics of human or social-ecological systems exposed to hazardous climatic (droughts, floods etc.) or non-climatic events and trends (increasing temperature, sea-level rise) (UNDRO, 1980; Cardona, 1986; Liverman, 1990; Cannon, 1994; Blaikie *et al.*, 1996; UNISDR, 2004; Cannon, 2006; Birkmann, 2006a; Thywissen, 2006; Füssel and Klein, 2006; UNISDR, 2009; IPCC, 2012a). Ecosystems or geographic areas can be classified as vulnerable, which is of particular concern if human vulnerability increases as a result of potential impairment of the related ecosystem services. The Millennium Ecosystem Assessment (MEA) for example identified ecosystem services that affect the vulnerability of societies and communities, such as provision of fresh water resources and air quality (Millenium Ecosystem Assessment, 2005). Examples in this chapter and other chapters in this report include the vulnerability of warm water coral reefs and respective ecosystem services for coastal communities (see Table 19-4 and CC-KR).

The new framework used here also underscores that the development process of a society has significant implications for exposure, vulnerability and risk. Climate change is not a risk per se; rather climate changes and related hazards interact with the evolving vulnerability and exposure of systems and therewith determine the changing level of risk (see Figure 19-1 and Table 19-4). Identifying key vulnerabilities facilitates estimating key risks when coupled with information about evolving hazards associated with climate change. This approach provides the basis for criteria developed in the following sections.

19.2.2. Criteria for Identifying Key Vulnerabilities and Key Risks

Vulnerability is dynamic and context specific, determined by human behavior and societal organization, which influences for example the susceptibility of people (e.g. by marginalization) and their coping and adaptive capacities to hazards (see IPCC, 2012a). In this regard coping mainly refers to capacities that allow a system to protect itself in the face of adverse consequences, while adaptation – by contrast – denotes a longer-term process that also involves adjustments in the system itself and refers to learning, experimentation and change (Yohe and Tol, 2002; Pelling, 2010; Birkmann *et al.*, 2013a). Perceptions and cognitive constructs about risks and adaptation options as well as cultural contexts influence adaptive capacities and thus vulnerability (Grothmann and Patt 2005; Rhomberg, 2009; Kuruppu and Liverman 2011; see section 19.6.1.4). SREX stressed that the consideration of multiple dimensions (e.g., social, economic, environmental, institutional, cultural), as well as different causal factors of vulnerability can improve strategies to reduce risks to climate change (see IPCC 2012c, p.17 and Cardona *et al*., 2012, p. 17, 67-106).

Key vulnerability and key risk are defined in Box 19-2. Vulnerabilities that have little influence on overall risk are not considered key. Similarly, the magnitude or other characteristics of climate change related hazards, such as glacier melting, sea level rise or heat waves, are not by themselves adequate to determine key risks, since the consequences of climate change also will be determined by the vulnerability of the exposed society or social-ecological system. Key vulnerabilities and key risks embody a normative component because different societies might rank the various vulnerability and risk factors and actual or potential types of loss and damage differently (see Lavell *et al*., 2012, p. 45; Schneider *et al*., 2007, p. 785). Generally, vulnerability merits particular attention when the survival of societies, communities, or ecosystems is threatened (see UNISDR 2011, 2013; Birkmann *et al.*, 2011a). Climate change will influence the nature of the climatic hazards people and ecosystems are exposed to and also contribute to deterioration or improvement of coping and adaptive capacities of those exposed to these changes. Consequently, many studies (Wisner *et al.*, 2004; Cardona, 2010; Birkmann *et al.*, 2011a) focus with a priority on the vulnerability of humans and societies as a central feature, rather than solely on the level of climatic change and respective hazards.

19.2.2.1. Criteria for Identifying Key Vulnerabilities

We reorganize and further develop criteria for identifying vulnerabilities as “key” used in AR4 based on the literature (Blaikie *et al.*, 1994; Bohle, 2001; Turner *et al.*, 2003a; Turner *et al.*, 2003b; Birkmann, 2006a; Villagrán de León, 2006; Cutter *et al.*, 2008; Cutter and Finch, 2008; ICSU - LAC, 2010a; ICSU - LAC, 2010b; UNISDR, 2011; Cardona, 2011; Birkmann, 2011a; IPCC, 2012a; Birkmann *et al.*, 2013a) and the differentiation of hazard, exposure, and vulnerability presented here. The criteria in this and succeeding sections were used to identify key vulnerabilities, key risks, and emergent risks in 19.6.2 and Table 19-4. Not all of the criteria need to be fulfilled to characterize a vulnerability or risk as key but the characterization of a phenomenon as a key vulnerability or key risk is usually supported by more than one criterion.

The following five criteria are used to judge whether vulnerabilities are key:

1) *Exposure of a society, community, or social-ecological system to climatic stressors.* While exposure is distinct from vulnerability, exposure is an important precondition for considering a specific vulnerability as key. If a system is not at present nor in the future exposed to hazardous climatic trends or events, its vulnerability to such hazards is not relevant in the current context. Exposure can be assessed based on spatial and temporal dimensions.
2) *Importance of the vulnerable system(s). Views on the importance of different aspects of societies or ecosystems can vary across regions and cultures* (see Kienberger, 2012). However, the identification of key vulnerabilities is less subjective when it involves characteristics that are crucial for the survival of societies or communities or social-ecological systems exposed to climatic hazards. Defining key vulnerabilities in the context of particular societal groups or ecosystem services also takes into account the conditions that make these population groups or ecosystems highly vulnerable, such as processes of social marginalization or the degradation of ecosystems (Leichenko and O'Brien, 2008; O'Brien *et al.*, 2008; IPCC, 2012a).
3) *Limited ability of societies, communities or social-ecological systems to cope with and to build adaptive capacities to reduce or limit the adverse consequences of climate-related hazard.* Coping and adaptive capacities are part of the formula that determines vulnerability (see IPCC, 2012a; Birkmann *et al*., 2013a). While coping describes actions taken within existing constraints to protect the current system and institutional settings, adaptation is a continuous process which encompasses learning and change of the system exposed – including changes of rule systems or modes of governance (Smithers and Smit, 1997; Pielke Jr, 1998; Smit *et al.*, 1999; Frankhauser *et al.*, 1999; Adger *et al.*, 2005; Smit and Wandel, 2006; Pelling, 2010; Kelly and Adger, 2000; Yohe, 2002; IPCC, 2012a; Pelling *et al.*, 2008; Garschagen, 2013; Tschakert and Dietrich; 2010; Birkmann *et al.*, 2013a). Severe limits of coping and adaptation provide criteria for defining a vulnerability as key, since they are core factors that increase vulnerability to climatic hazards (see e.g. Warner *et al*., 2012).
4) *Persistence of vulnerable conditions and degree of irreversibility of consequences.* Vulnerabilities are considered key when they are persistent and difficult to alter. This is particularly the case when the susceptibility is high and coping and adaptive capacities are very low due to conditions that are hard to change. Irreversible degradation of ecosystems (e.g. warm water coral reefs), chronic poverty and marginalization, and insecure land tenure arrangements are drivers of vulnerability that in combination with climatic hazards determine risks which often persist over decades (see CC-KR), for example as observed in the Sahel Zone. In this way, communities or social-ecological systems (e.g. coastal communities dependent on fishing or mountain communities dependent on specific soil conditions) may reach a tipping point (or critical threshold) that would cause a partial or full collapse of the system, including displacement (see Renaud *et al.*, 2010; section 19.4.2.1). Inability to replace such a system or compensate for potential and actual losses and damages (i.e., irreversibility) is a critical criterion for determining what is “key”.
5) *Presence of conditions that make societies highly susceptible to cumulative stressors in complex and multiple-interacting systems.* Conditions that make communities or social-ecological systems highly susceptible to the imposition of additional climatic hazards or that impinge upon their ability to cope and adapt, such as violent conflicts (e.g. during drought disaster in Somalia (see Menkhaus, 2010)) are considered under this criteria. Also, the critical dependence of societies on highly interdependent infrastructures (e.g. energy/power supply, transport and health care) (see Atzl and Keller, 2013; Rinaldi *et al*., 2001; Wang *et al*., 2012a) leads to key vulnerabilities regarding multiple-interacting systems where capacity to cope or adapt to their failure is low (see Reed *et al*., 2010; Copeland, 2005; Table 19-4).

19.2.2.2. Criteria for Identifying Key Risks

Risks are considered "key" due to high hazard or high vulnerability ("key vulnerability") of societies and systems exposed, or both. Criteria for determining key risks build on the criteria for key vulnerabilities, since vulnerability is a component of risk. As such, risk is strongly determined by coping and adaptive capacities. However, the criteria for identifying key risks also take into account the magnitude, frequency and intensity of hazardous events and trends linked to climate change to which vulnerable systems are exposed. Accordingly, the following four additional criteria are used to judge whether risks are key:

1) *Magnitude:* Risks are key if associated harmful consequences have a large magnitude, determined by a variety of metrics including human mortality and morbidity, economic loss, losses of cultural importance, and distributional consequences (see Schneider *et al.*, 2007; IPCC, 2012a). Magnitude and frequency of the hazard as well as socioeconomic factors that determine vulnerability and exposure contribute.
2) *Probability that significant risks will materialize and their timing.* Risks are considered key when there is a high probability that the hazard due to climate change will occur under circumstances where societies or social-ecological systems exposed are highly susceptible and have very limited capacities to cope or adapt and consequently potential consequences are severe. Both the timing of the hazard and the dynamics of vulnerability and exposure contribute. Risks which materialize in the near term may be evaluated differently than risks which materialize in the distant future, since the time available for building up adaptive capacities is different (Oppenheimer, 2005; Schneider *et al.,* 2007; Section 19.6.3.6*).*
3) *Irreversibility and persistence of conditions that determine risks.* Persistence of risks refers to the fact that underlying drivers and root causes of these risks, either socioeconomic (e.g. chronic poverty) or physical, cannot be rapidly reduced. The criteria for assessing key vulnerabilities include the persistence of socioeconomic conditions contributing to vulnerability that also apply here (Section 19.2.2.1, point 4). In addition, some hazards are associated with the potential for persistent physical impacts, such as loss of an ice sheet causing irreversible sea level rise or release of methane clathrates from the seabed.
4) *Limited ability to reduce the magnitude and frequency or other characteristics of hazardous climatic events and trends and the vulnerability of societies and social-ecological systems exposed.* Criterion 3 pertaining to key vulnerabilities (Section 19.2.2.1) discusses limited ability of societies to improve coping and adaptive capacities in order to manage risk. This criterion also applies here. In addition, risks are also considered to be key when societies together have very limited prospects for reducing the magnitude, frequency or intensity of the associated climate hazards. For example, risks that may be reduced or limited by greenhouse gas reductions which reduce the probability of the associated hazard are less threatening than those for which the likelihood of the hazard cannot be effectively altered (see also 19.7.1). For example, risks which are already projected to be large during the next few decades under a range of Representative Concentration Pathways (RCPs) are much more difficult to influence by reducing emissions than those projected to become large late in this century (for example, see discussion of risk from extreme heat in Section 19.6.3.3).

19.2.3. Criteria for Identifying Emergent Risks

A risk that arises from the interaction of phenomena in a complex system is defined here as an *emergent risk*. For example, feedback processes between climatic change, human interventions involving mitigation and adaptation, and processes in natural systems can be classified as emergent risks if they pose a threat to human security. Emergent risks could arise from unprecedented situations, such as the increasing urbanization of low lying coastal areas that are exposed to sea-level rise or where new pluvial flooding risk emerges due to urbanization of vulnerable areas not historically populated. Some emergent risks have been identified or discussed only recently in the scientific literature and as a result, our ability to assess whether they are key risks is limited. In this chapter, the only emergent risks discussed are those which have the potential to become key risks once sufficient understanding accumulates.

19.2.4. Identifying Key and Emergent Risks under Alternative Development Pathways

Key risks are determined by the interaction of climate-related hazards with exposure and vulnerabilities of societies or ecosystems. Development pathways describing possible trends in demographic, economic, technological, environmental, social and cultural conditions (Hallegatte *et al.*, 2011) will affect key risks because they influence both the likelihood and nature of climate-related hazards, and the societal and ecological conditions determining exposure and vulnerability. Therefore some risks could be judged to be key under some development pathways but not others. Emergent risks can depend on development pathways as well, since whether or not they become key risks may be contingent on future socio-economic conditions.

The effect of development pathways on climate-related hazards occurs through their effects on emissions and other radiative forcing factors such as land use change (see AR5 WGI Chapter 12). Components of development pathways such as economic growth, technical change, and policy will influence the rates and spatial distributions of emissions of greenhouse gases and aerosols, and of land use change, and therefore influence the magnitude, timing, and heterogeneity of hazards (see AR5 WGIII Chapter 5).

Development pathways will also influence the factors determining key vulnerabilities of human and ecological systems, including exposure, susceptibility or sensitivity to impacts, and adaptive capacity (Yohe and Tol, 2002; Füssel and Klein, 2006; Hallegatte *et al.*, 2011; O'Neill *et al.*, 2013; Birkmann *et al.*, 2013a). The magnitude of the aggregate exposure and sensitivity of socio-ecological systems will depend on population growth and spatial distribution, economic development patterns, and social systems. The particular elements of the social-ecological system that are most exposed and sensitive to climate hazards, and that are considered most important, will depend on spatial development patterns as well as on cultural preferences, attitudes toward nature/biodiversity, and reliance on climate-sensitive resources or services, among other factors (Adger, 2006; Füssel, 2009). The degree to which persistent or difficult to reverse vulnerabilities are built into social systems, as well as the degree of inequality in exposure and vulnerability across social groups or regions, also depend on characteristics of development pathways (Adger *et al.*, 2009).

19.2.5. Assessing Key Vulnerabilities and Emergent Risks

The criteria above for assessing vulnerability and risk provide a sequence of potential assessment steps. While the initial assessment phase would explore whether and how a society or social-ecological system is exposed to climate related hazards, the assessment would subsequently focus on the predisposition of societies or ecosystems to be adversely affected (vulnerability) and the potential occurrence of severe adverse consequences for humans and social-ecological systems once the hazard interacts with the vulnerability of societies and systems exposed. In addition, the importance of the system at risk and the ability of a society or system to cope and to adapt to these stressors would be assessed. Finally, the application of the criteria would also require the assessment of the irreversibility of the consequences and the persistence of vulnerable conditions. Hence, the assessment criteria for risks focus on the internal conditions of a person, a community (e.g. age structure, poverty), or a social-ecological system and the contextual conditions that influence their vulnerability (e.g. governance conditions and systems of norms), in addition to the assessment of hazards, such as storm intensity, heat waves, and sea level rise, which are directly influenced by climate change. Examples of such key vulnerabilities and key risks drawn from other chapters of this assessment are provided in section 19.6 and particularly Tables 19-4 and CC-KR.

19.3. Emergent Risk: Multiple Interacting Systems and Stresses

19.3.1. Limitations of Previous Approaches Imply Key Risks Overlooked

Interactions of climate change impacts on one sector with changes in exposure and vulnerability, or with adaptation and mitigation actions affecting the same or a different sector are generally not included or well integrated into projections of risk (Warren, 2011). However, their consideration leads to the identification of a variety of *emergent risks* that were not previously assessed or recognized. This chapter identifies several such complex-system interactions that increase vulnerability and risk synergistically [Section 19.3, *high confidence*]. There are a very large number of potential interactions, and many important ones have not yet been quantified, meaning that some key risks have been overlooked [*high confidence*]. In some cases, literature analyzing these risks is very recent. The six interaction processes listed below, while not exclusive, are systemic and may lead to further key vulnerabilities as well as a larger number of less significant impacts. Several of these are discussed in more detail in the following sections.

- Biodiversity loss induced by climate change that erodes ecosystem services, in turn increasing vulnerability and exposure of human systems dependent on those services. (*19.3.2.1)*
- Alterations in extreme weather events induced by climate change which affect human systems and ecosystems, increasing vulnerability and exposure to the effects of mean climate change. Most impacts projections are based only on changes in mean climate (Rosenzweig and Hillel, 2008; IPCC, 2012a, Box 3-1).
- The interaction between non-climate stressors such as those related to land management, water management, air pollution (which has drivers in common with climate change) and energy production and climate change. Heretofore, mainly climate interactions with population/economic growth were assessed (*19.3.2.2).*
- Climate changes which increase human exposure and vulnerability to disease. *(19.3.2.3)*
- Locations where risks in different sectors are compounded because impacts, hazards, vulnerability, and exposure interact non-additively. (*19.3.2.4)*
- Mitigation or sectoral adaptation that has unintended consequences for the functioning of another sector. (*19.3.2.5)*

19.3.2. Examples of Emergent Risks

19.3.2.1. Emergent Risks Arising from the Effects of Degradation of Ecosystem Services by Climate Change

Biodiversity loss is linked to disruption of ecosystem structure, function and services (Cardinale, 2012; Díaz *et al.*, 2006; Gaston and Fuller, 2008; Maestre *et al.*, 2012; Midgley, 2012, Duraiappah *et al.*, 2005). Terrestrial and freshwater species face increased extinction risks under projected climate change during and beyond the 21st Century, especially as climate change interacts with other pressures (*high confidence*; Section 4.3.2.5). A large number of modelling studies project that species ranges decline in size as mean climate changes (Section 4.3.2.5), e.g., a global scale study of 50,000 species found that the range sizes of 57±6% of widespread and common plants and 34±7% of widespread and common animals are projected to decline by over 50% by the 2080s if global temperatures increase by 3.5^0C relative to pre-industrial times, when allowing for species to disperse at observed rates to areas that become newly climatically suitable (Warren *et al.*, 2013a). AR4 (Fischlin *et al*., 2007) estimated that "approximately 20 to 30% of plant and animal species assessed so far (in an unbiased sample) are likely to be at increasingly high risk of extinction as global mean temperatures exceed a warming of 2 to 3°C above preindustrial levels (*medium confidence*)." Evaluation of various lines of evidence including a range of modelling approaches and, since AR4, new and/or improved techniques (e.g., multi-factorial driven species distribution models, species specific population dynamics, tree-based and trait based modeling (for an overview see Bellard *et al.*, 2012, Table 1; also Staudinger *et al.*, 2012; Murray *et al.*, 2011; Dullinger *et al*., 2012; Foden *et al*., 2013), imply similar levels of risk as in AR4 with some new estimates indicating higher fractions of species at risk. However, there is *low agreement* on the completeness of these lines of evidence for assigning specific numerical values for fraction of species at risk (see Sections 19.5.1 and 4.3.2.5).

These extinction risks and possible declines in species richness are associated with change in mean climate, but ecosystems and species are also expected to be affected by projected climate-change induced increases in short-term extreme weather events and increased fire frequency in some locations (see IPCC, 2012a (SREX); AR5 WGI Table SPM.1; AR5 WGI Sections 12.4.3 and 12.4.5). Accordingly, despite the recognition of additional uncertainties in numerical estimates since AR4 (Section 4.3.2.5), the evidence for risk to a substantial fraction of species associated with increasing GMT is *robust*.

In both terrestrial and marine environments, the potential for the disruption of ecosystem functionality as a result of climate change translates into a key risk of large-scale loss of ecosystem services (Mooney *et al.*, 2009; Midgley, 2012; Table 19-4). At-risk services include water purification by wetlands, removal and sequestration of carbon dioxide by forests, crop pollination by insects, coastal protection by mangroves and coral reefs, regulation of pests and disease, and recycling of waste nutrients (Sections 4.3.4, 22.4.5.6, 27.3.2.1, Table 23-2, Box CC-WE; Chivian and Bernstein, 2008). Biodiversity loss can lead to an increase in the transmission of infectious diseases such as Lyme, Schistosoma and hantavirus in humans, and West Nile virus in birds, creating a newly identified dimension to the emergent risks resulting from biodiversity loss (Keesing *et al.*, 2010).

There are a number of examples of projected yield losses in the agricultural sector due to increased prevalence of pest species under climate change including *Fusarium graminearum* (a fungal disease of wheat), the European corn borer, the Colorado beetle, bakanae disease and leaf blights of rice, and Western corn root worm (Petzoldt and Seaman, 2006; Kocmankova *et al.*, 2010; Huang *et al.*, 2010; Chakraborty and Newton, 2011; Magan *et al.*, 2011; Aragón and Lobo, 2012); or declines in pollinators (Section 4.3.4; Rosenzweig and Hillel, 2008; Kuhlmann *et al.*, 2012; Giannini *et al.*, 2012; Abrol, 2012; Bedford *et al.*, 2012). Climate change impacts on pollinators places these valuable services at risk, and affects animals which are dependent upon the plants (see Chapter 4). Although the impacts of CO_2 fertilisation on plant-pathogen systems is not well understood (Section 7.3.2.3), these processes operate simultaneous with climate change's direct effects on yields through changing temperature, precipitation, and carbon dioxide concentrations, creating an emergent risk. Climate change has caused, or is projected to cause range expansion in weeds that have the potential to become invasive (Bradley *et al.*, 2010; Clements and Ditommaso, 2011). These can damage agriculture and threaten other species with extinction, with costs to economies being extremely high (e.g. $120 billion annually in the USA, Pimentel *et al.,* 2005; Crowl *et al.*, 2008). Although there are also examples of projected decreases in insect damage to crops, there is a tendency for risk of insect damage to plants to increase with climate change (section 7.3.2.3). Any one of the above mechanisms could result in harmful outcomes that act in synergy with existing climate change impacts on agriculture. Hence, these various susceptibilities to loss of ecosystem services comprise a key vulnerability, and in interaction with climate change, imply a potential key risk that global scale yields of a number of crops will be reduced by such interactions.

Severe decline of coral reefs (section 19.3.2.4) would result in widespread loss of income for many countries, for example $Au5.4 billion to the Australian economy from international tourism, and of US$1.6 billion to the US economy from damage to Florida's reefs (CC-CR). More generally, for many Small Island Developing States, increases in vulnerability due to loss of such ecosystem services interact with physical impacts of climate change such as sea level rise to create an emergent risk (*high confidence*).

Various studies of ecosystem services nationally or globally, illustrate the very large values that are attributed to these services (Table 19-1). Such costs are represented only very crudely in aggregate global models of the economic impacts of climate change where 'non-market impacts' are estimated very broadly if at all (Section 19.6.3.5). These costs contribute to the large magnitude of the risks to human systems resulting from loss of ecosystem services, which in some cases would be irreversible. Hence the increase in vulnerability due to loss of ecosystem services interacting with climate change hazards comprises a key risk (*high confidence*). In some regions (e.g., South America) payment for ecosystem services (PES) has been implemented to support landowners to maintain the provision of services over time (Section 27.6.2, Table 27-8). Studies on degraded ecosystems examine the cost of restoring ecosystem services. Willingness to pay to restore degraded services along the Platte River (US) (Loomis *et al.*, 2000) greatly exceeded estimated costs of restoration. A meta-analysis of 89 studies looking at the restoration of ecosystem services measured using 526 different metrics found that restoration increased the amount of biodiversity and ecosystem services by 44 and 25% respectively, but restored services were still lower than in intact ecosystems (Benayas *et al.*, 2009). Hence, restoration of damaged ecosystems may be cost-effective, but can only partially compensate for loss of services.

Concomitant stress from land use change adds to the extinction risk from climate change, increasing the projected extinction rate (e.g. Şekercioğlu *et al*., 2012) - and contributing to the emergent risk of ecosystem service loss. A synthesis of empirical studies across the globe reveals that ecosystem impacts due to land use change correlate locally with current maximum temperature and recent precipitation decline, indicating a potential for climate change to exacerbate the impacts of land use change (Mantyka-Pringle *et al.*, 2012; Chapter 4).

Land clearing releases carbon to the atmosphere and removes carbon sinks (AR5 WGI Section 6.4.3.3) such as old growth forests which would otherwise accumulate carbon (Luyssaert *et al.*, 2008). Studies that value ecosystem services have tended to underestimate the importance of carbon sinks in ecosystems, due to a tendency to consider only the carbon currently stored in the systems and not the fluxes (Anderson-Teixeira and DeLucia, 2011) and overlooking other aspects such as changes in albedo (e.g. Betts *et al.*, 2012).

[INSERT TABLE 19-1 HERE
Table 19-1: Examples of global and national ecosystem service valuation studies. This table is not intended to be comprehensive. Furthermore, it encompasses studies based on a wide range of methodologies.]

19.3.2.2. Emergent Risk Involving Non-Climate Stressors: the Management of Water, Land, and Energy

Human management of water, land, and energy interacts with climate change and its impacts, to profoundly affect risks to the amount of carbon that can be stored in terrestrial ecosystems, the amount of water available for use by humans and ecosystems, and the viability of adaptation plans for cities or protected areas. Failure to manage land, water and energy in a synergistic fashion can exacerbate climate change impacts globally (Wise *et al*., 2009; Searchinger *et al.*, 2008; Lotze-Campen *et al.*; 2010; Warren *et al.*, 2011) producing emergent risks which are also potential key risks. For example, the use of water by the energy sector, by thermo-electric power generation, hydropower and geothermal energy, or biofuel production, can contribute to water stress in arid regions (Kelic, 2009; Pittock, 2011). Some energy technologies (biofuels, hydropower, thermal power plants), transportation fuels and modes, and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops) require more water than others (Sections 3.7.2, 7.3.2, 10.2, 10.3.4; McMahon and Price, 2011; Macknick *et al*., 2012a; Ackerman and Fisher, 2013). In irrigated agriculture, climate, crop choice and yields determine water requirements per unit of produced crop, and in areas where water must be pumped or treated, energy must be provided (Gerten *et al*., 2011). Recent studies address the energy, water, and land 'nexus' to explore risks to the agricultural and energy sectors (Tidwell *et al.*, 2011; Skaggs *et al.*, 2012; Smith *et al.*, 2013; Box CC-WE).

Biofuels can potentially mitigate GHG emissions when used in place of fossil fuels such as gasoline, diesel, and more carbon-intensive fuels from tar sands and heavy oil (Cherubini *et al.*, 2009). One simulation of stringent mitigation (e.g. RCP2.6, which constrains radiative forcing to 2.6 W/m^2 and therefore limits global mean temperature increase to 2°C over preindustrial levels during the 21st century) shows an increased reliance on biofuels (van Vuuren *et al.*, 2011). However, due to the potential negative consequences of its use as a mitigation strategy, bioenergy development leads to several emergent risks, which are summarized in Table 19-2. Systems that may be vulnerable to bioenergy development are food systems (*high confidence,* due to bioenergy feedstocks replacing food crops, see Table 19-2.iii, Sections 19.4.1.) and ecosystems (*high confidence*), where biofuel cropping can directly or indirectly induce land use change, displacing terrestrial ecosystems such as forests, which can otherwise also act as carbon sinks, see Table 19-2.i).

While *direct* land-use change (LUC) from impacts of biofuel development (from crop substitution and/or biofuel feedstock crop expansion, c) are a concern, *indirect* land-use change (iLUC) has received more attention in the literature – both due to the magnitude of its potential impact (twice as great as direct LUC, Mellilo *et al*., 2009) and controversy over the uncertainty in accurately quantifying it. iLUC connotes land-use change resulting from biofuel impacts on agricultural commodity markets (Fargione *et al.*, 2008; Searchinger *et al.*, 2008). Reductions of greenhouse gas emissions from biofuel production and use (compared to fossil fuels) may be offset partly or entirely for decades or centuries from iLUC-induced CO_2 emissions from deforestation and the draining of peatlands (*medium confidence,* IPCC, 2011 (SRREN), Chapter 2; Bringezu *et al.*, 2009; van Vuuren *et al.*, 2010, Miettinen *et al.*, 2012, Smith *et al.* 2013). In Brazil, further biofuel expansion would be expected to impinge upon the Cerrado, the Amazon and the Atlantic rainforest - all three of which have high levels of biodiversity (Table 19-2.v) and high levels of endemism (Lapola *et al.*, 2010). Another study of biofuel production in Brazil (Barr *et al.*, 2011) found that when pasture is accounted for, direct expansion into unexploited forest land is minor, i.e., most of additional cropland is predicted to come from conversion of pastureland. However, unless the density of livestock operations is increased in tandem, the latter can also lead to *i*LUC. To the extent that biofuel feedstock crops are grown on areas that were previously fallow or degraded, the iLUC effects might be minimized and CO_2 potentially sequestered (IPCC, 2011 (SRREN); Fargione *et al.*, 2010) – although the amount, alternative uses, and potential productivity of so-called degraded lands are still contested (Dauber *et al.*, 2012). (For more information on the effects of biofuel production on terrestrial ecosystems see 4.4.4; for more information on the effects of land acquisition for biofuel production on the poor, see 13.3.1.4)

Whether such land management dynamics confound or contribute to mitigation depends on important interactions with global emissions mitigation policies (Table 19-2.ii, Van Vuuren *et al.*, 2011). A failure to include land use change emissions within a carbon mitigation regime – for example by applying a carbon price to fossil fuel and industrial emissions only – has been projected to lead to large-scale deforestation of natural forests and conversion of many other natural ecosystems by the end of the 21st century in 450 ppmv CO_2-e and 550 ppmv CO_2-e scenarios (Wise *et al.*, 2009; Mellilo *et al.* 2009a). This dynamic is due primarily to enhanced bioenergy production without a corresponding incentive to limit the resulting land use change emissions. If, instead, an equal carbon price is applied to terrestrial carbon (which, however, presents monitoring difficulties) along with fossil and industrial carbon, deforestation could slow down or even reverse.

That said, there are many equally compelling reasons for a country to encourage biofuel production including: a means to produce downward pressure on oil prices, rural development and reduced oil imports – all of which could be prioritized over biofuels as a GHG mitigation strategy depending on the country (Cherubini *et al.*, 2009). Per-litre GHG emissions from biofuels *decrease* as agriculture is further intensified through row cropping, fertilizer and pesticide use, and irrigation, while other per-litre environmental impacts like eutrophication *increase* (Burney *et al.*, 2010; Grassini and Cassman, 2012). This creates an implicit conflict between alternative development priorities. Second-generation biofuels, such as those based on non-food crops (grasses, algae, timber) and agricultural residues, are expected to offer reduced emissions of GHG and other air pollutants compared to most first-generation biofuels. This is due primarily to their having a smaller adverse interaction with food systems resulting in less LUC and *i*LUC (Plevin, 2009; Cherubini and Ulgiati, 2010; Fargione, 2010; Sander and Murthy, 2010). Further, bioelectricity and biogas both may be more effective at mitigating GHG emissions than liquid biofuels (Power and Murphy, 2009; Campbell *et al.*, 2009).
Other emergent risks from bioenergy development are summarized in Table 19-2. Nearly all of the risks presented here are driven by the increased need for raw agricultural feedstocks. Competition for cultivable lands, irrigation resources (CC-WE), and other inputs are not unique to biofuel related issues. The approximate doubling of agricultural demand projected between 2005 and 2050 (Tilman *et al.*, 2011) similarly increases competition for land and water, and would be expected to exacerbate greenhouse gas emissions from agriculture (see also AR5 WGI Section 8.3.5).

[INSERT TABLE 19-2 HERE
Table 19-2: Emergent risks related to biofuel production as a mitigation strategy.]

Projected changes in the hydrological cycle due to climate change (AR5 WGI Section 12.4.5) combined with increasing water demand leads to an emergent, potentially key risk of water stress exacerbated by the reduction of groundwater which serves as ‘an historical buffer against climate variability’ (Green *et al.*, 2011), and potentially further exacerbated by existing governance constraints which can act as barriers to reduce vulnerability. Climate change and increasing food demand are expected to drive expansion of irrigated cropland (Wada *et al.* 2013), increasing the demand for energy intensive extraction and conveyance of (ground or desalinated sea) water for irrigation (CC-WE). If water is provided through groundwater extraction, pumping, or construction and use of de-salinisation plants, local energy demand (and greenhouse gas emissions) will increase, although advanced irrigation systems are available that minimize enhancement of emissions (Rothausen and Conway, 2011).

A further potential key risk arises from increased water stress due to unsustainable groundwater extraction, which is expected to increase as an adaptation to climate change. Groundwater extraction is generally increasing globally with particularly large extraction in India and China (Wang *et al.*, 2012b). The effects of climate change on groundwater are varied with some areas expecting decreased recharge whilst others are projected to experience increased recharge (Green *et al.*, 2011; Portmann *et al*., 2013). Where extraction rates increase or recharge decreases, water tables will be depleted with potential key risks to local ecosystems and human systems (such as agriculture, tourism and recreation), while water quality will decrease. One projection shows insufficient water availability in Africa, Latin America and the Caribbean to satisfy both agricultural demands and ideal environmental flow regulations for rivers by 2050, a situation that is exacerbated by climate change (Strzepek and Boehlert, 2010).

19.3.2.3. Emergent Risks Involving Health Effects

Climate change will act through numerous direct and indirect pathways to alter the prevalence and distribution of diseases that are climate and weather sensitive. These effects will differ substantially depending on baseline epidemiologic profiles, reflecting the level of development and access to clean and plentiful water, food and adequate sanitation and health care resources. Furthermore, the impact of climate change will differ within and between regions, depending upon the adaptive capacity of public health and medical services and key infrastructure that ensures access to clean food and water.

A principal emergent global public health risk is malnutrition secondary to ecological changes and disruptions in food production as a result of changing rainfall patterns, increases in extreme temperatures (IPCC, 2012a; Sections 7.3.2.5, 11.6.1; *high confidence*), and increased atmospheric CO_2 (Taub *et al.*, 2008; Lobell and Burke, 2010). Modeling of the magnitude of the effect of climate change on future under-nutrition in five regions in South Asia and sub-Saharan Africa in 2050 (using SRES A2 emissions scenario) suggests an increase in moderate nutritional stunting, an indicator linked to increased risk of death and poor health (Black *et al.*, 2008), of 1% to 29%, depending of the region assessed, compared to a future without climate change, and a much greater impact on severe stunting for particular regions, such as 23% for central sub-Saharan Africa and 62% for south Asia (Lloyd *et al.*, 2011). The impact of climate induced drought and precipitation changes in Mali include the southward movement of drought-prone areas which would result in a loss of critical agriculturally-productive land by 2025 and increase food insecurity (Jankowska *et al.*, 2012).

In densely populated megacities, especially those with a pronounced urban heat island effect, a principal emergent health risk results from the synergistic interaction between increased exposure to extreme heat and degraded air quality with the convergence of increasing vulnerability of an aging population and a global shift to urbanization (Sections 8.2.3.5, 8.2.4.6,11.5.3, CC-HS; *high confidence*). These trends will increase the risk of relatively higher mortality from exposure to excessive heat (Knowlton *et al.*, 2007, Luber and McGeehin, 2008, Kovats and Hajat, 2008). The health risks of such interactions include increased injuries and fatalities as a result of severe weather events including heat waves (see Section 19.6.3.3); increased aeroallergen production in urban areas leading to increases in allergic airway diseases (see Section 19.5.3); and respiratory and cardiovascular morbidity and mortality secondary to degraded air quality and ozone formation (see Section 19.6.3.3). While the association between ambient air quality and health is well established, there is an increasingly *robust* body of evidence linking spikes in respiratory diseases to weather events and to climate change. In New York City, for example, each single degree (Celsius) increase in summertime surface temperature has been associated with a 3% increase in same-day hospitalizations due to respiratory diseases, and an increase of up to 3.6% in hospitalizations due to cardiovascular diseases (Lin *et al.*, 2009). Respiratory health outcomes will be exacerbated by climate change through increased production and exposure to ground-level ozone (particularly in urban areas), wildfire smoke, and increased production of pollen (D'Amato *et al.*, 2010).

19.3.2.4. Spatial Convergence of Multiple Impacts: Areas of Compound Risk

In this chapter, we define an *area of compound risk* as a region where climate-change induced impacts in one sector affects other sectors in the same region, or a region where climate change impacts in different sectors are compounded, resulting in extreme or high-risk consequences. The frequent and ongoing spatial and temporal coincidence of impacts in different sectors in the same region has consequences that are more serious than simple summation of the sectoral impacts indicates (*medium confidence*). Such synergistic processes are difficult to identify through sectoral assessment and are apt to be overlooked in spite of their potential importance in considering key vulnerabilities and risks. For example, a large flood in a rural area may damage crop fields severely, causing food shortages (Stover and Vinck, 2008). The flood may simultaneously cause a deterioration of hygiene in the region and the spread of water borne diseases (Schnitzler, 2007; Hashizume *et al.*, 2008; Kovats and Akhtar, 2008). The coincidence of disease and malnutrition can thus create an area of compound risk for health impacts, with the elderly and children most at risk.

As a systematic approach, identification of areas of compound risk could be achieved by overlaying spatial data of impacts in multiple sectors, but this cannot indicate synergistic influences and dynamic changes in these influences quantitatively. For global analysis, certain types of integrated assessment models which allow spatial analysis of climate change impacts have been used to identify regions that are affected disproportionately by climate change (MNP, 2006; Kainuma *et al.*, 2007; Warren *et al.*, 2008; Füssel, 2010). Recent efforts attempt to collect and archive spatial data on impact projections and facilitate their public use. These have created overlays for identifying areas of compound risk with web-GIS technology (Adaptation Atlas (Resources for the Future, 2009). There are also efforts to coordinate impacts assessments adopting identical future climatic and/or socio-economic scenarios at various spatial scales (Parry *et al.*, 2004; Piontek *et al.*, 2013). Areas of compound risk identified by overlaying spatial data of impacts in multiple sectors can be used as a starting point for regional case studies on vulnerability and multifaceted adaptation strategies (Piontek *et al.*, 2013).

General equilibrium economic models (see Chapter 10) may facilitate quantitative evaluation of synergistic influences. An analysis of the EU by the PESETA project (Projections of economic impacts of climate change in sectors of Europe based on bottom-up analysis) showed sub-regional welfare loss by considering impacts on agriculture, coastal system, river floods, and tourism together in the CGE (Computable General Equilibrium) model, which is designed to represent interrelationships among economic activities of sectors. The result indicated the largest percentage loss due to climate change in Southern Europe (Ciscar *et al.*, 2011).

[INSERT FIGURE 19-2 HERE
Figure 19-2: Some examples of areas of compound risk identified in this assessment. Symbols indicate one or two of the main sectors or systems subject to compound risk but in each case, additional sectors and systems are at risk.]

The following examples illustrate different types of areas of compound risk where climate change impacts coincide and interact:

1) **Cities in deltas,** which are subject to sea level rise, storm surge, coastal erosion, saline intrusion and flooding. Extreme weather events can also disrupt access to food supplies, enhancing malnutrition risk (Ahmed *et al.*, 2009; Section 19.3.2.3). Based on national population projections, if contemporary rates of effective sea level rise (a net rate, defined by the combination of eustatic sea-level rise and local contributions from fluvial sediment deposition and subsidence and subsidence due to groundwater and hydrocarbon extraction) continue through 2050, over 6 million people would be at risk of enhanced inundation and increased coastal erosion in three megadeltas and 8.7 million in 40 deltas, absent measures to adapt (Ericson *et al.*, 2006). Examples of urbanized delta areas at risk include, for example, those where Mumbai and Dhaka are located (see Chapter 8, Chapter 24, Section 19.6.3.4, Table 19-4).
2) **The Arctic,** where indigenous people (Crowley, 2011) are projected to be exposed to the disruption, and possible destruction of, their hunting and food sharing culture (see Chapter 28). Risk arises from a combination of sea ice loss and the concomitant local extinctions of the animals dependent upon the ice (Johannessen and Miles, 2011). Thawing ground also disrupts land transportation, buildings and infrastructure whilst exposure of coastal settlements to storms also increases due to loss of sea ice. Arctic ecosystems are broadly at risk (Kittel *et al.*, 2011).
3) **Coral reefs,** which are highly threatened due to the synergistic effects of sea surface temperature rise and perturbed ocean chemistry, reducing calcification and also increasing sensitivity to other impacts such as the loss of coral symbionts (Chapter 6). The importance of reef sensitivity to climate change was recently highlighted in the near-equatorial Indo Pacific, the area of greatest reef diversity worldwide (Lough, 2012). A second highly diverse reef system at risk for warming was identified around Micronesia, Mariana Island and Papua New Guinea (Meissner *et al.*, 2012).

In Figure 19-2, these and other examples of areas of compound risk identified in this assessment are indicated on a world map. The map focuses on the key role that exposure plays in determining risk, particularly compound risk, rather than vulnerabilities per se.

19.4. Emergent Risk: Indirect, Trans-Boundary, and Long-Distance Impacts

Climate change impacts can have consequences beyond the regions in which they occur. Global trade systems transmit and mediate a variety of impacts – the most prominent example of this is the global food trade system. The competitive market forces which dominate trade do not account for considerations of justice, and thus can incidentally diminish or enhance inequality in the distribution on impacts (see 19.6.3.4). Where prices on food, land, and other resources increase, vulnerability increases, *ceteris paribus*, for those most in need and least able to pay (see section 19.6.1.2 on differential vulnerability). Additionally, both mitigation and other adaptation responses have unintended consequences beyond the locations in which they are implemented (Oppenheimer, 2013). All of these mechanisms can create emergent risks (*high confidence*).

19.4.1. Crop Production, Prices, and Risk of Increased Food Insecurity

Recent literature indicates that climate trends have already influenced the yield trends of important crops (e.g. Kucharik and Serbin, 2008; Tao *et al.*, 2008; Brisson *et al.*, 2010 and Lobell *et al.*, 2011). Chapters 7 and 18 provide a detailed overview of these impacts, and have assessed with *medium confidence* that the effects of climate trends on maize and wheat yield trends have been negative in many regions over the past several decades, and have been small for major rice and soybean production areas (see Sections 7.2.1.1. and 18.4.1.1.). For projected impacts, “Without adaptation, local temperature increases in excess of about 1^{o}C above pre-industrial is projected to have negative effects on yields for the major crops (wheat, rice and maize) in both tropical and temperate regions, although individual locations may benefit (*medium confidence*) (7.4, Figures 7-4,7-5,7-7)” (Chapter 7 ES). Across all studies projecting crop yield impacts (some of which include both CO_2 fertilization and adaptation, and some which account for only one or neither of these), negative impacts on average yields become *likely* from the 2030s (Figure 7-5). Median yield impacts of 0 to -2% per decade are projected for the rest of the century (compared to yields without climate change) (Figure 7-7), and after 2050 the risk of more severe impacts increases (*medium confidence*) (Chapter 7 ES, Figure 7-5). Among the smaller number of studies that have projected global yield and price impacts, negative net effects of climate change, CO_2 increases, and agronomic adaptation on global yields are *about as likely as not* by 2050 and *likely* later in the 21st century.

Climate impacts on crop production influence food prices directly and through complex interactions with a variety of factors, including biofuel crop production and mandates, as well as other domestic policies like crop export bans (Sections 7.1.2, 7.2.2, 7.4.4). If climate changes reduce crop yields, international food prices and the number of food insecure people are expected to increase globally (*limited evidence*, *high agreement*, Section 7.4.4). For example, global rice prices exhibit sensitivity both to yield impacts from climate changes as well as the loss of arable land to sea level rise (Chen *et al*., 2012). While the evidence base of how climate change will affect future food consumption patterns is limited (Section 7.3.3.2.), there are large numbers of households that would be especially vulnerable to a loss of food access if food prices were to increase, for example, agricultural producers in low-income countries who are net food buyers (Section 7.3.3.2, Table 7-1).

In addition to the direct impacts of climate change, biofuel production in service of climate change mitigation may also affect food prices. Accurately tracking and quantifying the direct and indirect impacts of biofuel production on the food-system has become an intense area of study since AR4. As witnessed in the United States, US maize-ethanol production increased 800% since 2000, with maize commodity prices more than tripling and harvested land growing by more than 10%, mainly at the expense of soy (EIA, 2013). Ethanol recently consumed one quarter of US maize production, even after accounting for feed by-products returned to the market (USDA, 2013). However, isolating biofuels’ exact contribution to food-system changes from other factors such as extreme weather events, climate change, changing diets, and increasing population have proven difficult (Zilberman et al., 2011). Still, estimates of the supply and demand elasticity of basic grain commodities lead to a prediction that the 2009 US Renewable Fuel standard could increase commodity prices of maize, wheat, rice, and soybeans by roughly 20%, *ceteris paribus*, assuming one third of the calories used in ethanol production can be recycled as animal feed

(Roberts and Schlenker, 2013). More generally, there is *high confidence* that pressure on land use for biofuels will further increase food prices (see Table 19-2.iii).

In summary, through the global food trade system, climate change impacts on agriculture can have consequences beyond the regions in which those impacts are directly felt. Food access can be inhibited by rising food price levels and volatility (Sections 7.3.1. and 7.3.3.2), as demonstrated during the recent 2007-2008 price rise episode that resulted from the combination of poor weather in certain world regions combined with a demand for biofuel feedstocks, increased demand for grain-fed meat, and historically low levels of food stocks (Abbot and Borot de Battisti, 2011; Adam and Ajakaiye, 2011; Figure 7-3). These episodes provide an analog elucidating how reduced crop yields due to impacts of climate variability and biofuel cropping work synergistically to create a risk of increased food insecurity: hence this interaction of climate change and mitigation actions with the food system via markets comprises an *emergent risk* of the impacts of climate change acting at a distance, affecting the food security of vulnerable households (Section 7.3.3.2.).

19.4.2. Indirect, Trans-boundary, and Long-Distance Impacts of Adaptation

Risk can also arise from unintended consequences of adaptation (see Section 14.7), and this can act across distance, if for example, there is migration of people or species from one region to another. Adaptation responses in human systems can include land use change, which can have both trans-boundary and long distance effects; and changes in water management, which often has downstream consequences.

19.4.2.1. Risks Associated with Human Migration and Displacement

Human migration is one of many possible adaptive strategies or responses to climate change (Reuveny, 2007; Piguet 2010; Tacoli, 2009; McLeman, 2011), assessed in detail in Chapter 12 in the context of the many other causes of migration. Displacement refers to situations where choices are limited and movement is more or less compelled by land loss due to sea level rise or extreme drought, for example (see Section 12.4). A number of studies have linked past climate variability to both local and long distance migration (see review by Lilleør and Van den Broeck, 2011). In addition to yielding positive and negative outcomes for the migrants, migration indirectly transmits consquences of climate variability and change at one location to people and states in the regions receiving migrants, sometimes at long distances. Consequences for receiving regions, which can be assessed by a variety of metrics, could be both positive and negative, as may also be the case for sending regions (McLeman, 2011; Foresight, 2011; Chapter 12). A rapidly growing literature examines potential changes in migration patterns due to future climate changes, but projections of specific positive or negative outcomes are not available. Furthermore, recent literature underscores risks previously ignored: risks arising from the lack of mobility in face of a changing climate, and risks entailed by those migrating into areas of direct climate-related risk, like low-lying coastal deltas (Foresight, 2011; see Section 12.4.1.2).

Climate change induced sea level rise, in conjunction with storm surges and flooding, creates a threat of temporary and eventually permanent displacement from low-lying coastal areas, the latter particularly the case for small island states (Pelling and Uitto 2001; Chapter 12). The distance and permanence of the displacement will depend on whether governments develop strategies such as relocating people from highly vulnerable to less vulnerable areas nearby, and conserving ecosystem services which provide storm surge protection (Perch-Nielsen, 2004) in addition to so-called "hardening" including building sea walls and surge barriers [CC-EA]. Numbers of people at risk from coastal land loss have been estimated on a regional basis (Nicholls and Tol, 2006; Ericson *et al.*, 2006; Nicholls *et al.*, 2011) yet projections of resulting anticipatory migration or permanent versus temporary displacement are not available.

Taken together, these studies indicate that climate change will bear significant consequences for migration flows at particular times and places, creating risks as well as benefits for migrants and for sending and receiving regions and states (*high confidence*). Urbanization is a pervasive aspect of recent migration which brings benefits but, in the climate change context, also significant risks (see 19.2.3, 19.6.1, 19.6.2; 19.6.3.3; 8.2.2.4). While the literature projecting climate-driven migration has grown recently (Chapter 12.4), there is as of yet insufficient literature to permit assessment of projected region-specific consequences of such migration. Nevertheless, the potential for negative outcomes from migration in such complex, interactive situations is an emergent risk of climate change, with the potential to become a key risk (CC-KR).

19.4.2.2. Risk of Conflict and Insecurity

Violent conflict between individuals or groups arises for a variety of reasons (Section 12.5). Factors such as poverty and economic shocks that are associated with a higher risk of violent conflict are themselves sensitive to climate change and variability (*high confidence*; Sections 12.5.1, 12.5.2; 13.2). In this section, we focus on evidence for the magnitude of a climate effect on violent conflict in order to assess its potential to become a key risk.

The only meta-analysis of the literature (Hsiang *et al.*, 2013), examining 60 quantitative empirical studies generally published since AR4, implicates climatic events as a contributing factor to the onset or intensification of several types of personal violence, group conflict and social instability in contexts around the world, at temporal scales ranging from a climatologically anomalous hour to an anomalous millennium and at spatial scales ranging from the individual level (Vrij *et al*., 1994; Ranson, 2012) to the communal level (Hidalgo *et al.*, 2010; O'Loughlin *et al*., 2012) to the national level (Burke *et al*., 2009; Dell *et al*., 2012) to the global level (Hsiang *et al.*, 2011). Nevertheless, some individual studies have been unable to obtain evidence that violence has a statistically significant association with climate (Buhaug, 2010; Theisen *et al.* 2011). In detection and attribution of their impact on human conflict, there is *low confidence* that climate change has an effect (Section 18.4.6) and *medium confidence* that climate variability has an effect.

Evidence suggests that climatic events over a large range of time and spatial scales contribute to the likelihood of violence through multiple pathways discussed in section 12.5 (Scheffran *et al*., 2012; Bernauer *et al.*, 2012; Hsiang and Burke, 2013). Results from modern contexts (1950-2010) indicate that the frequency of violence between individuals rises 2.3% and the frequency of intergroup conflict rises 13.2% for each standard deviation change towards warmer temperatures (Hsiang *et al.*, 2013). Because annual temperatures around the world are expected to rise 2-4 standard deviations (as measured over 1950-2008) above temperatures in 2000 by 2050 (A1B scenario) (Hsiang *et al.*, 2013), there is potential *ceteris paribus* for large relative changes to global patterns of personal violence, group conflict and social instability in the future.

Social, economic, technological, and political changes that might exacerbate or mitigate this potential impact are discussed in Chapter 12. These changes may cause future populations to respond to their climate differently than modern populations; however the influence of climate variability on rates of conflict is sufficiently large in magnitude that such advances may need to be dramatic to offset the potential influence of future climate changes.

The effect of climate change on conflict and insecurity has the potential to become a key risk because factors such as poverty and economic shocks that are associated with a higher risk of violent conflict are themselves sensitive to climate change (*medium confidence*; Sections 12.5.1, 12.5.2, 13.2) and in numerous statistical studies the influence of climate variability on human conflict is large in magnitude (*medium confidence*).

19.4.2.3. Risks Associated with Species Range Shifts

One of the primary ways species adapt to climate change is by moving to more climatically suitable areas (range shifts). These shifts will affect ecosystem functioning, potentially posing risks to ecosystem services (Dossena *et al.*, 2012; Millennium Ecosystem Assessment, 2005; *medium confidence*), including those related to climate regulation and carbon storage (Wardle *et al.*, 2011). One example of a key impact is the warming-driven expansion and intensification of Mountain pine beetle (*Dendroctonus ponderosae*) outbreaks in North American pine forests and its current and projected impacts on carbon regulation and economies (Section 26.4.2.1). Risks also arise from projected range shifts of important resource species (e.g. marine fishes; Sections 6.3.6, 6.4.6.1), as well as from potential introductions of diseases to people, livestock, crops and native species (see Sections 7.3.2.3, 28.2.3, 23.4.2, 26.6.1.6, 5.4.2.3, 22.3.5). Many newly arrived species prey on, outcompete or hybridize with existing biota (e.g., by becoming weeds or pests in agricultural systems, Section 4.2.4.6) . The ecological implications of species reshuffling into novel, no-analogue communities largely remain unknown and pose additional risks that cannot yet be assessed (Root and Schneider 2006; Sections 6.5.3, 19.5.1, 21.4.3).

Current legal frameworks and conservation strategies face the challenge of untangling desirable species range shifts from undesirable invasions (Webber and Scott, 2012), and identifying circumstances when movement should be facilitated versus inhibited. New agreements may be needed recognizing climate change impacts on existing, new, or altered trans-boundary migration, (e.g., under the Convention on Migratory Species). As target species and ecosystems move, protected area networks may become less effective, necessitating re-evaluation and adaptation, including possible addition of sites, particularly those important as either 'refugia' or migration corridors (Warren *et al*., 2013a; Sections 9.4.3.3, 24.4.2.5, 24.5.1). Assisted colonisation – moving individuals or populations from currently occupied areas to locations with higher probability of future persistence – is arising as a potential conservation tool for species unable to track changing climates (Sections 4.4.2.4, 21.4.3). The value of these approaches, however, is contested and implementation is very limited giving *low confidence* that this would be an effective technique (Loss *et al.*, 2011). *Ex situ* collections (Section 4.4.2.5) have often been put forward as fall-back resources for conserving threatened species, yet the expense and the relatively low representation of global species and genetic diversity (Balmford *et al*., 2011; Conde *et al.*, 2011) minimizes the effectiveness of this technique.

19.4.3. Indirect, Trans-Boundary, and Long-Distance Impacts of Mitigation Measures

Mitigation, too, can have unintended consequences beyond its boundaries, which may affect natural systems and/or human systems. If mitigation involves a form of land use change, then regional implications can ensue in the same way as they can for adaptation (see Section 14.7).

Mitigation can potentially reduce direct climate change impacts on biodiversity (Warren *et al.*, 2013a). However, impacts on biodiversity as a result of land use change induced by biofuel production can offset benefits associated with biofuels (see Box 4.1, Sections 4.2.4.1, 9.3.3.4, 19.3.2.2, 22.6.3, 24.6, Box 25-10, 27.2.2.1). Climate change mitigation through 'clean energy' substitution can also have negative impacts on biodiversity. However, attention to siting and monitoring can decrease some negative ecological and socioeconomic impacts (*medium confidence*) while maximizing positive ones (Section 4.4.4). For example, the U.S. Government performed an intensive study of suitable sites for solar power on public lands in the western U.S. The end result opened 285,000 acres of public land for large-scale solar deployment while blocking development on 78 million acres to protect "natural and cultural" resources (US BLM, 2012). The construction of large hydroelectric dams can affect both terrestrial and aquatic ecosystems along river systems (World Commission on Dams, 2000; Sections 3.7.2.1, 4.4.4, 24.4.2.3, 24.9.1).

Mitigation strategies will have a range of effects on human systems. Reforestation that properly mimics existing forest ecosystems in structure and composition would potentially benefit human systems by stabilizing micro-climatic variation (Canadell and Raupach, 2008) and allowing benefits from the sustainable harvest of non-timber forest products for food, medicine and other marketable commodities (Guariguata *et al.*, 2010). However, there is a generally longer time frame and greater expense involved in recreating a diverse forest system. Afforestation creates a similar set of costs and benefits (Sections 3.7.2.1, 17.4.1, 22.3.2.1, 22.6.3). Mitigation strategies designed to reduce dependence on carbon-intensive fuels present a very different set of circumstances in relation to human systems. The development of alternative and renewable energy sources will have significant economic and market effects potentially influencing food prices (see also Section 19.4.1). This would especially affect populations that already devote a considerable portion of their household income to food (Hymans and Shapiro, 1976).

19.5. Newly Assessed Risks

Newly assessed risks are those for which the evidence base in the scientific literature has only recently become sufficient to allow for assessment. Furthermore, these risks have at least the potential to become key based on the criteria in 19.2.2. Several of the emergent risks discussed in sections 19.3 and 19.4., including those associated with human migration [19.4.2.1] and mitigation measures [19.4. 3], can be considered newly assessed. Others are related to diverse aspects of climate change, including the impacts of a large temperature rise, ocean acidification and other direct consequences of CO_2 increases, and the potential impacts of geoengineering implemented as a climate change response strategy.

19.5.1. Risks from Large Global Temperature Rise >4°C Above Pre-Industrial Levels

Most climate change impact studies focus on climate change scenarios corresponding to global mean temperature rises of up to 3.5°C relative to 1990 (slightly more than 4°C above pre-industrial levels) with only a few examples of assessments of temperature rise significantly above that level (Parry *et al.*, 2004; Hare, 2006; Warren *et al.*, 2006; Fischlin *et al.*, 2007; Easterling *et al.*, 2007). Recently the potential for larger amounts of warming has received increasing attention and preliminary assessment of impacts above that level of warming is possible for agriculture, ecosystems, water, health and large-scale singular events. In this section all temperature changes are global and relative to pre-industrial levels. Relevant climate scenarios include those based on RCP8.5, which in 2081-2100 is projected to result in a temperature rise of 4.3+/- 0.7 °C with temperature above 4°C *as likely as not* (WGI section 12.4.1, Table 12.3), and some simulations using SRES A2 and A1FI, which can reach 5.9 and 6.9°C warming, respectively, by 2100 (AR4 WG1 SPM). Literature that uses these scenarios but assumes low climate sensitivity and hence less than 4°C of warming is excluded.

Relatively few studies have considered impacts on cropping systems for scenarios where global mean temperatures increase by 4°C or more (Section 7.4.1). Among these, one indicates substantial reductions in yields in sub-Saharan Africa (Thornton *et al.*, 2011) and another indicates reversal of gains in yields and substantial reductions for Finland (Rötter *et al.*, 2011). Other studies at or below 4 °C anticipate yield losses, particularly in tropical regions, even when taking agronomic adaptations into account (Section 7.5.1.1.1). The possibility of compensation for these losses due to other responses of the food system to impacts on production, such as land use change and adjustment of trade patterns, cannot yet be adequately assessed for a world with GMT>4°C (Sections 19.6.3.4 and 19.4.1).

Assessments of ecological impacts at and above 4°C warming imply a high risk of extensive loss of biodiversity with concomitant loss of ecosystem services (*high confidence*, 19.3.2.1, 4.3.2.5). AR4 estimated that 20-30% of species were likely at increasingly high risk of extinction as global mean temperatures exceed a warming of 2-3°C above pre-industrial levels (*medium confidence*; Fischlin *et al*., 2007); hence 4°C warming implies further increases to extinction risks for an even larger fraction of species. However, there is *low agreement* on the numerical assessment since as more realistic details have been considered in models, it has been shown that extinction risks may be either under- or overestimated when using the simpler models (Section 4.3.2.5), among other reasons due to the existence of microrefugias or to delay in population decline leading to extinction debts (e.g. Dullinger *et al.*, 2012). Additional risks include biome shifts of 400km (Gonzalez *et al*., 2010), the disappearance of analogs of current climates in regions of exceptional biodiversity in the Himalayas, Mesoamerica, E and S Africa, the Philippines and Indonesia (Beaumont *et al.*, 2011), and loss of more than half of the climatically determined geographic ranges of 57+/-6% of plants and 34+/-7% of animals studied (Warren *et al*., 2013a). Widespread coral reef mortality is expected at 4°C due to the concomitant effects of warming and a projected decline of ocean pH of 0.43 since preindustrial times (AR5 WG1 TS, AR5 WGII 5.4.2.4, Box CC-CR, Box CC-OA, *high confidence*). The corresponding CO_2 concentration in such a scenario is more than 900 ppm (AR5 WG1 Figure 12.36) whereas the onset of large scale dissolution of coral reefs is projected if CO_2 concentrations reach 560 ppm (Sections 5.4.1.6, 5.4.2.4, 26.4.2.1).

A number of studies project increases in water stress, flood and drought in a number of regions with > 4°C warming, and decreases in others (Li *et al.*, 2009; Arnell, 2011; Fung *et al.*, 2011; Dankers *et al.*, 2013; Gerten *et al*., 2013; Gosling and Arnell 2013). For example, projections of the proportion of global population exposed to water stress due to climate change range from 5-50% (Gosling and Arnell, 2013) by 2100. The proportion of cropland exposed to drought disaster (one or more months with PDSI drought indicator below -3) is projected to increase from 15% today to 44+/-6% by 2100, based on a range of projections including some that reach or exceed 4°C global warming (Li *et al*., 2009). Concurrently irrigation water demand in currently cultivated areas in the N. hemisphere is projected to rise by 20% in the summer by 2100 under RCP8.5 due to climate change alone (Wada *et al.* 2013), although this could be partly buffered by decreasing evapotranspiration due to plant physiological responses to increased atmospheric CO_2 (Konzmann *et al*., 2013; Box CC-VW). One study (Portmann *et al*., 2013) projects 27-50% of global population affected by a >10% decrease in groundwater recharge, mostly in water stressed arid areas, and although 20-45% also receive a >10% increase, this occurs mainly in areas of low population density where water stress is not an issue. Annual runoff is projected to fall by up to 75% across the Danube, Mississippi, Amazon and Murray Darling river basins, and to increase by up to 100% in the Nile and Ganges basins (Fung *et al.*, 2011) with 4°C warming. Under RCP8.5 in 2100, nine global hydrological models driven by five global circulation models project increases in flood frequency in over half of the land surface, and decreases in roughly a third of the land surface (Dankers *et al*., 2013). According to one study, even if human population remained constant in Europe, without adaptation, 3.5°C –4.8°C global warming by the 2080s would expose an additional 250,000 – 400,00 people to river flooding, doubling economic damages since the 1970s, and expose an additional 851,000 – 5,552,000 to coastal flooding (Ciscar *et al.*, 2011), compared to 36,000 in 1995.

Under 4°C warming most of the world land area will be experiencing 4-7°C higher temperatures than the recent past which means that important tipping points for health impacts may be exceeded in many areas of the world during this century, including coping mechanisms for daily temperature/humidity making potentially large areas seasonally uninhabitable for normal human activities, including growing food or working outdoors [11.8] (*high confidence*). Exceedance of human physiological limits is projected in some areas for a global warming of 7°C, and in most areas for global warming of 11-12°C (*low confidence,* Sherwood and Huber, 2010), a temperature increase that is possible by 2300 (AR5 WGI Figure 12.5).

The risk of large-scale singular events such as ice sheet disintegration, methane release from clathrates, and regime shifts in ecosystems (including Amazon dieback), is higher with increased warming (and therefore higher above 4°C than below it) although there is *low confidence* in the temperature changes at which thresholds might exist for these processes (Section 19.6.3.6; AR5 WGI Sections 12.4.5, 12.5.5, and 13.4). There are also more gradual changes that become large with global temperature rise of 4^0C or more, such as decline in the Atlantic Meridional Overturning Circulation (AMOC) and release of carbon from thawed permafrost (CTP). The AMOC is considered *very likely* to weaken for such warming, with best estimates of loss over the 21^{st} century under RCP8.5 ranging from 36-44% (AR5 WGI Sections 12.4.7.2 and 12.5.5.2). The best estimated range for CTP by 2100 is from 50 to more than 250 PgC for RCP8.5 (AR5 WGI Section 6.4.3.4) although there are large uncertainties. Larger decreases in AMOC and increases in CTP are thus implied for a global warming of above 4°C. Similarly, since a nearly ice-free Arctic Ocean in September before mid-century is *likely* under RCP8.5, by which time projected GMT rise amounts to 2.0 ± 0.4°C above the 1986-2005 baseline (*medium confidence,* AR5 WGI Section 12.4.61), the likelihood is even higher for global warming of above 4°C. Regions of the boreal forest could witness widespread forest dieback (*low confidence*) putting at risk the boreal carbon sink, estimated at 0.5 Pg $year^{-1}$ in 2000-2007 (AR5 WGI Section 12.5.5; AR5 WGII Section 4.3.3.1.1). Forest susceptibility to fire is projected to increase substantially in many areas for the high emissions scenario (RCP 8.5, Box 4-3) and hence larger changes are implied for global warming above 4°C.

Based on the assessment in this section, we conclude that climate change impacts at 4°C and above would be of greater magnitude and more widespread than at lower levels of global temperature rise (*medium evidence, high agreement, high confidence*), extending to higher temperature levels previous findings that risks increase with increasing global average temperature (AR4 WGII SPM.2; NRC, 2011). Few studies yet consider the interactions between these effects, which could create significant additional risks (Warren *et al.*, 2011; Section 19.7.5).

19.5.2. Risks from Ocean Acidification

Ocean acidification is defined as "a reduction in pH of the ocean over an extended period, typically decades or longer, caused primarily by the uptake of carbon dioxide from the atmosphere" (AR5 WGI 3.3.2, Box 3.2; Box CC-OA; see also WGII Glossary). Acidification is a physical and biogeochemical impact resulting from CO_2 emissions that poses risks to marine ecosystems and the societies that depend on them. Research on impacts on organisms, ecological responses, and consequences for ecosystem services is relatively new; the potential for associated risks to become key is magnified by the fact that acidification is a global phenomenon and, without a decrease in atmospheric CO_2 concentration, it is irreversible on century timescales.

It is *virtually certain* that ocean acidification is occurring now (AR5 WGI Section 3.9) and will continue to increase in magnitude as long as the atmospheric CO_2 concentration increases (NRC, 2010). Risks to society and ecosystems result from a chain of consequences beginning with direct effects on biogeochemical processes and organisms and extending to indirect effects on ecosystems, ecosystem services, and society (Figure 19-3). The degree of confidence in assessing risks decreases along this chain due to the complexity of interactions across these scales and the relatively small number of studies available for quantitative risk assessment.

[INSERT FIGURE 19-3 HERE
Figure 19-3: The pathways by which ocean acidification affects marine processes, organisms, ecosystems, and society. The confidence in quantifying the impacts decreases along the pathway.]

Most studies have focused on the direct effects of ocean acidification on marine organisms and biogeochemical processes. The overall effects on organisms can be assessed with *medium confidence* (Section 6.3.2; Box CC-OA), but the effects vary widely across processes (e.g., photosynthesis, growth, calcification; Section 6.3.2) and across organisms and their life stages (Section 6.3.2; Box CC-OA).

Far fewer studies have assessed the impacts on ecosystems (Section 6.3.2.5) and ecosystem services (Section 6.4.1), and most of these studies have focused on the economic impacts on fisheries (Section 6.4.1.1). For example, changes in overall availability and nutritional value of desired mollusk species could affect economies (Narita *et al.*, 2012) and food availability (Section 6.4.1.1). In Table 19-3, we assess the risks to ecosystem services through the impact of acidification on two key marine processes, marine calcification and nitrogen fixation, using the criteria for key risks (19.2.2.2).

[INSERT TABLE 19-3 HERE
Table 19-3: An assessment of the risks to ecosystem services posed by the impacts of ocean acidification on coral calcification and nitrogen fixation, based on the four criteria for key risks (19.2.2.2).]

Based on Table 19-3, the response of coral calcification to ocean acidification and the resulting consequences for coral reefs constitute a key risk to important ecosystem services (*high confidence*). The effect of ocean acidification on marine N_2-fixation could potentially become a key risk, given that it could have potentially large consequences for marine ecosystems, but currently there is *limited evidence* on the likelihood of this risk materializing.

19.5.3. Risks from CO_2 Health Effects

There is increasing evidence that the impacts of elevated atmospheric CO_2 on plant species will affect health via two distinct pathways: the increased production and allergenicity of pollen and allergenic compounds, and the nutritional quality of key food crops. The evidence for these impacts on plant species is increasingly *robust* and recent evidence in the public health literature points to a *medium to high confidence* in the potential for these risks to be sufficiently widespread in geographical scope and large in *magnitude* of their impact on human health to be considered key risks.

Climate change is expected to alter the spatial and temporal distribution of several key allergen-producing plant species (Shea, 2008), and increased atmospheric CO_2 concentration, independent of climate effects, has been shown to stimulate pollen production (Rasmussen, 2002; Clot, 2003; Galán *et al.*, 2005; Garcia-Mozo *et al.*, 2006; Ladeau and Clark, 2006; Damialis *et al.*, 2007; Frei and Gassner, 2008). A series of studies (Ziska *et al.* 2000; Ziska *et al.*, 2003; Ziska and Beggs, 2012) found an association of elevated CO_2 concentrations and temperature with faster growing and earlier flowering ragweed species *(Ambrosia artemisiifolia*) along with greater production of ragweed pollen (Wayne *et al.*, 2002; Singer *et al.*, 2005; Rogers *et al.*, 2006) leading, in some areas, to a measurable increase in hospital visits for allergic rhinitis (Breton *et al.*, 2006). Experimental studies have shown that poison ivy, another common allergenic species, responds to atmospheric CO_2 enrichment through increased photosynthesis, water use efficiency, growth, and biomass. This stimulation, exceeding that of most other woody species, also produces a more potent form of the primary allergenic compound, urushiol (Mohan *et al.*, 2006).

While climate change and variability is expected to affect crop production (see Chapter 7), emerging evidence suggests an additional stressor on the food system: the impact of elevated levels of CO_2 on the nutritional quality of important foods. A prominent example of the effect of elevated atmospheric CO_2 is the decrease in the nitrogen (N) concentration in vegetative plant parts as well as in seeds and grains and, related to this, the decrease in the protein concentrations (Cotrufo *et al.*, 1998; Taub *et al.*, 2008; Wieser *et al.*, 2008). Experimental studies of increasing CO_2 to 550 ppm demonstrated effects on crude protein, starch, total and soluble B-amylase, and single kernel hardiness, leading to a reduction in crude protein by 4 to 13% in wheat and 11 to 13% in barley (Erbs *et al*., 2010). Other CO_2 enrichment studies have shown changes in the composition of other macro- and micronutrients (Ca, K, Mg, Fe, Zn) and in concentrations of other nutritionally important components such as vitamins and sugars (Idso and Idso, 2001). Declining nutritional quality of important global crops is a potential risk that would broadly affect rates of protein-energy and micronutrient malnutrition in vulnerable populations. While there is *medium confidence* that this risk has the potential to become key when judged by its *magnitude* and other criteria (Sections 19.2.2.1, 19.2.2.2) there is currently insufficient information to assess under what ambient CO_2 concentrations this would occur.

19.5.4. Risks from Geoengineering (Solar Radiation Management)

Geoengineering refers to a set of proposed methods and technologies that aim to alter the climate system at a large scale to alleviate the impacts of climate change (WGII Glossary; IPCC, 2012b; AR5 WGI Sections 6.5 and 7.7; WGIII Chapter 6). The main intended benefit of geoengineering would be the reduction of climate change that would otherwise occur, and the associated reduction in impacts (Shepherd *et al.*, 2009). Here we focus on risks, consistent with the goal of this chapter. Although geoengineering is not a new idea (e.g., Rusin and Flit, 1960; Budyko and Miller, 1974; Enarson and Morrow, 1998, and a long history of geoengineering proposals as detailed by Fleming, 2010), it has received increasing attention in the recent scientific literature.

Geoengineering has come to refer to both carbon dioxide removal (CDR, discussed in detail in AR5 WGI Section 6.5, FAQ 7.3) and solar radiation management (SRM; Shepherd *et al.*, 2009; Lenton and Vaughan, 2009; Izrael, 2009; discussed in detail in AR5 WGI, Section 7.7, FAQ 7.3). These distinct approaches to climate control raise very different scientific (e.g., Shepherd *et al.*, 2009), ethical (Morrow *et al.*, 2009; Preston, 2013) and governance (Lloyd and Oppenheimer, 2013) issues. Many approaches to CDR are considered to more closely resemble mitigation rather than other geoengineering methods (AR5 WGI, Chapter 6.5; IPCC, 2012b). In addition, CDR is thought to produce fewer risks than SRM if the CO_2 can be stored safely (AR5 WGI Section 6.5; Shepherd *et al.*, 2009) and unintended consequences for land use, the food system and biodiversity can be avoided (19.4.3). For these reasons, in addition to the more substantial recent literature on SRM's potential impacts, we only address SRM in this section. SRM is a potential key risk because it is associated with impacts to society and ecosystems that could be large in magnitude and widespread. Current knowledge on SRM is limited and our confidence in the conclusions in this section is *low*.

Studies of impacts on society and ecosystems have been based on two of the various SRM schemes that have been suggested: stratospheric aerosols and marine cloud brightening. These approaches in theory could produce large-scale cooling (Salter *et al.*, 2008; Lenton and Vaughan, 2009), although it is not clear that it is even possible to produce a stratospheric sulfate aerosol layer sufficiently optically thick to be effective (Heckendorn et al., 2009; English *et al.*, 2012). Observations of volcanic eruptions, frequently used as an analogue for SRM (Robock *et al.*, 2013), indicate that while stratospheric aerosols can reduce the global average surface air temperature, they can also produce regional drought (e.g., Oman *et al.*, 2005; Oman *et al.*, 2006; Trenberth and Dai, 2007), cause ozone depletion (Solomon, 1999), and reduce electricity generation from solar generators that use focused direct sunlight (Murphy, 2009). Climate modeling studies show that the risk of ozone depletion depends in detail on how much and when stratospheric aerosols would be released in the stratosphere (Tilmes *et al.*, 2008) and find that global stratospheric SRM would produce uneven surface temperature responses and reduced precipitation (Schmidt *et al.*, 2012; Kravitz *et al.*, 2013), weaken the global hydrological cycle (Bala *et al.*, 2008), and reduce summer monsoon rainfall relative to current climate in Asia and Africa (Robock *et al.*, 2008). Hemispheric geoengineering would have even larger effects (Haywood *et al.*, 2013).

The net effect on crop productivity would depend on the specific scenario and region (Pongratz *et al.*, 2012). Use of SRM also poses a risk of rapid climate change if it fails or is halted suddenly (AR5 WGI Section 7.7; Jones *et al.*, 2013), which would have large negative impacts on ecosystems (Russell et al., 2012; *high confidence*) and could offset the benefits of SRM (Goes *et al.*, 2011). There is also a risk of "moral hazard;" if society thinks geoengineering will solve the global warming problem, there may be less attention given to mitigation (e.g., Lin, 2013). In addition, without global agreements on how and how much geoengineering to use, SRM presents a risk for international conflict (Brzoska *et al.*, 2012). Since the direct costs of stratospheric SRM have been estimated to be in the tens of billions of US dollars per year (Robock *et al.*, 2009; McClellan *et al.*, 2012), it could be undertaken by non-state actors or by small states acting on their own (Lloyd and Oppenheimer, 2012), potentially contributing to global or regional conflict (Robock, 2008a; Robock, 2008b). Based on magnitude of consequences and exposure of societies with limited ability to cope, geoengineering poses a potential key risk.

19.6. Key Vulnerabilities, Key Risks, and Reasons for Concern

In this section, we present key vulnerabilities, key risks, and emergent risks that have been identified by many of the chapters of this report based on the material assessed by each in light of criteria discussed in 19.2.2 and 19.2.3. We then discuss dynamic characteristics of exposure, vulnerability and risk, features which are influenced by development pathways in the past, present and future. Illustrative examples of climate-related hazards, key vulnerabilities, key risks and emergent risks in Table 19-4 are representative, having been selected from a larger number provided by the chapters of this report. The table demonstrates how these four categories are related, as well as how they differ, and how they interact with non-climate stressors. The table also provides information on how key risks actually develop due to changing climatic hazards and vulnerabilities. This knowledge is an important prerequisite for effective adaptation and risk reduction strategies that must address climate related hazards, non-climatic stressors and various vulnerabilities that often interact in complex ways and change over time.

19.6.1. Key Vulnerabilities

Several of the risks discussed in this and other chapters and noted in Table 19-4 arise because vulnerable people must cope and adapt not only to changing climate conditions, but to multiple, interacting stressors simultaneously (see Sections 19.3 and 19.4), which means that effective adaptation strategies would address these complexities and relationships.

19.6.1.1. Dynamics of Exposure and Vulnerability

This sub-section deals with the meaning and the importance of dynamics of exposure and vulnerability, while section 19.6.1.3 assesses recent literature regarding observed trends of vulnerability mostly at a global or regional scale. The literature provides increasing evidence that structures and processes that determine vulnerability are dynamic and spatially variable (IPCC, 2012a; and Section 19.6.1.3). SREX states with *high confidence* that vulnerability and exposure of communities or social-ecological systems to climatic hazards related to extreme events are dynamic, thus varying across temporal and spatial scales due to influences of and changes in social, economic, demographic, cultural, environmental, and governance factors (IPCC, 2012c, SPM.B).

Examples of such dynamics in exposure and vulnerability encompass, e.g. population dynamics, such as population growth or changes in poverty (Table 19-4; Birkmann *et al.*, 2013b) and increasing exposure of people and settlements in low lying coastal areas or flood plains in Asia (see Nicholls and Small, 2002; Fuchs *et al.*, 2011; IPCC, 2012a; Peduzzi *et al*., 2012). Also, demographic changes, such as aging of societies, have a significant influence on people's vulnerability to heat stress (see Stafoggia *et al*., 2006; Gosling *et al*., 2009). Changes in poverty or socio-economic status, ethnic compositions as well as age structures had a significant influence on the outcome of past crises and in addition were modified and reinforced through disasters triggered by climate and weather related hazards. For the United States for example, Cutter and Finch (2008) found that social vulnerability to natural hazards increased over time in some areas due to changes in socio-economic status, ethnic composition, age, and density of population. Changes in the strength of social-networks (e.g., resulting in social isolation of elderly) and physical abilities to cope with such extreme events modify vulnerability (see e.g. Khunwishit and Arlikatti, 2012).

In some cases human vulnerability might also change in different phases of crises and disasters. Hence, the factors that might determine vulnerability before a crisis or disaster (drought crises, flood disaster) might differ from those that determine vulnerability thereafter (post-disaster and recovery phases). Disaster response and reconstruction processes and policies can modify exposure and vulnerability e.g. of coastal communities (Birkmann and Fernando, 2008; Birkmann, 2011). A comprehensive assessment of vulnerability would account for these dynamics by evaluating long-distance impacts (e.g., resulting from migration or global influence of regional crop production failures following floods) and multiple-stressors (e.g. recovery policies after disasters) that often influence dynamics and generate complex crises and even emergent risks. Furthermore, the SREX also underscores that the increased intensity, frequency and duration of some extreme events as climate continues to change, might make adaptation based only on recent experience or the extrapolation of historical trends largely ineffective (Lavell *et al*., 2012, p. 44-47); hence understanding the dynamics of vulnerability and its different facets is crucial.

19.6.1.2. Differential Vulnerability and Exposure

Wealth, education, ethnicity, religion, gender, age, class/caste, disability, and health status exemplify and contribute to the differential exposure and vulnerability of individuals or societies to climate and non-climate related hazards (see IPCC, 2012a). Differential vulnerability is, for example, revealed by the fact that people and communities that are similarly exposed encounter different levels of harm, damage and loss as well as success of recovery (see Birkmann, 2006). The uneven effects and uneven suffering of different population groups and particularly marginalized groups is well documented in various studies (Bohle *et al.*, 1994; Kasperson and Kasperson, 2001; Thomalla *et al.*, 2006; Birkmann, 2006a; Sietz *et al.*, 2011; Sietz *et al.*, 2012). Factors that determine and influence these differential vulnerabilities to climate-related hazards include, e.g. ethnicity (Fothergill *et al.*, 1999; Elliott and Pais, 2006; Cutter and Finch, 2008), socioeconomic class (O'Keefe *et al.*, 1976; Peacock, 1997; Ray-Bennett, 2009), gender (Sen, 1981), age (Jabry, 2003; Wisner, 2006; Bartlett, 2008) as well as migration experience (Cutter and Finch, 2008) and homelessness (Wisner, 1998; IPCC, 2012a). Differential vulnerabilities of specific populations can often be discerned at a particular scale using quantitative or qualitative assessment methodologies (Cardona, 2006; Cardona, 2008; Birkmann *et al.*, 2013b). Various population groups are differentially exposed to and affected by hazards linked to climate change in terms of both gradual changes in mean properties and extreme events. For example, in urban areas, marginalized groups (particularly due to gender or wealth status or ethnicity) often settle along rivers or canals where they are highly exposed to flood hazards or potential sea-level rise (see Table 19-4) (e.g., Neal and Phillips, 1990; Enarson and Morrow, 1998; Neumayer and Plümper, 2007; Sietz *et al*., 2012). Studies emphasize that vulnerability in terms of gender is not determined through biology, but in most cases by social structures, institutions and rule systems; hence women and girls are often (not always) more vulnerable due to the fact that they are marginalized from decision making or experience discrimination in development and reconstruction efforts (Fordham, 1998; Houghton, 2009; Sultana, 2010; IPCC, 2012a).

19.6.1.3. Trends in Exposure and Vulnerability

Vulnerability and exposure of societies and social-ecological systems to hazards linked to climate change are dynamic and depend on economic, social, demographic, cultural, institutional, and governance factors (see IPCC, 2012c, p.7). The literature shows that there is a *high confidence* that rapid and unsustainable urban development, international financial pressures, increases in socioeconomic inequalities, failures in governance (e.g. corruption), and environmental degradation are key trends that modify vulnerability of societies, communities and social-ecological systems (Maskrey, 1993a; Maskrey, 1993b; Maskrey, 1994; Mansilla, 1996; Maskrey, 1998; Cannon, 2006; Birkmann, 2013; de Sherbinin, 2013) at different scales. Consequently, many of the factors that reveal and determine differential vulnerability change over time in terms of their spatial distribution. These dynamics unfold in different places differently and therefore local or regional specific strategies are needed that strengthen resilience (Garschagen and Kraas, 2011; Holdschlag and Ratter, 2013) and reduce exposure and vulnerability. For example, countries characterized by rapid urbanization coupled with low economic performance and high social development barriers face amongst the highest levels of climate change vulnerability. However, urbanization in some areas can yield conditions conducive to building up coping and adaptation capacities particularly when urban socio-economic development and risk management is properly implemented (see Garschagen and Romero-Lankao, 2013). The following section outlines observed trends in vulnerability according to different thematic dimensions (e.g., socio-economic, environmental, institutional), within the constraint that relevant socioeconomic data is limited.

19.6.1.3.1. Trends in socioeconomic vulnerability

Poverty is a critical factor determining vulnerability of societies to climate change and extreme events (Section 13.1.3). For example, risk due to droughts – particularly in sub-Sahara Africa - is intimately linked to poverty and rural vulnerability (see UNISDR, 2011, p. 62; Birkmann *et al.*, 2011b; Welle *et al.*, 2012; World Bank, 2010; *high confidence*). In interpreting the following estimates, it should be borne in mind that diverse concepts of poverty lead to different estimates but that for some regions, e.g., sub-Saharan Africa, the trends are *robust*. Recent evaluation of conditions in 119 countries found that at the international level there had been a clear decrease in global poverty over the previous six years (Chandy and Gertz, 2011). The number of poor people globally fell, from over 1.3 billion in 2005 to under 900 million in 2010. This trend is expected to continue (e.g. Chandy and Gertz 2011; Hughes *et al.*, 2009). However, regional trends vary, as do differences between emerging and least developed economies. As a result, there is a growing climate-related risk in some regions associated with chronic poverty. For example, approximately 47% of the population of the highly drought exposed region sub-Sahara Africa still lives in poverty (poverty headcount ration at $1.25 per day; see World Bank 2012) and this area already has been defined as a global risk hotspot (see Birkmann *et al.*, 2011b; Welle *et al.*, 2012). However, various national-level poverty statistics provide little information about the actual distribution of poverty, for example between rural-versus-urban areas. Income distribution trends show significant increases in inequality in some countries in Africa, and particularly in Asia, such as in China, India, Indonesia and Bangladesh (World Bank, 2012). In Asia and South East Asia this trend overlaps with areas of compound climate risk (19.3.2.4) in terms of people currently exposed to floods and tropical cyclones as well as sea-level rise (Förster *et al.*, 2011; Peduzzi *et al.*, 2012; IPCC, 2012a). Assessing vulnerability (and risk) in these countries requires in-depth analysis of trends and distribution patterns of poverty, income disparities and exposure of people to changing climatic hazards.

New socio-economic vulnerabilities are emerging in some countries, for example in developed countries, where the impoverishment of some population groups is observed. For example, research underscores that old age increases the risk of poverty in Greece, since the majority of people working as farmers or in the private sector receive small pensions which are below the poverty line (Karamessini, 2010, p. 279). These factors might interact with limited physical means of elderly to cope with climatic hazards, such as heat waves, and hence increase vulnerability.

Health status of individuals and population groups affects vulnerability to climate change by limiting capacities to cope and adapt to climate hazards (see Chapter 11). Although at a global scale the percentage of people undernourished is decreasing (FAO, 2012) and this trend is expected to continue (Hughes *et al.*, 2009), the regional and national differences are significant: during 2010-12, 870 million people remained chronically undernourished (FAO, 2012). Particularly in certain regions highly exposed to current and projected climate-related hazards, the number of people undernourished has increased. In Sub-Sahara Africa where exposure to drought is episodically high, the number of undernourished increased by 64 million or about 38% during 2010-12 compared to 1990-92 (FAO, 2012, p. 10; Hughes *et al.*, 2009). Moreover, at many locations, climate change is expected to reduce the access to and the quality of natural resources that are important to sustain rural and urban livelihoods as well as the capacities of states to provide help to sustain livelihoods (Barnett and Adger 2007; Section 19.3.2.1). These multi-risk contexts require new approaches for climate change adaptation.

While these trends mainly point to particularly large exposure and vulnerability in developing countries, studies regarding extreme heat vulnerability, for example, underscore that developed countries face increasing challenges to adaptation as well. Heat waves are projected to increase in duration, intensity, and extent (AR5 WGI 11.3.2). Advanced age represents one of the most significant risk factors for heat-related death (Bouchama and Knochel, 2002), since in addition to limited thermoregulatory and physiologic heat-adaptation capacities, elderly have often reduced social contacts, and higher prevalence of chronic illness and poor health (Section 11.3.3; Khosla and Guntupalli, 1999; Klinenberg, 2002; O'Neill, 2003). The trend towards an aging society, for example in Japan or Germany, therefore increases the vulnerability of these societies to extreme heat stress.

19.6.1.3.2. Trends in environmental vulnerability

Societies depend on ecosystem services for their survival; however, these ecosystem services and functions (see e.g. Millenium Ecosystem Assessment, 2005) are vulnerable to climate change (see Cardona *et al*., 2012, p. 76-77; Table 19-4; Section 19.3.2.1). Various societies and communities that rely heavily on the quality of ecosystem services, such as rural populations dependent on rain fed agriculture where drying is projected (see also Table 19-4), will experience increased risk from climate change due to its negative influence on ecosystem services (see Sections 4.3.4 and 6.4.1, *high confidence*). Although no global overview is available, recent reports (UNDP, 2007; IPCC, 2012a) underscore that a number of current environmental trends threaten human wellbeing and thus increase human vulnerability (UNEP, 2007). Many communities that have suffered large losses due to extreme weather events - for example coastal flooding - also experienced earlier degradation of ecosystems providing protective services. Recent global studies and local studies, such as for the US East Coast, underscore that intact ecosystems, such as marshes, can have an important protective role against coastal hazards e.g. by wave attenuation (Beck *et al.*, 2013; Shepard *et al.*, 2011). Hence, coastal degradation, such as destruction of coral reefs in Asia, is increasing the exposure of communities to such hazards (Welle *et al.*, 2012). Moreover, the extinctions of species and the loss of biodiversity pose a threat of diminution of genetic pools that otherwise buffer the adaptive capacities of social-ecological systems dependent on these services in the medium and long-run (e.g. in terms of medicine and agricultural production).

19.6.1.3.3. Trends in institutional vulnerability

Institutional vulnerability refers, among other issues, to the role of governance. Governance is increasingly recognized as a key factor that influences vulnerability and adaptive capacity of societies and communities exposed to extreme events and gradual climate change (Kahn, 2005; Nordås and Gleditsch, 2007; Welle *et al.*, 2011). People in countries or places that are facing severe failure of governance, such as violent conflicts (e.g. Somalia, Afghanistan) are particularly vulnerable to extreme events and climate change, since they are already exposed to complex emergency situations and hence have limited capacities to cope or undertake effective risk management (see Ahrens and Rudolph, 2006; Menkhaus 2010). Countries classified as failed states are often not able to guarantee their citizens basic standards of human security and consequently do not provide adequate or any support in crises or disaster situations for vulnerable people. The Failed State Index (Fund for Peace, 2012; Foreign Policy, 2012) as well as the Corruption Perception Index (Transparency International, 2012) are used to characterize institutional vulnerability and governance failure. Trends in the Failed State Index from 2006 to 2011 show that countries with severe problems in the functioning of the state cannot easily shift or change their situation (*persistence* of institutional vulnerability). Studies at the global level also confirm that countries classified as failed states and affected e.g. by violence are not able to effectively reduce poverty compared to countries without violence (see World Bank, 2011). Countries characterized in the literature as substantially failing in governance or in some particular aspects of governance during some period, such as Somalia and Ethiopia, Afghanistan, or Haiti have shown in the past severe difficulties in dealing with extreme events or supporting people that have to cope and adapt to severe droughts, storms or floods (see e.g. Lautze *et al.*, 2004; Ahrens and Rudolph, 2006; Menkhaus, 2010, p. 320-341; Heine and Thompson, 2011; Khazai *et al.*, 2011, p. 30-31). In addition, climate change is also likely to undermine the capacity of some states to provide the services and support that help people to sustain their livelihoods in a changing climate (Barnett and Adger, 2007). Governance failure and violence as characteristics of institutional vulnerability have significant influence on socio-economic, and therefore climatic vulnerability. Furthermore, corruption has been identified as an important factor that hinders effective adaptation policies and crisis response strategies (Birkmann *et al.*, 2011b; Welle *et al.*, 2012). At the local level, various aspects of governance in developing and developed countries, particularly institutional capacities and self-organization as well as political and cultural factors, are critical for social-learning, innovations and actions that can improve risk management and adaptation to climate related risks and for empowering highly vulnerable groups (IPCC, 2012a).

Overall, unless governance improves in countries with severe governance failure, risk will increase and human security will be further undermined there as a result of climate change and increased human vulnerability (Lautze *et al.*, 2004; Ahrens and Rudolph 2006, Barnett and Adger, 2007; Menkhaus 2010; *high confidence*).

19.6.1.4. Risk Perception

Risk perceptions influence the behavior of people in terms of risk preparedness and adaptation to climate change (Burton *et al.*, 1993; van Sluis and van Aalst, 2006; IPCC, 2012a). Factors that shape risk perceptions and therewith also influence actual and potential responses (and thus exposure, vulnerability and risk) include a) interpretations of the threat, including the understanding and knowledge of the root cause of the problem, b) exposure and personal experience with the events and respective negative consequences, particularly recently (i.e., availability) c) priorities of individuals, d) environmental values and value systems in general (see e.g. O'Connor *et al.*, 1999; Grothmann and Patt, 2005; Weber, 2006; Kuruppu and Liverman, 2011). Furthermore, the perceptions of risk and reactions to such risk and actual events are also shaped by motivational processes (Weber, 2010). In this context people will often ignore predictions of climate-related hazards if those predictions fail to elicit emotional reactions. In contrast, if the event or forecast of such an event elicits strong emotional feelings of fear, people may overreact and panic (see Slovic *et al.*, 1982; Slovic, 1993; Slovic, 2010; Weber, 2006). Public perceptions of risks are not solely determined by the "objective" information, but rather are the product of the interaction of such information with psychological, social, institutional, and cultural processes and norms which are partly subjective, as demonstrated in various crises in the context of extreme events (Kasperson *et al.*, 1988; Sagiya, 2011; Funabashi and Kitazawa, 2012). Risk perceptions particularly influence and increase vulnerability in terms of false perceptions of security (Cardona *et al*, 2012, p. 70). Finally, it is important to acknowledge that everyday concerns and satisfaction of basic needs may prove more pressing than attention and effort toward actions to address longer-term risk factors e.g., climate change (Maskrey, 1989; Wisner *et al.*, 2004; Maskrey, 2011). Rather, peoples' worldviews and political ideologies guide attention toward events that threaten their preferred social order (Douglas and Wildavsky, 1982; Kahan, 2010).

19.6.2. Key Risks

19.6.2.1. Assessing Key Risks

Key risks arise from the interaction of climate-related hazards and key vulnerabilities of societies, communities, or systems exposed (see Figure 19-1). Various chapters in this report have assessed key risks from their particular perspectives. We asked each chapter author team to provide Chapter 19 authors with the key risks of highest concern to their chapter based on the criteria for defining key risks and key vulnerabilities as outlined in 19.2.2. A complete presentation of the key risks provided by chapters is found in CC-KR (allowing for some condensation by authors of Chapter 19 to avoid repetition). The key risks provided by the chapters represent the issues most pressing to each set of experts. The list is neither unique nor exhaustive: other authors might express other preferences; however, this compilation provides important insights about key risks and their determinants: hazard, exposure, and vulnerability. Chapter 19 authors further consolidated these key risks in Table 19-4 in order to produce the following list which, in their judgment (*high confidence*), is representative of the range of key risks forwarded to this chapter. Roman numerals preceding each key risk correspond with entries in Table 19-4. Each key risk is followed with a notation in brackets indicating the Reason(s) for Concern (RFCs, see 19.6.3.) with which it is aligned. Additionally, a representative set of lines of sight is provided from across the chapters. Examples of these risks are also displayed geographically in Figure 19-2:

- **(i) Risk of death, injury, and disruption to livelihoods, food supplies, and drinking water, in addition to loss of common-pool resources, sense of place, and identity due to sea level rise, coastal flooding and storm surges affecting high concentrations of people, economic activity, biodiversity, and critical infrastructure in low-lying coastal zones and small island developing states.** These risks further increase in regions where the capacity to adapt long-lived coastal infrastructure (e.g. electricity, water and sanitation infrastructure) to local sea level rise beyond one meter is limited. Urban populations with substandard housing and inadequate insurance, as well as marginalized rural populations with multidimensional poverty and limited alternative livelihoods are particularly vulnerable to these hazards. Inadequate local governmental attention to disaster risk reduction and adaptation can further increase the vulnerability of people and also the risk of adverse consequences (AR5 WGI Sections 3.7.1, 13.5.1, Table 13.5; AR5 WGII Sections 5.4.3, 8.1.4, 8.2.3, 8.2.4, 13.1.4, 13.2.2, 24.4, 24.5, Box 25-1, Box 25-7, 26.7, 26.8, 29.3.1, 30.3.1). [*RFC 1, 2, 3, 4, and 5*]

- **(ii) Risk of food insecurity and the breakdown of food systems linked to warming, drought and precipitation variability particularly in regions that are characterized by poorer populations in urban and rural settings. This risk is a particular concern for** farmers who are net food buyers and people in low-income, agriculturally dependent economies that are net food importers). Climatic hazards and the vulnerability of people (see above) may exacerbate malnutrition, giving rise to a larger burden of disease in these groups, especially among elderly and female-headed households having limited ability to cope. The reversal of progress in reducing malnutrition is a potential outcome (AR5 WGI Section 11.3.2; AR5 WGII Sections 7.4, 7.5, 11.3, 11.6.1, 13.2.1, 13.2.2, 19.3.2, 19.4.1, 22.3.4, 24.4, 26.8, 27.3.4). [*RFC 2, 3 and 4*]
- **(iii) Risk of severe harm due to inland flooding and the limited coping and adaptive capacities of large urban populations.** Particularly vulnerable are marginalized and poverty-stricken residents in low-income informal settlements as well as children, the elderly, and the disabled that have limited means to cope and adapt. Risks are increasing due to rapid and unsustainable urbanization especially in areas where risk governance capacities are constrained or limited attention is given to risk reduction and adaptation measures. Also, overwhelmed, aging, poorly maintained and inadequate infrastructure (e.g. drainage infrastructure, electricity, water supply, etc.) can further increase the risk of severe harm and threats to human security in the case of inland flooding (AR5 WGI Section 11.3.2.5; AR5 WGII Sections 3.2.7, 3.4.8, 8.2.3, 8.2.4, 13.2.1, 25.10, Box 25-8, 26.3, 26.7, 26.8, 27.3.5). [*RFC 2 and 3*]
- **(iv) Risk of loss of rural livelihoods and income of rural residents due to insufficient access to drinking and irrigation water, and reduced agricultural productivity, as well as risk of food insecurity, particularly for farmers and pastoralists with minimal capital in semi-arid regions. Interaction of warming and drought with lack of alternative sources of income, and the presence of regional and national conditions that lead to a breakdown of food distribution and storage systems increases risk.** Especially vulnerable are those with limited ability to compensate for losses in water-dependent farming and pastoral systems, as well as those subject to conflict over natural resources. Additionally, insufficient supply of water due to droughts and institutional vulnerabilities (e.g., lack of state capacities, conflicts) for both industry and urban populations lacking running water, yielding severe economic impacts and other harms (AR5 WGI Section 12.4.1, 12.4.5; AR5 WGII Sections 3.2.7, 3.4.8, 3.5.1, 8.2.3, 8.2.4, 9.3.3, 9.3.5, 13.2.1, 19.3.2.2, 24.4). [*RFC 2 and 3*]
- **(v) Systemic risks due to multiple interacting hazards affecting infrastructure in combination with a high dependency of people on critical services (electricity, water supply, health and emergency services) which may break down during extreme events.** Interdependency of critical infrastructure increases the risk of systemic breakdowns of vital services, for example, the risk of failure in systems dependent on electric power (such as drainage systems reliant on electric pumps) during extreme events. Health and emergency services rely on critical infrastructure (e.g. telecommunication) that can be disrupted during such power failures. For example, Hurricane Katrina left 1,220 electricity-dependent drinking water systems in Louisiana, Mississippi, and Alabama inoperable for several weeks (Copeland, 2005). Overly hazard-specific management planning and infrastructure design and/or low forecasting capabilities exacerbate such risks (AR5 WGI 11.3.2; AR5 WGII Sections 8.1.4, 8.2.4, 10.2, 10.3, 12.6, 23.9, 25.10, 26.7, 26.8). [*RFC 2, 3, and 4*]
- **(vi) Risk of loss of marine ecosystems and the services they provide for coastal livelihoods. Biodiversity and coastal ecosystem services important for fishing communities in the tropics and the Arctic are especially at risk due to rising water temperature and the increase of stratification and ocean acidification.** Loss of Arctic sea ice and degradation of coral reefs, as well as other natural barriers, presents a high risk to ecosystem services where many people are exposed to coastal hazards and also depend on coastal resources for livelihoods, such as Alaska, the Philippines and Indonesia (AR5 WGI Section 11.3.3; AR5 WGII Sections 5.4.2, 6.3.1, 6.3.2, 7.4.2, 9.3.5, 22.3.2.3, 25.6, 27.3.3, 28.2, 28.3, 29.3.1, 30.5, 30. 6, CC-OA, CC-CR). [*RFC 1, 2, 3, 4, and 5*]

- **(vii) Risk of loss of terrestrial ecosystems and the services they provide for terrestrial livelihoods. Biodiversity and terrestrial ecosystem services are important for rural and urban communities globally. These services are at risk due to rising temperatures, changes in precipitation patterns, and extreme weather events. Risks are high for communities whose livelihoods depend on provisioning services.** Human and natural systems are susceptible to loss of provisioning services such as food and fibre, regulating services such as water quality, fire and erosion, and cultural services such as aesthetic values and tourism (AR5 WGI Section 11.3.2.5; AR5 WGII Sections 4.3.4, FAQ 4.4, 19.3.2.1, 22.4.5.6, Table 23-2, 27.3.2.1, Box CC-WE). [*RFC 1, 3 and 4*]
- **(viii) Risk of mortality, morbidity, and other harms during periods of extreme heat, particularly for urban populations of the elderly, infants, people with chronic diseases or compromised immune systems, and expectant mothers. Increasing frequency and intensity of extreme heat (including exposure to the urban heat island effect and air pollution) interacts with an inability of some local organizations that provide health, emergency, and social services to adapt to new risk levels for vulnerable groups.** In addition, the impact of heat stress on aging populations, such as during the heat wave disaster in 2003 in Europe, shows how changing climatic conditions interact with trends in population structure, health conditions and social isolation (characteristics of vulnerability) to create key risks [AR5 WGI Section 11.3.2; AR5 WGII Sections 8.2.3, 11.3, 11.4.1, 13.2, 23.5.1, 24.4.6, 25.8.1, 26.6, 26.8, CC-HS). [*RFC 2 and 3*]

An important common characteristic of all key risks associated with anthropogenic climate change is that they are determined by hazards due to changing climatic conditions on the one hand and the vulnerability of exposed societies, communities and social-ecological systems, e.g. in terms of livelihoods, infrastructure, ecosystem services and management/governance systems on the other (see Table 19-4). The compilation of key risks underscores that effective adaptation and risk reduction measures would address all three components of risk (*high confidence*).

[INSERT TABLE 19-4 HERE
Table 19-4: A selection of the hazards, key vulnerabilities, key risks, and emergent risks identified in various chapters in this report (Chapter 4, 6, 7, 8, 9, 11, 13, 19, 22, 23, 24, 25, 26, 27, 28, 29, 30). Key risks are determined by hazards interacting with vulnerability and exposure of human systems, and ecosystems or species. The table underscores the complexity of risks determined by various climate-related hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, unsustainable and rapid urbanization, other demographic changes, failure in governance and inadequate governmental attention to risk reduction, and tolerance limits of species and ecosystems which often provide important services to vulnerable communities, generate the context in which climatic change related harm and loss can occur. The table illustrates that current global megatrends (e.g. urbanization and other demographic changes) in combination and in specific development context (e.g. in low-lying coastal zones), can generate new systemic risks in their interaction with climate hazards that exceed existing adaptation and risk management capacities, particularly in highly vulnerable regions, such as dense urban areas of low-lying deltas. Roman numerals correspond with key risks listed in 19.6.2.1. A representative set of lines of sight is provided from across AR5 WGI and WGII. See Section 19.6.2.1 for a full description of the methods used to select these entries.]

19.6.2.2. The Role of Adaptation and Alternative Development Pathways

As discussed in section 19.2.4, the identification of key risks depends in part on the underlying socio-economic conditions assumed to occur in the future, which can differ widely across alternative development pathways. This section assesses literature that compares impacts across development pathways, compares the contributions of anthropogenic climate change and socio-economic development (through changes in vulnerability and exposure) to climate-related impacts, and examines the potential for adaptation to reduce those impacts. Based on this assessment, risks vary substantially across plausible alternative development pathways and the relative importance of development and climate change varies by sector, region and time period, but in general both are important to understanding possible outcomes (*high confidence)*. In some cases, there is substantial potential for adaptation to reduce risks, with development pathways playing a critical role in determining challenges to adaptation, including through their effects on ecosystems and ecosystem services (Rothman *et al.*, 2013).

Direct comparison of impacts across alternative development pathways shows, for example, that socio-economic conditions are an important determinant of the impacts of climate change on food security, water stress and the consequences of extreme events and sea level rise. The additional effect of climate change and CO_2 fertilization on the number of people at risk from hunger by 2080 generally spans a range of +/- 10-30 million across the four marker SRES scenarios, each of which assumes different socio-economic futures. However, in a scenario (A2) with high population growth and slow economic growth, this effect becomes as high as 120-170 million in some analyses (Schmidhuber and Tubiello, 2007). Similarly, the number of people exposed to water stress in a global study is sensitive to population growth assumptions (Arnell and Lloyd-Hughes, 2013), as are projected water resources in the Middle East under an A1B climate change scenario (Chenoweth et al., 2011). Assessments of the risks from river flooding depend on alternative future population and land use assumptions (Bouwer *et al.*, 2010; te Linde *et al.*, 2011), and sea level rise impacts depend on development pathways through their effect on the exposure of both the population and economic assets to coastal impacts, as well as on the capacity to invest in protection (Anthoff *et al.*, 2010).

The view that development pathways are an important determinant of risk related to climate change impacts is further supported by two other types of studies: those that examine the vulnerability of subgroups of the current population, and those that compare the relative importance of climate and socio-economic changes to future impacts. The first type finds that variation in current socio-economic conditions explains some of the variation in risks associated with climate and climate change, supporting the idea that alternative development pathways, which describe different patterns of change in these conditions over time, should influence the future risks of climate change. For example, socio-economic conditions have been found to be a key determinant of risks to low-income households due to climate change effects on agriculture (Ahmed *et al*., 2009; Hertel *et al.*, 2010), to sub-populations due to exposure to heterogeneous regional climate change (Diffenbaugh *et al.*, 2007), and to low-income coastal populations due to storm surges (Dasgupta *et al.*, 2009). Assessments of environmentally induced migration have concluded that migration responses are mediated by a number of social and governance characteristics that can vary widely across societies (Warner, 2010; see Sections 19.4.2.1, 12.4).

The second type of study finds that within a given projection of future climate change and change in socio-economic conditions, typically both are important to determining risks. In fact, the effect of the physical impacts of climate change on globally-aggregated changes in food consumption or risk of hunger have been found to be small relative to changes in these metrics driven by socio-economic development alone (Schmidhuber and Tubiello, 2007; Nelson *et al.*, 2010; Wiltshire *et al.*, 2013). Similarly, future population growth is found to be an equally (Murray *et al.*, 2012) or more (Fung *et al.*, 2011; Shewe *et al.*, in press) important determinant of globally-aggregated water stress as the level of climate change, and population growth, economic growth, and urbanization are expected to largely drive potential future damages to coastal cities due to flooding (*high confidence*, Section 5.4.3.1; Hallegatte *et al.*, 2013) and to be important determinants of damages from tropical cyclones (Bouwer *et al.*, 2007; Pielke Jr., 2007; Mendelsohn et al., 2012). At the regional level, socio-economic development has also been found to be equally or more important than climate change to impacts in Europe due to sea level rise, through coastal development (Hinkel *et al.*, 2010); heat stress, especially when acclimatization (Watkiss and Hunt, 2012) or aging (Lung *et al.*, 2013) is taken into account; and flood risks, through exposure due to land use and distributions of buildings and infrastructure (Feyen *et al.*, 2009; Bouwer *et al.*, 2010). Climate change was the dominant driver of flood risks in Europe when future changes in the value of buildings and infrastructure at risk were excluded from the analysis (te Linde *et al.*, 2011; Lung *et al.*, 2013) or when biophysical impacts such as stream discharge, rather than its consequences, were assessed (Ward *et al.*, 2011).

Land use is another socio-economic factor that can affect risks in addition to climate change, but until recently few studies have addressed the combined impacts of climate change and land use on ecosystems (Warren *et al.*, 2011). Studies of land use change scenarios alone project a large increase in extinction rates in the coming decades (Sala *et al.*, 2000; Millenium Ecosystem Assessment, 2005). A study of land bird extinction risk found some sensitivity to four alternative land use scenarios, but by 2100 risk was dominated by the climate change scenario (Şekercioğlu, 2008). A study of European land use found that while land use outcomes were more sensitive to the assumed socio-economic scenario, consequences for species depended more on the climate scenario (Berry *et al*., 2006).

Explicit assessments of the potential for adaptation to reduce risks have indicated that there is substantial scope for reducing impacts of several types, but the capacity to undertake this adaptation is dependent on underlying development pathways. Assessments of the impacts of sea level rise, for example, show that if development pathways allow for substantial investment of resources in adaptation through coastal protection, as opposed to accommodation or abandonment strategies, reducing impacts by investing in coastal protection can be an economically rational response for large areas of coastline globally (Nicholls *et al.*, 2008a; Nicholls *et al.*, 2008b; Anthoff *et al.*, 2010; Nicholls and Cazenave, 2010; Hallegatte *et al.*, 2013) and in Europe (Bosello *et al.*, 2012b). For the specific case of sea level rise impacts in Europe, adaptation in the form of increasing dike heights and nourishing beaches, at a cost reaching about €2 billion per year by 2100, was found to reduce the number of people affected by coastal flooding in 2100 from hundreds of thousands to a few thousand per year depending on the socio-economic and sea level rise scenario (A2 vs B1), and total economic damages from about €17 billion to about €2 billion per year (Hinkel *et al.*, 2010). In contrast, in some areas with higher current and anticipated future vulnerability such as low-lying island states and parts of Africa and Asia, impacts are expected to be greater and adaptation more difficult (Nicholls *et al.*, 2011).

Similarly, the risk to food security in many regions could be reduced if development pathways increase the capacity for policy and institutional reform, although most impact studies have focused on agricultural production and accounted for adaptation to a limited and varying degree (Lobell *et al.*, 2008; Nelson *et al.*, 2009; Ziervogel and Ericksen, 2010). A study of response options in Sub-Saharan Africa identified some scope for adapting to climate change associated with a global warming of 2°C above pre-industrial levels (Thornton *et al.*, 2011), given substantial investment in institutions, infrastructure, and technology, but was pessimistic about the prospects of adapting to a world with 4°C of warming (Thornton *et al.*, 2011; see also section 19.7.1). Improved water use efficiency and extension services have been identified as the highest priority agricultural adaptation options available in Europe (Iglesias *et al.*, 2012) and a potentially large role for expanded desalination has been identified for the Middle East (Chenoweth *et al.*, 2011).

19.6.3. Updating Reasons for Concern

The Reasons for Concern (RFCs) are the relationship between global mean temperature increase and five categories of impacts that were introduced in the IPCC TAR (Smith *et al.*, 2001) in order to facilitate interpretation of Article 2 (1.2.3, Box 19-2). In AR4, new literature related to the five RFCs was assessed, leading in most cases to confirmation or strengthening of the judgments about their relevance to defining dangerous anthropogenic interference based on evidence that some impacts were already apparent, higher likelihoods of some climate-related hazards, and improved identification of currently vulnerable populations (Schneider *et al.*, 2007; Smith *et al.*, 2009).

RFCs are related to the framework of key risks, climate-related hazards, and vulnerabilities used in this chapter because each RFC is understood to represent a broad category of key risks to society or ecosystems associated with a specific type of hazard (extreme events, large-scale singular events), system at risk (unique and threatened systems), or characteristic of risk to social-ecological systems (aggregate impacts on those systems, distribution of impacts to those systems). For example, the RFC for extreme events implies a concern for risks to society and ecosystems posed by extreme events, rather than a concern for extreme events *per se*. Accordingly, in this chapter we have reworded the definition of RFCs to emphasize risk.

In this section we assess new literature related to each of the RFCs, concluding that, compared to judgments presented in AR4 and in Smith *et al.* (2009), levels of risk associated with extreme events and distribution of impacts are similar but can be assessed with higher confidence; risks associated with aggregate impacts are similar and confidence in the assessment unchanged; and risks to unique and threatened systems and those associated with large-scale singular events are higher above 2°C (compared to a 1986-2005 baseline), than assessed previously. These judgments are illustrated in Figure 19-4, an updated version of the “burning embers” diagram that describes how the additional risk due to climate change for each RFC changes with increasing GMT. We retain the color scheme employed in previous versions of this figure (Smith *et al.* 2001; Smith *et al.*, 2009) with some refinement. White, yellow, and red indicate neutral, moderate, and high additional risk, respectively. Risk is low in the transition between white and yellow, and substantial in the transition between yellow and red. We add a new color (purple) indicating very high risk as elaborated below.

Sub-sections below assess risks for each RFC and locate transitions between colors using the criteria for key risks as a guide (19.2.2.2). The transition from white to yellow is partly defined by the GMT at which there is at least medium confidence that impacts associated with a given risk are both detectable and attributable to climate change, while also accounting for the magnitude of the risk. We draw on Section 18.6.4 to inform the placement of this transition relative to recent GMT. The transition from yellow to red is defined by increasing magnitude (including pervasiveness) or likelihood of impacts, with high risk (red color) defined as risk of severe and widespread impacts that is judged to be "high" on one or more criteria for assessing key risks (19.2.2.2). The transition from red to purple is defined by very high risk of severe impacts and the presence of significant irreversibilities or persistence of climate-related hazards combined with limited ability to adapt due to the nature of the hazard or impact. As was true in the TAR and Smith et al. (2009), transitions are fuzzy due to uncertainties in a variety of factors determining the relation between GMT and risk, including the rate of climate change, the time at which the temperature is reached, and the extent and agreement of the evidence base in the literature.

We also clarify the concept of RFCs: because risks depend not only on physical impacts of climate change but also on exposure and vulnerability of societies and ecosystems to those impacts, RFCs as a reflection of those risks depend on both factors as well (see also Section 19.1).

19.6.3.1. Variations in RFCs across Socio-Economic Pathways

The determination of key risks as reflected in the Reasons for Concern (RFCs) has not previously been distinguished across alternative development pathways. In the TAR and AR4, RFCs took only autonomous adaptation into account (Smith *et al.*, 2001; Schneider *et al*., 2007, AR4 WGII Chapter 19). However, the RFCs represent risks that are determined by both climate-related hazards and the vulnerability and exposure of social and ecological systems to climate change stressors. Figure 19-5 illustrates this dependence on vulnerability and exposure in a modified version of the burning embers diagram. Current literature is not sufficient to support confident assessment of specific RFCs using this approach.

As literature accumulates, it could inform new versions of this figure applied to specific RFCs. For example, studies that employ particular scenarios of socio-economic conditions could be categorized according to the levels of vulnerability represented by those scenarios (van Vuuren *et al.*, 2012) to locate results along the horizontal axes, while climate conditions assumed in those studies would locate results along the vertical axis. As with previous versions of the burning embers, however, this new figure does not explicitly address issues related to rates of climate change or to when impacts might be realized. The updates of RFCs in 19.6.3.2-19.6.3.6 which follow (and are illustrated in Figure 19-4) do not account for differences in vulnerability across development paths; rather, they are based on the same assessment framework as used in AR4 and Smith *et al.* (2009), but with additional elaboration.

[INSERT FIGURE 19-4 HERE
Figure 19-4: The dependence of risk associated with the Reasons for Concern (RFCs) on the level of climate change, updated from TAR and Smith *et al.* (2009). The color scheme indicates the additional risk due to climate change as described in the text. The shading of each ember provides a qualitative indication of the increase in risk with temperature for each individual "reason." The transition from red to purple, introduced here, is defined by very high risk of severe impacts and the presence of significant irreversibilities or persistence of climate-related hazards combined with limited ability to adapt due to the nature of the hazard or impact. Comparison of the increase of risk across RFCs indicates the relative sensitivity of RFCs to increases in GMT. In general, assessment of RFCs takes autonomous adaptation into account, as was done previously (Smith *et al.*, 2001; Schneider *et al.*, 2007, AR4 WGII Chapter 19). In addition, this assessment took into account limits to adaptation in the case of RFC1, RFC3, and RFC5, independent of the development pathway. The rate and timing of climate change and physical impacts, not illustrated explicitly in this diagram, was taken into account in assessing RFC1 and RFC5. Comments superimposed on RFCs provide additional details which were factored into the assessment. The levels of risk illustrated reflect the judgments of Chapter 19 authors.]

[INSERT FIGURE 19-5 HERE
Figure 19-5: Illustration of the dependence of risk associated with a Reason for Concern (RFC) on the level of climate change and exposure and vulnerability (E&V) of society. This figure is schematic; the degree of risk associated with particular levels of climate change or E&V has not been based on a literature assessment, nor associated with a particular RFC (the “burning ember” in the figure refers generically to any of the embers in Figure 19-4). The E&V axis is relative rather than absolute: “Medium” E&V indicates a future development path in which E&V changes over time are driven by moderate trends in socio-economic conditions. “Low” and “High” E&V indicate futures that are substantially more optimistic or pessimistic, respectively, regarding exposure and vulnerability. Judgments made in other burning ember diagrams of the RFCs (Smith *et al.*, 2001, 2009) including Figure 19-4, which do not explicitly take changes in E&V into account, are consistent with Medium future E&V. Arrows and dots illustrate the use of SRES scenario-based literature to locate particular impact or risk assessments on the figure according to the evolution of climate and socio-economic conditions over time. This figure does not explicitly address issues related to the rates of climate change or when impacts might be realized.]

19.6.3.2. Unique and Threatened Systems

Unique and threatened systems include a wide range of physical, biological and human systems that are restricted to relatively narrow geographical ranges and are threatened by future changes in climate (Smith *et al.*, 2001). Where consequences are *irreversible* and *importance* to society and other systems is high, the potential for loss of or damage to such systems constitutes a key risk. AR4 stated with *high confidence* that a warming of up to 2°C above preindustrial levels would result in significant impacts on many unique and vulnerable systems and would increase the endangered status of many threatened species, with increasing adverse impacts (and increasing confidence in this conclusion) at higher temperatures (Schneider *et al.*, 2007). Since AR4, there is a growing body of literature suggesting that the number of threatened systems and species is greater than previously thought.

Chapters 4, 22, 23, 24, 25, 26, and 27 highlight areas where unique and threatened systems are particularly vulnerable to climate change. Evidence for severe and widespread impacts to humans and social systems, ecosystems and species in polar regions as warming progresses has continued to accrue (Sections 4.3.3.4, 28.2). Projections of Arctic sea ice melt rates have increased since AR4 (WGI Section 12.4.6), increasing risks to the Inuit and the sea ice-dependent ecosystems upon which they subsist . CMIP5 model runs for September with all RCPs show substantial additional losses of Arctic Ocean ice for a global warming of 1^0C relative to 1986-2005 and a nearly ice-free Arctic Ocean for global warming greater than 2^0C (AR5 WGI Figures 12-30). Futhermore, a nearly ice-free Arctic Ocean in September before mid-century is *likely* under RCP8.5 (*medium confidence*, AR5 WGI Section 12.4.6).

Coral reef ecosystems are still considered amongst the most vulnerable of unique marine systems (Sections 5.4.2.4, 19.3.2.4), with corals’ evolutionary responses being outpaced by climate change (Hoegh-Guldberg, 2012) resulting in projections of extensive reef decline throughout the 21st century. Globally, large-scale reef dissolution may occur if CO_2 concentrations reach 560 ppm (Sections 5.4.2.4) due to the combined effects of warming and ocean acidification. Even if global temperature rise in the 2090s is constrained to 1.2-2.0°C above pre-industrial levels (AR5 WGI Table 12.3, RCP2.6), 9-60% of reefs are projected to be subject to long-term degradation; whilst 30-88% of reefs are projected to eventually degrade if global temperature rises in the 2090s by 1.9-2.9°C above pre-industrial levels (RCP4.5; Box CC-CR, Coral Reefs; temperatures from AR5 WGI Table 12.3). Loss of corals and mangrove ecosystems would endanger the livelihoods of unique human communities and cause economic damage (Section 4.3.3 for global discussion; Sections 22.3.2.3, 24.4.3, 25.6 for Africa, Asia, and Australia; section 26.4 for N. America; section 27.3.3.1 and Figure 27.5 for S. America).

There is a large and increasing amount of evidence for escalating risks of species range loss, extirpation and extinction based on studies for global temperatures exceeding 2°C above pre-industrial levels (1.4°C above 1986-2005; Warren *et al.*, 2011; Şekercioğlu *et al.*, 2012, Foden *et al.*, 2013; Warren *et al*., 2013a). An assessment of 16,857 species (Foden *et al.*, 2013) found that with approximately 2°C of warming above preindustrial (A1B, 2050s), 24-50% of the birds, 22-44% of the amphibians and 15-32% of the corals were highly vulnerable to climate change defined as having high sensitivity, high exposure, and low adaptive capacity.

An increasing number of threatened systems has been identified, in the form of projected species range losses and extinction risks, although without yet tying risks to specific levels of warming. Evidence of climate risks to unique mountain ecosystems and their numerous endemic alpine species has continued to accrue in Europe, Asia, Australia and South America (Sections 23.6.4, 24.4.2.3, 25.6.1, 27.3.2.1). Siberian, tropical, and desert ecosystems in Asia (24.4.2.3), Africa (Warren *et al.*, 2013a), and Mediterranean areas in Europe (Klausmeyer and Shaw, 2009; Maiorano *et al.*, 2011), the Southwest Kakadu, and Queensland rainforests in Australia (Section 25.6.1), Amazonian ecosystems in South America (Foden *et al.*, 2013; Warren *et al.*, 2013a) and freshwater ecosystems in Africa (specifically Ethiopia, Malawi, Mozambique, Zambia and Zimbabwe) (Sections 4.3.3.3, 22.3.2.2) are particularly at risk, as are the Fynbos and succulent Karoo areas of South Africa (Midgley and Thuiller, 2011; Kuhlmann *et al.*, 2012; Huntley and Barnard, 2012) and dune systems in temperate climates (Section 23.6.5). Recent research has identified risks to highly biodiverse tropical wet and dry forests (Sections 4.3.3 and 24.4.2.3; Wright et al., 2009; Kearney *et al.*, 2009, Toms *et al.*, 2012) and tropical island endemics (Fordham and Brook, 2010). Globally amphibians were found to be the most vulnerable of vertebrate taxa (Stuart *et* al., 2004; Brito, 2008; Rohr and Raffel, 2010; Liu *et al*., 2013; Warren *et al.*, 2013a).

Owing to higher projections of sea level rise than in AR4 (AR5 WGI Sections 13.5, 13.6, 13.7), risk of partial inundation of small island states has increased.

Since AR4, almost all glaciers world-wide have continued to shrink as revealed by the time series of measured changes in glacier length, area, volume and mass (*very high confidence*, AR5 WGI Chapter 4 ES). There is substantial new evidence that across most of Asia glaciers have been shrinking, except in some areas in the Karakorum and Pamir (section 18.5.3). In the Andes, glacier loss threatens to reduce the water and electricity supplies of large cities and hydropower projects, as well as the agricultural and tourism sectors (27.3.1.1, 27.3.1.2, Table 27.3, case study 27.6.1). Some climate model simulations show significant loss of glacial cover in central Asia by 2100 under "the higher climate change scenarios considered by IPCC AR4" (Section 24.9.2). Loss of glacial cover has been projected to significantly reduce water supplies in meltwater-dependent arid regions (Kaser, 2010), potentially threatening the food security of 60 million people in the Brahmaputra and Indus basins by the 2050s (Immerzeel *et al.*, 2010). A caveat is that recent work has suggested that glacier melt rates were overestimated and precipitation may increase, so that runoff would rise at least until 2050 (Immerzeel *et al*., 2013). Large uncertainties in projections of Himalayan ice cover and runoff dynamics remain (Bolch *et al.*, 2012).

In Figure 19-4, we locate the transition to moderate risk (white to yellow) below recent global temperatures because there is at least *medium confidence* in attribution of a major role for climate change for impacts on at least one each of ecosystems, physical systems, and human systems (AR5 WGII Section 18.6.4). A transition to purple is located around 2°C above 1986-2005 levels to reflect the very high risk to species and ecosystems projected to occur beyond that level as well as limited ability to adapt to impacts on coral reef systems and on Arctic sea ice-dependent systems (Chapters 4, 24) if that level of warming were exceeded (*high confidence)*. A transition to red is located at 1°C above 1986-2005 levels, midway between current temperature and the transition to purple, indicating the increasing risk to unique and threatened systems, including Arctic sea ice and coral reefs, as well as threatened species as temperature increases over this range.

19.6.3.3. Extreme Events

Extreme weather events (e.g., heat waves, intense precipitation, drought, tropical cyclones) trigger impacts that can pose key risks to societies that are exposed and vulnerable (Lavell *et al*., 2012 (SREX, Chapter 1)). With regard to the physical hazard aspect of risk, AR5 assesses a higher likelihood of attribution of heat waves and extreme hot days and nights to human activity than AR4. AR5 WGI states, "We assess that it is *very likely* that human influence has contributed to the observed changes in the frequency and intensity of daily temperature extremes on the global scale since the mid-20th century" (AR5 WGI 10.6.1.1) and "it is *likely* that human influence has substantially increased the probability of occurrence of heat waves in some locations" (AR5 WGI Section 10.6.2). WGI finds *medium confidence* in attribution of intensification of heavy precipitation over Northern Hemisphere land areas with sufficient data (AR5 WGI Section 10.6.1.2), and *low confidence* in detection and attribution of changes in drought over global land areas (AR5 WGI Section 10.6.1.3) and global changes in tropical cyclone activity (AR5 WGI Section 10.6.1.4) to human influence. There is *high confidence* in attribution of impacts of weather extremes (as opposed to the physical hazards alone) on coral reef systems (Section 18.6.4; Table 18-10; Section 19.6.3.2), with evidence for impact attribution limited and highly localized otherwise.

The likelihood of projected 21st century changes in extremes has not changed markedly since AR4 (AR5 WGI Chapters 10 and 12), but for the first time near-term changes (for the period 2016-2035 relative to 1986-2005) are assessed (AR5 WGI Chapter 1), a period during which the increase in the model and scenario averaged GMT is projected to remain below 1°C relative to 1986-2005 (AR5 WGI Figure 11.8; AR5 WGI Section 11.3.6.3). Among the conclusions are, "In most regions the frequency of warm days and warm nights will *likely* increase in the next decades, while that of cold days and cold nights will decrease" (AR5 WGI Chapter 11 ES). Specifically, 15% of currently observed maximum daily temperatures exceed the historical 90th percentile values (rather than the historical 10%) and by about 2035, 25-30% of daily maximums are projected to exceed the historical 90th percentile value (AR5 WGI Figures 11-17). WGI also notes that "Models project near-term increases in the duration, intensity and spatial extent of heat waves and warm spells" (AR5 WGI Section 11.3.2.5.1, Table SPM.1). With regard to extreme precipitation events, WGI finds "The frequency and intensity of heavy precipitation events over land will *likely* increase on average in the near term. However, this trend will not be apparent in all regions because of natural variability and possible influences of anthropogenic aerosols and land use change" (AR5 WGI Chapter 11 ES). In addition, SREX (Figure SPM 4B) projects a reduction in return period for historical once-in-20-yr precipitation events globally (land only) to about once-in-14-yr or less by 2046-65.

With regard to the vulnerability and exposure aspects of risk, SREX reviewed literature on the relationship between changes in these factors and the risk of extreme events (SREX Sections 4.5.4, 4.5.6). Increases in local vulnerability and exposure to extreme precipitation can lead to a disproportionate increase in overall risk (SREX sections 4.3.5.1, 9.2.8; Douglas *et al.*, 2008; Douglas, 2009; Hallegate *et al.*, 2011; Ranger, 2011). For example, growth of megacities both concentrates exposure and vulnerability and can generate "synchronous failure" that spreads beyond the immediate vicinity of extreme events. Megacities increase nighttime temperature extremes via the urban heat island effect (Section 8.2.3.1; IPCC, 2012a Section 4.4.5.2) while also enhancing exposure to high air pollution levels (Fang *et al*., 2013; IPCC, 2012 Section 9.2.1.2.3) and consequent health effects (Sections 11.5.3.2, 11.5.3.4, Table 11-2), with widespread impacts by midcentury in some studies. Densely populated areas of East and South Asia and North America are projected to be especially affected by climate-related air pollution (Fang *et al.*, 2013). Projections of the global socioeconomic (Mendelsohn *et al.*, 2013) impact of tropical cyclones demonstrate increasing risk due to interactions of increasing storm intensity with exposure. Hazard projection suggests a disproportionate increase in exposure to tropical cyclone risk with increasing temperature at New York City due to combined effects of storm intensification and sea level rise (Lin *et al.*, 2012). Other studies (Jongman *et al.*, 2012; Hallegate *et al*., 2013; Preston, 2013) project increasing coastal flood risk due to increasing exposure, although the first two do not disaggregate to specific types of extreme events. Taken together, this evidence supports a conclusion of disproportionate increase in risk associated with extreme events as temperature, and in many cases, exposure and vulnerability increase as well.

Based on the above assessments of the physical hazard alone, we find increased confidence in the AR4 assessment of the risk from extreme events. Based on the attribution of heat and precipitation extremes to anthropogenic climate change, the attribution to climate change of impacts of climate extremes on one unique and threatened system, and the current vulnerability of other exposed systems, we assign a "yellow" level of risk at recent temperatures in Figure 19-4 [*high confidence*], consistent with Smith *et al.*, (2009). We assign a transition to "red" beginning below 1°C compared to 1986-2005 (also consistent with Smith *et al.*, (2009)) based primarily on the *magnitude* and *likelihood* and *timing* (see 19.2.2.2) of the projected change in hazard of extreme events, indicating that impacts will become more severe and widespread over the next few decades [*medium confidence*].

19.6.3.4. Distribution of Impacts

The distribution of impacts is a category of climate change consequences that includes key risks to particular societies and social-ecological systems that may be disproportionately affected due to unequal distribution of hazards, exposure, or vulnerability. AR4 concluded that there is *high confidence* that low-latitude, less-developed areas are generally at greatest risk and found that, because vulnerability to climate change is also highly variable within countries, some population groups in developed countries are also highly vulnerable even to a warming of less than 2°C above 1990-2000 (Schneider *et al.*, 2007). These conclusions remain valid and are now supported by a limited number of impact studies that explicitly consider differences in socio-economic conditions that affect vulnerability across regions or populations (Müller *et al.* 2011, Mougou *et al.* 2011, Schewe *et al.* 2013, Gosling and Arnell, 2013). Furthermore, we have increased confidence in the AR4 assessment of the risk arising in the near term from the distribution of impacts from extreme events because, by their very nature, these events change in a locally and temporally variable fashion with, e.g., a larger change in extreme temperatures at higher latitudes (SREX Figure SPM 4A).

Impacts of climate change on food security depend on both production and non-production aspects of the food system, including not just yield effects but also changes in the amount of land in production and adjustments in trade patterns (Section 7.1.1). Effects on prices are often taken as an indicator of impacts on food security, and the combined effect of climate and CO_2 change (but ignoring O_3 and pest and disease impacts) appears *about as likely as not* to increase prices by 2050, with few new studies examining prospects at longer time horizons (Section 7.4.4). Most studies have focused on geographical differences in the effects of climate change on crop yields. With regard to such distributional consequences, yields of maize and wheat begin to decline with 1-2^{o}C of local warming in the tropics, with or without adaptation taken into account. Temperate maize and tropical rice yields are less clearly affected at these temperatures, but significantly affected with local warming of 3-5^{o}C particularly without adaptation (based on studies with various baselines, see Section 7.3.2.1). These data confirm AR4 findings that even small warming will decrease yields in low-latitude regions (*medium evidence, high agreement*) (Section 7.3.2.1.1), and increase the risk assigned to yields in mid- to high-latitude regions (compared to AR4), suggesting that temperate wheat yield decreases are *about as likely as not* for moderate warming.

Risks of climate change related to freshwater systems such as extreme water shortage increase with global mean temperature rise (*high agreement, medium evidence*) (Chapter 3 ES, Table 3-2). Climate change is projected to reduce renewable surface water and groundwater resources significantly in most dry subtropical regions (*high agreement, robust evidence)* (Section 3.5). One study using multiple climate and hydrological models to simulate impacts of scenario RCP8.5 and SSP2 project that global warming of 1.7 ^{o}C above pre-industrial will reduce water resources by more than one standard deviation, or by more than 20%, for 8% of the global population, whilst for warming of 2.7 ^{o}C above pre-industrial this increases to 14% (model range 10-30%) (Schewe *et al*., 2013); and for warming of 3.7 ^{o}C above pre-industrial it reaches a mean of 17% across models (Schewe *et al.* 2013). Additionally, in another study (Gosling and Arnell, 2013), climate change amplifies water scarcity by 30-40% for 1.7-2.7 ^{o}C of warming, with around 40% of the global population under increased water stress. In one model, exposure to water scarcity increases steeply up to 2.3^{o}C above pre-industrial in N and E Africa, Arabia and S. Asia (Gosling and Arnell, 2013). In Africa water resources risks are 'medium-high' at 2°C and 'high-very high' at 4°C (Chapter 22 Table 22-6). Model projections generally agree that discharge will decrease in the Mediterranean and in large parts of N. and S. America (Schewe *et al.*, 2013). However, there are opportunities for adaptation in the water resources sector, particular for municipal water supply (Section 3.6.5).

The first global scale analysis of climate change impacts on almost 50,000 species of plants and animals has highlighted that risks are not distributed equally, with sub-Saharan Africa, Central America, Amazonia and Australia at risk for plants and animals, and North Africa, Central Asia and Southeastern Europe for many plants (Warren *et al*., 2013a). A traits-based analysis of more than 16,000 species identified Amazonia and Mesoamerica as being at risk for birds and amphibians and central Eurasia, the Congo Basin, the Himalayas and Sundaland for birds, and the Coral Triangle region for corals (Foden *et al.*, 2013).

In summary, since AR4, new evidence has emerged highlighting the *magnitude* of risk for particular regions, for example in relation to the potential for regional impacts upon ecosystems (see Section 19.6.3.2), megadeltas (see

Sections 8.2.3.4 and Chapter 5], and agricultural systems, which is exacerbated by the potential for changes in the monsoon systems (see Section 19.6.3.5; AR5 WGI 12.5.5.). Overall there is increased evidence that low-latitude and less-developed areas generally face greater risk than higher-latitude and more-developed countries (Smith *et al.*, 2009). At the same time, there has been an increase in appreciation for vulnerability (e.g., to extreme events) in developed countries, especially, localised issues of differential vulnerability in particular areas of the developed world [SREX 2.5.1.2].

Regionally differentiated impacts on crop production have been detected and attributed to climate change *with medium to high confidence* (Section 18.4.1.1), and we interpret this as an early warning sign of attributable impacts on food security. For this reason, as well as for reasons of *timing* and *likelihood* and *magnitude* of these risks, the transition from “white” to “yellow” levels of risk in Figure 19-4 is assessed to occur at recent temperatures. Based on risks to regional crop production and water resources the transition from yellow to red is assessed to occur between 1° and 2°C above the 1986-2005 global mean temperature [*medium confidence*]. Both assessments are consistent with Smith *et al.*, (2009). Furthermore, given evidence that agronomic adaptations would be more than offset for tropical wheat and maize where increases in local temperature of more than 3°C above preindustrial occur (*limited evidence, medium agreement;* Section 7.5.1.1.1; AR5 WGII Chapter 7 ES) the intensity of red increases non-linearly toward purple in recognition of the temperature sensitivity of crop productivity and limited efficacy of agronomic adaptation above 2°C compared to 1986-2005.

19.6.3.5. Aggregate Impacts

The RFC pertaining to aggregate impacts includes risks that are aggregated globally into a single metric, such as monetary damages, lives affected, lives lost, or species or ecosystems lost. Estimates of the aggregate, economy-wide risks of climate change since AR4 continue to exhibit a *low level of agreement*. Studies at the sectoral level have been refined with new data and models, and have assessed new sectors.

AR4 stated with *medium confidence* that approximately 20-30% of the plant and animal species assessed to date are likely at increasing risk of extinction as global mean temperatures exceed a warming of 2-3°C above pre-industrial levels (Fischlin *et al.*, 2007). There is *high confidence* that climate change will contribute to increased extinction risk for terrestrial and marine species over the coming century (Section 4.3.2.5). Since AR4 a substantial amount of additional work has been done, looking at many more species and using new and/or improved modelling and traits-based techniques, strengthening the evidence of increasing risk of extinction with increasing temperature (e.g. Hunter *et al.*, 2010; Amstrup *et al.*, 2010; Pearman *et al.*, 2011; Lenoir *et al.*, 2008; Balint *et al.*, 2011; Barnosky *et al.*, 2012; Norberg *et al.*, 2012; Bellard *et al*., 2012; Foden *et al*., 2013). More studies have scrutinized caveats to previous studies and assesed their role in either under- or overestimating extinction risks (e.g. Beale *et al.*, 2008; Cressey, 2008; Randin *et al.*, 2009; He and Hubbell, 2011; Harte and Kitzes, 2012), including the role of evolution (Norberg *et al.*, 2012), while others have carefully examined risk considering other species traits (looking at exposure, sensitivity and potential adaptive capacity for large numbers of species; Foden *et al*., 2013).Literature incorporating multiple new assessment techniques quantifying extinction risks supports the conclusion that the dependence between increasing extinction risk and temperature is *robust* [*medium confidence]*, albeit varying across biota. However, there is *low agreement* on assigning specific numerical values for species at risk (Sections 19.3.2.1, 19.5.1).

Since AR4 it has been found that species that are widespread geographically, not only endemics (which have tended to be the focus of many previous studies) are at risk (Warren *et al.*, 2013a) implying a significant and widespread potential loss of ecosystem services (Section 4.3.2.5, Gaston and Fuller, 2008; Allesina *et al.*, 2009, Staudinger *et al.* 2012), comprising a new emergent risk (Table 19-4). At a global temperature rise of 3.5-4°C above preindustrial, Foden *et al.* (2013) estimated that 20 - 60% of the birds, amphibians and corals studied are highly vulnerable to climate change. Taking this estimate conservatively as a maximum (i.e., assuming all species not studied are able to adapt at least as well as the groups investigated), and combining this estimate with the finding of >50% loss of potential range in 57% of plants and 34% of animals studied globally for the a global temperature rise of 3.5-4°C by the 2080s allowing for realistic dispersal rates (Warren *et al.*, 2013a), there is *high confidence* that climate change will significantly affect biodiversity, and related ecosystem services.

Much new work has focused on future projected synergistic impacts of climate-change induced increases in fire, drought, disease, and pests (Flannigan *et al.*, 2009; Krawchuk *et al.*, 2009; Hegland *et al.*, 2009; Koeller *et al.*, 2009; Garamszegi, 2011). New work has demonstrated that the expected large turnovers of up to 60% in marine species assemblages in response to unmitigated (SRES A1B and SRES B1) climate change by the 2050s, combined with shrinkage of fish body weight of 14–24% (SRES A2) (Cheung *et al.*, 2009; Cheung *et al.*, 2012) put marine ecosystem functioning at risk with negative consequences for fishing industries, coastal communities and wildlife that are dependent on marine resources (Lam *et al.*, 2012).

Consistent with AR4, global aggregate economic impacts from climate change are highly uncertain, with most estimates a small fraction of gross world product up until at least 2.5°C of warming above preindustrial (Section 10.9.1). Some studies suggest net benefits of climate change at 1°C of warming (10.9.1). Little is known about global aggregate damages above 3°C (Sections 10.9.1, 19.5.1) (Ackerman *et al.*, 2010; Weitzman, 2010; Ackerman and Stanton, 2012; Kopp *et al.*, 2012). Aggregate damages vary with alternative development pathways, but the relationship between development pathway and aggregate damages is not well explored. In many sectors, damages as a fraction of output are expected to be larger in low-income economies, although monetized damages are expected to be larger in high-income economies (e.g., Anthoff and Tol, 2010). Adaptation is treated differently across modeling studies (Hope, 2006; de Bruin *et al.*, 2009; Bosello *et al.*, 2010; Füssel, 2010; Patt *et al.*, 2010) and affects aggregate damage estimates in ambiguous ways.

Estimates of global aggregate damages omit a number of factors (Yohe and Tirpak, 2008; Kopp and Mignone, 2012). While some studies of aggregate damages include market interactions between sectors in a computable general equilibrium framework (e.g., Bosello *et al.*, 2012a; Roson and van der Mensbrugghe, 2012), none treat non-market interactions between impacts (Warren, 2011), such as the effects of the loss of biodiversity among pollinators and wild crops on agriculture or the effects of land conversions owing to shifts in agriculture on terrestrial ecosystems (see sections 19.3, 19.4). They do not include the effects of the degradation of ecosystem services by climate change (19.3.2.1) and ocean acidification (19.5.2), and in general assume that market services can substitute perfectly for degraded environmental services (Kopp *et al.*, 2012; Sterner and Persson, 2008; Weitzman, 2010). The global aggregate damages associated with large-scale singular events (19.6.3.6) are not well explored (Kopp and Mignone, 2012; Lenton and Ciscar, 2013).

The risk associated with aggregate impacts is similar to that expressed in AR4 and Smith *et al.*, (2009) as indicated in Figure 19-4, with risk based primarily on economic damages and confidence in the assessment unchanged. For aggregate economic impacts, there is *low* to *medium* confidence in attribution of climate change influence on a few sectors (AR5 WGII Table 18-11 and Section 18.6.4) so that this RFC is still shaded white at recent temperature in Figure 19-4. The “white” to “yellow” transition occurs around 1°C warming compared to 1986-2005 reflecting increasing confidence that the global aggregate economic impact of climate change will become negative and moderate in magnitude [*medium confidence*]. The “yellow” to “red” transition occurs around 3°C, reflecting an increase in the *magnitude* and *likelihood* of both aggregate economic risks (*low confidence*) and risk of extensive loss of biodiversity with concomitant loss of ecosystem services (*high confidence*, 19.3.2.1).

19.6.3.6. Large-Scale Singular Events: Physical, Ecological, and Social System Thresholds and Irreversible Change

Large-scale singular events (sometimes called “tipping points”, or critical thresholds) are abrupt and drastic changes in physical, ecological, or social systems in response to smooth variations in driving forces (Smith *et al.*, 2001; Smith *et al*., 2009; McNeall *et al*., 2011). Combined with widespread vulnerability and exposure, they pose key risks because of the potential magnitude of the consequences, the rate at which they would occur, and depending on this rate, the limited ability of society to cope with them. Research on the societal impacts associated with such events is limited; we focus in this section on physical hazards and ecological thresholds.

Regarding singular events in physical systems, AR4 expressed *medium confidence* that at least partial deglaciation of the Greenland ice sheet, and possibly the West Antarctic Ice Sheet (WAIS), would occur over a period of time ranging from centuries to millennia for a global average temperature increase of 1-4°C (relative to 1990-2000), causing a contribution to sea-level rise of 4-6 m or more (Schneider *et al.*, 2007). Studies since AR4 are consistent with these judgments but provide a more detailed view (see AR5 WGI Chapter 13). The Greenland ice sheet (*very likely*) and the Antarctic ice sheet (*medium confidence*) contributed to the 5m (*very high confidence*) to 10m (*high confidence*) sea level rise that occurred during the Last Interglacial (AR5 WGI SPM; Kopp *et al.* 2009; McKay *et al.*, 2011; Dutton and Lambeck, 2012). This period provides a partial analog for the magnitude of mid-to-late 21st century warming because GMT was not more than 2°C warmer than pre-industrial (AR5 WGI SPM, *medium confidence*). However, the resulting sea level rise may have taken millennia to complete.

With regard to projection, AR5 WGI finds that "The available evidence indicates that sustained warming greater than a certain threshold above preindustrial would lead to the near-complete loss of the Greenland Ice Sheet over a millennium or more, causing a global mean sea level rise of up to 7 m. Current estimates indicate that the threshold is greater than 1°C but less than 4°C global mean warming with respect to preindustrial, but *confidence* is *low"* (AR5 WGI SPM). A threshold for the disintegration of WAIS remains difficult to identify due to shortcomings in various aspects of ice sheet modeling, including representation of the dynamical component of ice loss and ocean processes. AR5 notes that sea level rise by 2300 larger than 1-3m "could result from sustained mass loss by ice sheets, and some part of the mass loss might be irreversible" (AR5 WGI SPM). Extreme exposure and vulnerability to the *magnitude* of sea level rise associated with loss of a significant fraction of either ice sheet is found worldwide (Nicholls and Tol, 2006) but millennial timescales for ice loss allow greater opportunities to adapt successfully than do century scales so *timing* is a critical and highly uncertain factor in assessing the risk.

There is also additional evidence regarding singular events in other physical systems. Feedback processes in the Earth system could cause accelerated emissions of methane from wetlands, permafrost and ocean hydrates. There are large uncertainties in the size of carbon stores, the timescales of release and the fate of the carbon once released. The risk of substantial carbon release in the form of methane or carbon dioxide increases with warming. (AR5 WGI Section 6.4.7.3, Figure 6.37; Archer *et al*., 2009; O'Connor *et al.*, 2010). AR5 WGI finds "*low confidence* in modelling abilities to simulate transient changes in hydrate inventories, but large CH_4 release to the atmosphere during this century is *unlikely*" (AR5 WGI Section 6.4.7.3). Due to such uncertainties, the existence of a tipping point cannot be ascertained.

AR4 stated that Arctic summer sea ice disappears almost entirely in some projections by the end of the century (AR4 WGI Section 10.3); WGI AR5 finds that a "nearly ice-free Arctic Ocean (sea ice extent less than 1×10^6 km^2) in September before mid-century is *likely* under RCP8.5 (*medium confidence)* but global climate models show no evidence of a tipping point" (AR5 WGI Chapter 12 ES). Whether or not the physical process is reversible, effects of ice loss on biodiversity may not be.

Large uncertainties remain in estimating the probability of a shutdown of the Atlantic meridional overturning circulation (AMOC). One expert elicitation finds the chance of a shutdown to be between 0 and 60% for global average warming between 2-4°C, and between 5 and 95% for 4-8°C of warming relative to 2000 (Zickfeld *et al.*, 2007; Kriegler *et al.*, 2009). AR5 judges that "It is *very unlikely* that the AMOC will undergo an abrupt transition or collapse in the 21st century for the scenarios considered. There is *low confidence* in assessing the evolution of the AMOC beyond the 21st century because of the limited number of analyses and equivocal results. A collapse beyond the 21st century for large sustained warming cannot be excluded" (AR5 WGI SPM).

Regarding regime shifts in ecosystems, there are "early warning signs" from detection and attribution analysis that both Arctic and warm-water coral reef systems are experiencing irreversible regime shifts (Section 18.6.4). Recent observational evidence confirms the susceptibility of the Amazon to drought and fire (Adams *et al.*, 2009), and recent improvements to models provide increased confidence in the existence of a tipping point in the Amazon from humid tropical forest to seasonal forest or grassland as the dominant ecosystem (Jones *et al.*, 2009; Lapola *et al.*, 2009; Malhi *et al.*, 2009; Section 4.3.3.1). In contrast, one recent study suggests that the Amazon may be less susceptible to crossing a tipping point than previously thought (Cox *et al.*, 2013), although this is contingent upon the uncertain role of CO_2 fertilisation being as strong as models project. Overall, recent multi-model estimates based on different CMIP3 climate scenarios and different dynamic global vegetation models predict a moderate risk of tropical forest reduction in South America (AR5 WGI Section 12.4.8.2).

Based on the weight of the above evidence, we judge that the overall risk from large-scale singular events is somewhat higher than assessed in AR4 and indicated by Smith *et al.* (2009). The position of the transition from "white" to "yellow" between 0°C and 1°C compared to 1986-2005 remains as before but with higher confidence due to the existence of early warning signs regarding regime shifts in Arctic and warm-water coral reef systems. The transition from "yellow" to "red" occurs over the 1-4°C range, consistent with Smith et al. (2009) and based primarily on the uncertainty in the warming level associated with eventual ice sheet loss. However, we assess a faster increase in risk as temperature increases between 1°C and 2°C compared to 1986-2005, largely determined by the risk arising from a very large sea level rise due to ice sheet loss as occurred during the Last Interglacial (AR5 WGI Section 5.6.2) when GMT was no more than 2°C warmer than preindustrial (*medium confidence*). This assessment of risk is based primarily on the *magnitude* and *irreversibility* of such sea level rise and the widespread exposure and vulnerability to it. However, as noted, the slower the rate of rise, the more feasible becomes adaptation to reduce vulnerability and exposure. Due to this uncertainty in *timing*, we refrain from imposing a transition to purple in Figure 19-4.

19.7. Assessment of Response Strategies to Manage Risks

The management of key and newly identified risks of climate change can include mitigation that reduces the likelihood of climate changes and physical impacts and adaptation that reduces the exposure and vulnerability of society and ecosystems to both. Key risks, impacts, and vulnerabilities to which societies and ecosystems may be subject will depend in large part on the mix of mitigation and adaptation measures undertaken, as will the evaluation of Reasons for Concern (Section 19.6.3). This section therefore assesses relationships between mitigation, adaptation, and the residual impacts that generate key risks. It also considers limits to both mitigation and adaptation responses, because understanding where these limits lie is critical to anticipating risks that may be unavoidable. Potential impacts involving thresholds for large changes in physical, ecological, and social systems (Section 19.6.3.6) are particularly important elements of key risks, and the section therefore assesses response strategies aimed at avoiding them or adapting to crossing them.

19.7.1. Relationship between Adaptation Efforts, Mitigation Efforts, and Residual Impacts

Under any plausible scenario for mitigation and adaptation, some degree of risk from residual damages is unavoidable (*very high confidence*). Evaluating potential mixes of mitigation, adaptation, and impacts requires joint consideration of outcomes for climate change and socio-economic development. A principal way in which these different mixes are assessed is comparing the impacts that result from scenarios with little or no mitigation (and therefore more climate change) to those with substantial mitigation (and less climate change). Climate change mitigation costs have been extensively explored (AR5 WGIII Chapter 6), but there has been less work on quantifying the impacts avoided by mitigation and, with the exception of studies of the impacts of sea level rise (Nicholls *et al.*, 2011), treatment of adaptation has been limited and uneven. In this section, unless otherwise stated global temperature rise is given relative to pre-industrial levels.

Impact studies generally indicate that mitigation can reduce a large proportion of climate change impacts that would otherwise occur *(high confidence).* In one study, mitigation that stabilizes global CO_2 concentrations at 500ppm reduces by 80-95% the number of people additionally at risk of hunger (largely in Africa) in 2080 under a SRES A2 scenario with CO_2 concentrations of 800ppm, avoiding an estimated 23-34 billion US$ of damage to agricultural output (Tubiello and Fischer, 2007). In Africa, there are much greater impacts upon crop productivity, freshwater resources, and ecosystems at 4^{o}C than 2^{o}C with adaptation failing to reduce risk below a 'high' level at 4^{o}C ('very high' for crop productivity), whereas at 2^{o}C risks are lower and adaptation could reduce these risks to a 'medium' level (Chapter 22 Table 22-6). In North America, with 4^{o}C warming, adaptation is not expected to reduce risks below 'high' for urban flooding (both riverine and coastal) or for fire damage in ecosystems, or below 'medium' for heat-related human mortality. Without adaptation risk is 'very high' for these sectors. In contrast at 2^{o}C risks are 'high' in these sectors, with adaptation expected to reduce urban flooding risk to 'medium' and heat-related human mortality risk to 'low' (Chapter 26 Table 26-1). Impacts on water resources would also be reduced (Chapter 3 Table 3-2). Fung *et al.* (2011) and Gosling and Arnell *et al.* (2013) both found that climate change-induced increases in water stress (defined as persons with <1700 or <1000 m3/capita/yr respectively in the two studies) globally would be reduced significantly were global temperature rise to be constrained to 2°C rather than 3.5 °C. Reducing climate change from an RCP8.5 scenario to and RCP2.6 scenario reduces the proportion of the global population that experiences >10% declines in available groundwater from 27-50% to 11-39% (Portmann *et al*., 2013).

Figure 19-6 highlights results from three studies that estimated the global avoided impacts for multiple sectors when global average temperature is limited to 2ºC rather than following scenarios with no mitigation, such as the SRES A1B or A1FI baseline scenarios in which global average temperature reaches 4 and 5.6°C respectively (Arnell *et al.*, 2013; Warren *et al.*, 2013a; Warren *et al.*, 2013b). The studies isolate the effects of climate change by using common socioeconomic assumptions in mitigation and baseline scenarios. Overall, sector-specific impacts were reduced by 20-80%, with aggregate global economic damages reduced by about one half (Warren *et al*., 2013b). The largest impacts avoided were for crop productivity, drought in cropland, biodiversity, exposure to coastal and pluvial flooding, energy use for cooling, while avoided impacts were smaller for water resources stress. Since some areas become wetter and others drier (AR5 WGI Section 12.4.5) there are regions where climate change results in decreases in flood, drought or water stress. There are shown as the blue bars in Figure 19-6. Avoided impacts are significantly larger when an A1FI baseline is used compared to an A1B baseline (Figure 19-6) because emissions and global temperature rise is greater in the A1FI baseline scenario. All these studies employed an ensemble of climate change projections based on emulation of 7 different GCM models. The proportion of impacts avoided at the global scale was relatively robust to uncertainties in regional climate projection, but the magnitude of avoided impacts varied considerably with climate projection uncertainty.

The timing of emissions reductions strongly affects impacts. In general fewer impacts can be avoided when mitigation is delayed (Arnell *et al*., 2013; Warren *et al*., 2013a; Warren *et al.*, 2013b; Figure 19-6 panel b) because there are limits to how fast emissions can be reduced subsequently to compensate for the delay (19.7.2). For example, if global emissions peak in 2016 and are then reduced at 5% annually, one half of global aggregate economic impacts might be avoided (Figure 19-6, panel b, orange bars), or around 42% if emissions are reduced more slowly at 2% annually (Figure 19-6, panel b, pink bars); compared to only one third if emissions peak in 2030 even if emissions are reduced at 5% thereafter (Warren *et al.,* 2013b, Figure 19-6, panel b, brown bars).

Avoided impacts vary significantly across regions as well as sectors (*high confidence*) due to (a) differing levels of regional climate change, (b) differing numbers of people and levels of resources at risk in different regions, and (c) differing sensitivities and adaptive capacities of humans, species or ecosystems (Tubiello and Fischer, 2007; Ciscar *et al.*, 2011; Arnell *et al.*, 2013; Section 25.10.1). The length of time it takes for avoided impacts to accrue is determined partly by the nature of the climate system. Benefits accrue least rapidly for impacts associated with sea level rise such as coastal flooding, loss of mangroves and coastal wetlands because sea level rise responds very slowly to mitigation efforts (Meehl *et al.*, 2012). Nevertheless, mitigation limits 21st century impacts of increased coastal flood damage, dry land loss and wetland loss substantially (*limited evidence*, *medium agreement*) albeit there is *little agreement* on the exact magnitude of this reduction (Section 5.4.3.1). Benefits accrue more rapidly for impacts associated with global temperature change (AR5 WGI Section 12.5.2) and those associated with reduced ocean acidification since surface pH responds relatively quickly to changes in emissions of CO_2 (Chapter 30 FAQ 30.1).

[INSERT FIGURE 19-6 HERE
Figure 19-6: Panel **a**: Climate change impacts avoided by an early, rapid mitigation scenario in which global emissions peak in 2016 and are reduced at 5% thereafter, compared to two no-mitigation baseline cases SRES A1B (orange bars) and SRES A1FI (red bars). Impacts avoided are larger if the A1FI baseline scenario is used than if the A1B baseline is used, because greenhouse gas emissions in A1FI exceed those in A1B (see 19.7.1). Panel **b**: The dependence of the potential to avoid climate change impacts upon the timing of emission reductions is illustrated. Climate change impacts avoided by the same early, rapid mitigation scenario compared to the no-mitigation baseline case SRES A1B (orange bars) are shown. The information displayed is identical to the orange bars in panel a, but a comparison is now made with the impacts avoided from two other less stringent mitigation scenarios. Impacts avoided if global emissions peak in 2016 but are subsequently reduced more slowly (2% annually) are lower (pink bars compared to orange bars). However, if mitigation occurs later, so that global emissions do not peak until 2030, even if emissions are subsequently reduced at 5% annually, the avoided impacts are smaller than in either of the

other two cases (brown bars compared to orange and pink bars). Both panels show the uncertainty range (error bars) due to regional climate change projected with 7 GCMs. Errors due to uncertainty within impacts models are not shown. Uncertainties associated with sea level rise related impacts are smaller because the models used encompass a narrow range of alternative sea level rise projections. Since increases and decreases in water stress, flood risks and crop suitability are not co-located and affect different regions, these effects are not combined. From Arnell *et al.*, 2013, Warren *et al*, 2013a; Warren *et al.*, 2013b]

In AR5 WGIII Chapter 6, the emission scenarios in the literature (as collected in the AR5 database) have been categorized on the basis of the 2100 radiative forcing (in total 7 categories). Most IAM models provide information on concentration, forcing and temperature. However, as the climate components of the IAMs differ, all scenarios were reanalyzed in the simple climate model MAGICC (Meinshausen et al. 2011) using its probabilistic set-up. The results of this categorization can be used to connect emission trajectories to climate outcomes (Figure 19-7, panel a) and impacts and risks (Figure 19-7, panel b, and Table 19-4).

Mitigation scenarios in category 1 with a 2100 CO_2-equivalent concentration of 430-480 ppm CO_2e constrain global temperature rise to between 1.3 and 2.3^{o}C above pre-industrial (Figure 19-7, panel a). These scenarios correspond to a 2011-2100 cumulative emission level of around 800-1250 $GtCO_2$ (AR5 WGIII Table 6.3). Under these scenarios, based on the MAGICC calculations, warming is *likely* to stay below 2^{o}C and *very likely* to stay below 2.5^o C during the 21st century. This significantly reduces the key risks listed in Table 19-4, as well as others discussed in this chapter. Constraining global temperature rise to 2^{o}C would constrain the risks associated with Aggregate Impacts to the 'white' or 'neutral' level, to the 'yellow' or 'moderate' level for Large Scale Singular Events and Distribution of Impacts and to the lower part of the 'red' 'high' level for Unique and Threatened Systems and Extreme Weather Events. The temperature levels in the RCP2.6 scenario are 1.2-2.0^o C (AR5 WG1 Table 12.2) matching closely the scenarios in this category.

Mitigation scenarios in category 2 with a 2100 concentration of 480-530 ppm CO_2e in 2100 correspond to a global temperature rise between 1.4 and 2.7^{o}C in the MAGICC calculations. These scenarios correspond to a cumulative emission level over the 2011-2100 period on the order of 1000-1500 $GtCO_{2.}$ (AR5 WGIII Table 6.3) and lead to likelihood of staying below roughly 2^{o}C of *more-likely-than-not (50-66%)*. Thus, scenarios in category 2 also reduce risks, but to a lesser extent than for category 1. If global temperature rise reaches 2.5^o C in 2100, levels of risk due to Extreme Weather Events are at the 'red' 'high' level, whilst those to Unique and Threatened Systems now reach the 'very high' or 'purple' level reflecting inability to adapt. Risks associated with Aggregate Impacts reach the 'yellow' 'moderate' level, whilst risks to the Distribution of Impacts and Large Scale Singular Events closely approach the 'red' or 'high' level.

Mitigation scenarios in category 3 with 530-580 ppm CO_2e constrain temperature rise to between 1.7 and 2.9^o C above pre-industrial levels, affording little protection to coral reefs, so that risks to Unique and Threatened Systems remain 'high' or 'very high' indicating inability to adapt. Risks associated with Extreme Weather Events remain at the 'high' level. Risks to Distribution of Impacts may be 'moderate' or 'high'. Levels of risk in Aggregate Impacts and Large Scale Singular Events are constrained to the upper 'moderate' level.

Mitigation scenarios in category 4 with 580-720 ppm CO_2e result in range of possible temperature outcomes between 1.8 and 3.6^o C above pre-industrial levels, affording very little protection to coral reefs, whilst risks to Unique and Threatened Systems remain 'high' or 'very high' indicating inability to adapt. Risks associated with Extreme Weather Events and Distribution of Impacts remain 'high'. Levels of risk associated with Aggregate Impacts and Large Scale Singular Events may be 'moderate' or 'high'. *(high confidence).* Global temperature rise in RCP4.5 in 2100 is 1.9-2.9^o C above pre-industrial levels (AR5 WG1 Table 12.2) matching the low scenarios in this category.

Onset of large-scale dissolution of coral reefs is projected if CO_2 concentrations reach 560 ppm (Section 5.4.1.6, 5.4.2.4, 19.6.3.2, 26.4.2.1; Silverman *et al.* 2009), due to the combined effects of warming and ocean acidification. However already at 450 ppm, reef growth rates are projected to be reduced by more than 60% globally; and by at least 20% globally at 380ppm (Silvermann *et al.*, 2009). Coral organisms themselves are projected to be damaged by warming at concentrations below 560 ppm: specifically, RCP4.5 is projected to result in long term degradation of

2/3 of coral reefs, compared with 1/3 of them under RCP3PD (Box CC-CR) *(medium confidence)*. Hence, maintenance of moderately healthy coral reefs is consistent only with scenarios in the scenarios in the 430-480 ppm CO_2e category; while some reef protection is achieved with scenarios in the category 480-530 ppm CO_2e. A low level of protection exists for the category 530-580 ppm CO_2e while all other categories exceed the 560ppm level.

Finally, scenarios in category 6 with a concentration level above >1000 ppm CO_2e are projected to result in temperature rise of between 3.3 and 6.3^{o}C above pre-industrial with negligible chances to constrain it below 2.5^{o}C above pre-industrial (panel a) and would allow significant key risks to persist in all the areas listed in Table 19-4.Risk is at the 'red' level for all Reasons for Concern except Unique and Threatened Systems, where risk is at the purple level indicating infeasibility of adaptation. For Distribution of Impacts, risk reaches the transition to purple if temperatures rise in excess of 4^{o}C above pre-industrial levels. For the scenarios with a concentration level between 720 ppm and 1000 ppm, category 5, outcomes for risk levels are similar to the highest category, except that risk to Aggregate Impacts is at the 'yellow' 'moderate' level.

Scenarios with rapid, early mitigation (particularly those which with a 2100 CO_2-equivalent concentration of 430-480 ppm CO_2e) generally delay the onset of a given global annual mean temperature rise until several decades later in the century than is the case for scenarios with slower, delayed mitigation or no mitigation (such as those with a 2100 CO_2-equivalent concentration of 720-1000 ppm), thus allowing impacts to be further reduced by adaptation during this time.

[INSERT FIGURE 19-7 HERE
Figure 19-7: Relationship between mitigation scenarios considered in AR5 WGIII, in terms of their CO_2e concentrations and global temperature rise outcomes relative to pre-industrial times, and level of risk associated with Reasons for Concern. Panel **a** shows the projected increase in global mean temperature in 2100 compared to preindustrial, calculated using the MAGICC climate model for the scenarios defined in Chapter 6, Working Group III, indicating the uncertainty range resulting both from the range of emission scenario projections within each category and the uncertainty in the climate system as represented by MAGICC (data taken from Chapter 6 – AR5 WGIII). Panel **b** reproduces Figure 19-4 for ease of comparison. Note the different temperature baselines used in Figure 19-4. Beyond 2100, temperature, and therefore risk, decreases in most of the lowest three scenarios and increases further in most of the others.]

19.7.2. Limits to Mitigation

Mitigation possibilities, such as those implicit in scenarios discussed in 19.7.1, are not unlimited. Assessment of maximum feasible mitigation (and lowest feasible emissions pathways) must account for the fact that feasibility is a subjective concept encompassing technological, economic, political, and social dimensions (Hare *et al.*, 2010, UNEP Chapter 2). Most mitigation studies have focused on technical feasibility, for example demonstrating that it is possible to reduce emissions enough to have at least a 50% chance of limiting warming to less than 2 °C relative to pre-industrial (den Elzen and van Vuuren, 2007; Clarke *et al.*, 2009; Edenhofer *et al.*, 2010; Hare *et al.*, 2010; O'Neill *et al.*, 2010), taking into account uncertainty in climate and carbon cycle response to emissions (see AR5 WGI Section 12.5.4 for a discussion of uncertainties in the relationship between emissions and long-term climate stabilization targets). RCP2.6, based on an integrated assessment model-based mitigation scenario (van Vuuren et al., 2012), is *unlikely* to produce more than 2°C of warming relative to pre-industrial (*medium confidence*; AR5 WGI Section 12.4.1.1). Such scenarios lead to pathways in which global emissions peak within the next 1-2 decades and decline to 50-85% below 2000 levels by 2050 (or 40-70% compared to 1990 levels), and in some cases exhibit negative emissions before the end of the century (Metz *et al.*, 2007, den Elzen *et al.*, 2007, Den Elzen *et al.*, 2010, van Vuuren et al. 2012). Very few integrated assessment model-based scenarios in the literature demonstrate the feasibility of limiting warming to a maximum of 1.5 °C with at least 50% likelihood (Rogelj et al., 2012); most 1.5 °C scenarios have been based on stylized emissions pathways (Hare *et al.*., 2010; Ranger *et al.*, 2012). The highest emission reduction rate considered in most integrated modeling studies that attempt to minimize mitigation cost is typically between 3 and 4% but with larger values not ruled out although some studies find that for an additional cost higher rates may be achievable (den Elzen *et al.*, 2010; O'Neill *et al.*, 2010).

However, most studies of feasibility include a number of idealized assumptions, including availability of a wide range of mitigation technologies such as large-scale renewable and biomass energy, and carbon capture and storage (CCS). Most also assume universal participation in mitigation efforts beginning immediately, economically optimal reductions (i.e., reductions are made wherever they are cheapest), and no constraints on policy implementation. Any deviation from these idealized assumptions can significantly limit feasible mitigation reductions (Knopf *et al.*, 2010; Rogelj *et al.*, 2012). For example, delayed participation in reductions by non-OECD countries made concentration limits such as not exceeding 450 ppm CO_2eq (roughly consistent with a 50% chance of remaining below 2 °C relative to pre-industrial), and in some cases even 550 ppm CO_2eq, unachievable in some models unless temporary overshoot of these targets (Izrael and Semenov, 2006) were allowed (Clarke *et al.*, 2009), but not in others (Waldhoff and Fawcett, 2011). Technology limits, such as unavailability of CCS or limited expansion of renewables or biomass makes stabilization at 450 ppm CO_2eq (or 2 °C with a 50% chance) unachievable in some models (Krey and Riahi, 2009; van Vliet *et al.*, 2012). Similarly, if the political will to implement coordinated mitigation policies within or across a large number of countries were limited, peak emissions and subsequent reductions would be delayed (Webster *et al.*, 2010).

These considerations have led some analysts to doubt the plausibility of limiting warming to 2 °C (Anderson and Bows, 2008; Tol, 2009; Anderson and Bows, 2011). "Emergency mitigation" options have also been considered that would go beyond the measures considered in most mitigation analyses (Swart and Marinova, 2010). These include drastic emissions reductions achieved through limits on energy consumption (Anderson and Bows, 2011) or geoengineering through management of the earth's radiation budget (19.5.4; AR5 WGI Chapters 6, 7).

19.7.3. Avoiding Thresholds, Irreversible Change, and Large-Scale Singularities in the Earth System

Section 19.6.3.6 discussed the Reasons for Concern related to non-linear changes in the Earth system (“large-scale singular events”), whereby anthropogenic forcings might cause irreversible and potentially rapid transitions over a wide range of time scales (see, for example, WGI: SPM, TS, TFE5, and section 12.5, WGII: section 19.6.3, as well as Lenton *et al*., 2008). The risk of triggering such transitions generally increases with increasing anthropogenic climate forcings / climate change (Lenton *et al.*, 2008; Kriegler *et al.*, 2009; Levermann *et al.*, 2012). Reducing greenhouse gas emissions is projected to reduce the risks of triggering such transitions [*medium confidence*]. Adaptation could reduce their potential consequences, but the efficacy of adaptation might be limited, for example for rapid transitions (19.7.5).

Several studies have sought to identify levels of atmospheric greenhouse gas concentrations or global average temperature change that would limit the risks of triggering these transitions (e.g., Keller *et al.*, 2005, 2008; Kriegler *et al.*, 2009; Lenton *et al.*, 2008). Section 19.6.3.6 assesses evidence regarding the relationship between global average temperature and risks of disintegration of major ice sheets, loss of Arctic sea ice, shutdown of the Atlantic meridional overturning circulation (AMOC), carbon releases from temperature-related feedback processes, and regime shifts in ecosystems. Additional aspects of these risks are important to mitigation strategies. For example, it is important to distinguish between triggering and experiencing a threshold response because model simulations suggest that there can be sizeable delays between the two (e.g., Lenton *et al.*, 2008). The location of these trigger points can be difficult to determine from process-based models alone, as some of these models lack potentially important processes (see e.g., AR5 WGI Chapter 13). In this situation, expert elicitations can provide additional useful information for risk assessments. One such assessment based on expert elicitation (Lenton *et al.*, 2008) finds that limiting global mean temperature increase to approximately 3°C above recent (1980–1999) values would considerably reduce the risks of triggering some nonlinear responses. In general, there is *low confidence* in the location of such temperature limits due to disagreements among experts. Estimates of such temperature limits can change over time (Oppenheimer et al., 2008) and may be subject to overconfidence that can introduce a downward bias in risk estimates of low-probability events (Morgan and Henrion, 1990). The climate threshold responses can interact (e.g., Kriegler *et al*., 2009). Other climate change metrics (e.g., rates of changes or atmospheric carbon dioxide concentrations) can also be important in the consideration of response strategies aimed at reducing the risk of crossing thresholds (Lenton, 2011a; McAlpine *et al.*, 2010).

Several analyses have performed risk- and decision-analyses for specific thresholds, mostly focusing on a persistent weakening or collapse of the AMOC (Bahn *et al.*, 2011; McInerney *et al.*, 2012; Urban and Keller, 2010; Zickfeld and Bruckner, 2008). Experiencing AMOC collapse has been assessed as *very unlikely* in this century and there is *low confidence* in assessing the AMOC beyond the 21st century [AR5 WGI SPM]. However, due to lags in the ocean system, the probability of triggering an eventual collapse differs from that of experiencing such an outcome (Urban and Keller, 2010). A probabilistic analysis sampling a subset of the relevant uncertainties concluded that reducing the probability of a collapse within the next few centuries to one in ten requires emissions reductions of roughly 60% relative to a business-as-usual strategy by 2050 (McInerney and Keller, 2008). Bruckner and Zickfeld (2009) show that, under their worst-case assumptions about key parameter values, emissions mitigation would need to begin within the next two decades to avoid reducing the overturning rate by more than 50%.

Threshold risk estimates and evaluations of risk-management strategies are sensitive to factors such as the representation of uncertainties and the decision-making frameworks used (McInerney *et al.*, 2012; Polasky *et al.*, 2011). Several analyses have examined how the consideration of threshold events affects response strategies. For example, the design of risk-management strategies could be informed by observation and projection systems that would provide an actionable early warning signal of an approaching threshold response. Learning about key uncertain parameters (e.g., climate sensitivity or impacts of a threshold response) can considerably affect risk-management strategies and have a sizeable economic value of information (Keller *et al.*, 2004; Lorenz *et al.*, 2012). However, there is limited evidence about the feasibility and requirements for such systems due to the small number of studies and their focus on highly simplified situations (Keller and McInerney, 2008; Lenton, 2011b, Lorenz *et al.*, 2012). In some decision-analytic frameworks, knowing that a threshold has been crossed can lead to reductions in emissions mitigation and a shift of resources toward adaptation and/or geoengineering (Guillerminet and Tol, 2008; Keller *et al.*, 2004; Lenton, 2011b; Swart and Marinova, 2010).

19.7.4. Avoiding Tipping Points in Social/Ecological Systems

Tipping points (see Glossary) in socio-ecological systems are defined as thresholds beyond which impacts increase non-linearly to the detriment of both human and natural systems. These can be initiated rapidly, inducing a need for rapid response. For example, regime shifts have already occurred in marine food webs (Byrnes *et al.*, 2007; Alheit, 2009, Green *et al*., 2008, section 6.3.6) due to (observed) changes in sea surface temperature, changes in salinity, natural climate variability, and/or overfishing.

Because human and ecological systems are linked by the services that ecosystems provide to society (Lubchenko and Petes, 2010; McLeod and Leslie 2009), tipping points may be crossed when either the ecosystem services are disrupted and/or social/economic networks are disrupted (Renaud *et al.*, 2010). Climate change provides a stress that increases the risk that tipping points will be crossed, although they may be crossed due to other types of stresses even in the absence of climate change. For example, in dryland ecosystems overgrazing has caused grassland-to-desert transitions (Pimm, 2009). The likelihood of crossing tipping points due to climate change may be reduced by preserving ecosystem services through (i) limiting the level and rate of climate change [*medium confidence*] *and*/or (ii) removing concomitant stresses such as overgrazing, fishing, habitat destruction, and pollution. Most literature currently focuses on strategy (ii), and there is limited information about the exact levels and rates of climate change that specific coupled socio-economic systems can withstand. Examples of strategy (ii) include maintaining resilience of coral reefs, cephalopod or piscivorous seabird populations by removal of concomitant stress from fishing (Andre *et al*., 2010; Anthony *et al*., 2011; Sections 6.3.6, 30.6.2) or expanding protected area networks (Brodie *et al*., 2012). Removal of concomitant stress such as nutrient loading can reduce the chance of a regime shift (Jurgensone *et al*., 2011) in coral reef ecosystems (De'ath *et al.*, 2012). Sometimes management can reverse the crossing of a tipping point, e.g. by adding sediment to a submerged salt marsh (Stagg and Mendelssohn, 2010). Strategy (ii) is enhanced by resilience-based management approaches in ecosystems (Walker and Salt 2006; Lubchenko and Petes 2010; Allen *et al*. 2011; Selig *et al.*, 2012). A high level of biodiversity increases ecosystem resilience and can enable recovery after crossing a tipping point (Brierley and Kingsford, 2009; Lubchenko and Petes, 2010). Strategy (ii) generally becomes ineffective once climate changes beyond an uncertain and spatially variable threshold; also successive thresholds may be crossed as stress increases (Renaud *et al.*, 2010).

Monitoring that aims to detect a slow-down in the recovery of systems from small changes (van Nes and Scheffer, 2005) or to measure an appropriate indicator (Biggs *et al*., 2008) may give warning that a system is a approaching a regime shift, justifying intervention of type (ii) (Guttal and Jayaprakash, 2009; Brock and Carpenter, 2010). Such indicators have been identified for the desertification process in the Mediterranean (Alados *et al*., 2011) and for landscape fire dynamics (Zinck *et al.,* 2011; McKenzie and Kennedy, 2012).

19.7.5. Limits to Adaptation

Chapter 16.2 and 16.5 provide a thorough assessment of the literature on limits to adaptation. Discussions are beginning on the nature of such limits, e.g. in terms of different dimensions of the limits to adaptation, including financial or economic limits to adapt, but also social and political or cognitive limits of adaptation. Limits to adaptation (see e.g. Adger *et al.*, 2009) are also recognized in terms of specific geographies, for example small island developing states and their limited ability to adapt to increasing impacts of sea level rise, the limits to adaptation of urban agglomerations in low-laying coastal zones (see e.g. Birkmann *et al.*, 2010), or in relation to loss of water supplies as a result of glacier retreat (Orlove, 2009). Overall, the concept of limits to adaptation is closely related to key vulnerabilities and key risks including those identified in Table 19-4 and cross-chapter Box CC-KR, because this concept helps define residual risk.

Frequently Asked Questions

FAQ 19.1: Does science provide an answer to the question of how much warming is unacceptable?
[to be placed in Section 19.1.3]
No. Careful, critical scientific research and assessment can provide information to help society consider what levels of warming or climate change impacts are unacceptable. However, the answer is ultimately a subjective judgment that depends on values and culture, as well as socioeconomic and psychological factors, all of which influence how people perceive risk in general and the risk of climate change in particular. The question of what level of climate change impacts is unacceptable is ultimately not just a matter of the facts, but how we feel about those facts.

This question is raised in Article 2 of the UN Framework Convention on Climate Change (UNFCCC). The criterion, in the words of Article 2, is “dangerous anthropogenic interference with the climate system” - a framing that invokes both scientific analysis and human values.

Agreements reached by governments since 2009, meeting under the auspices of the UNFCCC, have recognized “the scientific view that the increase in global temperature should be below 2 degrees Celsius” (Chapter 19.1, UNFCCC, Copenhagen Accord). Still, as informed on the subject as the scientists referred to in this statement may be, theirs is just one valuable perspective. How each country or community will define acceptable or unacceptable levels, essentially deciding what is ‘dangerous’, is a societal judgment.

Science can certainly help society think about what is unacceptable. For example, science can identify how much monetary loss might occur if tropical cyclones grow more intense or heat waves more frequent, or identify the land that might be lost in coastal communities for various levels of higher seas. But “acceptability” depends on how each community values those losses. This question is more complex when loss of life is involved and yet more so when damage to future generations is involved. These are highly emotional and controversial value propositions that science can only inform, not decide.

The purpose of this chapter is to highlight key vulnerabilities and key risks that science has identified; however, it is up to people and governments to determine how the associated impacts should be valued, and whether and how the risks should be acted upon.

FAQ 19.2: How does climate change interact with and amplify pre-existing risks?
[to be placed in Section 19.3.2.4]
There are two components of risk: the probability of adverse events occurring and the impact or consequences of those events. Climate change increases the probability of several types of harmful events that societies and ecosystems already face, as well as the associated risks. For example, people in many regions have long faced threats associated with weather-related events like extreme temperatures and heavy precipitation (which can trigger flooding). Climate change will increase the likelihood of these two types of extremes as well as others. Climate

change means that impacts already affecting coastal areas, like erosion and loss of property in damaging storms, will become more likely due to sea level rise. In many areas, climate change increases the already high risks to people living in poverty or to people suffering from food insecurity or inadequate water supplies. Finally, climate and weather already pose risks for a wide range of economic sectors, including agriculture, fisheries, and forestry: climate change increases these risks for much of the world.

Climate change can amplify risks in many ways, including through indirect interactions with other risks. These are often not considered in projections of climate change impacts. For example, hotter weather contributes to increased amounts of ground level ozone (smog) in polluted areas, exacerbating an existing threat to human health, particularly for the elderly and the very young and those already in poor health. Also, efforts to mitigate or adapt to climate change can have negative as well as positive effects. For example, government policies encouraging expansion of biofuel production from maize have recently contributed to higher food prices for many, increasing food insecurity for populations already at risk, and threatening the livelihoods of those like the urban poor who are struggling with the inherent risks of poverty. Increased tapping of water resources for crop irrigation in one region in response to water shortages related to climate change can increase risks to adjacent areas that share those water resources. Climate change impacts can also reverberate by damaging critical infrastructure like power generation, transportation, or health care systems.

FAQ 19.3: How can climate change impacts on one region cause impacts on other distant areas?
[to be placed in Section 19.4.3.2]
People and societies are interconnected in many ways. Changes in one area can have ripple effects around the world through globally linked systems like the economy. Globalized food trade means that changed crop productivity as a result of extreme weather events or adverse climate trends in one area can shift food prices and food availability for a given commodity worldwide. Depletion of fish stocks in one region due to ocean temperature rise can cause impacts on the price of fish everywhere. Severe weather in one area that interferes with transportation or shipping of raw or finished goods, like refined oil, can have wider economic impacts.

In addition to triggering impacts via globally linked systems like markets, climate change can alter the movement of people, other species, and physical materials across the landscape, generating secondary impacts in places far removed from where these particular direct impacts of climate change occur. For example, climate change can create stresses in one area that prompt some human populations to migrate to adjacent or distant areas. Migration can affect many aspects of the regions people leave, as well as many aspects of their destination points, including income levels, land use and the availability of natural resources, and the health and security of the affected populations – these effects can be positive or negative. In addition to these indirect impacts, all regions experience the direct impacts of climate change.

Cross-Chapter Box

Box CC-KR. A Selection of the Hazards, Key Vulnerabilities, Key Risks, and Emergent Risks Identified in the WGII Contribution to the Fifth Assessment Report

The accompanying table provides a selection of the hazards, key vulnerabilities, key risks, and emergent risks identified in various chapters in this report (Chapter 4, 6, 7, 8, 9, 11, 13, 19, 22, 23, 24, 25, 26, 27, 28, 29, 30). Key risks are determined by hazards interacting with vulnerability and exposure of human systems, and ecosystems or species. The table underscores the complexity of risks determined by various climate-related hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, unsustainable and rapid urbanization, other demographic changes, failure in governance and inadequate governmental attention to risk reduction, and tolerance limits of species and ecosystems which often provide important services to vulnerable communities, generate the context in which climatic change related harm and loss can occur. The table illustrates that current global megatrends (e.g. urbanization and other demographic changes) in combination and in specific development context (e.g. in low-lying coastal zones), can generate new systemic risks in their interaction with climate hazards that exceed existing adaptation and risk management capacities, particularly in highly vulnerable regions, such as dense urban areas of low-lying deltas. A representative set of lines of sight is provided from across WGI and WGII. See Section 19.6.2.1 for a full description of the methods used to select these entries. [NB: See tables file for the table embedded in Box CC-KR.]

Table 19-2: Emergent risks related to biofuel production as a mitigation strategy.

Issue number	**Issue description**	**Nature of emergent risk**	**Reference**
(i) Direct and/or indirect land use change (iLUC)	Potential for enhancement of greenhouse gas emissions	Mitigation benefit of biofuels reduced or negated	Wise et al., 2009, Melillo et al., 2009, Khanna et al., 2011
(ii) Policies targeting only fossil carbon	Biofuel cropping competes with agricultural systems and ecosystems for land and water	Mitigation benefit of policies reduced, harmful interactions with other key systems	Wise et al., 2009, Mellilo et al., 2009, Searchinger et al., 2008, Fargione et al., 2010
(iii) Food/fuel competition for land	Competition for land driving up food prices	Emergent risk of food insecurity due to mitigation-driven land use change	Hertel et al., 2010, Searchinger et al., 2008, Pimentel et al., 2009
(iv) Biofuels production affects water resources	Competition for water affects biodiversity and food cropping	Emergent risk of biodiversity loss and food insecurity due to mitigation-driven water stress	Fargione et al., 2010, Fingerman et al., 2010, Yang et al., 2012, Poudel et al., 2012
(v) Biofuels production affects biodiversity	Competition for land reduces natural forest and biodiversity	Emerging risk of biodiversity loss due to mitigation-driven land use change	Lapola et al., 2010, Koh et al., 2009, Fizherbert et al., 2008, Fletcher Jr. et al., 2011
(vi) Land conversion causes air pollution	Potential for increased production of tropospheric ozone from palm/sugarcane-induced LUC	Emergent risk of GHG-mitigation-driven plant and human health damage caused by tropospheric ozone	Hewitt et al., 2009, Cançado et al., 2006
(vii) Fertilizer application	Potential for increased emissions of N2O	Offsets some benefits of other mitigation measures	Donner and Kucharik, 2008, Searchinger et al., 2008, Fargione et al., 2010
(viii) Invasive properties of biofuel crops	Potential to become an invasive species	Unintended consequences that damage agriculture and/or biodiversity	Barney and Ditomaso 2008, DiTomaso et al., 2007, Raghu et al., 2006

Table 19-3: An assessment of the risks to ecosystem services posed by the impacts of ocean acidification on coral calcification and nitrogen fixation, based on the four criteria for key risks (19.2.2.2).

Criterion for key risk	**Coral calcification**	**Nitrogen fixation**
1. Magnitude of consequences for ecosystem services	Ecosystem services include supporting habitats, provisioning of fish, regulating shoreline erosion, and tourism. Potential magnitude of consequences is *medium* to *high* (Box CC-CR).	Ecosystem services include nitrogen cycling, which supports ecosystem structure and food chains (Hutchins et al., 2009). Potential magnitude of consequences has not been investigated.
2. Likelihood that risks will materialize and their timing	A reduction in coral calcification rate and an increase in reef dissolution rates are *very likely* (6.1.2), so that reefs will progressively shift toward net dissolution (*medium confidence*, Section 5.4.2.4; Box CC-CR; Box CC-OA)	Both increases and decreases in nitrogen fixation have been observed in various N2-fixing organisms (Section 6.3.2.2) but there is *limited in situ evidence* and *medium agreement* on how N_2-fixation rates will change in response to ocean acidification.
3. Irreversibility and persistence of ocean acidification impacts	Decreases in ocean pH will persist as long as atmospheric CO2 levels remain elevated. (AR5 WGI Section 3.8.2). Reductions in coral calcification will persist unless corals can physiologically adapt to maintain calcification rates. Reversibility of impacts on ecosystem services of coral reefs is unknown and depends on ecological factors such as hysteresis.	Decreases in ocean pH will persist as long as atmospheric CO2 levels remain elevated. (AR5 WGI Section 3.8.2). Reversibility and persistence of impacts on nitrogen fixation are unknown.
4. Limited ability to reduce the magnitude and frequency or nature of ocean acidification impacts	Reduction of ocean acidification will require global reductions in atmospheric CO2. Feasibility of mitigating ocean acidification at the local scale is unknown.	Reduction of ocean acidification will require global reductions in atmospheric CO2.

Table 19-4: A selection of the hazards, key vulnerabilities, key risks, and emergent risks identified in various chapters in this report (Chapter 4, 6, 7, 8, 9, 11, 13, 19, 22, 23, 24, 25, 26, 27, 28, 29, 30). Key risks are determined by hazards interacting with vulnerability and exposure of human systems, and ecosystems or species. The table underscores the complexity of risks determined by various climate-related hazards, non-climatic stressors, and multifaceted vulnerabilities. The examples show that underlying phenomena, such as poverty or insecure land-tenure arrangements, unsustainable and rapid urbanization, other demographic changes, failure in governance and inadequate governmental attention to risk reduction, and tolerance limits of species and ecosystems which often provide important services to vulnerable communities, generate the context in which climatic change related harm and loss can occur. The table illustrates that current global megatrends (e.g. urbanization and other demographic changes) in combination and in specific development context (e.g. in low-lying coastal zones), can generate new systemic risks in their interaction with climate hazards that exceed existing adaptation and risk management capacities, particularly in highly vulnerable regions, such as dense urban areas of low-lying deltas. Roman numerals correspond with key risks listed in 19.6.2.1. A representative set of lines of sight is provided from across AR5 WGI and WGII. See Section 19.6.2.1 for a full description of the methods used to select these entries.

#	Hazard	Key vulnerabilities		Key risks	Emergent risks
i	Sea level rise, coastal flooding including storm surges. [AR5 WGI Sections 3.7.1, 13.5.1, Table 13-5; AR5 WGII Sections 5.4.3, 8.1.4, 8.2.3, 8.2.4, 13.1.4, 13.2.2, 24.4, 24.5, Box 25-1, Box 25-7, 26.7, 26.8, 29.3.1, 30.3.1]	High exposure of people, economic activity, and infrastructure in low-lying coastal zones and Small Island Developing States (SIDS). Urban population unprotected due to substandard housing and inadequate insurance. Marginalized rural population with multidimensional poverty and limited alternative livelihoods. Insufficient local governmental attention to disaster risk reduction.	exposure social vulnerability institutional vulnerability	Death, injury, and disruption to livelihoods, food supplies, and drinking water. Loss of common-pool resources, sense of place, and identity, especially among indigenous populations in rural coastal zones.	Interaction of rapid urbanization, sea level rise, increasing economic activity, disappearance of natural resources, and limits of insurance; burden of risk management shifted from the state to those at risk leading to greater inequality.
ii	Warming, drought, and precipitation variability [AR5 WGI Section 11.3.2; AR5 WGII Sections 7.4, 7.5, 11.3, 11.6.1, 13.2.1, 13.2.2, 19.3.2, 19.4.1, 22.3.4, 24.4, 26.8, 27.3.4]	Poorer populations in urban and rural settings are susceptible to resulting food insecurity; includes particularly farmers who are net food buyers and people in low-income, agriculturally dependent economies that are net food importers. Limited ability to cope among the elderly and female-headed households.	social vulnerability institutional vulnerability	Risk of harm and loss of life due to reversal of progress in reducing malnutrition.	Interactions of climate changes, population growth, reduced productivity, biofuel crop cultivation, and food prices with persistent inequality, and on-going food insecurity for the poor increases malnutrition, giving rise to larger burden of disease. Exhaustion of social networks reduces coping capacity.
iii	Extreme precipitation and inland flooding. [AR5 WGI Section 11.3.2.5; AR5 WGII Sections 3.2.7, 3.4.8, 8.2.3, 8.2.4, 13.2.1, 25.10, Box 25-8, 26.3, 26.7, 26.8, 27.3.5]	Large numbers of people exposed in urban areas to flood events, particularly in low-income informal settlements. Overwhelmed, aging, poorly maintained, and inadequate urban drainage infrastructure and limited ability to cope and adapt due to marginalization, high poverty, culturally imposed gender roles.	exposure social vulnerability	Death, injury, and disruption of human security, especially among children, elderly, and disabled.	Interaction of increasing frequency of intense precipitation, urbanization, and limits of insurance; burden of risk management shifted from the state to those at risk leading to greater inequality, eroded assets due to infrastructure damage, abandonment of urban districts, and the creation of high risk/high

		Inadequate governmental attention to disaster risk reduction.	institutional vulnerability		poverty spatial traps.
iv	Drought. [AR5 WGI Section 12.4.1, 12.4.5; AR5 WGII Sections 3.2.7, 3.4.8, 3.5.1, 8.2.3, 8.2.4, 9.3.3, 9.3.5, 13.2.1, 19.3.2.2, 24.4]	Urban populations with inadequate water services. Existing water shortages (and irregular supplies), and constraints on increasing supplies. Lack of capacity and resilience in water management regimes including rural-urban linkages.	social vulnerability institutional vulnerability	Insufficient water supply for people and industry yielding severe harm and economic impacts.	Interaction of urbanization, infrastructure insufficiency, groundwater depletion.
		Poorly endowed farmers in drylands or pastoralists with insufficient access to drinking and irrigation water. Limited ability to compensate for losses in water-dependent farming and pastoral systems, and conflict over natural resources. Lack of capacity and resilience in water management regimes, inappropriate land policy, and misperception and undermining of pastoral livelihoods.	exposure social vulnerability institutional vulnerability	Loss of agricultural productivity and/or income of rural people. Destruction of livelihoods particularly for those depending on water-intensive agriculture. Risk of food insecurity.	Interactions across human vulnerabilities: deteriorating livelihoods, poverty traps, heightened food insecurity, decreased land productivity, rural outmigration, and increase in new urban poor in low and middle income countries. Potential tipping point in rain-fed farming system and/or pastoralism.
v	Novel hazards yielding systemic risks. [AR5 WGI Section 11.3.2; AR5 WGII Sections 8.1.4, 8.2.4, 10.2, 10.3, 12.6, 23.9, 25.10, 26.7, 26.8]	Populations and infrastructure exposed and lacking historical experience with these hazards. Overly hazard-specific management planning and infrastructure design, and/or low forecasting capability.	exposure institutional vulnerability	Failure of systems coupled to electric power system, e.g., drainage systems reliant on electric pumps or emergency services reliant on tele-communications. Collapse of health and emergency services in extreme events.	Interactions due to dependence on coupled systems lead to magnification of impacts of extreme events. Reduced social cohesion due to loss of faith in management institutions undermines preparation and capacity for response.
vi	Rising ocean temperature, ocean acidification, and loss of Arctic sea ice [AR5 WGI Section 11.3.3; AR5 WGII Sections 5.4.2, 6.3.1, 6.3.2, 7.4.2, 9.3.5, 22.3.2.3, 25.6, 27.3.3, 28.2, 28.3, 29.3.1, 30.5, 30. 6, CC-OA, CC-CR]	High susceptibility of warm water coral reefs and respective ecosystem services for coastal communities; high susceptibility of polar systems, e.g., to invasive species Susceptibility of coastal and SIDS fishing communities depending on these ecosystem services; and of Arctic settlements and culture.	environmental vulnerability economic vulnerability environmental vulnerability	Loss of coral cover, Arctic species, and associated ecosystems with reduction of biodiversity and potential losses of important ecosystem services. Risk of loss of endemic species, mixing of ecosystem types, and increased dominance of invasive organisms.	Interactions of stressors such as acidification and warming on calcareous organisms enhancing risk.

vii	Rising land temperatures, changes in precipitation patterns, and frequency and intensity of extreme heat [AR5 WGI Section 11.3.2.5; AR5 WGII Sections 4.3.4, FAQ 4.4, 19.3.2.1, 22.4.5.6, Table 23-2, 27.3.2.1, Box CC-WE]	Susceptibility of societies to loss of provisioning, regulation, and cultural services from terrestrial ecosystems. Susceptibility of human systems, agro-ecosystems and natural ecosystems to (i) loss of regulation of pests and diseases, fire, landslide, erosion, flooding, avalanche, water quality, and local climate (ii) loss of provision of food, livestock, fibre, bioenergy (iii) loss of recreation, tourism, aesthetic and heritage values, and biodiversity,	economic vulnerability environmental vulnerability	Reduction of biodiversity and potential losses of important ecosystem services. Risk of loss of endemic species, mixing of ecosystem types, and increased dominance of invasive organisms.	Interaction of social-ecological systems with loss of ecosystem services upon which they depend.
viii	Increasing frequency and intensity of extreme heat, including urban heat island effect. [AR5 WGI Section 11.3.2; AR5 WGII Sections 8.2.3, 11.3, 11.4.1, 13.2, 23.5.1, 24.4.6, 25.8.1, 26.6, 26.8, CC-HS]	Increasing urban population of the elderly, the very young, expectant mothers, and people with chronic health problems in settlements subject to higher temperatures. Inability of local organizations which provide health, emergency and social services to adapt to new risk levels for vulnerable groups.	social vulnerability institutional vulnerability	Increased mortality and morbidity during periods of extreme heat.	Interaction of changes in regional temperature extremes, local heat island, and air pollution, with demographic shifts. Overloading of health and emergency services. Mortality, morbidity, and productivity loss among manual workers in hot climates.

Box CC-KR Table

Examples of Hazards/Stressors, Key Vulnerabilities, Key Risks and Emergent Risks (using input from chapter 4, 6, 7, 8, 9, 11, 13, 19, 22, 23, 24, 25, 26, 27, 28, 29, 30)			
Hazard	**Key vulnerabilities**	**Key risks**	**Emergent risks**
Terrestrial and inland water systems (chapter 4)			
Rising air, soil, and water temperature [4.2.4, 4.3.2, 4.3.3]	Exceedance of eco-physiological climate tolerance limits of species (limited coping and adaptive capacities), increased viability of alien organisms.	Risk of loss of native biodiversity, increase in non-native organism dominance.	Cascades of native species loss due to interdependencies.
	Health response to spread of temperature-sensitive vectors (insects).	Risk of novel and/or much more severe pest and pathogen outbreaks.	Interactions between pest, drought and fire can lead to new risks and large negative impacts on ecosystems.
Change in seasonality of rain [4.3.3]	Increasing susceptibility of plants and ecosystem services, due to mismatch between plant life strategy and growth opportunities.	Changes in plant functional type mix leading to biome change with respective risks for ecosystems and ecosystem services.	Fire-promoting grasses grow in winter-rainfall areas and provide fuel in dry summers.
Ocean systems (chapter 6)			
Rising water temperature, increase of (thermal and haline) stratification, and marine acidification [6.1.1]	Tolerance limits of endemic species surpassed (limited coping and adaptive capacities), increased abundance of invasive organisms, high susceptibility and sensitivity of warm water coral reefs and respective ecosystem services for coastal communities. [6.3.1, 6.4.1]	Risk of loss of endemic species, mixing of ecosystem types, increased dominance of invasive organisms. Increasing risk of loss of coral cover and associated ecosystem with reduction of biodiversity and ecosystem services. [6.3.1]	Enhancement of risk due to interactions, e.g., acidification and warming on calcareous organisms. [6.3.5]
	New vulnerabilities can emerge due to shifted productivity zones and species distribution ranges, largely from low to high latitudes [6.3.4, 6.5.1], shifting fishery catch potential with species migration. [6.3.1, 6.5.2, 6.5.3]	Risks due to unknown productivity and services of new ecosystem types. [6.4.1, 6.5.3]	Enhancement of risk due to interactions of warming, hypoxia, acidification, new biotic interactions. [6.3.5, 6.3.6]
Expansion of oxygen minimum zones and coastal dead zones with stratification and eutrophication. [6.1.1]	Increasing susceptibility because hypoxia tolerance limits of larger animals surpassed, habitat contraction and loss for midwater fishes and benthic invertebrates. [6.3.3]	Risk of loss of larger animals and plants, shifts to hypoxia adapted, largely microbial communities with reduced biodiversity. [6.3.3]	Enhancement of risk due to expanding hypoxia in warming and acidifying oceans. [6.3.5]
Enhanced harmful algal blooms in coastal areas due to rising water temperature.	Increasing susceptibility and limited adaptive capacities of important ecosystems and	Increasing risk due to enhanced frequency of dinoflagellate blooms and	Disproportionate enhancement of risk due to interactions of various

[6.4.2.3]	valuable services due to already existing multiple stresses. [6.3.5, 6.4.1]	respective potential losses and degradations of coastal ecosystems and ecosystem services. [6.4.2]	stresses. [6.3.5]
Food production systems and food security (chapter 7)			
Rising average temperatures and more frequent extreme temperatures [7.1, 7.2, 7.4, 7.5]	Susceptibility of all elements of the food system from production to consumption, particularly for key grain crops.	Risk of crop failures, breakdown of food distribution and storage processes.	Increase in the global population to ca. 9 billion combined with rising temperatures and other trace gases such as ozone affecting food production and quality. Upper temperature limit to the ability of some food systems to adapt.
Extreme precipitation and droughts [7.4]	Crops, pasture, and husbandry are susceptible and sensitive to drought and extreme precipitation.	Risk of crop failure, risk of limited food access and quality.	Flood and droughts affect crop yields and quality, and directly affect food access in most developing countries. [7.4]
Urban areas (chapter 8)			
Inland flooding [8.2.3, 8.2.4]	Large numbers of people exposed in urban areas to flood events. Particularly susceptible are people in low-income informal settlements with inadequate infrastructure (and often on flood plains or along river banks). These bring serious environmental health consequences from overwhelmed, aging, poorly maintained and inadequate urban drainage infrastructure and widespread impermeable surfaces. Local governments are often unable or unwilling to give attention to needed flood-related disaster risk reduction. Much of the urban population unable to get or afford housing that protects against flooding, or insurance. Certain groups more sensitive to ill health from flood impacts – that may include increased mosquito and water borne diseases.	Risks of deaths and injuries and disruptions to livelihoods/incomes, food supplies and drinking water.	In many urban areas, larger and more frequent flooding impacting much larger population. No insurance available or impacts reaching the limits of insurance. Shift in the burden of risk management from the state to those at risk leading to greater inequality and property blight, abandonment of urban districts and the creation of high risk/high poverty spatial traps.
Coastal flooding (including sea level rise and storm surge) [8.1.4, 8.2.3, 8.2.4]	High concentrations of people, businesses and physical assets including critical infrastructure	Risks from deaths and injuries and disruptions to livelihoods/incomes, food supplies and drinking water.	Additional 2 billion or so urban dwellers expected over the next 3 decades. Sea level rise means

	exposed in low-lying and unprotected coastal zones. Particularly susceptible is urban population that is unable to get or afford housing that protects against flooding or insurance. Local government unable or unwilling to give needed attention to disaster risk reduction.		increasing risks over time, yet with high and often increasing concentrations of population and economic activities on the coasts. No insurance available or reaching the limits of insurance; shift in the burden of risk management from the state to those at risk leading to greater inequality and property blight, abandonment of urban districts and the creation of high risk/high poverty spatial traps.
Heat and cold (including urban heat island effect) [8.2.3]	Particularly susceptible is a large and often increasing urban population of infants, young children, older age groups, expectant mothers, people with chronic diseases or compromised immune system in settlements exposed to higher temperatures (especially in heat islands) and unexpected cold spells. Inability of local organizations for health, emergency services and social services to adapt to new risk levels and set up needed initiatives for vulnerable groups.	Risk of mortality and morbidity increasing, including shifts in seasonal patterns and concentrations due to hot days with higher or more prolonged high temperatures or unexpected cold spells. Avoiding risks often most difficult for low-income groups.	Duration and variability of heat waves increasing risks over time for most locations due to interactions with multiple stressors such as air pollution.
Water shortages and drought in urban regions [8.2.3, 8.2.4]	Lack of piped water to homes of hundreds of millions of urban dwellers. Many urban areas subject to water shortages and irregular supplies, with constraints on increasing supplies. Lack of capacity and resilience in water management regimes including rural-urban linkages. Dependence on water resources in energy production systems.	Risks from constraints on urban water provision services to people and industry with human and economic impacts. Risk of damage and loss to urban ecology and its services including urban and peri-urban agriculture.	Cities' viability may be threatened by loss or depletion of freshwater sources – including for cities dependent on distant glacier melt water or on depleting groundwater resources.
Changes in urban meteorological regimes lead to enhanced air pollution [8.2.3]	Increases in exposure and in pollution levels with impacts most serious among physiologically susceptible populations. Limited coping and adaptive capacities, due to lacking implementation of pollution control legislation of urban governments.	Increasing risk of mortality and morbidity, lowered quality of life. These risks can also undermine the competitiveness of global cities to attract key workers and investment.	Complex and compounding health crises.
Geo-hydrological hazards	Local structures and	Risk of damage to	Potential for large local and

(salt water intrusion, mud/land slides, subsidence) [8.2.3, 8.2.4]	networked infrastructure (piped water, sanitation, drainage, communications, transport, electricity, gas) particularly susceptible. Inability of many low-income households to move to housing on safer sites.	networked infrastructure. Risk of loss of human life and property.	aggregate impacts. Knock on effects for urban activities and wellbeing.
Wind storms with higher intensity [8.1.4, 8.2.4]	Sub-standard buildings and physical infrastructure and the services and functions they support particularly susceptible. Old and difficult to retro-fit buildings and infrastructure in cities. Local government unable or unwilling to give attention to disaster risk reduction (limited coping and adaptive capacities).	Risk of damage to dwellings, businesses and public infrastructure. Risk of loss of function and services. Challenges to recovery, especially where insurance is absent.	Challenges to individuals, businesses and public agencies where the costs of retrofitting are high and other sectors or interests capture investment budgets; potential for tensions between development and risk reduction investments.
Changing hazard profile including novel hazards and new multi-hazard complexes [8.1.4, 8.2.4]	Newly exposed populations and infrastructure, especially those with limited capacity for multi-hazard risk forecasting and where risk reduction capacity is limited, e.g. where risk management planning is overly hazard specific including where physical infrastructure is predesigned in anticipation of other risks (e.g. geophysical rather than hydrometeorological).	Risks from failures within coupled systems, e.g. reliance of drainage systems on electric pumps, reliance of emergency services on roads and telecommunications. Potential of psychological shock from unanticipated risks.	Loss of faith in risk management institutions. Potential for extreme impacts that are magnified by a lack of preparation and capacity in response.
Compound slow-onset hazards including rising temperatures and variability in temperature and water [8.2.2, 8.2.4]	Large sections of the urban population in low- and middle-income nations with livelihoods or food supplies dependent on urban and peri-urban agriculture are especially susceptible.	Risk of damage to or degradation of soils, water catchment capacity, fuel wood production, urban and peri-urban agriculture and other productive or protective ecosystem services. Risk of knock-on impacts for urban and peri-urban livelihoods and urban health.	Collapsing of peri-urban economies and ecosystem services with wider implications for urban food security, service provision and disaster risk reduction.
Climate change induced or intensified hazard of more diseases and exposure to disease vectors [8.2.3, 8.2.4]	Large urban population that is exposed to foodborne and waterborne diseases and to malaria, dengue and other vector borne diseases that are influenced by climate change.	Risk due to increases in exposure to these diseases.	Lack of capacity of public health system to simultaneously address these health risks with other climate related risks like flooding.
Rural areas (chapter 9)			
Drought in pastoral areas [9.3.3.1, 9.3.5.2]	Increasing vulnerability due to encroachment on pastoral rangelands, inappropriate land policy, misperception	Risk of famine. Risk of loss of revenues from livestock trade.	Increasing risks for rural livelihoods through animal disease in pastoral areas combined with direct

	and undermining of pastoral livelihoods, conflict over natural resources, all driven by remoteness and lack of voice.		impacts of drought.
Effects of climate change on artisanal fisheries [9.3.3.1, 9.3.5.2]	Artisanal fisheries affected by pollution and mangrove loss, competition from aquaculture and the neglect of the sector by governments and researchers as well as complex property rights.	Risk of economic losses for artisanal fisherfolk, due to declining catches and incomes and damage to fishing gear and infrastructure.	Reduced dietary protein for those consuming artisinally-caught fish, combined with other climate-related risks.
Water shortages and drought in rural areas [9.3.5.1, 9.3.5.1]	Rural people lacking access to drinking and irrigation water. High dependence of rural people on natural resource-related activities. Lack of capacity and resilience in water management regimes (institutionally driven). Increased water demand from population pressure.	Risk of reduced agricultural productivity of rural people, including those dependent on rainfed or irrigated agriculture, or high-yield varieties, forestry and inland fisheries. Risk of food insecurity and decrease in incomes. Decreases in household nutritional status. [9.3.5.1]	Impacts on livelihoods driven by interaction with other factors (water management institutions, water demand, water used by non-food crops), including potential conflicts for access to water. Water-related diseases.
Human health (chapter 11)			
Increasing frequency and intensity of extreme heat	Older people living in cities are most susceptible to hot days and heat waves, as well as people with pre-existing health conditions. [11.3]	Risk of increased mortality and morbidity during hot days and heat waves. [11.4.1] Risk of mortality, morbidity and productivity loss, particularly amongst manual workers in hot climates.	The number of elderly people is projected to triple from 2010-2050. This can result in overloading of health and emergency services.
Increasing temperatures, increased variability in precipitation	Poorer populations are particularly susceptible to climate-induced reductions in local crop yields. Food insecurity may lead to undernutrition. Children are particularly vulnerable. [11.3]	Risk of a larger burden of disease and increased food insecurity for particular population groups. Increasing risk that progress in reducing mortality and morbidity from undernutrition may slow or reverse. [11.6.1]	Combined impacts of climate impacts, population growth, plateauing productivity gains, land demand for livestock, biofuels, persistent inequality, and on-going food insecurity for the poor.
Increasing temperatures, changing patterns of precipitation	Non-immune populations that are exposed to water- and vector-borne disease which are sensitive to meteorological conditions. [11.3]	Increasing health risks due to changing spatial and temporal distribution strains public health systems, especially if this occurs in combination with economic downturn. [11.5.1]	Rapid climate and other environmental change may promote emergence of new pathogens.
Increased variability in precipitation	People exposed to diarrhoea aggravated by higher temperatures, and unusually high or low precipitation. [11.3]	Risk that the progress to date in reducing childhood deaths from diarrhoeal disease is compromised. [11.5.2]	Increased rate of failure of water and sanitation infrastructure due to climate change leading to higher diarrhoea risk.
Livelihood and poverty (chapter 13)			
Increasing frequency and	Poorly endowed farmers	Risk of irreversible harm	Deteriorating livelihoods

severity of droughts, coupled with decreasing rainfall and/or increased unpredictability of rainfall [13.2.1.2; 13.2.1.4; 13.2.2.2]	(high and persistent poverty) particularly in drylands are susceptible to these hazards, since they have a very limited ability to compensate for losses in water-dependent farming systems and/or livestock.	due to short time for recovery between droughts, approaching tipping point in rain-fed farming system and/or pastoralism.	stuck in poverty traps, heightened food insecurity, decreased land productivity, outmigration, and new urban poor in LICs and MICs.
Floods and flash floods in informal urban settlements and mountain environments, destroying physical assets (e.g. homes, roads, terraces, irrigation canals) [13.2.1.1; 13.2.1.3; 13.2.1.4]	High exposure and susceptibility of people, particularly children and elderly as well as disabled in flood-prone areas. Inadequate infrastructure, culturally imposed gender roles, and limited ability to cope and adapt due to political and institutional marginalization and high poverty adds to the susceptibility of these people in informal urban settlements, limited political interest in development and building adaptive capacity.	Risk of a high morbidity and mortality to floods and flash floods. Factors that further increase risk may include a shift from transient to chronic poverty due to eroded human and economic assets (e.g. labor market); economic losses due to infrastructure damage	Exacerbated inequality between better-endowed households able to invest in flood-control measures and/or insurance and increasingly vulnerable populations prone to eviction, erosion of livelihoods, and outmigration.
Increased variability of precipitation; shifts in mean climate and extreme events [13.2.1.1; 13.2.1.4]	Limited ability to cope due to exhaustion of social networks, especially among the elderly and female-headed households; mobilization of labor and food no longer possible.	Hazard combines with vulnerability to shift populations from transient to chronic poverty due to persistent and irreversible socio-economic and political marginalization. In addition the lack of governmental support, as well as limited effectiveness of response options increase the risk.	Increasing yet invisible multidimensional vulnerability and deprivation at the convergence of climatic hazards and socio-economic stressors.
Successive and extreme events (floods, droughts) coupled with increasing temperatures and rising water demand [13, 2.1.1; 13.2.1.5]	Rural communities are particularly susceptible, due to the marginalization of rural water users to the benefit of urban users, given political and economic priorities (e.g. Australia, Andes, Himalayas, Caribbean).	Risk of loss of rural livelihoods, severe economic losses in agriculture and damage to cultural values and identity; mental health impacts (including increased rates of suicide).	Loss of rural livelihoods that have existed for generations, heightened outmigration to urban areas; emergence of new poverty in MICs and HICs.
Sea level rise [13.1.4; 13.2.1.1; 13.2.2.1; 13.2.2.3]	High number of people exposed in low-lying areas coupled with high susceptibility due to multidimensional poverty, limited alternative livelihood options among poor households, and exclusion from institutional decision-making structures.	Risk of severe harm and loss of livelihoods. Potential loss of common-pool resources; of sense of place, belonging, and identity, especially among indigenous populations.	Loss of livelihoods and mental health risks due to radical change in landscape, disappearance of natural resources, and potential relocation; increased migration.
Increasing temperatures and heat waves [13.2.2.4; 13.2.1.5; 13.2.2.3]	Agricultural wage labourers, small-scale farmers in areas with multidimensional	Risk of increased morbidity and mortality due to heat stress, among male and	Declining labor pool for agriculture coupled with new challenges for rural

	poverty and economic marginalization, children in urban slums, and the elderly particularly susceptible.	female workers, children, and the elderly, limited protection due to socio-economic discrimination and inadequate governmental responses.	health care systems in LICs and MICs; aging and low-income populations without safety nets in HICs at risk.
Increased variability of rainfall and/or extreme events (floods, droughts, heat waves) [13.2.1.1; 13.2.1.3; 13.2.1.4; 13.2.1.5]	People highly dependent on rain-fed agriculture particularly at risk. Persistent poverty among subsistence farmers and urban wage labourers who are net buyers of food with limited coping mechanisms.	Risk of crop failure, spikes in food prices, reduction in consumption to protect household assets, risk of food insecurity, shifts from transient to chronic poverty due to limited ability to reduce risks.	Food riots, child food poverty, global food crises, limits of insurance and other risk-spreading strategies.
Changing rainfall patterns (temporally and spatially)	Households or people with a high dependence on rain-fed agriculture and little access to alternative modes of income.	Risks of crop failure, food shortage, severe famine.	Coincidence of hazard with periods of high global food prices leads to risk of failure of coping strategies and adaptation mechanisms such as crop insurance (risk spreading).
Stressor from soaring demand (and prices) for biofuel feedstocks due to climate policies.	Farmers and groups that have unclear and/or insecure land tenure arrangements exposed to the dispossession of land due to land grabbing in developing countries.	Risk of harm and loss of livelihoods for some rural residents due to soaring demand for biofuel feedstocks and insecure land tenure and land grabbing.	Creation of large groups of landless farmers unable to support themselves. Social unrest due to disparities between intensive energy production and neglected food production.
Increasing frequency of extreme events (droughts, floods). For example if 1:20 year drought/flood becomes 1:5 year flood/drought.	Pastoralists and small farmers subject to damage to their productive assets (e.g. herds of livestock; dykes, fences, terraces).	Risk of the loss of livelihoods and harm due to shorter time for recovery between extremes. Pastoralists restocking after a drought may take several years; in terraced agriculture, need to rebuild terraces after flood, which may take several years.	Collapse of coping strategies with risk of collapsing livelihoods. Adaptation mechanisms such as insurance fail due to increasing frequency of claims.
Emergent risks and key vulnerabilities (chapter 19)			
Warming and drying (precipitation changes of uncertain magnitude) [AR5 WGI TS.5.3, WGI SPM, WGI 11.3, WGI 12.4]	Limits to coping capacity to deal with reduced water availability; increasing exposure and demand due to population increase; conflicting demands for alternative water uses; socio-cultural constraints on some adaptation options. [19.2.2, 19.6.1.1, 19.3.2.2 19.6.3.4]	Risk of harm and loss due to livelihood degradation from systematic constraints on water resource use that lead to supply falling far below demand. In addition limited coping and adaptation options increase the risk of harm and loss. [19.3.2.2, 19.6.3.4]	Competition for water from diverse sectors (e.g. energy, agriculture, industry) interacts with climate changes to produce locally severe shortages. [19.3.2.2, 19.6.3.4]
Changes in regional and seasonal temperature and precipitation over land [AR5 WGI TS.5.3, WGI SPM, WGI 11.3, WGI 12.4]	Communities highly dependent on ecosystem services [19.2.2.1, 19.3.2.1] which are negatively affected by changes in regional and seasonal temperature.	Risk of large-scale species richness loss over most of the global land surface. 57±6% of widespread & common plants and 34±7% of widespread & common animals expected to lose	Widespread loss of ecosystem services, including: *provisioning*, such as food and water; *regulating*, such as the control of climate and disease; *supporting*, such as

		≥50% of their current climatic range by the 2080s leading to loss of services. [19.3.2.1]	nutrient cycles and crop pollination; and *cultural*, such as spiritual and recreational benefit. [19.3.2.1, 19.6.3.4]
Africa (chapter 22)			
Increasing Temperature	Children, pregnant women, and those with compromised health status are particularly at risk for temperature-related changes in diarrheal and vector-borne diseases, and for temperature-related reductions in crop yields. Outdoor workers, older adults, and young children are most susceptible to hot weather and heat waves. [22.3.5.2, 22.3.5.4]	Risk of changes in the geographic distribution, seasonality, and incidence of infectious diseases, leading to increases in the health burden. Risk of increased burdens of stunting in children. Risk of increase in morbidity and mortality during hot days and heat waves.	Interactions among factors lead to emerging and re-emerging epidemics.
	Populations dependent on aquatic systems and aquatic ecosystem services that are sensitive to increased water temperatures.	Loss of aquatic ecosystems and risks for people who might depend on these resources; reduction in freshwater fisheries production. [22.3.2.2, 22.3.4.4]	Risk of loss of livelihoods due to interactions of loss of ecosystem services and other climate-related stressors on poor communities.
	Rural and urban populations whose food and livelihood security is diminished.	Risk of harm and loss due to increased heat stress on crops and livestock resulting in reduced productivity; Increased food storage losses due to spoilage. [22.3.4.1, 22.3.4.2]	Range expansion of crop pests and diseases to high elevation agroecosystems. [22.3.4.3]
Extreme Events, e.g. floods and flash floods (& drought)	Population groups living in informal settlements in highly exposed urban areas; women and children often the most vulnerable to disaster risk. [22.3.6, 22.4.3]	Increasing risk of mortality, harm and losses due to water logging triggered by heavy rainfall events.	Compounded risk of epidemics including diarrhoeal diseases (cholera).
	Susceptible groups include those who experience diminished access to food resulting from reduced capacity to transport, store, and market food, such as the urban poor.	Risk of food shortages and of damages to the food system due to storms and flooding.	Food price spikes due to convergence of climatic and non-climatic forces that reduce food access for the poor whose income is disproportionately spent on food. [22.3.4.5]
	Children, pregnant women, and those with compromised health status are particularly vulnerable to reduced access to safe water and improved sanitation and increasing food insecurity. [22.3.5.2, 22.3.5.3]	Risk of crop and livestock losses from drought. Risk of reduced water supply and quality for household use. [22.3.4.1, 22.3.4.2] Risk of increased incidence of food and waterborne diseases (e.g. cholera) and undernutrition. Risk of drinking water contamination due to heavy	Compound effects of high temperature and changes in rainfall on human and natural systems. Increased incidence of stunting in children. [22.3.5.3].

		precipitation events and flooding. [22.3.5.2]	
Europe (chapter 23)			
Extreme weather events [23.9]	Sectors with limited coping and adaptive capacity as well as high sensitivity to these extreme events, such as transport, energy and health are particularly susceptible.	Risk of new systemic threats due to stress on multiple and interconnected sectors. Risk of failure of service provision of one or more sectors.	Disproportionate intensification of risk due to increasing interdependencies.
Climate change increases the spatial distribution and seasonality of pests and diseases. [23.4.1, 23.4.3, 23.4.4]	High susceptibility of plants and animals that are exposed to pests and diseases.	Risk of increases in crop losses and animal diseases or even fatalities of livestock.	Increasing risks due to limited response options and various feedback processes in agriculture, e.g. use of pesticides or antibiotics to protect plants and livestock increases resistance of disease vectors.
Extreme weather events and reduced water availability due to climate change. [23.3.4]	Low adaptive capacity of power systems might lead to limited energy supply as well as higher supply costs during such extreme events and conditions.	Increasing risk of power shortages due to limited energy supply, e.g. of nuclear power plants due to limited cooling water during heat stress.	Continued underinvestment in adaptive energy systems might increase the risk of mismatches between limited energy supply during these events and increased demands, e.g. during a heat wave.
Asia (chapter 24)			
Rising average temperatures and more frequent extreme temperatures, as well as changing rainfall patterns (temporally and spatially).	Food systems and food production system for key grain crops, particularly rice and other cereal crop farming systems are highly susceptible. [24.4.4.3]	Risk of crop failures and lower crop yield also can increase the risk of major losses for farmers and rural livelihoods. [24.4.4.3]	Increase in Asian population combined with rising temperatures affecting food production. Upper temperature limit to the ability of some food systems to adapt could be reached.
Rising sea level	Paddy fields and farmers near the coasts are particularly susceptible. [24.4.4.3]	Risk of loss of arable areas due to submergence. [24.4.4.3]	Migration of farming communities to higher elevation areas entails risks for migrants and receiving regions.
Projected increase in frequency of various extreme events (heat-wave, floods and droughts) and sea level rise.	Increasing exposure due to convergence of livelihood and properties into coastal megacities. People in areas that are not sufficiently protected against natural hazards are particularly susceptible.	Risk of loss of life and assets due to coastal floods accompanied by increasing vulnerabilities.	Projected increase in disruption of basic services such as water supply, sanitation, energy provision, and transportation system, which themselves could increase vulnerabilities.
Australasia (chapter 25)			
Rising air and sea surface temperatures, drying trends, reduced snow cover, increased intensity of severe cyclones, ocean acidification [25.2, Table 25-1, Figure 25-4, AR5 WGI Chapter 14	Species that live in a limited climatic range and that suffer from habitat fragmentation as well as from external stressors (pollution, run-off, fishing, tourism, introduced	Risk of significant change in community composition and structure of coral reefs and montane ecosystems and risk of loss of some native species in Australia. [25.6.1, 25.6.2, 25.10.2]	Increasing risk from compound extreme events across time and space, and cumulative adaptation needs, with recovery and risk reduction measures hampered further by impacts

and Atlas]	predators and pests) are especially susceptible. [25.6.1, 25.6.2]		and responses reaching across different levels of government. [25.10.2, 25.10.3, Box 25-9]
Increased extreme rainfall related to flood risk in many locations [25.2, Table 25-1]	Adaptation deficit of existing infrastructure and settlements to current flood risk; expansion and densification of urban areas; effective adaptation includes transformative changes such as land-use controls and retreat. [25.3, Box 25-8, 25.10.2]	Increased frequency and intensity of flood damage to infrastructure and settlements in Australia and New Zealand. [Box 25-8, 25.10.2]	
Continuing sea level rise, with projections spanning a particularly large range and continuing beyond 2100, even under mitigation scenarios [25.2, Box 25-1, AR5 WGI Chapter 13]	Long-lived and high asset value coastal infrastructure, and low-lying ecosystems are highly susceptible. Expansion of coastal populations and assets into coastal zones increases the exposure. Conflicting priorities constrain adaptation options and limit effective response strategies. [25.3, Box 25-1]	Increasing risks to coastal infrastructure and low-lying ecosystems in Australia and New Zealand, with widespread damages towards the upper end of projected ranges. [Box 25-1, 25.6.1, 25.6.2, 25.10.2].	
North America (chapter 26)			
Increases in frequency and/or intensity of extreme events, such as heavy precipitation, river and coastal floods, heat waves and droughts. [26.2.2, 26.3.1, 26.8.1]	Physical infrastructure in a declining state in urban areas particularly susceptible. Also increases in income disparities and limited institutional capacities might result in larger proportions of people susceptible to these stressors due to limited economic resources. [26.7, 26.8.2]	Risk of harm and loss in urban areas, particularly in coastal and dry environments due to enhanced vulnerabilities of social groups, physical systems and institutional settings combined with the increases of extreme weather events. [26.8.1]	Inability to reduce vulnerability in many areas results in increase in risk more so than change in physical hazard. [26.8.3]
Higher temperatures, decreases in runoff and lower soil moisture due to climate change [26.2, 26.3]	Vulnerability of small rural landholders, particularly in Mexican agriculture, and of the poor in rural settlements. [26.5, 26.8.2.2]	Risk of increased losses and decreases in agricultural production. Risk of food and job insecurity for small landholders and social groups in regions exposed to these phenomena. [26.5, 26.8.2.2]	Increasing risks of social instability and local economic disruption due to internal migration. [26.2.1, 26.8.3]
Wildfires and drought conditions [Box 26-2]	Indigenous groups, low-income residents in peri-urban areas, and forest systems. [Box 26-2, 26.8.2]	Risk of loss of ecosystem integrity, property loss, human morbidity and mortality due to wildfires. [Box 26-2, 26.8.3]	
Extreme storm and heat events, air pollution, pollen, and infectious diseases [26.6.1]	Susceptibility of individuals is determined by factors such as economic status, pre-existing illness, age, and access to assets. [26.6.1]	Increasing risk of extreme temperature-, storm-, pollen, and infectious diseases-related human morbidity or mortality. [26.6.2]	
River and coastal floods, and sea level rise [26.2.2,	Increasing exposure of populations, property, as	Risk of property damage, supply chain disruption,	Multiple risks from interacting hazards on

26.4.2, 26.8.1]	well as ecosystems, partly resulting from overwhelmed drainage networks. Groups and economic sectors that highly depend on the functioning of different supply chains; public health institutions that can be disrupted; and groups that have limited coping capacities to deal with supply chain interruptions and disruptions to their livelihoods are particularly susceptible. [26.7, 26.8.1]	public health, water quality impairment, ecosystem disruption, infrastructure damage, and social system disruption from urban flooding due to river and coastal floods and floods of drainage networks. [26.4.2, 26.8.1]	populations' livelihoods, infrastructure and services. [26.7, 26.8.3]
Central and South America (chapter 27)			
Reduced water availability in semi arid regions and regions dependent on glacier meltwater; flooding in urban areas due to extreme precipitation [27.2.1, 27.3.3]	Groups that cannot keep agricultural livelihoods and are forced to migrate are especially vulnerable. Limited infrastructure and planning capacity can further increase the lack of coping and adaptive capacities to rapid changes expected (precipitation), especially in large cities.	Risk of loss of human lives, livelihood and property.	Increase in infections diseases. Economic impacts due to reallocation of populations.
Ocean acidification and warming [27.3.3, CC-OA]	Coral reef systems.	Risk of loss of biodiversity (species) and risk of a reduced fishing capacity with respective impacts for coastal livelihoods.	Economic losses and impact on food (fishery) production in certain regions.
Extremes of drought/precipitation [27.2.1, 27.3.4]	Elevated CO_2 decreases nutrient contents in plants, especially nitrogen in relation to carbon in food products.	Risk of loss of (food) production and productivity in some regions where extreme events may occur. Need to adjust diet due to decrease in food quality (e.g. less protein due to lower nitrogen assimilation). Decrease in bioenergy production.	Strong economic impacts related to the need to move crops to more suitable regions. Teleconnections (related to food quality) related to the intense exportation of food by the region. Impacts on energy system and carbon emissions with consequent increase in fossil fuel demand.
Higher temperatures and humidity leads to a spread of vector-borne diseases in altitude and latitude [27.3.7]	People exposed and vulnerable to vector borne diseases and an increase in mosquito biting rates that increase the probability of human infections.	Risk of increase in morbidity and in disability-adjusted life years (DALYs); Risk of loss of human lives; Risk of decrease in school and labour productivity.	High economic impacts owing to the necessity to increase the financing of health programs, as well as the costs of DALYs, increase in hospitals and medical infrastructure adequate enough to cope with increasing disease incidence rates, and the spread of diseases to newer regions.
Polar Systems (chapter 28)			

Loss of multi-year ice and reductions in the spatial extent of summer sea ice [28.2.5, 28.3.2, 28.4.1]	Indigenous communities that dependent on sea ice for traditional livelihoods are vulnerable to this hazard, particularly due to loss of breeding and foraging platforms for marine mammals.	Risk of loss of traditional livelihoods and food sources.	Top down shifts in food-webs.
	Ecosystems are vulnerable due to the shifts in the distribution and timing of ice algal and ocean phytoplankton blooms.	Risk of disruption of synchronized timing of zooplankton ontogeny and availability of prey. Increased variability in secondary production while zooplankton adapt to shifts in timing. Risks also to local marine foodwebs.	Bottom up shifts in food webs. Potential changes in pelagic and benthic coupling.
Ocean acidification [28.2.2, 28.3.2]	Tolerance limits of endemic species surpassed. Impacts on exoskeleton formation for some species and alteration of physiological and behavioural properties during larval development.	Localized loss of endemic species, local impacts on marine foodwebs.	Localized declines in commercial fisheries. Local declines in fish, shellfish, seabirds and marine mammals.
Shifts in boundaries of marine eco-regions due to rising water temperature, shifts in mixed layer depth, changes in the distribution and intensity of ocean currents. [28.2.2, 28.3.2]	Marine organisms that are susceptible to spatial shifts are particularly vulnerable.	Risk of changes in the structure and function of marine systems and potentially species invasions.	Disputes over international fisheries and shared stocks
Declining sea ice, changes in snow and ice timing and state, decreasing predictability of weather. [28.1, 28.4.1]	Many traditional subsistence food sources – especially for indigenous peoples - such as Arctic marine and land mammals, fish and waterfowl. Various traditional livelihoods are susceptible to these hazards.	Risk of loss of habitats and changes in migration patterns of marine species.	Enhancement of risk to food security and basic nutrition – especially for indigenous peoples - from loss of subsistence foods and increased risk to subsistence hunters', herders', and fishers' health and safety in changing ice conditions.
Increased river and coastal flooding and erosion and thawing of permafrost [28.2.4, 28.3.1, 28.3.4]	Rural and remote communities as well as urban communities in low-lying Arctic areas are exposed. Susceptibility and limited coping capacity of community water supplies due to potential damages to infrastructure.	Community and public health infrastructure damaged resulting in disease from contamination and sea water intrusion.	Reduced water quality and quantity may result in increased rates of infection, other medical problems and hospitalizations.
Extreme and rapidly changing weather, intense weather and precipitation events, rapid snow and ice melt, changing river and sea ice conditions, permafrost thaw. [28.2.4]	People living from subsistence travel and hunting, herding and fishing, for example indigenous peoples in remote and isolated communities are particularly susceptible.	Accidents, physical/mental injuries, death, and cold-related exposure, injuries and diseases.	Enhanced risks to safe travel or subsistence hunting, herding, fishing activities affect livelihoods and wellbeing.

Diminished sea ice; earlier sea ice melt-out; faster sea ice retreat; thinner, less predictable ice in general; greater variability in snow melt/freeze; ice, weather, winds, temperatures, precipitation. [28.2.5, 28.2.6, 28.4.1]	Livelihoods of many indigenous peoples (e.g. Inuit and Saami) depend upon subsistence hunting and access to and favourable conditions for animals. These livelihoods are susceptible. Also marine ecosystems are susceptible (e.g. marine mammals).	Risk of loss of livelihoods and damage due to: (e.g., Inuit: more difficult access to marine mammals associated with diminishing sea ice) and (e.g., Saami: loss of access by reindeer to their forage under snow due to ice layers formed by warming winter temperatures and "rain on snow").	Enhanced risk of loss of livelihoods and culture of increasing numbers of indigenous peoples, exacerbated by increasing loss of lands and sea ice for hunting, herding, fishing due to enhanced petroleum and mineral exploration and increased maritime traffic.
Small Islands (chapter 29)			
Increases in intensity of tropical cyclones [AR5 WGI 14.6, 14.8.4]	Various countries and communities are vulnerable to these hazards due to their high dependence on natural and ecological systems for security of settlements and tourism [29.3.3.1], human health [29.3.3.2] and water resources [29.3.2].	Risk of loss of ecosystems, settlements and infrastructure, as well as negative impacts on human health and island economies. [Figure 29-4]	Increased risk of interactions of damages to ecosystems, settlements, island economies and risks to human life. [29.6, Figure 29-4].
Ocean warming and acidification leading to coral bleaching [29.3.1.2, 30.5.4.2, 30.5.6.1.1, 30.5.6.2]	Tropical island communities are highly dependent on coral reef ecosystems for subsistence life styles, food security, coastal protection and beach and reef-based tourist economic activity and hence are highly susceptible to the hazard of coral bleaching. [29.3.1.2, 30.6.2.1.2]	Risk of decline and possible loss of coral reef ecosystems through thermal stress. Risk of serious harm and loss of subsistence lifestyles. Risk of loss of coastal protection and beaches, risk of loss of tourist revenue. [29.3.1.1, 29.3.1.2]	Impacts on human health and loss of subsistence lifestyles. Potential increase in internal migration / urbanisation. [29.3.3.3, Chapter 9]
Sea level rise [29.3.1.1, 30.3.1.2; AR5 WGI 3.7.1]	Many small island communities and associated settlements and infrastructure are in low-lying coastal zones (high exposure) and are also vulnerable to increasing inundation, erosion and wave incursion. [5.3.2, 29.3.1.1, Figure 29-2]	Risk of loss and harm due to sea level rise in small island communities. Global Mean Sea Level is likely to increase by 0.35 to 0.70 m for RCP 4.5 during the 21st century, threatening low-lying coastal areas and atoll islands. [29.4.3, Table 29-1; AR5 WGI 13.5.1, Table 13.5]	Incremental upwards shift in sea-level baselines results in increased frequency and extent of marine flooding during high tides and episodic storm surges These events could render soils and fresh groundwater resources unfit for human use before permanent inundation of low-lying areas. [29.3.1.1, 29.3.2, 29.3.3.1, 29.5.1].
Regional Oceans (chapter 30)			
Increasing ocean temperatures. Increased frequency of thermal extremes	Corals and other organisms whose tolerance limits are exceeded are particularly susceptible (especially CBS, STG, SES and EUS ocean regions). [30.5.2, 30.5.4, 30.5.5, CC-CR, 30.5.6, CC-OA, 6.2.2.1, 6.2.2.2]	Risk of increased mass coral bleaching and mortality (loss of coral cover) with severe risks for coastal fisheries, tourism and coastal protection. [30.5.2, 30.5.3, 30.5.4, 30.5.5, Box CC-CR, 6.3.2. 6.3.5, 5.4.2.4, 7.2.1.2, 6.4.1.4, 29.3.1.2]	Loss of coastal reef systems, risk of decreased food security and reduced livelihoods, and reduced coastal protection. [30.6.2.1, 30.6.5, 7.2.1.2]

	Marine species and ecosystems as well as fisheries and coastal livelihoods and tourism that cannot cope or adapt to changing temperatures and changes in the distribution are particularly vulnerable, especially for HLSBS, CBS, STG, and EBUE. [30.5, CC-BIO, 6.3.2, 6.3.4, 7.3.2.6]	Risk for fishery and coastal livelihoods. Fishery opportunity changes as stock abundance may rise or fall; increased risk of disease and invading species impacting ecosystems and fisheries. [6.3.5, 6.4.1.1, 6.5.3, 7.3.2.6, 7.4.2, 29.5.3, 29.5.4]	Significant risk of fisheries collapse may develop as the capacity for fisheries to resist fundamental change to fishery composition as well as the increased migration of disease and other organisms is accelerated. [6.5.3, 7.5.1.1.3]
	Coastal ecosystems and communities that might be exposed to phenomena of elevated rates of microbial respiration leading to reduced oxygen at depth and increased spread of dead zones are particularly vulnerable (particularly for EBUE, SES, EUS).	Risk of loss of habitats and fishery resources as well as losses of key fisheries species. Oxygen levels decrease leading to impacts on ecosystems (e.g. loss of habitat) and organisms (e.g. physiological performance of fish) results in reduced capture of key fisheries species.	Increasing risk of loss of livelihoods.
	Deep sea life is sensitive to hazards and to change given the very constant conditions under which it has evolved. [30.1.3.1.3, 30.5.2, 30.5.5]	Risk of fundamental changes in conditions associated with Deep Sea (e.g. oxygen, pH, carbonate, CO_2, temperature) drive fundamental changes that result in broad scale changes throughout the ocean. [30.1.3.1.3, 30.5.2, 30.5.5, CC-UP, CC-NPP]	Changes in the deep ocean may be a prelude to ocean wide changes with planetary implications.
Rising ocean acidification	Reef systems, corals and coastal ecosystems that are exposed to a reduced rate of calcification and greater decalcification leading to potential loss of carbonate reef systems, corals, molluscs and other calcifiers in key regions, such as the CBS, STG [6.2.2.2]	Risk of the alteration of ecosystem services including risks to food provisioning with impacts on fisheries and aquaculture. [7.2.1.2, 7.3.2, 7.4.2, 6.2.5.3]	Income and livelihoods for communities are reduced as productivity of fisheries and aquaculture diminish. [7.5.1.1.3, 30.6]
	Marine organisms that are susceptible to changes in pH and carbonate chemistry imply a large number of changes to the physiology and ecology of marine organisms (particularly in CBS, STG, SES regions). [30.3.2.2, .2 .2, 6.3.4, 6.2.5]	Risk of fundamental shifts in ecosystems composition as well is organism function occur, leading to broad scale and fundamental change. Income and livelihoods from dependent communities are affected as ecosystem goods and services decline, with the prospect that recovery may take tens of thousands of years. [6.1.1.2]	Risk to ecosystems and livelihoods is increased by the potential for interaction among ocean warming and acidification to create unknown impacts. [CC-OA]
	Coastal systems are increasingly exposed to upwelling in upwelling systems which results in	Risk of loss and harm to fishery and aquaculture operations and respective livelihoods (e.g. oyster	Background pH and carbonate chemistry are also such that harmful conditions are always present (avoiding

	periods of high CO_2, low 0_2 and pH. [CC-UP, 6.2.2.2, 6.2.5.3]	cultivation) especially those exposed periodically to harmful conditions during elevated upwelling, which trigger adaptation responses. [30.6.2.1.4]	impacts via adaptation not possible any more. [30.6.2.1.4]
Increased stratification as a result of ocean warming; Reduced ventilation.	Ocean ecosystems are vulnerable due to the reduced regeneration of nutrients as mixing between the ocean and its surface is reduced (EUS, STG and EBUE). [30.5.2, 30.5.4, 30.5.5; 6.2, 6.3, 6.5]	Risk of productivity losses of oceans and respective negative impacts on fisheries. The concentration of inorganic nutrients in the upper layers of the ocean is reduced leading to lower rates of primary productivity. [CC-NPP]	Reduced primary productivity of the ocean impacts fisheries productivity leading to lower catch rates and effects on livelihoods. [6.4.1.1, CC-NPP]
	Ecosystems and organisms that are sensitive to decreasing oxygen levels. [30.5.2, 30.5.3, 30.5.5, 30.5.6, 30.5.7]	Increased risk of dead (hypoxic) zones reducing key ecosystems and fisheries habitat. [30.3.2.3, .1 .1 .3]	
Changes to wind, wave height and storm intensity.	Shipping and industrial infrastructure is vulnerable to wave and storm intensity. [30.6.2]	Risk of increasing losses and damages to shipping and industrial infrastructure.	Risk of accidents increases for enterprises such as shipping, as well as deep sea oil gas and mineral extraction.

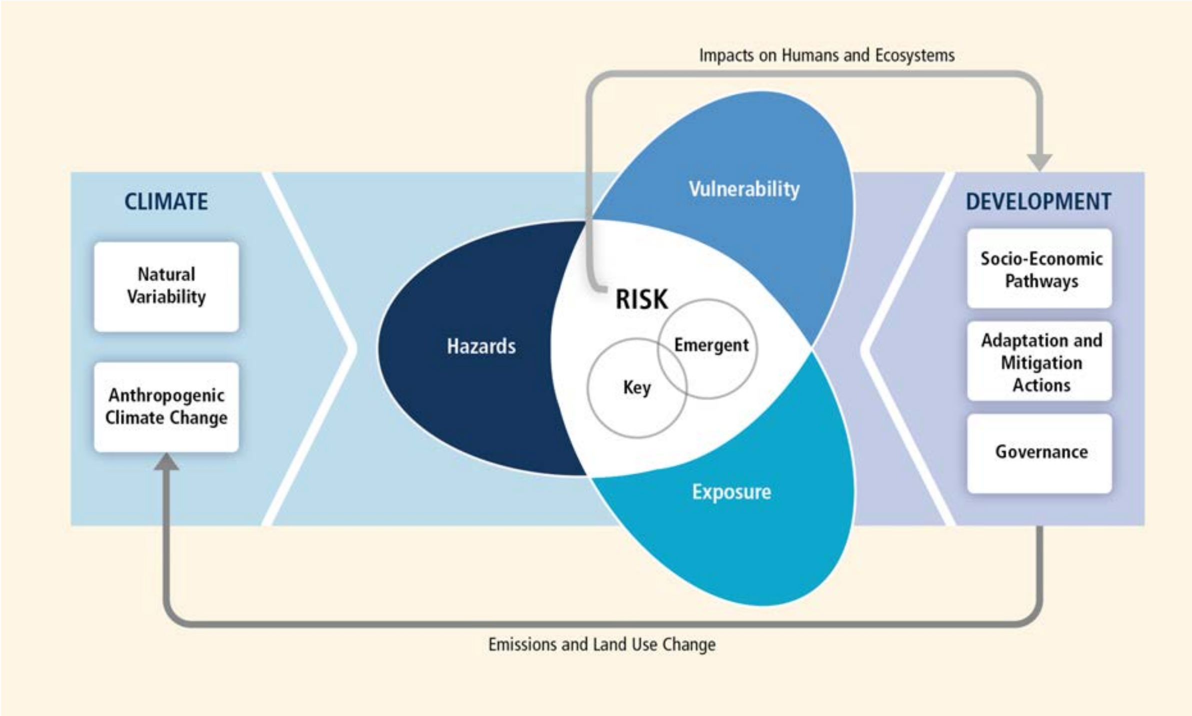

Figure 19-1: Schematic of the interaction among the physical climate system, exposure, and vulnerability producing risk. The figure visualizes the different terms and concepts discussed in this chapter. It underscores that risks are a product of a complex interaction between physical hazards associated with climate change and climate variability on the one hand, and the vulnerability of a society or a social-ecological system and its exposure to climate-related hazards on the other. The definition and use of “key” and “emergent” are indicated in Box 19-2 and the Glossary. Vulnerability and exposure are, as the figure shows, largely the result of socio-economic development pathways and societal conditions (although changing hazard patterns also play a role, see 19.6.1.1). Changes in both the climate system (left side) and development processes (right side) are key drivers of the different core components (vulnerability, exposure, and hazards) that constitute risk (modified version of Figure 1, IPCC 2012a).

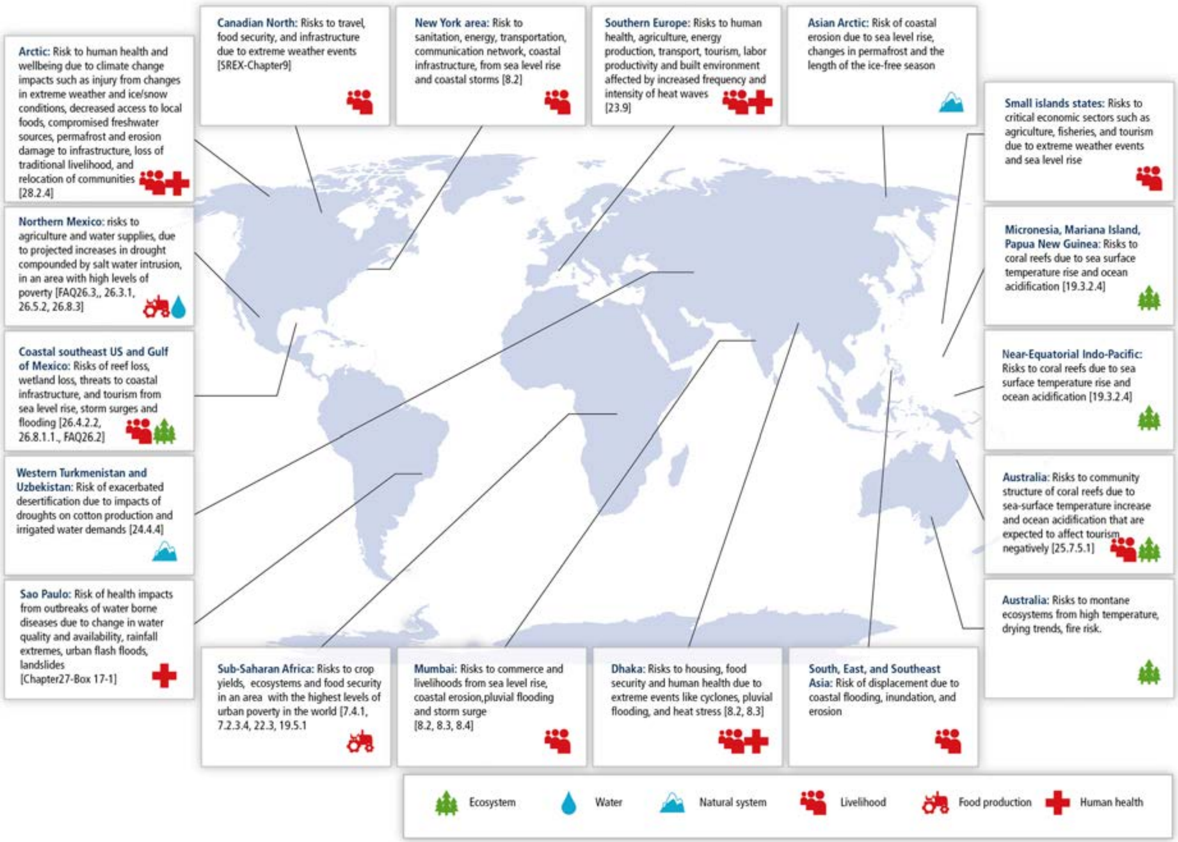

Figure 19-2: Some examples of areas of compound risk identified in this assessment. Symbols indicate one or two of the main sectors or systems subject to compound risk but in each case, additional sectors and systems are at risk.

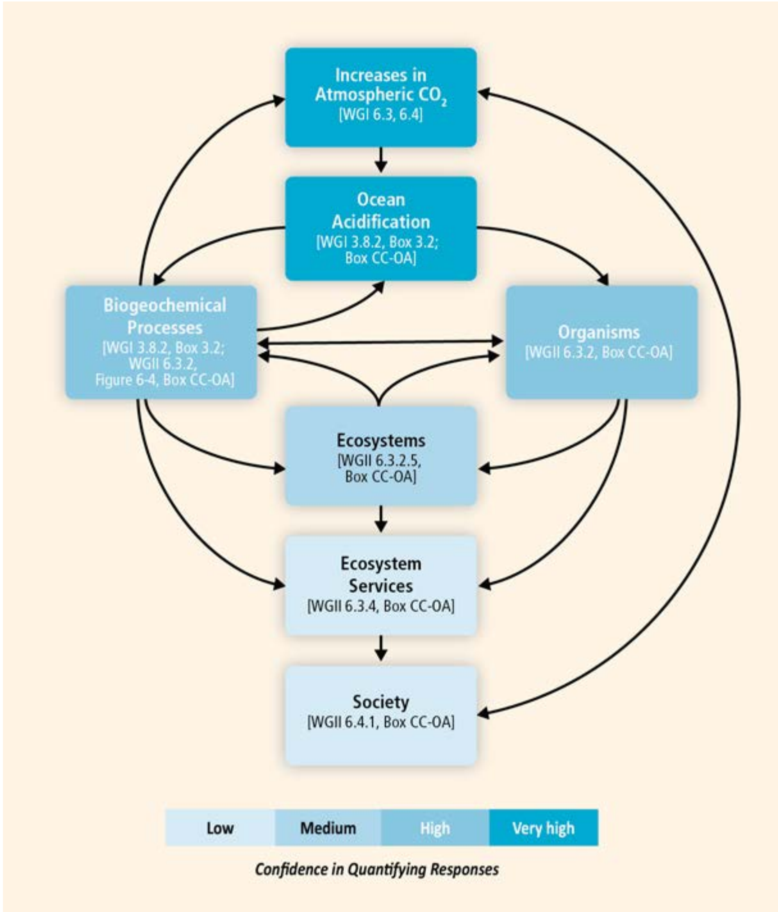

Figure 19-3: The pathways by which ocean acidification affects marine processes, organisms, ecosystems, and society. The confidence in quantifying the impacts decreases along the pathway.

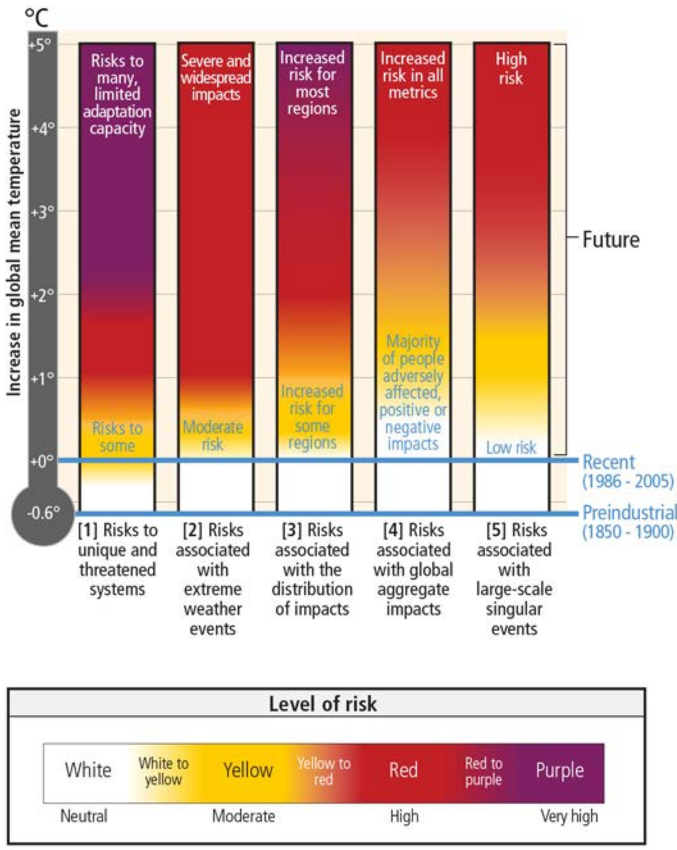

Figure 19-4: The dependence of risk associated with the Reasons for Concern (RFCs) on the level of climate change, updated from TAR and Smith *et al.* (2009). The color scheme indicates the additional risk due to climate change as described in the text. The shading of each ember provides a qualitative indication of the increase in risk with temperature for each individual "reason." The transition from red to purple, introduced here, is defined by very high risk of severe impacts and the presence of significant irreversibilities or persistence of climate-related hazards combined with limited ability to adapt due to the nature of the hazard or impact. Comparison of the increase of risk across RFCs indicates the relative sensitivity of RFCs to increases in GMT. In general, assessment of RFCs takes autonomous adaptation into account, as was done previously (Smith *et al.*, 2001; Schneider *et al.*, 2007, AR4 WGII Chapter 19). In addition, this assessment took into account limits to adaptation in the case of RFC1, RFC3, and RFC5, independent of the development pathway. The rate and timing of climate change and physical impacts, not illustrated explicitly in this diagram, was taken into account in assessing RFC1 and RFC5. Comments superimposed on RFCs provide additional details which were factored into the assessment. The levels of risk illustrated reflect the judgments of Chapter 19 authors.

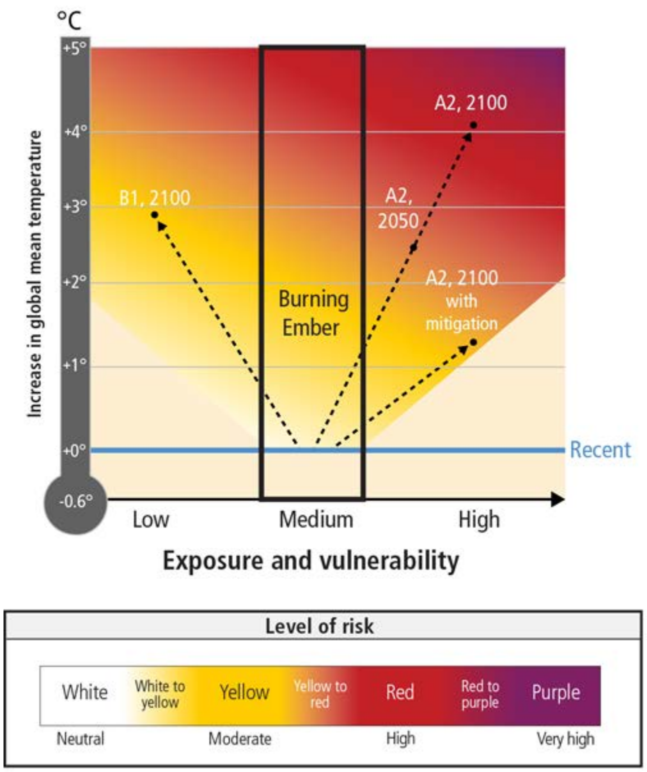

Figure 19-5: Illustration of the dependence of risk associated with a Reason for Concern (RFC) on the level of climate change and exposure and vulnerability (E&V) of society. This figure is schematic; the degree of risk associated with particular levels of climate change or E&V has not been based on a literature assessment, nor associated with a particular RFC (the "burning ember" in the figure refers generically to any of the embers in Figure 19-4). The E&V axis is relative rather than absolute: "Medium" E&V indicates a future development path in which E&V changes over time are driven by moderate trends in socio-economic conditions. "Low" and "High" E&V indicate futures that are substantially more optimistic or pessimistic, respectively, regarding exposure and vulnerability. Judgments made in other burning ember diagrams of the RFCs (Smith *et al.*, 2001, 2009) including Figure 19-4, which do not explicitly take changes in E&V into account, are consistent with Medium future E&V. Arrows and dots illustrate the use of SRES scenario-based literature to locate particular impact or risk assessments on the figure according to the evolution of climate and socio-economic conditions over time. This figure does not explicitly address issues related to the rates of climate change or when impacts might be realized.

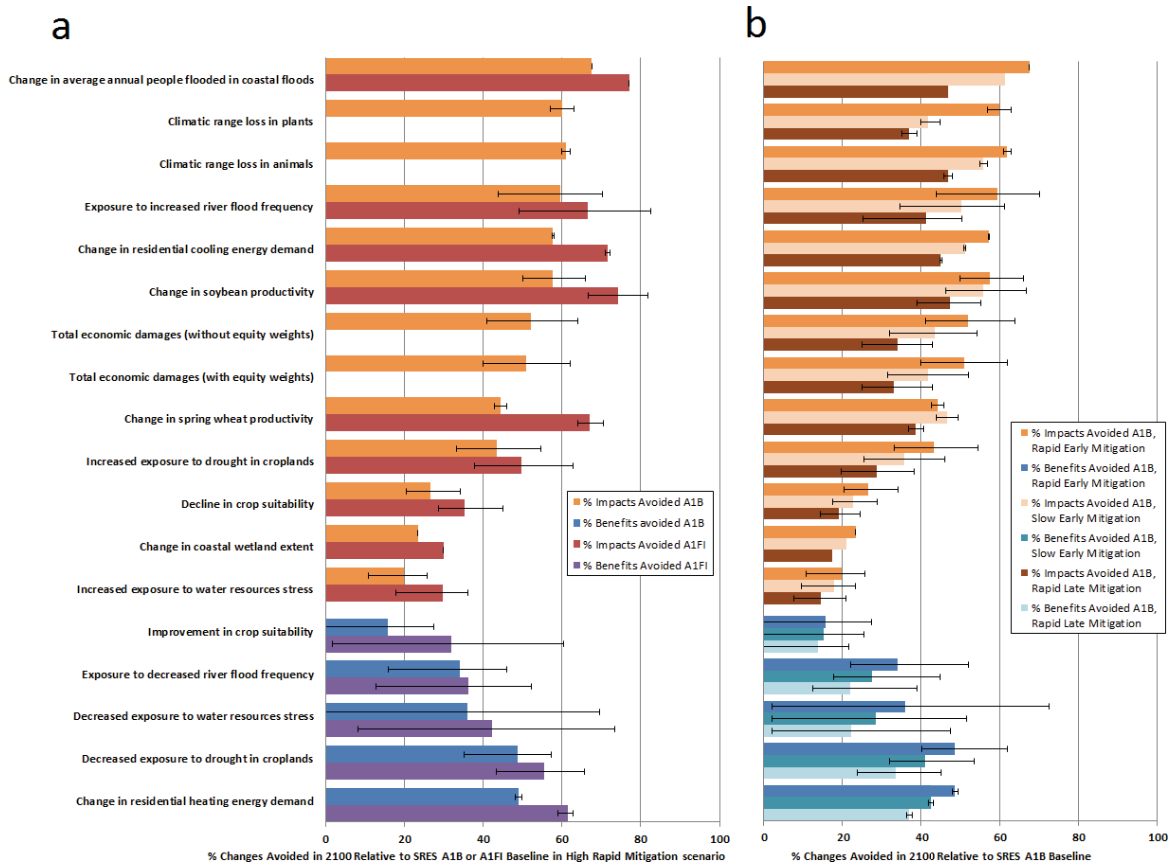

Figure 19-6: Panel **a**: Climate change impacts avoided by an early, rapid mitigation scenario in which global emissions peak in 2016 and are reduced at 5% thereafter, compared to two no-mitigation baseline cases SRES A1B (orange bars) and SRES A1FI (red bars). Impacts avoided are larger if the A1FI baseline scenario is used than if the A1B baseline is used, because greenhouse gas emissions in A1FI exceed those in A1B (see 19.7.1). Panel **b**: The dependence of the potential to avoid climate change impacts upon the timing of emission reductions is illustrated. Climate change impacts avoided by the same early, rapid mitigation scenario compared to the no-mitigation baseline case SRES A1B (orange bars) are shown. The information displayed is identical to the orange bars in panel a, but a comparison is now made with the impacts avoided from two other less stringent mitigation scenarios. Impacts avoided if global emissions peak in 2016 but are subsequently reduced more slowly (2% annually) are lower (pink bars compared to orange bars). However, if mitigation occurs later, so that global emissions do not peak until 2030, even if emissions are subsequently reduced at 5% annually, the avoided impacts are smaller than in either of the other two cases (brown bars compared to orange and pink bars). Both panels show the uncertainty range (error bars) due to regional climate change projected with 7 GCMs. Errors due to uncertainty within impacts models are not shown. Uncertainties associated with sea level rise related impacts are smaller because the models used encompass a narrow range of alternative sea level rise projections. Since increases and decreases in water stress, flood risks and crop suitability are not co-located and affect different regions, these effects are not combined. From Arnell *et al.*, 2013, Warren *et al*, 2013a; Warren *et al.*, 2013b.
[Illustration to be redrawn to conform to IPCC publication specifications.]

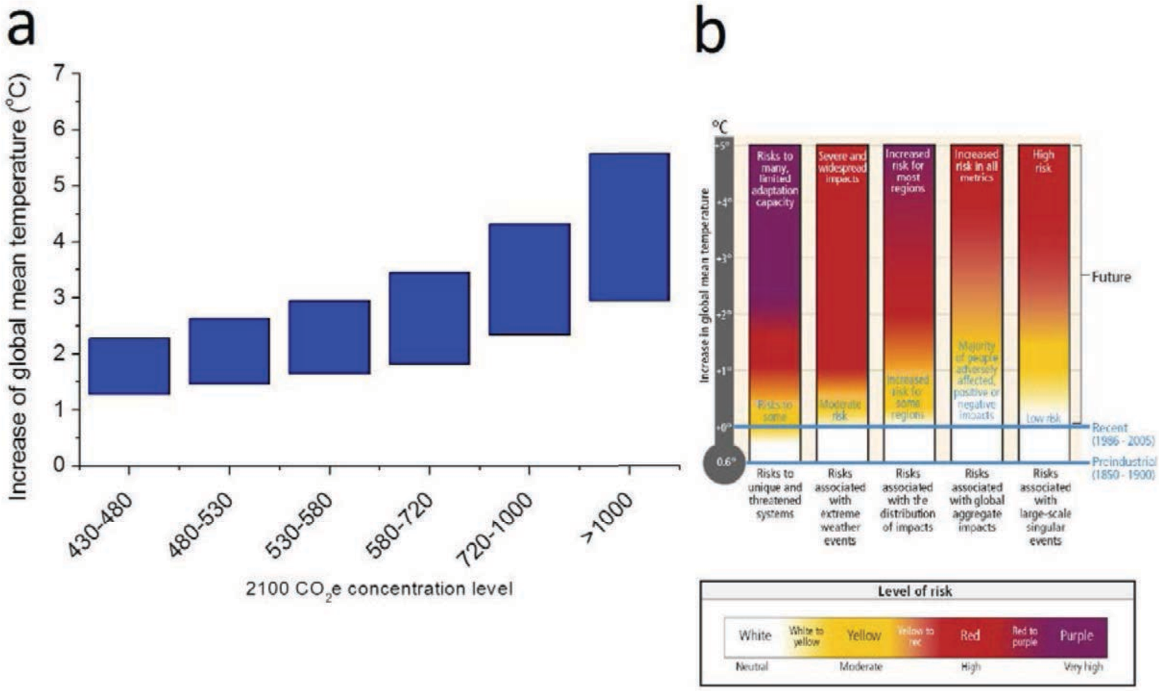

Figure 19-7: Relationship between mitigation scenarios considered in AR5 WGIII, in terms of their CO_2e concentrations and global temperature rise outcomes relative to pre-industrial times, and level of risk associated with Reasons for Concern. Panel **a** shows the projected increase in global mean temperature in 2100 compared to preindustrial, calculated using the MAGICC climate model for the scenarios defined in Chapter 6, Working Group III, indicating the uncertainty range resulting both from the range of emission scenario projections within each category and the uncertainty in the climate system as represented by MAGICC (data taken from Chapter 6 – AR5 WGIII). Panel **b** reproduces Figure 19-4 for ease of comparison. Note the different temperature baselines used in Figure 19-4. Beyond 2100, temperature, and therefore risk, decreases in most of the lowest three scenarios and increases further in most of the others.

Executive Summary

Climate change calls for new approaches to sustainable development that take into account complex interactions between climate and social and ecological systems. Climate-resilient pathways are development trajectories that combine adaptation and mitigation to realize the goal of sustainable development. They can be seen as iterative, continually evolving processes for managing change within complex systems.

This chapter integrates a variety of complex concepts in assessing climate-resilient pathways. It takes sustainable development as the ultimate goal, and considers mitigation as a way to keep climate change moderate rather than extreme. Adaptation is considered a response strategy to anticipate and cope with impacts that cannot be (or are not) avoided under different scenarios of climate change. In most cases, sustainable development will also involve capacities for implementing and sustaining appropriate risk management. Responses may differ from situation to situation, calling for a multi-scale perspective that takes the socioeconomic, cultural, biophysical, and institutional context into account. Nonetheless, most situations share at least one fundamental characteristic: threats to sustainable development are greater if climate change is substantial rather than moderate. Similarly, opportunities for sustainable development are greater if climate change is moderate rather than substantial.

Although findings from this chapter are based on a high level of consensus in source materials and in the expert communities, the amount of supporting evidence is relatively limited because so many aspects of sustainable development and climate change mitigation and adaptation have yet to be experienced and studied empirically. The task of this chapter is to suggest options to be considered for decision-making, both now and in the future, as elements of the evolving processes for a variety of locations and scales. This chapter's findings are as follows:

Climate change poses a moderate threat to current sustainable development and a severe threat to future sustainable development. (*high confidence*; *high agreement, medium evidence*). Some climate-related impacts on development are already being observed (e.g, changes in agriculture, increases in coastal vulnerability). Added to other stresses such as poverty, inequality, or diseases, the effects of climate change will make sustainable development objectives such as food and livelihood security, poverty reduction, health, and access to clean water more difficult to achieve for many locations, systems, and affected populations. [20.2.1]

Climate-resilient pathways include strategies, choices and actions that reduce climate change and its impacts. They also include actions to assure that effective risk management and adaptation can be implemented and sustained. (*high confidence*; *high agreement, medium evidence*). Adaptation and mitigation have the potential to both contribute to and impede sustainable development, and sustainable development strategies and choices have the potential to both contribute to and impede climate change responses. Both kinds of responses are needed, working together to reduce risks of disruptions from climate change. These actions, however, may introduce tradeoffs

between adaptation and mitigation, and between economic goals and environmental goals. In some cases, for example, adaptation may increase greenhouse gas emissions (e.g., increased fossil-based air conditioning in response to higher temperatures) and in some cases mitigation may impede adaptation (e.g., reduced energy availability in countries with growing populations). In many cases, strategies for climate changer responses and strategies for sustainable development are highly interactive. [20.3, 20.4]

The integration of adaptation and mitigation responses can in some cases generate mutual benefits, as well as introduce co-benefits with development policies. (*moderately high confidence*; *medium high agreement, medium evidence*). In many cases, reducing the risk of climate change can enhance capacities for management of other risks. Opportunities to take advantage of positive synergies may decrease with time, particularly if the limits to climate change adaptation are exceeded. [20.2.1, 20.3.2, 20.3.3, 20.5.1]

Prospects for climate-resilient pathways are related fundamentally to what the world accomplishes with climate change mitigation, but both mitigation and adaptation are essential for climate change risk management at all scales. (*high confidence*; *high agreement, medium evidence*). As the magnitude of climate change increases and the consequences become increasingly significant to many areas, systems, and populations, the challenges to sustainable development increase. Beyond some magnitudes and rates of climate change, the impacts on most systems would be great enough that sustainable development may no longer be possible for many systems and locations. At the local scale, governments, businesses, communities and individuals in many developing regions have limited capacities to mitigate climate change because they contribute very little to global emissions. They may also have relatively limited capacities to adapt for reasons of income, education, health, security, political power, or access to technology). At all scales, however, mitigation and adaptation actions are fundamental for effective implementation of climate risk management and reduction. [20.2.3, 20.3, 20.6.1]

To promote sustainable development within the context of climate change, climate-resilient pathways may involve significant transformations (*high confidence*; *high agreement, medium evidence*). Transformations in political, economic, and socio-technical systems can contribute to enhanced climate responses, both for mitigation and adaptation. Although transformations may be reactive, forced, or induced by random factors, they may also be deliberately created through social and political processes. Whether in relation to mitigation, adaptation, or sustainable development, it is possible to identify enabling conditions that support transformations. Nonetheless there are legitimate concerns about the equity and ethical dimensions of transformation. [20.5]

Strategies and actions can be pursued now that will move toward climate-resilient pathways while at the same time helping to improve livelihoods, social and economic well-being, and responsible environmental management (*high confidence*; *high agreement, medium evidence*). Actions at the present time will emphasize co-benefits and iterative learning, with risk management strategies and capacities refined continually on the bases of growing evidence, knowledge, and experience. [20.6.2]

Delayed action in the present may reduce options for climate resilient pathways in the future (*high confidence*; *high agreement, medium evidence*). In some parts of the world, current failures to address effects of emerging climate stressors are already eroding the basis for sustainable development and offsetting previous gains. Opportunities to design and implement solutions that promote climate resilient pathways exists now, and they can capture development co-benefits of improving livelihoods, social and economic well-being. Current actions will emphasize climate risk management and iterative learning and transformation, on the basis of growing evidence, knowledge, and experience. [20.6.2]

More research about the relationship between mitigation, adaptation, and sustainable development is needed, as well as research on the relationship between incremental changes and more significant transformations for sustainable development (*high confidence*; *high agreement, robust evidence*). Priorities for research include improving understandings of benefits, costs, synergies, tradeoffs and limitations of major mitigation and adaptation options, along with implications for equitable development to facilitate decision-making about climate resilient pathways. (high confidence; high agreement, strong evidence).

20.1. Introduction

Following summaries of *what we know* about climate change impacts, vulnerabilities, and prospects for adaptation (Chapter 18) and of *what we should be most worried about* (Chapter 19), this concluding chapter summarizes what is currently known about options regarding *what to do* in responding to these risks and concerns.

In terms of "what to do" to address climate change and threats to development now and in the future, the chapter identifies and discusses climate-resilient pathways. Climate-resilient pathways are defined in this chapter as development trajectories that combine adaptation and mitigation with effective institutions to realize the goal of sustainable development. They are seen as iterative, continually evolving processes for managing change within complex socio-ecological systems; taking necessary steps to reduce vulnerabilities to climate change impacts in the context of development needs and resources, building capacity to increase the options available for vulnerability reduction and coping with unexpected threats; monitoring the effectiveness of vulnerability reduction efforts; and revising risk reduction responses on the basis of continuous learning. As such, climate-resilient pathways include two main categories of responses:

- Actions to reduce human induced climate change and its impacts, including both mitigation and adaptation towards achieving sustainable development
- Actions to assure that effective institutions, strategies, and choices for risk management will be identified, implemented, and sustained as an integrated part of achieving sustainable development.

In many cases, each of the two categories of responses has the potential to benefit the other as well, offering potentials for win-win kinds of integration, although mechanisms and institutions are needed to address cases where the two elements have negative effects on each other and to assure that positive synergies are realized. Because climate change challenges are significant for many areas, systems, and populations, climate-resilient pathways will generally require transformations – beyond incremental approaches – in order to assure sustainable development (see Sections 20.2.3.1 and 20.6.2; for related UNFCCC language, see Box 20-1**).**

Incremental responses to climate change address immediate and anticipated threats based on current practices, management approaches or technical strategies. These may involve developing energy-efficient vehicles to mitigate climate change, or building higher dykes to adapt to sea-level rise. Incremental responses are often referred to as business-as-usual approaches, as they do not challenge or disrupt existing systems (Kates et al, 2012). Transformative responses, in contrast, involve innovations that contribute to systemic changes by challenging some of the assumptions that underlie business-as-usual approaches (O'Brien, 2012). Transformational adaptations, for example, change the nature, composition, and/or location of threatened systems (Smit and Wandel, 2006; Stringer et al., 2009; NRC, 2010a; Pelling, 2010; IPCC SREX, 2012). Importantly, transformations of the systems, structures, relations, and behaviors that contribute to climate change and social vulnerability may also be necessary to reduce risks to sustainable development, as discussed in Section 20.5.2.

Conceptual understandings of sustainable development have developed considerably, particularly over the past two decades, as the short- and long-term implications of climate change and extreme events have become better understood, although empirical evidence of progress with sustainable development is often elusive. The discussion of sustainable development in the IPCC process has evolved since the First Assessment Report, which focused on the technology and cost-effectiveness of mitigation activities, and the Second Assessment Report (SAR), which included issues related to equity and to environmental and social considerations. The Third Assessment Report (TAR) further broadened the treatment of sustainable development by addressing issues related to global sustainability, and the Fourth Assessment (AR4) included chapters on sustainable development in both WG II and III reports, with a focus on both climate-first and development-first literatures.

This chapter recognises climate change as a threat to sustainable development, given growing evidence that the world is on a trajectory toward relatively major climate change. The chapter emphasises that, as a result, transformational changes are very likely to be required for climate resilient pathways – both transformational adaptations and transformations of social processes that make such transformational adaptations feasible. The chapter integrates a variety of complex issues in assessing climate-resilient pathways in a variety of regions at a variety of scales: sustainable development as the ultimate aim, mitigation as the way to keep climate change impacts moderate rather than extreme, adaptation as a response strategy the way to keep climate change impacts moderate rather than extreme or to cope with impacts that cannot be (or are not) avoided, and development pathways as contexts that shape choices and actions. It stresses needs and opportunities to make progress toward climate-resilient pathways now, rather than postponing responses to an indefinite future.

_____ START BOX 20-1 HERE _____

Box 20-1. Goals for Climate-Resilient Pathways

Climate resilient pathways are development trajectories of combined mitigation and adaptation to realize the goal of sustainable development that help avoid "dangerous anthropogenic interference with the climate system" as specified in Article 2 of the Convention.

Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC) outlines its ultimate objective as the, '*stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system*… in order to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner'. Article 3.4 of the Convention recognizes that '*Parties have a right to, and should promote sustainable development*'. Number of recent decisions by the Conference of the Parties (COP) to the UNFCCC has attempted to recognize the scientific view that the increase in global temperature should be below 2 degrees Celsius and encourage long-term cooperative action to combat climate change. The Decisions agreed in Cancun at COP 16 recognizes '… *deep cuts in global greenhouse gas emissions are required according to science*, and as documented in the Fourth Assessment Report of the IPCC, with a view to reducing global greenhouse gas emissions so as to hold the increase in global average temperature below 2°C above preindustrial levels…consistent with science…[and] also recognizes the need to consider… strengthening the long-term global goal on the basis of the best available scientific knowledge'. In the preamble of the Cancun Decisions highlights the central importance of the link between climate change and employment and *'Realizes that addressing climate change requires a paradigm shift towards building a low-carbon society that offers substantial opportunities and ensures continued high growth and sustainable development, based on innovative technologies and more sustainable production and consumption and lifestyles, while ensuring a just transition of the workforce that creates decent work and quality jobs.' (UNFCCC, 2011, Decision 1/CP16).* The 2011 COP in a decision known as the Durban Platform increases the strength of the language in the decision 1/CP.17 to conclude, '… *climate change represents an urgent and potentially irreversible threat to human societies and the planet* and thus requires to be urgently addressed … with a view to accelerating the reduction of global greenhouse gas emissions....*'* This decision was followed by the decisions adopted in Doha at the 18th Conference of the Parties that noted with grave concern the significant gap between the aggregate effect of Parties' mitigation pledges in terms of global annual emissions of greenhouse gases by 2020 and aggregate emission pathways consistent with having a likely chance of holding the increase in global average temperature below 2 °C or 1.5 °C above pre-industrial levels. As such, the current UNFCCC negotiations have adopted +2°C or 1.5 C as the desirable target upper limit and equated this with "dangerous" in Article 2.

_____ END BOX 20-1 HERE _____

The chapter is organized in six parts: climate change as a threat to sustainable development, assessing links between sustainable development and climate change as well as defining climate resilient pathways (20.2), contributions to resilience through climate change responses (20.3), contributions to resilience through sustainable development strategies and choices (20.4), determinants of resilience in the face of serious threats (20.5), challenges in moving toward climate-resilient pathways (20.6), and priority gaps in knowledge (20.7). Several of the terms that are central to this chapter have been defined earlier in the Working Group II Fifth Assessment Report, including climate, adaptation, and mitigation. In addition, by "resilient" we mean a system's ability to anticipate, reduce, accommodate, and recover from disruptions in a timely, efficient, and fair manner (IPCC SREX, 2012). For literatures on "sustainable development," see the section below. A summary definition is development that achieves continuing improvements in human well-being and assures a sustainable relationship with a physical environment that is already under stress, reconciling tradeoffs among economic, environmental, and other social goals through institutional approaches that are equitable and participative in order themselves to be sustainable.

20.2. Climate Change as a Threat to Sustainable Development

Climate-resilient pathways bring together (a) sustainable development as the larger context for societies, regions, nations, and the global community with (b) climate change effects as threats to (and possibly opportunities for) sustainable development and (c) responses to reduce any effects that would undermine future development and even offset already achieved gains. Considering alternative climate-resilient pathways cannot be separated from levels of climate change. In principle, most climate change scientists, decisionmakers, and stakeholders agree that: (i) there is a level of climate change that is low enough that climate resilience for most systems could be achieved without enormous efforts and widespread transformational adaptation; (ii) there is a level of climate change that is high enough that climate resilience cannot be expected to cope with severe impacts on most systems (e.g., Rockstrom et al., 2009); and (iii) between those two levels the challenges to climate resilience grow as the level of climate change rises. Scientists do not, however, agree on what magnitude of climate change (e.g., average global warming) defines each of the two levels. Some experts support the view (Box 20-1 and Section 20.3.1) that any level above 2 degrees C would mean impacts that are incompatible with sustainable development (Metz et al., 2002**).** The Summary for Policymakers of the IPCC's Fourth Assessment Working Group II Report indicated that there is an approximate threshold between 2.5 and 3 degrees C of warming, above which impact concerns are severe but below which concerns are less severe (IPCC, 2007b: Figure SPM.2; also see Smith et al., 2009). Other scientists are unconvinced that system sensitivities to climate parameters such as temperature increase are understood well-enough to support any specific warming threshold (e.g., NRC, 2010c), and some scientists and policymakers are unconvinced that adaptive management and adaptive response capacities are well-enough understood to support determinations of limits to adaptation and resilience (Chapter 16). Most experts in all three groups, however, agree that prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation (e.g., New et al., 2012).

20.2.1. Links between Sustainable Development and Climate Change

20.2.1.1. Objectives of Sustainable Development

Different actors have used the concept of sustainable development to pursue a variety of objectives in policy and practice worldwide, with the common denominator of delivering improved human well-being while sustaining environmental services (Sen, 1999; Morgan and Farsides, 2009; Von Bernard and Gorbaran, 2010). "Sustainable development" is a concept rooted in concerns about balance in the relationships between society and nature (e.g., Brown, 1981). The Brundtland Report (WCED, 1987: 43) defines the idea as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." It contains within it two key concepts of 'needs': in particular the essential needs of the world's poorest, to which overriding priority should be given; and the idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs (Rao, 2000). It stresses that equitable economic development is key to addressing environmental problems both in developing and developed regions in ways that are sustainable for the long term (Halsnaes et al., 2008; Lafferty and Meadowcroft, 2010).

Historically, policy and science have subsequently influenced the development of the concept. Concerns about declining environmental quality, and increasing population growth, coupled with increasing rates of consumption (energy, natural resources, input-intensive living standards), motivated changes in some countries, related for example to:

- Water and air quality standards
- Management of hazardous materials
- Changes in regulation (although some literature says that current institutional controls and linkages are counterproductive (Scrieciu et al., 2013; Barker, 2008; O'Hara, 2009)
- Agricultural and industrial practices
- Water and solid waste management
- A movement toward greater efficiency in resource use including recycling

- An emphasis on energy efficiency, progressing toward renewable energy as an alternative to non-renewable fossil fuel resources (Frey and Linke, 2002**)**.

In this context, global discourse and practice have helped to establish principles and aspirational plans. Examples include Agenda 21, which is a comprehensive plan of action adopted at the 1992 Earth Summit by more than 178 governments (Sitarz, 1994) and the 2012 “Rio+20” conference, which issued a statement urging countries to renew their commitment to sustainable development. Improved understandings of the short- and long-term implications of climate change and extreme events (IPCC FAR, SAR, TAR, AR4, SREX) have influenced conceptualizations of sustainable development and related objectives such as poverty reduction, health, livelihood and food security, and other aspects of human welfare related to the idea of “climate resilient development”. These discussions occurred against an emerging understanding of “rights to development” (e.g. UNFCCC Article 2), juxtaposed with the lack of consensus about justifiable patterns of consumption and a recognition that development processes have altered global environmental systems, including climates (Crutzen and Stoermer, 2000; IPCC, 2007a, IPCC SREX, 2012, Oliver-Smith et al., 2012). However, in practice some national authorities interpret sustainable development as pursuing current economic development (Arndt et al., 2012; Beg et al., 2002; Swart et al., 2003; Yohe, 2012), as many countries aspire to carbon intensive development models akin to the systems in place in most industrialized countries – from food production, trade, and transport to household consumption (Brown, 2011; Grist, 2008; Sanwal, 2012).

In contrast, to many observers carbon-intensive development models in industrialized and developing countries appear broadly inconsistent with objectives such as poverty reduction, improving human health, securing food and livelihoods associated with the idea of sustainable development (Marston, 2012; Grist, 2008; Ehrenfeld, 2008; also see Victor, 2008, and Victor and Rosenbluth, 2007), and with efforts to define and establish “safe operating spaces” for humanity (Röckstrom et al., 2009, Preston et al., 2013). While diverse interpretations of the concept are used, the literature suggests that many indicators of human welfare are already being compromised to some degree and at different scales by climate related stressors (see Section 20.2.1.2).

One way that sustainable development pathways can contribute to climate resilience is by pursuing consumption patterns that assure social and economic development while reducing use of natural resources and maintaining ecosystem services. It is possible that the desired objectives of consumption might be met in ways that require fewer resources and produce fewer emissions (Kates, 2000b; also see Leiserowitz et al., 2005). Ideas about equity and values play a role in sustainable development and how policy makers perceive tradeoffs in aims to improve human well-being. In many cases, growth in consumption that raises human well-being (such as food and health services), especially among populations with incomes rising from low levels, is a catalyst for economic and social development (Clark et al., 2008; Deaton, 2008). In contrast, for populations already at high consumption levels, increasing material consumption does not necessarily translate into higher well-being (Easterlin, 1974 and 2001; Adger, 2010; also see IPCC Working Group III: Chapter 4). This observation is reflected in research on subjective human happiness, satisfaction, and material comfort (DeLeire and Kalil, 2010; Cafaro, 2010; Huesemann, 2006; Dolan and White, 2007; Fleurbaey, 2009).

20.2.1.2. Risks and Threats Posed by Climate Change, interacting with Other Factors and Driving Forces

As the extent of implications of climate change become better-understood (Chapter 18) and as particular reasons for concern have begun to come into focus (Chapter 19), climate change has been increasingly seen as an issue for sustainable development – with the potential either to aid or impede its successful implementation (e.g., Halsnaes et al., 2008; Munasinghe, 2010).

The links between sustainable development and climate adaptation and mitigation are cross-cutting and complex. First, the impacts of climate change and ill-designed responses to these impacts, may derail current sustainable development policy and potentially offset already achieved gains. These impacts are expected to affect numerous sectors such as agriculture, forestry and energy; threaten coastal zones and other vulnerable areas; and pose critical challenges to governance and political systems (World Bank, 2010: 39-69; Adger et al., 2011; IPCC SREX, 2012; also see Box 20-2 below and Chapters18 and 19). Examples include poverty and livelihoods (Chapter 13), food security (Chapter 7), human security (Chapter 12), rural and urban areas (Chapters 8 and 9), and economic sectors (Chapters 10 and 17). For instance, effects of climate change on key ecological resources and systems can jeopardize sustainable development in systems closely dependent on natural capital. Moreover, although impacts will affect both developed and developing regions, the latter are considered especially problematic due to lower adaptive capacity (World Bank, 2010: Chapter 13; Lemos et al., 2013). Second, mitigation has the potential to keep these threats at a moderate rather than extreme level, and adaptation will enhance the ability of different systems to cope with the remaining impacts, therefore modulating negative effects on sustainable development (IPCC, 2007a).

_____ START BOX 20-2 HERE _____

Box 20-2. Key Reasons for Concern about Climate Change Effects on Sustainable Development

Chapter 19 identifies a number of “Key Risks, Key Vulnerabilities, and Reasons for Concern” (see especially 19.6.3 and Table 19-4). Emergent risks from climate change related to sustainable development include losses of ecosystem services, challenges to land and water management, effects on human health, particular risks of severe harm and loss in certain vulnerable areas, increasing prices of food commodities on the global market, consequences for migration flows at particular times and places, increasing risks of flooding, risks of food insecurity, systemic risks to infrastructures from extreme events, loss of biodiversity, and risks for rural livelihoods. These risks differ according to the magnitude of climate change and both regional and socioeconomic differences in vulnerability. Some unique and threatened systems are at risk at current temperatures, with risks increasing at even relatively small increases in global mean temperature. Risks grow if the magnitude of warming increases.

_____ END BOX 20-2 HERE _____

Third, many of the conditions that define vulnerability to climate impact and the ability to mitigate and adapt to them are firmly rooted in development processes (e.g., structural deficits and available assets and entitlements) (Brooks et al., 2005; Lemos et al., 2013; Chapter 15, Section 15.2.1). Indeed, climate change will act as a threat multiplier and will create new poor in low-income countries and middle to high-income countries (Chapter 13). Fourth, sustainable development intersects with many of the drivers of climate change, especially regarding energy production and consumption and the ability to mitigate emissions (IPCC SRREN, 2012; also see Chapter 9). Fifth, because several of the desirable characteristics of climate responses and sustainable development may overlap (e.g. implementation of no-regrets options, equitable distribution of resources, increased adaptive capacity and livelihood capitals, functioning ecosystems and maintained biodiversity), systems that prioritize sustainable development may be better at designing and implementing successful mitigation and adaptation (Forsyth, 2007; Brown, 2011).

Finally, climate mitigation and adaptation, if planned and integrated well, have the potential to create opportunities to foster sustainable development (see Section 20.3.3 below). Under the threat of climate change, sustainable development depends on changes in social awareness and values that lead to innovative actions and practices, including increased attention to both disaster risk management and climate change adaptation in anticipation of (and in response to) changes in climate extremes (IPCC SREX, 2012). Understanding how to enhance positive feedbacks between mitigation, adaptation, and sustainable development (e.g. win-win and triple win interventions) while minimizing potential trade-offs between them (see Section 20.3.3) is an essential part of planning for and pursuing climate-resilient pathways. In the following paragraphs, we discuss these links in light of empirical research and specific examples (Box 20-2; also see discussions of Representative Concentration Pathways (RCPs) and Shared Socioeconomic Pathways (SSPs) in Chapter 1). While some of the links described above have been contemplated in the scholarly literature, there remain considerable gaps on our knowledge base to inform climate-resilient pathways.

The relationship between climatic change and development policy has often been theorized as essentially twofold. On the one hand, climate change will affect development policy as needs to respond to negative, and perhaps positive, impacts arise (Schipper, 2007; Burton et al., 2002; Halsnaes and Verhagen, 2007; IPCC, 2007a). On the other hand, development policy critically shapes carbon emission paths, the ability to develop sustainable adaptation and mitigation options, and to build overall adaptive capacity (Bizikova et al., 2007; Garg et al., 2009; Metz and Kok, 2008; Lemos et al., 2013). Because of the recognized relationship between development and climate change drivers and responses, some authors have called for a “political economy of climate change” that takes into consideration ideas, power, and resources at different scales from the local to the global (e.g., Tanner and Allouche, 2011).

Enhancing resilience to respond to effects of climate change includes adopting good development practices that are consonant with building sustainable livelihoods and, in some cases, challenging current models of development (Boyd et al., 2008; McSweeny and Coomes, 2011). Moreover, promoting development pathways that are both equitable and sustainable is also a key to addressing climate change (Wilbanks, 2003; Nelson et al., 2007). In this sense, integrating sustainable development and overall climate change policy can be all the more relevant if "cross-linkages between poverty, the use of natural capital and environmental degradation" are recognized (Veeman and Politylo, 2003: 317; also see Matthew and Hammill, 2009). Especially in less developed regions, the relationship between vulnerability to climate impacts and development is often very close and mutually dependent as such realities as low per capita income and inequitable distribution of resources, lack of education, health care, and safety, and weak institutions and unequal power relations fundamentally shape sensitivity, exposure and adaptive capacity to climate impact (Garg et al., 2009; McSweeny and Coomes, 2011; Adger et al., 2003; Kates, 2000a; Lemos et al. 2013). In these regions, reducing risks that affect resource-dependent communities is increasingly viewed as a necessary but insufficient way to tackle the myriad of problems associated with climate change impacts (Jerneck and Olsson, 2008). Building the capacity of individuals, communities and governance systems to adapt to climate impacts is both a function of dealing with developmental deficits (e.g. poverty alleviation, reducing risks related to famine and food insecurity, enabling/implementing public health and mass education and literacy programs) and of improving risk management (e.g. alert systems, disaster relief, crop insurance, seasonal climate forecasts, risk insurance) (Mirza, 2003; Schipper and Pelling, 2006; IPCC SREX, 2012; Warner, Kreft, et al., 2012; Chapters 12 and 13). Hence, it is important not only to understand the relative importance of different kinds of interventions (climate and non-climate) in building adaptive capacity but also the potential positive and negative synergies between them (Lemos et al., 2013).

While research increasingly highlights the intersection between vulnerability, adaptive capacity, and developmental structural deficits (see chapter 13 for a detailed discussion), there is also growing recognition that the intractability of many of these problems may inhibit the development of climate-resilient pathways. For example, in Northeast Brazil, the fact that local traditional politics relied on patron-client relationships with drought-affected households to maintain power suggests that there was little incentive for policies that dramatically decreased their level of vulnerability (Tompkins et al., 2008). Omolo, 2010, argues that in the northwestern Kenya, in pastoralist societies of Turkana, in spite of increasing numbers of women headed households, participation of women in key decisions such as investment, resource allocation, and planning on where to move or settle in the aftermath of drought and floods is still quite low. A serious concern is that our inability to readily address these kinds of structural problems may limit options for future generations of marginalized social groups to be active agents of a climate resilient future. In this sense, it is critical to understand how existing path-dependent trajectories (e.g., socio-technical, behavioral, institutional) that form the contextual basis for climate change action at different scales (Burch, 2010) may inhibit (or help) the realization of future climate resilient pathways.

A number of studies recognize that not every possible response to climate change is consistent with sustainable development, since some strategies and actions may have negative impacts on the well-being of others and of future generations (Eriksen et al., 2011; Gardiner et al., 2010; see also Chapter 19, Section 19.3.2.5). For example, some mitigation interventions such as the subsidization of the ethanol industry in the US might compromise long-term resilience through both undesirable ecological effects (e.g. loss of crop diversity, soil erosion and aquifer depletion) and social effects (e.g. reduction of flexibility for alternative fuel development, potential for food insecurity (Adger et al., 2011). Likewise, in central Vietnam some responses to climate change impact, such as building dams to prevent flooding and saltwater intrusion and to generate power, threaten the livelihood of poor communities. First, the relocation of communities and the inundation of forestland to build dams limit households' access to land and forest products. Second, a government focus on irrigated rice agriculture can reduce poor households' ability to diversify their income portfolio, decreasing their long-term adaptive capacity (Beckman, 2011). Indeed, the consequences of responses to climate change, whether related to mitigation or adaptation, can negatively influence future vulnerability, unless there is awareness of and response to these interactions (Ericksen et al., 2011). Here, the role of values in responding to climate change becomes important from a variety of perspectives, including intergenerational, particularly when those currently in positions of power and authority assume that their prioritized values will be shared by future generations (O'Brien, 2009; Ericksen et al., 2011). Acknowledging the importance of intergenerational equity, it has been argued that participatory processes and 'deliberative democracy' can include the concerns, values and perceptions of a wide range of stakeholders, raising some of the ethical impacts attached to climate related risks (Backstrand, 2003; also see Deere-Birebeck, 2009). Such an approach could have a bearing on the way risks are assessed and addressed at the science-policy interface, with significant implications for sustainable development. For example, research by Wolf et al., 2009, on climate change responses in western Canada shows that individual quests to minimize their environmental impact and sense of responsibility (normatively defined as ecological citizenship) play an important role in the identification and implementation of sustainable responses to water scarcity. In contrast, inequitable distribution of power among those affected by climate impact can suppress innovative decisions about the future by limiting participation in designing solutions. In light of the complex interactions among climate change responses and sustainable development, there is a need for more holistic responses that place human well-being and security at the forefront, while building on existing strengths and capacities (Tompkins and Adger, 2004; O'Brien et al., 2010). This entails integrating multiple objectives and policy goals in order to promote responses to climate change that contribute to resilience and that are sustainable as social and policy conditions change (Meadowcroft, 2000; Tompkins and Adger, 2004; Pintér et al., 2011).

A reality in many countries may be that development in its many forms (economic, human and sustainable) can enhance the capacity to adapt (Lemos et al., 2013), while at the same time adding to greenhouse gas emissions. Yet, the World Development Report 2010 suggests that climate change responses have the potential to contribute to sustainable development as, for example, in the case of financial assistance with transition to low-carbon growth paths (World Bank, 2010) or in the case of mitigation policies that could increase income and/or enhance the quality of growth in vulnerable groups such as REDD+ (Reducing Emissions from Deforestation and Forest Degradation in Developing Countries). And while vulnerable sectors such as agriculture give us particular reasons for concern (see Box 20-2), they may offer opportunities in some instances to reduce climate related risks and threats by integrating both adaptation and mitigation strategies as a lever for reducing poverty and promoting climate resilient pathways. Particularly necessary is addressing institutional and social capacities for responding to both climate change impacts and mitigation responses. For example, Chhatre and Agrawal (2009), show that climate change mitigation can benefit livelihoods if ownership of forest commons is transferred to local communities.

Some interventions related to climate change responses aim to combine goals of sustainable development, climate change adaptation, and climate change mitigation into "win-win" or "triple win" approaches that highlight overlaps between these goals. Examples include mechanisms such as the Clean Development Mechanism (CDM) and Joint Implementation (JI) (e.g., Millar et al., 2007), which may seek to offset carbon emissions, build adaptive capacities of local communities, and provide sustainable development dividends despite mixed results in terms of accomplishing these goals in practice (Corbera and Brown, 2008). Specifically in the case of the CDM, robust empirical research shows overwhelming negative results in win-win terms—while the goal of offsetting carbon emissions has fared better, generating sustainable development dividend has been difficult. For example, after examining sixteen existing CDM projects around the world, Sutter and Parreno, 2007, found that whereas they could meet 72% of their emissions reduction goals, less than 1% might actually contribute significantly to sustainable development in the host country. Furthermore, their research suggests that there might be an actual tradeoff between the goals of efficient generation of certified emissions reduction (CERs) and the broader generation of the sustainable development dividend (also see Winkelman and Moore, 2011). Even when relatively successful, triple-win interventions may result in unequal distribution of benefits across mitigation, adaptation and sustainable development (Bryan et al., 2013). Because relationships among the three goals can lead to both positive and negative consequences, it is important to unravel conditions that lead to desirable outcomes (Chhartre and Agrawal, 2009) (see Section 20.3.3). Moreover, the fact that currently available institutional arrangements that attempt to combine mitigation and sustainable development (such as CDM) are not achieving win-win goals indicates the need for rapidly developing means for evaluating, changing and improving current policy instruments and mechanisms (Dovers and Hezri, 2010).

Given these connections, there is growing consensus in the literature about a need to integrate development and climate policies; however, the means to achieve this integration differ and are not without controversy (see, for example, Seballos and Kreft, 2011). An approach often described in the literature is mainstreaming, where governments incorporate climate-related concerns into existing policy (Dovers and Hezri, 2010). A major factor constraining the 'mainstreaming' of climate adaptation into development is the disconnect between access to globally available adaptation funds and developing countries' own development agendas (Hardee and Mutunga, 2009; Seballos and Kreft, 2011). This disconnect can potentially inhibit the development of robust local organizations and institutions that effectively integrate or mainstream climate change considerations into development priorities. In particular, research focusing on the National Adaptation Programmes of Action (NAPAs) and the Strategic Programmes for Climate Resilience (SPCRs), designed to support least developed countries to mainstream adaptation, shows that lack of coordination between government sectors, lack of technical capacity and discrepancies between long term development goals and short term adaptation interventions still constrain mainstreaming efforts (Chapter 15: Section 15.2; Saito, 2013). Even where climate-related initiatives and programs are reasonably well-coordinated, bureaucratic complexities can cause communities to be overlooked (Chukwumerije and Schroeder, 2009). For example, in Mexico, despite the governmental discourse supporting climate change policy, actual implementation of mitigation and adaptation actions have been constrained by lack of resources and institutional coordination and limited societal involvement (Sosa-Rodriguez, 2013). Other factors -- such as lack of financial and human resources, unclear distribution of costs and benefits, fragmented management, mismatches in scale of governance and implementation, lack and unequal distribution of climate information, lack of institutional memory, and trade-offs with other priorities – may also limit the smooth mainstreaming of climate adaptation action into development (Agrawala and van Aalst, 2008; Bizikova et al., 2007; Eakin and Lemos, 2006; Kok et al., 2008; Metz and Kok, 2008, Sietz et al., 2011). Finally, empirical evidence suggests that the relationship between development variables and climate change responses can be a mixture of positives and negatives, if development variables are not managed well (Garg et al., 2009). For example, in a study of the relationship between malaria incidence, development and climate variables in India, Garg et al., 2009, found that while some development interventions such as building irrigation canals and dams can, in some cases, increase the incidence of malaria and water-borne diseases (when they exacerbate potential breeding grounds for malarial parasites), others such as higher per capita income can reduce negative health impacts of climate change significantly – although the distribution of benefits can differ between types of interventions (also see Campbell-Landrum and Woodruff, 2006). Understanding how development variables intersect with climate responses is especially important because governments and other actors rarely make decisions in isolation; rather they respond to multiple stressors both in rural and urban environments (Agrawal, 2008; Eakin, 2005; Wilbanks and Kates, 2010; Lemos et al., 2013). Moreover, some evidence suggests that, in practice, decisionmakers (from heads of households to policy-makers) often do not place climate change at the top of their priority list of critical issues to address (Garg et al., 2007; Kok et al., 2008), although this situation seems to be changing. Moreover the increasing importance of climatic change in shaping social and governmental policy agendas has resulted a growing number of examples of specific interventions to respond to climate change, both in developed and developing regions (Ayers and Huq, 2009; Burch, 2010; Bierbaum et al., 2013; for examples of adaptation planning see Chapter 15, especially Section 15.2, and Chapter 14, especially Section 14.3).

20.2.3. Climate-Resilient Pathways

20.2.3.1. Framing Climate-Resilient Pathways

Climate-resilient pathways integrate current and evolving understandings of climate change consequences and conventional and alternative development pathways to meet the goals of sustainable development (see IPCC Working Group III: Chapter 4). They can be seen as development trajectories that include both mitigation and adaptation, as well as effective development institutions. Climate resilient pathways represent iterative processes for managing change within complex systems, where unintended consequences are common due to feedbacks, teleconnections, cross-scale linkages, thresholds, and non-linear effects (Folke et al., 2002; Scheffer et al., 2009; Lenton, 2011a). Climate-resilient pathways recognize that increasing atmospheric concentrations of greenhouse gases can lead to impacts that have long-term implications for sustainable development. The observed and projected impacts of climate change on poverty and livelihoods, food and water security, health, and human security are well-documented in this report (see Chapters 11, 12, 13).

The pursuit of climate-resilient pathways involves identifying vulnerabilities to climate change impacts; assessing opportunities for reducing risks; and taking actions that are consistent with the goals of sustainable development.

These actions may involve a combination of incremental and transformative responses that take into account: 1) current and anticipated changes in both climate averages and extremes; 2) the dynamic development context that influences social vulnerability, risk perception, conflict resolution, and resilience; and 3) recognition of human agency and capacity to influence the future. This last point is significant, as humans have the capacity to manage risk and to decrease vulnerability through both mitigation and adaptation, as well as through choices of development goals and strategies (IPCC SREX, 2012**)**.

Climate resilient pathways call for decisions and actions that take into account both short- and long-term time horizons. In the short term, society will have to adapt to changes in the climate that are linked to past emissions, and both incremental and transformative adaptation may thus be significant. Mitigation responses taken in the short term will have a strong influence on climate-resilient pathways for sustainable development in the future, shaping needs for transformative adaptation over a long time horizon. Considering the potential for non-linear impacts associated with increasing global temperatures, the threats to sustainable development are likely to become greater over time (Wilbanks et al., 2007; Stafford et al., 2010; Chapter 12). Discussions of climate-resilient pathways thus cannot be separated from levels of climate change.

20.2.3.2. Elements of Climate-Resilient Pathways

If climate change continues on its current path toward relatively significant impacts (NRC, 2010b), climate-resilient pathways will become increasingly challenging, requiring explicit attention to responses in virtually all regions, sectors, and systems in order to avoid disruptions of development processes. Climate-resilient pathways include two overarching attributes: (1) actions in order to reduce climate change and its impacts, including both mitigation and adaptation, and (2) actions to assure that effective risk management institutions, strategies, and choices can be identified, implemented, and sustained as an integrated part of development processes (Edenhofer et al., 2012). Box 20-3 lists a number of attributes of climate-resilient pathways categorized into awareness and capacity, resources and practices. Each of the items is amenable to strategy development in appropriate national, regional, and local contexts. For example, in many cases effective response to extreme events can benefit both from iterative problem-solving and bottom-up engagement in risk management, and from human development to enhance capacities for risk management and adaptive behavior (Tompkins et al., 2008). Folke (2006) characterizes resilience as a process of innovation and development. Pathways should therefore be continuously moving toward a more adapted and less vulnerable state; in some instances, there may be stages of slow development followed by periods where progress increases speed. Further, the nonlinearity, variability and uncertainty of climate impacts necessitates a system that allows for the flexibility to adapt to unexpected and even extreme events (Holling, 1973). This is especially true in light of political, economic or resource constraints, where pathways at the local level will need to not only be flexible but also practical and feasible in both the short term and long term. One of the most challenging aspects of climate-resilient pathways is that they exist in distinctive local contexts, where they are shaped by external linkages that connect them across geographic scales and time. For example, resilience cannot be achieved in a few privileged places if it is not achieved in other connected places, because instabilities in adversely impacted situations will spill over to other situations through such effects as resource supply constraints, conflict, migration, or disease transmission (Wilbanks, 2009; IPCC SREX, 2012: Chapter 7).

_____ START BOX 20-3 HERE _____

Box 20-3. Selected Elements of Climate-Resilient Pathways

Awareness and capacity

- A high level of social awareness of climate change risks
- A demonstrated commitment to contribute appropriately to reducing net GHG emissions, integrated with national development strategies
- Institutional change for more effective resource management through collective action
- Human capital development to improve risk management and adaptive capacities
- Leadership for sustainability that effectively responds to complex challenges

Resources

- Access to scientific and technological expertise and options for problem-solving, including effective mechanisms for providing climate information, services and standards
- Access to financing for appropriate climate change response strategies and actions
- Information linkages in order to learn from experiences of others with mitigation and adaptation

Practices

- Continuing development and evaluation of institutionalized vulnerability assessments and risk management strategy development, and refinement based on emerging information and experience
- Monitoring of emerging climate change impacts and contingency planning for responding to them, including possible needs for transformational responses
- Policy, regulatory, and legal frameworks that encourage and support distributed voluntary actions for climate change risk management
- Effective programs to assist the most vulnerable populations and systems in coping with impacts of climate change

_____ END BOX 20-3 HERE _____

Climate resilient pathways are in fact a process, not an outcome (Manyena, 2006), involving both incremental and transformational changes. The pathways therefore need to be built on a foundation of constantly advancing knowledge, where information is adjusted based on changing scientific knowledge climate parameters and altering social, economic and natural resource situations (Berkes, 2007). While some measures will be reactive, the main elements of a pathway are intentional and proactive: anticipating future change and developing appropriate plans and responses. Although payoffs from specific long-term pathways may be unknown, strategies and actions can be pursued now that will contribute significantly to moving toward climate-resilient pathways while helping to improve human livelihoods, social and economic well-being, and responsible environmental management (Section 20.6.2).

20.3. Contributions to Resilience through Climate Change Responses

Climate change responses include mitigation, adaptation, and integrated mitigation and adaptation strategies. Related to these responses but generally considered a separate response issue is “geoengineering” (Box 20-4, after Section 20.3.2).

20.3.1. Mitigation

In IPCC’s assessment reports, mitigation is the subject of Working Group III, to which the reader is referred for comprehensive information about options and strategies for reducing GHG emissions and increasing GHG uptakes by the earth system. For this chapter, the issue is how climate change mitigation relates to sustainable development, which was addressed by Chapter 12 of Working Group III’s Fourth Assessment Report (IPCC 2007a) and is also the focus of Chapter 4 of its Fifth Assessment Report, including attention to equity issues.

In general terms, mitigation is recognized to be important for sustainable development in two ways (Riahi, 2000). First, it reduces the rate and magnitude of climate change, which reduces climate-related stresses on sustainable development, including effects of climate extremes and extreme events (IPCC SREX, 2012; Section 20.2; Box 20-1; Washington et al., 2009; Lenton, 2011b). Perspectives among countries and other parties about mitigation targets differ as to whether they should be framed in terms of an aspirational ceiling on average global warming, such as 2 degrees or 1.5 degrees C, or in terms of an aspirational ceiling on the greenhouse gas concentration level in the atmosphere, such as 450 parts per million; and they differ in how to make progress toward stabilization. But recent observations of the rate of increase in global greenhouse emissions (e.g., Peters et al., 2013) suggest that the challenge of stabilizing greenhouse gas emission and/or concentrations is growing (for further information about international accords, national pledges and inventory reports, and continuing negotiations, along with summaries of current and projected progress with mitigation, see the Working Group III Fifth Assessment Report).

Second, trajectories for technological and institutional change in order to reduce net GHG emissions interact with development pathways. In some cases, national pledges to achieve mitigation targets (e.g., Figure 20-1) may be congruent with sustainable development in urban settings, such as green growth strategies that reduce local and regional air pollution, enhancing prospects for multi-level governance and integrated management of resources, and encouraging broader participation in development processes (Seto et al., 2010; Lebel, 2005). In other cases, such effects as higher energy prices associated with transitions from fossil fuels to renewable energy sources have the potential to have adverse effects on local and regional economic and social development (IPCC SRREN, 2012: Chapter 9).

_____ START BOX 20-4 HERE _____

Box 20-4. Considering Geoengineering Responses

If climate change mitigation leads to socially unacceptable pain and distress, policymakers may be faced with demands to find further ways to reduce climate change and its effects.

Such options include intentional large-scale interventions in the earth system either to reduce the sun’s radiation that reaches the surface of the earth or to increase the uptake of carbon dioxide from the atmosphere. An example of the former is to inject sulfates into the stratosphere. Examples of the latter include facilities to scrub carbon dioxide from the air and chemical interventions to increase uptakes by oceans, soil, or biomass (UK Royal Society, 2009; Chapter 19; IPCC Working Group III: Chapter 6; and Working Group I, Chapters 6 and 7).

Discussions of geoengineering have only recently become an active area of discourse in science, despite a longer history of efforts to modify climate (Schneider, 1996, 2009; Keith, 2000; Crutzen, 2006). Many of the possible options are known to be technically feasible, but their costs, effectiveness, and side-effects are exceedingly poorly understood (NRC, 2010b; MacCracken, 2011; Vaughan and Lenten, 2011; Goes et al., 2011). For example, some interventions in the atmosphere might not be unacceptably expensive in terms of direct costs, but they might affect the behavior of such earth system processes as the Asian monsoons (Robock et al., 2008; Brovkin et al., 2009). Some interventions to increase carbon uptakes, such as scrubbing carbon dioxide from the earth’s atmosphere, might be socially acceptable but economically very expensive. Moreover, it is possible that optimism about geoengineering options might invite complacency regarding mitigation efforts.

In any case, implications for sustainable development are largely unknown. Even though some views have been expressed that geoengineering is needed now in order to avoid irreversible impact such as the loss of ocean corals (while many governments have not begun to consider it at all), several countries consider it a research priority rather than a current decision-making option (NRC, 2010b). The challenge is to understand what geoengineering options would do to moderate global climate change and also to understand what their ancillary effects might be. This would allow policymakers in the future to respond if severe disruptions appear and, as a result, there is a need to consider rather dramatic technology alternatives. Some observers propose that research efforts should include limited experiments with geoengineering options, but agreement has not been reached about criteria for determining what experiments are appropriate or ethical (e.g., Blackstock and Long, 2010; Gardiner, 2010).

_____ END BOX 20-4 HERE _____

The challenge for climate-resilient pathways is to identify and implement mixes of technological and governance options that reduce net carbon emissions and at the same time support sustainable economic and social growth in a context where rising demands for economic and social development need to be combined with technology transitions without disrupting the development process. For example, strategies such as increasing carbon uptakes and decreasing carbon losses in the soil through better agricultural management practices – which can reduce net emissions – can improve soil water storage capacity. Practices such as conservation tillage can also increase water retention in drought conditions and help to sequester carbon in soils **(**Halsnaes et al., 2008**).** In many cases, however, this challenge remains very difficult to meet.

[INSERT FIGURE 20-1 HERE
Figure 20-1: Pledges by Annex 1 and Annex 2 countries in response to the Copenhagen Accord. Sources: http://unfccc.int/meetings/copenhagen_dec_2009/items/5264.php, http://unfccc.int/meetings/cop_15/copenhagen_accord/items5265.php.]

Mitigation and development also interact in a third way in that different groups and countries' ability to implement mitigation critically depends on their "mitigative capacity" (Yohe, 2001): their "ability to reduce anthropogenic greenhouse gas emissions or enhance natural sinks" and the "skills, competencies, fitness, and proficiencies that a country has attained which can contribute to GHG emissions mitigation" (Winkler et al., 2007). Here, many of the determinants of mitigative capacity are fundamentally shaped by different countries' level of development, including their current level of emissions, their stock of human, financial and technological capital, such as the ability to pay for mitigation; the magnitude and cost of available abatement opportunities; the regulatory effectiveness and market rules; the education and skills base; the suite of mitigation technologies available; the ability to absorb new technologies; and the level of infrastructure development (see Box 20-4).

20.3.2. Adaptation

Adaptation is the subject of four chapters of this Working Group II Fifth Assessment Report (14-17), to which the reader is referred for comprehensive descriptions of concepts, options, strategies, and examples of adaptation practices. For this section, we focus on the intersection between adaptation and sustainable development. Overall, climate adaptation and sustainable development are linked in several ways: first, many of the determinants of adaptive capacity to respond to climate impact and indicators of sustainable development overlap; second, adaptive capacity building may critically contribute to the well-being of both social and ecological systems; and third, building adaptive capacity within a sustainable development framework may require transformational changes (Dovers and Hezri, 2010; Lemos et al., 2013; Kates et al., 2012).

Around the globe, the ability of communities and individuals to respond to climate change in predicated on a number of capacities (e.g. human capital, information and technology, material resources and infrastructure, organizational and social capital, political capital, wealth and financial capital, institutions and entitlements) that typically overlap with indicators of development (Smit and Pilifozofa, 2001; Yohe and Tol, 2002; Eakin and Lemos, 2006). However, building these capacities both in developed and less developed regions has implications for sustainable development because it might increase the consumption of materials and create potential negative effects on ecosystems (e.g. building of new infrastructure and increasing consumption). In terms of governance, climate change adaptation and sustainable development share many characteristics (e.g. issues of spatial and temporal scales, uncertainty, poorly defined jurisdictions (Dovers and Hezri, 2010), and designing and implementing successful interventions require different kinds of capacities, including political and administrative structures (Wilbanks et al., 2007; Eakin and Lemos, 2006).

Building adaptive capacity may critically contribute to the improvement of the well-being of both social and ecological systems by bettering livelihoods and reducing pressure on the environment, especially in less developed regions (see Section 20.40.3). Regarding social systems, it is important to consider not only the factors that enable the building of different capacities (e.g. institutions and governance) but also how to guarantee that those who need it the most have access to them (Gupta et al., 2010; Nelson et al., 2007). It is also vital to understand how different capacities influence each other, positively and negatively (Lemos et al., 2013) and how they may affect the long-term resilience of social-ecological systems (Adger et al., 2011; Box 20-5). Indeed, adaptation can be important in reducing stresses on development processes, especially in vulnerable areas where it can help to promote and support sustainable development. For example, where adaptation planning stimulates participatory social processes, including equity and legitimacy, as well as discussions regarding different adaptation options, it can encourage communities to think more clearly about broader sustainable development goals and pathways (NRC, 2010a).

Given recent trends in GHG emissions and projections of climate futures that suggest impacts of climate change will be serious and widespread (e.g., Auerswald et al., 2011; Smith et al., 2011), adaptation may require considering transformational changes, in which potentially impacted systems move to fundamentally new patterns, dynamics, and/or locations (Schipper, 2007; Kates et al., 2012; Park et al., 2012; Marshall et al., 2012). Desirable adaptation strategies may vary according to specific kinds climate change threat, location, impacted system, the geographical scale of attention, and the time frame of strategic risk management planning (Heltberg et al., 2009; Thomalla et al., 2006; NRC, 2010a). Transformational adaptation policy at different scales needs to take into consideration the goals of sustainable development, both by fostering positive synergies and by avoiding negative feedbacks between them. This is especially important because some adaptation options might lead to inequitable and unsustainable outcomes, and some adaptations at one scale may negatively affect vulnerability in another (Thomas and Twyman, 2005; Eriksen et al., 2011; Eriksen and Brown, 2011; see also Sections 20.3.3 and 20.4.4 and Chapter 14 for a more detailed discussion). For example, in the U.S. building adaptive capacity for water management through drought preparedness plans at one scale (the state level) may constrain the flexibility of managers at lower scales (community water systems) to successfully respond to drought (Engle, 2013).

Indeed, adaptation pathways can foster food and water security, human health, and air and water quality and natural resource management, while promoting gender equality and other desirable outcomes consistent with sustainable development goals. However, creating the conditions for the emergence of such outcomes will require better integration in the implementation of policies and programs at all scales. By selecting materials not harmful to the environment, promoting the conservation of energy, water and other resources, promoting re-use and recycling, minimizing waste generation, protecting habitat and addressing needs of marginalized groups, adaptation can contribute to win-win and triple win options that can support a diverse array of development goals (Bizikova et al., 2007; Seto et al., 2010; see also Section 20.3.3, Chapter 15 Section 15.3.1, and UNFCCC, 2011).

_____ START BOX 20-5 HERE _____

Box 20-5. Case Studies from China

Water-saving irrigation has enhanced climate change adaptation capacity, improved ecosystem services, and promoted regional sustainable development in China.

- **Water-Saving Irrigation Measures in Cropland Adaptation to Climate Change**. Water-saving irrigation is one effective measure to deal with the water scarcity and food security issues caused by climate change (Hanjra and Qureshi, 2010; Tejero et al., 2011). Given an increase in non-agricultural water consumption, China's agriculture could be faced with a severe shortage of water resources (Xiong et al., 2010). Through water-saving irrigation practices, water saved from 2007-2009 added up to 30.7-34.92 $10^9 m^3$ for each year, which accounted for 5.6%-11.8% of the national total water consumption and saved about 9.59-20.85 Mt of standard coal and reduced 21.83-47.48 Mt CO_2 emissions. Therefore, water saving irrigation has had a positive effect in dealing with climate change and sustainable development (Zhou et al., 2012).

	2007	***2008***	***2009***
Water saved (Btu^2)	19.37 - 40.86	19.86 - 41.55	22.58 - 57.25
Energy saved (Mt)	2.92 - 6.39	3.08 - 6.72	3.57 - 7.73
CO_2 emission reduction (Mt)	6.66 - 14.58	7.02 - 15.31	8.15 - 17.59

- **Water-Saving Irrigation Measures in Alpine Grassland for Adapting to Climate Change** In recent years, the rise in precipitation and temperature results has led to the melting of glaciers and expansion to inland high mountain lakes, contributing to alpine grassland degradation in Northern Tibet (Gao et al., 2010). Among many grassland protection measures, alpine grassland water saving irrigation measures could be effective in redistributing and making full use of increased precipitation and lake water in the dry period, which would reduce the negative effects of climate change and make full use of favourable conditions (Editorial Board of National Climate Change Assessment, 2011; Gao et al., 2012). A three-year demonstration of alpine grassland water saving irrigation measures showed that alpine grassland primary productivity nearly doubled while the number of plant species increased from 91 to 129, helping to protect and restore the alpine grassland ecosystem and ecosystem services and to promote regional socioeconomic sustainable development in Northern Tibet (Gao et al., 2012).

_____ END BOX 20-5 HERE _____

20.3.3. Integrating Climate Change Adaptation and Mitigation for Sustainable Risk Management

Because both adaptation and mitigation are parts of climate-resilient pathways, and because each benefits from progress with the other (e.g, 20.2), integrating the two kinds of climate change responses within the broader context of sustainable development has been suggested as an aspirational goal (Wilbanks et al., 2007; Bizikova et al., 2010), especially when policy attention and financial commitments to climate change responses must consider the pursuit of both adaptation and mitigation. In practice, however, mitigation and adaptation tend to involve different time frames, communities of interest, and decision-making responsibilities (IPCC, 2007a; Wilbanks et al., 2007).

Integration of climate change responses with development processes is a further aspirational goal. Recent research suggests that mitigation and adaptation are likely to be more effective when they are designed and implemented in the context of other interventions within the broader context of sustainability and resilience (Wilbanks and Kates, 2010; Asian Development Bank, 2012). Moreover, studies focusing on the intersection between sustainable development and climate policy point out that integration between the two is a desirable although complex path (20.2.1.2; Halsnaes et al., 2008; Wilson and McDaniels, 2007; Ayers and Huq, 2009; Robinson et al., 2006; Swart and Raes, 2007; Beg et al., 2002). Wilson and McDaniels suggest three reasons to integrate across adaptation, mitigation and sustainable development: (1) many dimensions of the *values* that are important for decision-making are common to all three decision contexts; (2) impacts from any one of the three decision contexts may have important *consequences* for the other contexts; and (3) the *choice among alternatives* in one context can be a means for achieving the underlying values important in the other contexts.

A key factor in integrating climate change adaptation and mitigation into sustainable risk management is to understand the processes of decision-making at different scales. The distribution of costs and benefits of mitigation and adaptation differ -- e.g., mitigation benefits are more global, adaptation benefits are often more localized, the research and policy discourses are often unrelated, and the constituencies and decisionmakers are often different (mitigation may involve powerful industrial stakeholders from the energy sector concentrated at higher levels of decision-making, while adaptation may involve more dispersed stakeholders at the local level across sectors) (Wilbanks et al., 2007). To significantly reduce total global emissions, mitigation decisions must be taken either by major emitters, or by groups of countries. At the national and international level, direct responsibilities to curb the main drivers of global climate change are dispersed across countries (Banerjee, 2012). In contrast, adaptation often falls to practitioners where local responsibility is clearer, although it often depends on support from national and global scale (Tanner and Allouche, 2011).

In many cases, the challenge of fostering synergies while avoiding negative feedbacks often comes into focus in place-based discussions of climate change responses and development objectives such as localities and small regions (Wilbanks, 2003; Bulkeley and Schroeder, 2012; Dang et al., 2003). Globally, a particular hurdle is the practice of applying available mitigation resources only for reducing emissions beyond that which would have occurred without those resources ("*additionality*"), when access to resources for adaptation efforts should take into account the critical role of *co-benefits* in supporting development in other ways while at the same time reducing vulnerabilities to climate change impacts (NRC, 2010a; also see Section 20.4.1).

Choices in integrating adaptation and mitigation will vary according to the circumstances of each country and each locality (De Boer et al., 2010; Wilbanks, 2003). In highly vulnerable countries, adaptation may be seen as the highest priority because there are immediate benefits to be obtained by reducing vulnerabilities to current climate variability and extremes as well as future climate changes. In the case of developed countries, adaptation initiatives have often been seen as a lower priority because it is perceived that there is abundant adaptive capacity (Naess et al., 2005). Yet major losses and damages in some industrialized countries related to climatic variability and extremes challenge this perception (e.g., Hurricane Sandy, tornadoes, and drought in the US in 2011 and 2012). Mitigation may be seen as more acute political question—involving well-organized stakeholders concerned about costs—in countries that contribute a large proportion of GHG emissions (e.g., NRC, 2011), and it may be seen as an investment opportunity for the domestic private sector.

As indicated above, one emerging strategy to integrate climate and development policies is the design of "win-win" and "triple-win" interventions that seek to achieve an appropriate mix of mitigation and adaptation within the context of sustainable development (Pyke et al., 2007; Swart and Raes, 2007). Swart and Raes suggest a number of factors that should be taken into consideration when evaluating combined adaptation and mitigation policy designs, including: (1) *avoiding trade-offs* - when designing policies for mitigation or adaptation, (2) *identifying synergies,* (3) *enhancing response capacity,* (4) *developing institutional links* between adaptation and mitigation - e.g. in national institutions and in international negotiations, and (5) *mainstreaming* adaptation and mitigation considerations into broader sustainable development policies. Box 20-5 provides a case study of an initiative in China that has been a winner for both climate change responses and regional sustainable development The potential for climate-resilient pathways may already be limited, however, in part because of path dependency stemming from choices on mitigation, adaptation, and political interpretations and subsequent choices around "sustainable" development (Barker, 2008; Swart et al., 2003); and in many cases interventions have not delivered win-win results, which raises questions about the actual attainability of win-win strategies given legal, political, economic, and/or institutional obstacles **(**Warner, van der Geest, et al., 2012; 20.2.1.2).

In synthesizing evidence from a series of empirical articles focusing on the intersection between mitigation and adaptation (M&A), Wilbanks and Sathaye (2007) argue that mitigation and adaptation pathways might be alternatives in reducing costs, complementary and reinforcing to each other (e.g., improvements in building energy efficiency), or competitive and mutually contradictory (e.g., coastal protection vs. reductions in sea level rise). In Bangladesh, for example, waste-to-compost projects contribute to mitigation through reducing methane emissions; to adaptation through soil improvement in drought-prone areas; and to sustainable development through the preservation of ecosystem services (Ayers and Huq, 2009; also see Vergara et al., 2012, regarding possible development benefits of mitigation and adaptation in Latin America and the Caribbean). Land management and forestry activities contribute to ecosystem-based mitigation, for example through the reduction of emissions from deforestation and forest degradation, and adaptation, for example through the conservation of hydrological services provided to people facing water problems, as well as renewable energy (see several cases of ecosystem-based adaptation in Pramova et al., 2012). However, tradeoffs are also possible, for example if ecosystem management for mitigation purposes reduces the livelihood opportunities and the adaptive capacity of local people (Locatelli et al., 2011). The scale of these examples is often local, however, and longer-term success of these pathways will depend on the broader context of mitigation and facilitation of adaptation options (Metz et al., 2002).

When integrating across the goal of finding climate resilient pathways (and win-win solutions), decisionmakers often need to address issues of scale, along with trade-offs in values such as economic profitability versus stability of food and livelihood security (e.g. in agricultural policy), relationships between development ends and means, uncertainty and path dependencies, and institutional complexity (Klein et al., 2005; Tol, 2004; Wilson and McDaniels, 2007). They also need to consider the possibility of ancillary co-benefits, complementarities and potential contradictions, opportunity costs, and unknown negative and positive feedbacks (for example interactions among options and paybacks (NRC, 2010a; Kok et al., 2008; Wilbanks and Sathaye, 2007; Swart and Raes, 2007; Rosenzweig and Tubiello, 2007; IPCC, 2007a: Chapter 18). Current research is examining tradeoffs and complementarities between mitigation and adaptation in different sectors. In the energy sector, for instance, Kopytko and Perkins (2011) have examined to what extent the siting of nuclear power plants might constrain future adaptation to sea-level rise. Others ask about such issues as adaptation implications of the production of biofuels (La Rovere et al., 2009); agriculture and water (Rounsevell et al., 2010; Turner et al., 2010; Rosenzweig and Tubiello, 2007; Falloon and Betts, 2010; Shah, 2009); conservation (Rounsevell et al., 2010; Turner et al., 2010); use of mitigation programs to finance adaptation (Hof et al., 2009); and the urban environment (Biesbroek et al., 2009; Hamin and Gurran, 2009; Roy, 2009; Romero-Lankao and Wilbanks, 2011; and Viguié and Hallegatte, 2012).

20.4. Contributions to Resilience through Sustainable Development Strategies and Choices

Although climate change responses can contribute significantly to climate-resilient development pathways, some of the key elements of resilience lie in sustainable development implementation, which can make resilience either more or less achievable. Examples of ways that development strategies and choices can contribute to climate resilience include being capable of resolving tradeoffs among economic and environmental goals (e.g., Bamuri and

Opeschoor, 2007), assuring effective institutions in developing, implementing, and sustaining resilient strategies, and enhancing the range of choices through innovation (e.g., Hallegatte, 2009; Chuku, 2009; Folke et al., 2002).

20.4.1. Resolving Tradeoffs between Economic and Environmental Goals

Sustainable development pathways will be more climate-resilient if they develop and utilize socioeconomic and institutional structures that are effective in resolving tradeoffs among social, economic, and environmental goals – a central tenet of sustainable development (Section 20.2.1.1). As climate change poses risks to goals such as poverty reduction, food and livelihood security, human health, and economic prosperity (Chapter 19), societies face the task of defining how to manage these risks and what levels of risk without compromising what they value most and what defines their societies. The management of risk – and the weighting of various categories of risk – depends on social definitions of what consequences are acceptable, tolerable, or intolerable (Chapter 16).

There is a longstanding assumption that economic growth is in conflict with environmental management (Victor and Rosenbluth, 2007; Hueting, 2010). Much of this thinking can be traced back to Malthus and his assertions that population growth (and associated consumption) would expand at an increasing rate until the limits of the earth's capacity were reached (Malthus, 1798). The very idea of sustainable development itself springs from a need to respond to such Malthusian ideas. The views expounded in the Brundtland Report, for example, are that development should not be unconstrained but should rather be modified into a "sustainable" form (WCED, 1987). Views about relationships between economic growth and environmental protection range widely from arguments that sustainable development is inconsistent with continued economic growth (e.g., Robinson, 2004) to arguments that economic growth and associated technological innovation can enhance options for environmental management (Lovins and Cohen, 2011). Relationships between affluence and environmental protection are complex, as poverty can lead to land degradation and affluence can afford support for nature preservation, while economic growth is built on levels of resource extraction and use that require significant changes in environments. Sustainable development cannot escape continuing tensions between economic growth and environmental management goals, where strongly held views across society often differ so fundamentally that conflict results unless social processes and institutional mechanisms are effective in resolving a host of tradeoffs (Boyd et al., 2008), with both values and processes varying according to development context.

Examples of frameworks of thought often related to addressing tradeoffs are multi-metric valuation and co-benefits (see also Ness et al., 2007, regarding tools for sustainability assessment; Pew Center, 2010; Bizikova et al., 2008: Appendix 1):

- *Multi-metric valuation*. In evaluating development pathways, there are often needs to combine a number of dimensions associated with different valuation metrics and information requirements, such as monetary measures of returns and non-monetary metrics of risk. Fields ranging from aquatic ecology to risk assessment and financial management have developed tools for such complex valuations, including graphical mapping (e.g., UNFCCC, 2011; Moed and Plume, 2011; Rose, 2010; Sheppard and Meitner, 2005) and the construction of multi-metric indexes (e.g., Johnston et al., 2011). Multi-metric indicators have been widely studied and critiqued, and they are an active topic of research (e.g., Drouineau et al., 2012; Schoolmaster, 2013). A key challenge is weighting different valuations being combined quantitatively, which may be addressed in part by constructing multiple indices. More commonly in collective decision-making, however, analytical-deliberative group processes are used to evaluate, weight, and combine different dimensions and metrics qualitatively (NRC, 1996).
- *Co-benefits*. An issue in both climate and development policy, related in some cases to access to financial support (e.g., Miller, 2008), is the fact that a specific resilience-enhancing action may have benefits for both development and for addressing concerns about climate change. International funding for mitigation projects has often adopted the concept of "additionality," which takes the position that financial support should be limited to those climate change response benefits that are *in addition to* what would be happening in development processes otherwise (e.g., Muller, 2009). This general concept (e.g., "incremental" costs and benefits) has been applied in financial support for adaptation as well. A co-benefits approach, on the other hand, takes the position that actions which benefit *both* development and climate change responses simultaneously should be encouraged and that a combination of both kinds of benefits should increase the

attractiveness of a proposed action (Section 20.3.3). Co-benefits of mitigation actions, such as health benefits, have been extensively analyzed (e.g., WHO, 2011; Netherlands Environmental Assessment Agency, 2009; EPA, 2012; and Younger et al., 2008); and they are being actively explored for adaptation as well (e.g., UNFCCC, 2011; NRC, 2010a).

As an example of co-benefits, such mechanisms as REDD+ have the potential to achieve both carbon emissions reduction and to benefit livelihoods of those living in forested areas, as well as supporting benefits to social equity (Anglesen et al., 2009; UNEP, 2013). As one instance, the government of Ethiopia has recognized the multiple benefits that can be derived from REDD+ and has incorporated a REDD+ initiative in critical sectors of the economy in order to develop an environmentally sustainable growth path in Ethiopia (FDRE, 2011).
Tools for analyzing such issues are associated with research on "externalities" (e.g., Baumol and Oates, 1989; Klenow and Rodriguez-Clare, 2005; also see Chapter 17 and multi-metric valuations above), but participative planning and decision-making usually incorporate a co-benefits perspective as a matter of course.

In practice, tradeoffs between different development goals (Stoorvogel et al., 2004) may or not be resolved in coherent ways (Metz et al., 2002). In many cases, resolutions emerge through untidy social processes of evolution and attrition, reflecting dynamics of values, power, control, and surprises, rather than through formal analysis (Bizikova et al., 2008). In some cases, tradeoffs are addressed with the assistance of scenario development, the creation of descriptive narratives, and other projections of future contingencies (IPCC SREX: Chapter 8), along with participative vulnerability assessments (NRC, 2010a).

20.4.2. Assuring Effective Institutions in Developing, Implementing, and Sustaining Resilient Strategies

Climate resilient pathways will benefit from institutions that are effective and flexible in the face of a wider range of challenges, of which climate change is only one (Gupta et al., 2010). Governance systems, including public and private organizations, will need resources (e.g. human, financial, political, technological) to enable vulnerable societies that are sensitive to the impacts of climate change to transform their lives. Effective management of natural capital and ecosystem goods and services can only be accomplished where there are strong institutions as stewards and a regulatory force to ensure that vulnerable communities are protected from climate shocks and stresses and that growth from climate change is inclusive (Mitchell and Tanner, 2006). Moderating the impacts of climate change will also require strong a foundation in science and technology; but the deployment of science and relevant technologies cannot take place in a vacuum. It will need effective institutional arrangements to bolster both adaptation and mitigation demands and to combine technology options with local knowledge (20.4.3).

"Institutions" refer not only to formal structures and processes but also to the rules of the game and the norms and cultures that underpin environmental values and belief systems. Ostrom (1986) defines institutions as the rules, norms and practices defining social behavior in a particular context, the action arena. Institutions define roles and provide social context for action and structure social interactions (Hodgson, 2003). Definitions of sustainability are largely shaped by institutional values, cultures and norms. Institutions also critically influence our ability to govern and manage the resources and systems that shape adaptation, mitigation and sustainable development. Fostering climate-resilient pathways requires strong institutions that are able to create an enabling environment through which adaptive and mitigative capacities can be built (Gupta et al., 2010; IPCC, 2007a: Chapter 20). Implicit in institutional resilience is the capacity of the exposed unit and the players within an action arena to devise rules that allows them to recover from environmental shocks, and equally ones that provides incentives and benefits that equitably distributes resources across social groups (McSweeny and Coomes, 2011; Handmer and Dovers, 1996). Hence, the trajectory to a climate resilient pathway requires institutional arrangements that foster innovation, monitoring, and evaluation of strategies for managing climate impacts and reducing risks.

Transformative action within a framework of climate resilient pathways is rooted in strong and viable institutions and in an institutional context that adaptively manages the allocation of resources and processes of change. Institutions at different levels are the object of societal pressures and challenges relating to environmental change. Local institutions are particularly adroit in coping with multiple changes. These changes often force local actors and organizations to rethink their institutional arrangements and make adjustments that will allow them to cope with multiple vulnerabilities (McSweeny and Coomes, 2011), and their bottom-up initiatives are critically important to climate-resilient pathways. Organizational mechanisms are central to building linkages between local level adaptation action and national level planning; however, in six cases studies in West Africa and Latin America, Agrawal et al. (2011) found that while these connections are missing in almost all the countries studied, external policy support can catalyze adaptation action through three types of intervention mechanisms: information, incentives, and institutions.

Local institutions crucially influence the ability of communities to adapt and benefit from adaptation and mitigation programs in rural and urban settings (Agrawal, 2008; Chhartre and Agrawal, 2009; Corbera and Brown, 2008). For instance, institutions tend to play an influential role in shaping farmers' decisions and helping them make strategic choices with several implications for livelihoods and sustainable development (Agrawal, 2008). In rural areas, current socioeconomic dynamics, rapid population growth, commercialized agriculture, new agricultural trends and technological advancements in agriculture have meant that local organizations and actors have seen a change in their role managing environmental resources; local institutions are themselves in a state of flux as they are subjected to uncertainties in climatic condition (Senaratne and Wickramasinghe, 2010*)*. However, in developing countries, particularly in Africa, where traditional knowledge could moderate this uncertainty, it is often not recognized as a reference point for managing climate risks and emerging threats. In Kenya, the importance of indigenous knowledge, given increased uncertainty and climate related risks, has compelled national agencies such as the Kenyan Meteorological Agencies and vulnerable groups such as the indigenous communities commonly known as rainmakers to form strategic reciprocal links. By working closely together to calibrate their forecasts and test the efficacy of the results against climate change impacts on agricultural productivity, the two groups have been able to demonstrate the benefits of western science and traditional knowledge systems to increase effectiveness (Ziervogel and Opere, 2010). In integrating different kinds of knowledge, participatory processes, which call for a deliberative form of decision making among stakeholders are well suited to the governance culture necessary for effective adaptation and mitigation. However, findings in the literature regarding the effectiveness of participatory processes are mixed. For example while some scholars have argued that deliberative democracy methods can bring diverse stakeholders and kinds of knowledge (e.g., lay, expert and indigenous) together thus putting in place a more communicative model of science delivery (Benn et al., 2009), empirical research shows that stakeholder participation does not always lead to consensus (Rowe and Frewer, 2004; Bell et al., 2011; also see Salter et al., 2010).

In addition, better institutions are needed to handle the large flows of funds and other resources that are associated with managing and improving the delivery systems that will allow people and organizations to take advantage of opportunities that will trigger a set of actions to combat the negative impacts of climate change. The complexity of different resource flows and distributional effects related to adaptation and mitigation is at the heart of the sustainable development debate, with numerous implications for equity and justice (O'Brien and Leichenko, 2003; Roberts and Parks, 2006). The nature and dynamics of climate change call for flexibility to 'allow society to modify its institutions at a rate commensurate with the rapid rate of environmental change' (Gupta et al., 2008). Here, institutional 'renewal' is essential to achieve a degree of social cohesion and transformation.

An institutional response to climate change is even more fundamental in common pool property resources such as freshwater, especially because in a changing climate, many river basins are subjected to increased precipitation or water scarcity that affects both their ecosystems and the resources that support the livelihoods of those communities dependent on them. The quality and performance of the organizations and mechanisms created to manage these resources are largely shaped by the rules they follow and the suitability of these rules to the social ecological system in which they are embedded (Bisaro et al., 2010). Indeed, a climate-resilient pathway is one that will not only manage biophysical changes, but address inherent institutional asymmetries that can further reinforce current inequalities in the way common pool resources are managed. In this context, the monitoring and mediation capacities and the degree to which resource management organizations are embedded at different scales across the governance regime will largely shape its adaptive capacity and sustainability. Thus, the vulnerability of large river basins will largely depend not only on the changing biophysical conditions, but also on institutional architecture that is put in place to manage risks and build resilience. For example, Schlager and Heikkila, 2011, argue that compacts that have fixed allocation rules tend to exhibit greater vulnerability to climate change mainly because the system is far too rigid and does not allow for much flexibility in dealing with the changing hydrologic regime. States such as

Colorado in the United States have dealt with water scarcity more efficiently mainly because users of the basin have access to venues that allow them to design and review current rules (Schlager and Heikkila, 2011).

Common problems with institutional arrangements for adaptively managing natural resources include a frequent incompatibility of current governance structures with many of those that may be necessary for promoting social and ecological resilience'. For example, some major tenets of traditional management styles have 'in many cases operated through exclusion of users and the top-down application of scientific knowledge in rigid programmes' (Tompkins and Adger, 2004: 10).

20.4.3. Enhancing the Range of Choices through Innovation

Finally, climate resilience will in most cases depend on innovation, developing new ideas and options or adapting robust familiar ideas and options to meet emerging new needs and to respond to surprises (also see IPCC Working Group III: Chapter 6). As indicated in the previous section, integrated strategies for climate resilience can benefit from considering possibilities to develop new options through social, institutional, and technological innovation. For example, if a climate-resilient pathway for a particular region calls for coping with greater water scarcity, innovations might consider changes in water rights practices, improving the understanding of groundwater dynamics and recharge, improving technologies and policies for water-use efficiency improvements, and in coastal areas the development of more affordable technologies for desalination (NRC, 2010a; Lebel, 2005). One key issue for risk management, therefore, is assessing needs for and possible benefits from targeting innovation efforts on critical vulnerabilities.

Innovations can include both technological and social changes, which in many cases are closely related (Rohracher, 2008; Raven et al., 2010), as technology and society evolve together (Kemp, 1994). An important characteristic of such socio-technical transitions are the interactions and conflicts between new, emerging systems and established regimes, with strong actors defending business as usual (IPCC SREX, 2012; Kemp, 1994; Perez, 2002).

Effective use of innovations depends on more than idea and/or technology development alone. Unless the innovations, the skills required to use them, and the institutional approaches appropriate to deploy them are effectively transferred from providers to users, effects of innovations – however promising – are minimized (IPCC SREX, 2012). Challenges in putting science and technology to use for sustainable development have received considerable attention (e.g., Nelson and Winter, 1982; Patel and Pavit, 1995; NRC, 1999; International Council for Science, 2002; and Kristjanson et al., 2009). These studies emphasize the wide range of contexts that shape both barriers and potentials and the importance of "co-production" of knowledge, integrating general scientific knowledge with other forms of knowledge (e.g., local, indigenous, practical knowledge, experience, and expertise). If obstacles related to intellectual property rights can be overcome, however, the growing power of the information technology revolution could accelerate the transfer of technologies and other innovations (linked with local knowledge) in ways that would be very promising for strengthening local resilience (Wilbanks and Wilbanks, 2010).

New technologies have the potential to allow a number of developing countries to benefit from a knowledge in ways that will given them considerable advantage in building the relevant social and institutional infrastructure in order to sustain a climate-resilient pathway. Advances in mobile technologies in developing countries, for example, have increased the accessibility of farmers to critical information related to disease surveillance, information related to agricultural inputs, and market prices for crops (Juma, 2011; Hazell et al., 2010). Biotechnology applications in biological system have the potential to lead to increased food security and sustainable forestry practices, as well as improving health in developing countries by enhancing food nutrition.

20.5. Determinants of Resilience in the Face of Serious Threats

Climate change is not the only type of change occurring in the 21st century. Many households, communities, organizations, countries and regions are confronting a confluence of economic, political, demographic, social, cultural and environmental changes. Issues such as poverty, economic crisis, increasing inequality, and violent conflict often draw attention away from concerns about climate change, the loss of biodiversity and ecosystem services, and other global environmental issues. However, the impacts of climate change and extreme events can exacerbate food insecurity, slow down the pace of poverty reduction in urban areas, influence human health, and jeopardize sustainable development (chapters 11, 12 and 13). Resilience is a concept that takes into account how systems, communities, sectors, or households deal with disturbance, uncertainty and surprise over time, and it is characterized by both adaptability and transformability (Walker and Salt, 2006; Folke et al., 2010; Westley et al., 2011). The sections below consider two important components of climate resilient pathways: transformational adaptation in response to the impacts of climate change, and transformational change to reduce vulnerability and the risk of high magnitude climate change.

20.5.1. Relationships between the Magnitude and Rate of Climate Change and Requirements for Transformational Adaptation

The timing and ambition levels of global greenhouse gas mitigation efforts will influence the magnitude and rate of climate change and its impacts, particularly in the second half of the 21st century and beyond (Kriegler et al., 2012; Rogelj et al., 2013; Peters et al., 2013; Box 20-3). Model results based on integrated scenarios that take into account geophysical, technological, social and political uncertainties indicate that reaching the often-discussed limit of a 2°C average global temperature increase call for mitigation of emissions through increased energy efficiency and lower energy demand well before 2020 (Rogelj et al., 2013; Peters et al., 2013; Section 20.6.1).

If the magnitude and rate of climate change is kept minimal or moderate, incremental adaptation may be a sufficient response to consequences in many locations and contexts. However, in cases where vulnerability is currently high, transformational adaptation may be needed to respond to changes in climate and climate variability. In the absence of ambitious mitigation efforts, the impacts of climate change can be expected to increase dramatically from the second half of the 21st century onward (see Chapter 19). In this case, transformational adaptation may be required in advance of disruptive impacts to reduce risks and vulnerabilities (Kates et al., 2012).

This distinction between incremental and transformational adaptation is significant: incremental adaptation can be considered extensions of actions and behaviors that already are in place to reduce losses or enhance benefits associated with climate change, often where the goal is to maintain the essence and integrity of an existing system or process at a given scale (Kates et al., 2012; Park et al., 2012). Transformational adaptation, in contrast, includes actions that change the fundamental attributes of a system in response to actual or expected impacts of climate change. These may involve adaptations at a larger scale or greater intensity than previously experienced; adaptations that are new to a region or system; or adaptations that transform places or lead to a shift in the location of activities (Kates et al., 2012). Such transformations are expected to occur when the rate and magnitude of climate change threatens to overwhelm the resilience of existing systems, or when vulnerability is high (Kates et al., 2012). Transformational adaptation often occurs in continuous interaction with incremental adaptations (Park et al., 2012, see IPCC SREX, 2012: Figure 8-1).

Although thresholds or tipping points in complex systems are difficult to predict, studies from a variety of disciplines indicate some generic properties associated with transitions between different states, including an increase in recovery times from disturbances such as extreme weather events (Scheffer et al., 2009; Lenton, 2011a). The risks associated with a high magnitude and rate of climate change and its impacts on natural and managed resources and systems are considerable. The limits to adaptation, discussed in Chapter 16, suggest that transformational change may be a requirement for sustainable development in a changing climate (Westley et al., 2011; O'Brien, 2013).

20.5.2. Elements of and Potentials for Transformational Change

Transformational change can be considered a means of reducing risk and vulnerability, not only by adapting to the to the impacts of climate change, but also by challenging the systems and structures, economic and social relations, and beliefs and behaviors that contribute to climate change and social vulnerability. In cases where current development pathways are considered as the root causes of climate risk and vulnerability, transformation of wider political, economic and social systems may be necessary (Pelling, 2010; IPCC SREX, 2012; Lemos et al., 2013).

Transformation is defined as a change in the fundamental attributes of a system, often based on altered paradigms, goals, or values. It can occur in technological, biological or financial systems, or regulatory, legislative, or administrative regimes (see glossary). Transformations can occur quite suddenly, in response to a specific event or a momentous incident, or they may emerge gradually over time (Loorbach, 2007). Transformational change is often difficult to order or plan, and there are many social, political, and cultural barriers and resistances. Transformational change can threaten vested interests, or prioritize the interests of some over the well-being of others, and it is never a neutral process (Meadowcroft, 2009; Smith and Stirling, 2010). While not every transformation is considered ethical, equitable or sustainable, it is possible to promote deliberate transformations that reduce climate risk and vulnerability and contribute to global sustainability (Folke et al., 2010; O’Brien, 2013; Kates et al., 2012).

There is an extensive literature on transitions and transformations covering a variety of sectors and factors that influence changes in systems and behaviors (Calvin et al., 2009; Berkhout et al., 2010; Shove and Walker, 2010; Pelling 2010; Geels, 2002; IPCC Working Group III: Chapter 6). Transformations can be promoted by creating enabling conditions, which include a supportive social environment, information flows, and access to options, resources, and incentives for change (Kates et al., 2012). Transformations can also be stimulated through rules and regulations that necessitate innovations, alternative options or new behaviors. Finally, transformations may result when alternative systems and structures eventually make old ones seem outdated. Often, dramatic focal events can draw attention to the need for change and mobilize groups or networks to advocate transformational change (Hernes, 2011).

Transformation processes are linked to learning, leadership, empowerment and collaboration within and across institutions, organizations and groups (IPCC SREX, 2012: Chapter 8; Heifetz et al., 2010; Kates et al., 2012; O’Brien 2013). Other key elements associated with transformations include adaptable institutions (cultural, economic and governance), all types of capital, diversity in landscapes, seascapes and institutions, learning platforms, collective action and networks, as well as reflexivity and the capacity to take different perspectives (Loorbach 2007; Folke et al., 2010; Westley et al., 2011; Schlitz et al., 2010). Many of the elements of climate-resilient pathways discussed in Box 20-3 can, in fact, support transformation.

Transformations can take place within diverse realms or spheres (see Figure 20-2). Within each sphere, there exist both catalysts and constraints to transformation. The core of transformational change occurs in what is labelled in Figure 20-2 as the “practical sphere.” Here, measures such as technological innovations and economic incentives are used to influence sustainable behaviors and responses. The outcomes of transformations in this sphere are observable and measurable; many sustainability policies and initiatives target transformations in this sphere. However, these transformations are often constrained by larger systems and structures, including financial, political, legal, social, economic, ecological and cultural systems that define the boundaries for action. The “political sphere” is where systems and structures are transformed (intentionally or unintentionally) through politics and social movements, or through changes in social and cultural norms and power relations. Systems and structures often reflect dominant cultural beliefs and worldviews, and it is here where value conflicts may be experienced or resolved. A third sphere of transformation is the “personal sphere,” which includes individual and collective beliefs, values, and worldviews, as well as the dominant paradigms. Transformations in this sphere can influence systems, structures, behaviors and responses, and thus they represent important leverage points for sustainability. Attention to transformations in all three spheres is considered necessary in response to the observed and anticipated impacts of climate change (Beddoe et al., 2009; O’Brien and Sygna 2013).

[INSERT FIGURE 20-2 HERE
Figure 20-2: The three spheres of transformation. Transformational change may be an effective leverage point for promoting climate-resilient pathways for sustainable development. This figure depicts three interacting spheres or realms where transformational changes towards sustainability may be initiated. Transformations in the outer two spheres can have a large influence on behaviors and technical responses, contributing to non-linear transformations to sustainability. Source: O'Brien and Sygna, 2013.]

20.6. Toward Climate-Resilient Pathways

20.6.1. Alternative Climate-Resilient Pathways

Climate-resilient pathways consist of future trajectories of development that combine adaptation and mitigation in the context of sustainable development implementation. At any scale (local or regional) there are multiple paths leading to the same total amount of climate resilience: alternative stable states (Holling, 1973). At any time along a pathway, more or less resilience maybe observed at specified points within the system (or locality), while the total amount of resilience within the entire system remains unchanged (Folke, 2006). Each potential alternative pathway can be strengthened and evaluated based on certain risk management characteristics/elements, the capacity nto: a) foresee risk/vulnerability, b) decrease climate change impacts, c) respond rapidly to unpredictable, uneven and extreme events, d) include considerable amounts of proactive adaptation, and e) evolve in support of societal advancement and balanced environmental management.

Many of the choices involved in framing and supporting attempts to increase and sustain climate resilience are made largely at global and national levels, but many of the actions to sustain resilience are made at local levels. The global pathways that emerge are accumulations of these local and national choices. In these processes, path dependence is strong enough such that risk management decisions in the near term are more likely to lead to resilience if long term objectives are included as well as a wider spatial scale up to and including the global level.

A central issue in considering alternative pathways is the extent to which they may fail to meet a criterion of climate resilience. Or to put the question more simply, “are there any boundaries on the envelope of climate resilience”? The answer is highly scale dependent. We have a carbon legacy in the atmosphere, and total prevention/avoidance of impacts is now unachievable (Dickinson, 2007). At any level of stabilization of GHG concentrations, with even the strongest emissions reduction targets, some localities or systems or populations will be vulnerable to disruptions because there is in effect no limit below which universal prevention of residual loss and damages can be assured. Transformational change will therefore need to be a key component in nearly all alternative climate resilient pathways.

In the event that global surface mean temperatures rise through +2^{o}C to +4^{o}C and higher (Schneider, 2009; New et al., 2012; Anderson and Bows, 2008), sustainability will become significantly more difficult to achieve (food security is a notable example: Chapter 7). For example, a business-as-usual future society where unsustainable development paths are the norm, where technology transfer between countries is lacking, population growth increases rapidly, GHG emission go unabated, and institutions and governance structures are ineffective at creating effective climate change policies, would almost certainly result in losses so widespread that development pathway would not be resilient (Riahi et al., 2011; Arnell et al., 2013). A pathway that included these elements would fall outside the ‘boundaries of the envelope of climate resilience’.

Within these boundaries, climate-resilient pathways can be made up of a collective of alternative choices at the regional level, where they are dependent upon specific demographics, potentials for economic development and growth, ecological and ecosystem services, access to natural resources, institutional and governance structures, and technological development and transfer. This concept at the global level offers a conceptual framework for considering alternative mixes of actions in support of climate resilience. Pathways can be developed to illustrate a range or possible futures, as a basis for discussion, following different yet distinct storylines. These dimensions can then be related to socioeconomic challenges confronting climate change mitigation and adaptation (as one aspect of sustainable development). One such pathway could have relatively limited challenges to both adaptation and mitigation, while another has substantial challenges to both adaptation and mitigation. Any pathway characterised by low challenges to both has a high potential to be more climate- resilient at the global scale and in many local or national situations. A pathway characterised by high challenges to both adaptation and mitigation has a high potential to be less climate-resilient at the global scale and in many localities and countries.

20.6.2. Implications for Current Sustainable Development Strategies and Choices

Decisionmakers face an array of choices in their efforts to define and implement pathways that will help to improve human well-being now and in the future in the face of climate change and other stressors.

Although payoffs from specific long-term pathways may be uncertain at this time, growing evidence (IPCC 2007; Chapters 8 – 13, 16, 17, 18 and 19) suggests that decision points and actions are at hand now. Climate-resilient development pathways are not only about actions taken in the future, but they are also about strategies and choices that are taken today. In fact, damage and loss patterns are not limited to future vulnerabilities; in many areas they are impeding food production and other essential development services in ways that deepen and widen poverty (Chapter 13), contribute to involuntary migration (Chapter 12; Warner and Afifi, forthcoming), and pressure food production and food prices (Chapters 7 and 17; Warner, van der Geest, 2013).

In this sense, delaying action in the present may reduce options for climate resilient pathways in the future. In some parts of the world, inadequate efforts to address effects of emerging climate stressors are already eroding the basis for sustainable development. New studies find that among people who who attempt to cope with current stresses, most experienced negative residual impacts and as a consequence faced eroding household income and food security, health, education opportunities, more likely to migrate, and losing housing and livelihood assets (Warner and van der Geest, 2013; Rabbani et al., 2013, Yaffa, 2013, Monnereau and Abraham, 2013, Traore et al., 2013). For example, in the Punakha district in Bhutan, 87% of households that adopted coping measures reported that they were still experiencing adverse effects of changing monsoon patterns despite the adaptation measures (Kusters and Wangdi, 2013). Evidence (Chapters 7, 8, 12, 13, 16, 19) suggests that waiting to take more effective action may reduce the range of choices for climate resilient pathways in the future (NRC, 2011b).

More generally, IPCC SREX, 2012, makes the case that a window of opportunity exists now for considering possible strategies that would increase climate resilience while at the same time helping to improve human livelihoods and social and economic well-being. It suggests that a process of iterative monitoring, evaluation, learning, innovation, and contingency planning will reduce climate change disaster risks, promote adaptive management, and contribute significantly to prospects for climate-resilient pathways. In this sense, strategies and actions can be pursued now that will move toward climate-resilient pathways while at the same time helping to improve human livelihoods, social and economic well-being, and responsible environmental management.

As policy makers explore what pathways to pursue, they will increasingly face questions about managing discourses about what societal objectives to pursue unchanged, where compromises in objectives are tolerable, and what consequences including loss and damage may be associated with different pathways. In considering possible needs for transformational pathways (Section 20.5), extreme weather occurrences such as major floods, wildfires, cyclones and heat waves may focus societal attention on vulnerabilities and stressors and provide a “policy window” for major changes (Kingdon, 1995; Birkland, 2006; Kates et al., 2012). Discussions of transformation may require broader-based social discourse (Pelling et al., 2007) and iterative institutional learning (Berkhout et al., 2006), on the basis of growing evidence, knowledge, and experience. Systems to monitor emerging stresses and threats will aid decisionmakers at different scales to evaluate alternative pathways (Kates et al., 2012).

20.7. Priority Research/Knowledge Gaps

Because integrating climate change mitigation, climate change adaptation, and sustainable development is a relatively new challenge, research should be a very high priority indeed in order to inform strategies and actions. The most salient research need is to improve the understanding of how climate change mitigation and adaptation can be combined with resilient sustainable development pathways in a wide variety of regional and sectoral contexts (Wilbanks, 2010). One starting point is simply improving the capacity to characterize benefits, costs, potentials, and limitations of major mitigation and adaptation options, along with their external implications for equitable development, so that integrated climate change response strategies can be evaluated more carefully (Wilbanks et al., 2007; NRC, 2011). What are the major tradeoffs? What are the potential synergies? How do implications of integrated mitigation/adaptation strategies vary with location, climate change risks and vulnerabilities, scale, and development objectives and capacities? (e.g., Hugé et al., 2011). In these regards, the best of global science needs to be combined with national and local expertise to advance knowledge related to climate-resilient pathways.

Related to this general priority are at least three specific research needs:

- Advances in conceptual and methodological understandings of, and tools to support research on, multiple drivers of development pathways and climate change impacts; possible feedback effects among mitigation, adaptation, and development; possible thresholds/tipping points that could cause particular challenges for development; and possible transformations to reduce losses and damages and support sustainable development (NRC, 2009, 2010a; Section 20.5).
- Advances in knowledge about how to respond sustainably to climate change extremes and extreme events, when and where they pose development challenges that would appear to require transformative changes in affected human and/or environmental systems. What might the response options be, and how can they be facilitated where they merit consideration? (e.g., Pelling, 2010; Lemos et al., 2013).
- Research on how to reconcile the importance of synergies between climate change adaptation and mitigation actions with widespread use of the concept of "additionality." For example, how might criteria be established for access to financial support for adaptation that incorporates the development importance of co-benefits? Such research could inform discourses about differences between adaptation and development in ways that enable the flow of financial resources to support adaptations (NRC, 2010a).

Further research needs include:

- Research attention to potentials for technological and institutional innovations to ease threats to sustainable development from climate change impacts and responses. In other words, how might climate change responses represent opportunities for innovative development paths? How might technological development be part of a strategy for development/climate change response integration? (Wilbanks, 2010)
- Research on strategies for institutional development, including improving understandings of how social institutions affect resource use (NRC, 2009), improving understandings of risk-related judgment and decision-making under uncertainty (NRC, 2009), and best practices in creating institutions that will effectively integrate climate change responses with sustainable development characteristics such as participation, equity, and accountability
- Research on strategies for the implementation of adaptive management and risk reduction for development. Examples of important research needs include improving the understanding of respective roles and interactions between autonomous response behavior and policy initiatives, improving the body of empirical evidence about how to implement changes that are judged to be desirable: e.g., adaptive management and governance capacity, and improving the understanding of differences between retrofitting older infrastructures (the challenge in many industrialized countries) and designing new infrastructures (the challenge in many rapidly developing countries) (IPCC SREX, 2012: Chapter 8).
- Research to improve the understanding of how to build social inclusiveness into development/climate change response integration. As suggested above, research is needed on issues of social values/climate justice/equity/participation and how they intersect with the deployment of mitigation, adaptation interventions and sustainable development policy in different regional/sociopolitical contexts (IPCC SREX, 2012: Chapter 8).
- Research on factors that influence deliberate transformations that are ethical, equitable, and sustainable (O'Brien, 2012; Kates et al., 2012).
- The development of structures for learning from emerging integrated climate change response/development experience: e.g., approaches and structures for monitoring, recording, evaluating, and learning from experience, identifying "best practices" and their characteristics (NRC, 2010a; IPCC SREX, 2012: Chapter 8; Hilden, 2011).

Finally, it is very possible that progress with global climate change mitigation will not be sufficient to avoid relatively high levels of regional and sectoral impacts, and that such conditions would pose growing challenges to the capacity of adaptation to avoid serious disruptions to development processes. If this were to become a reality later in this century, one response could be a rush toward geoengineering approaches. In preparation for such a contingency, and perhaps as an additional way to show how important progress with mitigation will be in framing prospects for sustainable development in many contexts, there is a very serious need for research on geoengineering costs, benefits, risks, a wide range of possible impacts, and fair and equitable structures for global policymaking and decision-making (UK Royal Society, 2009; Kates et al., 2012).

But a fundamental aim of research to improve capacities for climate-resilient pathways for sustainable development is to avoid such an unfortunate outcome. It seeks to do so by strengthening the base of knowledge that underlies and supports effective actions by viewing climate change mitigation, climate change adaptation, and sustainable development in an integrative and mutually supportive way.

Frequently Asked Questions

FAQ 20.1: What is a climate-resilient pathway for development? *[to be placed before Box 20-1]*
A climate-resilient pathway for development is a continuing process for managing changes in the climate and other driving forces affecting development, combining flexibility, innovativeness, and participative problem-solving with effectiveness in mitigating and adapting to climate change. If effects of climate change are relatively severe, this process is likely to require considerations of transformational changes in threatened systems if development is to be sustained without major disruptions.

FAQ 20.2: What do you mean by" transformational changes"? *[to be placed after Box 20-1]*
Transformational change is a fundamental change in a system, its nature, and/or its location that can occur in human institutions, technological and biological systems and elsewhere. It most often happens in responding to significantly disruptive events or concerns about them. For climate-resilient pathways for development, transformations in social processes may be required in order to get voluntary social agreement to undertake transformational adaptations that avoid serious disruptions of sustainable development.

FAQ 20.3: Why are climate-resilient pathways needed for sustainable development? *[to be placed in Section 20.2]*
Sustainable development requires managing many threats and risks, including climate change. Because climate change is a growing threat to development, sustainability will be more difficult to achieve for many locations, systems, and populations unless development pathways are pursued that are resilient to effects of climate change.

FAQ 20.4: Are there things that we can be doing now that will put us on the right track toward climate-resilient pathways? *[to be placed in Section 20.6.2]*
Yes. Climate-resilient pathways begin now, because it is time to consider possible strategies that would increase climate resilience while at the same time helping to improve human livelihoods and social and economic well-being. Combining these strategies with a process of iterative monitoring, evaluation, learning, innovation, and contingency planning will reduce climate change disaster risks, promote adaptive management, and contribute significantly to prospects for climate-resilient pathways.

Chapter 21. Regional Context

Coordinating Lead Authors
Bruce Hewitson (South Africa), Anthony C. Janetos (USA)

Lead Authors
Timothy R. Carter (Finland), Filippo Giorgi (Italy), Richard G. Jones (UK), Won-Tae Kwon (Republic of Korea), Linda O. Mearns (USA), E. Lisa F. Schipper (Sweden), Maarten K. van Aalst (Netherlands)

Contributing Authors
Eren Bilir (USA), Monalisa Chatterjee (USA / India), Grace Redmond (UK), Carol McSweeney (UK), Katharine Mach (USA), Vanessa Schweizer (USA), Luke Wirth (USA), Claire van Wyk (South Africa)

Review Editors
Thomas Downing (USA), Phil Duffy (USA)

Volunteer Chapter Scientist
Kristin Kuntz-Duriseti (USA)

Contents

Executive Summary

There has been an evolution in the treatment of regional aspects of climate change in IPCC reports from a patchwork of case examples in early assessments towards recent attempts at a more systematic coverage of regional issues at continental and sub-continental scales (21.2.2). Key topics requiring a regional treatment include: changes in the climate itself and in other aspects of the climate system (such as the cryosphere, oceans, sea level and atmospheric composition), climate change impacts on natural resource sectors and on human activities and infrastructure, factors determining adaptive capacity for adjusting to these impacts, emissions of greenhouse gases and aerosols and their cycling through the Earth system, and human responses to climate change through mitigation and adaptation.

A good understanding of decision-making contexts is essential to define the type and scale of information on climate change related risks required from physical climate science and impacts, adaptation and vulnerability assessments (21.2.1) (*high confidence*). This is a general issue for all impacts, adaptation and vulnerability assessments, but is especially important in the context of regional issues. Many studies still rely on global datasets, models and assessment methods to inform regional decisions. However, tailored regional approaches are often more effective in accounting for variations in trans-national, national and local decision-making contexts, as well as across different groups of stakeholders and sectors. There is a growing body of literature offering guidance on how to provide the most relevant climate risk information to suit specific decision-making scales and processes.

A greater range of regional scale climate information is now available which provides a more coherent picture of past and future regional changes with associated uncertainties (21.3.3). More targeted analyses of reference and projected climate information for impact assessment studies have been carried out. Leading messages include:

- Significant improvements have been made in the amount and quality of climate data that are available for establishing baseline reference states of climate-sensitive systems (21.5.3.1). These include new and improved observational datasets, rescue and digitisation of historical datasets, and a range of improved global reconstructions of weather sequences.
- A larger set of global and regional (both dynamical and statistical) model projections allow a better characterization of ranges of plausible climate futures than in the AR4 (21.3.3), and more methods are available to produce regional probabilistic projections of changes for use in IAV assessment work (21.5.3).
- Better process understanding would strengthen the emerging messages on future climate change where there remains significant regional variation in their reliability (21.3.3).
- Confidence in past climate trends has different regional variability and in many regions there is higher confidence in future changes, often due to a lack of evidence on observed changes (21.3, Box 21-4).

In spite of improvements, the available information is limited by the lack of comprehensive observations of regional climate, or analyses of these, and different levels of confidence in projected climate change (*high confidence*). Some trends that are of particular significance for regional impacts and adaptation include (21.3.3.1; WG I SPM):

- The globally averaged combined land and ocean surface temperature data show a warming of 0.85 [0.65 to 1.06] °C, over the period 1880–2012. There is regional variation in the global trend, but overall the entire globe has warmed during the period 1901-2012. (WGI SPM) Future warming is *very likely* to be larger over land areas than over oceans. (WGI SPM)
- Averaged over mid-latitude land areas, precipitation has increased since 1901(*medium confidence* before and *high confidence* after 1951), but for other regions there is low confidence in the assessment of precipitation trends (WGI SPM).
- There are *likely* more land regions where the number of heavy precipitation events has increased than where it has decreased. The frequency or intensity of heavy precipitation events has *likely* increased in North America and Europe. In other continents, confidence in changes in heavy precipitation events is at most *medium*. The frequency and intensity of drought has *likely* increased in the Mediterranean and West Africa and *likely* decreased in central North America and north-west Australia.
- The annual mean Arctic sea ice extent decreased over the period 1979–2012 with a rate that was *very likely* in the range 3.5 to 4.1% per decade. Climate models indicate a nearly ice-free Arctic Ocean in September before mid-century is *likely* under the high forcing scenario RCP8.5 (*medium confidence*).
- The average rate of ice loss from glaciers worldwide, excluding those near the Greenland and Antarctic ice sheets, was *very likely* 275 [140 to 410] Gt yr^{-1} over the period 1993-2009. By the end of the 21st century, the volume of glaciers (excluding those near the Antarctic ice sheet), is projected to decrease by 15 to 55% for RCP2.6, and by 35 to 85% for RCP8.5, relative to 1986-2005 (*medium confidence*).
- The rate of global mean sea-level rise during the 21st century is *very likely* to exceed the rate observed during 1971–2010, under all RCP scenarios (21.3.3.5; WG I SPM). By the end of the 21st century it is *very likely* that sea level will rise in more than about 95% of the ocean area, with about 70% of the global coastlines projected to experience a sea level change within 20% of the global mean change. Sea-level rise along coasts will also be a function of local and regional conditions, including land subsidence or uplift and patterns of development near the coast.

There is substantial regional variation in observations and projections of climate change impacts, both because the impacts themselves vary, and because of unequal research attention (21.3.1). Evidence linking observed impacts on biological, physical and (increasingly) human systems to recent and ongoing regional temperature and (in some cases) precipitation changes have become more compelling since the AR4. This is due both to the greater availability of statistically robust, calibrated satellite records, and to improved reporting from monitoring sites in hitherto under-represented regions, though the disparity still remains large between data rich and data-poor regions. Regional variations in physical impacts such as vegetation changes, sea-level rise, and ocean acidification are increasingly well documented, though their consequences for ecosystems and humans are less well studied or understood. Projections of future impacts rely primarily on a diverse suite of biophysical, economic and integrated models operating from global- to site-scales, though some physical experiments are also conducted to study processes in altered environments. New research initiatives are beginning to exploit the diversity of impact model projections, through cross-scale model inter-comparison exercises.

There are large variations in the degree to which adaptation processes, practices and policy have been studied and implemented in different regions (21.3.2) (*high confidence*). Europe and Australia have had extensive research programs on climate change adaptation, while research in Africa and Asia has been dominated by international partners and relies heavily on case studies of community-based adaptation. National adaptation strategies are common in Europe, and adaptation plans are in place in some cities in Europe, the Americas and Australasia, with agriculture, water and land use management the primary sectors of activity. However, it is still the case that implementation lags behind planning in most regions of the world.

Contested definitions and alternative approaches to describing regional vulnerability to climate change pose problems for interpreting vulnerability indicators (21.3.1.2; 21.5.1.1). There are numerous studies that use indicators to define aspects of vulnerability, quantifying these across regional units (e.g. by country or municipality), often weighting and merging them into vulnerability indices and presenting them regionally as maps. However, methods of constructing indices are subjective, often lack transparency and can be difficult to interpret. Moreover, indices commonly combine indicators reflecting current conditions (e.g. of socio-economic capacity) with other indicators describing projected changes (e.g. of future climate or population), and have failed to reflect the dynamic nature of the different indicator variables.

Hotspots draw attention, from various perspectives and often controversially, to locations judged to be especially vulnerable to climate change (21.5.1.2). Identifying hotspots is an approach that has been used to indicate locations that stand out in terms of impacts, vulnerability or adaptive capacity (or combinations of these). The approach exists in many fields and the meaning and use of the term hotspots differs, though their purpose is generally to set priorities for policy action or for further research. Hotspots can be very effective as communication tools, but may also suffer from methodological weaknesses. They are often subjectively defined, relationships between indicator variables may be poorly understood and they can be highly scale-dependent. In part due to these ambiguities, there has been controversy surrounding the growing use of hotspots in decision making, particularly in relation to prioritising regions for climate change funding.

Cross-regional phenomena can be crucial for understanding the ramifications of climate change at regional scales, and its impacts and policies of response (21.4) (*high confidence*). These include global trade and international financial transactions, which are linked to climate change as a direct or indirect cause of anthropogenic emissions, as a predisposing factor for regional vulnerability, through their sensitivity to climate trends and extreme climate events, and as an instrument for implementing mitigation and adaptation policies. Migration is also a cross-regional phenomenon, whether of people or of ecosystems, both requiring trans-boundary consideration of their causes, implications and possible interventions to alleviate human suffering and promote biodiversity.

Downscaling of global climate reconstructions and models has advanced to bring the climate data to a closer match for the temporal and spatial resolution requirements for assessing many regional impacts, and the application of downscaled climate data has expanded substantially since AR4 (21.3.3; 21.5.3). This information remains weakly coordinated, and current results indicate that high resolution downscaled reconstructions of the current climate can have significant errors. The increase in downscaled data sets has not narrowed the uncertainty range. Integrating these data with historical change and process based understanding remains an important challenge.

Characterization of uncertainty in climate change research on regional scales has advanced well beyond quantifying uncertainties in regional climate projections alone, to incorporating uncertainties in simulations of future impacts as well as considering uncertainties in projections of societal vulnerability (21.3.3, 21.5.3, 21.5.1. 21.5.2). In particular, intercomparison studies are now examining the uncertainties in impacts models (e.g., AgMIP and ISIMIP) and combining them with uncertainties in regional climate projections. Some results indicate that a larger portion of the uncertainty in estimates of future impacts can be attributed to the impact models applied rather than to the climate projections assumed. In addition, the deeper uncertainties associated with aspects of defining societal vulnerability to climate change related to the alternative approaches to defining vulnerability are becoming appreciated. As yet there has been little research actively to quantify these uncertainties or to combine them with physical impact and climate uncertainties.

Studies of multiple stressors and assessments of potential global and regional futures using scenarios with multiple, non-climate elements are becoming increasingly common (21.5.3.2; 21.5.3.3). Non-climatic factors relevant to assessing a system's vulnerability generally involve a complex mix of influences such as environmental changes (e.g. in air, water and soil quality, sea level, resource depletion), land use and land cover changes, and socio-economic changes (e.g. in population, income, technology, education, equity, governance). All of these non-climate factors have important regional variations. There is significant variation in vulnerability due to variability in these factors.

21.1. Introduction

This chapter serves as an introduction to Part B of this volume. It provides context for an assessment of regional aspects of climate change in different parts of the world, which are presented in the following nine chapters. While the main focus of those chapters is on the regional dimensions of impacts, adaptation and vulnerability, this chapter also offers links to regional aspects of the physical climate reported by Working Group I and of mitigation analysis reported by Working Group III. The chapter frames the discussion of both global and regional issues in a decision-making context. This context identifies different scales of decisions that are made (e.g. global, international, regional, national, subnational, local) and the different economic or impact sectors that are often the objects of decision-making (e.g. agriculture, water resources, energy).

Within this framing, the chapter then provides three levels of synthesis. First there is an evaluation of the state of knowledge of changes in the physical climate system, and associated impacts and vulnerabilities, and the degree of confidence that we have in understanding those on a regional basis as relevant to decision-making. Second, the regional context of the sectoral findings presented in Part A of this volume is discussed. Third, there is an analysis of the regional variation revealed in subsequent chapters of Part B. In so doing, the goal is to examine how the chapters reflect differences or similarities in how decision-making is being addressed by policy and informed by research in different regions of the world, and whether there is commonality of experience among regions that could be useful for enhancing decisions in the future.

Having analyzed similarities and differences among IPCC regions, the chapter then discusses trans-regional and cross-regional issues that affect both human systems (e.g. trade and financial flows) and natural systems (e.g. ecosystem migration). Finally, the chapter evaluates methods of assessing regional vulnerabilities and adaptation, impact analyses, and the development and application of baselines and scenarios of the future. These evaluations provide guidance for understanding how such methods might ultimately be enhanced, so that the confidence in research about possible future conditions and consequences might ultimately improve.

21.2. Defining Regional Context

The climate system may be global in extent, but its manifestations – through atmospheric processes, ocean circulation, bioclimatic zones, daily weather and longer-term climate trends – are regional or local in their occurrence, character and implications. Moreover, the decisions that are or could be taken on the basis of climate change science play out on a range of scales, and the relevance and limitations of information on both biophysical impacts and social vulnerability differ strongly from global- to local-scale, and from one region to another. Explicit recognition of geographical diversity is therefore important for any scientific assessment of anthropogenic climate change. The following sections emphasize some of the crucial regional issues to be pursued in Part B of this report.

21.2.1. Decision-Making Context

A good understanding of decision-making contexts is essential to define the type and resolution and characteristics of information on climate change related risks required from physical climate science and impacts, adaptation and vulnerability assessments (e.g. IPCC, 2012a). This is a general issue for all impacts, adaptation and vulnerability assessments (cf. the chapters in Part A), but is especially important in the context of regional issues. Many studies still rely on global datasets, models and assessment methods to inform regional decisions. However, tailored regional approaches are often more effective in accounting for variations in trans-national, national and local decision-making contexts, as well as across different groups of stakeholders and sectors. There is a growing body of literature offering guidance on how to provide the most relevant climate risk information to suit specific decision-making scales and processes (e.g., Willows and Connell, 2003; ADB, 2005; Kandlikar *et al.*, 2011).

Table 21-1 illustrates the range of actors involved in decision-making to be informed by climate information at different scales in different sectors, ranging from international policy makers and agencies, to national and local government departments, to civil society organizations and the private sector at all levels, all the way to communities and individual households. The table illustrates how policy makers face a dual challenge in achieving policy integration – vertically, through multiple levels of governance, and horizontally, across different sectors (policy coherence).

[INSERT TABLE 21-1 HERE
Table 21-1: Dimensions of the institutions and actors involved in climate change decision-making, including example entries referred to in chapters of this volume. Vertical integration can occur within as well as between levels. Decison-making domains are illustrative. Modified and extended from Mickwitz (2009).]

Many climate change risk assessments have traditionally been undertaken either in the context of international climate policy-making (especially the United National Framework Convention on Climate Change – UNFCCC), or by (or for) national governments (e.g. CCRA, 2012; SEI, 2009; GCAP, 2011; Roshydromet, 2008). In those cases, climate risk information commonly assumes a central role in the decision-making, for instance to inform mitigation policy, or for plans or projects designed specifically to adapt to a changing climate. In recent years, increasing attention has been paid to more sector- or project-specific risk assessments, intended to guide planning and practice by a range of actors (e.g. Liu *et al.*, 2008; Rosenzweig *et al.*, 2011). In those contexts, climate may often be considered as only one contributor among a much wider set of considerations for a particular decision. In such cases, there is uncertainty about not only the future climate, but also many other aspects of the system at risk. Moreover, while analysts will seek the best available climate risk information to inform the relative costs and benefits of the options available to manage that risk, they will also need to consider the various constraints to action faced by the actors involved.

Some of these decision-making contexts, such as the design of large infrastructure projects, may require rigorous quantitative information to feed formal evaluations, often including cost-benefit analysis (e.g. PriceWaterHouseCoopers, 2010; and see chapter 17). Others, especially at local level, such as decision-making in traditional communities, are often made more intuitively, with a much greater role for a wide range of social and cultural aspects. These may benefit much more from experience-based approaches, participatory risk assessments or story-telling to evaluate future implications of possible decisions (e.g. Van Aalst *et al.*, 2008, World Bank, 2010). Multi-criteria analysis, scenario planning, and flexible decision paths offer options for taking action when faced with large uncertainties or incomplete information, and can help bridge adaptation strategies across scales (in particular between the national and local level). In most cases, an understanding of the context in which the risk plays out, and the alternative options that may be considered to manage it, are not an afterthought, but a defining feature of an appropriate climate risk analysis, which requires a much closer interplay between decision-makers and providers of climate risk information than often occurs in practice (e.g., Cardona *et al.*, 2012; Hellmuth *et al.*, 2010; Mendler de Suarez *et al.*, 2012).

The different decision-making contexts also determine the types of climate information required, including the climate variables of interest and the geographic and time scales on which they need to be provided. Many climate change impact assessments have traditionally focused on changes over longer time horizons (often out to 2100, though recently studies have begun to concentrate more on mid-century or earlier). In contrast, most decisions taken today have a planning horizon ranging from a few months to about two decades (e.g. Wilby et al., 2009). For many such shorter-term decisions, recent climate variability and observed trends are commonly regarded as sufficient to inform adaptation (e.g. Hallegatte, 2009). However, in so doing, there is often scope to make better use of observed climatological information as well as seasonal and maybe also decadal climate forecasts (e.g. Wang *et al.*, 2009;

Ziervogel *et al.*, 2010; Mehta *et al.*, 2011; Kirtman *et al.*, 2014., HLT, 2011). For longer-term decisions, such as decisions with irreversible long-term implications and investments with a long investment horizon and substantial vulnerability to changing climate conditions, longer-term climate risk information is needed (e.g. Reeder and Ranger, 2010). However, while that longer-term information is often used simply to plan for a best-guess scenario to optimize for most probable conditions, there is increasing attention for informing concerns about maladaptation (Barnett and O'Neill, 2010) and sequencing of potential adaptation options in a wider range of possible outcomes, requiring a stronger focus on ranges of possible outcomes and guidance on managing uncertainties, especially at regional, national and sub-national levels (Hall *et al.*, 2012; Gersonius *et al.*, 2013).

Section 21.3 summarizes different approaches that have been applied at different scales looking at vulnerabilities and impacts, adaptation, and climate science in a regional context, paying special attention to information contained in the regional chapters.

21.2.2. Defining Regions

There has been an evolution in the treatment of regional aspects of climate change in IPCC reports (Table 21-2) from a patchwork of case examples in the First Assessment Report (FAR) and its supplements, through to attempts at a more systematic coverage of regional issues following a request from governments, beginning with the Special Report on the Regional Impacts of Climate Change in 1998. That report distilled information from the Second Assessment Report (SAR) for ten continental scale regions, and the subsequent Third (TAR) and Fourth (AR4) assessments each contained comparable chapters on impacts, adaptation and vulnerability in the Working Group (WG) II volumes. WG I and III reports have also addressed regional issues in various chapters, using different methods of mapping, statistical aggregation and spatial averaging to provide regional information.

[INSERT TABLE 21-2 HERE
Table 21-2: Selected examples of regional treatment in previous IPCC Assessment Reports and Special Reports (SR). Major assessments are subdivided by the three Working Group reports, each described by generic titles.**]**

Part B of this WG II Fifth Assessment (AR5) is the first to address regional issues treated in all three WGs. It comprises chapters on the six major continental land regions, Polar Regions, Small Islands and The Ocean. These are depicted in Figure 21-1.

[INSERT FIGURE 21-1 HERE
Figure 21-1: Specification of the world regions described in chapters 22-30 of this volume.]

Some of the main topics benefiting from a regional treatment are:

- *Changes in climate*, typically represented over sub-continental regions, a scale at which global climate models simulate well the pattern of observed surface temperatures, though more modestly the pattern of precipitation (Flato *et al.*, 2014). While maps are widely used to represent climatic patterns, regional aggregation of this (typically gridded) information is still required to summarise the processes and trends they depict. Examples, including information on climate extremes, are presented elsewhere in this chapter, with systematic coverage of all regions provided in supplementary material. Selected time series plots of temperature and precipitation change from an atlas of global and regional climate projections accompanying the WG I report (Collins *et al.*, 2014b) can also be found in several regional chapters of this volume. In Figure 21-1, the sub-continental regions used for summarising climate information are overlaid on a map of the nine regions treated in Part B.
- *Changes in other aspects of the climate system*, such as the cryosphere, oceans, sea level, and atmospheric composition. A regional treatment of these phenomena is often extremely important to gauge real risks, for example when regional changes in land movements and local ocean currents counter or reinforce global sea level rise (Nicholls *et al.*, 2013).
- *Climate change impacts* on natural resource sectors, such as agriculture, forestry, ecosystems, water resources and fisheries, and on human activities and infrastructure, often with regional treatment according

to biogeographical characteristics (e.g. biomes, climatic zones, physiographic features such as mountains, river basins, coastlines or deltas, or combinations of these).

- *Adaptive capacity*, which is a measure of society's ability to adjust to the potential impacts of climate change, sometimes characterised in relation to social vulnerability (Füssel, 2010), and sometimes represented in regional statistics through the use of socio-economic indicators.
- *Emissions* of greenhouse gases and aerosols and their cycling through the Earth system (Blanco et al., 2014; Ciais *et al*., 2014).
- *Human responses to climate change through mitigation and adaptation*, which can require both global and regional approaches (e.g. Stavins *et al.*, 2014; Agrawala *et al.*, 2014; Somanathan *et al.*, 2014; and see chapters 14 to 16).

Detailed examples of these elements will be referred to throughout this chapter and the regional chapters that follow. Some of the more important international political groupings that are pertinent to the climate change issue are described and catalogued in Supplementary material (section SM21.1). Table SM21-1 in section SM21.1 lists UN member states and other territories, their status in September 2013 with respect to some illustrative groupings of potential relevance for international climate change policy making, and the regional chapters in which they are considered in this report.

Finally, new global socioeconomic and environmental scenarios for climate change research have emerged since the AR4 that are richer, more diverse and offer a higher level of regional detail than previous scenarios taken from the IPCC Special Report on Emissions Scenarios (SRES). These are introduced in Box 21-1.

_____ START BOX 21-1 HERE _____

Box 21-1. A New Framework of Global Scenarios for Regional Assessment

The major socio-economic driving factors of future emissions and their effects on the global climate system were characterized in the TAR and AR4 using scenarios derived from the IPCC Special Report on Emissions Scenarios (SRES – IPCC, 2000). However, these scenarios are becoming outdated in terms of their data and projections, and their scope is too narrow to serve contemporary user needs (Ebi *et al*., 2013). More recently a new approach to developing climate and socio-economic scenarios has been adopted in which concentration trajectories for atmospheric greenhouse gases and aerosols were developed first (Representative Concentration Pathways or RCPs – Moss et al., 2010), thereby allowing climate modeling work to proceed much earlier in the process than for SRES. Different possible Shared Socio-economic Pathways (SSPs), intended for shared use among different climate change research communities, were to be determined later, recognizing that more than one socio-economic pathway can lead to the same concentrations of greenhouse gases and aerosols (Kriegler *et al.,* 2012).

Four different RCPs were developed, corresponding to four different levels of radiative forcing of the atmosphere by 2100 relative to pre-industrial levels, expressed in units of Wm^{-2}: RCP 8.5, 6.0, 4.5, and 2.6 (van Vuuren et al., 2012). These embrace the range of scenarios found in the literature, and all except RCP 8.5 also include explicit stabilization strategies, which were missing from the SRES set. An approximate mapping of the SRES scenarios onto the RCPs on the basis of a resemblance in radiative forcing by 2100 is presented in chapter 1 (this volume), pairing RCP 8.5 with SRES A2 and RCP 4.5 with B1 and noting that RCP 6.0 lies between B1 and B2. No SRES scenarios result in forcing as low as RCP 2.6, though mitigation scenarios developed from initial SRES trajectories have been applied in a few climate model experiments (e.g. the E1 scenario – Johns et al., 2011).

In addition, five SSPs have been proposed, representing a wide range of possible development pathways (van Vuuren et al., 2013). An inverse approach is applied, whereby the SSPs are constructed in terms of outcomes most relevant to IAV and mitigation analysis, depicted as challenges to mitigation and adaptation (Chapter 20, Figure 20-3). Narrative storylines for the SSPs have been outlined and preliminary quantifications of the socio-economic variables are underway (O'Neill et al., 2013). Priority has been given to a set of *basic* SSPs with the minimum detail and comprehensiveness needed to provide inputs to IAV and integrated assessment models, primarily at global or large regional scales. Building on the basic SSPs, a second stage will construct *extended* SSPs, designed for finer-scale regional and sectoral applications (O'Neill *et al*., 2013).

An overall scenario architecture has been designed for integrating RCPs and SSPs (Ebi et al., 2013; van Vuuren et al., 2013), for considering mitigation and adaptation policies using Shared Policy Assumptions (SPAs – Kriegler et al., 2013) and for providing relevant socio-economic information at the scales required for IAV analysis (van Ruijven et al., 2013). Additional information on these scenarios can be found in chapter 1 of this report (section 1.1.3) and elsewhere in the assessment (Blanco et al., 2014.; Collins et al., 2014a.; Kunreuther et al., 2014). However, due to the time lags that still exist between the generation of RCP-based climate change projections in CMIP5 (the Coupled Model Intercomparison Project – Taylor *et al*., 2012) and the development of SSPs, few of the IAV studies assessed in this report actively use these scenarios. Instead, most of the scenario-related studies in the assessed literature still rely on the SRES.

_____ END BOX 21-1 HERE _____

21.2.3. Introduction to Methods and Information

There has been significant confusion and debate about the definitions of key terms (Janssen and Ostrom, 2006), such as vulnerability (Adger, 2006), adaptation (Stafford Smith *et al.,* 2011), adaptive capacity (Smit and Wandel, 2006) and resilience (Klein et al., 2003). One explanation is that the terms are not independent concepts, but defined by each other, thus making it impossible to remove the confusion around the definitions (Hinkel, 2011). The differences in the definitions relate to the different entry points for looking at climate change risk (IPCC, 2012).

Table 21-3 shows two ways to think about vulnerability, demonstrating that different objectives (e.g., improving well-being and livelihoods or reducing climate change impacts) lead to different sets of questions being asked. This results in the selection of different methods to arrive at the answers. The two approaches portrayed in the middle and right hand columns of Table 21-3 have also been characterised in terms of top-down (middle column) and bottom-up (right column) perspectives, with the former identifying physical vulnerability and the latter social vulnerability (Dessai and Hulme, 2004). In the middle column, the climate change impacts are the starting point for the analysis, revealing that people and/or ecosystems are vulnerable to climate change. This approach commonly applies global-scale scenario information and seeks to refine this to the region of interest through downscaling procedures. For the approach illustrated on the right, the development context is the starting point (i.e., social vulnerability), commonly focusing on local scales, on top of which climate change occurs. The task is then to identify what changes are needed in the broader-scale development pathways in order to reduce vulnerability to climate change. Another difference is a contrast in time-frames, where a climate change focused approach tends to look to the future to see how to adjust to expected changes, whereas a vulnerability focused approach is centred on addressing the drivers of current vulnerability. A similar approach is described by McGray *et al.* (2009).

[INSERT TABLE 21-3 HERE
Table 21-3: Two possible entry points for thinking about vulnerability to climate change (illustrative and adapted from Füssel 2007).]

The information assessed in this chapter stems from different entry points, framings and conceptual frameworks for thinking about risk. They merge social and natural science perspectives with transdisciplinary ones. There is no single "best" conceptual model: the approaches change as scientific thinking evolves. The IPCC itself is an example of this: IPCC SREX (IPCC, 2012) presented an approach that has been adjusted and adapted in Chapter 19 of this volume. Chapter 2 describes other conceptual models for decision making in the context of risk. While this diversity in approaches enriches our understanding of climate change, it can also create difficulties in comparisons. For instance, findings that are described as vulnerabilities in some studies may be classified as impacts in others; lack of adaptive capacity in one setting might be described as social vulnerability in another.

21.3. Synthesis of Key Regional Issues

This section presents information on vulnerabilities and impacts, adaptation, and climate science in a regional context. To illustrate how these different elements play out in actual decision-making contexts, Table 21-4 presents examples drawn from the regional and thematic chapters, which illustrate how information about vulnerability and exposure, and climate science at different scales, inform adaptation (implemented in policy and practice as part of a wider decision-making context). These show that decision-making is informed by a combination of different types of information. However, this section is organized by the three constituent elements: vulnerabilities and impacts; adaptation; and climate science.

[INSERT TABLE 21-4 HERE
Table 21-4: Illustrative examples of adaptation experience, as well as approaches to reduce vulnerability and enhance resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerabilities, inequalities, and climate change come to the fore. At the same time, place-based examples illustrate how larger-level drivers and stressors shape differential risks and livelihood trajectories, often mediated by institutions.]

The following two sub-sections offer a brief synopsis of the approaches being reported in the different regional chapters on impacts and vulnerability studies (21.3.1) and adaptation studies (21.3.2), aiming to particularly highlight similarities and differences among regions. Table 21-5 serves as a rough template for organising this discussion which is limited to the literature that has been assessed by the regional chapters. It is organized according to the broad research approach applied, distinguishing impacts and vulnerability approaches from adaptation approaches; and according to scales of application ranging from global to local.

[INSERT TABLE 21-5 HERE
Table 21-5: Dimensions of assessments of impacts and vulnerability and of adaptation drawn upon to serve different target fields (cf. Table 21-1). Scales refer to the level of aggregation at which study results are presented. Entries are illustrations of different types of study approaches reported and evaluated in this volume, with references given both to the original studies and to the chapters in which they are cited. Aspects of some of the studies in this table are also alluded to in Section 21.5.]

Section 21.3.3 then provides an analysis of advances in understanding of the physical climate system for the different regions covered in chapters 22-30, introducing new regional information to complement the large-scale and process-oriented findings presented by Working Group I. Understanding the reliability of this information is of crucial importance. In the context of IAV studies it is relevant to a very wide range of scales and it comes with a similarly wide range of reliabilities. Using a similar classification of spatial scales to that presented in Table 21-5, Table 21-6 provides a summary assessment of the reliability of information on two basic climate variables of relevance, surface temperature and precipitation. It is drawn from the extensive assessment and supporting literature from the IPCC SREX (IPCC, 2012) and the AR5 WG1 reports. Some discussion of relevant methodologies and related issues and results are also presented in section 21.5.

[INSERT TABLE 21-6 HERE
Table 21-6: Reliability of climate information on temperature and precipitation over a range of spatial and temporal scales. Reliability is assigned to one of seven broad categories from Very High (VH) to Medium (M) through to Very Low (VL).]

Table 21-6 shows there are significant variations in reliability with finer scales information generally less reliable given the need for a greater density of observations and/or for models to maintain accuracy at high resolutions. The reliability of information on past climate depends on the availability and quality of observations which is higher for temperature than precipitation as observations of temperature are easier to make and generally more representative of surrounding areas than is the case for precipitation. Future climate change reliability depends on the performance of the models used for the projections in simulating the processes that lead to these changes. Again, information on temperature is generally more reliable due to the models' demonstrated ability to simulate the relevant processes when reproducing past changes. The significant geographical variations, in the case of the observations, result from issues with availability and/or quality of data in many regions, especially for precipitation. For future climate change, data availability is less of an issue with the advent of large ensembles of climate model projections but quality is a significant problem in some regions where the models perform poorly and there is little confidence that processes driving the projected changes are accurately captured. A framework for summary information on model projections of future climate change placed this in the context of observed changes is presented in Box 21-2.

_____ START BOX 21-2 HERE _____

Box 21-2. Summary Regional Climate Projection Information

Summary figures on observed and projected changes in temperature and precipitation are presented in the following regional chapters. These provide some context to the risks associated with climate change vulnerability and impacts and the decision-making on adaptations being planned and implemented in response to these risks. Figure 21-2 provides an example for Africa. The information is identical to that displayed in Box CC-RC.

[INSERT FIGURE 21-2 HERE
Figure 21-2: Observed and projected changes in annual average temperature and precipitation. (Top panel, left) Observed temperature trends from 1901-2012 determined by linear regression. [WGI AR5 Figures SPM.1 and 2.21] (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression. [WGI AR5 Figure SPM.2] For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See alsoAnnex I of WGI AR5. [Boxes 21-3 and CC-RC]]

These figures provide a very broad overview of the projected regional climate changes but in dealing with only annual averages they are not able to convey any information about projected changes on seasonal timescales or shorter, such as for extremes. In addition, they are derived solely from the CMIP5 general circulation models (GCMs) and do not display any information derived from CMIP3 data which are widely used in many of the studies assessed within the AR5 WG2 report. To provide additional context two additional sets of figures are presented here and in Box 21-4 that display temperature and precipitation changes at the seasonal and daily timescales respectively.

Figure 21-3 displays projected seasonal and annual changes averaged over the regions defined in the IPCC SREX report, "Managing the risks of extreme events and disasters to advance climate change adaptation" (IPCC 2012), for Central and South America for the four RCP scenarios and three of the SRES scenarios. The temperature and precipitation changes for the period 2071-2100 compared to a baseline of 1961-1990 are plotted for the four standard three months seasons with the changes from each CMIP3 or CMIP5 represented by a symbol. Symbols showing the CMIP3 model projections are all grey but differ in shape depending on the driving SRES concentrations scenario and those showing the CMIP5 projections differ in colour depending on the driving RCP emissions/concentrations scenario (see figure legend for details and Box 21-1 for more information on the SRES and RCP scenarios). The thirty year periods were chosen for consistency with the figures displayed in Box 21-4 (Figures 21-7 and 21-8) showing changes in daily temperatures and precipitation. Figures presenting similar information for the SREX regions contained in the other inhabited continents are presented in supplementary figures SM21-1 to SM21-7.

[INSERT FIGURE 21-3 HERE
Figure 21-3: Regional average change in seasonal and annual mean temperature and precipitation over five sub-regions covering South and Central America for the period 2071-2100 relative to 1961-90 in GCM projections from 35 CMIP5 ensemble under four RCP scenarios (van Vuuren et al., 2011) compared with GCM projections from 22 CMIP3 ensemble under three SRES scenarios (IPCC, 2000); see Table 21-1 for details of the relationship between the SRES and RCP scenarios. Regional averages are based on SREX region definitions (see Figure 21-3). Temperature changes are given in ºC and precipitation changes in mm/day with axes scaled relative to the maximum changes projected across the range of models. The models which generated the data displayed are listed in supplementary material Table SM21-3.]

_____ END BOX 21-2 HERE _____

21.3.1. Vulnerabilities and Impacts

21.3.1.1. Observed Impacts

The evidence linking observed impacts on biological, physical and (increasingly) human systems to recent and ongoing regional climate changes has become more compelling since the AR4 (see chapter 18). One reason for this is the improved reporting of published studies from hitherto under-represented regions of the world, especially in the tropics (Rosenzweig and Neofotis, 2013). That said, the disparity is still large between the copious evidence being presented from Europe and North America, as well as good quality data emerging from Australasia, polar regions, many ocean areas and some parts of Asia and South America, compared to the much sparser coverage of studies from Africa, large parts of Asia, central and South America and many small islands. On the other hand, as the time series of well-calibrated satellite observations become longer in duration, and hence statistically more robust, these are increasingly providing a near global coverage of changes in surface characteristics such as vegetation, hydrology, and snow and ice conditions that can usefully complement or substitute for surface observations (see Table 21-4 and chapter 18 for examples). Changes in climate variables other than temperature, such as precipitation. evapotranspiration and CO_2 concentration, are also being related to observed impacts in a growing number of studies (Rosenzweig and Neofotis, 2013; and see examples from Australia in chapter 25, Table 25-3 and south eastern South America in chapter 27, Figure 27-7).

Other regional differences in observed changes worth pointing out include trends in relative sea level, which is rising on average globally (Church *et al*., 2014), but displays large regional variations in magnitude, or even sign, due to a combination of influences ranging from El Niño/La Nina cycles to local tectonic activity (Nicholls et al., 2013), making general conclusions about ongoing and future risks of sea level change very difficult to draw across diverse regional groupings such as small islands (see chapter 29). There are also regional variations in another ongoing effect of rising CO_2 concentration – ocean acidification, with a greater pH decrease at high latitudes consistent with the generally lower buffer capacities of the high latitude oceans compared to lower latitudes (Rhein et al., 2014, section 3.8.2). Calcifying organisms are expected to show responses to these trends in future, but key uncertainties remain at organismal to ecosystem levels (chapter 30, Box CC-OA).

21.3.1.2. Future Impacts and Vulnerability

21.3.1.2.1. Impact models

The long-term monitoring of environmental variables, as well as serving a critical role in the detection and attribution of observed impacts, also provides basic calibration material used for the development and testing of impact models. These include process-based or statistical models used to simulate the biophysical impacts of climate on outcomes such as crop yield, forest productivity, river runoff, coastal inundation or human mortality and morbidity (see chapters 2-7; 11). They also encompass various types of economic models that can be applied to evaluate the costs incurred by biophysical impacts (see, for example, chapters 10 and 17). There are also integrated assessment models (IAMs), Earth System Models, and other more loosely linked integrated model frameworks that represent multiple systems and processes (e.g. energy, emissions, climate, land use change, biophysical impacts, economic effects, global trade) and the various interactions and feedbacks between them. For examples of these, see chapter 17, section 17.6.3 and Flato *et al.* (2014).

21.3.1.2.2. Vulnerability mapping

A second approach to projecting potential future impacts is to construct vulnerability maps. These usually combine information on three components: exposure to a hazard (commonly defined by the magnitude of climate change, sensitivity to that hazard), the magnitude of response for a given level of climate change, and adaptive capacity (describing the social and economic means to withstand the impacts of climate change (IPCC, 2001)). Key indicators are selected to represent each of the three components, which are sometimes combined into a single index of vulnerability. Indicators are usually measured quantities taken from statistical sources (e.g. income, population), or have been modelled separately (e.g. key climate variables). Vulnerability indices have received close scrutiny in several recent reviews (Füssel, 2010; Hinkel, 2011; Malone and Engle, 2011; Preston *et al.*, 2011; Kienberger et al., 2012), and a number of global studies have been critiqued by Füssel (2010).

A variant of vulnerability mapping is risk mapping (e.g., Tran et al., 2009; Ogden et al., 2008). This commonly identifies a single indicator of hazard (e.g. a level of flood expected with a given return period), which can be mapped accurately to define those regions at risk from such an event (e.g. in a flood plain). Combined with information on changing return periods of such events under a changing climate would enable some estimate of altered risk to be determined.

21.3.1.2.3. Experiments

A final approach for gaining insights on potential future impacts, concerns physical experiments designed to simulate future altered environments of climate (e.g. temperature, humidity and moisture), and atmospheric composition (e.g. CO_2, surface ozone and sulphur dioxide concentrations). These are typically conducted to study responses of crop plants, trees and natural vegetation, using open top chambers, greenhouses or free air gas release systems (e.g., Craufurd *et al.*, 2013), or responses of aquatic organisms such as plankton, macrophytes or fish, using experimental water enclosures known as mesocosms (e.g., Sommer et al., 2007; Lassen et al., 2010).

21.3.1.2.4. Scale issues

Impact models operate at a range of spatial and temporal resolutions, and while their outputs are sometimes presented as fine resolution maps, key model findings are rarely produced at the finest resolution of the simulations (i.e. they are commonly aggregated to political or topographic units of interest to the target audience, e.g. watershed, municipality, national or even global). Aggregation of data to coarse-scale units is also essential for allowing comparison of outputs from models operating at different resolutions, but it also means that sometimes quite useful detail may be overlooked when model outputs are presented at the scale of the coarsest common denominator. Conversely, if outputs from impact models are required as inputs to other models, the outputs may need to be harmonized to a finer grid than the original data. In such cases, downscaling methods are commonly applied. This was the case, for example, when providing spatially explicit projections of future land use from different IAMs (Hurtt et al., 2011) for climate modellers to apply in the CMIP5 process (Collins et al., 2014a). It is also a common procedure used in matching climate model outputs to impact models designed to be applied locally (e.g. over a river basin or an urban area – see section 21.3.3.2).

Even if the same metrics are being used to compare aggregate model results (e.g. developed versus developing country income under a given future scenario) estimates may have been obtained using completely different types of models operating at different resolutions. Moreover, many models that have a large-scale coverage (e.g. continental or global) may nonetheless simulate processes at a relatively fine spatial resolution, offering a potentially useful source of spatially explicit information that is unfamiliar to analysts working in specific regions, who may defer to models more commonly applied at the regional scale. Examples include comparison of hydrological models with a global and regional scope (Todd *et al.*, 2011) and bioclimatic models of vascular plant distributions with a European and local scope (Trivedi *et al.*, 2008). Vulnerability mapping exercises can also be undermined by the inappropriate merging of indicator datasets that resolve information to a different level of precision (e.g. Tzanopoulos *et al.*, 2013). There is scope for considerably enhanced cross-scale model intercomparison work in the future, and projects such as AgMIP (Rosenzweig *et al.*, 2013) and ISI-MIP (Schiermeier, 2012, – see section 21.5) have provision for just such exercises.

21.3.2. Adaptation

This section draws on material from the regional chapters (22-30) as well as the examples described in Table 21-4. Material from chapters 14-17 is also considered. See also Table 16.4 for a synthesis from the perspective of adaptation constrains and limits.

21.3.2.1. Similarities and Differences in Regions

As described in the regional chapters, a large portion of adaptation knowledge is based on conclusions drawn from case studies in specific locations, the conceptual findings are typically being applied globally (chapters 14-17).). It is this empirical knowledge on adaptation that guides understandings in the different regions. This is especially the case for developing regions. Thus, regional approaches to adaptation vary in their degree of generality. One of the most striking differences between regions in terms of adaptation is the extent to which it has been studied and implemented. Australia and Europe have invested heavily in research on adaptation since the AR4, and the result is a rich body of literature published by local scientists. The ability to advance in adaptation knowledge may be related to the amount and quality of reliable climate information, the lack of which has been identified as a constraint to developing adaptation measures in Africa (22.4.2). Many case studies, especially of community-based adaptation, stem from Asia, Africa, Central and South America and Small Islands but the majority of this work has been undertaken and authored by international non-governmental organisations, as well as by other non-local researchers. In Africa, most planned adaptation work is considered to be pilot, and seen as part of learning about adaptation, although there has been significant progress since the AR4 (22.4.4.2).

Most regional chapters report lags in policy work on adaptation (see also 16.5.2). While most European countries have adaptation strategies, few have been implemented (23.1.2). Lack of implementation of plans is also the case for Africa (22.4). In North (26.8.4.1.2*)* and Central and South America (27.5.3.2), adaptation plans are in place for some cities. In Australasia, there are few adaptation plans (25.4.2). In the Arctic, they are in their infancy (28.4). At the same time, civil society and local communities have the opportunity to play a role in decision making about adaptation in Europe and Asia (23.7.2, 24.4.6.5). In Africa, social learning and collective action are used to promote adaptation (22.4.5.3). Adaptation is observed as mostly autonomous (spontaneous) in Africa, although socio-ecological changes are creating constraints for autonomous adaptation (22.4.5.4). There is a disconnect in most parts of Africa between policy and planning levels, and the majority of work is still autonomous and unsupported (22.4.1). In the case of UNFCCC-supported activities, such as National Adaptation Programmes of Action, few projects from the African (22.4.4.2) least developed countries have been funded, thus limiting the effectiveness of these investments. Several chapters (Africa, Europe, North America, Central and South America and Small Islands) explicitly point out that climate change is only one of multiple factors that affect societies and ecosystems and drives vulnerability or challenges adaptation (22.4.2, 23.10.1, 26.8.3.1, 27.3.1.2, 29.6.3*)*. For example, North America reports that for water resources, most adaptation actions are ‘no-regrets’, meaning that they have benefits beyond just adaptation to climate change (26.3.4). In Australasia, the limited role of socio-economic information in vulnerability assessments restricts confidence regarding the conclusions about future vulnerability and adaptive capacity (25.3.2).

Some chapters (Polar Regions, North America, Australasia) emphasise the challenges faced by indigenous peoples and communities in dealing with climate change (28.4.1, 26.8.2.2, 25.8.2). Although they are described as having some degree of adaptive capacity to deal with climate variability, shifts in lifestyles combined with a loss of traditional knowledge leave many groups more vulnerable to climate change (28.2.4.2). Also, traditional responses have been found to be maladaptive because they are unable to adjust to the rate of change, or the broader context in which the change is taking place, as seen in the Arctic (28.4.1). In response to changing environmental conditions, people are taking on maladaptive behaviour – for instance, by going further to hunt because of changed fish-stocks and thus exposing themselves to greater risk, or changing to different species and depleting stocks (28.4.1). Limits to traditional approaches for responding to changing conditions have also been observed in several Small Island States (29.8).

Most populated regions have experience with adaptation strategies in agriculture, where exposure to the impacts of climate variability over centuries provides a starting point for making adjustments to new changes in climate. Water and land use management strategies stand out in the literature in common across all of the main continental regions.

The link between adaptation and development is explicit in Africa, where livelihood diversification has been key to reducing vulnerability (22.4.5.2). At the same time, there is evidence that many short-term development initiatives have been responsible for increasing vulnerability (22.4.4.2). Other chapters mention constraints or barriers to adaptation in their regions. For example, the low priority accorded to adaptation in parts of Asia, compared to more pressing issues of employment and education, is attributed in part to a lack of awareness of the potential impacts of climate change and the need to adapt, a feature common to many regions (22.5.4). All developing regions cite insufficient financial resources for implementing adaptation as a significant limitation.

21.3.2.2. Adaptation Examples in Multiple Regions

Across regions, similar responses to climate variability and change can be noted. Heat waves are an interesting example (Table 21-4), as early warning systems are gaining use for helping people reduce exposure to heat waves. At the global scale, the length and frequency of warm spells, including heat waves, has increased since 1950 (*medium confidence*), and over most land areas on a regional scale, more frequent and/or longer heat waves or warm spells are *likely* by 2016-2035 and *very likely* by 2081-2100 (IPCC, 2014d). Warning systems are now planned and implemented in Europe, the US, Canada, Asia and Australia.

Use of mangroves to reduce flood risks and protect coastal areas from storm surges is a measure promoted in Asia, Africa, the Pacific and South America (Table 21-4). Often, mangroves have been cut down to provide coastal access, so there is a need to restore and rehabilitate them. This is an example that is considered low-regrets because it brings multiple benefits to communities besides protecting them from storm surges, such as providing food security and enhancing ecosystem services. Mangrove forests also store carbon, offering synergies with mitigation.

In several African countries, as well as in India, index-based insurance for agriculture has been used to address food insecurity and loss of crops resulting from more hot and fewer cold nights, an increase in heavy precipitation events and longer warm spells (Table 21-4). A predetermined weather threshold typically associated with high loss triggers an insurance pay-out. The mechanism shares risk across communities and can help encourage adaptive responses and foster risk awareness and risk reduction. However, limited availability of accurate weather data mean that establishing which weather conditions causes losses can be challenging. Furthermore, if there are losses but not enough to trigger payout, farmers may lose trust in the mechanism.

21.3.2.3. Adaptation Examples in Single Regions

Although conditions are distinct in each region and location, practical lessons can often be drawn from looking at examples of adaptation in different locations. Experience with similar approaches in different regions offers additional lessons that can be useful when deciding whether an approach is appropriate.

Community-based adaptation is happening and being planned in many developing regions, especially in locations that are particularly poor. In small islands, where a significant increase in the occurrence of future sea-level extremes by 2050 and 2100 is anticipated, traditional technologies and skills may still be relevant for adapting (Table 21-4). In the Solomon Islands, relevant traditional practices include elevating concrete floors to keep them dry during heavy precipitation events and building low aerodynamic houses with palm leaves as roofing to avoid hazards from flying debris during cyclones, supported by perceptions that traditional construction methods are more resilient to extreme weather. In Fiji after cyclone Ami in 2003, mutual support and risk sharing formed a central pillar for community-based adaptation, with unaffected households fishing to support those with damaged homes. Participatory consultations across stakeholders and sectors within communities and capacity building taking into account traditional practices can be vital to the success of adaptation initiatives in island communities, such as in Fiji or Samoa. These actions provide more than just the immediate benefits; they empower people to feel in control of their situations.

In Europe, several governments have made ambitious efforts to address risks of inland and coastal flooding due to higher precipitation and sea level rise during the coming century (Table 21-4). Efforts include a multitude of options. One of the key ingredients is strong political leadership or government champions. In the Netherlands, government recommendations include ‘soft’ measures preserving land from development to accommodate increased river inundation; raising the level of lakes to ensure continuous freshwater supply; restoring natural estuary and tidal regimes; maintaining coastal protection through beach nourishment; and ensuring necessary political-administrative, legal, and financial resources. The British government has also developed extensive adaptation plans to adjust and improve flood defenses and restrict development in flood risk areas in order to protect London from future storm surges and river flooding. They undertook a multi-stage process, engaging stakeholders and using multi-criteria analysis. Pathways have been analyzed for different adaptation options and decisions, depending on eventual sea level rise, with ongoing monitoring of the drivers of risk informing decisions.

In Australia, farmers and industries are responding to experienced and expected changes in temperature, rainfall, and water availability by relocating parts of their operations, such as for rice, wine, or peanuts, or changing land use completely (Table 21-4). In South Australia, for instance, there has been some switching from grazing to cropping. The response is transformational adaptation, and can have positive or negative implications for communities in both origin and destination regions. This type of adaptation requires a greater level of commitment, access to more resources and greater integration across decision-making levels because it spans regions, livelihoods and economic sectors.

21.3.3. Climate System

This section places the regional chapters in a broader context of regional climate information, particularly regarding cross regional aspects, but does not provide a detailed region-by-region assessment. Boxes 21-2 and 21-4 introduce examples of regional information for continental/sub-continental regions but other regional definitions are often relevant (see Box 21-3). The focus in this section is on the summary of new and emerging knowledge since the AR4 relevant to vulnerability, impacts and adaptation research, with emphasis on material deriving from dynamical and statistical downscaling work which is often of greater relevance for VIA applications than the coarser resolution global climate model data. In a regional context, the AR5 WG1 Chapter 14 (Regional Phenomena) is particularly relevant for the projections and evaluation of confidence in models’ ability to simulate temperature, precipitation and phenomena, together with an assessed implication for the general level of confidence in projections for 2080-2099 of regional temperature and precipitation (See WG1, Ch 14, Table 14.2).

_____ START BOX 21-3 HERE _____

Box 21-3. Developing Regional Climate Information Relevant to Political and Economic Regions

In many world regions, countries form political and/or economic groupings that coordinate activities to further the interests of the constituent nations and their peoples. For example, the Intergovernmental Authority on Development (IGAD) of the countries of the Greater Horn of Africa recognizes that the region is prone to extreme climate events such as droughts and floods that have severe negative impacts on key socio-economic sectors in all its countries. In response it has set up the IGAD Climate Prediction and Applications Centre (ICPAC). ICPAC provides and supports application of early warning and related climate information for the management of climate-related risks (for more details see http://www.icpac.net/). In addition it coordinates the development and dissemination of seasonal climate forecasts for the IGAD countries as part of a WMO-sponsored Regional Climate Outlook Forum process (Ogallo et al., 2008) which perform the same function in many regions. A more recent WMO initiative, the Global Framework for Climate Services (Hewitt et al., 2012), aims to build on these and other global, regional and national activities and institutions to develop climate information services for all nations.

As socio-economic factors are important contributors to both the vulnerability and adaptability of human and natural systems, it clearly makes sense to summarise and assess available climate and climate change information for these regions, as this will be relevant to policy decisions taken within these groupings on their responses to climate change. For example, Figure 22-2 in Chapter 22 illustrates the presentation of observed and projected climate changes of two summary statistics for 5 political/economic regions covering much of Africa. It conveys several important pieces of information: the models are able to reproduce the observed trends in temperature; they simulate significantly lower temperatures without the anthropogenic forcings and significantly higher future temperatures under typical emissions paths; for most regions the models project that future variations in the annual average will be similar to those simulated for the past. However, for a more comprehensive understanding additional information needs to be included on other important aspects of climate, e.g. extremes (see Box 21-4).

_____ END BOX 21-3 HERE _____

21.3.3.1. Global context

21.3.3.1.1. Observed changes

Temperature and precipitation

New estimates of global surface air temperatures give a warming of about 0.89 ºC (0.69 ºC – 1.08 ºC) for the period of 1901-2012 and about 0.72 ºC (0.49 ºC – 0.79 ºC) for the period 1951-2012 (WGI Chapter 2, Section 2.4.3). Positive annual temperature trends are found over most land areas, particularly since 1981. Over the period 1981-2012, relatively large trends have occurred over areas of Europe, the Sahara and middle East, central and northern Asia, north-eastern North America (WGI Chapter 2, Section 2.4.3).

For precipitation, the Northern Hemisphere mid to high latitudes show a *likely* increasing trend (*medium confidence* prior to 1950, *high confidence* afterwards) (WGI Chapter 2, Section 2.5.1). Observed precipitation trends show a high degree of spatial and temporal variability, with both positive and negative values (WGI Chapter 2, Section 2.5). The human influence on warming since the middle of the 20th century is *likely* over every continental region, except Antarctica (WGI Chapter 10, Section 10.3.1), while the attribution of changes in hydrological variables is *less confident* (WGI Chapter 10, Section 10.3.2).

Cryosphere

New data have become available since the AR4 to evaluate changes in the cryosphere (WGI Chapter 4, Section 4.1) showing that the retreat of annual Arctic sea ice extent has continued, at a *very likely* rate of 3.5-4.1% *per* decade during the period 1979-2012. The perennial sea ice extent (sea ice area at summer minimum) decreased at a rate of 11.5 ± 2.1% *per* decade (*very likely*) over the same period 1979-2012 (WGI Chapter 4, Section 4.2.2). The thickness, concentration and volume of arctic ice have also decreased. Conversely, the total annual extent of Antarctic ice has increased slightly (*very likely* 1.2-1.8% *per* decade between 1979 and 2011), with strong regional differences (WGI Chapter 4, Section 4.2.3).

Almost all glaciers worldwide have continued to shrink since the AR4, with varying rates across regions (WG1 Chapter 4, Sections 4.3.1, 4.3.3). In particular, during the last decade most ice loss has been observed from glaciers in Alaska, the Canadian Arctic, the Southern Andes, the Asian mountains and the periphery of the Greenland Ice Sheet. Several hundred glaciers globally have completely disappeared in the last 30 years (WG1 Chapter 4, 4.3.3).

Because of better techniques and more data, confidence has increased in the measurements of Greenland and Antarctica ice sheets. These indicate that parts of the Antarctic and Greenland ice sheets have been losing mass over the last two decades (*high confidence)*, mostly due to changes in ice flow in Antarctica, and a mix of changes in ice flow and increases in snow/ice melt in Greenland. Ice shelves in the Antarctic Peninsula are continuing a long-term trend of thinning and partial collapse started some decades ago (WGI Chapter 4, Sections 4.4.2, 4.4.3, 4.4.5).

21.3.3.1.2. Near-term and long-term climate projections

The uncertainty in near term CMIP5 projections is dominated by internal variability of the climate system (see Glossary entry on Climate Variability), initial ocean conditions and inter-model response, particularly at smaller spatial and temporal scales (Hawkins and Sutton 2009, 2011). In the medium and long term, emission profiles may affect the climate response. Global warming of 0.3-0.7ºC is *likely* for the period of 2016-2035 compared to 1986-2005 based on the CMIP5 multi model ensemble, and spatial patterns of near term warming are generally consistent with the AR4 (WGI Chapter 11, Section 11.3.6). For precipitation (2016-2035 vs. 1986-2005), zonal mean precipitation will *very likely* increase in high and some of the mid-latitudes, and will *more likely than not* decrease in the subtropics (WGI Chapter 11, Section 11.3.2). Results from multi-decadal near term prediction experiments (up to 2035) with initialized ocean state show that there is some evidence of predictability of yearly to decadal temperature averages both globally and for some geographical regions (WGI Chapter 11, Section 11.2.3).

Moving to long term projections (up to 2100), analyses of the CMIP5 ensemble have shown that, in general, the mean temperature and precipitation regional change patterns are similar to those found for CMIP3, with a pattern correlation between CMIP5 and CMIP3 ensemble mean late 21st century change greater than 0.9 for temperature and greater than 0.8 for precipitation (WGI Chapter 12, Section 12.4). Given the increased comprehensiveness and higher resolution of the CMIP5 models this adds an element of robustness to the projected regional change patterns.

Some of the main characteristics of the projected late 21st century regional temperature and precipitation changes derived from the CMIP5 ensemble can be broadly summarized as follows (from WGI Chapter 12 and the WGI Atlas) with further details provided in Box 21-2 and accompanying supplementary material.

Temperature

Regions that exhibit relatively high projected temperature changes (often greater than the global mean by 50% or more) are high latitude Northern Hemisphere land areas and the Arctic, especially in December-January-February, and Central North America, portions of the Amazon, the Mediterranean, and Central Asia in June-July-August (Figure 21-4).

[INSERT FIGURE 21-4 HERE
Figure 21-4: CMIP5 ensemble median ratio of local:global average temperature change in the period 2071-2100 relative to 1961-90 under the RCP8.5 emissions/concentrations scenario. The values are displayed on a common 2.5ºx3.75º grid onto which each models' data were regridded and they were calculated as follows: 1) for each model the local change was calculated between 1961 and 1990 at each grid cell, and is divided by the global average change in that model projection over the same period; 2) the median ratio value across all models at each grid cell is identified and shown. Data used are from the 35 CMIP5 models for which monthly projections were available under RCP8.5 which are listed in supplementary Table 21-3. Overplotted polygons indicate the SREX regions (IPCC, 2012) used to define the sub-regions used to summarise information in Chapters 21 and some of the subsequent regional chapters.]

Precipitation

Changes in precipitation are regionally highly variable, with different areas projected to experience positive or negative changes (Box 21-2). By the end of the century in the RCP8.5 scenario, the high latitudes will *very likely* experience greater amounts of precipitation, some mid-latitude arid and semi-arid regions will *likely* experience drying, while some moist mid-latitude regions will *likely* experience increased precipitation (WG1 Chapter 12, Section 12.4.5).

Studies have also attempted to obtain regional information based on pattern scaling techniques in which regional temperature and precipitation changes are derived as a function of global temperature change (e.g. Giorgi 2008; Watterson 2008; Watterson and Whetton 2011; Watterson 2011 Ishizaki et al. 2012, 2013a, 2013b). Figure 21-5 from Harris et al. (2013) provides an example of Probability Density Functions (PDFs) of temperature and precipitation change over sub-continental scale regions obtained using a Bayesian method complemented by pattern scaling and performance-based model weighting.

[INSERT FIGURE 21-5 HERE
Figure 21-5: Evolution of the 5%, 17%, 33%, 50%, 66%, 83% and 95% percentiles of the distribution functions for annual surface air temperature changes (upper panel) and annual precipitation (lower panel) for the Giorgi-Francisco (2000) regions and the globe with the SRES A1B forcing scenario combining results from a perturbed physics ensemble and the CMIP3 ensemble. Twenty year means relative to the 1961-1990 baseline are plotted in decadal steps using a common y-axis scale. The 5%, 50% and 95% percentile values for the period 2080-2099 are displayed for each region. (From Harris et al. 2012).]

21.3.3.2. Dynamically and Statistically Downscaled Climate Projections

Dynamical and statistical downscaling techniques have been increasingly applied to produce regional climate change projections, often as part of multi-model intercomparison projects (Görgen et al, 2010). A large number of RCM-based climate projections for the European region were produced as part of the European projects PRUDENCE (Christensen et al. 2007; Deque et al. 2007) and ENSEMBLES (Hewitt 2005; Deque and Somot 2010). High resolution projections (grid interval of ~12 km) were also produced as part of Euro-CORDEX (Jacob et al 2013). All these studies provide a generally consistent picture of seasonally and latitudinally varying patterns of change, which Giorgi and Coppola (2007) summarized with the term “European Climate Change Oscillation (ECO)”. The ECO consists of a dipole pattern of precipitation change, with decreased precipitation to the south (Mediterranean) and increased to the north (Northern Europe) following a latitudinal/seasonal oscillation. As a result, the Mediterranean region is projected to be much drier and hotter than today in the warm seasons (Giorgi and Lionello 2008), and central/northern Europe much warmer and wetter in the cold seasons (Kjellstrom and Ruosteenoja, 2007). An increase of interannual variability of precipitation and summer temperature is also projected throughout Europe, with a decrease in winter temperature variability over Northern Europe (Schar et al. 2004; Giorgi and Coppola 2007; Lenderink et al. 2007). This leads to broader seasonal anomaly distributions and a higher frequency and intensity of extreme hot and dry summers (e.g. Schar et al. 2004; Seneviratne et al. 2006; Beniston et al. 2007; Coppola and Giorgi 2010), for which a substantial contribution is given by land-atmosphere feedbacks (Seneviratne et al. 2006; Fischer et al. 2007; Seneviratne et al. 2010; Hirschi et al. 2011; Jaeger and Seneviratne 2011). The broad patterns of change in regional model simulations generally follow those of the driving global models (Christensen and Christensen 2007; Deque et al. 2007; Zanis et al. 2009), however fine scale differences related to local topographical, land use and coastline features are produced (e.g. Gao et al. 2006; Coppola and Giorgi 2010; Tolika et al. 2012).

As part of the ENSEMBLES and AMMA projects, multiple RCMs were run for the period 1990-2050 (A1B scenario) over domains encompassing the West Africa region with lateral boundary conditions from different GCMs. The RCM-simulated West Africa monsoon showed a wide range of response in the projections, even when the models were driven by the same GCMs (Paeth et al. 2011) (Figure 21-6). Although at least some of the response patterns may be within the natural variability, this result suggests that for Africa, and probably more generally the tropical regions, local processes and how they are represented in models play a key factor in determining the precipitation change signal, leading to a relatively high uncertainty (Engelbrecht et al. 2009; Haensler et al. 2011; Mariotti et al. 2011; Diallo et al. 2012). Statistical downscaling techniques have also been applied to the Africa region (Hewitson and Crane 2006; Lumsden et al. 2009; Paeth and Diederich 2010; Goergen et al., 2010; Benestad 2011). In this regard, methodological developments since the AR4 have been limited (see, for example reviews in Brown et al. 2008; Paeth et al. 2011) and activities have focused more on the applications (e.g. Mukheibir 2007; Gerbaux et al. 2009) for regional specific activities in the context of IAV work.

[INSERT FIGURE 21-6 HERE
Figure 21-6: Linear changes (i.e. changes obtained by fitting the time series at each grid point with straight lines) of annual precipitation during the 2001-2050 period from 10 individual RCM experiments and the MME mean under the A1B emission scenario. The top middle panels also account for projected land cover changes (see Paeth et al. 2011 for further explanation). Note that the REMO trends in both panels arise from a three-member ensemble whereas all other RCMs are represented by one single simulation. Trends statistically significant at the 95% level are marked by black dots. From Paeth et al. (2011).]

Several RCM and time-slice high resolution GCM experiments have been conducted or analyzed for the South America continent (Nunez et al. 2009; Menendez et al. 2010; Sorensson et al. 2010; Marengo et al. 2009, 2010; Cabre et al. 2010; Kitoh et al. 2011). Overall, these studies revealed varied patterns of temperature and precipitation change, depending on the global and regional models used, however a consistent change found in many of these studies was an increase in both precipitation intensity and extremes, especially in areas where mean precipitation was projected to also increase. The Central American region has emerged as a prominent climate change hot-spot since the AR4, especially in terms of a consistent decrease of precipitation projected by most models, particularly in June-July (Rauscher et al 2008, 2011). Regional model studies focusing specifically on Central America projections are however still too sparse to provide robust conclusions (e.g. Campbell et al. 2010).

Since the AR4 there has been considerable attention to producing higher resolution climate change projections over North America based on RCMs and high resolution global time slices (e.g. Salathe et al. 2008, 2010; Dominguez et al. 2010; Subin et al. 2011), in particular as part of the North American Regional Climate Change Assessment Program (NARCCAP – Mearns et al. 2009; 2012; 2013). Results indicate variations (and thus uncertainty) in future climate based on the different RCMs, even when driven by the same GCM in certain subdomains (De Elia and Cote 2010; Mearns et al., 2013; Bukovsky et al. 2013). However, in the NARCCAP suite of simulations there were also some important commonalities in the climate changes produced by the RCMs. For example, they produced larger and more consistent decreases in precipitation throughout the Great Plains in summer than did the driving GCMs or the full suite of CMIP3 GCM simulations as well as larger increases in precipitation in the northern part of the domain in winter. In the realm of statistical downscaling and spatial disaggregation, considerable efforts have been devoted to applying different statistical models for the entire US and parts of Canada (e.g., Maurer et al. 2007; Hayhoe et al. 2010; Schoof et al., 2010).

Numerous high resolution RCM projections have been carried out over the East Asia continent. While some of these find increases in monsoon precipitation over South Asia in agreement with the driving GCMs (Kumar et al. 2013) others also produce results that are not in line with those from GCMs. For example, both Ashfaq et al. (2009) and Gao et al. (2011) found in high resolution RCM experiments (20 and 25 km grid spacing, respectively) decreases in monsoon precipitation over areas of India and China in which the driving GCMs projected an increase in monsoon rain. Other high resolution (20 km grid spacing) projections include a series of double nested RCM scenario runs for the Korea peninsula (Im et al. 2007a; 2008a,b; 2010; 2011; Im and Ahn, 2011) indicating a complex fine scale structure of the climate change signal in response to local topographical forcing. Finally, very high resolution simulations were also performed. Using a 5-km mesh non-hydrostatic RCM nested within a 20-km mesh AGCM, Kitoh et al. (2009) and Kanada et al. (2012) projected a significant increase in intense daily precipitation around western Japan during the late Baiu season.

Finally, a range of RCM, variable resolution and statistical downscaling 21st century projections have been conducted over the Australian continent or some of its sub-regions (Nunez and Mc Gregor 2007; Watterson et al.

2008; Song et al. 2008, Timbal et al. 2008; Yin et al. 2010, Grose et al 2012a,b; Bennett et al 2012), showing that a local fine scale modulation of the large scale climate signal occurs in response to topographical and coastal forcings.

21.3.3.3. Projected Changes in Hydroclimatic Regimes, Major Modes of Variability, and Regional Circulations

By modifying the Earth's energy and water budgets, climate change may possibly lead to significant changes in hydroclimatic regimes and major modes of climate variability (Trenberth et al. 2003). For example, Giorgi et al. (2011) defined an index of hydroclimatic intensity (HY-INT) incorporating a combined measure of precipitation intensity and mean dry spell length. Based on an analysis of observations, global and regional climate model simulations, they found that a ubiquitous global and regional increase in HY-INT was a strong hydroclimatic signature in model projections consistent with observations for the late decades of the 20th century. This suggests that global warming may lead to a hydroclimatic regime shift towards more intense and less frequent precipitation events, which would increase the risk of both flood and drought associated with global warming.

ENSO is a regional mode of variability that substantially affects human and natural systems (Mc Phaden et al. 2006). Although model projections indicate that ENSO remains a major mode of tropical variability in the future, there is little evidence to indicate changes forced by GHG warming which are outside the natural modulation of ENSO occurrences (WGI Chapter 14, Sections 14.4, 14.8).

The North Atlantic Oscillation (NAO) is a major mode of variability for the northern Hemisphere mid-latitude climate. Model projections indicate that the NAO phase is *likely* to become slightly more positive (WGI Chapter 14 ES) due to GHG forcing, but the NAO will be dominated by its large natural fluctuations. Model projections indicate that the Southern Annular Mode (SAM), a major mode of variability for the southern hemisphere, is *likely* going to weaken as ozone concentrations recover through the mid-21st century (WGI Chapter 14, Sections 14.5, 14.8).

Regional circulations, such as the monsoon, are expected to change. The global monsoon precipitation, aggregated over all monsoon systems, is *likely* to strengthen in the 21st century with increases in its area and intensity, while the monsoon circulation weakens. Different regional monsoon systems, however, exhibit different responses to GHG forcing in the 21st century (WGI Chapter 14, Section 14.2.1).

21.3.3.4. Projected Changes in Extreme Climate Events

CMIP5 projections confirm results from the CMIP3; a decrease in the frequency of cold days and nights, an increase in the frequency of warm days and nights, an increase in the duration of heat waves and an increase in the frequency and intensity of high precipitation events, both in the near term and far future (IPCC (2012), 3.3.2, 3.4.4; WGI Chapter 12, 12.4.5). Increases in intensity of precipitation (and thus risk of flood) and summer drought occurrence over some mid-continental land areas is a robust signature of global warming, both in observations for recent decades and in model projections (Trenberth 2011; WG1 Chapter 12, 12.4.5). For tropical cyclones there is still little confidence in past trends and near term projections (Seneviratne et al 2012). Globally, tropical cyclone frequency is projected to either not change or decrease and, overall, wind speed and precipitation is *likely* to increase though basin scale specific conclusions are still unclear (Knutson et al. 2010). A summary of observed and projections extremes along with some statistics on CMIP5 projections of changes in daily temperature and precipitation extremes over the main continents and the SREX regions (Figure 21-4) are introduced in Box 21-4 and accompanying supplementary material.

_____ START BOX 21-4 HERE _____

Box 21-4. Synthesis of Projected Changes in Extremes Related to Temperature and Precipitation

The IPCC report, "Managing the risks of extreme events and disasters to advance climate change adaptation" (IPCC 2012), or SREX for short, provides an in depth assessment of observed and projected changes in climate extremes.

Due to the relevance of this material for assessing risks associated with climate change vulnerability and impacts and responses to these risks, summary information is presented here both drawing from and building on the material in the SREX report, including additional analyses of CMIP5 data (only CMIP3 data were used in SREX).

Summaries of SREX findings relevant to three continents Latin America (Cameron et al., 2012), Asia and Africa (available from http://cdkn.org/srex/) have been developed using material from SREX Chapter 3. A synthesis of this material for all SREX regions, along with additional material from WG1 AR5, is presented in Table 21-7. This demonstrates that in many areas of the world there is higher confidence in future changes in extreme events than there is in past trends, often due to a lack of evidence on observed changes.

[INSERT TABLE 21-7 HERE
Table 21-7: An assessment of observed and projected future changes in temperature and precipitation extremes over 26 sub-continental regions as defined in the SREX report (IPCC 2012; see also Figure 21-4 and Table SM21.2). Confidence levels are indicated by colour coding of the symbols. Likelihood terms are given only for high confidence statements and are specified in the text. Observed trends in temperature and precipitation extremes, including dryness, are generally calculated from 1950, using the period 1961-1990 as a baseline (see Box 3-1 of IPCC (2012a)). The future changes are derived from global and regional climate model projections of the climate of 2071-2100 compared with 1961-1990 or 2080-2100 compared with 1980-2000. Table entries are summaries of information in Tables 3-2 and 3-3 of IPCC (2012a) supplemented with or superseded by material from Chapters 2 (section 2.6 and Table 2-13) and 14 (section 14.4) of the IPCC AR5 WG1 report and Table 25-1 of the IPCC WG2 report. The source(s) of information for each entry are indicated by the superscripts a (Table 3-2 of IPCC, 2012a), b (Table 3-3 of IPCC, 2012a), c (Chapter 2 (section 2.6 and Table 2-13) IPCC AR5 WG1 report), d (Chapter 14 (section 14.4) of the IPCC AR5 WG1 report) and e (Table 25-1 of the IPCC WG2 report).]

In the SREX report, the only coordinated global multi-model ensemble information available was from the CMIP3. In order to provide information consistent with the projections assessed elsewhere in WG1 and 2, changes in daily temperature and precipitation projected by the CMIP5 models are presented here for two example indices, the 90th percentiles of the daily maximum temperature and daily precipitation amounts on wet days. Changes in these indices were calculated over 30 year periods (1961-1990 for the baseline and two future periods, 2041-2070 and 2071-2100) and the analysis was focused on the less extreme daily events to reduce problems with the number needed to be sampled to generate robust statistics (Kendon et. al, 2008). Projected changes were calculated for RCPs 4.5 and 8.5 and the results are displayed as a map for a given continental region and also regional averages over the SREX regions within that continent. Two examples are provided, for temperature changes over N America (Figure 21-7) and precipitation changes over Asia (Figure 21-8). A full set can be found in supplementary Figures SM21-8 to SM21-19.

[INSERT FIGURE 21-7 HERE
Figure 21-7: The frequency of 'warm days' (defined here as the 90th percentile daily maximum temperature during a baseline period of 1961-1990) projected for the 2071-2100 period by 26 CMIP5 GCMs for North America. Map: Ensemble median frequency of 'warm days' during 2071-2100 under RCP8.5. Graphs: Box-and-whisker plots indicate the range of regionally-averaged 'hot-day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5 across the 26 CMIP5 models for each SREX sub-regions in North America. Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of ‘warm days’ of 10% is represented on the graphs by the dashed line. A full list of CMIP5 models for which data is shown here can be found in supplementary material Table SM21-4.]

[INSERT FIGURE 21-8 HERE
Figure 21-8: The frequency of 'very wet days' (defined here as the 90th percentile of daily precipitation on wet days during a baseline period of 1961-1990 with wet days defined as days with 1mm of precipitation or more) projected for the 2071-2100 period by 26 CMIP5 GCMs for Asia. Map: Ensemble median frequency of 'very wet days' during 2071-2100 under RCP8.5. Graphs: Box-and-whisker plots indicate the range of regionally-averaged 'very wet day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5 across the 26 CMIP5 models for each SREX sub-regions in Asia Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of ‘Very wet days’ of 10% is represented on the graphs by the dashed line. A full

list of CMIP5 models for which data is shown here can be found in supplementary material Table SM21-4. (Note the WMO Expert Team on Climate Change Detection Indices defines “very wet days” threshold as the 95%-ile daily precipitation event.]

_____ END BOX 21-4 HERE _____

21.3.3.5. Projected Changes in Sea Level

Projections of regional sea level changes, both based on the CMIP3 and CMIP5 models, indicate a large regional variability of sea level rise (even more than 100% of the global mean sea level rise) in response to different regional processes (WGI Chapter 13, Section 13.6.5). However, by the end of the 21st century it is *very likely* that over about 95% of the oceans will undergo sea level rise, with about 70% of coastlines experiencing a sea level rise within 20% of the global value and most regions experiencing sea level fall being located near current and former glaciers and ice sheets (WGI Chapter 13, Section 13.6.5). Some preliminary analysis of the CMIP5 ensembles indicates areas of maximum steric sea level rise in the Northern Atlantic, the northwestern Pacific off the East Asia coasts, the eastern coastal oceanic regions of the Bay of Bengal and the western coastal regions of the Arabian Sea (WGI Chapter 13, Section 13.6.5).

21.3.3.6. Projected Changes in Air Quality

Since the AR4 more studies have become available addressing the issue of the effects of both climate and emission changes on air quality. Most of these studies focused on the continental United States and Europe, and utilized both global and regional climate and air quality models run in off-line or coupled mode. Regional modeling studies over the United States or some of its sub-regions include, for example, those of Hogrefe et al. (2004), Knowlton et al. (2004), Steiner et al. (2006), Dawson et al. (2006), Lin et al. (2008), Zhang et al. (2008), Weaver et al. (2009), while examples of global modeling studies include Murazaki and Hess (2006), Stevenson et al. (2006), Shindell et al. (2006), Doherty et al. (2006). Weaver et al. (2009) provide a synthesis of simulated effects of climate change on ozone concentrations in the U.S. using an ensemble of regional and global climate and air quality models, indicating a predominant increase in near-surface ozone concentrations, particularly in the Eastern U.S. (Figure 21-9) mostly tied to higher temperatures and corresponding biogenic emissions. An even greater increase was found in the frequency and intensity of extreme ozone concentration events, which are the most dangerous for human health. Examples of regional studies of air quality changes in response to climate change over Europe include Langner et al. (2005), Forkel and Knocke (2006) , Szopa and Hauglustaine (2007), and Meleux et al. (2007), Kruger et al (2008), Engardt et al. (2009), Carvalho et al. (2010), Andersson and Engardt (2010), Athanassiadou et al. (2010), Katragkou et al. (2010, 2011), Zanis et al. (2011), Huszar et al. (2011), Juda-Rezler et al. (2012). All these studies indicated the potential of large increases in near surface summer ozone concentrations especially in Central and Southern Europe due to much warmer and drier projected summer seasons.

[INSERT FIGURE 21-9 HERE
Figure 21-9 Mean (top panels) and standard deviation (bottom panels) in future-minus-present (2050s minus 1990s) MDA8 summer ozone concentrations across (left-hand panels) all seven experiments (five regional and 2 global) and for comparison purposes (right hand panels), not including the WSU experiment (which simulated July only conditions). The different experiments use different pollutant emission and SRES GHG emission scenarios. The pollutant emissions are the same in the present and future simulations (from Weaver et al., 2009).]

21.4. Cross-Regional Phenomena

Thus far, this chapter has covered climate change-related issues that have a regional expression in one part of the world or another. In principle, these issues can be studied and described, *in situ*, in the regions in which they occur. However, there is a separate class of issues that transcends regional boundaries and demands a different treatment. In order to understand such cross-regional phenomena, knowledge is required of critical but geographically remote associations and of dynamic cross-boundary flows. The following sections consider some examples of these phenomena, focusing on trade and financial flows and migration. Though these issues are treated in more detail in Part A of this report, they are restated here in Part B to stress the importance of a global perspective in appreciating climate change challenges and potential solutions at the regional scale.

21.4.1. Trade and Financial Flows

Global trade and international financial transactions are the motors of modern global economic activity. Their role as key instruments for implementing mitigation and adaptation policies is explored in detail in chapters 14-17 and in the Working Group III report – Stavins et al., 2014; Gupta et al., 2014). They are also inextricably linked to climate change (WTO-UNEP, 2009) through a number of other interrelated pathways that are expanded here: (i) as a direct or indirect cause of anthropogenic emissions (e.g., Peters et al., 2011), (ii) as contributory factors for regional vulnerability to the impacts of climate change (e.g. Leichenko and O'Brien, 2008), and (iii) through their sensitivity to climate trends and extreme climate events (e.g., Nelson et al., 2009a; Headey, 2011).

21.4.1.1. International Trade and Emissions

The contemporary world is highly dependent on trading relationships between countries in the import and export of raw materials, food and fibre commodities and manufactured goods. Bulk transport of these products, whether by air, sea or over land, is now a significant contributor to emissions of greenhouse gases and aerosols (Stavins et al., 2014). Furthermore, the relocation of manufacturing has transferred net emissions via international trade from developed to developing countries (see Figure 21-10), and most developed countries have increased their consumption-based emissions faster than their domestic (territorial) emissions (Peters *et al.*, 2011). This regional transfer of emissions is commonly referred to in climate policy negotiations as "carbon leakage" (Barker *et al.*, 2007), though only a very small portion of this can be attributed to climate policy ("strong carbon leakage"), a substantial majority being due to the effect of non-climate policies on international trade ("weak carbon leakage" – Peters, 2010). A particular example of strong carbon leakage concerns the conversion of land use from the production of food to bioenergy crops. These crops sequester carbon otherwise extracted from the ground as fossil fuels, but in the process displace demand for food production to land in other regions, often inducing land clearance and hence an increase in emissions (Searchinger *et al.*, 2008), though the empirical basis for this latter assertion is disputed (see Kline and Dale, 2008).

[INSERT FIGURE 21-10 HERE
Figure 21-10: Growth rates from 1990-2008 of international trade, its embodied CO_2 emissions and net emissions transfers from Annex B and non-Annex B countries compared to other global macrovariables, all indexed to 1990 (Peters et al., 2011). Annex B and non-Annex B Parties to the UNFCCC are listed in the supplementary material.]

21.4.1.2. Trade and Financial Flows as Factors Influencing Vulnerability

The increasingly international nature of trade and financial flows (commonly referred to as globalisation), while offering potential benefits for economic development and competitiveness in developing countries, also presents high exposure to climate-related risks for some of the populations already most vulnerable to climate change (Leichenko and O'Brien, 2008). Examples of these risks, explored further in Chapters 7-9, 12, 13 and 19 of Part A, include:

- Severe impacts of food price spikes in many developing countries (including food riots and increased incidence of child malnutrition) such as occurred in 2008 following shortfalls in staple cereals, due to a coincidence of regional weather extremes (e.g. drought) in producer countries, the reallocation of food crops by some major exporters for use as biofuels (an outcome of climate policy – see previous section) and market speculation (Ziervogel and Ericksen, 2010). Prices subsequently fell back as the world economy went into recession, but spiked again in early 2011 for many of the same reasons (Trostle *et al.*,

2011), with some commentators predicting a period of rising and volatile prices due to increasing demand and competition from biofuels (Godfray *et al.*, 2010).
- A growing dependence of the rural poor on supplementary income from seasonal urban employment by family members and/or on international financial remittances from migrant workers (Davies *et al.*, 2009). These workers are commonly the first to lose their jobs in times of economic recession, which automatically decreases the resilience of recipient communities in the event of adverse climate conditions.On the other hand, schemes to provide more effective communication with the diaspora in times of severe weather and other extreme events can provide rapid access to resources to aid recovery and reduce vulnerability (Downing, 2012).
- Some aspects of international disaster relief, especially the provision of emergency food aid over protracted periods, has been cited as an impediment to enhancing adaptive capacity to cope with climate-related hazards in many developing countries (Schipper and Pelling, 2006). Here, international intervention, while well-intentioned to relieve short-term stress, may actually be counter-productive in regard to the building of long-term resilience.

21.4.1.3. Sensitivity of International Trade to Climate

Climate trends and extreme climate events can have significant implications for regional resource exploitation and international trade flows. The clearest example of an anticipated, potentially major impact of climate change concerns the opening of Arctic shipping routes as well as exploitation of mineral resources in the exclusive economic zones (EEZs) of Canada, Greenland/Denmark, Norway, Russia and the USA (Figure 21-11, and see chapter 28, section 28.3.4). For instance, the CCSM4 climate and sea ice model has been used to provide projections under RCP4.5, RCP6.0 and RCP8.5 forcing (see Box 21-1) of future accessibility for shipping to the sea ice hazard zone of the Arctic marine environment defined by the International Maritime Organization (Stephenson et al., 2013 – Figure 21-11 (central map). Results suggest that moderately ice-strengthened ships (Polar Class 6), which are estimated under baseline (1980-1999) conditions to be able to access annually about 36 % of the IMO zone, would increase this access to 45-48 % by 2011-2030, 58-69% by 2046-2065 and 68-93% by 2080-2099, with almost complete accessibility projected for summer (90-98% in July-October) by the end of the century (Stephenson *et al.*, 2013). The robustness of those findings was confirmed using seven sea ice models in an analysis of optimal sea routes in peak season (September) for 2050-2069 under RCP 4.5 and RCP8.5 forcing (Smith and Stephenson, 2013). All studies imply increased access to the three major cross Arctic routes: the Northwest Passage, Northern Sea Route (which is part of the Northeast Passage), and Trans-Polar Route (Figure 21-11), which could represent significant distance savings for trans-continental shipping currently using routes via the Panama and Suez Canals (Stephenson *et al.*, 2011). Indeed, in 2009 two ice-hardened cargo vessels – the Beluga Fraternity and Beluga Foresight – became the first to successfully traverse the Northeast Passage from South Korea to the Netherlands, a reduction of 5,500 km and 10 days compared to their traditional 20,000 km route via the Suez Canal, translating into an estimated saving of some $300,000 per ship, including the cost of standby icebreaker assistance (Smith, 2009; Det Norsk Veritas, 2010). A projection using an earlier version of the CCSM sea ice model under the SRES A1B scenario, but offering similar results (with forcing by mid-century lying just below RCP8.5 – chapter 1, Figure 1-5a), is presented in Figure 21-11 (peripheral maps), which also portrays winter transportation routes on frozen ground. These routes are heavily relied upon for supplying remote communities and for activities such as forestry and, in contrast to the shipping routes, are projected to decline in many regions.

[INSERT FIGURE 21-11 HERE
Figure 21-11: Central map: Marine exclusive environmental zones (EEZs – dashed lines) of Canada, Greenland/Denmark, Norway, Russia, and the USA, and location of the Northwest Passage, Northern Sea Route, Trans-Polar Route, and international high seas within the IMO Guidelines Boundary for Arctic shipping (thick black border). After Stephenson et al. (2013). Peripheral monthly maps: Projected change in accessibility of maritime and land-based transportation by mid-century (2045-2059 relative to 2000-2014) using the Arctic Transport Accessibility Model and CCSM3 climate and sea ice estimates assuming an SRES A1B scenario. Dark blue areas denote new maritime access to Polar Class 6 vessels (light icebreaker); white areas remain inaccessible. Red delimits areas of lost winter road potential for ground vehicles exceeding 2 metric tonnes (Stephenson et al., 2011).]

A second illustration of how the risk of adverse climate changes may have contributed to anticipatory adaptive actions affecting countries in other regions of the world and potentially influencing commodity markets, relates to the purchase or renting of large tracts of productive land in parts of Africa, Latin America, Central Asia and Southeast Asia by countries in Europe, Africa, the Gulf and South and East Asia (De Schutter, 2009; Cotula *et al.*, 2011; Zoomers, 2011). While there is clearly a profit motive in many of these purchases (i.e., cheap and fertile land and the opportunity to cultivate high value food or biofuel crops), there is also a concern that domestic agricultural production in some countries will be unable to keep pace with rapid growth in domestic demand and changing dietary preferences, especially in agricultural regions affected by frequent shortfalls due to droughts, floods and cyclones (Cotula *et al.*, 2011), or threatened by sea-level rise (Zoomers, 2011). Land acquisition on such a large scale raises a number of ethical issues relating to local access to food and the appropriate and sustainable management of the land (Deininger and Byerlee, 2012). These issues have led the UN Special Rapporteur on the right to food to recommend a list of eleven principles for ensuring informed participation of local communities, adequate benefit sharing and the respect of human rights (De Schutter, 2009). This issue is elaborated with respect to livelihoods and poverty in chapter 13, section 13.4.3.4, and land dispossession is categorised a key risk in chapter 19, section 19.6.2.

Extreme climate phenomena that may be harbingers of similar and more frequent events in a warmer world, already exact devastating consequences in some regions that extend well beyond country boundaries. A recent event that disrupted international trade and commodity flows was the severe 2010/2011 flooding in eastern Australia (Giles, 2011; Queensland Floods Commission of Inquiry, 2012; and see chapter 25, Box 25-8), which combined with damaging cyclones in Queensland and Western Australia curtailed numerous mining operations and damaged transportation networks, leading to declines in both thermal and metallurgical coal exports (by 31% and 19%, respectively, relative to the previous quarter – ABARES, 2011) with a sharp rise in their monthly price between November 2010 and January 2011 (Index Mundi, 2012). The severe weather was the primary factor contributing to a fall in Australian GDP of 1.2% during January-March 2011 compared with a rise of 0.7% in the preceding three-month period (Australian Bureau of Statistics, 2011). Other examples of how extreme climate events can affect international trade are reported by Oh and Reuveny (2010) and Handmer et al. (2012).

21.4.2. Human Migration

There has been considerable debate in recent years around the postulate that anthropogenic climate change and environmental degradation could lead to mass migration (Perch-Nielsen *et al.*, 2008; Feng *et al.*, 2010; Warner, 2010; Black *et al.*, 2011; Government Office for Science, 2011; Assan and Rosenfeld, 2012). The issue is treated at length in Chapters 9, 12 and 19 of Part A, so only a few aspects are touched on here, to highlight the growing significance of migration in all regions of the world. Four possible pathways through which climate change could affect migration are suggested by Martin (2009):

1) Intensification of natural disasters
2) Increased warming and drought that affects agricultural production and access to clean water
3) Sea-level rise, which makes coastal areas and some island states increasingly uninhabitable
4) Competition over natural resources, leading to conflict and displacement of inhabitants.

Abundant historical evidence exists to suggest that changes in climatic conditions have been a contributory factor in migration, including large population displacements in the wake of severe events such as Hurricane Katrina in New Orleans, Louisiana in 2005 (Cutter *et al.*, 2012), Hurricane Mitch in Central America in 1998 and the northern Ethiopian famines of the 1980s (McLeman and Smit, 2006). Other examples are provided in Chapter 12, Table 12-3. However, the evidence is not clear cut (Black, 2001), with counter examples also available of migration being limited due to economic hardship (e.g. during the Sahel drought of the mid-1980s in Mali – Findley, 1994).

The spatial dimension of climate-related migration is most commonly internal to nations (e.g. from affected regions to safer zones – Naik, 2009). In this context it is also worth pointing out that internal migration for other (predominantly economic) reasons may actually expose populations to increased climate risk. For instance, there are large cities in developing countries in low elevation coastal zones that are vulnerable to sea-level rise. Increased migration to these cities could exacerbate the problems with the migrants themselves being especially vulnerable (Nordås and Gleditsch, 2007; UNFPA, 2007).

Migration can also be international, though this is less common in response to extreme weather events, and where it does happen it usually occurs along well established routes. For example, emigration following Hurricane Mitch tripled from Honduras and increased from Nicaragua by 40%, mainly to the southern States of the US (already a traditional destination for migrants), and was aided by a relaxation of temporary residency requirements by the United States (Naik, 2009).

The causal chains and links between climate change and migration are complex and can be difficult to demonstrate (e.g., Perch-Nielsen et al., 2008; Piguet, 2010; Tänzler et al., 2010; ADB, 2012; Oliver-Smith, 2012; Chapter 12, section 12.4; Chapter 9, section 9.3.3.3.1; Chapter 19, section 19.4.2.1), though useful insights can be gained from studying past abandonment of settlements (McLeman, 2011). Thus projecting future climate-related migration remains a challenging research topic (Feng et al., 2010). There are also psychological, symbolic, cultural and emotional aspects to place attachment, which are well documented from other non-climate causes of forced migration, and are also applicable to cases of managed coastal retreat due to sea-level rise (e.g., Agyeman *et al.*, 2009).

Forced migration appears to be an emerging issue requiring more scrutiny by governments in organising development co-operation, and to be factored into international policy making as well as international refugee policies. For example, it has been suggested that the National Adaptation Plans of Action (NAPAs) under the UNFCCC, by ignoring transboundary issues (such as water scarcity), and propounding nationally-orientated adaptation actions (e.g. upstream river management, to the detriment of downstream users in neighbouring countries), could potentially be a trigger for conflict, with its inevitable human consequences. Currently there is no category in the United Nations High Commission for Refugees classification system for environmental refugees, but it is possible that this group of refugees will increase in the future and their needs and rights will need to be taken into consideration (Brown, 2008). The Nansen Initiative, put forward jointly by Norway and Switzerland at a 2011 ministerial meeting, pledges "to cooperate with interested states and relevant actors, including UNHCR, to obtain a better understanding of cross-border movements provoked by new factors such as climate change, identify best practices and develop a consensus on how best to protect and assist those affected ", and may eventually result in a soft law or policy framework (Kolmannskog, 2012). However, migration should not always be regarded as a problem; in those circumstances where it contributes to adaptation (e.g. through remittances) it can be part of the solution (Laczko and Aghazarm, 2009).

21.4.3. Migration of Natural Ecosystems

One of the more obvious consequences of climate change is the displacement of biogeographical zones and the natural migration of species (see Chapters 4, 6 and 19). General warming of the climate can be expected to result in migration of ecosystems towards higher latitudes and upward into higher elevations (Chapter 4, section 4.3.2.5) or downward to cooler depths in marine environments (Chapter 6, section 6.3.2.1). Species shifts are already occurring in response to recent climate changes in many parts of the world (Rosenzweig et al., 2008), with average poleward shifts in species' range boundaries of 6 km per decade being reported (Parmesan et al., 2011).

Study of the estimated shifts of climatic zones alone can provide insights into the types of climatic regimes to anticipate under projected future anthropogenic climate change. By grouping different combinations and levels of climatic variables it is possible not only to track the shifts in the zones in which they occur, but also to identify newly emerging combinations of conditions not found at the present day as well as combinations that may not survive global climate change (known respectively as novel and disappearing climates – Williams *et al.*, 2007; and see Chapter 19, section 19.5.1). These analyses can help define what types of climatic niches may be available in the future and where they will be located. Such a spatial analogue approach can delimit those regions that might currently or potentially (in the future) be susceptible to invasion by undesirable aquatic (e.g., EPA, 2008) or terrestrial (e.g., Mainka and Howard, 2010) alien species or alternatively might be candidates for targetting translocation (assisted colonisation) of species endangered in their native habitats (e.g., Brooker et al., 2011;

Thomas, 2011). However, there are many questions about the viability of such actions, including genetic implications (e.g., Weeks et al., 2011), inadvertent transport of pests or pathogens with the introduced stock (e.g., Brooker et al., 2011) and risk of invasiveness (e.g., Mueller and Hellmann, 2008).

The ability of species to migrate with climate change must next be judged, in the first instance, against the rate at which the climatic zones shift over space (e.g. Loarie et al., 2009; Burrows et al., 2011; Diffenbaugh and Field, 2013; Chapter 4, section 4.3.2.5). For projecting potential future species shifts, this is the most straightforward part of the calculation. In contrast, the ecological capacity of species to migrate is a highly complex function of factors, including their ability to:

- Reproduce, propagate or disperse
- Compete for resources
- Adapt to different soils, terrain, water quality and daylength
- Overcome physical barriers (e.g. mountains, water/land obstacles)
- Contend with obstacles imposed by human activity (e.g. land use, pollution or dams).

Conservation policy under a changing climate is largely a matter of promoting the natural adaptation of ecosystems, if this is even feasible for many species given the rapidity of projected climate change. Studies stress the risks of potential mismatching in responses of co-dependent species to climate change (e.g., Schweiger *et al.*, 2012) as well as the importance of maintaining species diversity as insurance for the provision of basic ecosystem services (e.g., Traill et al., 2010; Isbell et al., 2011). Four priorities have been identified for conservation stakeholders to apply to climate change planning and adaptation (Heller and Zavaleta, 2009): (i) regional institutional coordination for reserve planning and management and to improve landscape connectivity; (ii) a broadening of spatial and temporal perspectives in management activities and practice, and actions to enhance system resilience; (iii) mainstreaming of climate change into all conservation planning and actions; and (iv) holistic treatment of multiple threats and global change drivers, also accounting for human communities and cultures. The regional aspects of conservation planning transcend political boundaries, again arguing for a regional (rather than exclusively national) approach to adaptation policy. This issue is elaborated in Chapters 4 (section 4.4.2) and 19 (section 19.4.2.3).

21.5. Analysis and Reliability of Approaches to Regional Impacts, Adaptation, and Vulnerability Studies

Assessing climate vulnerability or options for adapting to climate impacts in human and natural systems requires an understanding of all factors influencing the system and how change may be effected within the system or applied to one or more of the external influencing factors. This will require, in general, a wide range of climate and non-climate information and methods to apply this to enhance the adaptive capacity of the system. There are both areas of commonality across and differences between regions in the information and methods and these are explored in this section. It initially focuses on advances in methods to study vulnerability and adaptive capacity and to assess impacts (studies of practical adaptation and the processes of adaptation decision-making are treated in detail in Chapters 14-17 and so not addressed here). This is followed by assessments of new information on, and thinking related to: (a) baseline and recent trends in factors needed to assess vulnerability and define impacts baselines; and (b) future scenarios used to assess impacts, changes in vulnerability and adaptive capacity; and then assessment of the credibility of the various types of information presented.

21.5.1. Analyses of Vulnerability and Adaptive Capacity

Multiple approaches exist for assessing vulnerability and for exploring adaptive capacity (Schipper et al 2010, UNFCCC 2008). The choice of method is influenced by objectives and starting point (see Table 21-3) as well as the type of information available. Qualitative assessments usually draw on different methods and inputs from quantitative assessments. Qualitative information cannot always be translated to quantitative information, or *vice versa*, yet both approaches can sometimes be used to answer the same questions. Indicators, indices and mapping are the most common ways to aggregate the resulting vulnerability and adaptive capacity information to compare across regions (section 21.5.1.1) or to identify "hotspots" (section 21.5.1.2). .

21.5.1.1. Indicators and Indices

Several attempts have been made to develop vulnerability indicators and indices (Birkmann 2011; Chen et al. 2011; Barr et al 2010; Cardona, 2007; Luers et al 2003; Lawrence *et al.*, 2003, Villa and McLeod, 2002, Downing *et al.* 2001, Atkins *et al.*, 2000; Moss *et al.* 2001). Representation on a map or through an index is a common way to depict global vulnerability information and requires quantification of selected variables in order to measure them against a selected baseline, even though quantification of some qualitative information may not be possible (Hinkel, 2011; Edwards et al, 2007; Luers et al 2003). Vulnerability is differentiated according to factors such as gender, age, livelihood or access to social networks, among many other factors (Cardona et al 2012; Wisner et al 2005), which may not be represented accurately through some indicators. One approach used to create regional comparisons is to use indices, which are composites of several indicators thought to contribute to vulnerability, each normalised and sometimes weighted so they can be combined (Rygel et al 2006, Adger et al 2004). The approach has been critiqued extensively because the weights assigned the indicators depends on expert opinion which can result in different regions appearing more or less vulnerable, as Füssel (2010) found in reviewing global vulnerability maps based on different indices.

Vulnerability indices developed to date have failed to reflect the dynamic nature of component indicator variables. This is illustrated by the (in)ability to characterise how the selected indicators contribute to determining vulnerability over time. Importantly, the relative importance of the indicator may change from season-to-season (e.g. access to irrigation water) or may gradually or rapidly become obsolete. Hinkel's (2011) review of literature on vulnerability indicators suggests that vulnerability has been confused as a proxy for unsustainable or insufficient development so that simple measurements are seen as sufficient to tell a story about vulnerability. Hinkel (2011) suggests that the simplification of information to create vulnerability indicators is what limits their utility.

Indicator systems have also been developed to improve understanding of adaptive capacity. These are used both to measure adaptive capacity and identify entry points for enhancing it (Adaptation Sub-Committee, 2011; Lioubimtseva and Henebry, 2009; Swanson et al., 2007; Adger and Vincent, 2005; Eriksen and Kelly, 2007). For example, the Global Adaptation Index, developed by the Global Adaptation Alliance (GAIN, n.d.) uses a national approach to assess vulnerability to climate change and other global challenges and compare this with a country's "Readiness to improve resilience" (GAIN, n.d.) to assist public and private sectors to prioritise financial investments in adaptation activities.

21.5.1.2. Hotspots

A special case of the use of indicators concerns the identification of hotspots, a term original used in the context of biodiversity, where a "biodiversity hotspot" is a biologically diverse region typically under threat from human activity, climate change or other drivers (Myers, 1988). The term typically relates to a geographical location, which emerges as a concern when multiple layers of information are compiled to define it. In climate change analysis, hotspots are used to indicate locations that stand out in terms of impacts, vulnerability or adaptive capacity (or all three). Examples of hotspot mapping include how climate change can influence disease risk (de Wet et al., 2001), extinctions of endemic species (Malcolm et al., 2006), and disaster risk (Dilley, 2006). Hotspots analysis is used to serve various purposes, such as setting priorities for policy action, identifying focal regions for further research (de Sherbinin, 2013; Dilley, 2006, Ericksen et al., 2011, see www.climatehotmap.org), or, increasingly, helping distinguish priority locations for funding. Examples of the latter purpose include guiding the allocation of global resources to pre-empt, or combat, disease emergence (Jones et al 2008) or funding for disaster risk management (Arnold et al 2005). Because identifying hotspots raises important methodological issues about the limitation of using indicators to integrate quantitative impacts with qualitative dimensions of vulnerability, their use to compare regions leads to a subjective ranking of locations as having priority for climate change investment. This can be controversial and considered politically-motivated (Klein 2009).

Certain locations are considered hotspots because of their regional or global importance. These can be defined by population size and growth rate, contributions to regional or global economies, productive significance (e.g., food production) as well as by disaster frequency and magnitude, and projected climate change impacts. The choice of variables may result in different locations being identified as hotspots (Füssel, 2009). For example, the Consultative Group on International Agricultural Research (CGIAR) Research Program on Climate Change Agriculture and Food Security (CCAFS) mapped hotspots of food insecurity and climate change in the tropics (Ericksen et al, 2011) using stunted growth as a proxy for food security, but other variables could also have been selected. Scale matters in representing hotspots and they will look different on a global scale than on a finer scale (Arnold et al., 2006).

The rationale for identifying such hotspots is that they may gradually evolve into locations of conflict or disaster, where a combination of factors lead to the degradation of resources and social fabric. Climate change hotspots have been defined as locations where impacts of climate change are "well pronounced and well documented" (UCS 2011). A climate change hotspot can describe (a) a region for which potential climate change impacts on the environment or different activity sectors can be particularly pronounced or (b) a region whose climate is especially responsive to global change (Giorgi 2006). An example of the former is given by Fraser et al (2013), combining hydrological modelling with quantitatively modelled adaptive capacity (defined as the inverse of sensitivity to drought) to identify vulnerability hotspots for wheat and maize. Examples of the latter are given by Giorgi (2006), Diffenbaugh et al. (2008), Giorgi and Bi (2009), Xu et al. (2009), Diffenbaugh and Scherer (2011) and Diffenbaugh and Giorgi (2012) who used different regional climate change indices, including changes in mean and interannual variability of temperature and precipitation and metrics of seasonal extremes, to identify the Mediterranean Basin, Central America, Central and West Africa, the Northern high latitude regions, the Amazon, the southwestern United States, Southeast Asia and the Tibetan Plateau as prominent hot-spots.

21.5.2. Impacts Analyses

In recent years, there has been increased scrutiny of the methods and tools applied in impact assessment, especially quantitative models that are used to project the biophysical and socio-economic impacts of future climate change (see chapter 2, 2.3.2.1), but also encompassing qualitative methods, including studies of indigenous knowledge (Galloway McLean, 2010, and see chapter 12, 12.3.3). In an advance from previous assessments, different types of impact models are now being applied for the first time in many regions of the world. This is largely due to burgeoning international development support for climate change vulnerability and adaptation studies (Fankhauser, 2010). It is also related to a surge of interest in regional economic assessments in the wake of the Stern review (Stern, 2007) as well as to the evolution of climate models into Earth system models that incorporate a more realistic representation of land surface processes (Flato et al., 2014) and their increased application to study hydrological (chapter 3, 3.4.1), ecophysiological (chapter 4, 4.3.3) and cryospheric (Vaughan et al., 2014) impacts.

Potential impacts have been simulated for single as well as multiple sectors, at spatial scales ranging from site or household to global, and over a range of temporal scales and time horizons (Table 21-5). A majority of impact studies still follow the conventional approach where future impacts are modelled based on a set of assumptions (scenarios) about future climate and socioeconomic conditions (see 21.2.3, left hand side of Table 21-3),. However, an increasing number are being undertaken that follow a "socio-institutional" approach to adaptation planning (Downing, 2012), right hand side of Table 21-3, which emphasises the importance of adaptive flexibility and climate resilience given the often intractable, "deep" uncertainties implicit in many projections of future change (e.g., Donley *et al.*, 2012; Garrett *et al.*, 2013; Gersonius *et al.*, 2013).

Impact modelling studies also commonly treat aspects of adaptation, either explicitly as modelled options or implicitly as built-in autonomous responses (Dickinson, 2007; White *et al.*, 2011). Furthermore, as an anthropogenic signature is attributed to ongoing climate changes in many regions (Bindoff et al., 2014), and with growing evidence that these changes are having impacts on natural and human systems in many more regions than reported in the AR4 (chapter 18, Rosenzweig and Neofotis, 2013), it is now possible in some regions and sectors to test impact models' projections against observed impacts of recent climate change (e.g. Araújo *et al.*, 2005; Barnett *et al.*, 2008; Lobell *et al.*, 2011). This is also an essential element in the attribution of observed impacts (Chapter 18, 18.3, 18.4, 18.5).

Uncertainties in and Reliability of Impacts Analyses

Literature on uncertainty in impacts analyses has focused mainly on the uncertainties in impacts that result from the uncertainties in future climate (Mearns et al., 2001; Carter et al., 2007), and this literature continues to grow since AR4, particularly in the realm of agriculture and water resources (e.g., Wetterhall et al., 20011; Ferrise et al., 2011; Ficklin et al., 2012; Littell et al., 2011, Osborne et al., 2013), but also in other areas such as flood risk (Ward et al., 2013). Furthermore, research has advanced to establish which future climate uncertainties are most important to the resultant uncertainties about crop yields (e.g., Lobell and Burke, 2008) and to apply future resource uncertainties to adaptation studies (Howden et al., 2007). Use of multiple global or regional model scenarios is now found in many more studies (e.g. Gosling et al., 2011; Bae et al., 2011; Arnell, 2011; Olsson et al., 2011) and the use of probabilistic quantification of climate uncertainties has produced estimates of probabilities of changes in future resources such as agriculture and water (e.g., Watterson and Whetton, 2011; Tebaldi and Lobell, 2008). Some studies have developed probability distributions of future impacts by combining results from multiple climate projections and, sometimes, different emissions scenarios, making different assumptions about the relative weight to give to each scenario (Brekke et al., 2009). Nobrega et al. (2011) apply 6 different GCMs and 4 different SRES emissions scenarios to study the impacts of climate change on water resources in the Rio Grande Basin in Brazil and found that choice of GCM was the major source of uncertainty in terms of river discharge.

With an ever-increasing number of impacts' projections appearing in the literature and the unprecedented rate and magnitude of climate change projected for many regions, some authors have begun to question both the robustness of the impacts models being applied (e.g., Heikkinen *et al.*, 2006; Fitzpatrick and Hargrove, 2009; Watkiss, 2011a) as well as the methods used to represent key uncertainties in impacts' projections (e.g., Arnell, 2011; Rötter *et al.*, 2011; White *et al.*, 2011). This is being addressed through several prominent international research efforts, Agricultural Model Intercomparison and Improvement Project, involving crop and economic models at different scales (AgMIP – Rosenzweig *et al.*, 2013), the Carbon Cycle Model Intercomparison Project (C^4MIP – Friedlingstein *et al.*, 2006; Sitch *et al.*, 2008; Arora *et al.*, 2013) and the Water Model Intercomparison Project (WaterMIP – Haddeland *et al.*, 2011). Modelling groups from these projects are also participating in the Inter-Sectoral Impact Model Intercomparison Project, initially focusing on intercomparing global impact models for agriculture, ecosystems, water resources, health and coasts under RCP- and SSP-based scenarios (see Box 21-1) with regional models being considered in a second phase of work (ISI-MIP – Schiermeier, 2012). AgMIP results for 27wheat models run at contrasting sites worldwide indicate that projections of yield to the mid-21st century are more sensitive to crop model differences than to global climate model scenario differences (Asseng et al., 2013; Carter, 2013). WaterMIP's analysis of runoff and evapotranspiration from five global hydrologic and six land surface models indicate substantial differences in the models' estimates in these key parameters (Haddelenad et al., 2011). Finally, as in climate modelling, researchers are now applying multiple impact model and perturbed parameter ensemble approaches to future projections (e.g., Araújo and New, 2007; Jiang *et al.*, 2007; Palosuo *et al.*, 2011), usually in combination with ensemble climate projections treated discretely (e.g., New *et al.*, 2007; Graux *et al.*, 2013; Tao and Zhang, 2013) or probabilistically (e.g., Luo *et al.*, 2007; Fronzek *et al.*, 2009, 2011; Børgesen and Olesen, 2011; Ferrise *et al.*, 2011; Wetterhall *et al.*, 2011).

These new impact MIPs, and similar initiatives, have the common purpose of mobilising the research community to address some long-recognised but pervasive problems encountered in impact modelling. A sample of recent papers illustrate the variety of issues being highlighted, e.g. forest model typology and comparison (Medlyn *et al.*, 2011), crop pest and disease modelling and evaluation (Sutherst *et al.*, 2011; Garrett *et al.*, 2013), modelling responses to extreme weather events (Lobell *et al.*, 2010; Asseng *et al.*, 2013), field experimentation for model calibration and testing (Long *et al.*, 2006; Craufurd *et al.*, 2013) and data quality considerations for model input and calibration (Lobell, 2013). Greater attention is also being paid to methods of economic evaluation of the costs of impacts and adaptation at scales ranging from global (e.g., UNFCCC, 2007; Nelson *et al.*, 2009b; Parry *et al.*, 2009; Fankhauser, 2010; Füssel, 2010; Patt *et al.*, 2010), through regional (e.g., EEA, 2007; World Bank, 2010; Ciscar *et al.*, 2011; Watkiss, 2011b), to national (SEI, 2009; GCAP, 2011) and local level (e.g., Perrels *et al.*, 2010).

21.5.3. Development and Application of Baseline and Scenario Information

21.5.3.1. Baseline Information: Context, Current Status, and Recent Advances

This section deals with defining baseline information for assessing climate change impacts, adaptation and vulnerability The baseline refers to a reference state or behaviour of a system, e.g. current biodiversity of an ecosystem, or a reference state of factors (e.g. agricultural activity, climate) which influence that system (see Glossary entry). For example, the UNFCCC defines the pre-industrial baseline climate, prior to atmospheric composition changes from its baseline pre-industrial state, as a reference for measuring global average temperature rises. A baseline may be used to characterise average conditions and/or variability during a reference period, or may allude to a single point in time, such as a reference year. It may provide information on physical factors such as climate, sea level or atmospheric composition, or on a range of non-climate factors, such as technological, land -use or socio-economic conditions. In many cases a baseline needs to capture much of system's variability to enable assessment of its vulnerability or to test whether significant changes have taken place. Thus the information used to establish this baseline must account for the variability of the factors influencing the system. In the case of climate factors often this requires 30 years of data (e.g. Jones et al., 1997) and sometimes substantially more (e.g. Kendon et al., 2008). Also temporal and spatial properties of systems will influence the information required. Many depend on high resolution information, for example urban drainage systems (high spatial scales) or temperature sensitive organisms (sub-daily time-scales). This section assesses methods to derive relevant climatic and non-climatic information and its reliability.

21.5.3.1.1. Climate baselines and their credibility

Observed weather data are generally used as climate baselines, e.g. with an impacts model to form a relevant impacts baseline, though downscaled climate model data are now being used as well. For example Bell et al. (2012) use dynamically and statistically downscaled hourly rainfall data with a 1km river flow model to generate realistic high resolution baseline river flows. These were then compared with future river flows derived used corresponding downscaled future climate projections to generate projected impacts representing realistic responses to the imposed climate perturbations. This use of high resolution data was important to ensure that changes in climate variability the system was sensitive to were taken into account (see also Hawkins et al., 2013). Underscoring the importance of including the full spectrum of climate variability when assessing climate impacts, Kay and Jones (2012) showed a greater range of projected changes in UK river flows resulted when using high time-resolution (daily rather than monthly) climate data.

Thus to develop the baseline of a climate-sensitive system it is important to have a good description of the baseline climate, thus including information on its variability on timescales of days to decades. This has motivated significant efforts to enhance the quality, length and homogeneity of, and make available, observed climate records (also important for monitoring, detecting and attributing observed climate change – Hartmann et al., 2014; Rhein et al., 2014; Vaughan et al., 2014; Masson-Delmotte et al., 2014; Bindoff et al., 2014). This has included generating new datasets such as APHRODITE (a gridded rain-gauge based dataset for Asia, Yatagai, et al., 2012), coordinated analyses of regional climate indices and extremes by CLIVAR's ETCCDI (see e.g. Zhang et al., 2011) and data rescue work typified by the ACRE initiative (Allan et al., 2011) resulting in analysis and digitization of many daily or sub-daily weather records from all over the world. Also, estimates of uncertainty in the observations are either being directly calculated, e.g. for the HadCRUT4 near-surface temperature record (Morice et al., 2012), or can be generated from multiple datasets, e.g. for precipitation using datasets such as GPCC (Rudolf et al., 2011), TRMM (Huffman et al., 2010) and APHRODITE, Yatagi et al.; 2012.

Significant progress has also been made in developing improved and new global reanalyses. These use climate models constrained by long time-series of observations from across the globe to reconstruct the temporal evolution of weather patterns during the period of the observations. An important new development has been the use of digitized surface pressure data from ACRE by the 20th Century Reanalysis (20CR) project (Compo et al., 2011) covering 1871 to the present day. 20CR provides the basis for estimating historical climate variability from the sub-daily to the multi-decadal timescale (Figure 21-12) at any location. It can be used directly, or via downscaling, to develop estimates of the baseline sensitivity of a system to climate and addressing related issues such as establishing links between historical climate events and their impacts. Other advances in reanalyses (http://reanalyses.org) have focused on developing higher quality reconstructions for the recent past. They include a new European Centre for Medium Range Weather Forecasts Reanalyses (ERA) dataset, ERA-Interim (Dee et al., 2011) and the NASA Modern Era Reanalysis for Research and Applications (MERRA – Rienecker et al., 2011), 1979-present, the NCEP Climate Forecast System Reanalysis (CFSR), 1979-Jan 2010 (Saha et al., 2010) and regional reanalyses such as the North American Regional Reanalysis (NARR) (Mesinger et al., 2006) and EURO4M (http://www.euro4m.eu/).

[INSERT FIGURE 21-12 HERE
Figure 21-12: Time series of seasonally averaged climate indices representing three modes of large-scale climate variability: (a) the tropical September to January Pacific Walker Circulation (PWC); (b) the December to March North Atlantic Oscillation (NAO); (c) the December to March Pacific North America (PNA) pattern. Indices (as defined in Brönnimann etal. (2009) are calculated (with respect to the overlapping 1989–1999 period) from various observed, reanalysis and model sources: statistical reconstructions of the PWC, the PNA and the NAO, see Brönnimann et al. (2009) for details, (all cyan); 20CR (pink); NCEP–NCAR reanalyses (NNR; dark blue); ERA-40 (green); ERA-Interim (orange). The black line and grey shading represent the ensemble mean and spread from a climate model ensemble with a lower boundary condition of observed seas-surface temperatures and sea-ice from the HadISST dataset (Rayner et al. 2003), see Brönnimann etal. (2009) for details. The model results provide a measure of the predictability of these modes of variability from sea-surface temperature and sea-ice alone and demonstrate that the reanalyses have significantly higher skill in reproduces these modes of variability.]

In many regions high temporal and spatial resolution baseline climate information is not available (e.g. Washington et al. 2006, World Weather Watch 2005). Recent reanalyses may provide globally complete and temporally detailed reconstructions of the climate of the recent past but generally lack the spatial resolution or have significant biases (Thorne and Vose, 2010; Dee et al., 2011; Cerezo-Mota et al., 2011). Downscaling the reanalyses can be used with available observations to estimate the error in the resulting reconstructions which can often be significant (Duryan et al., 2010; Mearns et al., 2012). Advances in this area are expected through the WCRP-sponsored Coordinated Regional Downscaling Experiment (CORDEX) project (http://wcrp.ipsl.jussieu.fr/SF_RCD_CORDEX.html; Giorgi et al., 2009) which includes downscaling ERA-Interim over all land and enclosed sea areas (e.g. Nikulin et al. 2012).

21.5.3.1.2. Non-climatic baselines and their credibility

Climate-sensitive systems can be influenced by many non-climatic factors, so information on the baseline state of these factors is also commonly required (Carter et al., 2001; Carter et al., 2007). Examples of physical non-climatic factors include availability of irrigation systems, effectiveness of disease prevention or flood protection. Examples of socio-economic factors include levels of social, educational and economic development, political/governance background and available technology. Significant work has been undertaken to collect and make this information available. Local and national governments and international agencies (e.g. UN agencies, World Bank) have been collecting data (http://data.worldbank.org/data-catalog) on the human-related factors for many decades and similarly information on technological developments is widely available. Often these factors are evolving quickly and the baseline is taken as the reference state at a particular point in time rather than aggregated over a longer period. In the case of the physical factors, information on many of these have been refined and updated as they are critical inputs to deriving the climate forcings in the Representative Concentration Pathways (RCPs, van Vuuren et al., 2011) used in CMIP5 (Taylor et al., 2012). This includes updated information on land-use change (Hurtt et al., 2011), atmospheric composition (Meinshausen et al., 2011) and aerosols (Grainer et al., 2011, Lamarque et al., 2011).

The importance of establishing an appropriate physical baseline is illustrated in a study of potential climate change impacts on flow in the River Thames in the UK over a 126 year period. No long-term trend is seen in annual maximum flows despite increases in temperature and a major change in the seasonal partitioning of rainfall, winter rainfall becoming larger than summer (Marsh 2004). An investigation of the physical environment found that it had been significantly modified as part of river management activities with increases in channel capacity of 30% over 70 years leading to fewer floods. Thus establishing a baseline for river channel capacity explained the current reduced vulnerability of the Thames to flooding. In a study of the potential for crop adaptation (Challinor et al., 2009), the relevant non-climatic factor identified was technological. Detailed field studies demonstrated that the current germplasm included varieties with a wide range of tolerance to higher temperatures (Badigannavar et al., 2002). This established an agricultural technology baseline, current crop properties, which demonstrated the potential to reduce vulnerability in the system to compensate for the projected climate change impact.

21.5.3.2. Development of Projections and Scenarios

Since the AR4 there have been several new developments in the realm of scenarios and projections: 1) a new approach to the construction of global scenarios for use in climate change analysis, initiated with the development of representative concentration pathways (RCPs) (see Box 21.1 for a full description); 2) the development and application of a greater number of higher resolution climate scenarios (21.3.3.2); and 3) further use of multiple scenario elements as opposed to use of climate change scenarios only and greater focus on multiple stressors.

21.5.3.2.1. Application of high-resolution future climate information

There are now many examples of the generation and application of high resolution climate scenarios for assessing impacts and adaptation planning. These provide information at resolutions relevant for many impacts and adaptation studies but also, particularly with regard to dynamical downscaling, account for higher resolution forcings, such as complex topography (e.g., Salathé et al., 2010) or more detailed land-atmosphere feedbacks such as in West Africa (Taylor et al. 2011). In an analysis of climate impacts including possible adaptations in the Pacific North West of North America (Miles et al., 2010) application of two dynamically downscaled scenarios was particularly useful for the assessment of effects of climate change on storm water infrastructure (Rosenberg et al., 2010). More widely in North America results from NARCCAP have been used to assess impacts of climate change on available wind energy (Pryor and Barthelmie, 2011), road safety (Hambly et al., 2012), hydrology (Burger et al., 2011; Shrestha et al., 2011), forest drought (Williams et al., 2012), and human health (Li et al., 2012).

Several European-led projects have generated and applied high resolution climate scenarios to investigate the impacts of climate change over Europe for agriculture, river flooding, human health, and tourism (Christensen et al. 2012) and on energy demand, forest fire risk, wind storms damage, crop yields and water resources (Morse et al., 2009). The UK developed new UK Climate Projections in 2009 (UKCP09) combining the CMIP3, a perturbed physics GCM and a regional climate model ensemble to develop probabilities of changes in temperature and precipitation at a 25 km resolution (Murphy et al., 2009) to determine probabilities of different impacts of climate change and possible adaptations. In general, with all of this work a range of different techniques have been used with little assessment or guidance on the relative merits of each.

21.5.3.2.2. Use of multiple scenario elements and focus on multiple stressors

Many more impacts and adaptation studies now use multiple scenario elements, and focus on multiple stressors as opposed to climate change scenarios and effects alone (e.g., 3.3.2, 4.2.4, and 7.1.2). Good examples of use of multiple scenario elements involve studies of climate change and human health considering additional factors such as urban heat island (e.g., Knowlton et al., 2008; Rosenzweig et al., 2009), population increase and expanded urban areas (McCarthy et al., 2010) and population and socio-economic conditions (Watkiss and Hunt, 2012). As these studies are often undertaken at small scales, local scale information on relevant factors may be inconsistent with larger scale scenario elements used in quantifying other stressors. In recognition of this, efforts have been or are being made to downscale the large-scale scenario elements, e.g. the SRES scenarios were downscaled for Europe (van Vuuren and O'Neill, 2006) and economic activity information has been downscaled to 0.5 degree grids in some regions (Gaffin et al., 2004; Grübler et al., 2007; van Vuuren et al., 2010) However, this information is far from comprehensive and has not yet been examined carefully in the impacts and vulnerability literature (van Ruijven et al., 2013).

Typical non-climate stressors include changes in population, migration, land use, economic factors, technological development, social capital, air pollution, and governance structures. They can have independent, synergistic, or antagonistic effects and their importance varies regionally. Land-use and socio-economic changes are stressors of equal importance to climate change for some studies in Latin America (27.2.2.1), numerous changes in addition to climate strongly affect ocean ecosystem health (6.6.1) and in Asia rapid urbanization, industrialization and economic development are identified as major stressors expected to be compounded by climate change in (24.4-7). Most multiple stressor studies are regional or local in scope. For example Ziervogel and Taylor (2008) examined two different villages in South Africa and found that a suite of stressors are present such as high unemployment, health status (e.g., increased concern about AIDs), and access to education with climate change concerns present only in the context of other impacts such as availability of water. In a study on the Great Lakes region, additional stressors included land use change, population increase, and point source pollution (Danz et al., 2007). Mawdesly et al. (2009) considered wildlife management and biodiversity conservation and noted that reducing pressure from other stressors can maximize flexibility for adaptation to climate change. This increased focus on multiple stressors obviously increases the need for a much wider range of data and wider range of projections for the wide range of stressors, across multiple spatial scales.

21.5.3.3. Credibility of Projections and Scenarios

21.5.3.3.1. Credibility of regional climate projections

Obtaining robust regional projections of climate change (i.e. at least a clear indication of the direction of change), requires combining projections with detailed analysis and understanding of the drivers of the changes. The most successful example of this is the application of the attribution of observed global and regional temperature changes using global models incorporating known natural and anthropogenic climate forcing factors (Flato et al., 2014, section 10.3). The ability of GCMs to reproduce the observed variations in temperature, the quantification of the influence of the different forcings factors and how well these influences are captured in the models provide confidence that models capture correctly the physical processes driving the changes. This can also provide confidence in projections of precipitation when physically linked to changes in temperature (Rowell and Jones, 2006; Kendon et al. 2010). It is important, especially with precipitation where regional change may appear to differ in direction from one model to another, to distinguish when changes are significant (Tebaldi et al. 2011, Collins et al., 2014b, Box 12.1). Significant future projections of opposite direction are found with neither possibility able to be excluded on the basis of our physical understanding of the drivers of these changes. For example, McSweeney et al. (2012) found that in an ensemble of GCM projections over south-east Asia, all models simulated the important monsoon processes and rainfall well but projected both positive and negative changes in monsoon precipitation and significantly different patterns of change.

Model trends or projections may also be inconsistent with trends in available observations and in these cases, their projections are less credible. For example, the magnitude of the significant drying trend seen in the Sahel from the 1960s to the 1990s is not captured by models driven by observed sea-surface temperatures (SSTs) (e.g. Held et al. 2005) despite statistical analysis demonstrating the role of SSTs in driving Sahel rainfall variability. Thus our understanding of the system and its drivers, and their representation in the models, is incomplete, which complicates the interpretation of future projected changes in this region (e.g. Biasutti et al., 2008, Druyan, 2010). It implies that other processes are important and so research is required to identify these and ensure they are correctly represented in the models, without which projections of rainfall changes over this region cannot be considered reliable.

21.5.3.3.1. Credibility regarding socioeconomic scenario elements

Cash et al. (2003) distinguish three criteria for linking scientific knowledge to policy action; credibility (scientific adequacy of a policy-relevant study), salience (relevance of a study’s findings to the needs of decision-makers), and legitimacy (the perception that the study is respectful of divergent values and beliefs). Studies examining the performance of scenarios in climate change research across all three of these criteria are rare, but a general conclusion has been that much less attention is paid to salience and legitimacy (Hulme and Dessai 2008, Garb et al.

2008, Girod et al. 2009). Recognising this a new framework for global scenarios has been developed (Box 21-1), providing researchers greater freedom than hitherto for customizing information provided by global scenarios. These innovations may pose challenges for scientific credibility, and it is unclear how difficult it will be to bring independently developed climate and socioeconomic projections together as scenarios in an internally consistent manner, especially when some of these may include fine-scale regional detail (O'Neill and Schweizer, 2011; O'Neill et al., 2013).

Due to the common practice for scenario development of using narrative descriptions of alternative futures as the inspiration for socioeconomic simulations (the Story and Simulation approach – Alcamo 2008) it has been suggested that the exclusion of some details in socioeconomic scenario studies can affect the internal consistency and therefore the overall credibility of a study (e.g. Lloyd and Schweizer, 2013; Schweizer and Kriegler, 2012). Storylines can offer a point of entry for multi-scalar scenario analyses (Rounsevell and Metzger, 2010), and such sub-global scenario studies have been on the rise (Kok et al. 2011, Preston et al. 2011, Sietz et al. 2011, van Ruijven et al., 2013).

Environmental scenario exercises crossing geographical scales suggests that linkages between scenarios at different scales can be hard or soft (Zurek and Henrichs 2007), where downscaling (van Vuuren et al. 2010) would be an example of a hard linkage while other similarities between scenarios would be soft linkages. How to apply flexible interpretations of scientific adequacy and maintain scenario credibility is relatively unexplored, and there is thus a need for studies to document best practices in this respect.

21.6. Knowledge Gaps and Research Needs

Understanding of the regional nature of climate change, its impacts, regional and cross-regional vulnerabilities, and options for adaptation is still at a rudimentary level. There are both fundamental and methodological research issues in the physical sciences concerned with the projection of regional changes in the climate system and the potential impacts of those changes on various resource sectors and natural systems. Of equal importance, there are also fundamental gaps in our understanding of the determinants of vulnerability and adaptive capacity, thus presenting methodological challenges for projecting how societal vulnerability might evolve as the climate system changes. While development of new scenarios is a part of the underlying research agenda, they will inevitably be limited without further progress in our knowledge of the determinants of vulnerability.

Table 21-8 summarizes major research gaps in the physical, ecological, and social sciences that impede the scientific communities' progress in understanding the regional context of climate changes, their consequences, and societies' responses.

Frequently Asked Questions

FAQ 21.1: How does this report stand alongside previous assessments for informing regional adaptation?
[to be inserted in Section 21.3]
The five major Working Group II Assessment Reports produced since 1990 all share a common focus that addresses the environmental and socioeconomic implications of climate change. In a general sense, the earlier assessments are still valid, but the assessments have become much more complete over time, evolving from making very simple, general statements about sectoral impacts, through greater concern with regions regarding observed and projected impacts and associated vulnerabilities, through to an enhanced emphasis on sustainability and equity, with a deeper examination of adaptation options. Finally, in the current report there is a much improved appreciation of the context for regional adaptation and a more explicit treatment of the challenges of decision-making within a risk management framework.

Obviously one can learn about the latest understanding of regional impacts, vulnerability and adaptation in the context of climate change by looking at the most recent report. This builds on the information presented in previous reports by reporting developments in key topics. New and emergent findings are given prominence, as these may present fresh challenges for decision-makers. Differences with the previous reports are also highlighted – whether reinforcing, contradicting or offering new perspectives on earlier findings – as these too may have a bearing on past and present decisions. Following its introduction in the Third Assessment Report (TAR), uncertainty language has been available to convey the level of confidence in key conclusions, thus offering an opportunity for calibrated comparison across successive reports. Regional aspects have been addressed in dedicated chapters for major world regions, first defined following the Second Assessment and used with minor variations in the three subsequent assessments. These comprise the continental regions of Africa, Europe, Asia, Australasia, North America, Central and South America, Polar Regions and Small Islands , with a new chapter on The Oceans added for the present assessment.

FAQ 21.2: Do local and regional impacts of climate change affect other parts of the world?
[to be inserted in Section 21.3.1]
Local and regional impacts of climate change, both adverse and beneficial, may indeed have significant ramifications in other parts of the world. Climate change is a global phenomenon, but often expresses itself in local and regional shocks and trends impacting vulnerable systems and communities. These impacts often materialize in the same place as the shock or trend, but also much farther afield, sometimes in completely different parts of the world. Regional interdependencies include both the global physical climate system as well as economic, social and political systems that are becoming increasingly globalised.

In the physical climate system, some geophysical impacts can have large-scale repercussions well beyond the regions in which they occur. A well-known example of this is the melting of land-based ice, which is contributing to sea-level rise (and adding to the effects of thermal expansion of the oceans), with implications for low-lying areas far beyond the polar and mountain regions where the melting is taking place.

Other local impacts can have wider socio-economic and geopolitical consequences. For instance, extreme weather events in one region may impact production of commodities that are traded internationally, contributing to shortages of supply and hence increased prices to consumers, influencing financial markets and disrupting food security worldwide, with social unrest a possible outcome of food shortages. Another example, in response to longer-term trends is the potential prospect of large-scale migration due to climate change. While hotly contested, this link is already seen in the context of natural disasters, and could become an issue of increasing importance to national and international policy makers. A third example is the shrinkage of Arctic sea ice, opening Arctic shipping routes as well as providing access to valuable mineral resources in the exclusive economic zones of countries bordering the Arctic, with all the associated risks and opportunities. Other examples involving both risks and opportunities include changes of investment flows to regions where future climate change impacts may be beneficial for productivity

Finally, some impacts that are entirely local and may have little or no direct effect outside the regions in which they occur still threaten values of global significance, and thus trigger international concern. Examples include humanitarian relief in response to local disasters or conservation of locally threatened and globally valued biodiversity.

FAQ 21.3: What regional information should I take into account for climate risk management for the 20 year time horizon? *[to be inserted in Section 21.3.2]*
The fundamental information required for climate risk management is to understand the climate events that put the system being studied at risk and what is the likelihood of these arising. The starting point for assembling this information is a good knowledge of the climate of the recent past including any trends in aspects of these events (e.g. their frequency or intensity). It is also be important to consider that many aspects of the climate are changing, to understand how the future projected changes may influence the characteristics of these events and that these changes will, in general, be regionally variable. However, it should be noted that over the coming 20 years the magnitude of projected changes may not be sufficient to have a large influence the frequency and intensity of these events. Finally, it is also essential to understand which other factors influence the vulnerability of the system. These may be important determinants in managing the risks and also if they are changing at faster rates than the climate then changes in the latter become a secondary issue.

For managing climate risks over a 20-year time horizon it is essential to identify the climate variables which the system at risk is vulnerable to. It could be a simple event such as extreme precipitation or a tropical cyclone or a more complex sequence of a late onset of the monsoon coupled with prolonged dry spells within the rainy season.

The current vulnerability of the system can then be estimated from historical climate data on these variables including any information on trends in the variables. These historical data would give a good estimate of the vulnerability assuming the record was long enough to provide a large sample of the relevant climate variables and that the reasons for any trends, e.g. clearly resulting from climate change, were understood. It should be noted that in many regions sufficiently long historical records of the relevant climate variables are often not available.

It is also important to recognize that many aspect of the climate of the next 20 years will be different from the past. Temperatures are continuing to rise with consequent increases in evaporation and atmospheric humidity and reductions in snow amount and snow season length in many regions. Average precipitation is changing in many regions with both increases and decreases and there is a general tendency for increases in extreme precipitation observed over land areas. There is a general consensus amongst climate projections that further increases in heavy precipitation will be seen as the climate continues to warm and more regions will see significant increases or decreases in average precipitation. In all cases the models project a range of changes for all these variables which are generally different for different regions.

Many of these changes may often be relatively small compared to their natural variations but it is the influence of these changes on the specific climate variables which the system is at risk from that is important. Thus information needs to be derived from the projected climate changes on how the characteristics of these variables, e.g. the likelihood of their occurrence or magnitude, will change over the coming 20 years. These projected future characteristics in some cases may be indistinguishable from those historically observed but in other cases some or all models will project significant changes. In the latter situation, the effect of the projected climate changes will then result in a range of changes in either the frequency or magnitude of the climate event, or both. The climate risk management strategy would then need to adapt to accounting for either a greater range or changed magnitude of risk. This implies that in these cases a careful analysis of the implications of projected changes for the specific temporal and spatial characteristic of the climate variables relevant to the system at risk is required.

FAQ 21.4: Is the highest resolution climate projection the best to use for performing impacts assessments?
[to be inserted in Section 21.5.3.3]
A common perception is that higher resolution (i.e., more spatial detail) equates to more useable and robust information. Unfortunately data does not equal information, and more high resolution data does not necessarily translate to more or better information. Hence, while high resolution global climate models (GCMs) and many downscaling methods can provide high resolution data, and add value in, for example, regions of complex topography, it is not a given that there will be more value in the final climate change message. This partially depends upon how the higher resolution data were obtained. For example, simple approaches such as spatial interpolation or adding climate changes from GCMs to observed data fields do increase the spatial resolution but add no new information on high resolution climate change. Nonetheless, these data sets are useful for running impacts models. Many impacts settings are somewhat tuned to a certain resolution, such as the nested size categorizations of hydrologic basins down to watershed size, commonly used in hydrologic modeling. Using dynamical or statistical downscaling methods will add a new high resolution component, providing extra confidence that sub-GCM scale processes are being represented more accurately. However, , there are new errors associated with the additional method applied which need to be considered. More importantly, if downscaling is applied to only one or two GCMs then the resulting high resolution scenarios will not span the full range of projected changes that a large GCM ensemble would indicate are plausible futures. Spanning that full range is important in being able to properly sample the uncertainty of the climate as it applies in an impacts context. Thus for many applications, such as understanding the full envelope of possible impacts resulting from our current best estimates of regional climate change, lower resolution data may be more informative. At the end of the day, no one data set is best, and it is through the integration of multiple sources of information that robust understanding of change is developed. What is important in many climate change impacts contexts is appropriately sampling the full range of known uncertainties, regardless of spatial resolution. It is through the integration of multiple sources of information that robust understanding of change is developed.

Cross-Chapter Box

Box CC-RC. Regional Climate Summary Figures

[Noah Diffenbaugh (USA), Dáithí Stone (Canada / South Africa / USA), Peter Thorne (USA / Norway / UK), Filippo Giorgi (Italy), Bruce Hewitson (South Africa), Richard Jones (UK), Geert Jan van Oldenborgh (Netherlands)]

Information about the likelihood of regional climate change, assessed by WGI, is foundational for the Working Group II assessment of climate-related risks. To help communicate this assessment, the regional chapters of WGII present a coordinated set of regional climate figures, which summarize observed and projected change in annual average temperature and precipitation during the near-term and the longer-term for RCP2.6 and RCP8.5. These WGII regional climate summary figures use the same temperature and precipitation fields that are assessed in WGI Chapter 2 and WGI Chapter 12, with spatial boundaries, uncertainty metrics, and data classes tuned to support the WGII assessment of climate-related risks and options for risk management. Additional details on regional climate and regional climate processes can be found in WGI Chapter 14 and WGI Annex 1.

The WGII maps of observed annual temperature and precipitation use the same source data, calculations of data sufficiency, and calculations of trend significance as WGI Chapter 2 and WGI Figures SPM.1 and SPM.2. (A full description of the observational data selection and significance testing can be found in WGI Box 2.2.) Observed trends are determined by linear regression over the 1901-2012 period of MLOST for annual temperature, and over the 1951-2010 period of GPCC for annual precipitation. Data points on the maps are classified into three categories, reflecting the categories used in WGI Figures SPM.1 and SPM.2:

1) Solid colors indicate areas where (i) sufficient data exist to permit a robust estimate of the trend (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period), and (ii) the trend is significant at the 10% level (after accounting for autocorrelation effects on significance testing).
2) Diagonal lines indicate areas where sufficient data exist to permit a robust estimate of the trend, but the trend is not significant at the 10% level.
3) White indicates areas where there are not sufficient data to permit a robust estimate of the trend.

The WGII maps of projected annual temperature and precipitation are based on the climate model simulations from Phase 5 of the Coupled Model Intercomparison Project (CMIP5) (Taylor et al., 2012), which also form the basis for the figures presented in WGI (including WGI Chapter 12, Chapter 14, and Annex I). The CMIP5 archive includes output from atmosphere-ocean general circulation models (AOGCMs), AOGCMs with coupled vegetation and/or carbon cycle components, and AOGCMs with coupled atmospheric chemistry components. The number of models from which output is available, and the number of realizations of each model, varies between the different CMIP5 experiments.

The WGII regional climate maps use the same source data as WGI Chapter 12 (e.g., Box 12.1 Figure 1), including the WGI multi-model mean values; the WGI individual model values; the WGI measure of baseline ("internal") variability; and the WGI time periods for the reference (1986-2005), mid-21st-century (2046-2065), and late-21st-century (2081-2100) periods. The full description of the selection of models, the selection of realizations, the definition of internal variability, and the interpolation to a common grid can be found in WGI Chapter 12 and Annex 1.

In contrast to Phase 3 of the Coupled Model Intercomparison Project (CMIP3) (Meehl et al., 2007), which used the IPCC SRES emission scenarios (IPCC, 2000), CMIP5 uses the Representative Concentration Pathways (RCPs) (van Vuuren et al., 2011) to characterize possible trajectories of climate forcing over the 21st century. The WGII regional climate projection maps include RCP2.6 and RCP8.5, which represent the high and low end of the RCP range at the end of the 21st century. Projected changes in global mean temperature are similar across the RCPs over the next few decades (Figure RC-1; WGI Fig. 12.5). During this near-term era of committed climate change, risks will evolve as socioeconomic trends interact with the changing climate. In addition, societal responses, particularly adaptations, will influence near-term outcomes. In the second half of the 21st century and beyond, the magnitude of global temperature increase diverges across the RCPs (Figure RC-1; WGI Fig. 12.5). For this longer-term era of climate options, near-term and ongoing mitigation and adaptation, as well as development pathways, will determine the risks of climate change. The benefits of mitigation and adaptation thereby occur over different timeframes, and present-day choices thus affect the risks of climate change throughout the 21st century.

[INSERT FIGURE RC-1 HERE
Figure RC-1: Observed and projected changes in global annual average temperature. Values are expressed relative to 1986-2005. Black lines show the GISTEMP, NCDC-MLOST, and HadCRUT4.2 estimates from observational measurements. Colored shading denotes the ±1.64 standard deviation range based on simulations from 32 models for RCP2.6 (blue) and 39 models for RCP8.5 (red). Blue and red lines denote the scenario mean for RCP2.6 and RCP8.5, respectively.]

The projection maps plot differences in annual average temperature and precipitation between the future and reference periods (Figure RC-2 and Figure RC-3), categorized into four classes. The classes are constructed based on the IPCC uncertainty guidance, providing a quantitative basis for assigning likelihood (Mastrandrea et al., 2010), with "likely" defined as 66-100% and "very likely" defined as 90-100%.

The classifications in the WGII regional climate projection figures are based on two aspects of likelihood (e.g., WGI Box 12.1 and Knutti et al. (2010)). The first is the likelihood that projected changes exceed differences arising from internal climate variability (e.g., Tebaldi et al. (2011)). The second is agreement among models on the sign of change (e.g., Christensen et al. (2007) and IPCC (2012)).

The four classifications of projected change depicted in the WGII regional climate maps are:

1) Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. These criteria (and the areas that fall into this category) are identical to the highest-confidence category in WGI Box 12.1. This category supersedes other categories in the WGII regional climate maps.
2) Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability, and >66% of models agree on sign of change.
3) Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change.
4) Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability. It should be noted that areas that fall in this category for the annual average could still exhibit significant change at seasonal, monthly and/or daily timescales.

[INSERT FIGURE RC-2 HERE
Figure RC-2: Observed and projected changes in annual average temperature. (A) Observed temperature trends from 1901-2012 are determined by linear regression. Trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level (after accounting for autocorrelation effects on significance testing). Diagonal lines indicate areas where change is not significant. Observed data are from WGI AR5 Figures SPM.1 and 2.21. The range of grid-point values is -0.53 to +2.50°C over period. (B) CMIP5 multi-model mean projections of annual average temperature changes for 2046-2065 and 2081-2100 under RCP2.6 and RCP8.5, relative to 1986-2005. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability and >90% of models agree on the sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on the sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on the sign of change. Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability (although there may be significant change at shorter timescales such as seasons, months, or days). Analysis uses model data from WGI AR5 Figure SPM.8, Box 12.1, and Annex I. The range of grid-point values for the multi-model mean is: +0.19 to +4.08˚C for mid-21st century of RCP2.6; +0.06 to +3.85˚C for late-21st century of RCP2.6; +0.70 to +7.04˚C for mid-21st century of RCP8.5; and +1.38 to +11.71°C for late-21st century of RCP8.5.]

[INSERT FIGURE RC-3 HERE
Figure RC-3: Observed and projected changes in annual average precipitation. (A) Observed precipitation trends from 1951-2010 are determined by linear regression. Trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level (after accounting for autocorrelation effects on significance testing). Diagonal lines indicate areas where change is not significant. Observed data are from WGI AR5 Figures SPM.2. The range of grid-point values is -185 to +111 mm/year/decade. (B) CMIP5 multi-model mean projections of annual average precipitation changes for 2046-2065 and 2081-2100 under RCP2.6 and RCP8.5, relative to 1986-2005. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability and >90% of models agree on the sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on the sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on the sign of change. Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability (although there may be significant change at shorter timescales such as seasons, months, or days). Analysis uses model data from WGI AR5 Figure SPM.8, Box 12.1, and Annex I. The range of grid-point values for the multi-model mean is: -10 to +24% for mid-21st century of RCP2.6; -9 to +22% for late-21st century of RCP2.6; -19 to +57% for mid-21st century of RCP8.5; and -34 to +112% for late-21st century of RCP8.5.]

IPCC, 1996: Climate Change 1995: Economic and Social Dimensions of Climate Change. Contribution of Working Group III to the Second Assessment Report of the Intergovernmental Panel on Climate Change.[Bruce, J.P., H. Lee, E.F. Haites(eds.)]. Cambridge, pp. 448.

IPCC, 1998: Land Use, Land-Use Change and Forestry: A Special Report of the IPCC, Intergovernmental Panel on Climate Change.[Watson, R.T., I.R. Noble, B. Bolin, N.H. Ravindranath, D.J. Verardo, D.J. Dokken(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 377.

IPCC, 1998: The Regional Impacts of Climate Change: An Assessment of Vulnerability. A Special Report of IPCC Working Group II, Intergovernmental Panel on Climate Change.[Watson, R.T., M.C. Zinyowera, R.H. Moss, D.J. Dokken(eds.)]. Cambridge, United Kingdom, pp. 517.

IPCC, 1999: Aviation and the Global Atmosphere: A Special Report of Working Groups I and III of the Intergovernmental Panel on Climate Change.[J.E.Penner, D.H.Lister, D.J.Griggs, D.J.Dokken, M.McFarland(eds.)]. Cambridge, United Kingdom, pp. 373.

IPCC, 2000: Special Report on Emissions Scenarios: A Special Report of Working Group III of the Intergovernmental Panel on Climate Change.[Nakićenović, N., J. Alcamo, G. Davis, B. DeVries, J. Fenhann, S. Gaffin *et al.*(eds.)]. Cambridge, pp. 600.

IPCC, 2000: Methodological and Technological Issues in Technology Transfer. A Special Report of IPCC Working Group III, Intergovernmental Panel on Climate Change.[Metz, B., O.R. Davidson, J. Martens, N.M.v.R. Sascha, L.V.W. McGrory(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 466.

IPCC, 2001: Climate Change 2001: The Scientific Basis. Contribution of Working Group I to the Third Assessment Report of the Intergovernmental Panel on Climate Change.[Houghton, J.T., Y. Ding, D.J. Griggs, M. Noguer, P.J. van der Linden, X. Dai *et al.*(eds.)]. Cambridge and New York, pp. 881.

IPCC, 2001: Climate Change 2001: Impacts, Adaptation, and Vulnerability. Contribution of Working Group II to the Third Assessment Report of the Intergovernmental Panel on Climate Change.[McCarthy, J.J., O.F. Canziani, N.A. Leary, D.J. Docken, K.S. White(eds.)]. Cambridge and New York, pp. 1032.

IPCC, 2001: Climate Change 2001: Mitigation. Contribution of Working Group III to the Third Assessment Report of the Intergovernmental Panel on Climate Change.[Metz, B., O. Davidson, R. Swart, J. Pan(eds.)]. Cambridge and New York, pp. 752.

IPCC, 2005: IPCC Special Report on Carbon Dioxide Capture and Storage. Prepared by Working Group III of the Intergovernmental Panel on Climate Change.[Metz, B., O. Davidson, H.C.d. Coninck, M. Loos, L.A. Meyer(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 442.

IPCC, 2007: Climate Change 2007: Impacts, Adaptation and Vulnerability. Contribution of Working Group II to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change.[M.L., P., O.F. Canziani, J.P. Palutikof, P.J.v.d. Linden, C.E. Hanson(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 976.

IPCC, 2007: Climate Change 2007: The Physical Science Basis. Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change.[Solomon, S., D. Qin, M. Manning, Z. Chen, M. Marquis, K.B. Averyt *et al.*(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 996.

IPCC, 2007: Climate Change 2007: Mitigation. Contribution of Working Group III to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change.[Metz, B., O.R. Davidson, P.R. Bosch, R. Dave, L.A. Meyer(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 851.

IPCC (ed.), 2012: *Renewable Energy Sources and Climate Change Mitigation. Special Report of the Intergovernmental Panel on Climate Change.* Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 1076.

IPCC, 2012: *Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation. A Special Report of Working Groups I and II of the Intergovernmental Panel on Climate Change.* Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 582.

IPCC, 2014: Climate Change 2014: Mitigation of Climate Change. Contribution of Working Group III to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change.[Edenhofer, O.,et al. (ed.)]. Cambridge, UK and New York, USA, pp. 2.

IPCC, 2014: Climate Change 2014: The Physical Science Basis. Contribution of Working Group I to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change.[Stocker, T.,et al. (ed.)]. Cambridge, UK and New York, USA, pp. 12.

IPCC/TEAP, 2005: Special Report on Safeguarding the Ozone Layer and the Global Climate System: Issues Related to Hydrofluorocarbons and Perfluorocarbons. prepared by the Intergovernmental Panel on Climate Change (IPCC) Working Groups I and III and the Montreal Protocol Technology and Economic Assessment Panel (TEAP).[Metz, B., L. Kuijpers, S. Solomon, S.O. Andersen, O. Davidson, J. Pons *et al.*(eds.)]. Cambridge, United Kingdom and New York, NY, USA, pp. 478.

Isbell, F., V. Calcagno, A. Hector, J. Connolly, W.S. Harpole, P.B. Reich, M. Scherer-Lorenzen, B. Schmid, D. Tilman, J. van Ruijven, A. Weigelt, B.J. Wilsey, E.S. Zavaleta, and M. Loreau, 2011: High plant diversity is needed to maintain ecosystem services. *Nature,* **477**, 199-202.

America, C. Asia); MRC – Mekong River Commission For Sustainable Development; Lake Victoria Basin Commission.

Table 21-2: Selected examples of regional treatment in previous IPCC Assessment Reports and Special Reports (SR). Major assessments are subdivided by the three Working Group reports, each described by generic titles.

IPCC report [references]	**Year**	**Treatment of regions**
First Assessment Report (FAR) [1, 2, 3]	1990	*Climate*: Climate projections for 2030 in 5 sub-continental regions; Observations averaged for northern/southern hemisphere, by selected regions and by 20° latitude x 60° longitude grid boxes
		Impacts: Agriculture by continent (7 regions); Ecosystem impacts for 4 biomes; water resources for case study regions; Oceans and Coastal Zones treated separately
		Responses: Emissions scenarios by 5 economic groupings; Energy and Industry by 9 regions; Coastal Zone and Wetlands by 20 world regions
Supplements to FAR [4, 5]	1992	*Climate*: IS92 emissions scenarios by 7 world regions
		Impacts: Agriculture by continent (6 regions); Ocean Ecology by 3 latitude zones; Questionnaire to governments on current activities on impacts by 6 WMO regions
SR: *Climate Change 1994* [6]	1994	Evaluation of IS92 emissions scenarios by 4 world regions: OECD, USSR/E. Europe, China/Centrally Planned Asia and Other.
Second Assessment Report (SAR) [7, 8, 9]	1995	*Climate*: Gridded proportional circle maps for observed climate trends (5° latitude/ longitude); climate projections for 7 sub-continental regions
		Impacts, Adaptations, Mitigation: Energy production statistics by 10 world regions; Forests, Wood Production and Management by three zones: Tropical, Temperate, Boreal; separate chapters by physiographic types: Deserts, Mountain Regions, Wetlands, Cryosphere, Oceans, and Coastal Zones and small islands; country case studies, Agriculture by 8 continental-scale regions; Energy supply by 8 world regions
		Economic and Social Dimensions: Social Costs and Response Options by 6 economic regions
SR: *Regional Impacts* [10]	1998	10 continental-scale regions: Africa, Arctic and Antarctic, Australasia, Europe, Latin America, Middle East and Arid Asia, North America, Small Island States, Temperate Asia, Tropical Asia. Subdivisions applied in some regions; Vegetation shifts mapped by 9 biomes; Baseline (1990) Socio-Economic data provided by country and for all regions except polar.
SR: *Land-Use Change and Forestry* [11]	1998	9 Biomes; 15 land-use categories; National and Regional case studies.
SR: *Aviation* [12]	1999	Observed and projected emissions by 22 regional air routes; Inventories by 5 economic regions
SR: *Technology Transfer* [13]	2000	Country case studies; Indicators of technology transfer by 6-7 economic regions
SR: *Emissions Scenarios* [14]	2000	4 SRES world regions defined in common across integrated assessment models; 11 sub-regions; Driving Factors by 6 continental regions
Third Assessment Report (TAR) [15, 16, 17]	2001	*Climate*: gridded observations of Climate trends; 20 example Glaciers; 9 Biomes for Carbon Cycle; Circulation Regimes for model evaluation; 23 "Giorgi" regions for regional climate projections
		Impacts, adaptation and vulnerability: Example projections from 32 "modified-Giorgi" regions; Basins by continent; 5 Coastal types; Urban/Rural Settlements; Insurance by economic regions; 8 continental-scale regions equivalent to 1998 Special report but with single chapter for Asia; Subdivisions used for each region (Africa, Asia and Latin America by climate zones; North America by 6 core regions and 3 border regions)
		Mitigation: Country examples; Developed (Annex I) and Developing (non-Annex I); Various economic regions; Policies, Measures and Instruments by 4 blocs: OECD, Economies in Transition, China and Centrally Planned Asia, and Rest of the World.
SR: *Ozone Layer* [18]	2005	Various economic regions/countries depending on sources and uses of chemicals;
SR: *Carbon Capture and Storage* [19]	2005	CO_2 sources by 9 economic regions; potential storage facilities: by geological formation, by oil/gas wells, by ocean depth,; costs, by 4 economic groupings

Fourth Assessment Report (AR4) [20, 21, 22]	2007	*Climate*: Land-use types for surface forcing of climate; Observations by 19 "Giorgi" regions; Modes of variability for Model Evaluation; Attribution of climate change by 22 "Giorgi-type" regions and by 6 ocean regions; Climate statistics for 30 "Giorgi-type" regions; PDFs of projections for 26 regions; summary graphs for 8 continental regions
		Impacts, adaptation and vulnerability: Studies reporting observed impacts by 7 IPCC regions; comparison of TAR and AR4 climate projections for 32 Giorgi regions; Ecosystems by 11 biomes; Agriculture by latitudinal zone; Examples of Coastal mega-Deltas; Industry and settlement by continetal region; 8 continental regions, as in TAR, but Small Islands not Small Island States; Sub-regional summary maps for each region, using physiographic, biogeographic or geographic definitions; Example vulnerability maps at sub-national scale and globally by country.
		Mitigation: 17 global economic regions for GDP; Energy supply by continent, by economic regions, by 3 UNFCCC groupings; Trends in CO_2 emissions (and projections) , waste and carbon balance by economic regions.
SR*: Renewable Energy Sources and Climate Change Mitigation* [23]	2012	Global maps showing potential resources for renewable energy: land suitability for bioenergy production, global irradiance for solar, geoethermal, hydropower, ocean waves/tidal range, wind); Various economic/continental regions: installed capacity (realised vs. potential), types of technologies, investment cost, cost effectiveness, various scenario-based projections; Country comparisons of deployment and uptake of technologies, share of energy market.
SR*: Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation* [24]	2012	Trends in observed (tables) and projected (maps and tables) climate extremes (Tmax, Tmin, heat waves, heavy precipitation and dryness) by 26 sub-continental regions covering most land areas of the globe; Attribution studies of return periods of extreme temperatures for 15 "Giorgi-type" regions; Gridded global maps of projected extremes of temperature, precipitation, windspeed, dry spells and soil moisture anomalies; Continental-scale estimates of projected changes in impacts of extremes (floods, cyclones, coastal inundation) as well as frequencies of observed climate extremes and their estimated costs); Distinctions drawn between local, country and international/global actors with respect to risk management and its financing.
Fifth Assessment Report (AR5) [25, 26, 27]	2014	*Climate*: Gridded global maps of observed changes in climate; Cryosphere observations from 19 glacierized regions and 3 Arctic permafrost zones; Paleoclimatic reconstructions for 7 continental regions; CO_2 fluxes for 11 land and 10 ocean regions; Observed aerosol concentrations for 6 continental regions and projections for 9 regions; Detection and attribution of changes in mean and extreme climate for 7 continental and 8 ocean regions; Climate model evaluation and multi-model projections of extremes for 26 sub-continental regions; Maps and time series of seasonal and annual multi-model simulated climate changes for 19 sub-continental regions and global over 1900-2100.
		Impacts, adaptation and vulnerability – Part A Global and sectoral aspects: Gridded global maps of water resources, species distributions, ocean productivity; Global map of 51 ocean biomes; Detection and attribution of observed impacts, key risks and vulnerabilities and adaptation synthesis by IPCC regions. *Part B Regional aspects:* Nine continental-scale regions, eight as in AR4 plus the ocean; Sub-regions in Africa (5), Europe (5), Asia (6), Central and South America (5 or 7); Polar (2); Small Islands (4), Oceans (7); Other disaggregation by gridded maps or countries.
		Mitigation: Economic statistics by development (3 or 5 categories) or by income; 5 country groupings (plus international transport) for emission-related scenario analysis (RCP5: OECD 1990 countries, Reforming Economies, Latin America and Caribbean, Middle East and Africa, Asia) with further disaggregation to 10 regions (RCP10) for regional development; Land use regions for forest (13) and agriculture (11); Most other analyses by example countries.

1. IPCC (1990c); 2. IPCC (1990a); 3. IPCC (1990b); 4. IPCC (1992b); 5. IPCC (1992a); 6. IPCC (1994) 7. IPCC (1996c); 8. IPCC (1996b); 9. IPCC (1996a); 10. IPCC (1998b); 11. IPCC (1998a); 12. Table 21-3: Two possible entry points for thinking about vulnerability to climate change (illustrative and adapted from Füssel 2007).

Context	**Climate change impacts perspective**	**Vulnerability perspective**
Root problem	Climate change	Social vulnerability
Policy context	Climate change mitigation, compensation, technical adaptation	Social adaptation, sustainable development
Illustrative policy question	What are the benefits of climate change mitigation?	How can the vulnerability of societies to climatic hazards be reduced?
Illustrative research question	What are the expected net impacts of climate change in different regions?	Why are some groups more affected by climatic hazards than others?
Vulnerability and adaptive capacity	Adaptive capacity determines vulnerability	Vulnerability determines adaptive capacity
Reference for adaptive capacity	Adaptation to future climate change	Adaptation to current climate variability
Starting point of analysis	Scenarios of future climate change	Current vulnerability to climatic variabilty
Analytical function	Descriptive, positivist	Explanatory, normative
Main discipline	Natural science	Social science
Meaning of ‘vulnerability’	Expected net damage for a given level of global climate change	Susceptibility to climate change and variability as determined by socioeconomic factors
Vulnerability approach	Integrated, risk-hazard	Political economy
Reference	IPCC (2001a)	Adger (1999)

Table 21-4: Illustrative examples of adaptation experience, as well as approaches to reduce vulnerability and enhance resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerabilities, inequalities, and climate change come to the fore. At the same time, place-based examples illustrate how larger-level drivers and stressors shape differential risks and livelihood trajectories, often mediated by institutions.

Early warning systems for heat
EXPOSURE AND VULNERABILITY: Factors affecting exposure and vulnerability include age, pre-existing health status, level of outdoor activity, socioeconomic factors including poverty and social isolation, access to and use of cooling, physiological and behavioral adaptation of the population, urban heat island effects, and urban infrastructure. [8.2.3-4, 11.3.3-4, 11.4.1, 11.7, 13.2.1, 19.3.2, 23.5.1, 25.3, 25.8.1, SREX Table SPM.1]
CLIMATE INFORMATION AT THE GLOBAL SCALE: **Observed:** *Very likely* decrease in the number of cold days and nights and increase in the number of warm days and nights, on the global scale between 1951 and 2010. [WGI AR5 2.6.1] *Medium confidence* that the length and frequency of warm spells, including heat waves, has increased globally since 1950. [WGI AR5 2.6.1] **Projected:** *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 12.4.3]
CLIMATE INFORMATION AT THE REGIONAL SCALE: **Observed:** *Likely* that heat wave frequency has increased since 1950 in large parts of Europe, Asia, and Australia. [WGI AR5 2.6.1] *Medium confidence* in overall increase in heat waves and warm spells in North America since 1960. Insufficient evidence for assessment or spatially varying trends in heat waves or warm spells for South America and most of Africa. [SREX Table 3-2; WGI AR5 2.6.1] **Projected:** *Likely* that, by the end of the 21st century under RCP8.5 in most land regions, a current 20-year high temperature event will at least double its frequency and in many regions occur every two years or annually, while a current 20-year low temperature event will become exceedingly rare. [WGI AR5 12.4.3] *Very likely* more frequent and/or longer heat waves or warm spells over most land areas. [WGI AR5 12.4.3]
DESCRIPTION: Heat-health early warning systems are instruments to prevent negative health impacts during heat waves. Weather forecasts are used to predict situations associated with increased mortality or morbidity. Components of effective heatwave and health warning systems include identifying weather situations that adversely affect human health, monitoring weather forecasts, communicating heatwave and prevention responses, targeting notifications to vulnerable populations, and evaluating and revising the system to increase effectiveness in a changing climate. Warning systems for heat waves have been planned and implemented broadly, for example in Europe, the United States, Asia, and Australia. [11.7.3, 24.4.6, 25.8.1, 26.6, Box 25-6]
BROADER CONTEXT: •Heat health warning systems can be combined with other elements of a health protection plan, for example building capacity to support communities most at risk, supporting and funding health services, and distributing public health information. •In Africa, Asia, and elsewhere, early warning systems have been used to provide warning of and reduce a variety of risks, related to famine and food insecurity; flooding and other weather-related hazards; exposure to air pollution from fire; and vector-borne and food-borne disease outbreaks. [7.5.1, 11.7,15.4.2, 22.4.5, 24.4.6, 25.8.1, 26.6.3, Box 25-6]
Mangrove restoration to reduce flood risks and protect shorelines from storm surge
EXPOSURE AND VULNERABILITY : Loss of mangroves increases exposure of coastlines to storm surge, coastal erosion, saline intrusion, and tropical cyclones. Exposed infrastructure, livelihoods, and people are vulnerable to associated damage. Areas with development in the coastal zone, such as on small islands, can be particularly vulnerable. [5.4.3, 5.5.6, 29.7.2, Box CC-EA]
CLIMATE INFORMATION AT THE GLOBAL SCALE: **Observed:** *Likely* increase in the magnitude of extreme high sea level events since 1970, mostly explained by rising mean sea

level. [WGI AR5 3.7.5]
Low confidence in long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. [WGI AR5 2.6.3]
Projected: *Very likely* significant increase in the occurrence of future sea level extremes by 2050 and 2100. [WGI AR5 13.7.2]
In the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged.
Likely increase in both global mean tropical cyclone maximum wind speed and rainfall rates. [WGI AR5 14.6]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: Change in sea level relative to the land (relative sea level) can be significantly different from the global mean sea level change because of changes in the distribution of water in the ocean and vertical movement of the land. [WGI AR5 3.7.3]
Projected: *Low confidence* in region-specific projections of storminess and associated storm surges. [WGI AR5 13.7.2]
Projections of regional changes in sea level reach values of up to 30% above the global mean value in the Southern Ocean and around North America, and between 10% to 20% above the global mean value in equatorial regions. [WGI AR5 13.6.5]
More likely than not substantial increase in the frequency of the most intense tropical cyclones in the western North Pacific and North Atlantic. [WGI AR5 14.6]

DESCRIPTION:
Mangrove restoration and rehabilitation has occurred in a number of locations (e.g., Vietnam, Djibouti, and Brazil) to reduce coastal flooding risks and protect shorelines from storm surge. Restored mangroves have been shown to attenuate wave height and thus reduce wave damage and erosion. They protect aquaculture industry from storm damage and reduce saltwater intrusion. [2.4.3, 5.5.4, 8.3.3, 22.4.5, 27.3.3]

BROADER CONTEXT:
•Considered a low-regrets option benefiting sustainable development, livelihood improvement, and human well-being through improvements for food security and reduced risks from flooding, saline intrusion, wave damage, and erosion. Restoration and rehabilitation of mangroves, as well as of wetlands or deltas, is ecosystem-based adaptation that enhances ecosystem services.
•Synergies with mitigation given that mangrove forests represent large stores of carbon.
•Well-integrated ecosystem-based adaptation can be more cost effective and sustainable than non-integrated physical engineering approaches.
[5.5, 8.4.2, 14.3.1, 24.6, 29.3.1, 29.7.2, 30.6.1-2, Table 5-4, Box CC-EA]

Community-based adaptation and traditional practices in small island contexts

EXPOSURE AND VULNERABILITY:
With small land area, often low elevation coasts, and concentration of human communities and infrastructure in coastal zones, small islands are particularly vulnerable to rising sea levels and impacts such as inundation, saltwater intrusion, and shoreline change. [29.3.1, 29.3.3, 29.6.1-2, 29.7.2]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Likely* increase in the magnitude of extreme high sea level events since 1970, mostly explained by rising mean sea level. [WGI AR5 3.7.5]
Low confidence in long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. [WGI AR5 2.6.3]
Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]
Projected: *Very likely* significant increase in the occurrence of future sea level extremes by 2050 and 2100. [WGI AR5 13.7.2]
In the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged.
Likely increase in both global mean tropical cyclone maximum wind speed and rainfall rates. [WGI AR5 14.6]
Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: Change in sea level relative to the land (relative sea level) can be significantly different from the global mean sea level change because of changes in the distribution of water in the ocean and vertical movement of the land. [WGI AR5 3.7.3]
Projected: *Low confidence* in region-specific projections of storminess and associated storm surges. [WGI AR5 13.7.2]
Projections of regional changes in sea level reach values of up to 30% above the global mean value in the Southern Ocean and around North America, and between 10% to 20% above the global mean value in equatorial regions. [WGI AR5 13.6.5]
More likely than not substantial increase in the frequency of the most intense tropical cyclones in the western North Pacific and North Atlantic. [WGI AR5 14.6]

DESCRIPTION:

Traditional technologies and skills can be relevant for climate adaptation in small island contexts. In the Solomon Islands, relevant traditional practices include elevating concrete floors to keep them dry during heavy precipitation events and building low aerodynamic houses with palm leaves as roofing to avoid hazards from flying debris during cyclones, supported by perceptions that traditional construction methods are more resilient to extreme weather. In Fiji after cyclone Ami in 2003, mutual support and risk sharing formed a central pillar for community-based adaptation, with unaffected households fishing to support those with damaged homes. Participatory consultations across stakeholders and sectors within communities and capacity building taking into account traditional practices can be vital to the success of adaptation initiatives in island communities, such as in Fiji or Samoa. [29.6.2]

BROADER CONTEXT:

• Perceptions of self-efficacy and adaptive capacity in addressing climate stress can be important in determining resilience and identifying useful solutions.

•The relevance of community-based adaptation principles to island communities, as a facilitating factor in adaptation planning and implementation, has been highlighted, for example with focus on empowerment and learning-by-doing, while addressing local priorities and building on local knowledge and capacity. Community-based adaptation can include measures that cut across sectors and technological, social, and institutional processes, recognizing that technology by itself is only one component of successful adaptation.

[5.5.4, 29.6.2]

Adaptive approaches to flood defense in Europe

EXPOSURE AND VULNERABILITY :

Increased exposure of persons and property in flood risk areas has contributed to increased damages from flood events over recent decades.

[5.4.3-4, 5.5.5, 23.3.1, Box 5-1]

CLIMATE INFORMATION AT THE GLOBAL SCALE:

Observed: *Likely* increase in the magnitude of extreme high sea level events since 1970, mostly explained by rising mean sea level. [WGI AR5 3.7.5]

Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]

Projected: *Very likely* that the time-mean rate of global mean sea level rise during the 21st century will exceed the rate observed during 1971-2010 for all RCP scenarios. [WGI AR5 13.5.1]

Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:

Observed: *Likely* increase in the frequency or intensity of heavy precipitation in Europe, with some seasonal and/or regional variations. [WGI AR5 2.6.2] Increase in heavy precipitation in winter since the 1950s in some areas of northern Europe (*medium confidence*). Increase in heavy precipitation since the 1950s in some parts of west-central Europe and European Russia, especially in winter (*medium confidence*). [SREX Table 3-2]

Increasing mean sea level with regional variations, except in the Baltic sea where the relative sea level is decreasing due to vertical crustal motion. [5.3.2, 23.2.2]

Projected: Over most of the mid-latitude land-masses, extreme precipitation events will *very likely* be more intense and more frequent in a warmer world. [WGI AR5 12.4.5]

Overall precipitation increase in northern Europe and decrease in southern Europe (*medium confidence*). [23.2.2]

Increased extreme precipitation in northern Europe during all seasons, particularly winter, and in central Europe except in summer (*high confidence*). [23.2.2; SREX Table 3-3]

DESCRIPTION:

Several governments have made ambitious efforts to address flood risk and sea level rise over the coming century. In the Netherlands, government recommendations include “soft” measures preserving land from development to accommodate increased river inundation, maintaining coastal protection through beach nourishment, and ensuring necessary political-administrative, legal, and financial resources. Through a multi-stage process, the British government has also developed extensive adaptation plans to adjust and improve flood defenses in order to protect London from future storm surges and river flooding. Pathways have been analyzed for different adaptation options and decisions, depending on eventual sea level rise, with ongoing monitoring of the drivers of risk informing decisions. [5.5.4, 23.7.1, Box 5-1]

BROADER CONTEXT:

•The Dutch plan is considered a paradigm shift, addressing coastal protection by “working with nature” and providing “room for

river."
•The British plan incorporates iterative, adaptive decisions depending on the eventual sea level rise with numerous and diverse measures possible over the next 50-100 years to reduce risk to acceptable levels.
• In cities in Europe and elsewhere, the importance of strong political leadership or government champions in driving successful adaptation action has been noted.
[5.5.3-4, 8.4.3, 23.7.1-2, 23.7.4, Boxes 5-1 and 26-3]

Index-based insurance for agriculture in Africa

EXPOSURE AND VULNERABILITY:
Susceptibility to food insecurity and depletion of farmers' productive assets following crop failure. Low prevalence of insurance due to absent or poorly developed insurance markets or to amount of premium payments. The most marginalized and resource-poor especially may have limited ability to afford insurance premiums. [10.7.6, 13.3.2, Box 22-1]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Very likely* decrease in the number of cold days and nights and increase in the number of warm days and nights, on the global scale between 1951 and 2010. [WGI AR5 2.6.1]
Medium confidence that the length and frequency of warm spells, including heat waves, has increased globally since 1950. [WGI AR5 2.6.1]
Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]
Low confidence in a global-scale observed trend in drought or dryness (lack of rainfall). [WGI AR5 2.6.2]
Projected: *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 12.4.3]
Regional to global-scale projected decreases in soil moisture and increased risk of agricultural drought are *likely* in presently dry regions, and are projected with *medium confidence* by the end of this century under the RCP8.5 scenario. [WGI AR5 12.4.5]
Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: *Medium confidence* in increase in frequency of warm days and decrease in frequency of cold days and nights in southern Africa. [SREX Table 3-2]
Medium confidence in increase in frequency of warm nights in northern and southern Africa. [SREX Table 3-2]
Projected: *Likely* surface drying in southern Africa by the end of this century under RCP8.5 (*high confidence*). [WGI AR5 12.4.5]
Likely increase in warm days and nights and decrease in cold days and nights in all regions of Africa (*high confidence*). Increase in warm days largest in summer and fall (*medium confidence*). [Table SREX 3-3]
Likely more frequent and/or longer heat waves and warm spells in Africa (*high confidence*). [Table SREX 3-3]

DESCRIPTION:
A recently introduced mechanism that has been piloted in a number of rural locations, including in Malawi, Sudan, and Ethiopia, as well as in India. When physical conditions reach a particular predetermined threshold where significant losses are expected to occur--weather conditions such as excessively high or low cumulative rainfall or temperature peaks--the insurance pays out. [9.4.2, 13.3.2, 15.4.4, Box 22-1]

BROADER CONTEXT:
•Index-based weather insurance is considered well-suited to the agricultural sector in developing countries.
•The mechanism allows risk to be shared across communities, with costs spread over time, while overcoming obstacles to traditional agricultural and disaster insurance markets. It can be integrated with other strategies such as micro-finance and social protection programs.
•Risk-based premiums can help encourage adaptive responses and foster risk awareness and risk reduction by providing financial incentives to policyholders to reduce their risk profile.
•Challenges can be associated with limited availability of accurate weather data and difficulties in establishing which weather conditions cause losses. Basis risk (i.e., farmers suffer losses but no payout is triggered based on weather data) can promote distrust. There can also be difficulty in scaling up pilot schemes.
•Insurance for work programs can enable cash-poor farmers to work for insurance premiums by engaging in community-identified disaster risk reduction projects.
[10.7.4-6, 13.3.2, 15.4.4, Table 10-7, Box 22-1, Box 25-7]

Relocation of agricultural industries in Australia
EXPOSURE AND VULNERABILITY : Crops sensitive to changing patterns of temperature, rainfall, and water availability. [7.3, 7.5.2]
CLIMATE INFORMATION AT THE GLOBAL SCALE: **Observed:** *Very likely* decrease in the number of cold days and nights and increase in the number of warm days and nights, on the global scale between 1951 and 2010. [WGI AR5 2.6.1] *Medium confidence* that the length and frequency of warm spells, including heat waves, has increased globally since 1950. [WGI AR5 2.6.1] *Medium confidence* in precipitation change over global land areas since 1950. [WGI AR5 2.5.1] Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2] *Low confidence* in a global-scale observed trend in drought or dryness (lack of rainfall). [WGI AR5 2.6.2] **Projected:** *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 12.4.3] *Virtually certain* increase in global precipitation as global mean surface temperature increases. [WGI AR5 12.4.1] Regional to global-scale projected decreases in soil moisture and increased risk of agricultural drought are *likely* in presently dry regions, and are projected with *medium confidence* by the end of this century under the RCP8.5 scenario. [WGI AR5 12.4.5] Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]
CLIMATE INFORMATION AT THE REGIONAL SCALE: **Observed:** Cool extremes rarer and hot extremes more frequent and intense over Australia and New Zealand, since 1950 (*high confidence*). [Table 25-1] *Likely* increase in heat wave frequency since 1950 in large parts of Australia. [WGI AR5 2.6.1] Late autumn/winter decreases in precipitation in Southwestern Australia since the 1970s and Southeastern Australia since the mid-1990s, and annual increases in precipitation in Northwestern Australia since the 1950s (*very high confidence*). [Table 25-1] Mixed or insignificant trends in annual daily precipitation extremes, but a tendency to significant increase in annual intensity of heavy precipitation in recent decades for sub-daily events in Australia (*high confidence*). [Table 25-1] **Projected:** Hot days and nights more frequent and cold days and nights less frequent during the 21st century in Australia and New Zealand (*high confidence*). [Table 25-1] Annual decline in precipitation over southwestern Australia (*high confidence*) and elsewhere in southern Australia (*medium confidence*). Reductions strongest in the winter half-year (*high confidence*). [Table 25-1] Increase in most regions in the intensity of rare daily rainfall extremes and in sub-daily extremes (*medium confidence*) in Australia and New Zealand. [Table 25-1] Drought occurrence to increase in Southern Australia (*medium confidence*). [Table 25-1] Snow depth and snow area to decline in Australia (*very high confidence*). [Table 25-1] Freshwater resources projected to decline in far southeastern and far southwest Australia (*high confidence*). [25.5.2]
DESCRIPTION: Industries and individual farmers are relocating parts of their operations, for example for rice, wine, or peanuts in Australia, or are changing land use in situ in response to recent climate change or expectations of future change. For example, there has been some switching from grazing to cropping in South Australia. Adaptive movement of crops has also occurred elsewhere. [7.5.1, 25.7.2, Table 9-7, Box 25-5]
BROADER CONTEXT: •Considered transformational adaptation in response to impacts of climate change. •Positive or negative implications for the wider communities in origin and destination regions. [25.7.2, Box 25-5]

Table 21-5: Dimensions of assessments of impacts and vulnerability and of adaptation drawn upon to serve different target fields (cf. Table 21-1). Scales refer to the level of aggregation at which study results are presented. Entries are illustrations of different types of study approaches reported and evaluated in this volume, with references given both to the original studies and to the chapters in which they are cited. Aspects of some of the studies in this table are also alluded to in Section 21.5.

Approach/field: **Scale:**	**Impacts/vulnerability**	**Adaptation**	**Target field**
Global	Resource availability[1,2,3] Impact costs[4,5,6,7] Vulnerability/risk mapping[8,9,10] Hotspots analysis[11]	Adaptation costs[4,5,6,7,12]	- Policy negotiations - Development aid - Disaster planning - Capacity building
Continental/ biome	Observed impacts[13,14,15] Future biophysical impacts[16,17] Impact costs[5,16] Vulnerability/risk mapping[18]	Adaptation costs[5] Modelled adaptation[19]	- Capacity building - International law - Policy negotiations - Regional development
National/ state/province	Observed impacts[20,21,22] Future impacts/risks[23,24] Vulnerability assessment[24] Impact costs[25]	Observed adaptation[26] Adaptation assessment[24,27]	- National adaptation plan/strategy - Nat. Communication - Legal requirement - Regulation
Municipality/ basin/patch/ delta/farm	Hazard/risk mapping[28] Pest/disease risk mapping[29] Urban risks/vulnerabilities[30]	Adaptation cost[28] Urban adaptation[30,31]	- Spatial planning - Extension services - Water utilities - Private sector
Site/field/tree/ floodplain/ household	Field experiments[32]	Coping studies[33,34] Economic modelling[35] Agent-based modelling[36]	- Individual actors - Local planners

Table 21-7: An assessment of observed and projected future changes in temperature and precipitation extremes over 26 sub-continental regions as defined in the SREX report (IPCC 2012; see also Figure 21.4 and Table SM21.2). Confidence levels are indicated by colour coding of the symbols. Likelihood terms are given only for high confidence statements and are specified in the text. Observed trends in temperature and precipitation extremes, including dryness, are generally calculated from 1950, using the period 1961-1990 as a baseline (see Box 3.1 chapter 3 of IPCC (2012a)). The future changes are derived from global and regional climate model projections of the climate of 2071-2100 compared with 1961-1990 or 2080-2100 compared with 1980-2000. Table entries are summaries of information in Tables 3.2 and 3.3 of IPCC (2012a) supplemented with or superseded by material from Chapters 2 (section 2.6 and Table 2.13) and 14 (section 14.4) of the IPCC AR5 WG1 report and Table 25-1 of the IPCC WG2 report. The source(s) of information for each entry are indicated by the superscripts a (Table 3.2 of IPCC, 2012a), b (Table 3.3 of IPCC, 2012a), c (Chapter 2 (section 2.6 and Table 2.13) IPCC AR5 WG1 report), d (Chapter 14 (section 14.4) of the IPCC AR5 WG1 report) and e (Table 25-1 of the IPCC WG2 report).

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in nighttime temperature extremes (frequency of warm and cold nights)		Trends in heat waves/warm spells		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected
West North America WNA, 3	*Very likely* large increases in hot days (large decreases in cool days)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Very likely* large decreases in cold nights (large increases in warm nights)[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	Increase in warm spell duration[a]	*Likely* more frequent, longer and/or more intense heat waves and warm spells[b]	Spatially varying trends. General increase, decrease in some areas[a]	Increase in 20-year return value of annual maximum daily precipitation and other metrics over northern part of the region (Canada)[b] Less confidence in Southern part of the region, due to inconsistent signal in these other metrics[b]	No or overall slight decrease in dryness[a]	Inconsistent signal[b]
Central North America CNA, 4	Spatially varying trends: small increases in hot days in the north, decreases in the south[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends: Small increase in cold nights (and decreases in warm nights) in south and vice versa in the north[a]	*Very likely* increase in warm nights (decrease in cold nights[b]	Spatially varying trends[a]	*Likely* more frequent, longer and/or more intense heat waves and warm spells[b]	*Very likely* increase since 1950[a]	Increase in 20-year return value of annual maximum daily precipitation[b] Inconsistent signal in other heavy precipitation days metrics[b]	*Likely* decrease[a, c]	Increase in consecutive dry days and soil moisture in southern part of Central North America[b] Inconsistent signal in the rest of the region[b]
East North America ENA, 5	Spatially varying trends. Overall increases in hot days (decreases in cool days), opposite or insignificant signal in a few areas[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Weak and spatially varying trends[a]	*Very likely* increase in warm nights (decrease in cold nights[b]	Spatially varying trends, many areas with increase in duration, some areas with decrease[a]	*Likely* more frequent, longer and/or more intense heat waves and warm spells[b]	*Very likely* increase since 1950[a]	Increase in 20-year return value of annual maximum daily precipitation. Additional metrics support an increase in heavy precipitation over northern part of the region[b] No signal or inconsistent signal in these other metrics in the southern part of the region[b]	Slight decrease in dryness since 1950[a]	Inconsistent signal in consecutive dry days, some consistent decrease in soil moisture[b]
Alaska/ Northwest Canada ALA, 1	*Very likely* large increases in warm days (decreases in cold days)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Very likely* large decreases in cold nights, increases in warm nights[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent, and/or longer heat waves and warm spells[b]	Slight tendency for increase[a] No significant trend in southern Alaska[a]	*Likely* increase in heavy precipitation[b]	Inconsistent trends[a] Increases in dryness in part of the region[a]	Inconsistent signal[b]

Key

Symbols

- Increasing trend or signal
- Decreasing trend or signal
- Both increasing and decreasing trends or signals
- Inconsistent trend or signal or insufficient evidence
- No or only slight change

Level of confidence in findings

- Low confidence
- Medium confidence
- High confidence

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in nighttime temperature extremes (frequency of warm and cold nights)		Trends in heat waves/warm spells		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected
East Canada, Greenland, Iceland CGI, 2	*Likely* increases in hot days (decreases in cool days) in some areas, decrease in hot days (increase in cool days) in others[a]	*Very likely* increase in warm days (decrease in cold days)[b]	Small increases in unusually cold nights and decreases in warm nights in northeastern Canada[a] Small decrease in cold nights and increase in warm nights in south-eastern/central Canada[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	Some areas with warm spell duration increase, some with decrease[a]	*Likely* more frequent, and/or longer heat waves and warm spells[b]	Increase in a few areas[a]	*Likely* increase in heavy precipitation[b]	Insufficent evidence[a]	Inconsistent signal[b]
Northern Europe NEU, 11	Increase in hot days (decrease in cool days), but generally not significant at the local scale[a]	*Very likely* increase in hot days (decrease in cool days) [but smaller trends than in central and southern Europe][b]	Increase in warm nights (decrease in cold nights) over the whole region, but generally not significant at the local scale[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	Increase in heat waves. Consistent tendency for increase in heat wave duration and intensity, but no significant trend[a]	*Likely* more frequent, longer and/or more intense heat waves/ warm spells, but summer increases smaller than in southern Europe[b] Little change over Scandinavia[b]	Increase in winter in some areas, but often insignificant or inconsistent trends at subregional scale, particularly in summer[a]	*Likely* increase in 20-year return value of annual maximum daily precipitation. *Very likely* increases in heavy preciptation intensity and frequency in winter in the north[b]	Spatially varying trends. Overall only slight or no increase in dryness, slight decrease in dryness in part of the region[a]	No major changes in dryness[b]
Central Europe CEU, 12	*Likely* overall increase in hot days (decrease in cool days) since 1950 in most regions. *Very likely* increase in hot days (likely decrease in cool days) in west Central Europe[a] Lower confidence in trends in east Central Europe (due to lack of literature, partial lack of access to observations, overall weaker signals, and change point in trends)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Likely* overall increase in warm nights (decrease in cold nights) at the yearly timescale. Some regional and seasonal variations in significance and in a few cases sign of trends. *Very likely* increase in warm nights (decrease in cold nights) in west Central Europe[a] Lower confidence in trends in east Central Europe (due to lack of literature, partial lack of access to observations, overall weaker signals, and change point in trends)[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	Increase in heat waves. Consistent increase in heat wave duration and intensity, but no significant trend. Significant increase in maximum heatwave duration in west Central Europe in summer[a]	*Likely* more frequent, longer and/or more intense heat waves/ warm spells[b]	Increase in part of the region, in particular central Western Europe and European Russia, especially in winter[a] Insignificant or inconsistent trends elsewhere, in particular in summer[a]	*Likely* increase in 20-year return value of annual maximum daily precipitation. Additional metrics support an increase in heavy precipitation in large part of the region over winter[b] Less confidence in summer, due to inconsistent evidence[b]	Spatially varying trends. Increase in dryness in part of the region but some regional variation in dryness trends and dependence of trends on studies considered (index, time period)[a]	Increase in dryness in central Europe and increase in short-term droughts[b]
Southern Europe and Mediterra-nean MED, 13	*Likely* increase in hot days (decrease in cool days) in most of the region. Some regional and temporal variations in the significance of the trends. Likely strongest and most significant trends in Iberian peninsula and southern France[a] Smaller or less significant trends in southeastern Europe and Italy due to change point in trends, strongest increase in hot days since 1976[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease in cold nights) in most of the region. Some regional variations in the significance of the trends.Very likely overall increase in warm nights (decrease in cold nights in S.W. Europe/W. Mediterranean[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	*Likely* increase in most regions[a]	*Likely* more frequent, longer and/or more intense heat waves and warm spells (*likely* largest increases in SW, S and E of the region)[b]	Inconsistent trends across the region and across studies[a]	Inconsistent changes and/or regional variations[b]	Overall increase in dryness, *likely* increase in the Mediterranean[a,c]	Increase in dryness. Consistent increase in area of drought[b,d]

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in nighttime temperature extremes (frequency of warm and cold nights)		Trends in heat waves/warm spells		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected
West Africa WAF, 15	Significant increase in temperature of hottest day and coolest day in some parts[a] Insufficient evidence in other parts[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increasing frequency of warm nights. Decrease in cold nights in western central Africa, Nigeria, and Gambia[a] Insufficient evidence on trends in cold nights in other parts[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Insufficient evidence for most of the region[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Rainfall intensity increased[a]	Slight or no change in heavy precipitation indicators in most areas[b] Low model agreement in northern areas[b]	*Likely* increase but 1970s Sahel drought dominates the trend; greater inter- annual variation in recent years[a,c]	Inconsistent signal[b]
East Africa EAF, 16	Lack of evidence due to lack of literature and spatially non-uniform trends[a] Increases in hot days in Southern tip (decrease in cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends in most areas[a] Increases in warm nights in Southern tip (decrease in cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Insufficient evidence[a] Increase in warm spell duration in Southern tip of the region[a]	*Likely* Likely more frequent and/or longer heat waves and warm spells[b]	Insufficient evidence[a]	*Likely* increase in heavy precipitation[b]	Spatially varying trends in dryness[a]	Decreasing dryness in large areas[b]
Southern Africa SAF, 17	*Likely* increase in hot days (decrease in cool days)[a,c]	*Likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease in cold nights)[a,c]	*Likely* increase in warm nights (decrease in cold nights)[b]	Increase in warm spell duration[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Increases in more regions than decreases but spatially varying trends[a]	Lack of agreement in signal for region as a whole[b] Some evidence of increase in heavy precipitation in southeast regions[b]	General increase in dryness[a]	Increase in dryness, except eastern part[b,d] Consistent increase in area of drought[b]
Sahara SAH, 14	Lack of literature[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increase in warm nights[a] Lack of literature on trends in cold nights[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Insufficient evidence[a]	Low agreement[b]	Limited data, spatial variation of the trends[a]	Inconsistent signal of change[b]
Central America and Mexico CAM, 6	Increases in the number of hot days, decreases in the number of cool days[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increases in number of warm nights (decrease in number of cold nights)[a]	*Likely* increase in warm nights (*likely* decrease in cold nights)[b]	Spatially varying trends (increases in some areas, decreases in others)[a]	*Likely* more frequent, longer and/or more intense heat waves/ warm spells in most of the region[b]	Spatially varying trends. Increase in many areas, decrease in a few others[a]	Inconsistent trends[b]	Varying and inconsistent trends[a]	Increase in dryness in Central America and Mexico, with less confidence in trend in extreme South of region[b]
Amazon AMZ, 7	Insufficient evidence to identify trends[a]	Hot days *likely* to increase (cool days *likely* to decrease)[b]	Insufficient evidence to identify trends[a]	*Very likely* increase in warm nights (*likely* decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent and longer heat waves and warm spells[b]	Increases in many areas, decreases in a few[a]	Tendency for increases in heavy precipitation events in some metrics[b]	Decrease in dryness for much of the region. Some opposite trends and inconsistencies[a]	Inconsistent signals[b]
Northeastern Brazil NEB, 8	Increases in the number of hot days[a]	Hot days *likely* to increase (cool days *likely* to decrease)[b]	Increases in the number of warm nights[a]	*Likely* increase in warm nights (*likely* decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent and longer heat waves and warm spells in some studies[b]	Increases in many areas, decreases in a few[a]	Slight or no change[b]	Varying and inconsistent trends[a]	Increase in dryness[b]
Southeast-ern South America SSA, 10	Spatially varying trends (increases in some areas decreases in others)[a]	Hot days *likely* to increase (cool days *likely* decrease)[b]	Increases in number of warm nights (decreases in number of cold nights)[a]	*Very likely* increase in warm nights (*likely* decrease in cold nights)[b]	Spatially varying trends (increases in some areas, decreases in others)[a]	Tendency for more frequent and longer heat waves and warm spells[b]	Increases in northern areas[a] Insufficient evidence in southern areas[a]	Increases in northern areas[b] Insufficient evidence in southern areas[b]	Varying and inconsistent trends[a]	Inconsistent signals[b]
West Coast South America WSA, 9	Spatially varying trends (increases in some areas decreases in others)[a]	Hot days *likely* to increase (cool days *likely* decrease)[b]	Increases in number of warm nights (decreases in number of cold nights)[a]	*Likely* increase in warm nights (*likely* decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent and longer heat waves and warm spells[b]	Increases in many areas, decrease in a few areas[a]	Increases in tropics[b] Low confidence in extratropics[b]	Varying and inconsistent trends[a]	Decrease in consecutive dry days in the tropics, and increase in the extratropics[b] Increase in consecutive dry days and soil moisture in southwest South America[b]

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in nighttime temperature extremes (frequency of warm and cold nights)		Trends in heat waves/warm spells		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected	Observed	Projected
North Asia NAS, 18	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Spatially varying trends[a]	*Likely* more frequent and/or longer heat waves and warm spells[a]	Increase in some regions, but spatial variation[a]	*Likely* increase in heavy precipitation for most regions[b]	Spatially varying trends[a]	Inconsistent signal of change[b]
Central Asia CAS, 20	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Increase in warm spell duration in a few areas[a] Insufficient evidence in others[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Spatially varying trends[a]	Inconsistent signal in models[b]	Spatially varying trends[a]	Inconsistent signal of change[b]
East Asia EAS, 22	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increase in warm nights (decrease cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Increase heat wave in China[a] Increase in warm spell duration in northern China, decrease in southern China[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Spatially varying trends[a]	Increase in heavy precipitation across the region[b]	Tendency for increased dryness[a]	Inconsistent signal of change[b]
Southeast Asia SEA, 24	Increase in hot days (decrease cool days) for northern areas[a] Insufficient evidence for Malay Archipelago[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increase in warm nights (decrease cold nights) for northern areas[a] Insufficient evidence for Malay Archipelago[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent and/or longer heat waves and warm spells over continental areas[b] Low confidence in changes for some areas[b]	Spatially varying trends, partial lack of evidence[a]	Increases in most metrics over most (especially non-continental) regions. One metric shows inconsistent signals of change[b]	Spatially varying trends[a]	Inconsistent signal of change[b]
South Asia SAS, 23	Increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increase in warm nights (decrease in cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Insufficient evidence[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Mixed signal in India[a]	More frequent and intense heavy precipitation days over parts of S. Asia. Either no change or some consistent increases in other metrics[b]	Inconsistent signal for different studies and indices[a]	Inconsistent signal of change[b]
West Asia WAS, 19	*Very likely* increase in hot days (decrease in cool days *more likely than not*)[a]	*Likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease in cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Increase in warm spell duration[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Decrease in heavy precipitation events[a]	Inconsistent signal of change[b]	Lack of studies, mixed results[a]	Inconsistent signal of change[b]
Tibetan Plateau TIB, 21	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease cold nights)[a]	*Likely* increase in warm nights (decrease in cold nights)[b]	Spatially varying trends[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Insufficient evidence[a]	Increase in heavy precipitation[b]	Insufficient evidence. Tendency to decreased dryness[a]	Inconsistent signal of change[b]
North Australia NAU, 25	*Likely* increase in hot days (decrease in cool days). Weaker trends in northwest[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Likely* increase in warm nights (decrease in cold nights)[a]	*Very likely* increase in warm nights (decrease of cold nights)[b]	Insufficient literature[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Spatially varying trends, which mostly reflect changes in mean rainfall[e]	Increase in most regions in the intensity of extreme (i.e. current 20 year return period) heavy rainfall events[e]	No significant change in drought occurrence over Australia (defined using rainfall anomalies)[e]	Inconsistent signal[b]
South Australia/ New Zealand SAU, 26	*Very likely* increase in hot days (decrease in cool days)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Very likely* increase in warm nights (decrease in cold nights)[a]	*Very likely* increase in warm nights (decrease in cold nights)[b]	Increase in warm spells across southern Australia[a]	*Likely* more frequent and/or longer heat waves and warm spells[b]	Spatially varying trends in S Australia, which mostly reflect changes in mean rainfall[e] Spatially varying trends in NZ, which mostly reflect changes in mean rainfall[e]	Increase in most regions in the intensity of extreme (i.e. current 20 year return period) heavy rainfall events[e]	No significant change in drought occurrence over Australia (defined using rainfall anomalies)[e] No trend in drought occurrence over New Zealand (defined using a soil water balance model) since 1972[e]	Increase in drought frequency in southern Australia, and in many regions of New Zealand[e]

Table 21-8: Leading knowledge gaps and related research needs.

	Knowledge Gap	Research need
1	There is no clear understanding of how to integrate the diversity of climate change projections data. The full associated uncertainty is weakly characterized and quantifying how much of an observed or simulated climate change is due to internal variability or external forcings is difficult in many situations. Collectively this results in data products with differing time and space resolution, differing dependencies and assumptions and that can have conflicting messages. At present individual products are plausible and mostly defensible in-so-far as they have physical basis within the assumptions of the method. However, at decision-relevant scales understanding where (or whether) the true outcome will lie within the range of the products collectively is often not possible and thus the products are often not strongly actionable.	Research is needed to distinguish the relative stochastic and deterministic sources of variability and change as a function of scale, variable, and application. The need is to develop further and build on physical understanding of the drivers of climate variability and change and how to represent these realistically within models to understand the source of the spread and any contradictions in the regional projections at scales relevant to users –and then to provide guidance on a likely range of outcomes within which the true response would be expected to lie. Similarly, there is a need is to articulate the real inherent uncertainty within climate projection data and to understand when climate information is useful at the scales of need. This also requires stronger dialogues with users of climate information to inform choices of variables and ways to characterize envelopes of risk and uncertainties.
2.	The growth of multi-model, multi-method, and multi-generational data for climate projections creates confusion for the IAV community. The lack of a clear approach to handling this diversity leads to choosing one or other subset, and where one choice may substantially alter the IAV conclusion compared to a different subset.	Methodological and conceptual advances are needed to facilitate the synthesis of diverse data sets on different scales from methods with different assumptions, and to integrate these into cohesive and defensible understanding of projected regional change.
3	The attributes of regional climate change through which impacts are manifest, such as the intensity, persistence, distribution, recurrence, and frequency of weather events is poorly understood. The information conveyed to the adaptation community is dominated by aggregates in time and space (e.g. SREX regional averages, or time averages), which hide the important attributes underlying these aggregated changes. In part this is a consequence of (1) above.	The research need is to be able to demonstrate how to unpack the regional projections into terms relevant for impacts and adaptation. For example, how is the shape of the distribution of weather events changing (not just the extremes), or how stable are the critical global teleconnection patterns that contribute to the variability of a region?
4	The historical record for many regions, especially those regions most vulnerable to climate change, is poor to the extent that the historical record is at best an estimate with unknown uncertainty. This severely undermines the development of regional change analysis, limits the evaluation of model skill, and presents a weak baseline against which to assess change signals or to develop impacts, adaptation or vulnerability baselines.	The research need is to integrate the multiplicity of historical data as represented by the raw observations processed gridded products (e.g. CRU and GPCP), satellite data, and reanalysis data sets. Involving national scientists with their inherent local knowledge and rescue and digitization of the many national archives still inaccessible to the wider research community would significantly enhance this research activity.
5	Impact model sensitivity studies and inter-comparison exercises are beginning to reveal fundamental flaws and omissions in some impact models in the representation of key processes that are expected to be important under projected climate changes. For example, high temperature constraints, and CO2 and drought effects on agricultural yields are poorly represented in many crop models.	Intensified efforts are needed to refine, test and inter-compare impact models over a wider range of sectors and environments than hitherto. These should be supported, where applicable, by targeted field, chamber and laboratory experiments under controlled atmospheric composition and climate conditions, to improve understanding of key physical, biological and chemical processes operating in changed environments. Such experiments are needed across a range of terrestrial and aquatic biogeographical zones in different regions of the world

6	New global scenarios are under development, based on climate projections for different representative concentration pathways (RCPs) and socio-economic scenarios based on shared socio-economic pathways (SSPs). However, there is currently little or no guidance on how these projections are to be accessed or applied in IAV studies. Moreover, as yet, quantitative SSPs are available only for large regions (basic SSPs), and regional SSPs that are consistent with the global SSPs (extended SSPs) along with scenarios that include mitigation and adaptation policies (shared policy assumptions – SPAs) have not yet been developed.,	Extended SSPs for major sub-continental regions of the world, including variables that define aspects of adaptive capacity and guidance on how to combine RCP-based regional climate projections with regional SSPs and SPAs to form plausible regional scenarios for application in IAV analysis.
7	The determinants and regional variability of vulnerability, exposure and adaptive capacity are not well understood, and methods for projecting changes in them are under-developed. Furthermore, given these lacks of understanding uncertainties of these three elements are poorly characterized and quantified	Case studies and underlying theory of these features of societies, and documentation of the effectiveness of actions taken are needed in conjunction with methods development for projections. More attention placed on determining their uncertainties, in national and regional assessments.

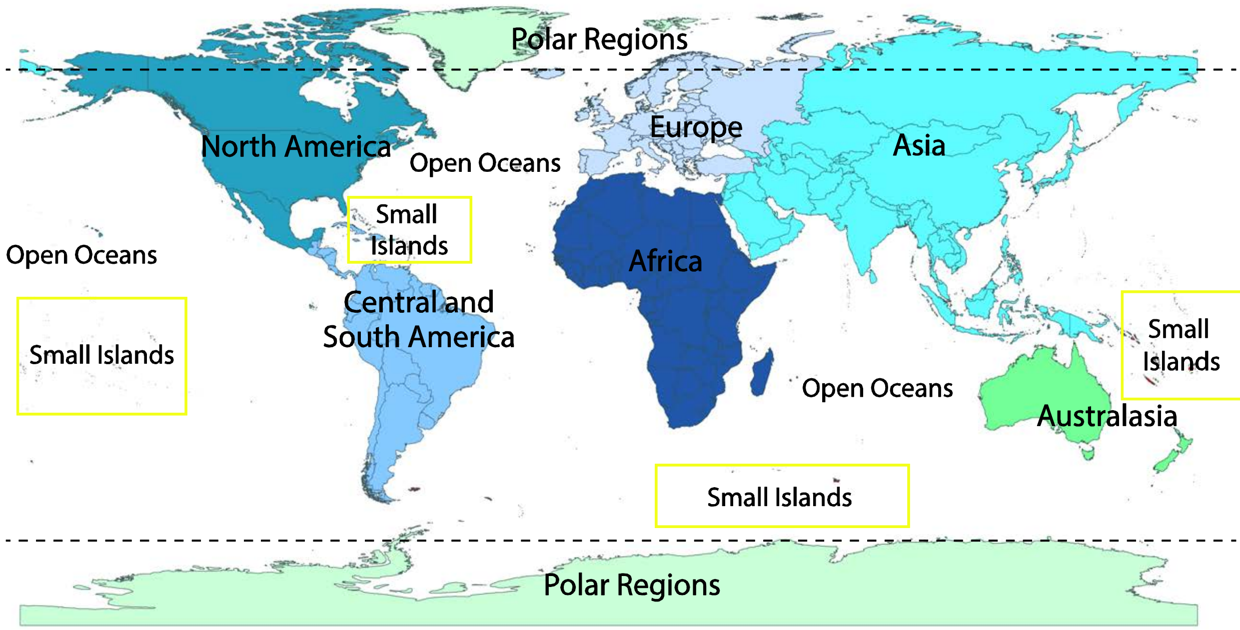

Figure 21-1: Specification of the world regions described in chapters 22-30 of this volume.
[Illustration to be redrawn to conform to IPCC publication specifications.]

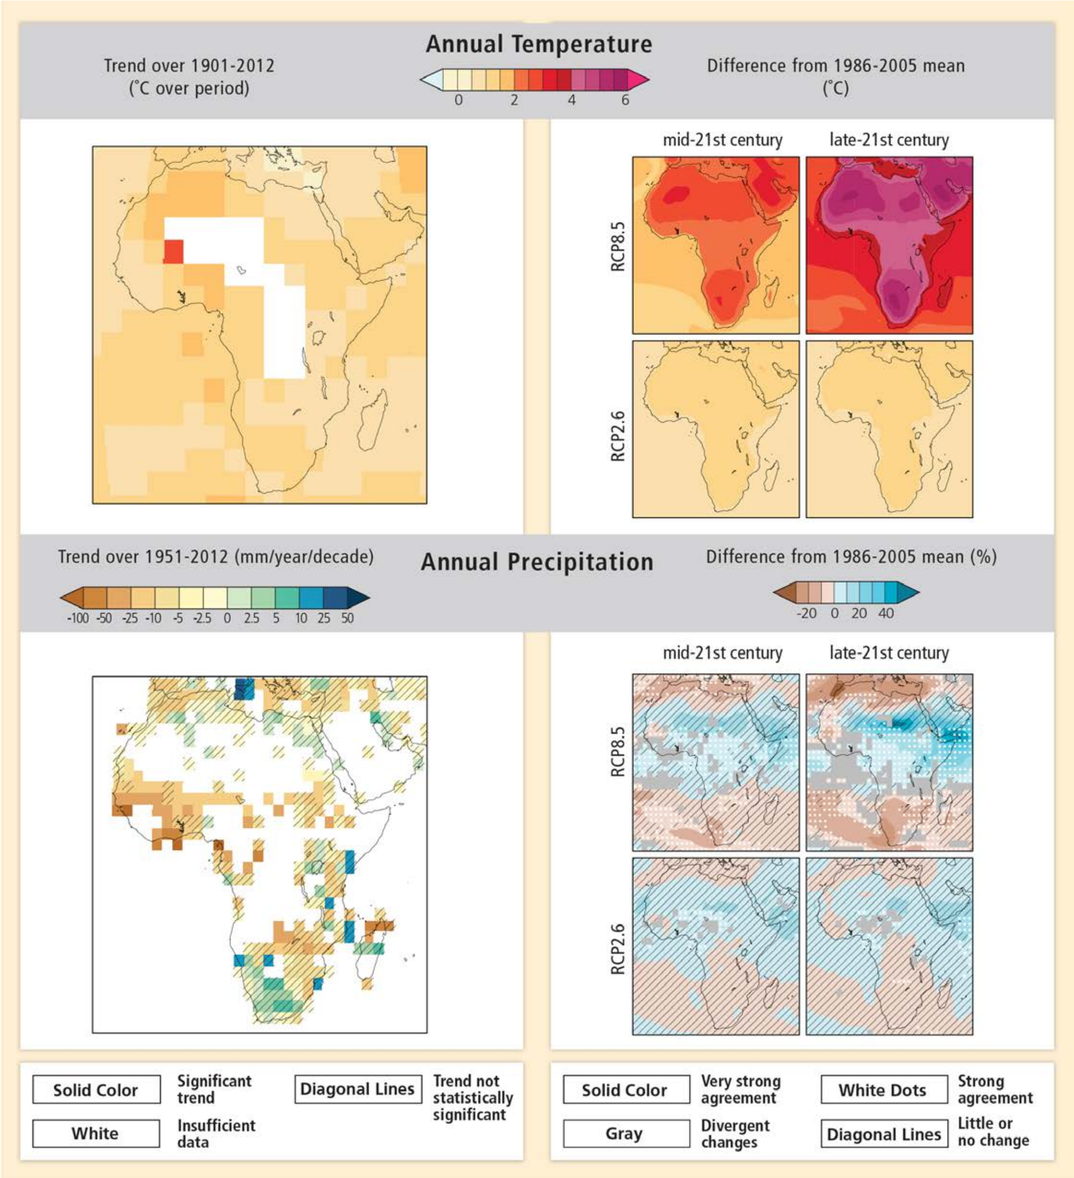

Figure 21-2: Observed and projected changes in annual average temperature and precipitation. (Top panel, left) Observed temperature trends from 1901-2012 determined by linear regression. [WGI AR5 Figures SPM.1 and 2.21] (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression. [WGI AR5 Figure SPM.2] For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See alsoAnnex I of WGI AR5. [Boxes 21-3 and CC-RC]

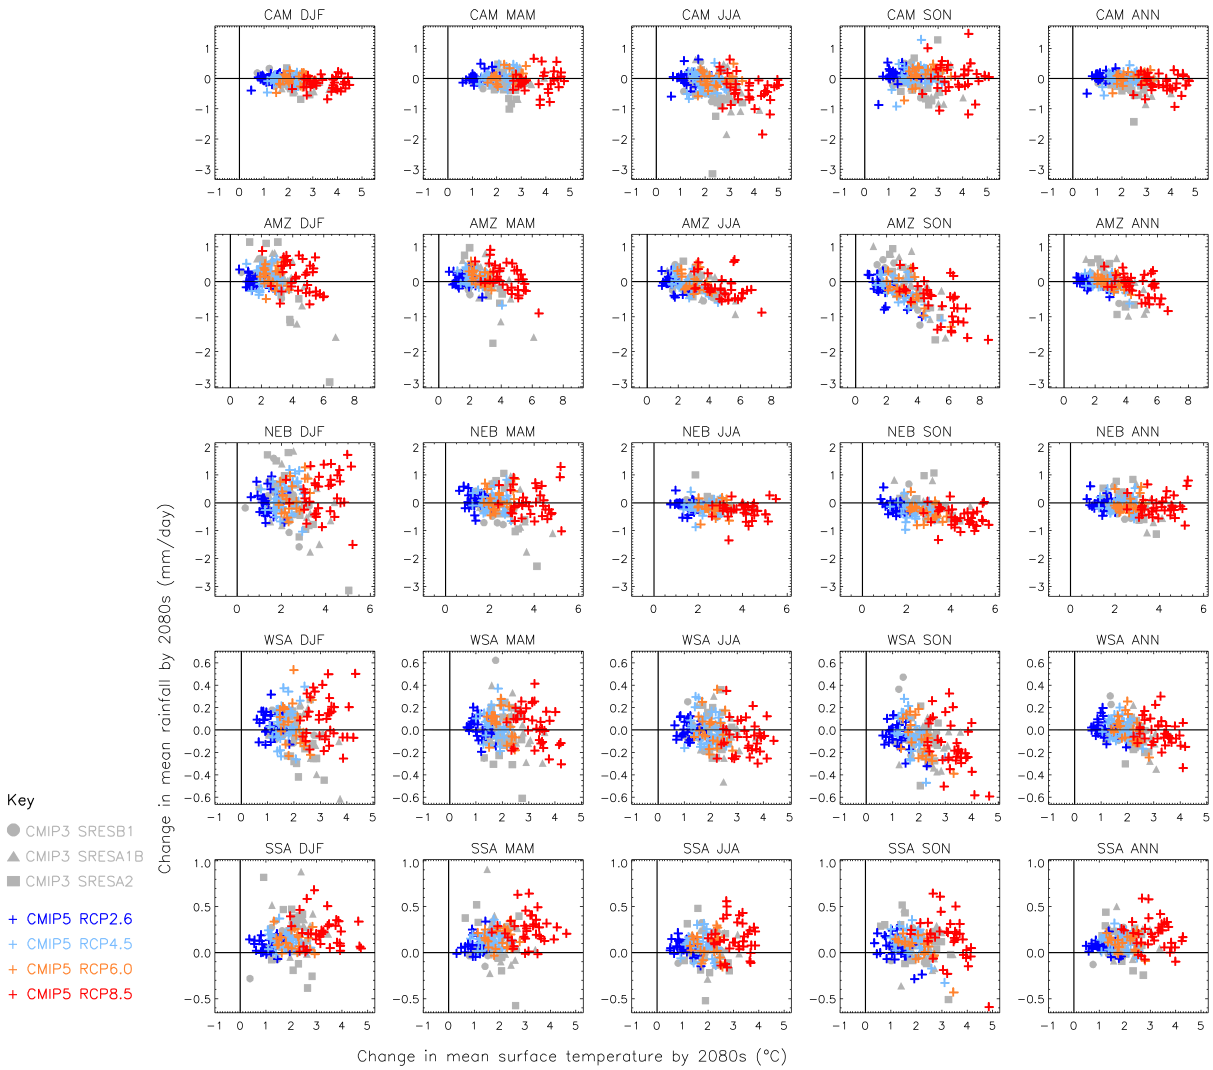

Figure 21-3: Regional average change in seasonal and annual mean temperature and precipitation over five sub-regions covering South and Central America for the period 2071-2100 relative to 1961-90 in GCM projections from 35 CMIP5 ensemble under four RCP scenarios (van Vuuren et al., 2011) compared with GCM projections from 22 CMIP3 ensemble under three SRES scenarios (IPCC, 2000); see Table 21-1 for details of the relationship between the SRES and RCP scenarios. Regional averages are based on SREX region definitions (see Figure 21-3). Temperature changes are given in ºC and precipitation changes in mm/day with axes scaled relative to the maximum changes projected across the range of models. The models which generated the data displayed are listed in supplementary material Table SM21-3.

[Illustration to be redrawn to conform to IPCC publication specifications.]

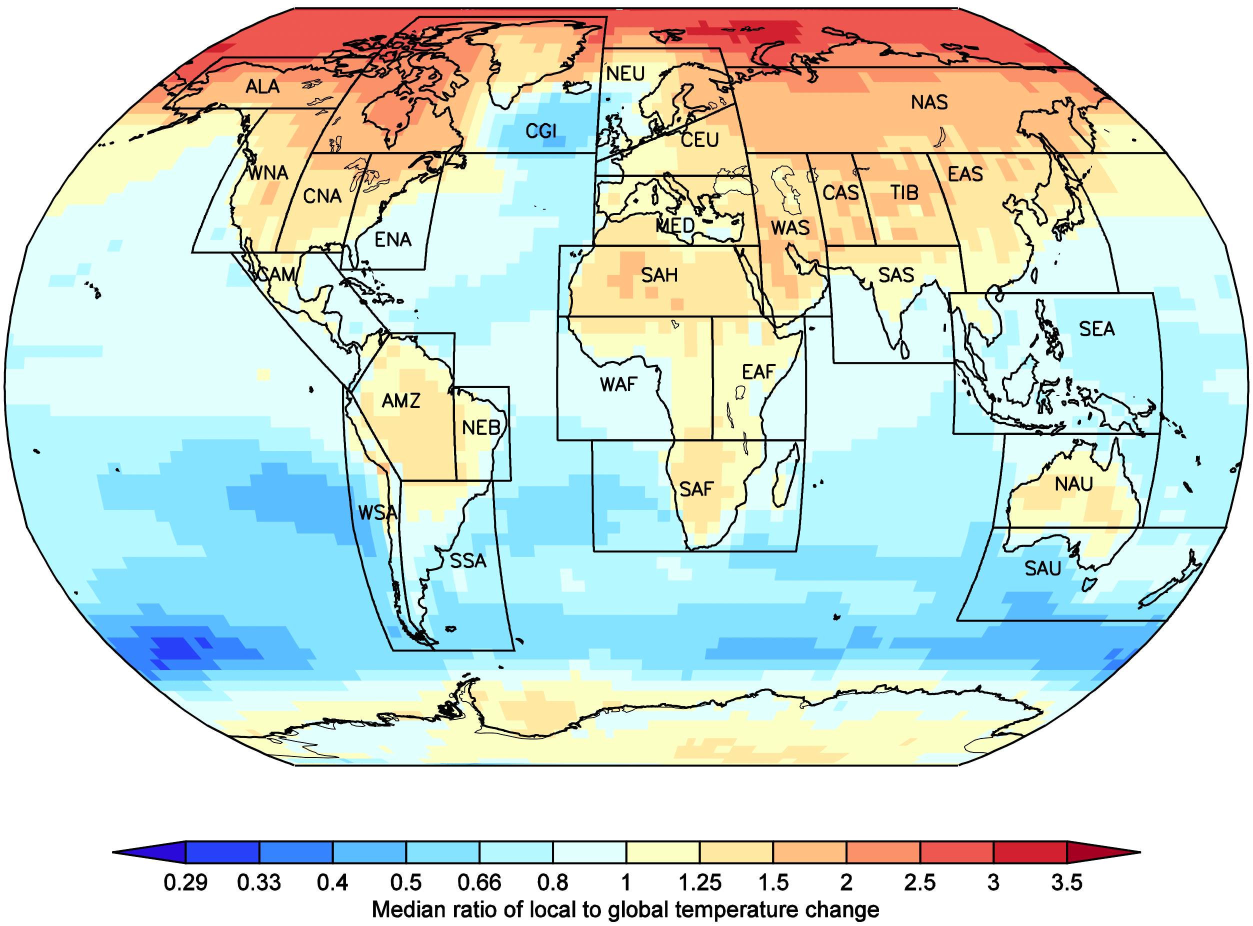

Figure 21-4: CMIP5 ensemble median ratio of local:global average temperature change in the period 2071-2100 relative to 1961-90 under the RCP8.5 emissions/concentrations scenario. The values are displayed on a common 2.5ºx3.75º grid onto which each models' data were regridded and they were calculated as follows: 1) for each model the local change was calculated between 1961 and 1990 at each grid cell, and is divided by the global average change in that model projection over the same period; 2) the median ratio value across all models at each grid cell is identified and shown. Data used are from the 35 CMIP5 models for which monthly projections were available under RCP8.5 which are listed in supplementary Table 21-3. Overplotted polygons indicate the SREX regions (IPCC, 2012) used to define the sub-regions used to summarise information in Chapters 21 and some of the subsequent regional chapters**. [Illustration to be redrawn to conform to IPCC publication specifications.]**

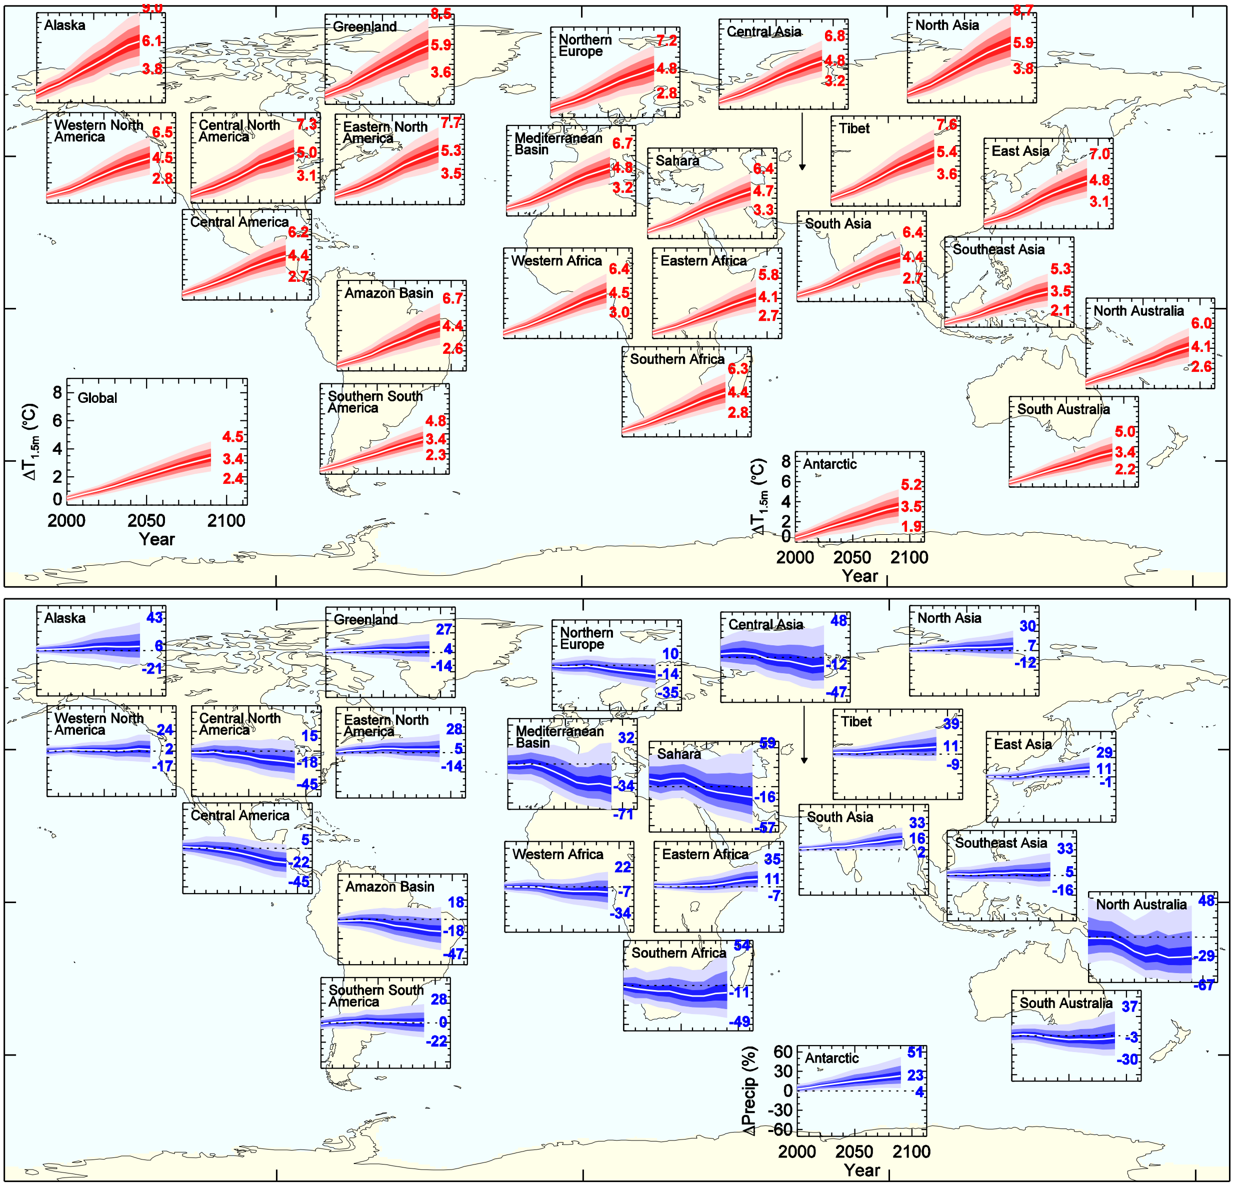

Figure 21-5: Evolution of the 5%, 17%, 33%, 50%, 66%, 83% and 95% percentiles of the distribution functions for annual surface air temperature changes (upper panel) and annual precipitation (lower panel) for the Giorgi-Francisco (2000) regions and the globe with the SRES A1B forcing scenario combining results from a perturbed physics ensemble and the CMIP3 ensemble. Twenty year means relative to the 1961-1990 baseline are plotted in decadal steps using a common y-axis scale. The 5%, 50% and 95% percentile values for the period 2080-2099 are displayed for each region. (From Harris et al. 2012).

[Illustration to be redrawn to conform to IPCC publication specifications.]

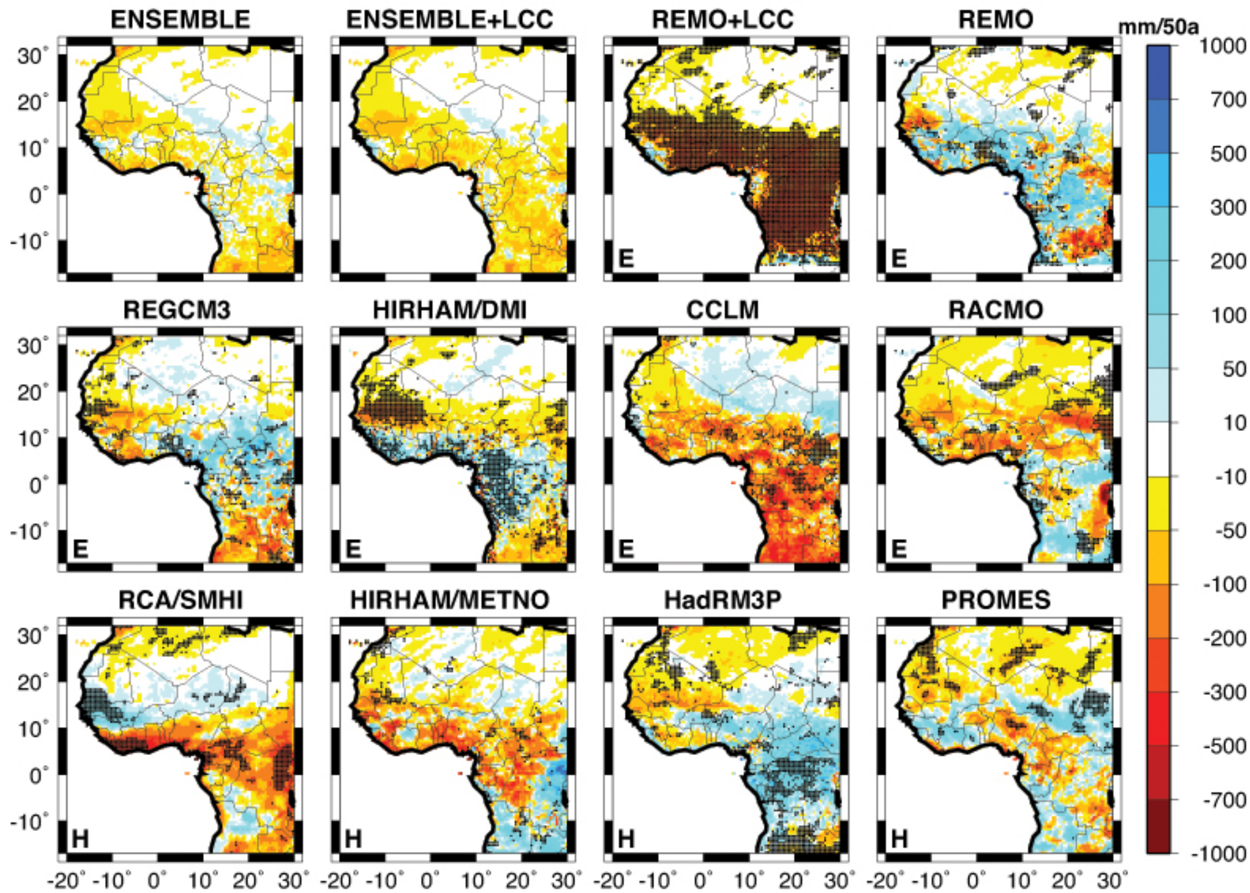

Figure 21-6: Linear changes (i.e. changes obtained by fitting the time series at each grid point with straight lines) of annual precipitation during the 2001-2050 period from 10 individual RCM experiments and the MME mean under the A1B emission scenario. The top middle panels also account for projected land cover changes (see Paeth et al. 2011 for further explanation). Note that the REMO trends in both panels arise from a three-member ensemble whereas all other RCMs are represented by one single simulation. Trends statistically significant at the 95% level are marked by black dots. From Paeth et al. (2011).
[Illustration to be redrawn to conform to IPCC publication specifications.]

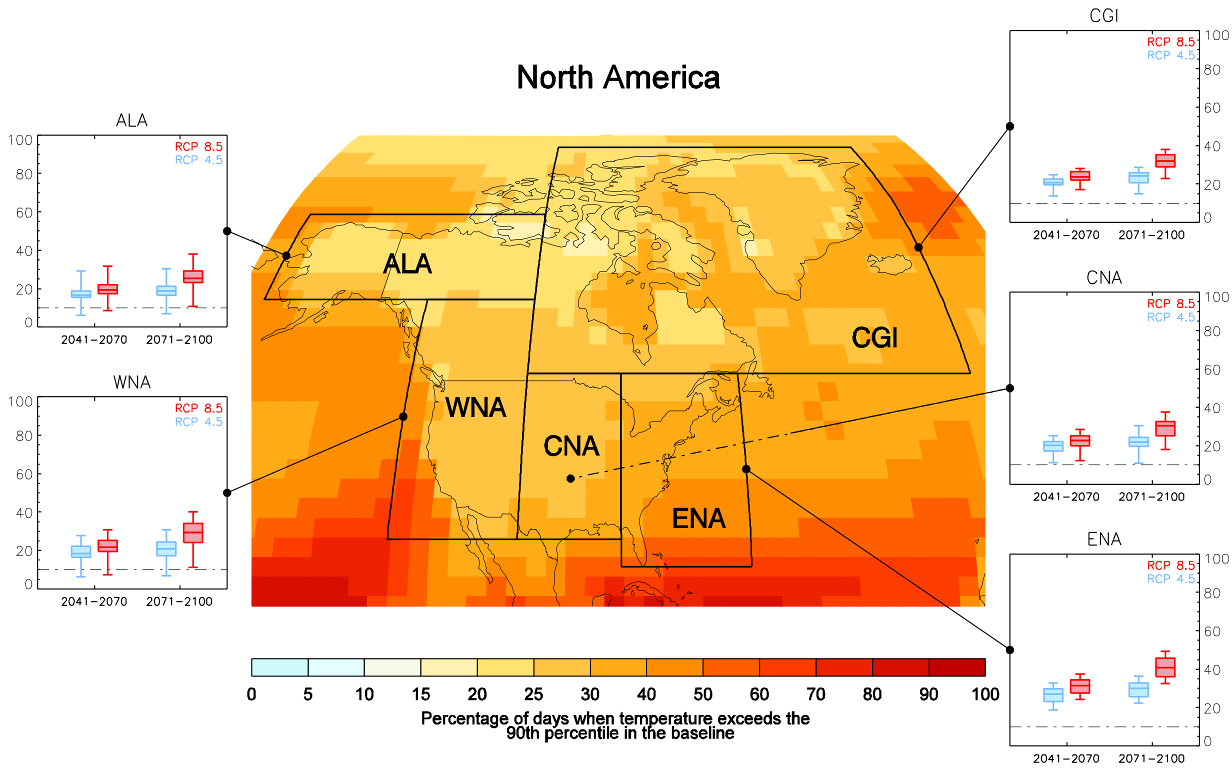

Figure 21-7: The frequency of 'warm days' (defined here as the 90th percentile daily maximum temperature during a baseline period of 1961-1990) projected for the 2071-2100 period by 26 CMIP5 GCMs for North America. Map: Ensemble median frequency of 'warm days' during 2071-2100 under RCP8.5. Graphs: Box-and-whisker plots indicate the range of regionally-averaged 'hot-day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5 across the 26 CMIP5 models for each SREX sub-regions in North America. Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of 'warm days' of 10% is represented on the graphs by the dashed line. A full list of CMIP5 models for which data is shown here can be found in supplementary material Table SM21-4.
[Illustration to be redrawn to conform to IPCC publication specifications.]

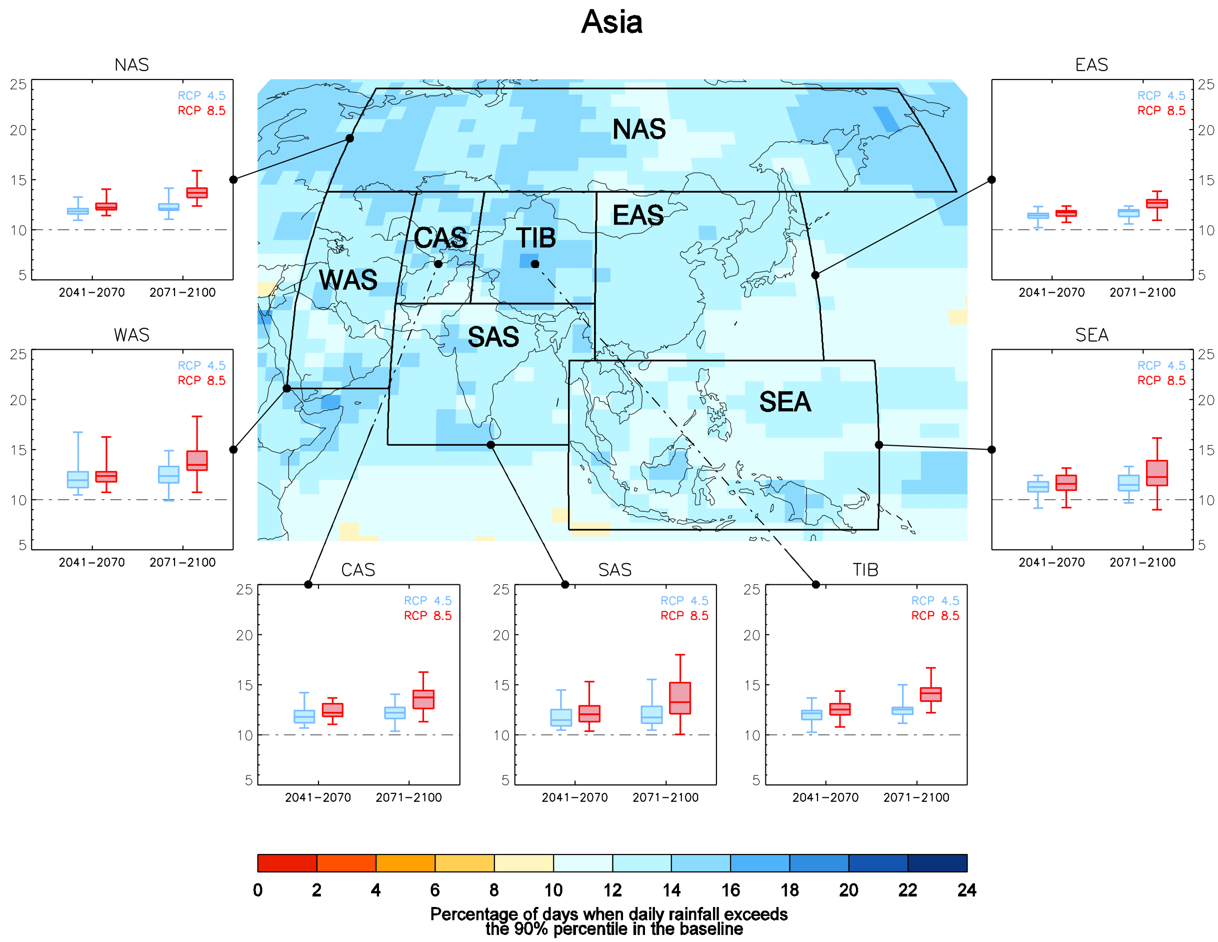

Figure 21-8: The frequency of 'very wet days' (defined here as the 90th percentile of daily precipitation on wet days during a baseline period of 1961-1990 with wet days defined as days with 1mm of precipitation or more) projected for the 2071-2100 period by 26 CMIP5 GCMs for Asia. Map: Ensemble median frequency of 'very wet days' during 2071-2100 under RCP8.5. Graphs: Box-and-whisker plots indicate the range of regionally-averaged 'very wet day' frequency by 2041-2070 and 2071-2100 under RCPs 4.5 and 8.5 across the 26 CMIP5 models for each SREX sub-regions in Asia Boxes represent inter-quartile range and whiskers indicate full range of projections across the ensemble. The baseline frequency of ‘Very wet days’ of 10% is represented on the graphs by the dashed line. A full list of CMIP5 models for which data is shown here can be found in supplementary material Table SM21-4. (Note the WMO Expert Team on Climate Change Detection Indices defines “very wet days” threshold as the 95%-ile daily precipitation event. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

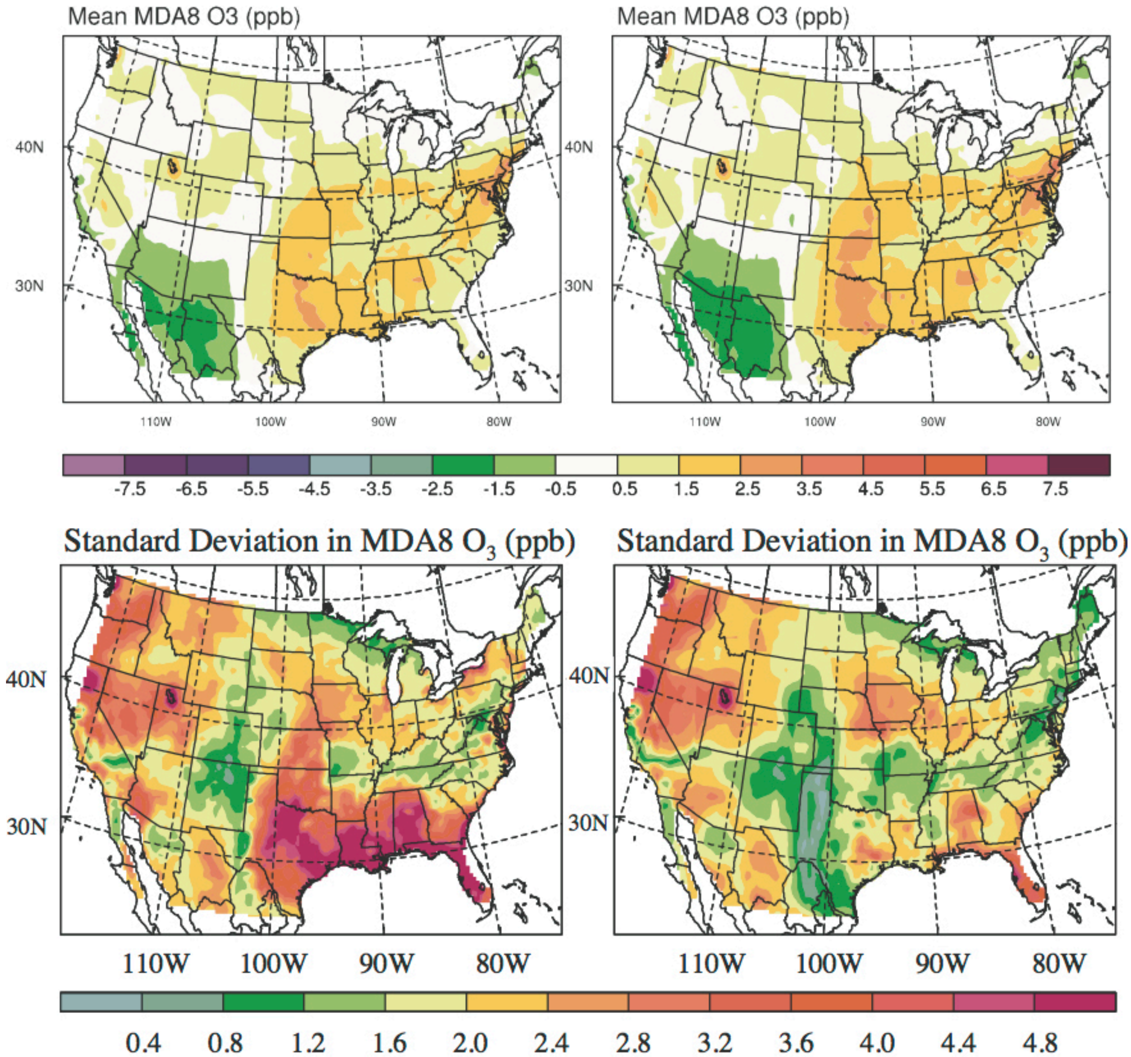

Figure 21-9: Mean (top panels) and standard deviation (bottom panels) in future-minus-present (2050s minus 1990s) MDA8 summer ozone concentrations across (left-hand panels) all seven experiments (five regional and 2 global) and for comparison purposes (right hand panels), not including the WSU experiment (which simulated July only conditions). The different experiments use different pollutant emission and SRES GHG emission scenarios. The pollutant emissions are the same in the present and future simulations (from Weaver et al., 2009).
[Illustration to be redrawn to conform to IPCC publication specifications.]

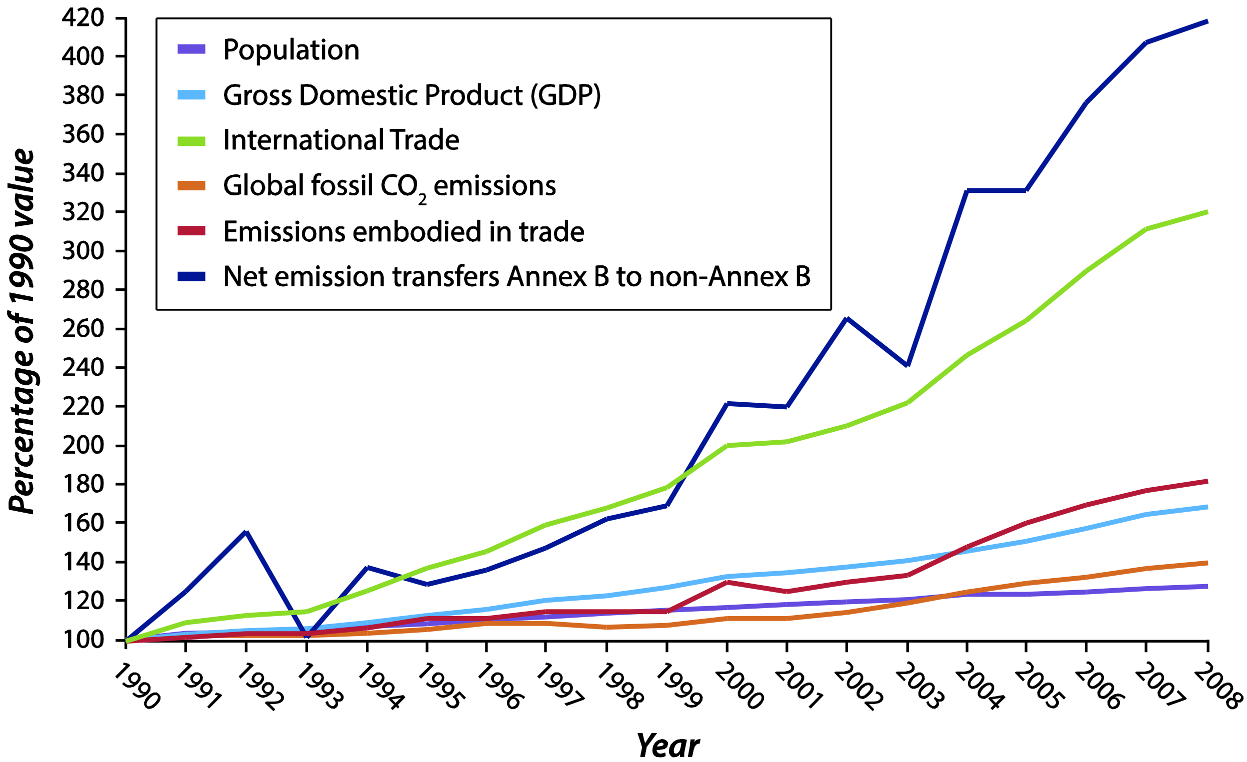

Figure 21-10: Growth rates from 1990-2008 of international trade, its embodied CO_2 emissions and net emissions transfers from Annex B and non-Annex B countries compared to other global macrovariables, all indexed to 1990 (Peters et al., 2011). Annex B and non-Annex B Parties to the UNFCCC are listed in the supplementary material. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

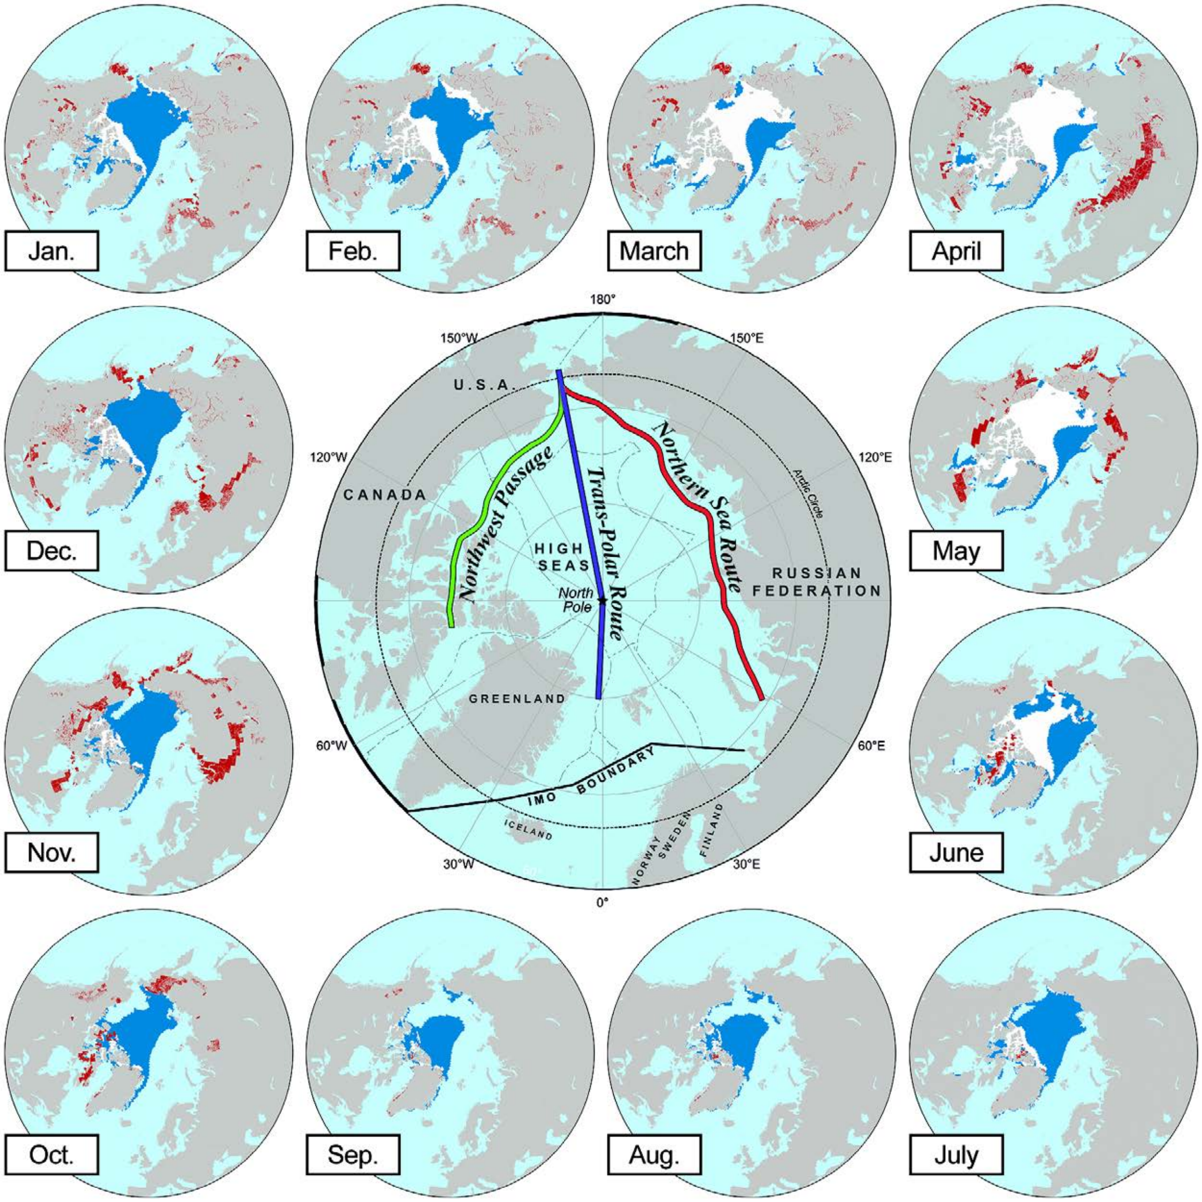

Figure 21-11: Central map: Marine exclusive environmental zones (EEZs – dashed lines) of Canada, Greenland/Denmark, Norway, Russia, and the USA, and location of the Northwest Passage, Northern Sea Route, Trans-Polar Route, and international high seas within the IMO Guidelines Boundary for Arctic shipping (thick black border). After Stephenson et al. (2013). Peripheral monthly maps: Projected change in accessibility of maritime and land-based transportation by mid-century (2045-2059 relative to 2000-2014) using the Arctic Transport Accessibility Model and CCSM3 climate and sea ice estimates assuming an SRES A1B scenario. Dark blue areas denote new maritime access to Polar Class 6 vessels (light icebreaker); white areas remain inaccessible. Red delimits areas of lost winter road potential for ground vehicles exceeding 2 metric tonnes (Stephenson et al., 2011).
[Illustration to be redrawn to conform to IPCC publication specifications.]

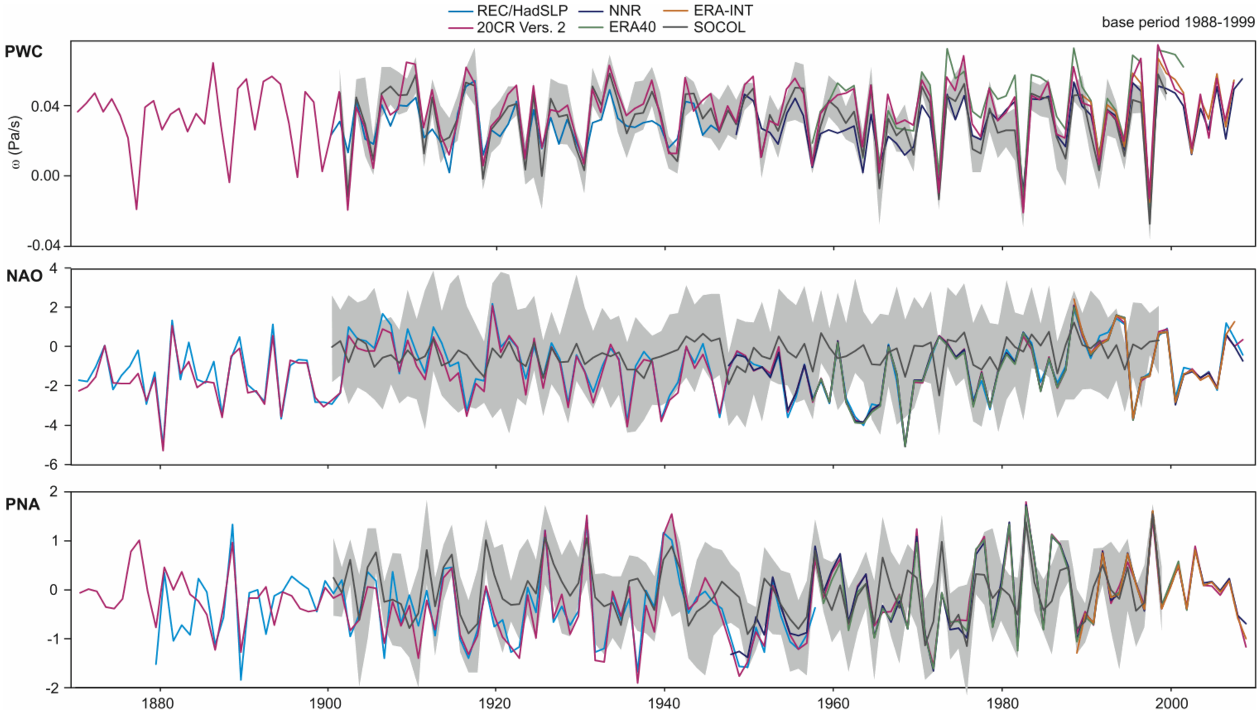

Figure 21-12: Time series of seasonally averaged climate indices representing three modes of large-scale climate variability: (a) the tropical September to January Pacific Walker Circulation (PWC); (b) the December to March North Atlantic Oscillation (NAO); (c) the December to March Pacific North America (PNA) pattern. Indices (as defined in Brönnimann etal. (2009) are calculated (with respect to the overlapping 1989–1999 period) from various observed, reanalysis and model sources: statistical reconstructions of the PWC, the PNA and the NAO, see Brönnimann et al. (2009) for details, (all cyan); 20CR (pink); NCEP–NCAR reanalyses (NNR; dark blue); ERA-40 (green); ERA-Interim (orange). The black line and grey shading represent the ensemble mean and spread from a climate model ensemble with a lower boundary condition of observed seas-surface temperatures and sea-ice from the HadISST dataset (Rayner et al. 2003), see Brönnimann etal. (2009) for details. The model results provide a measure of the predictability of these modes of variability from sea-surface temperature and sea-ice alone and demonstrate that the reanalyses have significantly higher skill in reproduces these modes of variability. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

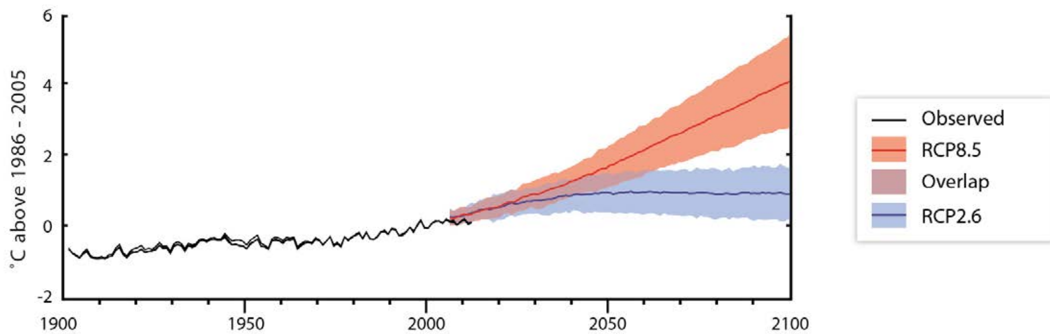

Figure RC-1: Observed and projected changes in global annual average temperature. Values are expressed relative to 1986-2005. Black lines show the GISTEMP, NCDC-MLOST, and HadCRUT4.2 estimates from observational measurements. Colored shading denotes the ±1.64 standard deviation range based on simulations from 32 models for RCP2.6 (blue) and 39 models for RCP8.5 (red). Blue and red lines denote the scenario mean for RCP2.6 and RCP8.5, respectively. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

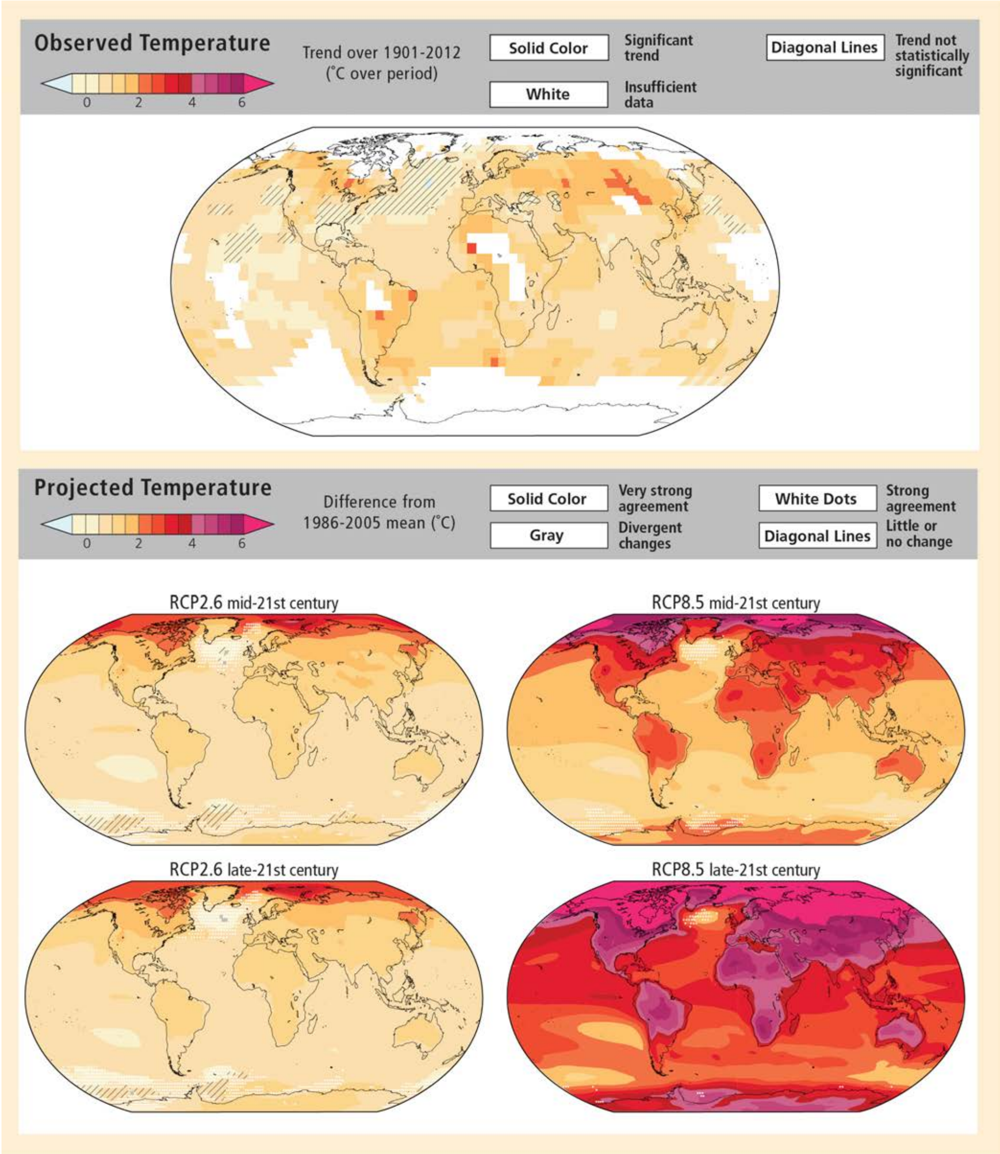

Figure RC-2: Observed and projected changes in annual average temperature. (A) Observed temperature trends from 1901-2012 are determined by linear regression. Trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level (after accounting for autocorrelation effects on significance testing). Diagonal lines indicate areas where change is not significant. Observed data are from WGI AR5 Figures SPM.1 and 2.21. The range of grid-point values is -0.53 to +2.50°C over period. (B) CMIP5 multi-model mean projections of annual average temperature changes for 2046-2065 and 2081-2100 under RCP2.6 and RCP8.5, relative to 1986-2005. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability and >90% of models agree on the sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on the sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on the sign of change. Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability (although there may be significant change at shorter timescales such as seasons, months, or days). Analysis uses model data from WGI AR5 Figure SPM.8, Box 12.1, and Annex I. The range of grid-point values for the multi-model mean is: +0.19 to +4.08˚C for mid-21st century of RCP2.6; +0.06 to +3.85˚C for late-21st century of RCP2.6; +0.70 to +7.04˚C for mid-21st century of RCP8.5; and +1.38 to +11.71°C for late-21st century of RCP8.5.

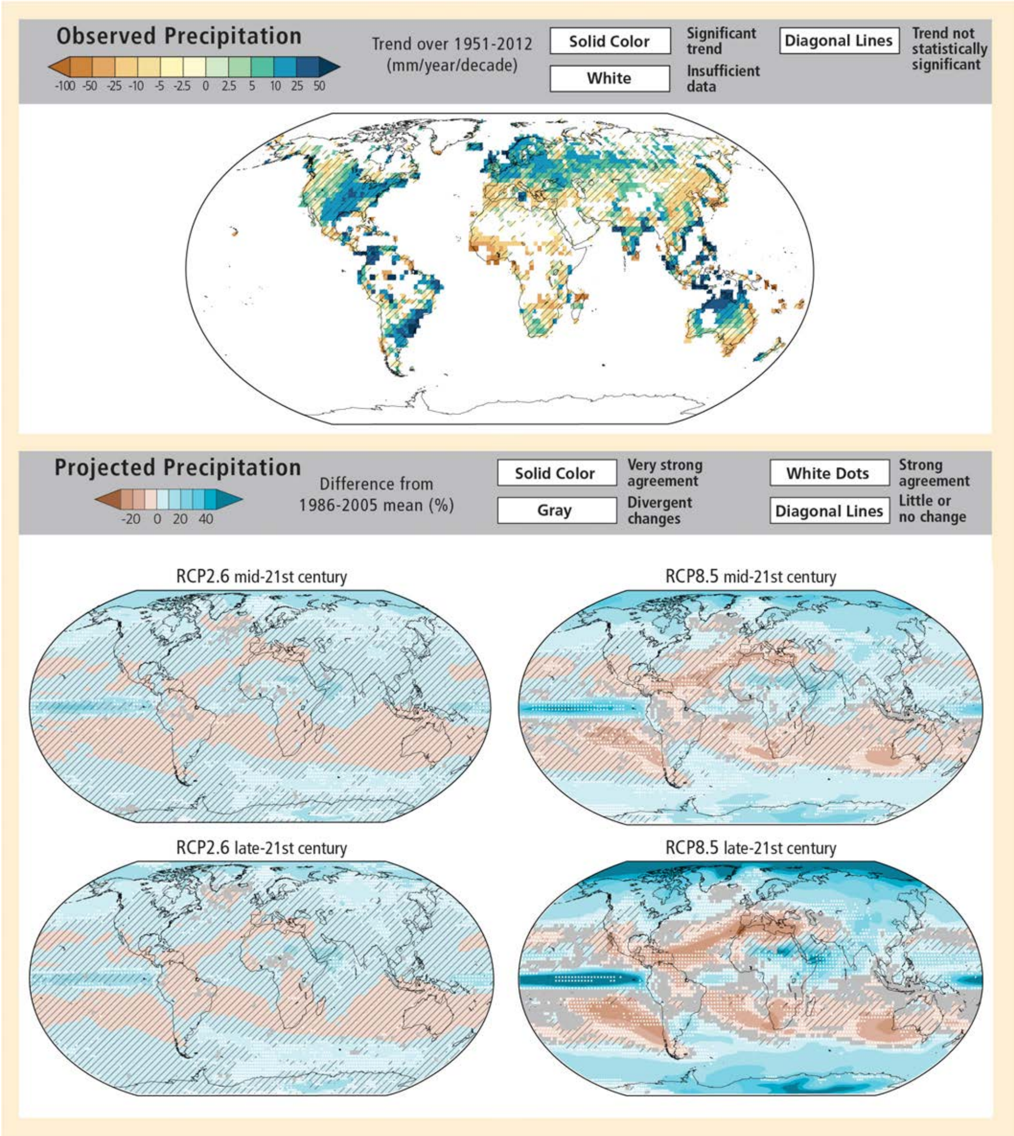

Figure RC-3: Observed and projected changes in annual average precipitation. (A) Observed precipitation trends from 1951-2010 are determined by linear regression. Trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level (after accounting for autocorrelation effects on significance testing). Diagonal lines indicate areas where change is not significant. Observed data are from WGI AR5 Figures SPM.2. The range of grid-point values is -185 to +111 mm/year/decade. (B) CMIP5 multi-model mean projections of annual average precipitation changes for 2046-2065 and 2081-2100 under RCP2.6 and RCP8.5, relative to 1986-2005. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability and >90% of models agree on the sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on the sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on the sign of change. Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability (although there may be significant change at shorter timescales such as seasons, months, or days). Analysis uses model data from WGI AR5 Figure SPM.8, Box 12.1, and Annex I. The range of grid-point values for the multi-model mean is: -10 to +24% for mid-21st century of RCP2.6; -9 to +22% for late-21st century of RCP2.6; -19 to +57% for mid-21st century of RCP8.5; and -34 to +112% for late-21st century of RCP8.5.

Frequently Asked Questions

Executive Summary

Evidence of warming over land regions across Africa, consistent with anthropogenic climate change, has increased (*high confidence*). Decadal analyses of temperatures strongly point to an increased warming trend across the continent over the last 50-100 years. [22.2.1.1]

Mean annual temperature rise over Africa, relative to the late 20th Century mean annual temperature, is *likely* to exceed 2° C in the A1B and A2 scenarios by the end of this century (*medium confidence*). Warming projections under medium scenarios indicate that extensive areas of Africa will exceed 2° C by the last two decades of this century relative to the late 20th Century mean annual temperature and all of Africa under high emission scenarios. Under a high RCP, that exceedence could occur by mid-century across much of Africa and reach between 3 and 6° C by the end of the century. It is *likely* that land temperatures over Africa will rise faster than the global land average, particularly in the more arid regions, and that the rate of increase in minimum temperatures will exceed that of maximum temperatures. [22.2.1.2]

A reduction in precipitation is *likely* over Northern Africa and the south-western parts of South Africa by the end of the 21st Century under the A1B and A2 scenarios (*medium to high confidence*). Projected rainfall change over sub-Sarahan Africa in the mid- and late 21st Century is uncertain. In regions of high or complex topography such as the Ethopian Highlands, downscaled projections indicate *likely* increases in rainfall and extreme rainfall by the end of the 21st Century. [22.2.2.2, 22.2.3]

African ecosystems are already being affected by climate change, and futre impacts are expected to be substantial (*high confidence*). There is emerging evidence on shifting ranges of some species and ecosystems due to elevated CO_2 and climate change, beyond the effects of land-use change and other non-climate stressors (*high confidence*). Ocean ecosystems, in particular coral reefs, will be affected by ocean acidification and warming as well as changes in ocean upwellings, thus negatively affecting economic sectors such as fisheries (*medium confidence*). [22.3.2, Table 22-3]

Climate change will amplify existing stress on water availability in Africa (*high confidence*). Water resources are subjected to high hydro-climatic variability over space and time, and are a key constraint on the continent’s continued economic development. The impacts of climate change will be superimposed onto already water-stressed catchments with complex land uses, engineered water systems, and a strong historical socio-political and economic footprint. Strategies that integrate land and water management, and disaster risk reduction, within a framework of emerging climate change risks would bolster resilient development in the face of projected impacts of climate change. [22.3.2.2, 22.3.3]

Climate change will interact with non-climate drivers and stressors to exacerbate vulnerability of agricultural systems, particularly in semi-arid areas (*high confidence*). Increasing temperatures and changes in precipitation are *very likely* to reduce cereal crop productivity. This will have strong adverse effects on food security. New evidence is also emerging that high-value perennial crops could also be adversely affected by temperature rise (*medium confidence*). Pest, weed and disease pressure on crops and livestock is expected to increase as a result of climate change combined with other factors (*low confidence*). Moreover, new challenges to food security are emerging as a result of strong urbanization trends on the continent and increasingly globalized food chains, which require better understanding of the multi-stressor context of food and livelihood security in both urban and rural contexts in Africa. [22.3.4, 22.3.4.3, 22.3.4.5]

Progress has been achieved on managing risks to food production from current climate variability and near-term climate change but these will not be sufficient to address long-term impacts of climate change (*high confidence*). Livelihood-based approaches for managing risks to food production from multiple stressors, including rainfall variability, have increased substantially in Africa since the IPCC's Fourth Assessment Report (AR4). While these efforts can improve the resiliency of agricultural systems in Africa over the near term, current adaptations will be insufficient for managing risks from long-term climate change, which will be variable across regions and farming system types. Nonetheless, processes such as collaborative, participatory research that includes scientists and farmers, strengthening of communication systems for anticipating and responding to climate risks, and increased flexibility in livelihood options, which serve to strengthen coping strategies in agriculture for near-term risks from climate variability, provide potential pathways for strengthening adaptive capacities for climate change. [22.4.5.4, 22.4.5.7, 22.4.6, 22.6.2]

Climate change may increase the burden of a range of climate-relevant health outcomes (*medium confidence*). Climate change is a multiplier of existing health vulnerabilities (*high confidence*) including insufficient access to safe water and improved sanitation, food insecurity, and limited access to health care and education. [22.3.5.1] Detection and attribution of trends is difficult because of the complexity of disease transmission, with many drivers other than weather and climate, and short and often incomplete datasets. Evidence is growing that highland areas, especially in East Africa, could experience increased malaria epidemics due to climate change (medium evidence, very high agreement). The strong seasonality of meningococcal meningitis and associations with weather and climate variability suggest the disease burden could be negatively affected by climate change (*medium evidence* and *high agreement*). The frequency of leishmaniasis epidemics in sub-Saharan Africa is changing, with spatial spread to peri-urban areas and to adjacent geographic regions, with possible contributions from changing rainfall patterns (*low confidence*). Climate change is projected to increase the burden of malnutrition *(medium confidence*), with the highest toll expected in children. [22.3.5.3]

In all regions of the continent, national governments are initiating governance systems for adaptation and responding to climate change, but evolving institutional frameworks cannot yet effectively co-ordinate the range of adaptation initiatives being implemented (*high confidence)*. Progress on national and sub-national policies and strategies has initiated the mainstreaming of adaptation into sectoral planning. [22.4.4] However, incomplete, under-resourced and fragmented institutional frameworks and overall low levels of adaptive capacity, especially competency at local government level, to manage complex socio-ecological change translate into a largely *ad hoc* and project-level approach, which is often donor-driven. [22.4.2, 22.4.4.3, 22.4.4.4] Overall adaptive capacity is considered to be low. [22.4.2] Disaster risk reduction, social protection, technological and infrastructural adaptation, ecosystem-based approaches and livelihood diversification are reducing vulnerability, but largely in isolated initiatives. [22.4.5] and most adaptation remain autonomous and reactive to short-term motivations. [22.4.3, 22.4.4.5]

Conservation agriculture provides a viable means for strengthening resilience in agroecosystems and livelihoods that also advance adaptation goals *(high confidence*). A wide array of conservation agriculture practices, including agroforestry and farmer-managed natural tree regeneration, conservation tillage, contouring and terracing, and mulching are being increasingly adopted in Africa. These practices strengthen resilience of the land base to extreme events and broaden sources of livelihoods, both of which have strongly positive implications for climate risk management and adaptation. Moreover, conservation agriculture has direct adaptation-mitigation co-benefits. Addressing constraints to broader adoption of these practices, such as land tenure/usufruct stability, access to peer-to-peer learning, gender-oriented extension and credit and markets, as well as identification of perverse policy incentives would help to enable larger scale transformation of agricultural landscapes. [22.4.5.6, 22.4.5.7, 22.4.6, 22.6.2]

Despite implementation limitations, Africa's adaptation experiences nonetheless highlight valuable lessons for enhancing and scaling up the adaptation response, including principles for good practice and integrated approaches to adaptation (*high confidence*). Five common principles for adaptation and building adaptive capacity can be distilled: (i) supporting autonomous adaptation through policy that recognises the multiple stressor nature of vulnerable livelihoods; (ii) increasing attention to the cultural, ethical, and rights considerations of adaptation by increasing the participation of women, youth and poor and vulnerable people in adaptation policy and implementation; [22.4.5] (iii) combining 'soft path' options and flexible and iterative learning approaches with technological and infrastructural approaches and blending scientific, local and indigenous knowledge when developing adaptation strategies; (iv) focusing on building resilience and implementing low-regrets adaptation with development synergies, in the face of future climate and socio-economic uncertainties; and (v) building adaptive management and social and institutional learning into adaptation processes at all levels. [22.4] Ecosystem-based approaches and pro-poor integrated adaptation-mitigation initiatives hold promise for a more sustainable and system-orientedapproach to adaptation, as does promoting equity goals, key for future resilience, through emphasising gender aspects and highly vulnerable groups such as children. . [22.4.2, 22.4.5.6, 22.6.2, Table 22-5]

Strengthened inter-linkages between adaptation and development pathways and a focus on building resilience would help to counter the current adaptation deficit and reduce future maladaptation risks (*high confidence*). [22.4.3] Development strategies are currently not able to counter current climate risks, as highlighted by the impacts of recent extreme events; national policies that disregard cultural, traditional and context-specific factors can act as barriers to local adaptation; and there is increased knowledge of maladaptation risks from narrowly conceived development interventions and sectoral adaptation strategies that decrease resilience in other sectors or ecosystems. [22.4.4, 22.4.6] Given multiple uncertainties in the African context, successful adaptation will depend upon building resilience. [22.4, 22.5, 22.6] Options for pro-poor adaptation/resilient livelihoods include improved social protection, social services and safety nets; better water and land governance and tenure security over land and vital assets; enhanced water storage, water harvesting and post-harvest services; strengthened civil society and greater involvement in planning; and more attention to urban and peri-urban areas heavily affected by migration of poor people. [22.4.2, 22.4.4, 22.4.5, 22.4.6]

Growing understanding of the multiple interlinked constraints on increasing adaptive capacity is beginning to indicate potential limits to adaptation in Africa (*medium confidence*). Climate change combined with other external changes (environmental, social, political, technological) may overwhelm the ability of people to cope and adapt, especially if the root causes of poverty and vulnerability are not addressed. Evidence is growing for the effectiveness of flexible and diverse development systems that are designed to reduce vulnerability, spread risk, and build adaptive capacity. These points indicate the benefits of new development trajectories that place climate resilience, ecosystem stability, equity and justice at the centre of development efforts. [22.4.6]

There is increased evidence of the significant financial resources, technological support and investment in institutional and capacity development needed to address climate risk, build adaptive capacity and implement robust adaptation strategies (*high confidence*). Funding and technology transfer and support isto both address Africa's current adaptation deficit and to protect rural and urban livelihoods, societies and economies from climate change impacts at different local scales. [22.4,] [22.6.4] Strengthening institutional capacities and governance mechanisms to enhance the ability of national governments and scientific institutions in Africa to absorb and effectively manage large amounts of funds allocated for adaptation, will assure the effectiveness of adaptation initiatives (*medium confidence*). [22.6.4]

Climate change and climate variability have the potential to exacerbate or multiply existing threats to human security including food, health and economic insecurity, all being of particular concern for Africa (*medium confidence*). [22.6.1, 22.6.1.1] Many of these threats are known drivers of conflict (*high confidence*). Causality between climate change and violent conflict is difficult to establish due to the presence of these and other interconnected causes, including country-specific sociopolitical, economic and cultural factors. For example, the degradation of natural resources as a result of both overexploitation and climate change will contribute to increased conflicts over the distribution of these resources. [22.6.1.1] Many of the interacting social, demographic and economic drivers of observed urbanization and migration in Africa are sensitive to climate change impacts. [22.6.1.2]

A wide range of data and research gaps constrain decisionmaking in processes to reduce vulnerability, build resilience and plan and implement adaptation strategies at different levels in Africa (*high confidence)*.

Overarching data and research gaps identified include data management and monitoring of climate parameters and development of climate change scenarios; monitoring systems to address climate change impacts in the different sectors; research and improved methodologies to assess and quantify the impact of climate change on different sectors and systems; and socio-economic consequences of the loss of ecosystems, of economic activities, of certain mitigation choices, such as biofuels, and of adaptation strategies. [22.7]

Of nine climate-related key regional risks identified for Africa, eight pose medium or higher risk even with highly adapted systems, while only one key risk assessed can be potentially reduced with high adaptation to below a medium risk level, for the end of the 21st century under 2°C global mean temperature increase above pre-industrial levels (*medium confidence*). Key regional risks relating to shifts in biome distribution, loss of coral reefs, reduced crop productivity, adverse effects on livestock, vector- and water-borne diseases, undernutrition, and migration are assessed as either medium or high for the present under current adaptation, reflecting Africa's existing adaptation deficit. [22.3.1, 22.3.2, 22.3.4, 22.3.5, 22.6.1.2] The assessment of significant residual impacts in a 2°C world at the end of the 21st century suggests that even under high levels of adaptation, there could be very high levels of risk for Africa. At a global mean temperature increase of 4°C, risks for Africa's food security (see key risks on livestock and crop production) are assessed as very high, with limited potential for risk reduction through adaptation. [22.3.4, 22.4.5, 22.5, Table 22-6]

22.1. Introduction

Africa as a whole is one of the most vulnerable continents due to its high exposure and low adaptive capacity Climate, ecology and political boundaries in Africa vary across the continent. Since the African Union, together with its Regional Economic Communities (RECs), are encharged of the adaptation policies we have used these divisions for regional assessment within the chapter.

22.1.1. Structure of the Regions

The African continent (including Madagascar) is the world's second largest and most populous continent (1,031,084,000 in 2010) behind Asia (UN DESA, 2013). The continent is organized at the regional level under the African Union (AU).[1] The AU's Assembly of Heads of State and Government has officially recognized eight Regional Economic Communities (RECs) (Ruppel, 2009). Except for the Sahrawi Arab Democratic Republic,[2] all AU member states are affiliated with one or more of these RECs. These RECs include the Arab Maghreb Union (AMU), with 5 countries in Northern Africa; the Community of Sahel-Saharan States (CEN-SAD), grouping 27 countries; the Common Market for Eastern and Southern Africa (COMESA), grouping 19 countries in Eastern and Southern Africa; the East African Community (EAC), with 5 countries; the Economic Community of Central African States (ECCAS), with 10 countries; the Economic Community of West African States (ECOWAS), with 15 countries; the Intergovernmental Authority on Development (IGAD) with 8 countries; and the Southern African Development Community (SADC), with 15 countries. The regional subdivision of African countries into REC's is a structure used by the AU and the New Partnership for Africa (NEPAD).

[FOOTNOTE 1: Due to the controversies regarding the Sahrawi Arab Democratic Republic, Morocco withdrew from the Organization of African Unity (OAU) in protest in 1984 and, since South Africa's admittance in 1994, remains the only African nation not within what is now the AU.]

[FOOTNOTE 2: Although the Sahrawi Arab Democratic Republic has been a full member of the OAU since 1984 and remains a member of the AU, the republic is not generally recognized as a sovereign state and has no representation in the UN.]

22.1.2. Major Conclusions from Previous Assessments

22.1.2.1. Regional Special Report and Assessment Reports

Refer to Table 22-1 for a brief summary of conclusions from previous IPCC assessments.

[INSERT TABLE 22-1 HERE
Table 22-1: Major conclusions from previous IPCC assessments.]

22.1.2.2. Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)

The Special Report of the IPCC on managing the risks of extreme events and disasters to advance climate change adaptation (IPCC, 2012) is of particular relevance to the African continent. There is *low* to *medium confidence* in historical extreme temperature and heavy rainfall trends over most of Africa because of partial lack of data, literature and lack of consistency of reported patterns in the literature (Seneviratne *et al.*, 2012). However, most regions within Africa for which data is available have recorded an increase in extreme temperatures (Seneviratne *et al.*, 2012). For projected temperature extreme there is *high confidence* that heat waves and warm spell durations will increase, suggesting an increased persistence of hot days (90^{th} percentile) toward the end of the century (Tebaldi *et al.*, 2006; Orlowsky and Seneviratne, 2012). There is *high confidence* for projected shorter extreme maximum temperature return periods across the B1, A1B and A2 scenarios for the near and far future as well as a reduction of the number of cold extremes (Seneviratne *et al.*, 2012). In East and southern Africa, there is *medium confidence* that droughts will intensify in the 21st Century in some seasons, due to reduced precipitation and/or increased evapotranspiration. There is *low confidence* in projected increases of heavy precipitation over most of Africa except over East Africa where there is a *high confidence* in a projected increase in heavy precipitation (Seneviratne *et al.*, 2012).

22.2. Observed Climate Trends and Future Projections

22.2.1. Temperature

22.2.1.1. Observed Trends

Near surface temperatures have increased by 0.5°C or more during the last 50-100 years over most parts of Africa with minimum temperatures warming more rapidly than maximum temperatures (Hulme *et al.*, 2001; Jones and Moberg, 2003; Kruger and Shongwe, 2004; Schreck and Semazzi, 2004; New *et al.*, 2006; IPCC, 2007; Rosenzweig *et al*., 2007; Trentberth *et al.*, 2007; Christy *et al.*, 2009; Collins 2011; Grab and Craparo, 2011; Hoffman *et al.*, 2011; Mohamed, 2011; Stern *et al.* 2011; Funk *et al*., 2012; Nicholson *et al.*, 2013). Near surface air temperature anomalies in Africa were significantly higher for the period 1995–2010 compared to the period 1979–1994 (Collins, 2011). Figure 22-1 shows that it is *very likely* that mean annual temperature has increased over the past century over most of the African continent, with the exception of areas of the interior of the continent where the data coverage has been determined to be insufficient to draw conclusions about temperature trends (Figure 22-1, Box CC-RC). There is strong evidence of an anthropogenic signal in continent-wide temperature increases in the 20th century (WGI 10.3.1; Stott, 2003; Min and Hense, 2007, Stott *et al.*, 2010; Stott *et al.*, 2011).

In recent decades North African annual and seasonal observed trends in mean near surface temperature indicates an overall warming that is significantly beyond the range of changes due to natural (internal) variability (Barkhordarian *et al*., 2012a). During the warm seasons (March-April-May, June-July-August) an increase in near surface temperature is shown over north Algeria and Morocco which is very unlikely due to natural variability or natural forcing alone (Barkhordarian et al., 2012b). The region has also experienced positive trends in annual minimum and maximum temperature (Vizy and Cook, 2012).

Over West Africa and the Sahel near surface temperatures have increased over the last 50 years. Using indices developed by the Expert Team on Climate Change Detection and Indices (ETCCDI), New *et al.* (2006) show the number of cold days and cold nights have decreased and the number of warm days and warm nights have increased between 1961 and 2000. Many of these trends are statistically significant at the 90% level and they find similar trends in extreme temperature indices. Collins (2011) shows statistically significant warming of between 0.5-0.8 degrees between 1970 and 2010 over the region using remotely sensed data with a greater magnitude of change in the latter 20 years of the period compared to the former.

The equatorial and southern parts of eastern Africa have experienced a significant increase in temperature since the beginning of the early 1980s (Anyah and Qiu, 2012). Similarly, recent reports from the Famine Early Warning Systems Network (FEWS NET) indicate that there has been an increase in seasonal mean temperature in many areas of Ethiopia, Kenya, South Sudan, and Uganda over the last 50 years (Funk *et al.*, 2011, 2012). In addition, warming of the near surface temperature and an increase in the frequency of extreme warm events has been observed for countries bordering the western Indian Ocean between 1961 and 2008 (Vincent *et al.*, 2011b).

In recent decades, most of southern Africa has also experienced upward trends in annual mean, maximum, and minimum temperature over large extents of the subregion during the last half of the 20th century, with the most significant warming occurring during the last two decades (Zhou *et al.*, 2010; Collins, 2011; Kruger and Sekele, 2012). Minimum temperatures have increased more rapidly relative to maximum temperatures over inland southern Africa (New *et al.*, 2006).

22.2.1.2. Projected Trends

Temperatures in Africa are projected to rise faster than the global average increase during the 21st Century (Christensen *et al.*, 2007; Joshi *et al.* 2011; Sanderson *et al.*, 2011; James and Washington, 2013). Global average near-surface air temperature are projected to move beyond 20th Century simulated variability by 2069 (±18 years) under RCP4.5 and by 2047 (±14 years) under RCP8.5 (Mora *et al.* 2013). However, in the tropics, especially tropical West Africa, these unprecedented climates are projected to occur one to two decades earlier the global average because the relatively small natural climate variability in this region generates narrow climate bounds that can be easily surpassed by relatively small climate changes. Figure 22-1 shows projected temperature increases based on the CMIP5 ensemble. Increases in mean annual temperature over all land areas are *very likely* in the mid- and late-21st-century periods for RCP2.6 and RCP8.5 (Figure 22-1, Box CC-RC). Ensemble-mean changes in mean annual temperature exceed 2˚C above the late-20th-century baseline over most land areas of the continent in the mid-21st-century for RCP8.5, and exceed 4˚C over most land areas in the late-21st-century for RCP8.5. Changes in mean annual temperature for RCP8.5 follow a pattern of larger changes in magnitude over northern and southern Africa, with (relatively) smaller changes in magnitude over central Africa. The ensemble-mean changes are less than 2˚C above the late-20th-century baseline in both the mid- and late-21st-century for RCP2.6.

Over North Africa under the A1B scenario, both annual minimum and maximum temperature are *likely* to increase in the future, with greater increase in minimum temperature (Vizy and Cook, 2012). The faster increase in minimum temperature is consistent with greater warming at night, resulting in a decrease in the future extreme temperature range (Vizy and Cook, 2012). Higher temperature increases are projected during boreal summer by CMIP5 GCMs (WGI Annex 1). A strengthening of the North African thermal low in 21st century is associated with a surface temperature increase (Paeth *et al.*, 2009; Patricola and Cook, 2010; Barkhordarian *et al.*, 2012a; Cook and Vizy, 2012).

Temperature projections over West Africa for the end of the 21st Century from both the CMIP3 GCMs (A2 and A1B scenarios) and CMIP5 GCMs (RCP4.5 and RCP8.5) range between 3-6°C above the late 20th Century baseline (Meehl *et al.* 2007; Fontaine *et al*. 2011; Diallo *et al.*, 2012; Monrie *et al*. 2012; Figure 22-1; Figure 22-2). Regional downscalings over the region produce a similar range of projected change (Patricola and Cook, 2010; Mariotti *et al.*, 2011; Patricola and Cook, 2011; Vizy *et al.*, 2012). Diffenbaugh and Giorgi (2012) identify the Sahel and tropical West Africa as a hotspot of climate change for both RCP4.5 and RCP8.5 pathways and unprecedented climates are projected to occur earliest (late 2030s to early 2040s) in these regions (Mora *et al.*, 2013).

Climate model projections under the A2 and B1 scenarios over Ethiopia show warming in all four seasons across the country, which may cause a higher frequency of heat waves as well as higher rates of evaporation (Conway and Schipper, 2011). Projected maximum and minimum temperatures over equatorial eastern Africa show a significant increase in the number of days warmer than 2°C above the 1981–2000 average by the middle and end of the 21st century under the A1B and A2 scenarios (Anyah and Qiu, 2012). Elshamy *et al*. (2009) show a temperature increase over the upper Blue Nile of between 2°C and 5°C at the end of the 21st Century under the A1B scenario compared to a 1961-1990 baseline.

Mean land surface warming in Southern Africa is *likely* to exceed the global mean land surface temperature increase in all seasons (Sillmann and Roeckner, 2008; Watterson, 2009; Mariotti *et al.*, 2011; James and Washington, 2013; Orlowsky and Seneviratne, 2012). Furthermore, towards the end of the 21st Century the projected warming of between 3.4-4.2ºC above the 1981-2000 average under the A2 scenario far exceeds natural climate variability (Moise and Hudson, 2008). High warming rates are projected over the semi-arid southwestern parts of the subregion covering northwestern South Africa, Botswana, and Namibia (WGI Annex 1; Moise and Hudson, 2008; Engelbrecht *et al.*, 2009; Watterson, 2009; Shongwe *et al.*, 2009). Observed and simulated variations in past and projected future annual average temperature over five African regions (UMA, SADC, ECCAS, ECOWAS, and COMESA) are captured in Figure 22-2 which indicates the projected temperature rise is *very likely* to exceed the 1986-2005 baseline by between 3 and 6 °C across these regions by the end of this century under RCP8.5.

[INSERT FIGURE 22-1 HERE
Figure 22-1: Observed and simulated variations in past and projected future annual average precipitation and temperature. Observed differences in the Climate Research Unit, University of East Anglia data (CRU) are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Grey indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st Century period is 2081-2100. The mid-21st century period is 2046-2065.]

[INSERT FIGURE 22-2 HERE
Figure 22-2: Observed and simulated variations in past and projected future annual average temperature over EAC-IGAD-Egypt, ECCAS, ECOWAS, SADC and UMA. Black lines show various estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (63 simulations), historical changes in "natural" drivers only (34), the "RCP2.6" emissions scenario (63), and the "RCP8.5" (63). Data are anomalies from the 1986-2005 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.]

22.2.2. Precipitation

22.2.2.1. Observed Changes

Most areas of the African continent lack sufficient observational data to draw conclusions about trends in annual precipitation over the past century (Figure 22-1, Box CC-RC). Additionally, in many regions of the continent discrepancies exist between different observed precipitation datasets (Nikulin *et al.* 2012; Sylla *et al.*, 2012; Kim *et* *al*. 2013; Kalognomou *et al.*, 2013). Areas where there are sufficient data include *very likely* decreases in annual precipitation over the past century over parts of the western and eastern Sahel region in northern Africa, along with *very likely* increases over parts of eastern and southern Africa.

Over the last few decades the northern regions of North Africa (north of the Atlas Mountains and along the Mediterranean coast of Algeria and Tunisia) have experienced a strong decrease in the amount of precipitation received in winter and early spring (Barkhordarian *et al.,* 2013). The observed record also indicates greater than 330 dry days (with less than 1 mm/day rainfall) per year over the 1997 - 2008 time period (Vizy and Cook, 2012). However, in autumn (September, October, November) observations show a positive trend in precipitation in some parts of North Algeria and Morocco (Barkhordarian *et al.*, 2013). The Sahara Desert, which receives less than 25 mm/year, shows little seasonal change (Liebmann *et al*., 2012).

Rainfall over the Sahel has experienced an overall reduction over the course of the 20th Century with a recovery toward the last 20 years of the century (WGI 14.3.7.1; Nicholson *et al.*, 2000; Lebel and Ali, 2009; Ackerley *et al.,* 2011; Mohamed, 2011; Biasutti, 2013). The occurrence of a large number of droughts in the Sahel during the 1970s and 1980s is well documented and understood (Biasutti and Giannini, 2006; Biasutti *et al.*, 2008; Greene *et al.*, 2009). The recovery of the rains may be due to natural variability (Mohino *et al*., 2011) or a forced response to increased greenhouse gases (Haarsma *et al*., 2005; Biasutti, 2013) or reduced aerosols (Ackerley *et al.*, 2011).

Precipitation in eastern Africa shows a high degree of temporal and spatial variability dominated by a variety of physical processes (Rosell and Holmer, 2007; Hession and Moore, 2011). Williams and Funk (2011) and Funk *et al*. (2008) indicate that over the last three decades rainfall has decreased over eastern Africa between March and May/June. The suggested physical link to the decrease in rainfall is the rapid warming of Indian Ocean, which causes an increase in convection and precipitation over the tropical Indian Ocean and thus contributes to increased subsidence over eastern Africa and a decrease in rainfall during March to May/June (Funk *et al.*, 2008; Williams and Funk, 2011). Similarly, Lyon and DeWitt (2012) show a decline in the March–May seasonal rainfall over eastern Africa. Summer (June–September) monsoonal precipitation has declined throughout much of the Great Horn of Africa over the last 60 years [during the 1948–2009 period; Williams *et al.*, (2012)] as a result of the changing sea level pressure (SLP) gradient between Sudan and the southern coast of the Mediterranean Sea and the southern tropical Indian Ocean region (Williams *et al.*, 2012).

Over Southern Africa a reduction in late austral summer precipitation has been reported over its western parts, extending from Namibia, through Angola, and toward the Congo during the second half of the 20th Century (Hoerling *et al.*, 2006; New *et al*., 2006). The drying is associated with an upward trend in tropical Indian Ocean Sea Surface Temperatures (SSTs). Modest downward trends in rainfall are found in Botswana, Zimbabwe, and western South Africa. Apart from changes in total or mean summer rainfall, certain intra-seasonal characteristics of seasonal rainfall such as onset, duration, dry spell frequencies, and rainfall intensity as well as delay of rainfall onset have changed (Tadross *et al.*, 2005; Thomas *et al.*, 2007; Tadross *et al.*, 2009; Kniveton *et al.*, 2009). An increasing frequency of dry spells is accompanied by an increasing trend in daily rainfall intensity which has implications for run-off characteristics (New *et al.*, 2006).

22.2.2.2. Projected Changes

Precipitation projections are more uncertain than temperature projections (Rowell, 2012) and exhibit higher spatial and seasonal dependence than temperature projections (Orlowsky and Seneviratne, 2012). The CMIP5 ensemble projects *very likely* decreases in mean annual precipitation over the Mediterranean region of northern Africa in the mid- and late-21st century periods for RCP8.5 (Figure 22-1, Box CC-RC). CMIP5 also projects *very likely* decreases in mean annual precipitation over areas of southern Africa beginning in the mid-21st-century for RCP8.5 and expanding substantially in the late-21st-century for RCP8.5. In contrast, CMIP5 projects *likely* increases in mean annual precipitation over areas of central and eastern Africa beginning the mid-21st-century for RCP8.5. Most areas of the African continent do not exhibit changes in mean annual precipitation that exceed the baseline variability in more than 66% of the models in either the mid- or late-21st-century periods for RCP2.6. Observed and simulated variations in past and projected future annual average precipitation over five African regions (UMA, ECCAS, ECOWAS, SADC and COMESA) are captured in Figure 22-2.

A reduction in rainfall over northern Africa is *very likely* by the end of the 21st Century. The annual and seasonal drying/warming signal over the Northern African region (including North of Morocco, Algeria, Libya, Egypt and Tunisia) is a consistent feature in the global (Giorgi and Lionello, 2008; Barkhordarian et al., 2013) and the regional (Lionello and Giorgi, 2007; Gao and Giorgi, 2008; Paeth *et al*., 2009; Patricola and Cook, 2010) climate change projections for the 21st Century under the A1B and A2 scenarios. Furthermore, over the northern basin of Tunisia, climate models under the A1B scenario project a significant decrease in the median, and 10th and 90th percentiles values of precipitation in winter and spring seasons (Bargaoui *et al*., 2013).

West African precipitation projections in the CMIP-3 and CMIP-5 archives show inter-model variation in both the amplitude and direction of change that is partially attributed to the inability of GCMs to resolve convective rainfall (WGI 14.8.7; Biasutti *et al.*, 2008; Druyan, 2011; Fontaine *et al*., 2011; Roehrig *et al.*, 2013). Many CMIP-5 models indicate a wetter core rainfall season with a small delay to rainy season by the end of the 21st Century (WGI 14.8.7; Biasutti, 2013). However, regional climate models (RCMs) can alter the sign of rainfall change of the driving GCM especially in regions of high or complex topography (WGI 14.3.7.1; WGI 9.6.4; Sylla *et al.*, 2012; Cook and Vizy, 2013; Saeed *et al.* 2013). There is therefore *low* to *medium confidence* in the robustness of projected regional precipitation change until a larger body of regional results become available through, for example, the coordinated regional downscaling experiment, CORDEX (Giorgi *et al*., 2009, Jones *et al*., 2011, Hewitson *et al.*, 2012).

An assessment of 12 CMIP-3 GCMs over eastern Africa suggest that by the end of the 21st Century there will be a wetter climate with more intense wet seasons and less severe droughts during October-November-December (OND) and March-April-May (MAM) (WGI 14.8.7; Moise and Hudson, 2008; Shongwe *et al.*, 2011). These results indicate a reversal of historical trend in these months (Williams and Funk, 2011; Funk *et al*. 2008). Lyon and DeWitt (2012) ascribe this reversal to recent cooling in the eastern equatorial Pacific that offsets the equatorial Pacific SST warming projected by CMIP3 GCMs in future scenarios. However, GCM projections over Ethiopia indicate a wide range of rainfall spatial pattern changes (Conway and Schipper, 2011) and in some regions GCMs do not agree on the direction of precipitation change, e.g. in the upper Blue Nile basin in the late 21st Century (Elshamy *et al*., 2009). Regional climate model studies suggest drying over most parts of Uganda, Kenya, and South Sudan in August and September by the end of the 21st Century as a result of a weakening Somali jet and Indian monsoon (Patricola and Cook, 2011). Cook and Vizy (2013) indicate truncated boreal spring rains in the mid-21st Century over eastern Ethiopia, Somalia, Tanzania and southern Kenya while the boreal fall season is lengthened in the southern Kenya and Tanzania (Nakaegawa *et al*., 2012). These regional studies highlight the importance of resolving both regional scale atmospheric processes and local effects like land surface on rainfall simulation across the region (WGI 14.8.7).

Over southern Africa CMIP3 GCM projections show a drying signal in the annual mean over the climatologically dry southwest, extending northeastward from the desert areas in Namibia and Botswana (Moise and Hudson, 2008; James and Washington, 2013; Orlowsky and Seneviratne, 2012). This pattern is replicated by CMIP5 GCMs (see Figure 22-1). During the austral summer months, dry conditions are projected in the southwest while downscaled projections indicate wetter conditions in the southeast of South Africa and the Drakensberg mountain range (Hewitson and Crane, 2006; Engelbrecht *et al.*, 2009). Consistent with the AR4, drier winters are projected over a large area in southern Africa by the end of the century as a result of the poleward displacement of mid-latitude storm tracks (WGI 14.8.7; Moise and Hudson, 2008; Engelbrecht *et al.*, 2009; Shongwe *et al.*, 2009; Seth *et al.*, 2011; James and Washington, 2013). Rainfall decreases are also projected during austral spring months, implying a delay in the onset of seasonal rains over a large part of the summer rainfall region of Southern Africa (Shongwe *et al.*, 2009; Seth *et al.*, 2011). The sign, magnitude and spatial extent of projected precipitation changes are dependent on the coupled general circulation model (CGCM) employed, due primarily to parameterization schemes used and their interaction with model dynamics (Hewitson and Crane, 2006; Rocha *et al.*, 2008). Changes in the parameterization schemes of a single regional climate model produced opposite rainfall biases over the region (Crétat *et al*., 2012) so multiple ensemble downscalings, such as those being produced through CORDEX, are important to more fully describe the uncertainty associated with projected rainfall changes across the African continent (WGI 9.6.5; Laprise *et al.*, 2013).

22.2.3. Observed and Projected Changes in Extreme Temperature and Rainfall

In Northern Africa the north western Sahara experienced 40-50 heat wave days per year during the 1989-2009 time period (Vizy and Cook, 2012). There is a projected increase in this number of heat wave days over the 21st century (Patricola and Cook, 2010; Vizy and Cook, 2012).

Over West Africa there is *low* to *medium confidence* in projected changes of heavy precipitation by the end of the 21st Century based on CMIP-3 GCMs (Seneviratne *et al.*, 2012). Regional model studies suggest an increase in the number of extreme rainfall days over West Africa and the Sahel during May and July (Vizy and Cook, 2012) and more intense and more frequent occurrences of extreme rainfall over the Guinea Highlands and Cameroun Mountains (Sylla *et al.*, 2012; Haensler *et al*., 2013. The ability of regional climate models to resolve complex topography captures the amplifying role of topography in producing extreme rainfall that GCMs cannot.

Extreme precipitation changes over Eastern Africa such as droughts and heavy rainfall have been experienced more frequently during the last 30-60 years (Funk *et al.*, 2008; Williams and Funk, 2011; Shongwe *et al.*, 2011; Lyon and DeWitt, 2012). A continued warming in the Indian–Pacific warm pool has been shown to contribute to more frequent East African droughts over the past 30 years during the spring and summer seasons (Williams and Funk, 2011). It is unclear whether these changes are due to anthropogenic influences or multidecadal natural variability (Lyon and DeWitt, 2012; Lyon *et al.*, 2013). Projected increases in heavy precipitation over the region have been reported with high certainty in the SREX (Seneviratne *et al.*, 2012) and Vizy and Cook (2012) indicate an increase in the number of extreme wet days by the mid-20th Century.

Over southern Africa an increase in extreme warm ETCCDI indices (hot days, hot nights, hottest days) and a decrease in extreme cold indices (cold days and cold nights) in recent decades is consistent with the general warming trend (New *et al.*, 2006; Tebaldi *et al.*, 2006; Aguilar et al. 2009; Kruger and Sekele, 2012). The probability of austral summer heat waves over South Africa increased over the last two decades of the 20th century compared to 1961 to 1980 (Lyon, 2009). Enhanced heat wave probabilities are associated with deficient rainfall conditions that tend to occur during El Niño events. The southwestern regions are projected to be at a high risk to severe droughts during the 21st Century and beyond (Hoerling *et al.*, 2006; Shongwe *et al.*, 2011). Large uncertainties surround projected changes in tropical cyclone landfall from the southwest Indian Ocean that have resulted in intense floods during the 20th Century. Future precipitation projections show changes in the scale of the rainfall probability distribution, indicating that extremes of both signs may become more frequent in the future (Kay and Washington, 2008).

22.3. Vulnerability and Impacts

This section highlights Africa's vulnerability to climate change, as well as the main observed and potential impacts on natural resources, ecosystems, and economic sectors. Figure 22-3 summarizes the main conclusions regarding observed changes in regional climate and their relation to anthropogenic climate change (described in 22.2) as well as regarding observed changes in natural and human systems and their relation to observed regional climate change (described in this section). Confidence in detection and attribution of anthropogenically-driven climate change is highest for temperature measures. In many regions of Africa, evidence is constrained by limited monitoring. However, impacts of observed precipitation changes are amongst the observed impacts with the highest assessment of confidence, implying that some of the potentially more significant impacts of anthropogenic climate change for Africa are of a nature that challenges detection and attribution analysis (18.5.1).

[INSERT FIGURE 22-3 HERE
Left: Confidence in detection and in attribution of observed climate change over Africa to anthropogenic emissions. All detection assessments are against a reference of no change, while all attribution assessments concern a major role of anthropogenic emissions in the observed changes. See 22.2, and SREX-3, and WGI AR5 10 for details. Right: Confidence in detection and in attribution of the impacts of observed regional climate change on various African systems. All detection assessments are against a reference of no change, except "Kenyan Highlands malaria"

(changes due to vaccination, drug resistance, demography, and livelihoods), "Great Lakes fisheries" (changes due to fisheries management and land use) and “Adapting South African farmers” (economic changes). Attribution is to a major role or a minor role of observed climate change, as indicated. See 22.2.2, 22.3.2.1, 22.3.2.2, 2.3.3, 22.4.2, 22.3.4.4, 22.3.5.4, 22.4.5.7 and Tables 18-5, 18-6, 18-7, and 18-9 for details. Assessments follow the methods outlined in 18.2.]

22.3.1. Socioeconomic and Environmental Context Influencing Vulnerability and Adaptive Capacity

Equitable socioeconomic development in Africa may strengthen its resilience to various external shocks, including climate change. In 2009, the Human Rights Council adopted Resolution 10/4[3] which noted the effects of climate change on the enjoyment of human rights, and reaffirmed the potential of human rights obligations and commitments to inform and strengthen international and national policy making.

[FOOTNOTE 3: U.N. Doc. A/HRC/10/L.11.]

The impacts of climate change on human rights have been explicitly recognised by the African Commission on Human and Peoples’ Rights (hereafter African Commission) in its Resolution on Climate Change and Human Rights and the Need to Study its Impact in Africa (ACHPR/Res 153 XLV09). The 1981 African (Banjul) Charter on Human and Peoples’ Rights (hereafter African Charter) protects the right of peoples to a ‘general satisfactory environment favorable to their development’ (Article 24). The recognition of this right and the progressive jurisprudence by the African Commission in environmental matters underline the relevance of potential linkages between climate change and human rights (Ruppel, 2012).

The link between climate change and humans is not only associated with human rights. Rather, strong links exist between climate change and the MDGs: climate change may adversely affect progress toward attaining the MDGs, as climate change can increase the pressure not only economic activities, such as agriculture (22.3.4) and fishing (22.3.4.4) but also adversely affect urban areas located in coastal zones (22.3.6). Slow progress in attaining most MDGs may, meanwhile, reduce the resilience and adaptive capabilities of African individuals, communities, states, and nations (ECA *et al.*, 2009, 2012; UNDP *et al*., 2011).

The African continent has made significant progress on some MDGs; however, not all MDGs have been achieved, yet with high levels of spatial and group disparities. Additionally, progress on all MDG indicators is skewed in favor of higher-income groups and urban populations, which means further marginalization of already excluded groups (UN *et al.*, 2008; AfDB *et al.*, 2010; World Bank and IMF, 2010). As a whole, the continent is experiencing a number of demographic and economic constraints, with the population having more than doubled since 1980; exceeding one billion in 2010 and expected to reach three billion by the year 2050, should fertility remain constant (Muchena *et al.*, 2005; Fermont *et al.*, 2008; UN DESA, 2011). The global economic crisis is adding additional constraints on economic development efforts leading to increased loss of livelihood and widespread poverty (Moyo, 2009; Easterly, 2009; Adesina, 2010). The percent of the population below the poverty line has decreased from 56.5% in 1990 to 47.5% in 2008 (excluding North Africa); however a significant proportion of the population living below the poverty line remains chronically poor (ECA *et al.*, 2012). Although poverty in rural areas in Sub-Saharan Africa has declined from 64.9% in 1998 to 61.6% in 2008, it is still double the prevailing average in developing countries in other regions (IFAD, 2010).

Agriculture, which is the main economic activity in terms of employment share, is 98% rain fed in the sub-Saharan region (FAO, 2002).[4] Stagnant agricultural yields, relative to the region’s population growth, have led to a fall in per capita food availability since the 1970s (UN *et al.*, 2008).[5] Such stagnation was reversed with an improved performance of the agricultural sector in sub Saharan Africa during the 2000–2010. However, most of this improvement was the result of countries recovering from the poor performance of the 1980s and 1990s along with favorable domestic prices (Nin-Pratt *et al.*, 2012).

In addition, recent increases in global food prices aggravate food insecurity among the urban poor, increasing the risk of malnutrition and its consequences (UN *et al.*, 2008). For example, it was estimated that the global rise in food prices has contributed to the deaths of an additional 30,000 to 50,000 children suffering from malnutrition in 2009 in sub-Saharan Africa (Friedman and Schady, 2009) see Table 22.2. This situation may be complicated further by changes in rainfall variability and extreme weather events affecting the agriculture sector (Yabi and Afouda, 2012).

In response, the New Partnership for Africa's Development (NEPAD) was founded in 2001, for Africans to take the lead in efforts to achieve the development vision espoused in the AU Constitutive Act as well as the MDGs and to support regional integration as a mechanism for inclusive growth and development in Africa (NEPAD *et al.*, 2012). Furthermore, the Comprehensive Africa Agriculture Development Program (CAADP), which works under the umbrella of NEPAD, was established in 2003 to help African countries reach a higher path of economic growth through agriculture-led development. For this to happen, it focuses on four pillars for action: land and water management, market access, food supply and hunger, and agricultural research (NEPAD, 2010).

[INSERT TABLE 22-2 HERE
Table 22-2: Under-nourishment in Africa, by number and % of total population.]

[FOOTNOTE 4: However, mining and energy sectors, where active, are undergoing expansion, stimulating growth and adding potentially to state revenues but are also highly vulnerable to global recession. overall, the limited production and export structures of the continent are likely to maintain its historical vulnerability to external shocks (ECA and AUC, 2011).]

[FOOTNOTE 5: Lack of extension services for farmers in Africa can also contribute to low utilization and spread of innovations and technologies that can help mitigate climate change.]

Africa has made much progress in the achievement of universal primary education; however, the results are unevenly distributed. Nevertheless, a considerable number of children, especially girls from poor backgrounds and rural communities, still do not have access to primary education (UN *et al.*, 2008).

From the livelihood perspective, African women are vulnerable to the impacts of climate change because they shoulder an enormous but imprecisely recorded portion of the responsibility for subsistence agriculture, the productivity of which can be expected to be adversely affected by climate change and over-exploited soil (Viatte *et al.*, 2009; see also 22.4.2 and Table 22-5).[6] Global financial crises, such as the one experienced in 2007/2008, as well as downturn economic trends at national level, may cause job losses in the formal sector and men may compete for jobs in the informal sector that were previously undertaken by women, making them more vulnerable (AfDB *et al.*, 2010).

[FOOTNOTE 6: For instance, 84% of women in sub-Saharan Africa, compared with 69.5% of men, are engaged in such jobs. In Northern Africa, even though informal or self-employment is less predominant, the gender gap is stark, with much higher proportion of women compared to men are in the more vulnerable informal and self-employed status (56.7% of women compared with 34.9% of men) (UN DESA, 2011).]

Significant efforts have been made to improve access to safe drinking water and sanitation in Africa, with access to safe drinking water increasing from 56 to 65% between 1990 and 2008 (UNDP *et al*., 2011), with sub-Saharan Africa nearly doubling the number of people using an improved drinking water source – from 252 to 492 million over the same period (UN, 2011). Despite such progress, significant disparities in access to safe water and sanitation, between not only urban and rural but also between large- and medium- and small-sized cities, still exist (UNDP *et al.*, 2011). Use of improved sanitation facilities, meanwhile, is generally low in Africa, reaching 41% in 2010 compared to 36% in 1990 (UNDP *et al.*, 2011).

22.3.2. Ecosystems

It is recognized that interactions between the different drivers of ecosystem structure, composition, and function are complex, which makes the prediction of the impacts of climate change more difficult (see Chapter 4). In AR4, the chapter on Africa indicated that extensive pressure is exerted on different ecosystems by human activities (deforestation, forest degradation, biomass utilisation for energy) as well as processes inducing changes such as fires or desertification (see WGII AR4 9.2.2.7). Even if the trend is toward better preservation of ecosystems and a decrease in degradation (like deforestation), pressures linked, for example, to agriculture and food security, energy demand, and urbanization are increasing, putting these ecosystems at risk. This chapter emphasizes new information since AR4 regarding the vulnerability to and impacts of climate change for some terrestrial, fresh water and coastal/ocean ecosystems.

22.3.2.1. Terrestrial Ecosystems

Changes are occurring in the distribution and dynamics of all types of terrestrial ecosystems in Africa, including deserts, grasslands and shrublands, savannas and woodlands, and forests (*high confidence*) (see also 4.3.2.5). Since AR4, three primary trends have been observed at the continental scale. The first is a small overall expansion of desert and contraction of the total vegetated area (Brink and Eva, 2009) (*low confidence*). The second is a large increase in the extent of human influence within the vegetated area, accompanied by a decrease in the extent of natural vegetation (Brink and Eva, 2009; Potapov *et al.*, 2012; Mayaux *et al.*, 2013) (*high confidence*). The third is a complex set of shifts in the spatial distribution of the remaining natural vegetation types, with net decreases in woody vegetation in western Africa (Vincke *et al.*, 2010; Ruelland *et al.*, 2011; Gonzalez *et al.*, 2012) and net increases in woody vegetation in central, eastern, and southern Africa (Wigley *et al*., 2009; Wigley *et al*., 2010; Buitenwerf *et al*., 2012; Mitchard and Flintrop, 2013) (*high confidence*).

Overall, the primary driver of these changes is anthropogenic land use change, particularly the expansion of agriculture, livestock grazing, and fuelwood harvesting (Brink and Eva, 2009; Kutsch *et al*., 2011; Bond and Midgley, 2012; Gonzalez *et al.*, 2012) (*high confidence*). Natural climate variability, anthropogenic climate change, and interactions between these drivers and anthropogenic land use change have important additional and interacting effects (Foden *et al*., 2007; Touchan *et al*., 2008; Brink and Eva, 2009; Bond and Midgley, 2012; Gonzalez *et al.*, 2012) (*high confidence*). Due to these interactions, it has been difficult to determine the role of climate change in isolation from the other drivers (Malhi *et al*., 2013). In general, while there are already many examples of changes in terrestrial ecosystems that are consistent with a climate change signal and have been detected with *high confidence*, attribution to climate change has tended to be characterized by *low confidence* [see Table 22-3]. New observations and approaches are improving confidence in attribution (*e.g.*, Buitenwerf *et al*., 2012, Gonzalez *et al.*, 2012, Pettorelli *et al.*, 2012, Otto *et al*., 2013).

There is *high agreement* that continuing changes in precipitation, temperature, and CO_2 associated with climate change are *very likely* to drive important future changes in terrestrial ecosystems throughout Africa (*high confidence*) [see examples in 4.3.3.1, 4.3.3.2]. Modeling studies focusing on vegetation responses to climate have projected a variety of biome shifts, primarily related to the extent of woody vegetation (Delire *et al.*, 2008; Gonzalez *et al.*, 2010; Bergengren *et al.*, 2011; Zelazowski *et al.*, 2011; Midgley, 2013). For an example of such projections, see Figure 22-4. However, substantial uncertainties are inherent in these projections because vegetation across much of the continent is not deterministically driven by climate alone (*high confidence*). Advances in understanding how vegetation dynamics are affected by fire, grazing, and the interaction of fire and grazing with climate are expected to enable more sophisticated representations of these processes in coupled models (Scheiter and Higgins, 2009; Staver *et al*., 2011a; Staver *et al*., 2011b). Improvements in forecasting vegetation responses to climate change should reduce the uncertainties that are currently associated with vegetation feedbacks to climate forcing, as well as the uncertainties about impacts on water resources, agriculture, and health (Alo and Wang, 2008; Sitch *et al.*, 2008) [see 4.5].

[INSERT FIGURE 22-4 HERE
Figure 22-4: Left – Projected biome change from the periods 1961-1990 to 2071-2100 using the MC1 Dynamic Vegetation Model. Change is indicated if any of nine combinations of three GCMs (CSIRO Mk3, HadCM3, MIROC 3.2 medres) and three emissions scenarios (B1, A1B, A2) project change and is thus a worst-case scenario. Colours represent the future biome predicted. Right – Vulnerability of ecosystems to biome shifts based on historical climate (1901-2002) and projected vegetation (2071-2100), where all nine GCM-emissions scenario combinations agree on the projected biome change. Source: Gonzalez et al. (2010).]

22.3.2.2. Freshwater Ecosystems

Freshwater ecosystems in Africa are at risk from anthropogenic land use change, over-extraction of water and diversions from rivers and lakes, and increased pollution and sedimentation loading in water bodies (Vörösmarty *et al*., 2005; Vié *et al.*, 2009; Darwall *et al.*, 2011). Climate change is also beginning to affect freshwater ecosystems (see also Chapter 3.5.2.4, as evident by elevated water temperatures reported in surface waters of Lakes Kariba, Kivu, Tanganyika, Victoria, and Malawi (Odada *et al.*, 2006; Verburg and Hecky, 2009; Marshall *et al.*, 2009; Hecky *et al.*, 2010; Magadza, 2010; Tierney *et al.*, 2010; Olaka *et al.*, 2010; Magadza, 2011; Ndebele-Murisa, 2011; Woltering *et al.*, 2011; Osborne, 2012; Ndebele-Murisa *et al.*, 2012) (*medium confidence*).

Small variations in climate cause wide fluctuations in the thermal dynamics of freshwaters (Odada *et al.*, 2006; Stenuite *et al.*, 2007; Verburg and Hecky, 2009; Moss, 2010; Olaka *et al.*, 2010). Thermal stratification in the regions' lakes, for instance, isolates nutrients from the euphotic zone, and is strongly linked to hydrodynamic and climatic conditions (Sarmento *et al.*, 2006; Ndebele-Murisa *et al.*, 2010). Moderate warming may be contributing to reduced lake water inflows and therefore nutrients, which subsequently destabilizes plankton dynamics and thereby adversely affects food resources for higher trophic levels of mainly planktivorous fish (*low confidence*) (Magadza, 2008; Verburg and Hecky, 2009; Magadza, 2010; Ndebele-Murisa *et al.*, 2011). However, the interacting drivers of fisheries decline in African lakes are uncertain, given the extent to which other factors, such as overfishing, pollution, and invasive species also impact lake ecosystems and fisheries production (Phoon *et al*., 2004; Sarvala *et al*., 2006; Verburg *et al*., 2007; Tumbare, 2008; Hecky *et al*., 2010; Marshall, 2012).

22.3.2.3. Coastal and Ocean Systems

Coastal and ocean systems are important for the economies and livelihoods of African countries, and climate change will increase challenges from existing stressors, such as overexploitation of resources, habitat degradation, loss of biodiversity, salinization, pollution, and coastal erosion (Arthurton *et al.*, 2006; UNEP and IOC-UNESCO, 2009; Diop *et al.*, 2011). Coastal systems will experience impacts through sea level rise. They will also experience impacts through high sea levels combined with storm swells, for example as observed in Durban in March 2007, when a storm swell up to 14 m due to winds generated by a cyclone combined with a high astronomic tide at 2.2 m, leading to damages estimated at US$ 100 million (Mather and Stretch, 2012). Other climate change impacts (such as flooding of river deltas or an increased migration toward coastal towns due to increased drought induced by climate change (Rain *et al.*, 2011) will also affect coastal zones.

Some South African sea bird species have moved farther south over recent decades, but land use change may also have contributed to this migration (Hockey and Midgley, 2009; Hockey *et al.*, 2011). However, it is considered that South African seabirds could be a valuable signal for climate change, particularly of the changes induced on prey species related to changes in physical oceanography, if we are able to separate the influences of climate parameters from other environmental ones (Crawford and Altwegg, 2009).

Upwellings, including Eastern Boundary Upwelling Ecosystems (EUBEs) and Equatorial Upwelling Systems (EUSs) are the most biologically active systems in the Oceans (Box CC-UP). In addition to equatorial upwelling, the primary upwelling systems that affect Africa are the Benguela and Canary currents along the Atlantic coast (both EBUEs).The waters of the Benguela current have not shown warming over the period 1950-2009 (30.5.5.1.2), whereas most observations suggest that the Canary current has warmed since the early 1980s, and there is *medium evidence* and *agreement* that primary production in the Canary current has decreased over the past two decades (30.5.5.1.1). Changing temperatures in the Canary current has resulted in changes to important fisheries species (e.g., Mauritanian waters have become increasingly suitable for *Sardinella aurita*) (30.5.5.1.1). Upwellings are areas of naturally low pH and high CO_2 concentrations, and, consequently, may be vulnerable to ocean acidification and its impacts (Box CC-OA, Box CC-UP, 30.5.5). Warming is projected to continue in the Canary current, and the synergies between this increase in water temperature and ocean acidification could influence a number of biological processes (30.5.5.2). Regarding the Benguela current upwelling, there is *medium agreement* despite *limited evidence* that the Benguela system will experience changes in upwelling intensity as a result of climate change (30.5.5.1.2). There is considerable debate as to whether or not climate change will drive an intensification of upwelling (e.g. Bakun *et al.*, 2010; Narayan *et al.*, 2010) in all regions. Discussion of the various hypotheses for how climate change may affect coastal upwelling is presented in Box 30-1.

Ocean acidification (OA) is the term used to describe the process whereby increased CO_2 in the atmosphere, upon absorption, causes lowering of the pH of seawater (CC-OA). Projections indicate that severe impairment of reef accretion by organisms such as corals (Hoegh-Guldberg *et al.*, 2007) and coralline algae (Kuffner *et al.*, 2008) are substantial potential impacts of ocean acidification, and the combined effects of global warming and ocean acidification have been further demonstrated to lower both coral reef productivity (Anthony *et al.*, 2008) and resilience (Anthony *et al.*, 2011). These effects will have consequences for reef biodiversity, ecology, and ecosystem services (6.3.1, 6.3.2, 6.3.5, 6.4.1, 30.3.2, Box CC-CR).

Coral vulnerability to heat anomalies is high in the Western Indian Ocean (30.5.6.1.2). Corals in the southwestern Indian Ocean (Comoros, Madagascar, Mauritius, Mayotte, Réunion and Rodrigues) appeared to be more resilient than those in eastern locations (30.5.6.1.2). Social adaptive capacity to cope with such change varies, and societal responses (such as closures to fishing) can have a positive impact on reef recovery, as observed in Tanzania (McClanahan *et al.*, 2009). In Africa, fisheries mainly depend on either coral reefs (on the eastern coast) or coastal upwelling (on the western coast). These two ecosystems will be affected by climate change through ocean acidification, a rise in sea surface temperatures, and changes in upwelling (see Box CC-OA, Box CC-CR, Box CC-UP).

[INSERT TABLE 22-3
Table 22-3: Examples of detected changes in species, natural ecosystems, and managed ecosystems in Africa that are both consistent with a climate change signal and published since the AR4. Confidence in detection of change is based on the length of study, and the type, amount and quality of data in relation to the natural variability in the particular species or system. Confidence in the role of climate being a major driver of the change is based on the extent to which the detected change is consistent with that expected under climate change, and to which other confounding or interacting non-climate factors have been considered and been found insufficient to explain the observed change.]

22.3.3. Water Resources

Knowledge has advanced since the AR4 regarding current drivers of water resource abundance in Africa, and in understanding of potential future impacts on water resources from climate change and other drivers. However, inadequate observational data in Africa remains a systemic limitation with respect to fully estimating future freshwater availability (Neumann *et al.*, 2007; Batisani, 2011). Detection of and attribution to climate change are difficult given that surface and groundwater hydrology are governed by multiple, interacting drivers and factors, such as land use change, water withdrawals, and natural climate variability (see also Chapter 3.2.1 and Box CC-WE). There is poor understanding in Africa of how climate change will affect water quality. This is an important knowledge gap.

A growing body of literature generated since the AR4 suggests that climate change in Africa will have an overall modest effect on future water scarcity relative to other drivers, such as population growth, urbanization, agricultural growth, and land use change (*high confidence)* (Alcamo *et al.*, 2007; Carter and Parker, 2009; MacDonald *et al.*, 2009; Taylor *et al.*, 2009; Calow and MacDonald, 2009; Abouabdillah *et al.*, 2010; Beck and Bernauer, 2011; Droogers *et al.*, 2012; Notter *et al.*, 2012; Tshimanga and Hughes, 2012). However, broad-scale assumptions about drivers of future water shortages can mask significant sub-regional variability of climate impacts, particularly in water-stressed regions that are projected to become drier, such as northern Africa and parts of southern Africa. For example, rainfed agriculture in northern Africa is highly dependent on winter precipitation and would be negatively impacted if total precipitation and the frequency of wet days declines across North Africa as has been indicated in recent studies (Born *et al.*, 2008; Driouech *et al.*, 2010; Abouabdillah *et al.*, 2010; García-Ruiz *et al.*, 2011). Similarly, climate model predictions based on average rainfall years do not adequately capture interannual and interdecadal variability that can positively or negatively influence surface water runoff (Beck and Bernauer, 2011; Notter *et al.*, 2012; Wolski *et al.*, 2012). Key challenges for estimating future water abundance in Africa lie in better understanding relationships between evapotranspiration, soil moisture, and land use change dynamics under varying temperature and precipitation projections (Goulden *et al.*, 2009a) and to understand how compound risks such as heat waves and seasonal rainfall variability might interact in the future to impact water resources.

Several studies from Africa point to a future decrease in water abundance due to a range of drivers and stresses, including climate change in Southern and northern Africa (*medium confidence*). For example, all countries within the Zambezi River Basin could contend with increasing water shortages (A2 scenario) although non-climate drivers (e.g., population and economic growth, expansion of irrigated agriculture, and water transfers) are expected to have a strong influence on future water availability in this basin (Beck and Bernauer, 2011). In Zimbabwe, climate change is estimated to increase water shortages for downstream users dependent on the Rozva dam (Ncube *et al.*, 2011). Water shortages are also estimated for the Okavango Delta, from both climate change and increased water withdrawals for irrigation (Murray-Hudson *et al.*, 2006; Milzow *et al.*, 2010; Wolski *et al.*, 2012), and the Breede River in South Africa (Steynor *et al.*, 2009). For North Africa, Droogers *et al.* (2012) estimated that in 2050 climate change will account for 22% of future water shortages in the region while 78% of increased future water shortages can be attributed to socioeconomic factors. Abouabdillah *et al.* (2010) estimated that higher temperatures and declining rainfall (A2 and B1 scenarios) would reduce water resources in Tunisia. Reduced snowpack in the Atlas Mountains from a combination of warming and reduced precipitation, combined with more rapid springtime melting is expected to reduce supplies of seasonal meltwater for lowland areas of Morocco (García-Ruiz *et al.*, 2011).

In Eastern Africa, potential climate change impacts on the Nile Basin are of particular concern given the basin’s geopolitical and socioeconomic importance. Reduced flows in the Blue Nile are estimated by late century due to a combination of climate change (higher temperatures and declining precipitation) and upstream water development for irrigation and hydropower (Elshamy *et al.*, 2009; McCartney and Menker Girma, 2012). Beyene *et al.* (2010) estimated that streamflow in the Nile River will increase in the medium term (2010–2039) but will decline in the latter half of this century (A2 and B1 scenarios) as a result of both declining rainfall and increased evaporative demand, with subsequent diminution of water allocation for irrigated agriculture downstream from the High Aswan Dam. Kingston and Taylor (2010) reached a similar conclusion about an initial increase followed by a decline in surface water discharge in the Upper Nile Basin in Uganda. Seasonal runoff volumes in the Lake Tana Basin are estimated to decrease by the 2080s under the A2 and B2 scenarios (Abdo *et al.*, 2009), while Taye *et al.* (2011) reported inconclusive findings as to changes in runoff in this basin. The Mara, Nyando, and Tana rivers in Eastern Africa, are projected to have increased flow in the second half of this century (Taye *et al.*, 2011; Dessu and Melesse, 2012; Nakaegawa *et al*., 2012)).

Estimating the influence of climate change on water resources in West Africa is limited by the significant climate model uncertainties with regards to the region’s future precipitation. For example, Itiveh and Bigg (2008) estimate higher future rainfall in the Niger River Basin (A1, A2 and B1 scenarios), whereas Oguntunde and Abiodun (2013) report a strong seasonal component with reduced precipitation in the basin during the rainy season and increased precipitation during the dry season (A1B scenario). The Volta Basin is projected to experience a slight mean increase in precipitation (Kunstmann *et al.*, 2008), and the Bani River Basin in Mali is estimated to experience substantial reductions in runoff (A2 scenario) due to reduced rainfall (Ruelland *et al.*, 2012). The impact of climate change on total runoff in the Congo Basin is estimated to be minimal (A2 scenario) (Tshimanga and Hughes, 2012). Continental wide studies (e.g. De Wit and Stankiewicz, 2006) indicate that surface drainage in dry areas is more sensitive to, and will be more adversely affected by, reduced rainfall than would surface drainage in wetter areas that experience comparable rainfall reductions.

The overall impact of climate change on groundwater resources in Africa is expected to be relatively small in comparison with impacts from non-climatic drivers such as population growth, urbanization, increased reliance on irrigation to meet food demand, and land use change (Calow and MacDonald, 2009; Carter and Parker, 2009; MacDonald *et al.*, 2009; and Taylor *et al.*, 2009). Climate change impacts on groundwater will vary across climatic zones. (See also Chapter 3.4.6). An analysis by MacDonald *et al.* (2009) indicated that changes in rainfall would not be expected to impact the recharge of deep aquifers in areas receiving below 200 mm rainfall per year, where recharge is negligible due to low rainfall. Groundwater recharge may also not be significantly affected by climate change in areas that receive more than 500 mm per year, where sufficient recharge would remain even if rainfall diminished, assuming current groundwater extraction rates. By contrast, areas receiving between 200 to 500 mm per year, including the Sahel, the Horn of Africa, and southern Africa, may experience a decline in groundwater recharge with climate change to the extent that prolonged drought and other precipitation anomalies becomes more frequent with climate change, particularly in shallow aquifers, which respond more quickly to seasonal and yearly changes in rainfall than do deep aquifers (Barthel *et al.*, 2009).

Coastal aquifers are additionally vulnerable to climate change because of high rates of groundwater extraction, which leads to saltwater intrusion in aquifers, coupled with increased saltwater ingression resulting from sea level rise (Moustadraf *et al.*, 2008; Bouchaou *et al.*, 2008; Al-Gamal and Dodo, 2009; Kerrou *et al.*, 2010). Some studies have shown additional impacts of sea level rise on aquifer salinization with salinity potentially reaching very high levels (Carneiro *et al.*, 2010; Niang *et al.*, 2010; Research Institute for Groundwater, 2011). Although these effects are expected to be localized, in some cases they will occur in densely populated areas (Niang *et al.*, 2010). The profitability of irrigated agriculture in Morocco is expected to decline (under both B1 and A1B scenarios) due to increased pumping of groundwater and increased salinization risk for aquifers (Heidecke and Heckelei, 2010).

The capacity of groundwater delivery systems to meet demand may take on increasing importance with climate change (Calow and MacDonald, 2009). For example, where groundwater pumping and delivery infrastructure is poor, and the number of point sources limited, prolonged pumping can lead to periodic drawdowns and increased failure of water delivery systems or increased saline intrusion (Moustadraf *et al.*, 2008). To the extent that drought conditions become more prevalent in Africa with climate change, stress on groundwater delivery infrastructures will increase.

Future development of groundwater resources to address direct and indirect impacts of climate change, population growth, industrialization, and expansion of irrigated agriculture, will require much more knowledge of groundwater resources and aquifer recharge potentials than currently exists in Africa. Observational data on groundwater resources in Africa are extremely limited and significant effort needs to be expended to assess groundwater recharge potential across the continent (Taylor *et al.*, 2009). A preliminary analysis by MacDonald et al. (2012) indicates that total groundwater storage in Africa is 0.66 million km^3, which is “more than 100 times the annual renewable freshwater resources, and 20 times the freshwater stored in African lakes.” However, borehole yields are variable and in many places water yields are relatively low. Detailed analysis of groundwater conditions for water resource planning would need to consider these constraints.

22.3.4. Agriculture and Food Security

Africa’s food production systems are among the world’s most vulnerable because of extensive reliance on rainfed crop production, high intra- and inter-seasonal climate variability, recurrent droughts and floods that affect both crops and livestock, and persistent poverty that limits the capacity to adapt (Boko *et al.*, 2007). In the near term, better managing risks associated with climate variability may help to build adaptive capacities for climate change (Washington *et al.*, 2006; Cooper *et al.*, 2008; Funk *et al.*, 2008). However, agriculture in Africa will face significant challenges in adapting to climate changes projected to occur by mid-century, as negative effects of high temperatures become increasingly prominent under an A1B scenario (Battisti and Naylor, 2009; Burke *et al.*, 2009a), thus increasing the likelihood of diminished yield potential of major crops in Africa (Schlenker and Lobell, 2010; Sultan et al., 2013). Changes in growing season length are possible, with a tendency towards reduced growing season length (Thornton *et al.*, 2011), though with potential for some areas to experience longer growing seasons (Cook and Vizy, 2012). The composition of farming systems from mixed crop-livestock to more livestock dominated food production may occur as a result of reduced growing season length for annual crops and increases in the frequency and prevalence of failed seasons (Jones and Thornton, 2009; Thornton *et al.*, 2010). Transition zones, where livestock keeping is projected to replace crop cultivation by 2050, include the West African Sahel and coastal and mid-altitude areas in eastern and southeastern Africa (Jones and Thornton, 2009), areas that currently support 35 million people and are chronically food insecure.

22.3.4.1. Crops

Climate change is *very likely* to have an overall negative effect on yields of major cereal crops across Africa, with strong regional variability in the degree of yield reduction (see also Chapter 7.3.2.1) (Lobell *et al.*, 2008; Liu *et al.*, 2008; Walker and Schulze, 2008; Thornton *et al.*, 2009a; Lobell *et al.*, 2011; Roudier *et al.*, 2011; Berg *et al.*, 2013) (*high confidence*). One exception is in eastern Africa where maize production could benefit from warming at sites above roughly 1,700 m in elevation (A1FI scenario) (Thornton *et al.*, 2009a), although the majority of current maize production occurs at lower elevations thereby implying a potential change in the distribution of maize cropping. Maize-based systems, particularly in southern Africa, are among the most vulnerable to climate change (Lobell *et al.*, 2008). Estimated yield losses at mid-century range from 18% for southern Africa (Zinyengere *et al.*, 2013) to 22% aggregated across SSA, with yield losses for South Africa and Zimbabwe in excess of 30% (Schlenker and Lobell, 2010). Simulations that combine all regions south of the Sahara suggest consistently negative effects of climate change on major cereal crops in Africa, ranging from 2% for sorghum to 35% for wheat by 2050 under an A2 scenario (Nelson *et al.*, 2009). Studies in North Africa by Eid *et al.*, 2007; Hegazy *et al.*, 2008; Drine, 2011; Mougou *et al.*, 2011 also indicate a high vulnerability of wheat production to projected warming trends. In West Africa, temperature increases above 2° C (relative to a 1961-1990 baseline) are estimated to counteract positive effects on millet and sorghum yields of increased precipitation (for B1, A1B and A2 scenarios) (Figure 22.5), with negative effects stronger in the savannah than in the Sahel, and with modern cereal varieties compared with traditional ones (Sultan et al., 2013).

Several recent studies since the AR4 indicate that climate change will have variable impacts on non-cereal crops, with both production losses and gains possible (*low confidence*). Cassava yields in eastern Africa are estimated to moderately increase up to the 2030s assuming CO2 fertilization and under a range of low to high emissions scenarios (Liu *et al.*, 2008), findings that were similar to Lobell et al. (2008). Suitability for growing cassava is estimated to increase with the greatest improvement in suitability in eastern and central Africa (A1B scenario) (Jarvis *et al.*, 2012). However, Schlenker and Lobell (2010) estimated negative impacts from climate change on cassava at mid-century, although with impacts estimated to be less than those for cereal crops. Given cassava's hardiness to higher temperatures and sporadic rainfall relative to many cereal crops, it may provide a potential option for crop substitution of cereals as an adaptation response to climate change (Rosenthal and Ort, 2012; Jarvis *et al.*, 2012). Bean yields in Eastern Africa are estimated to experience yield reductions by the 2030s under an intermediate emissions scenario (A1B) (Jarvis *et al.*, 2012) and by the 2050s under low (B1) and high (A1FI) emissions scenarios (Thornton *et al.*, 2011). For peanuts, some studies indicate a positive effect from climate change (A2 and B2 scenarios) (Tingem and Rivington, 2009) and others a negative one (Lobell *et al.*, 2008; Schlenker and Lobell, 2010). Bambara groundnuts (*Vigna subterranea*) are estimated to benefit from moderate climate change (Tingem and Rivington, 2009) (A2 and B2 scenarios) although the effect could be highly variable across varieties (Berchie *et al.*, 2012). Banana and plantain production could decline in West Africa and lowland areas of East Africa, whereas in highland areas of East Africa it could increase with temperature rise (Ramirez *et al.*, 2011). Much more research is needed to better establish climate change impacts on these two crops.

Suitable agro-climatic zones for growing economically important perennial crops are estimated to significantly diminish, largely due to the effects of rising temperatures (Läderach *et al.*, 2010; Eitzinger *et al.*, 2011a; Läderach *et al.*, 2011a; Eitzinger *et al.*, 2011b; Läderach *et al.*, 2011b; Läderach *et al.*, 2011c). Under an A2 scenario, by mid-century suitable agro-climatic zones that are currently classified as very good to good for perennial crops may become more marginal, and what are currently marginally suitable zones may become unsuitable; the constriction of crop suitability could be severe in some cases (Table 22-4). Movement of perennial crops to higher altitudes would serve to mitigate the loss of suitability at lower altitudes but this option is limited. Loss of productivity of high-value crops such as tea, coffee and cocoa would have detrimental impacts on export earnings.

[INSERT TABLE 22-4 HERE
Table 22-4. Projected changes in agro-climatic suitability for perennial crops in Africa by mid-century under an A2 scenario.]

[INSERT FIGURE 22-5 HERE
Figure 22-5: The effect of rainfall and temperature changes on mean crop yield. Mean crop yield change (%) relative to the 1961–90 baseline for 7 temperatures (x-axis) and 5 rainfall (y-axis) scenarios. Results are shown as the average over the 35 stations across West Africa and the 6 cultivars of sorghum and millet. White triangles and circles are the projected anomalies computed by several CMIP3 GCMs and three IPCC emission scenarios (B1, A1B, A2) for 2071–90 and 2031–50, respectively. Projections from CMIP5 GCMs and three RCPs (4.5, 6.0 and 8.5) are represented by grey triangles and circles. Models and scenarios names are displayed in figure S2 (available atstacks.iop.org/ERL/8/014040/mmedia). Past observed climate anomalies from CRU data are also projected by computing 10-year averages (e.g. '1940' is for 1941–50). All mean yield changes are significant at a 5% level except boxes with a diagonal line. Source: Sultan et al., 2013.].

22.3.4.2. Livestock

Livestock systems in Africa face multiple stressors that can interact with climate change and variability to amplify the vulnerability of livestock-keeping communities. These stressors include rangeland degradation, increased variability in access to water, fragmentation of grazing areas, sedentarization, changes in land tenure from communal towards private ownership, in-migration of non-pastoralists into grazing areas, lack of opportunities to diversify livelihoods, conflict and political crisis, weak social safety nets, and insecure access to land, markets, and other resources (Solomon *et al.*, 2007; Smucker and Wisner, 2008; Galvin, 2009; Thornton *et al.*, 2009b; Dougill *et al.*, 2010; Ifejika Speranza, 2010). (See also Chapter 7.3.2.4.)

Loss of livestock under prolonged drought conditions is a critical risk given the extensive rangeland in Africa that is prone to drought. Regions that are projected to become drier with climate change, such as Northern and Southern Africa, are of particular concern (Solomon *et al.*, 2007; Masike and Urich, 2008; Thornton *et al.*, 2009b; Dougill *et al.*, 2010; Freier *et al.*, 2012; Schilling *et al.*, 2012). Adequate provision of water for livestock production could become more difficult under climate change. For example, Masike and Urich (2009) estimated that the cost of supplying livestock water from boreholes in Botswana will increase by 23% by 2050 under an A2 scenario due to increased hours of groundwater pumping needed to meet livestock water demands under warmer and drier conditions. Although small in comparison to the water needed for feed production, drinking water provision for livestock is critical, and can have a strong impact on overall resource use efficiency in warm environments (Peden *et al.*, 2009; van Breugel *et al.*, 2010; Descheemaeker *et al.*, 2010; Descheemaeker *et al.*, 2011). Livestock production will be indirectly affected by water scarcity through its impact on crop production and subsequently the availability of crop residues for livestock feeding. Thornton et al. (2010) estimated that maize stover availability per head of cattle will decrease in several East African countries by 2050.

The extent to which increased heat stress associated with climate change will affect livestock productivity has not been well established, particularly in the tropics and sub-tropics (Thornton *et al.*, 2009b), although a few studies point to the possibility that keeping heat-tolerant livestock will become more prevalent in response to warming trends. For example, higher temperatures in lowland areas of Africa could result in reduced stocking of dairy cows in favor of cattle (Kabubo-Mariara, 2008), a shift from cattle to sheep and goats (Kabubo-Mariara, 2008; Seo and Mendelsohn, 2008), and decreasing reliance on poultry (Seo and Mendelsohn, 2008). Livestock keeping in highland areas of East Africa, which is currently cold-limited, would potentially benefit from increased temperatures (Thornton *et al.*, 2010). Lunde and Lindtjørn (2013) challenge a finding in the AR4 that there is direct proportionality between range-fed livestock numbers and changes in annual precipitation in Africa. Their analysis indicates that this relationship may hold in dry environments but not in humid ones.

22.3.4.3. Agricultural Pests, Diseases, and Weeds

Since the AR4, understanding of how climate change will potentially affect crop and livestock pests and diseases and agricultural weeds in Africa is beginning to emerge. Climate change in interaction with other environmental and production factors could intensify damage to crops from pests, weeds and diseases (7.3.2.3).

Warming in highland regions of eastern Africa could lead to range expansion of crop pests into cold-limited areas (*low confidence*). For example, in highland arabica coffee-producing areas of eastern Africa, warming trends may result in the coffee berry borer (*Hypothenemus hampei*) becoming a serious threat in coffee-growing regions of Ethiopia, Kenya, Uganda, Rwanda, and Burundi (Jaramillo *et al.*, 2011). Temperature increases in highland banana-producing areas of eastern Africa enhance the risk of altitudinal range expansion of the highly destructive burrowing nematode, *Radopholus similis* (Nicholls *et al.*, 2008); however, no detailed studies have assessed this risk. Ramirez et al. (2011) estimated that increasing minimum temperatures by 2020 would expand the suitable range of Black Leaf Streak disease (Mycosphaerella fijiensis M.) of banana in Angola and Guinea.

Climate change may also affect the distribution of economically important pests in lowland and dryland areas of Africa (*low confidence*). Under A2A and B2A for 2020, Cotter et al. (2012) estimated that changes in temperature, rainfall, and seasonality will result in more suitable habitats for *Striga hermonthica* in central Africa, whereas the Sahel region may become less suitable for this weed. Striga weed infestations are a major cause of cereal yield reduction in Sub-Saharan Africa. Climate change could also lead to an overall decrease in the suitable range of major cassava pests – whitefly, cassava brown streak virus, cassava mosaic geminivirus, and cassava mealybug (Jarvis *et al.*, 2012), although southeast Africa and Madagascar is estimated to experience increased suitability for cassava pests (Bellotti *et al.*, 2012).

In the case of livestock, Olwoch et al. (2008) estimated that the distribution of the main tick vector species (*Rhipicephalus appendiculatus*) of East Coast fever disease in cattle could be altered by a 2°C temperature increase over mean annual temperatures throughout the 1990s, and changes in mean precipitation resulting in the climatically suitable range of the tick shifting southward. However, a number of environmental and socio-economic factors (e.g., habitat destruction, land use and cover change, and host density) in addition to climatic ones influence tick distribution and need to be considered in assigning causality (Rogers and Randolph, 2006).

22.3.4.4. Fisheries

Fisheries are an important source of food security in Africa. Capture fisheries (marine and inland) and aquaculture combined contribute over one-third of Africa's animal protein intake (Welcomme, 2011), while in some coastal countries fish contribute up to two-thirds of total animal protein intake (Allison *et al.*, 2009). Demand for fish is projected to increase substantially in Africa over the next few decades (De Silva and Soto, 2009). To meet fish food demand by 2020, De Silva and Soto (2009) estimated that aquaculture production in Africa would have to increase nearly 500%.

The vulnerability of national economies to climate change impacts on fisheries can be linked to exposure to the physical effects of climate change, the sensitivity of the country to impacts on fisheries, and adaptive capacity within the country (Allison *et al.*, 2009). In an analysis of fisheries in 132 countries Allison et al. (2009) estimated that two-thirds of the most vulnerable countries were in Africa. Among these countries, the most vulnerable were Angola, DR Congo, Mauritania and Senegal, due to the importance of fisheries to the poor and the close link between climate variability and fisheries production. Coastal countries of West Africa will experience a significant negative impact from climate change. Lam et al. (2012) projected that by 2050 (under an A1B scenario) the annual landed value of fish for that region is estimated to decline by 21%, resulting in a nearly 50% decline in fisheries-related employment and a total annual loss of US$ 311 million to the region's economy.

22.3.4.5. Food Security

Food security in Africa faces multiple threats stemming from entrenched poverty, environmental degradation, rapid urbanization, high population growth rates, and climate change and variability. The intertwined issues of markets and food security have emerged as an important issue in Africa and elsewhere in the developing world since the AR4. Price spikes for globally traded food commodities in 2007–2008 and food price volatility and higher overall food prices in subsequent years have undercut recent gains in food security across Africa (Brown *et al.*, 2009; Hadley *et al.*, 2011; Mason *et al.*, 2011; Tawodzera, 2011; Alem and Söderbom, 2012; Levine, 2012). Among the most affected groups are the urban poor, who typically allocate more than half of their income to food purchases (Cohen and Garrett, 2010; Crush and Frayne, 2010). The proportion of smallholder farmers that are net food buyers of staple grains exceeds 50% in Mozambique, Kenya and Ethiopia (Jayne et al., 2006), thus food security of rural producers is also sensitive to food spikes, particularly in the case of female-headed households, which generally have fewer assets than male-headed households (Kumar and Quisumbing, 2011). Although the recent spike in global food prices can be attributed to a convergence of several factors, the intensification of climate change impacts could become more important in the future in terms of exerting upward pressure on food prices of basic cereals (Nelson *et al.*, 2009; Hertel *et al.*, 2010), which would have serious implications for Africa's food security. As the recent wave of food price crises demonstrates, factors in other regions profoundly impact food security in Africa. Much more research is needed to understand better the potential interactions between climate change and other key drivers of food prices that act at national, regional, and global scales. (See also Chapter 7.2.2.)

Africa is undergoing both rapid urbanization and subsequent transformation of its food systems to accommodate changes in food processing and marketing as well as in food consumption patterns. Considering the increasing reliance on purchased food in urban areas, approaches for addressing the impacts of climate change on food security will need to encompass a food systems approach (production as well as processing, transport, storage, and preparation) that moves food from production to consumption (Battersby, 2012). Weaknesses in the food system may be exacerbated by climate change in the region as high temperatures increase spoilage and the potential for increased flooding places food transportation infrastructure at higher risk of damage. In this respect, high post-harvest losses in Africa resulting in a large part from inadequate transport and storage infrastructure (Godfray *et al.*, 2010; Parfitt *et al.*, 2010) are an important concern.

22.3.5. Health

22.3.5.1. Introduction

Africa currently experiences high burdens of health outcomes whose incidence and geographic range could be affected by changing temperature and precipitation patterns, including malnutrition, diarrheal diseases, and malaria and other vector-borne diseases, with most of the impact on women and children (WHO 2013a). In 2010, there were 451,000 to 813,000 deaths from malaria in Africa, continuing a slow decline since approximately 2004 (WHO, 2012). There are insufficient data series to assess trends in incidence in most affected countries in Africa. Parasite prevalence rates in children less than 5 years of age are highest in poorer populations and rural areas; factors increasing vulnerability include living in housing with little mosquito protection and limited access to health care facilities offering effective diagnostic testing and treatment. Of the 3.6 million annual childhood deaths in Africa, 11% are due to diarrheal diseases (Liu *et al*., 2012).

Drivers of these and other climate-relevant health outcomes include inadequate human and financial resources, inadequate public health and health care systems, insufficient access to safe water and improved sanitation, food insecurity, and poor governance. Although progress has been made on improving safe water and sanitation coverage, sub-Saharan Africa still has the lowest coverage, highlighting high vulnerability to the health risks of climate change (UNICEF and WHO, 2008; UNICEF and WHO, 2012). Vulnerabilities also arise from policies and measures implemented in other sectors, including adaptation and mitigation options. Collaboration between sectors is essential. For example, the construction of the Akosombo dam in the 1960s to create Lake Volta in Ghana was associated with a subsequent increase in the prevalence of schistosomiasis (Scott *et al*., 1982).

22.3.5.2. Food- and Water-Borne Diseases

Cholera is primarily associated with poor sanitation, poor governance, and poverty, with associations with weather and climate variability suggesting possible changes in incidence and geographic range with climate change (Rodó *et al.*, 2002; Koelle *et al.*, 2005; Olago *et al.*, 2007; Murray *et al.*, 2012). The frequency and duration of cholera outbreaks are associated with heavy rainfall in Ghana, Senegal, other coastal West African countries, and South Africa, with a possible association with the El Niño-Southern Oscillation (ENSO) (de Magny *et al.*, 2007;

Mendelsohn and Dawson, 2008; de Magny *et al*., 2012). In Zanzibar, Tanzania, and Zambia, an increase in temperature or rainfall increases the number of cholera cases (Luque Fernández *et al*., 2009; Reyburn *et al*., 2011). The worst outbreak of cholera in recent African history occurred in Zimbabwe from August 2008 to June 2009. The epidemic was associated with the rainy season and caused more than 92,000 cases and 4,000 deaths. Contamination of water sources spread the disease (Mason, 2009). Poor governance, poor infrastructure, limited human resources, and underlying population susceptibility (high burden of malnutrition) contributed to the severity and extent of the outbreak (Murray *et al.*, 2012). Other mechanisms for increases in cholera incidence have been described in Chapter 11 (11.5.2.1). As discussed above in section 22.2 there are projected increases in precipitation in areas in Africa for example West Africa where cholera is already endemic. This possibly will lead to more frequent cholera outbreaks in the sub-regions affected. However, further research is needed to quantify the climatic impacts.

22.3.5.3. Nutrition

Malnutrition: Detailed spatial analyses of climate and health dynamics among children in Mali and Kenya suggest associations between livelihoods and measures of malnutrition, and between weather variables and stunting (Grace *et al*., 2012; Jankowska *et al*., 2012). Projections of climate and demographic change to 2025 for Mali (based on 2010-2039 climatology from the Famine Early Warning System Network FCLIM method), suggest approximately 250,000 children will suffer stunting, nearly 200,000 will be malnourished, and over 100,000 will become anemic, assuming constant morbidity levels; the authors conclude that climate change will cause a statistically significant proportion of stunted children (Jankowska *et al*., 2012).

Using a process-driven approach, (Lloyd *et al.*, 2011) projected future child malnutrition (as measured by severe stunting) in 2050 for four regions in sub-Saharan Africa, taking into consideration food and nonfood (socioeconomic) causes, and using regional scenario data based on the A2 scenario. Current baseline prevalence rates of severe stunting were 12-20%. Considering only future socioeconomic change, the prevalence of severe stunting in 2050 would be 7-17% (e.g. a net decline). However, including climate change, the prevalence of severe stunting would be 9-22%, or an increase of 31-55%in the relative percent of children severely stunted. Western sub-Saharan Africa was projected to experience a decline in severe stunting from 16% at present to 9% in 2050 when considering socioeconomic and climate change. Projected changes for central, south, and east sub-Saharan Africa are close to current prevalence rates, indicating climate change would counteract the beneficial consequences of socioeconomic development. Local economic activity and food accessibility can reduce the incidence of malnutrition (Funk *et al.*, 2008; Rowhani *et al.*, 2011).

22.3.5.4. Vector-Borne Diseases and Other Climate-Sensitive Health Outcomes

A wide range of vector-borne diseases contribute to premature morbidity and mortality in Africa, including malaria, leishmaniasis, Rift Valley fever, as well as tick- and rodent-borne diseases.

Malaria: Weather and climate are among the environmental, social, and economic determinants of the geographic range and incidence of malaria (Reiter 2008). The association between temperature and malaria varies regionally, (Chaves and Koenraadt, 2010; Paaijmans *et al.*, 2010a; Alonso *et al.*, 2011; Gilioli and Mariani, 2011). Malaria transmission peaks at 25°C and declines above 28°C (Lunde *et al.*, 2013; Mordecai *et al*., 2013). Total precipitation, rainfall patterns, temperature variability, and the water temperature of breeding sites are expected to alter disease susceptibility (Bomblies and Eltahir, 2010; Paaijmans *et al.*, 2010b; Afrane *et al.*, 2012; Blanford *et al.*, 2013; Lyons *et al.*, 2013). ENSO events also may contribute to malaria epidemics (Mabaso *et al.*, 2007; Ototo *et al.*, 2011). The complexity of the malaria transmission cycle makes it difficult to determine whether the distribution of the pathogen and vector are already changing due to climate change. Other factors like the Indian Ocean Dipole have been proposed to affect malaria incidence (Hashizume et al., 2009, Chaves et al., 2012, Hashizume et al., 2012).

Climate change is expected to affect the geographic range and incidence of malaria, particularly along the current edges of its distribution, with contractions and expansions, and increasing and decreasing incidence (Yé *et al.*, 2007; Peterson, 2009; Parham and Michael, 2010; Paaijmans *et al.*, 2010b; Alonso *et al.*, 2011; Egbendewe-Mondzozo *et* *al.*, 2011; Chaves *et al.*, 2012; Paaijmans *et al.*, 2012; Parham *et al.*, 2012; Ermert *et al.*, 2012), depending on other drivers, such as public health interventions, factors influencing the geographic range and reproductive potential of malaria vectors, land use change (e.g., deforestation), and drug resistance, as well as the interactions of these drivers with weather and climate patterns (Chaves *et al.*, 2008; Kelly-Hope *et al.*, 2009; Paaijmans *et al.*, 2009; Saugeon *et al.*, 2009; Artzy-Randrup *et al.*, 2010; Dondorp *et al.*, 2010; Gething *et al.*, 2010; Jackson *et al.*, 2010; Kulkarni *et al.*, 2010; Loha and Lindtjørn, 2010; Tonnang *et al.*, 2010; Stern *et al.*, 2011; Caminade *et al.*, 2011; Omumbo *et al.*, 2011; Afrane *et al.*, 2012; Edlund *et al.*, 2012; Githeko *et al.*, 2012; Himeidan and Kweka, 2012; Jima *et al.*, 2012; Lyons *et al.*, 2012; Ermert *et al.*, 2012; Stryker and Bomblies, 2012; Mordecai *et al.*, 2013). Movement of the parasite into new regions is associated with epidemics with high morbidity and mortality. Because various *Anopheles* species are adapted to different climatic conditions, changing weather and climate patterns could affect species composition differentially, which could, in turn affect malaria transmission (Afrane *et al.*, 2012; Lyons *et al.*, 2013).

Consensus is growing that highland areas, especially in East Africa, will experience increased malaria epidemics, with areas above 2,000 m, with temperatures currently too low to support malaria transmission, particularly affected (Pascual *et al.*, 2006; Peterson, 2009; Gething *et al.*, 2010; Lou and Zhao, 2010; Paaijmans *et al.*, 2010a; Ermert *et al.*, 2012). Reasons for different projections across models include use of different scenarios; use of global versus regional climate models (Ermert *et al.*, 2012); the need for finer-scale and higher-resolution models of the sharp climate variations with altitude (Bouma *et al.*, 2011); and the extent to malaria transmission and the drivers of its geographic range and incidence of malaria respond to and interact with climate change.

Leishmaniasis: Directly or indirectly, climate change may increase the incidence and geographic range of leishmaniasis, a highly neglected disease that has recently become a significant health problem in northern Africa (Postigo, 2010), with a rising concern in western Africa because of co-infection with HIV (Kimutai *et al.*, 2006). The epidemiology of the disease appears to be changing (Dondji, 2001; Yiougo *et al.*, 2007; WHO, 2009; Postigo, 2010). During the 20th century, zoonotic cutaneous leishmaniasis emerged as an epidemic disease in Algeria, Morocco, and Tunisia, and is now endemic (Salah *et al.*, 2007; Aoun *et al.*, 2008; Rhajaoui, 2011; Toumi *et al.*, 2012; Bounoua *et al.*, 2013). Previously an urban disease in Algeria, leishmaniasis now has a peri-urban distribution linked to changes in the distribution of the rodent host and of the vector since the early 1990s (Aoun *et al.*, 2008). Cutaneous leishmaniasis has expanded its range from its historical focus at Biskra, Algeria into the semi-arid steppe, with an associated upward trend in reported cases. In Morocco, sporadic cases of leishmania major (vector *Phlebotomus papatasi*) appeared early in the 20th century; since that time there have been occasional epidemics of up to 2,000 cases, interspersed with long periods with few or no cases (Rhajaoui, 2011). Outbreaks of zoonotic cutaneous leishmaniasis have become more frequent in Tunisia (where it emerged as an epidemic disease in 1991) (Salah *et al.*, 2007; Toumi *et al*., 2012). The disease has since spread to adjacent areas in West Africa and East Africa (Dondji, 2001; Yiougo *et al.*, 2007; WHO, 2009). Disease incidence is associated with rainfall and minimum temperature (Toumi *et al.*, 2012; Bounoua *et al.*, 2013). Relationships between decadal shifts over 1990-2009 in northwest Algeria and northeast Morocco in the number of cases and climate indicators suggested increased minimum temperatures created conditions suitable for endemicity (Bounoua *et al.*, 2013). Environmental modifications, such as construction of dams, can change the temperature and humidity of the soil and thus affect vegetation that may result in changes in the composition and density of sandfly species and rodent vectors. More research however, is needed to quantity the climate related impacts because there are multiple underlying factors.

Rift Vally fever (RVF): RVF epidemics in the Horn of Africa are associated with altered rainfall patterns. Additional climate variability and change could further increase its incidence and spread. Rift Valley fever is endemic in numerous African countries, with sporadic repeated epidemics. Epidemics in 2006–2007 in the Horn of Africa (Nguku *et al.*, 2007; WHO, 2007; Adam *et al.*, 2010; Andriamandimby *et al.*, 2010; Hightower *et al*., 2012) and southern Africa were associated with heavy rainfall (Chevalier *et al.*, 2011), strengthening earlier analyses by Anyamba *et al.* (2009) showing that RVF epizootics and epidemics are closely linked to the occurrence of the warm phase of ENSO and La Nina events (Linthicum *et al.*, 1999; Anyamba *et al.*, 2012) and elevated Indian Ocean temperatures. These conditions lead to heavy rainfall and flooding of habitats suitable for the production of the immature *Aedes* and *Culex* mosquitoes that serve as the primary RVF virus vectors in East Africa. Flooding of mosquito habitats also may introduce the virus into domestic animal populations.

Ticks and tick-borne diseases: Changing weather patterns could expand the distribution of ticks causing animal disease, particularly in East and South Africa. Ticks carry theileriosis (East Coast Fever), which causes anemia and skin damage that expose cattle to secondary infections. Habitat destruction, land use and cover change, and host density also affect tick distribution (Rogers and Randolph, 2006). Using a climate envelope and a species prediction model, Olwoch *et al*. (2007) projected that by 2020s, under the A2 scenario, East Africa and South Africa would be particularly vulnerable to climate-related changes in tick distributions and tick-borne diseases: more than 50% of the 30 *Rhipicephalus* species examined showed significant range expansion and shifts. More than 70% of this range expansion was found in tick species of economic importance.

Schistosomiasis: Worldwide, approximately 243 million people required treatment for schistosomiasis in 2011, of which 90% lived in underdeveloped areas of Africa (WHO, 2013b). Water resource development, such as irrigation dams recommended for adaptation in agriculture, can amplify the risk of schistosomiasis (Huang and Manderson, 1992; Hunter *et al.*, 1993; Jobin, 1999). Migration and sanitation play a significant role in the spread of schistosomiasis from rural areas to urban environments (Babiker *et al.*, 1985; WHO, 2013b). Temperature and precipitation patterns may play a role in transmission (Odongo-Aginya *et al.*, 2008; Mutuku *et al.*, 2011; Huang *et al*., 2011). Projections for the period 2070-2099, under A2 and B2 emission scenarios, suggest that although the geographic areas suitable for transmission will increase with climate change, snail regions are expected to contract and/or move to cooler areas; these results highlight the importance of understanding how climate change could alter snail habitats when projecting future human schistosomiasis prevelance under different scenarios (Stensgaard *et al*. 2011).

Meningococcal meningitis: There is a strong environmental relationship between the seasonal cycle of meningococcal meningitis and climate, including a relationship between the seasonal pattern of the Harmattan dusty winds and onset of disease. Transmission of meningitis occurs throughout Africa in the dry season and coincides with periods of very low humidity and wind-driven dusty conditions, ending with the onset of the rains (Molesworth *et al.*, 2003). Research corroborates earlier hypothesized relationships between weather and meningitis (Yaka *et al.*, 2008; Palmgren, 2009; Roberts, 2010; Dukić *et al.*, 2012; Agier *et al*., 2013). In the northern region of Ghana, exposure to smoke from cooking fires increased the risk of contracting meningococcal meningitis (Hodgson *et al.*, 2001). This increased risk suggests that exposure to elevated concentrations of air pollutants, such as carbon monoxide (CO) and particulate matter, may be linked to illness. More research is needed to clarify the possible impact of climate change on atmospheric concentrations of aerosols and particulates that can impact human health and any associations between meningitis and these aerosols and particles. The relationship between the environment and the location of the epidemics suggest connections between epidemics and regional climate variability (Molesworth *et al.*, 2003; Sultan *et al.*, 2005; Thomson *et al.*, 2006) which may allow for early warning systems for predicting the location and onset of epidemics.

Hantavirus: Novel hantaviruses with unknown pathogenic potential have been identified in some insectivores (shrews and a mole) in Africa (Klempa, 2009), with suggestions that weather and climate, among other drivers, could affect natural reservoirs and their geographic range, and thus alter species composition in ways that could be epidemiologically important (Klempa, 2009).

Other health issues: Research into other health issues has begun. It has been noted that any increase in food insecurity due to climate change would be expected to further compromise the poor nutrition of people living with HIV/AIDs (Drimie and Gillespie, 2010). Laboratory studies suggest that the geographic range of the tsetse fly (*Glossina* species), the vector of human and animal trypanosomiasis in Africa, may be reduced with climate change (Terblanche *et al.*, 2008). More studies are needed to clarify the role of climate change on HIV and other disease vectors.

Heat waves and high ambient temperatures: Heat waves and heat-related health effects are only beginning to attract attention in Africa. High ambient temperatures are associated with increased mortality in Ghana, Burkina Faso, and Nairobi with associations varying by age, gender, and cause of death (Azongo *et al*., 2012; Diboulo *et al*., 2012; Egondi *et al*., 2012). Children are particularly at risk. Heat-related health effects also may be of concern in West and southern Africa (Dapi *et al.*, 2010; Mathee *et al.*, 2010). Chapter 11 (11.4.1) assesses the literature on the health impacts of heat waves and high ambient temperatures. Low ambient temperatures are associated with mortality in

Nairobi and Tanzania (Egondi *et al*., 2012; Mrema *et al*., 2012). Chapter 11 discusses the relationship between heat and work capacity loss. This is an important issue for Africa because of the number of workers engaged in agriculture.

Air quality: Climate change is anticipated to affect the sources of air pollutants as well as the ability of pollutants to be dispersed in the atmosphere (Denman *et al.*, 2007). Assessments of the impacts of projected climate change on atmospheric concentrations of aerosols and particules that can adversely affect human health indicate that changes in surface temperature, land cover, and lightning may alter natural sources of ozone precursor gases and consequently ozone levels over Africa (Stevenson *et al.*, 2005; Brasseur *et al.*, 2006; Zeng *et al.*, 2008). However, insufficient climate and emissions data for Africa prevent a more comprehensive assessment and further research is needed to better understand the implications of climate change on air quality in Africa.

22.3.6. Urbanization

The urban population in Africa is projected to triple by2050, increasing by 0.8 billion (UN DESA, 2010). African countries are experiencing some of the world's highest urbanization rates (UN-Habitat, 2008). Many of Africa's evolving cities are unplanned and have been associated with growth of informal settlements, inadequate housing and basic services, and urban poverty (Yuen and Kumssa, 2011).[7]

[FOOTNOTE 7: However, community-driven upgrading may contribute to reducing the vulnerability of such informal areas (for more details see Chapter 8).]

Climate change could affect the size and characteristics of rural and urban human settlements in Africa because the scale and type of rural-urban migration are partially driven by climate change (UN-Habitat and UNEP, 2010; Yuen and Kumssa, 2011). The majority of migration flows observed in response to environmental change are within country boundaries (Jäger *et al.*, 2009; Tacoli, 2009). For large urban centers located on mega-deltas (e.g., Alexandria in Egypt in the Nile delta, and Benin City, Port Harcourt, and Aba in Nigeria in the Niger delta), urbanization through migration may also lead to increasing numbers of people vulnerable to coastal climate change impacts (Seto, 2011). Floods are exerting considerable impacts on cities and smaller urban centers in many African nations – for example, heavy rains in East Africa in 2002 caused floods and mudslides, which forced tens of thousands to leave their homes in Rwanda, Kenya, Burundi, Tanzania and Uganda, and the very serious floods in Port Harcourt and Addis Ababa in 2006 (Douglas *et al.*, 2008).

Additionally sea level rise along coastal zones including coastal settlements could disrupt economic activities such as tourism and fisheries (Naidu *et al*., 2006; Kebede *et al.*, 2012, Kebede and Nicholls, 2012). More than a quarter of Africa's population lives within 100 km of the coast and more than half of Africa's total population living in low-elevation coastal zones is urban, accounting for 11.5% of the total urban population of the continent (UN-Habitat, 2008).

In eastern Africa, an assessment of the impact of coastal flooding due to sea level rise in Kenya found that, by 2030, 10,000 to 86,000 people would be affected, with associated economic costs ranging between US$ 7 million to US$ 58 million (SEI, 2009). Detailed assessments of damages arising from extreme events have also been made for some coastal cities, including Mombasa and Dar-es-Salaam. In Mombasa, by 2030 the population and assets at risk of 1 in 100-year return period extreme water levels is estimated to be between 170,700 to 266,300 inhabitants, while economic assets at risk are between US$ 0.68 billion and 1.06 billion (Kebede *et al.*, 2012). In Dar-es-Salaam, the population and economic assets at risk of 1 in 100-year return period extreme water levels by 2030 range between 30,300 and 110,000 inhabitants and US$ 35.6 million to US$ 404.1 million (Kebede and Nicholls, 2012). For both city assessments, the breadth of these ranges encompasses three different population growth scenarios and four different sea-level rise scenarios (low (B1), medium (A1B), high (A1FI), and Rahmstorf (based on Rahmstorf, 2007)); these four sea-level rise scenarios were also the basis for the broader assessment of the coast of Kenya (SEI, 2009). The scale of the damages projected in the city-specific studies highlights the risks of extremes in the context of projected sea-level rise.

In southern Africa, urban climate change risk assessments have been made at the regional scale (Theron and Rossouw, 2008) as well as at the city level for Durban, Cape Town, and the uMhlathuze local municipality. For these cities, risk assessments have focused on a broad range of sectors, including business and tourism; air quality, heath, and food security; infrastructure and services; biodiversity; and water resources (Naidu *et al.*, 2006; Cartwright, 2008; Zitholele Consulting, 2009).

Assessments for western Africa (Appeaning Addo *et al.*, 2008; Niang *et al.*, 2010) and northern Africa (Snoussi *et al.*, 2009; World Bank, 2011) share similarities with those for eastern and southern Africa. For instance, it was suggested that by the end of the 21st century, about 23 %, 42 %, and 49 % of the total area of coastal governorates of the Nile Delta would be susceptible to inundation under the A1FI, Rahmstorf and Pfeffer scenarios of SLR. It was also suggested that a considerable proportion of these areas (ranging between 32% and 54 %) are currently either wetland or undeveloped areas (Hassaan and Abdrabo, 2013). Another study, assessing the economic impacts of sea level rise on the Nile Delta, suggested that losses in terms of housing and road would range between 1 and 2 billion EGP in 2030 and between 2 and 16 billion EGP in 2060 under the A1FI and B1 emissions scenarios as well as current sea level rise trends (Smith *et al.*, 2013).

African cities and towns represent highly vulnerable locations to the impacts of climate change and climate variability (Boko *et al.*, 2007; Diagne, 2007; Dossou and Gléhouenou-Dossou, 2007; Douglas *et al.*, 2008; Adelekan, 2010; Kithiia, 2011). Rapid rates of urbanization represent a burden on the economies of African urban areas, due to the massive investments needed to create job opportunities and provide infrastructure and services. Basic infrastructure services are not keeping up with urban growth, which has resulted in a decline in the coverage of many services, compared to 1990 levels (Banerjee *et al.*, 2007). Squatter and poor areas typically lack provisions to reduce flood risks or to manage floods when they happen (Douglas *et al.*, 2008).

African small- and medium-sized cities have limited adaptive capacity to deal not only with future climate impacts but also with the current range of climate variability (Satterthwaite *et al*., 2009; UN-Habitat, 2011); for more details see Chapter 5 and Chapter 8). African cities, despite frequently having more services compared to rural areas (e.g., piped water, sanitation, schools and healthcare) that lead to human life spans above their respective national averages, show a shortfall in infrastructure due to low quality and short lifespan which may be of particular concern, when climate change impacts are taken into consideration (Satterthwaite *et al*., 2009). It is not possible, however, “to climate-proof infrastructure that is not there” (Satterthwaite *et al.*, 2009). At the same time, hard infrastructural responses such as seawalls and channelized drainage lines are costly and can be maladaptive (Dossou and Gléhouenou-Dossou, 2007; Douglas *et al.*, 2008; Kithiia and Lyth, 2011).

High levels of vulnerability and low adaptive capacity results from structural factors, particularly local governments with poor capacities and resources (Kithiia, 2011). Weak local government creates and exacerbates problems including the lack of appropriate regulatory structures and mandates; poor or no planning; lack of or poor data; lack of disaster risk reduction strategies; poor servicing and infrastructure (particularly waste management and drainage); uncontrolled settlement of high-risk areas such as floodplains, wetlands, and coastlines; ecosystem degradation competing development priorities and timelines; and a lack of coordination among government agencies (AMCEN and UNEP, 2006; Diagne, 2007; Dossou and Gléhouenou-Dossou, 2007; Mukheibir and Ziervogel, 2007; Douglas *et al.*, 2008; Roberts, 2008; Adelekan, 2010; Kithiia and Dowling, 2010; Kithiia, 2011).

22.4. Adaptation

22.4.1. Introduction

Since 2007, Africa has gained experience in conceptualizing, planning and beginning to implement and support adaptation activities, from local to national levels and across a growing range of sectors (22.4.4, 22.4.5). However, across the continent, most of the adaptation to climate variability and change is reactive in response to short-term motivations, is occurring autonomously at the individual / household level, and lacks support from government stakeholders and policies (Vermuelen *et al.*, 2008; Ziervogel *et al.*, 2008; Berrang-Ford *et al.*, 2011). A complex web of interacting barriers to local-level adaptation, manifesting from national to local scales, both constrains and highlights potential limits to adaptation (22.4.6).

22.4.2. Adaptation Needs, Gaps, and Adaptive Capacity

Africa's urgent adaptation needs stem from the continent's foremost sensitivity and vulnerability to climate change, together with its low levels of adaptive capacity (Ludi *et al.*, 2012; 22.3). While overall adaptive capacity is considered low in Africa due to economic, demographic, health, education, infrastructure, governance and natural factors, levels vary within countries and across sub-regions, with some indication of higher adaptive capacity in North Africa and some other countries; individual or household level adaptive capacity depends, in addition to functional institutions and access to assets, on the ability of people to make informed decisions to respond to climatic and other changes (Vincent, 2007; Ludi *et al.*, 2012).

Inherent adaptation-related strengths in Africa include the continent's wealth in natural resources, well-developed social networks, and longstanding traditional mechanisms of managing variability through, for example, crop and livelihood diversification, migration and small-scale enterprises, all of which are underpinned by local or indigenous knowledge systems for sustainable resource management (Eyong, 2007; Nyong *et al.*, 2007; UNFCCC, 2007; Cooper *et al.*, 2008; Macchi *et al.*, 2008; Nielsen, 2010; Castro *et al.*, 2012;). However, it is uncertain to what extent these strategies will be capable of dealing with future changes, among them climate change and its interaction with other development processes (Leary *et al.*, 2008b; Paavola, 2008; van Aalst *et al.*, 2008; Conway, 2009; Jones, 2012, section 22.4.6). Since Africa is extensively exposed to a range of multiple stressors (22.3) that interact in complex ways ith longer term climate change, adaptation needs are broad, encompassing institutional, social, physical and infrastructure needs, ecosystem services and environmental needs, and financial and capacity needs.

Making climate change information more reliable and accessible is one of the most pressing and cross-cutting adaptation needs, but providing information is insufficient to guarantee adaptation, which requires behavioural change (22.4.5.5, 22.4.6). As noted in the AR4 and emphasised in subsequent literature, monitoring networks in Africa are insufficient and characterised by sparse coverage and short and fragmented digitised records, which makes modelling difficult (Boko *et al.*, 2007; Goulden *et al.*, 2009b; Ziervogel and Zermoglio, 2009; Jalloh *et al.*, 2011a). Adding to this is the shortage of relevant information and skills, in particular for downscaling climate models and using scenario outputs for development and adaptation planning, which is exacerbated by under-resourcing of Meteorological Agencies and a lack of in-country expertise on climate science; and the capacity of civil society and government organisations' to access, interpret and use climate information for planning and decisionmaking (Ziervogel and Zermoglio, 2009; Brown *et al.*, 2010; Ndegwa *et al.*, 2010; Dinku *et al.*, 2011; Jalloh *et al.*, 2011a).

Given its economic dependence on natural resources, most research on strengthening adaptive capacity in Africa is focused on agriculture, forestry or fisheries-based livelihoods (Collier *et al.*, 2008; Berrang-Ford *et al.*, 2011). The rural emphasis is now being expanded through a growing focus on requirements for enhancing peri-urban and urban adaptive capacity (Lwasa, 2010; Ricci, 2012). Many African countries have prioritised the following knowledge needs: vulnerability and impact assessments with greater continuity in countries; country-specific socio-economic scenarios and greater knowledge on costs and benefits of different adaptation measures; comprehensive programmes that promote adaptation through a more holistic development approach, including integrated programmes on desertification, water management and irrigation; promoting sustainable agricultural practices and the use of appropriate technologies and innovations to address shorter growing seasons, extreme temperatures, droughts, and floods; developing alternative sources of energy; and approaches to deal with water shortages, food security and loss of livelihoods (UNFCCC, 2007; Bryan *et al.*, 2009; Eriksen and Silva, 2009; Chikozho, 2010; Gbetibouo *et al.*, 2010b; Jalloh *et al.*, 2011b; Sissoko *et al.*, 2011; AAP, 2012). The literature, however, stresses the vast variety of contexts that shape adaptation and adaptive capacity - even when people are faced with the same climatic changes and livelihood stressors, responses vary greatly (Cooper *et al.*, 2008; Vermuelen *et al.*, 2008; Ziervogel *et al.*, 2008; Gbetibouo, 2009; Westerhoff & Smit, 2009)

Despite significant data and vulnerability assessment gaps, the literature highlights that delayed action on adaptation due to this would not be in the best interests of building resilience commensurate with the urgent needs (UNFCCC, 2007; Jobbins, 2011). See section 22.6.4 for a discussion of adaptation costs and climate finance.

22.4.3. Adaptation, Equity, and Sustainable Development

Multiple uncertainties in the African context mean that successful adaptation will depend upon developing resilience in the face of uncertainty (*high confidence)* (Adger *et al.,* 2011; Conway, 2011; Ludi *et al.,* 2012). The limited ability of developmental strategies to counter current climate risks, in some cases due to significant implementation challenges related to complex cultural, political and insitutional factors, has led to an adaptation deficit, which reinforces the desirability for strong inter-linkages between adaptation and development, and for low-regrets adaptation strategies (see AR5 Glossary) that produce developmental co-benefits (*high confidence*) (Bauer and Scholz, 2010; Smith *et al.*, 2011).

Research has highlighted that no single adaptation strategy exists to meet the needs of all communities and contexts in Africa (*high confidence*) (22.4.4, 22.4.5). In recognition of the socioeconomic dimensions of vulnerability (Bauer and Scholz, 2010), the previous focus on technological solutions to directly address specific impacts is now evolving toward a broader view that highlights the importance of building resilience, through social, institutional, policy, knowledge, and informational approaches (ADF, 2010; Chambwera and Anderson, 2011), as well as on linking the diverse range of adaptation options to the multiple livelihood–vulnerability risks faced by many people in Africa (Tschakert and Dietrich, 2010), and on taking into account local norms and practices in adaptation strategies (Nyong *et al.*, 2007; Ifejika Speranza *et al.*, 2010; section 22.4.5.4). Moreover, effective adaptation responses necessitate differentiated and targeted actions from the local to national levels, given the differentiated social impacts based on gender, age, disability, ethnicity, geographical location, livelihood, and migrant status (Tanner and Mitchell, 2008; IPCC, 2012). Additional attention to equity and social justice aspects in adaptation efforts in Africa, including the differential distribution of adaptation benefits and costs, would serve to enhance adaptive capacity (Burton *et al.*, 2002; Brooks *et al.,* 2005; Thomas and Twyman, 2005; Madzwamuse, 2010); nevertheless, some valuable experience has been gained recently on gender-equitable adaptation, human rights based-approaches, and involvement of vulnerable or marginalized groups such as indigenous peoples and children, aged and disabled people, internally displaced persons and refugees (ADF, 2010; UNICEF, 2010; Levine *et al.*, 2011; UNICEF, 2011; Romero González *et al.*, 2011; IDS, 2012; Tanner and Seballos, 2012) (Table 22-5). See also CC-GC on Gender and Climate Change.

[INSERT TABLE 22-5 HERE
Table 22-5: Cross-cutting approaches for equity and social justice in adaptation.]

22.4.4. Experiences in Building the Governance System for Adaptation, and Lessons Learned

22.4.4.1. Introduction

Section 22.4.4 assesses progress made in developing policy, planning and institutional systems for climate adaptation at regional, national and sub-national levels in Africa, with some assessment of implementation. This includes an assessment of community-based adaptation, as an important local level response, and a consideration of adaptation decisionmaking and monitoring.

22.4.4.2. Regional and National Adaptation Planning and Implementation

Regional policies and strategies for adaptation, as well as transboundary adaptation, are still in their infancy. Early examples include the Climate Change Strategies and Action Plans being developed by the Southern African Development Community and the Lake Victoria Basin Committee, as well as efforts being made by six highly forested Congo basin countries to co-ordinate conservation and sustainable forest management of the Central African forest ecosystem, and obtain payments for ecosystem services (Harmeling *et al.*, 2011; AfDB, 2012).

At the national level, African countries have initiated comprehensive planning processes for adaptation by developing National Adaptation Programmes of Action (NAPAs), in the case of the Least Developed Countries, or National Climate Change Response Strategies (NCCRS); implementation is, however, lagging and integration with economic and development planning is limited but growing (*high confidence*). Prioritized adaptation measures in the NAPAs tend to focus narrowly on agriculture, food security, water resources, forestry, and disaster management; and onprojects, technical solutions, education and capacity development, with little integration with economic planning and poverty reduction processes (Madzwamuse, 2010; Mamouda, 2011; Pramova *et al.*, 2012). Only a small percentage of the NAPA activities have been funded to date, although additional funding is in the pipeline (Prowse *et al.*, 2009; Madzwamuse, 2010; Mamouda, 2011; Romero González *et al.*, 2011).

Subsequent to the NAPAs and early experience with the NCCRS, there is some evidence of evolution to a more integrated, multi-level and multi-sector approach to adaptation planning (*medium confidence*). Examples include Ethiopia’s Programme of Adaptation to Climate Change, which includes sectoral, regional, national and local community levels (Hunde, 2012); Lesotho’s co-ordinated policy framework involving all ministries and stakeholders (Corsi *et al.*, 2012); and Mali’s experience with a methodology for integrating adaptation into multiple sectors (Fröde *et al.*, 2013). Cross-sectoral adaptation planning and risk management is occurring through mainstreaming initiatives like the twenty country Africa Adaptation Programme (AAP), initiated in 2008 (UNDP, 2009; Siegel, 2011). Examples of the more programmatic approach of national climate resilient development strategies include Rwanda’s National Strategy on Climate Change and Low Carbon Development, under development in 2012, and the Pilot Programmes for Climate Resilience in Niger, Zambia and Mozambique (Climate Investment Fund, 2009). Inter-sectoral climate risk management approaches can be detected in integrated water resources management, integrated coastal zone management, disaster risk reduction, and land use planning initiatives (Boateng, 2006; Koch *et al*., 2007; Awuor *et al.*, 2008; Cartwright *et al.*, 2008; Kebede and Nicholls, 2011; Kebede *et al.*, 2012), while in South Africa, climate change design principles have been incorporated into existing systematic biodiversity planning to guide land use planning (Petersen and Holness, 2011).

The move to a more integrated approach to adaptation planning is occurring within efforts to construct enabling national policy environments for adaptation in many countries. Examples include Namibia’s National Policy on Climate Change; Zambia’s National Climate Change Response Strategy and Policy, and South Africa’s National Climate Change Response Policy White Paper. Ten countries were developing new climate change laws or formal policies at the end of 2012, including the proposed National Coastal Adaptation Law in Gabon (Corsi *et al.*, 2012).

Despite this progress in mainstreaming climate risk in policy and planning, significant disconnects still exist at the national level, and implementation of a more integrated adaptation response remains tentative (*high confidence*) (Koch *et al.*, 2007; Fankhauser and Schmidt-Traub, 2010; Madzwamuse, 2010; Oates *et al*., 2011; UNDP-UNEP Poverty-Environment Initiative, 2011a). Legislative and policy frameworks for adaptation remain fragmented, adaptation policy approaches seldom take into account realities in the political and institutional spheres, and national policies are often at odds with autonomous local adaptation strategies, which can act as a barrier to adaptation, especially where cultural, traditional and context-specific factors are ignored (Dube and Sekhwela, 2008; Patt and Schröter, 2008; Stringer *et al.*, 2009; Bele *et al.* 2010; Hisali *et al.*, 2011; Kalame *et al.* 2011; Naess *et al.*, 2011; Lockwood, 2012; Sonwa *et al.* 2012; section 22.4.6). While climate resilience is starting to be mainstreamed into economic planning documents - for example, Zambia’s Sixth National Development Plan 2011-2015, and the new Economic and Social Investment Plan in Niger (Corsi *et al.*, 2012), measures to promote foreign direct investment and industrial competitiveness can undercut adaptive capacity of poor people (Madzwamuse, 2010), while poor business environments impede both foreign direct investment and adaptation (Collier *et al*., 2008). Stakeholders in climate-sensitive sectors – for example, Botswana’s tourism industry - have yet to develop and implement adaptation strategies (Saarinen *et al*., 2012).

22.4.4.3. Institutional Frameworks for Adaptation

Global adaptation institutions, both within and outside of the UNFCCC, are critically important for Africa's ability to move forward on adaptation (14.2.3). Regional institutions focused on specific ecosystems rather than on political groupings, such as the Commission of Central African Forests (COMIFAC), present an opportunity to strengthen the institutional framework for adaptation. National frameworks include a number of institutions that cover all aspects of climate change: most countries have inter-ministerial coordinating bodies and inter-sectoral technical working groups, while an increasing number now have multi-stakeholder co-ordinating bodies (Harmeling et al, 2011) and are establishing national institutions to serve as conduits for climate finance (Gomez-Echeverri, 2010; Smith *et al.*, 2011).

Many studies in Africa show that under uncertain climatic futures, replacing hierarchical governance systems that operate within siloes with more adaptive, integrated, multi-level and flexible governance approaches, and with inclusive decisionmaking that can operate successfully across multiple scales – or adaptive governance and co-management – will enhance adaptive capacity and the effectivess of the adaptation response (Folke *et al.*, 2005; Olsson *et al.*, 2006; Koch *et al.*, 2007; Berkes, 2009; Pahl-Wostl, 2009; Armitage and Plummer, 2010; Bunce *et al.*, 2010a; Plummer, 2012). Despite some progress with developing the institutional framework for governing adaptation, there are significant problems with both transversal and vertical coordination, including institutional duplication with other inter-sectoral platforms, such for disaster risk reduction; while in fragile states, institutions for reducing climate risk and promoting adaptation may be extremely weak or almost non-existent (Hartmann and Sugulle, 2009; Sietz *et al.*, 2011; Simane *et al.*, 2012). Facilitating institutional linkages and co-ordinating responses across all boundaries of government, private sector and civil society would enhance adaptive capacity (Brown *et al.*, 2010). Resolving well-documented institutional challenges of natural resource management, including lack of co-ordination, monitoring and enforcement, is a fundamental step towards more effective climate governance. For example, concerning groundwater, developing organizational frameworks and strengthening institutional capacities for more effectively assessing and managing groundwater resources over the long term are critically important (Nyenje and Batelaan, 2009; Braune and Xu, 2010).

22.4.4.4. Sub-National Adaptation Governance

Since AR4, there has been additional effort on sub-national adaptation planning in African countries, but adaptation strategies at provincial and municipal levels are mostly still under development, with many local governments lacking the capacity and resources for the necessary decentralised adaptation response (*high confidence*). Provinces in some countries have developed policies and strategies on climate change: for example, Lagos State's 2012 Adaptation Strategy in Nigeria (BNRCC, 2012); mainstreaming adaptation into district development plans in Ghana; and communal climate resilience plans in Morocco (Corsi *et al.*, 2012). Promising approaches include sub-national strategies that integrate adaptation and mitigation for low-carbon climate resilient development, as is being done in Delta State in Nigeria, and in other countries (UNDP, 2011a). In response to the identified institutional weaknesses, capacity development has been implemented in many cities and towns, including initiatives in Lagos, Nigeria, Durban and Cape Town in South Africa: notable examples include Maputo's specialized local government unit to implement climate change response, ecosystem-based adaptation and improved city wetlands; and participatory skills development in integrating community-based disaster risk reduction and climate adaptation into local development planning in Ethiopia (Madzwamuse, 2010; ACCRA, 2012; Castán Broto, *et al.*, 2013).

22.4.4.5. Community-Based Adaptation and Local Institutions

Since AR4, there has been progress in Africa in implementing and researching community-based adaptation (*high confidence*), with broad agreement that support to local-level adaptation is best achieved by starting with existing local adaptive capacity, and incorporating and building upon present coping strategies and norms, including indigenous practices (Dube and Sekhwela, 2007; Archer *et al.*, 2008; Huq, 2011). Community-based adaptation (CBA) is community initiated, and/or draws upon community knowledge or resources – refer to AR5 glossary. Some relevant initiatives include the Community-based Adaptation in Africa (CBAA) project, which implemented community-level pilot projects in eight African countries (Sudan, Tanzania, Uganda, Zambia, Malawi, Kenya, Zimbabwe, South Africa) through a learning-by-doing approach; the Adaptation Learning Program, implemented in Ghana, Niger, Kenya and Mozambique (CARE International, 2012); and UNESCO Biosphere Reserves where good practices were developed in Ethiopia, Kenya, South Africa and Senegal (German Commission for UNESCO, 2011). See also section 22.4.5.6 on institutions for CBA. The literature includes a wide range of case studies detailing involvement of local communities in adaptation initiatives and projects facilitated by NGOs and researchers (for example, Leary *et al*., 2008a; CCAA, 2011; CARE International, 2012; Chishakwe *et al.,* 2012); these and other initiatives have generated process-related lessons (22.4.5), with positive assessments of effectiveness in improving adaptive capacity of African communities, local organisations and researchers (Lafontaine *et al*., 2012).

The key role for local institutions in enabling community resilience to climate change has been recognised, particularly with respect to natural resource dependent communities – for example, the role of NGOs and CBOs in catalysing agricultural adaptation or in building resilience through enhanced forest governance and sustainable management of non-timber forest products; institutions managing access to and tenure of land and other natural resources, which are vital assets for the rural and peri-urban poor, are particularly crucial for enabling CBA and enhancing adaptive capacity in Africa (Bryan *et al*., 2009; Brown *et al*., 2010; Mogoi *et al.*, 2010). Local studies and adaptation planning have revealed the following priorities for pro-poor adaptation: social protection, social services and safety nets; better water and land governance; action research to improve resilience of under-researched food crops of poor people; enhanced water storage and harvesting; better post-harvest services; strengthened civil society and greater involvement in planning; and more attention to urban and peri-urban areas heavily affected by migration of poor people (Moser and Satterthwaite, 2008; Urquhart, 2009; Bizikova *et al*., 2010).

22.4.4.6. Adaptation Decisionmaking and Monitoring

Emerging patterns in Africa regarding adaptation decision-making, a critical component of adaptive capacity, include limited inclusive governance at the national level, with greater involvement in local initiatives of vulnerable and exposed people in assessing and choosing adaptation responses (*high confidence*). Civil society institutions and communities have to date played a limited role in formulation of national adaptation policies and strategies, highlighting the need for governments to widen the political space for citizens and institutions to participate in decision-making, for both effectiveness and to ensure rights are met (Madzwamuse, 2010; Castro *et al*., 2012). Building African leadership for climate change may assist with this (CCAA, 2011; Chandani, 2011; Corsi *et al.*, 2012). A critical issue is how planning and decisionmaking for adaptation uses scientific evidence and projections, while also managing the uncertainties within the projections (Conway, 2011; Dodman and Carmin, 2011).

A range of tools has been used in adaptation planning in Africa, including vulnerability assessment (22.4.5), risk assessment, cost-benefit analysis, cost-effectiveness, multi-criteria analysis, and participatory scenario planning (see for example Cartwright *et al.*, 2008; Kemp-Benedict and Agyemang-Bonsu, 2008; Njie *et al*., 2008; Mather and Stretch, 2012), but further development and uptake of decision tools would facilitate enhanced decisionmaking. A related point is that monitoring and assessing adaptation is still relatively undeveloped in Africa, with national co-ordinating systems for collating data and synthesizing lessons not in place. Approaches for assessing adaptation action at local and regional levels have been developed (see for example Hahn *et al.,* 2009; Gbetibouo *et al.,* 2010a; Below *et al*., 2012), while there are positive examples of local monitoring of adaptation at the project level (see for example Archer *et al.*, 2008; Below *et al*., 2012). Chapter 2 contains additional discussion of the foundations for decisionmaking on climate change matters.

22.4.5. Experiences with Adaptation Measures in Africa and Lessons Learned

22.4.5.1. Overview

Section 22.4.5 provides a cross-cutting assessment of experience gained in Africa with a range of adaptation approaches, encompassing climate risk reduction measures; processes for participatory learning and knowledge development and sharing; communication, education and training; ecosystem-based measures; and technological and infrastructural approaches; concluding with a discussion of maladaptation.

Common priority sectors across countries for implementing adaptation measures since 2008 include agriculture, food security, forestry, energy, water, and education (Corsi *et al.*, 2012), which reflects a broadening of focus since the AR4. While there has been little planning focus on regional adaptation (22.4.4.2, 22.4.4.3), the potential for this has been recognized (UNFCCC, 2007; Sonwa *et al.*, 2009; Niang, 2012).

Attention is increasing on identifying opportunities inherent in the continent's adaptation needs, as well as delineating key success factors for adaptation. A number of studies identify the opportunity inherent in implementing relatively low-cost and simple low-regrets adaptation measures that reduce people's vulnerability to current climate variability, have multiple developmental benefits, and are well-positioned to reduce vulnerability to longer-term climate change as well (UNFCCC, 2007; Conway and Schipper, 2011; see also Section 22.4.3). Responding to climate change provides an opportunity to enhance awareness that maintaining ecosystem functioning underpins human survival and development in a most fundamental way (Shackleton and Shackleton, 2012), and to motivate for new development trajectories (22.4.6). While it is difficult to assess adaptation success, given temporal and spatial scale issues, and local specificities, Osbahr *et al.* (2010) highlight the role of social networks and institutions, social resilience, and innovation as possible key success factors for adaptation in small-scale farming livelihoods in southern Africa. Kalame *et al.* (2008) note opportunities for enhancing adaptation through forest governance reforms to improve community access to forest resources, while Martens *et al.* (2009) emphasise the importance of 'soft path' measures for adaptation strategies (see also section 22.4.5.6).

The following discussion of adaptation approaches under discrete headings does not imply that these are mutually exclusive – adaptation initiatives usually employ a range of approaches simultaneously, and indeed, the literature increasingly recognizes the importance of this for building resilience.

22.4.5.2. Climate Risk Reduction, Risk Transfer, and Livelihood Diversification

Risk reduction strategies used in African countries to offset the impacts of natural hazards on individual households, communities, and the wider economy include early warning systems, emerging risk transfer schemes, social safety nets, disaster risk contingency funds and budgeting, livelihood diversification, and migration (World Bank, 2010; UNISDR, 2011).

Disaster risk reduction (DRR) platforms are being built at national and local levels, with the synergies between DRR and adaptation to climate change being increasingly recognized in Africa (Westgate, 2010; UNISDR, 2011; Hunde, 2012); however, Conway and Schipper (2011) find that additional effort is needed for a longer-term vulnerability reduction perspective in disaster management institutions.

Early warning systems (EWS) are gaining prominence as multiple stakeholders strengthen capabilities to assess and monitor risks and warn communities of a potential crisis, through regional systems such as the Permanent Inter-States Committee for Drought Control in the Sahel (CILSS) and the Famine Early Warning System Network (FEWS-NET), as well as national, local and community-based EWS on for example food and agriculture (Pantuliano and Wekesa, 2008; Sissoko *et al.*, 2011; FAO, 2011). Some of the recent EWS emphasise a gendered approach, and may incorporate local knowledge systems used for making short-, medium-, and long-term decisions about farming and livestock-keeping, as in Kenya (UNDP, 2011b). The health sector has employed EWS used to predict disease for adaptation planning and implementation, such as the prediction of conditions expected to lead to an outbreak of Rift Valley fever in the Horn of Africa in 2006/2007 (Anyamba *et al.*, 2010). Progress has been made in prediction of meningitis and in linking climate/weather variability and extremes to the disease (Thomson *et al.*, 2006; Cuevas *et al.*, 2007).

Local projects often use participatory vulnerability assessment or screening to design adaptation strategies (van Vliet, 2010; GEF Evaluation Office, 2011; Hambira, 2011), but vulnerability assessment at the local government level is often lacking, and assessments to develop national adaptation plans and strategies have not always been conducted in a participatory fashion (Madzwamuse, 2010). Kienberger (2012) details spatial modelling of social and economic vulnerability to floods at the district level in Búzi, Mozambique. Lessons from vulnerability analysis highlight that the highest exposure and risk do not always correlate with vulnerable ecosystems, socially marginalized groups, and areas with at-risk infrastructure, but may also lie in unexpected segments of the population (Moench, 2011).

Community-level DRR initiatives include activities that link food security, household resilience, environmental conservation, asset creation, and infrastructure development objectives and co-benefits (Parry *et al.*, 2009a; UNISDR, 2011; Frankenberger *et al.*, 2012). Food security and nutrition-related safety nets and social protection mechanisms can mutually reinforce each other for DRR that promotes adaptation, as in Uganda's Karamoja Productive Assets Programme (Government of Uganda and WFP 2010; WFP, 2011). Initiatives in Kenya, South Africa, Swaziland and Tanzania have also sought to deploy local and traditional knowledge for the purposes of disaster preparedness and risk management (Mwaura, 2008; Galloway McLean, 2010). Haan *et al.* (2012) highlight the need for increased donor commitment to the resilience-building agenda within the framework of DRR, based on lessons from the 2011 famine in Somalia.

Social protection[8], a key element of the African Union social policy framework, is being increasingly used in Ethiopia, Rwanda, Malawi, Mozambique, South Africa, and other countries to buffer against shocks by building assets and increasing resilience of chronically and transiently poor households; in some cases this surpasses repeated relief interventions to address slower onset climate shocks, as in Ethiopia's Productive Safety Net Program (Brown *et al.*, 2007; Heltberg *et al.* 2009). While social protection is helping with *ex post* and *ex ante* DRR and will be increasingly important for securing livelihoods should climate variability increase, less evidence exists for its effectiveness against the most extreme climatic shocks associated with higher emissions scenarios, which would require reducing dependence on climate-sensitive livelihood activities (Davies *et al.*, 2009; Wiseman *et al.*, 2009; Pelham *et al.*, 2011; Béné *et al.*, 2012). Social protection could further build adaptive capacity if based on improved understanding of the structural causes of poverty, including political and institutional dimensions (Brown *et al.*, 2007; Davies *et al.*, 2009; Levine *et al.*, 2011).

[FOOTNOTE 8: Social protection can include social transfers (cash or food), minimum standards such as for child labor, and social insurance.]

Risk spreading mechanisms used in the African context include kinship networks; community funds; and disaster relief and insurance, which can provide financial security against extreme events such as droughts, floods, and tropical cyclones, and concurrently reduce poverty and enhance adaptive capacity[9] (Leary *et al.*, 2008a; Linnerooth-Bayer *et al.* 2009; Coe and Stern, 2011). Recent developments include the emergence of index-based insurance contracts (Box 22-1), which pay out not with the actual loss, but with a measurable event that could cause loss.

[FOOTNOTE 9: Climate (or disaster) risk financing instruments include contingency funds; agricultural and property (private) insurance; sovereign insurance; reallocation of program expenditures; weather derivatives; and bonds.]

_____ START BOX 22-1 HERE _____

Box 22-1. Experience with Index-Based Weather Insurance in Africa

Malawi's initial experience of dealing with drought risk through index-based weather insurance directly to smallholders appears positive: 892 farmers purchased the insurance in the first trial period, which was bundled with a loan for groundnut production inputs (Hellmuth *et al.*, 2009). In the next year, the pilot expanded, with the addition of maize, taking numbers up to 1,710 farmers and stimulating interest among banks, financiers, and supply chain participants such as processing and trading companies and input suppliers. A pilot insurance project in Ethiopia was designed to pay claims to the government based on a drought index that uses a time window between observed lack of rain and actual materialization of losses. This allows stakeholders to address threats to food security in ways that prevent the depletion of farmers' productive assets, which reduces the future demand for humanitarian aid by enabling households to produce more food during subsequent seasons (Krishnamurty, 2011).

Another key innovation in Ethiopia is the insurance for work program that allows cash-poor farmers to work for their insurance premiums by engaging in community-identified disaster risk reduction products, such as soil management and improved irrigation (WFP, 2011), which makes insurance affordable to the most marginalized and resource-poor sectors of society.

_____ END BOX 22-1 HERE _____

The challenges associated with current risk reduction strategies include political and institutional challenges in translating early warning into early action (Bailey, 2013); communication challenges related to EWS: conveying useful information in local languages and communicating EWS in remote areas; national-level mistrust of locally collected data, which are perceived to be inflated to leverage more relief resources (Hellmuth *et al.*, 2007; Pantuliano and Wekesa, 2008; Cartwright *et al.*, 2008; FAO, 2011); the call for improved user-friendliness of early warning information, including at smaller spatial scales; the need for increased capacity in National Meteorological centres (22.4.2); and the need for better linkages between early warning, response, and prevention (Haan *et al.*, 2012).

Evidence is increasing that livelihood diversification, long used by African households to cope with climate shocks, can also assist with building resilience for longer term climate change by spreading risk. Over the past 20 years, households in the Sahel have reduced their vulnerability and increased their wealth through livelihood diversification, particularly when diversifying out of agriculture (Mertz *et al.*, 2011). Households may employ a range of strategies, including on-farm diversification or specialization (Sissoko *et al.*, 2011; Tacoli, 2011). Motsholapheko *et al.* (2011) show how livelihood diversification is used as an adaptation to flooding in the Okavango Delta, Botswana, and Badjeck *et al.* (2010) recommend private and public insurance schemes to help fishing communities rebuild after extreme events, and education and skills upgrading to enable broader choices when fishery activities can no longer be sustained. See Chapter 9 for a fuller discussion of the role of livelihood diversification in adaptation, particularly 9.3.3.1 and 9.3.5.2). Remittances are a longstanding and important means of reducing risk to climate variability and other household stressors, and of contributing to recovery from climatic shocks, as further discussed in Chapter 9 (9.3.3.3, 9.3.5.2).

While livelihood diversification is an important adaptation strategy, it may replace formerly sustainable practices with livelihood activities that have negative environmental impacts (22.4.5.8).

Rural finance and micro-credit can be enabling activities for adaptive response, which are also used by women for resilience-building activities (e.g., as documented in Sudan by Osman-Elasha *et al.*, 2008). Credit and storage systems are instrumental in supporting families during the lean period, to prevent the sale of assets to buy food when market prices are higher (Romero González *et al.*, 2011). Long seen as a fundamental process for most African families to incorporate choice into their risk profile and adapt to climate variability (Goldstone, 2002; Urdal, 2005; Reuveny, 2007; Fox and Hoelscher, 2010), there is evidence in some areas of the increased importance of migration (discussed in section 22.6.1, 8.2, 9.3.3.3, 12.4) and trade for livelihood strategies, as opposed to subsistence agriculture, as shown by Mertz *et al.* (2011) for the Sudano-Sahelian region of West Africa.

22.4.5.3. Adaptation as a Participatory Learning Process

Since AR4, there has been more focus on the importance of flexible and iterative learning approaches for effective adaptation (*medium evidence, high agreement*). Due to the variety of intersecting social, environmental, and economic factors that affect societal adaptation, governments, communities, and individuals (Jones *et al.*, 2010; Jones, 2012), adaptation is increasingly recognized as a complex process involving multiple linked steps at several scales, rather than a series of simple planned technical interventions (Moser and Ekstrom, 2010). Implementing adaptation as a participatory learning process enables people to adopt a proactive or anticipatory stance to avoid 'learning by shock' (Tschakert and Dietrich, 2010).

Iterative and experiential learning allows for flexible adaptation planning, appropriate considering the uncertainty inherent in climate projections that is compounded by other sources of flux affecting populations in Africa (Suarez *et al.*, 2008; Dodman and Carmin, 2011; Huq, 2011; Koelle and Annecke, 2011). Many studies have highlighted the utility of participatory action research, social and experiential learning, and creating enabling spaces for multi-stakeholder dialogue for managing uncertainty and unlocking the social and behavioral change required for adaptation (e.g., Tompkins and Adger, 2003; Ziervogel and Opere, 2010; Bizikova *et al.*, 2010; Tschakert and Dietrich 2010; CCAA, 2011; Ebi *et al.*, 2011; UNDP-UNEP Poverty-Environment Initiative, 2011b; Thorn, 2011; Faysse *et al.*, 2012). Transdisciplinary approaches, which hold promise for enhancing linkages between sectors and thus reducing maladaptation are also starting to be adopted, as for example in the urban context (Evans, 2011). Learning approaches for adaptation may involve co-production of knowledge – such as combining local and traditional knowledge with scientific knowledge (22.4.5.4).

Adaptive co-management[10] holds potential to develop capacity to deal with change (Watkiss *et al.*, 2010; Plummer, 2012); the implications of strategic adaptive management for adaptation in aquatic protected areas in South Africa are being explored (Kingsford *et al.*, 2011).

[FOOTNOTE 10: Adaptive co-management is understood as “a process by which institutional arrangements and ecological knowledge are tested and revised in a dynamic, ongoing, self-organized process of learning-by-doing” (Folke *et al.*, 2002).]

Caveats and constraints to viewing adaptation as a participatory learning process include the time and resources required from both local actors and external facilitators, the challenges of multidisciplinary research, the politics of stakeholder participation and the effects of power imbalances, and the need to consider not only the consensus approach but also the role of conflicts (Aylett, 2010; Tschakert and Dietrich, 2010; Beardon and Newman, 2011; Jobbins, 2011; Shankland and Chambote, 2011). Learning throughout the adaptation process necessitates additional emphasis on ways of sharing experiences between communities and other stakeholders, both horizontally and vertically (22.4.5.4). Information and communication technologies, including mobile phones, radio, and the internet, can play a role in facilitating participatory learning processes and helping to overcome some of the challenges (Harvey *et al.*, 2012).

The increased emphasis on the importance of innovation for successful adaptation, in both rural and urban contexts, relates to interventions that employ innovative methods, as well as the innovation role of institutions (Tschakert and Dietrich, 2010; Dodman and Carmin, 2011; Rodima-Taylor, 2012; Scheffran *et al.*, 2012). Scheffran *et al.* (2012) demonstrate how migrant social organizations in the western Sahel initiate innovations across regions by transferring technology and knowledge, as well as remittances and resources. While relevant, high-quality data is important as a basis for adaptation planning, innovative methods are being used to overcome data gaps, particularly local climatic data and analysis capability (Tschakert and Dietrich, 2010; GEF Evaluation Office, 2011).

22.4.5.4. Knowledge Development and Sharing

Recent literature has confirmed the positive role of local and traditional knowledge in building resilience and adaptive capacity, and shaping responses to climatic variability and change in Africa (Nyong *et al.*, 2007; Osbahr *et al.*, 2007; Goulden *et al.*, 2009b; Ifejika Speranza *et al.*, 2010; Jalloh *et al.*, 2011b; Newsham and Thomas, 2011). This is particularly so at the community scale, where there may be limited access to, quality of, or ability to use scientific information. The recent report on extreme events and disasters (IPCC, 2012) supports this view, finding *high agreement* and *robust evidence* of the positive impacts of integrating indigenous and scientific knowledge for adaptation. Concerns about the future adequacy of local knowledge to respond to climate impacts within the multi-stressor context include the decline in intergenerational transmission; a perceived decline in the reliability of local indicators for variability and change, as a result of socio-cultural, environmental, and climate changes (Hitchcock 2009; Jennings and Magrath 2009); and challenges of the emerging and anticipated climatic changes seeming to overrun indigenous knowledge and coping mechanisms of farmers (Berkes, 2009; Ifejika Speranza *et al.*, 2010; Jalloh *et al.*, 2011b; section 22.4.6). Based on analysis of the responses to the Sahel droughts during the 1970s and 1980s, Mortimore (2010) argues that local knowledge systems are more dynamic and robust than is often acknowledged. Linking indigenous and conventional climate observations can add value to climate change adaptation within different local communities in Africa (Roncoli *et al.*, 2002; Nyong *et al.*, 2007; Chang'a *et al.*, 2010; Guthiga and Newsham, 2011).

Choosing specific adaptation actions that are informed by users' perceptions and supported by accurate climate information, relevant to the scale where decisions are made, would be supportive of the largely autonomous adaptation taking place in Africa (Vogel and O'Brien, 2006; Ziervogel *et al.*, 2008; Bryan *et al.*, 2009; Godfrey *et al.*, 2010). Key problems regarding how science can inform decision making and policy are how best to match scientific information, for example about uncertainty of change, with decision needs; how to tailor information to different constituencies; and what criteria to use to assess whether or not information is legitimate to influence policy and decisionmaking (Vogel *et al.*, 2007; Hirsch Hadorn *et al.*, 2008). Institutional innovation is one solution: for example, Nigeria established the Science Committee on Climate Change to develop strategies to bridge the gap between increasing scientific knowledge and policy (Corsi *et al.*, 2012).

There is agreement that culture, or the shaping social norms, values, and rules including those related to ethnicity, class, gender, health, age, social status, cast, and hierarchy, is of crucial importance for adaptive capacity as a positive attribute but also as a barrier to successful local adaptation (22.4.6); further research is required in this field, not least because culture is highly heterogeneous within a society or locality (Adger *et al.*, 2007, 2009; Ensor and Berger, 2009; Nielsen and Reenberg, 2010; Jones, 2012). Studies show that while it is important to further develop the evidence base for the effectiveness of traditional knowledge, integrating cultural components such as stories, myths, and oral history into initiatives to document local and traditional knowledge on adaptive or coping mechanisms is a key to better understanding how climate vulnerability and adaptation are framed and experienced (Urquhart, 2009; Beardon and Newman, 2011; Ford *et al.*, 2012). Appropriate and equitable processes of participation and communication between scientists and local people have been found to prevent misuse or misappropriation of local and scientific knowledge (Nyong *et al.*, 2007; Orlove *et al.*, 2010; Crane, 2010).

While multi-stakeholder platforms promote collaborative adaptation responses (CARE, 2012), adaptation initiatives in Africa lack comprehensive, institutionalised and proactive systems for knowledge sharing (GEF Evaluation Office, 2011; AAP, 2012).

22.4.5.5. Communication, Education, and Capacity Development

Capacity development and awareness raising to enhance understanding of climate impacts and adaptation competencies and engender behavioural change have been undertaken through civil society-driven approaches or by institutions, such as regional and national research institutes, international and national programs and non-governmental organizations (UNFCCC, 2007; Reid *et al.*, 2010; CCAA, 2011; START, 2011; Figueiredo and Perkins, 2012). Promising examples include youth ambassadors in Lesotho and civil society organizations in Tanzania (Corsi *et al.*, 2012), and children as effective communicators and advocates for adaptation-related behavioral and policy change (22.4.3). Progress on inclusion of climate change into formal education is mixed, occurring within the relatively low priority given to environmental education in most countries (UNFCCC, 2007; Corsi *et al.*, 2012; Mukute *et al.*, 2012).

Innovative methods used to communicate climate change include participatory video, photo stories, oral history videos, vernacular drama, radio, television and festivals, with an emphasis on the important rle of the media (Suarez *et al.*, 2008; Harvey, 2011; Chikapa, 2012; Corsi *et al.*, 2012). Better evidence-based communication processes will enhance awareness raising of the diverse range of stakeholders at all levels on the different aspects of climate change (Niang, 2007; Simane *et al.*, 2012). A better understanding of the dimensions of the problem could be achieved by bringing together multiple users and producers of scientific and local knowledgein a trans-disciplinary process (Vogel *et al.*, 2007; Hirsch Hadorn *et al.*, 2008; Ziervogel *et al.*, 2008; Koné *et al.*, 2011)

22.4.5.6. Ecosystem Services, Biodiversity, and Natural Resource Management

Africa's longstanding experiences with natural resource management, biodiversity use, and ecosystem-based responses such as afforestation, rangeland regeneration, catchment rehabilitation and community-based natural resource management (CBNRM) can be harnessed to develop effective and ecologically sustainable local adaptation strategies (*high confidence*). Relevant specific experiences include using mobile grazing to deal with both spatial and temporal rainfall variability in the Sahel (Djoudi *et al.*, 2013); reducing the negative impacts of drought and floods on agricultural and livestock-based livelihoods through forest goods and services in Mali, Tanzania, and Zambia (Robledo *et al.*, 2012); and ensuring food security and improved livelihoods for indigenous and local communities in West and Central Africa through the rich diversity of plant and animal genetic resources (Jalloh *et al.*, 2011b).

Natural resource management (NRM) practices that improve ecosystem resilience can serve as proactive, low regrets adaptation strategies for vulnerable livelihoods (*high confidence*). Two relevant widespread dual-benefit practices, developed to address desertification, are natural regeneration of local trees (Box 22-2) and water harvesting. Water harvesting practices[11] have increased soil organic matter, improved soil structure, and increased agricultural yields at sites in Burkina Faso, Mali, Niger, and elsewhere, and are used by 60% of farmers in one area of Burkina Faso (Fatondji *et al.*, 2009; Vohland and Barry, 2009; Barbier *et al.*, 2009; Larwanou and Saadou, 2011). Although these and other practices serve as adaptations to climate change, revenue generation and other concerns may outweigh climate change as a motivating factor in their adoption (Mertz *et al.*, 2009; Nielsen and Reenberg, 2010). While destocking of livestock during drought periods may also address desertification and adaptation, the lack of individual incentives and marketing mechanisms to destock and other cultural barriers inhibit their widespread adoption in the Sahel (Hein *et al.*, 2009; Nielsen and Reenberg, 2010). Despite these provisos and other constraints (see for example Nelson and Agrawal, 2008; section 22.4.6 further highlights local-level institutional constraints), local stakeholder institutions for CBNRM do enable a more flexible response to changing climatic conditions; CBNRM is also a vehicle for improving links between ecosystem services and poverty reduction, to enable sustainable adaptation approaches (Shackleton *et al.*, 2010; Chishakwe *et al.*, 2012; Girot *et al.*, 2012). Based on lessons learned in Botswana, Malawi, Mozambique, Namibia, Tanzania, Zambia and Zimbabwe, Chishakwe *et al.* (2012) point out the synergies between CBNRM and adaptation at the community level, notwithstanding institutional and other constraints experienced with CBNRM.

[FOOTNOTE 11: Water harvesting refers to a collection of traditional practices in which farmers use small planting pits, half-moon berms, rock bunds along contours, and other structures to capture runoff from episodic rain events (Kandji *et al.*, 2006).]

_____ START BOX 22-2 HERE _____

Box 22-2. African Success Story: Integrating Trees into Annual Cropping Systems

Recent success stories from smallholder systems in Africa illustrate the potential for transforming degraded agricultural landscapes into more productive, sustainable and resilient systems by integrating trees into annual cropping systems. For example, in Zambia and Malawi, an integrated strategy for replenishing soil fertility on degraded lands, which combines planting of nitrogen-fixing *Faidherbia* trees with small doses of mineral fertilizers, has consistently more than doubled yields of maize leading to increased food security and greater income generation (Garrity *et al.*, 2010). In the Sahel, natural regeneration, or the traditional selection and protection of small trees to maturity by farmers and herders has, perhaps for centuries, produced extensive parks of *Acacia albida* (winter thorn) in Senegal (Lericollais, 1989), *Adansonia digitata* (baobab) in West and southern Africa (Sanchez *et al.*, 2011), and *Butyrospermum parkii* (Shea butter) in Burkina Faso (Gijsbers *et al.*, 1994). Recent natural regeneration efforts have increased tree density and species richness at locations in Burkina Faso (Ræbild *et al.*, 2012) and Niger (Larwanou and Saadou, 2011), though adoption and success is somewhat dependent on soil type (Haglund *et al.*, 2011; Larwanou and Saadou, 2011). In southern Niger, farmer-managed natural regeneration of *Faidherbia albida* and other field trees, which began in earnest in the late 1980s, has led to large-scale increase in tree cover across 4.8 million ha, and to decreased sensitivity to drought of the production systems, compared to other regions in Niger (Reij *et al.*, 2009; Tougiani *et al.*, 2009; Sendzimir *et al.*, 2011).

_____ END BOX 22-2 HERE _____

Differentiation in the literature is growing between 'hard path' and 'soft path' approaches to adaptation (Sovacool, 2011; Kundzewicz, 2011), with 'soft path', low-regrets approaches, such as using intact wetlands for flood risk management, often the first line of defence for poor people in Africa; as contrasted with 'hard path' approaches like embankments and dams for flood control (McCully, 2007; Kundzewicz, 2011). Intact ecosystem services and biodiversity are recognized as critical components of successful human adaptation to climate change that may be more effective and incur lower costs than 'hard' or engineered solutions (Abramovitz *et al.*, 2002; Petersen and Holness, 2011; UNDP-UNEP Poverty-Environment Initiative, 2011a; Girot et al, 2012; Pramova *et al*., 2012; Roberts *et al.*, 2012; Box 22-2). This provides a compelling reason for linking biodiversity, developmental, and social goals, as taken up, for example, in Djibouti's NAPA project on mangrove restoration to reduce salt water intrusion and coastal production losses due to climate hazards (Pramova *et al.*, 2012).

The emerging global concept of ecosystem-based adaptation (EbA) provides a system-oriented approach for Africa's longstanding local NRM practices. Despite the evidence from studies cited in this section, scaling-up to prioritize ecosystem responses and EbA in plans and policy has been slow; a broad understanding that EbA is an integral component of the developmental agenda, rather than a competing 'green' agenda, would promote this process. Adaptive environmental governance represents one of the future challenges for the implementation of EbA strategies in Africa, together with sustainable use of resources, secure access to meet needs under climate change, and strong local institutions to enable this (Robledo *et al.*, 2012). Ecosystem-based adaptation could be an important approach to consider for the globally significant Congo Basin forests, particularly given the predominance of REDD+ approaches for this region that risk neglecting adaptation responses, or may result in maladaptation (Somorin *et al.*, 2012; Sonwa *et al.*, 2012; sections 22.4.5.8, 22.6.2). Ecosystem-based approaches are further discussed in WGII Chapter 4, and Box CC-EA.

22.4.5.7. Technological and Infrastructural Adaptation Responses

Since AR4, experience has been gained on technological and infrastructural adaptation in agricultural and water management responses, for climate-proofing infrastructure, and for improved food storage and management to reduce post-harvest losses; this has been increasingly in conjunction with 'soft' measures.

There is increased evidence that farmers are changing their production practices in response to increased food security risks linked to climate change and variability, through both technical and behavioural means. Examples include planting cereal crop varieties that are better suited to shorter and more variable growing seasons (Akullo *et al.*, 2007; Thomas *et al.*, 2007; Yesuf *et al.*, 2008; Yaro, 2010; Laube *et al.*, 2012), constructing bunds to more effectively capture rainwater and reduce soil erosion (Nyssen *et al.*, 2007; Thomas *et al.*, 2007; Reij *et al.*, 2009), reduced tillage practices and crop residue management to more effectively bridge dry spells (Ngigi *et al*., 2006; Marongwe *et al.*, 2011), and adjusting planting dates to match shifts in the timing of rainfall (Abou-Hadid, 2006; Vincent *et al.*, 2011b).

Conservation agriculture has good potential to both bolster food production and enable better management of climate risks (*high confidence)* (Verchot *et al.*, 2007; Thomas, 2008; Syampungani *et al.*, 2010; Thierfelder and Wall, 2010; Kassam *et al.*, 2012). Such practices, which include conservation/zero tillage, soil incorporation of crop residues and green manures, building of stone bunds, agroforestry, and afforestation/reforestation of croplands, reduce runoff and protect soils from erosion, increase rainwater capture and soil water-holding capacity, replenish soil fertility, and increase carbon storage in agricultural landscapes. Conservation agriculture systems have potential to lower the costs of tillage and weed control with subsequent increase in net returns, as found in Malawi by Ngwira *et al.* (2012).

Expansion of irrigation in sub-Saharan Africa holds significant potential for spurring agricultural growth while also better managing water deficiency risks associated with climate change (Dillon, 2011; You *et al.*, 2011). Embedding irrigation expansion within systems-level planning that considers the multi-stressor context in which irrigation expansion is occurring can help to ensure that efforts to promote irrigation can be sustained and do not instead generate a new set of hurdles for producers or engender conflict (van de Giesen *et al.*, 2010; Burney and Naylor, 2012; Laube *et al.*, 2012). Suitable approaches to expand irrigation in Africa include using low-pressure drip irrigation technologies and construction of small reservoirs, both of which can help to foster diversification toward irrigated high-value horticultural crops (Karlberg *et al.*, 2007; Woltering *et al.*, 2011; Biazin *et al.*, 2012). If drought risk increases and rainfall patterns change, adaptation in agricultural water management would be enhanced through a strategic approach that encompasses overall water use efficiency for both rainfed and irrigated production (Weiβ *et al.*, 2009), embeds irrigation expansion efforts within a larger rural development context that includes increased access to agricultural inputs and markets (You *et al.*, 2011; Burney and Naylor, 2012), and that involves an integrated suite of options (e.g., plant breeding and improved pest and disease and soil fertility management, and *in situ* rainwater harvesting) to increase water productivity (Passioura, 2006; Biazin *et al.*, 2012).

Experience has been gained since the AR4 on adaptation of infrastructure (transportation, buildings, food storage, coastal), with evidence that this can sometimes be achieved at low cost, and additional implementation of soft measures such as building codes and zone planning (UNFCCC, 2007; Halsnæs and and Trarup, 2009; Urquhart, 2009; UN-Habitat and UNEP, 2010; AfDB, 2011; Mosha, 2011; Siegel, 2011; Corsi *et al.*, 2012). Examples of adaptation actions for road and transportation infrastructure include submersible roads in Madagascar and building dikes to avoid flooding in Djibouti (UNFCCC, 2007; Urquhart, 2009). Infrastructural climate change impact assessments and enhanced construction and infrastructural standards - such as raising foundations of buildings, strengthening roads, and increasing storm water drainage capacity - are steps to safeguard buildings in vulnerable locations or with inadequate construction (UN-Habitat and UNEP, 2010; Mosha, 2011; Corsi *et al.*, 2012). Mainstreaming adaptation into infrastructure development can be achieved at low cost, as has been shown for flood-prone roads in Mozambique (Halsnæs and and Trarup, 2009). Integrating climate change considerations into infrastructure at the design stage is preferable from a cost and feasibility perspective than trying to retrofit infrastructure (Chigwada, 2005; Siegel, 2011). Softer measures, such as building codes and zone planning are being implemented and are needed to complement and/or provide strategic guidance for hard infrastructural climate proofing, for example, the adoption of cyclone-resistant standards for public buildings in Madagascar (AfDB, 2011). Research in South Africa has recognized that the best option for adaptation in the coastal zone is not to combat coastal erosion in the long term, but rather to allow progression of the natural processes (Naidu *et al.*, 2006; Zitholele Consulting, 2009).

Reducing post-harvest losses through improved food storage, food preservation, greater access to processing facilities, and improved systems of transportation to markets are important means to enhance food security (Brown *et al.*, 2009; Godfray *et al.*, 2010; Codjoe and Owusu 2011). Low cost farm-level storage options, such as metal silos (Tefera *et al.*, 2011), and triple-sealed plastic bags (Baoua *et al.*, 2012) are effective for reducing post-harvest losses from pests and pathogens. Better storage allows farmers greater flexibility in when they sell their grain, with related income benefits (Brown *et al.*, 2009), and reduces post-harvest infection of grain by aflatoxins, which is widespread in Africa and increases with drought stress and high humidity during storage (Cotty and Jaime-Garcia, 2007; Shephard, 2008).

22.4.5.8. Maladaptation Risks

The literature increasingly highlights the need, when designing development or adaptation research, policies and initiatives, to adopt a longer-term view and to consider the multi-stressor context in which people live, in order to avoid maladaptation, or outcomes that may serve short-term goals but come with future costs to society (refer to Glossary). The short-term nature of policy and other interventions, especially if they favor economic growth and modernization over resilience and human security, may themselves act as stressors or allow people to only react to short-term climate variability (Bryan *et al.*, 2009; Brooks *et al.*, 2009; Bunce *et al.*, 2010a; Levine et al, 2011). The political context can also undermine autonomous adaptation and lead to maladaptation; for instance, Smucker and Wisner (2008) found that political and economic changes in Kenya meant that farmers could no longer use traditional strategies for coping with climatic shocks and stressors, with the poorest increasingly having to resort to coping strategies that undermined their long-term livelihood security, also known as erosive coping, such as more intensive grazing of livestock and shorter crop rotations (van der Geest and Dietz, 2004). In a case from the Simiyu wetlands in Tanzania, Hamisi *et al.* (2012) find that coping and reactive adaptation strategies may lead to maladaptation – for instance, through negative impacts on natural vegetation because of increased intensity of farming in wetter parts of the floodplain, where farmers have moved to exploit the higher soil water content.

Some diversification strategies, such as charcoal production and artisanal mining, may increase risk through promoting ecological change and the loss of ecosystem services to fall back on (Paavola, 2008; Adger et al, 2011; Shackleton and Shackleton, 2012). Studies also highlight risks that traditional adaptive pastoralism systems may be replaced by maladaptive activities. For example, charcoal production has become a major source of income for 70% of poor and middle-income pastoralists in some areas of Somaliland, with resultant deforestation (Hartmann and Sugulle, 2009).

Another example of maladaptation provided in the literature is the potential long-term hydro-dependency risks and threats to ecosystem health and community resilience as a result of increased dam building in Africa, which may be underpinned by policies of multi-lateral donors (Avery, 2012; Beilfuss, 2012; Jones *et al*., 2012). While increased rainwater storage will assist with buffering dry periods, and hydropower can play a key role in ending energy poverty, it is important that this is designed to promote environmental and social sustainability; that costs and benefits are equitably shared; and that water storage and energy generation infrastructure is itself climate proofed. Additional substantive review of such international development projects would assist in assuring that these do not result in maladaptation. See WGII Chapter 4 for a discussion of the unwanted consequences of building more and larger impoundments and increased water abstraction on terrestrial and freshwater ecosystems; health aspects of this are noted in sections 22.3.5.1 and 22.3.5.4. See section 22.6.2 on avoiding undesirable trade-offs between REDD+ approaches and adaptation that have the potential to result in significant maladaptation.

22.4.6. Barriers and Limits to Adaptation in Africa

A complex web of interacting barriers to local-level adaptation exists that manifests from national to local scales to constrain adaptation, which includes institutional, political, social, cultural, biophysical, cognitive and behavioral, and gender-related (*high confidence*). While relatively few studies from Africa have focused specifically on barriers and limits to adaptation, perceived and experienced constraints distilled from the literature encompass the resources needed for adaptation, the factors influencing adaptive capacity, the reasons for not employing particular adaptive strategies or not responding to climate change signals, and the reasons why some groups or individuals adapt but not others (Roncoli *et al.*, 2010; Bryan *et al.*, 2011; Nyanga *et al.*, 2011; Ludi *et al.*, 2012).

At the local level, institutional barriers hamper adaptation through elite capture and corruption; poor survival of institutions without social roots; and lack of attention to the institutional requirements of new technological interventions (Ludi *et al.*, 2012). Tenure security over land and vital assets is widely accepted as being crucial for enabling people to make longer-term and forward-looking decisions in the face of uncertainty, such as changing farming practices, farming systems, or even transforming livelihoods altogether (Bryan *et al.*, 2009; Brown *et al.*, 2010; Romero González *et al.*, 2011). In addition to unclear land tenure, legislation forbidding ecosystem use is one of the issues strengthening underlying conflicts over resources in Africa; resolving this would enable ecosystems to contribute to adaptation beyond short-term coping (Robledo *et al.*, 2012). There is also evidence that innovation may be suppressed if the dominant culture disapproves of departure from the ‘normal way of doing things’ (Ludi *et al.*, 2012; Jones 2012).

Characteristics such as wealth, gender, ethnicity, religion, class, caste, or profession can act as social barriers for some to adapt successfully or acquire the required adaptive capacities (Ziervogel *et al.*, 2008; Godfrey *et al.* 2010; Jones and Boyd, 2011). Based on field research conducted in the Borana area of southern Ethiopia, Debsu (2012) highlights the complex way in which external interventions may affect local and indigenous institutions by strengthening some coping and adaptive mechanisms and weakening others. Restrictive institutions can block attempts to enhance local adaptive capacity by maintaining structural inequities related to gender and ethnic minorities (Jones, 2012). Constraints faced by women, often through customs and legal barriers, include limited access to land and natural resources; lack of credit and input in decisionmaking, limited ability to take financial risk, lack of confidence, limited access to information and new ideas, and under-valuation of women’s opinions

(McFerson, 2010; Peach Brown, 2011, Djoudi and Brockhaus 2011; Jones 2012; Ludi *et al.*, 2012; Goh, 2012; Codjoe *et al.* 2012).

Few small-scale farmers across Africa are able to adapt to climatic changes, while others are restricted by a suite of overlapping barriers (*high agreement, robust evidence*). Constraints identified in Kenya, South Africa, Ethiopia, Malawi, Mozambique, Zimbabwe, Zambia and Ghana included poverty and a lack of cash or credit (financial barriers); limited access to water and land, poor soil quality, land fragmentation, poor roads, and pests and diseases (biophysical and infrastructural barriers); lack of access to inputs, shortage of labor, poor quality of seed and inputs attributed to a lack of quality controls by government and corrupt business practices by traders, insecure tenure, and poor market access (institutional, technological, and political barriers); and finally a lack of information on agroforestry/afforestation, different crop varieties, climate change predictions and weather, and adaptation strategies (informational barriers) (Bryan *et al.* 2009, 2011; Barbier *et al.*, 2009; Clover and Eriksen, 2009; Deressa *et al.*, 2009; Roncoli *et al.*, 2010; Mandleni and Anim, 2011; Nhemachena and Hassan, 2011; Nyanga *et al.*,2011; Vincent *et al.*, 2011a).

Recognition is increasing that understanding psychological factors such as mindsets and risk perceptions is crucial for supporting adaptation (Grothmann and Patt, 2005; Patt and Schröter, 2008; Jones, 2012). Cognitive barriers to adaptation include alternative explanations of extreme events and weather such as religion (God's will), the ancestors, and witchcraft, or seeing these changes as out of people's own control (Byran *et al.*, 2009; Roncoli *et al.*, 2010; Mandleni and Anim, 2011; Artur and Hilhorst, 2012; Jones, 2012; Mubaya *et al.* 2012).

Climate uncertainty, high levels of variability, lack of access to appropriate real-time and future climate information, and poor predictive capacity at a local scale are commonly cited barriers to adaptation from the individual to national level (Repetto, 2008; Dinku *et al.*, 2011; Jones, 2012; Mather and Stretch, 2012). Despite the cultural and psychological barriers noted above, several studies have shown that farmers with access to climate information are more predisposed to adjust their behaviour in response to perceived climate changes (Mubaya *et al.*, 2012).

At a policy level, studies have detected political, institutional and discursive barriers to adaptation. Adaptation options in southern Africa have been blocked by political and institutional inefficiencies, lack of prioritization of climate change, and the dominance of other discourses, such as the mitigation discourse in South Africa and short-term disaster-focused views of climate variability (Madzwamuse, 2010; Bele *et al.*, 2011; Berrang-Ford *et al.*, 2011; Conway and Schipper, 2011; Kalame *et al.*, 2011; Chevallier, 2012; Toteng, 2012; Leck *et al.*, 2012). Lack of local participation in policy formulation, the neglect of social and cultural context, and the inadvertent undermining of local coping and adaptive strategies have also been identified by several commentators as barriers to appropriate national policies and frameworks that would support local-level adaptation (e.g., Brockhaus and Djoudi, 2008; Bele *et al.*, 2011; Chevallier, 2012).

Many of these constraints to adaptation are well entrenched and will be far from easy to overcome; some may act as limits to adaptation for particular social groups (*high confidence)*. Biophysical barriers to adaptation in the arid areas could present as limits for more vulnerable groups if current climate change trends continue (Leary *et al.*, 2008b; Sallu *et al.*, 2010; Roncoli *et al.*, 2010). Traditional and autonomous adaptation strategies, particularly in the drylands, have been constrained by social-ecological change and drivers such as population growth, land privatization, land degradation, widespread poverty, HIV/AIDS, poorly conceived policies and modernization, obstacles to mobility and use of indigenous knowledge, as well as erosion of traditional knowledge, to the extent that it is difficult or no longer possible to respond to climate variability and risk in ways that people did in the past (Leary *et al.*, 2008b; Dabi *et al.*, 2008; Paavola, 2008; Smucker and Wisner, 2008; Clover and Eriksen, 2009; Conway, 2009; UNCCD *et al.*, 2009; Bunce *et al.*, 2010b; Quinn *et al.*, 2011; Jones, 2012; section 22.4.5.4). As a result of these multiple stressors working together, the number of response options has decreased and traditional coping strategies are no longer sufficient (Dube and Sekhwela, 2008). Studies have shown that most autonomous adaptation usually involves minor adjustments to current practices (e.g. changes in planting decisions); there are simply too many barriers to implementing substantial changes that require investment (e.g., agroforestry and irrigation) (Bryan *et al.*, 2011). Such adaptation strategies would be enhanced through government and private sector/NGO support, without which many poor groups in Africa may face real limits to adaptation (Vincent *et al.*, 2011a; Jones, 2012).

These findings highlight the benefits of transformational change in situations where high levels of vulnerability and low adaptive capacity detract from the possibility for systems to adapt sustainably. This is in agreement with the Special Report on Extreme Events, which additionally found *high agreement* and *robust evidence* for the importance of a spectrum of actions ranging from incremental steps to transformational changes in order to reduce climate risks (IPCC, 2012). In support of such solutions, Moench (2011) has called for distilling common principles for building adaptive capacity at different stages, and adaptive management and learning are seen as critical approaches for facilitating transformation (Section 22.4.5.3; IPCC, 2012). Chapter 16 provides further discussion on how encountering limits to adaptation may trigger transformational change, which can be a means of adapting to hard limits.

22.5. Key Risks for Africa

Table 22-6 highlights key risks for Africa (see also Table 19-4 and CC-KR), as identified through assessment of the literature and expert judgement of the author team, with supporting evaluation of evidence and agreement in the sections of this chapter, as referenced in the caption.

[INSERT TABLE 22-6 HERE
Table 22-6: Key risks from climate change and the potential for risk reduction through mitigation and adaptation in Africa. Key risks are identified based on assessment of the literature and expert judgments made by authors of the various WGII AR5 chapters, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.]

As indicated in Table 22-6, seven of the nine key regional risks are assessed for the present as being either medium or high under current adaptation levels, reflecting both the severity of multiple relevant stressors and Africa's existing adaptation deficit. This is the case for risks relating to shifts in biome distribution (22.3.2.1), degradation of coral reefs (22.3.2.3), reduced crop productivity (22.3.4.1), adverse effects on livestock (22.3.4.2), vector- and water-borne diseases (22.3.5.2, 22.3.5.4), under nutrition (22.3.5.3), and migration (22.6.1.2). This assessment indicates that allowing current emissions levels to result in a +4°C world (above pre-industrial levels) by the 2080-2100 period would have negative impacts on Africa's food security, as even under high adaptation levels, risks of reduced crop productivity and adverse effects on livestock are assessed as remaining very high. Moreover, our assessment is that even if high levels of adaptation were achieved, risks of stress on water resources (22.3.3), degradation of coral reefs (22.3.2.3), and the destructive effects of sea level rise and extreme weather events (22.3.6) would remain high. However, even under a lower emissions scenario leading to a long-term 2°C warming, all nine key regional risks are assessed as remaining high or very high under current levels of adaptation. The assessment indicates that even under high adaptation, residual impacts in a 2°C world would be significant, with only risk associated with migration rated as being capable of reduction to low under high levels of adaptation. High adaptation would be enabled by concerted effort and substantial funding; even if this is realized, no risk is assessed as being capable of reduction to below medium status.

22.6. Emerging Issues

22.6.1. Human Security

Although the significance of human security cannot be overestimated, the evidence of the impact of climate change on human security in Africa is disputable (see Chapters 12 and 19). Adverse climate events potentially impact all aspects of human security, either directly or indirectly (on mapping climate security vulnerability in Africa see Busby *et al*., 2013). Food security, water stress, land use and, health security, violent conflict, changing migration patterns, and human settlements are interrelating issues of discussions between climate change and human security. Violent conflict and migration are discussed below (for further details see Chapter 12).

22.6.1.1 Violent Conflict

While there seems to be consensus that the environment is only one of several interconnected causes of conflict and is rarely considered to be the most decisive factor (Kolmannskog, 2010), it remains disputed whether, and if so, how, the changing climate directly increases the risk of violent conflict in Africa (for more details see also Chapters 12 and 19, in particular 12.5.1; 19.4; Gleditsch, 2012). However, views are emerging that there is a positive relationship between increases in temperature and increases in human conflict (Hsiang *et al*., 2013). Some of the factors which may increase the risk of violent conflict, such as low per capita incomes, economic contraction and inconsistent state institutions are sensitive to climate change (12.5.1). For the African Sahel States it has been argued that the propensity for communal conflict across ethnic groups within Africa is influenced by political and economic vulnerability to climate change (Raleigh, 2010). Evidence on the question of whether, and if so to what extent, climate change and variability increases the risk of civil war in Africa is contested (Burke *et al.*, 2009b; Buhaug, 2010; Devitt and Tol, 2012). It has been suggested that due to the depletion of natural resources in Africa as a result of overexploitation and the impact of climate change on environmental degradation, competition for scarce resources could increase and lead to violent conflict (Kumssa and Jones, 2010). For East Africa it has been suggested that increased levels of malnutrition are related to armed conflicts (Rowhani *et al.*, 2011). There is some agreement that rainfall variation has an inconsistent relationship to conflict: both higher and lower anomalous rainfall is associated with increased communal conflict levels; although dry conditions have a lesser effect (Raleigh and Kniveton, 2012; Hendrix and Salehyan 2012; Theisen 2012).

22.6.1.2 Migration

Human migration has social, political, demographic, economic and environmental drivers, which may operate independently or in combination (for more in-depth discussions see Chapters 12.4 and 19.4.2.1; Perch-Nielsen *et al.*, 2008; Piguet, 2010; Foresight, 2011; Piguet *et al.*, 2011; Black *et al.*, 2011a; Van der Geest, 2011). Many of these drivers are climate sensitive (Black *et al.*, 2011c; 12.4.1.). People migrate either temporarily or permanently, within their country or across borders (12.4.1.2; Figure 12-1; Table 12-3; Warner *et al.*, 2010; Kälin and Schrepfer, 2012). The evidence base in the field of migration in Africa is both varied and patchy. Evidence suggests that migration is a strategy to adapt to climate change (12.4.2). Mobility is indeed a strategy (not a reaction) to high levels of climatic variation that is characteristic of Africa (Tacoli, 2011) and the specifics of the response are determined by the economic context of the specific communities.

Besides low-lying islands and coastal and deltaic regions in general, sub-Saharan Africa is one of the regions that would particularly be affected by environmentally induced migration (Gemenne, 2011a). Case studies from Somalia and Burundi emphasize the interaction of climate change, disaster, conflict, displacement, and migration (Kolmannskog, 2010). In Ghana for example, an African country with few conflicts caused by political, ethnic, or religious tensions, and thus with migration drivers more likely related to economic and environmental motivators (Tschakert and Tutu, 2010), some different types of migration flows are considered to have different sensitivity to climate change (Black *et al.*, 2011a). The floods of the Zambezi River in Mozambique in 2008 have displaced 90,000 people, and it has been observed that along the Zambezi River Valley, with approximately 1 million people living in the flood-affected areas, temporary mass displacement is taking on permanent characteristics (Jäger *et al.*, 2009; Warner *et al.*, 2010).

Different assessments of future trends have recently produced contradictory conclusions (e.g., UN-OCAH and IDMC, 2009; Naude, 2010; ADB, 2011; Tacoli, 2011, IDMC, 2011). One approach in assessing future migration potentials, with considerable relevance to the African context, focused on capturing the net effect of environmental change on aggregate migration through analysis of both its interactions with other migration drivers and the role of migration within adaptation strategies, rather than identifying specific groups as potential 'environmental migrants' (Foresight, 2011). Even if Africa's population doubles by 2050 to 2 billion (Lutz and K.C., 2010) and the potential for displacement rises as a consequence of the impact of extreme weather events, recent analyses (Foresight, 2011; Black *et al.*, 2011b) show that the picture for future migration is much more complex than previous assessments of a rise in climate induced migration suggest, and relates to the intersection of multiple drivers with rates of global growth, levels of governance, and climate change.

The empirical base for major migration consequences is weak (Lilleør and Van den Broeck, 2011; Black *et al.*, 2011a; Gemenne, 2011b) and non-existent for international migration patterns (Marchiori *et al.*, 2011). Even across the same type of extreme weather event, the responses can vary (Findlay, 2011; Gray, 2011 for Kenya and Uganda; Raleigh, 2011 for the African Sahel States)).

22.6.2. Integrated Adaptation / Mitigation Approaches

Relevant experience gained in Africa since AR4 in implementing integrated adaptation–mitigation responses within a pro-poor orientation that leverages developmental benefits encompasses some participation of farmers and local communities in carbon offset systems, increasing the use of relevant technologies such as agroforestry and farmer-assisted tree regeneration (22.4.5.6), and emerging Green Economy policy responses. The recognition that adaptation and mitigation are complementary elements of the global response to climate change, and not trade-offs, is gaining traction in Africa (Goklany, 2007; Nyong *et al.*, 2007; UNCCD *et al.*, 2009; Woodfine, 2009; Jalloh *et al.*, 2011b; Milder *et al.*, 2011).

While the suitability of on- and off-farm techniques for an integrated adaptation-mitigation response depends on local physical conditions as well as political and institutional factors, sustainable land management techniques are particularly beneficial for an integrated response in Africa; these include agroforestry, including through farmer-managed natural regeneration; and conservation agriculture (Woodfine, 2009; Milder *et al.*, 2011; Mutonyi and Fungo, 2011; section 22.4.5.6; Box 22-2). An emerging area is multiple-benefit initiatives that aim to reduce poverty, promote adaptation through restoring local ecosystems, and deliver benefits from carbon markets. Brown *et al.*, (2011) note the example of a community-based project in Humbo, Ethiopia, which is facilitating adaptation and generating temporary certified emissions reductions under the Clean Development Mechanism, by restoration of degraded native forests (2,728 ha) through farmer-managed natural regeneration.

The key role of local communities in carbon offset systems through community forestry entails land use flexibility (Purdon, 2010), but can be constrained by the lack of supportive policy environments – for example, for conservation agriculture (Milder *et al.*, 2011).

The literature highlights the desirability of responding to climate change through integrated adaptation–mitigation approaches, including through spatial planning, in the implementation of REDD+ in Africa, especially given the significant contribution to food security and livelihoods of forest systems (Bwango *et al.*, 2000; Guariguata et al., 2008; Nkem *et al.*, 2007; Nasi *et al.*, 2008; Biesbroek *et al.*, 2009; Somorin *et al.*, 2012). However, forests are mainly used for reactive coping and not anticipatory adaptation; studies show that governments favour mitigation while local communities prioritise adaptation (Fisher *et al.*, 2010; Somorin *et al.*, 2012). Flexible REDD+ models that include agriculture and adaptation hold promise for generating co-benefits for poverty reduction, given food security and adaptation priorities, and help to avoid trade-offs between REDD+ implementation and adaptive capacities of communities, ecosystems, and nations (Nkem *et al.*, 2008; Thomson *et al.*, 2010; CIFOR, 2011; Richard *et al.*, 2011; Wertz-Kanounnikoff *et al.*, 2011).

Integrated adaptation–mitigation responses are being considered within the context of the emerging Green Economy discussions. African leaders agreed in 2011 to develop an African Green Growth Strategy, to build a shared vision for promoting sustainable low-carbon growth through a linked adaptation–mitigation approach, with adaptation seen as an urgent priority. A national example is the launch of Ethiopia's Climate Resilient Green Economy Facility in 2012 (Corsi *et al.*, 2012).

22.6.3. Biofuels and Land Use

The potential for first-generation biofuel production in Africa, derived from bioethanol from starch sources and biodiesel production from oilseeds, is significant given the continent's extensive arable lands, labor availability, and favorable climate for biofuel crop production (Amigun *et al.*, 2011; Arndt *et al.*, 2011; Hanff *et al.*, 2011). While biofuel production has positive energy security and economic growth implications, the prospect of wide-scale biofuel production in Africa carries with it significant risks related to about environmental and social sustainability. Among the concerns are competition for land and water between fuel and food crops, adverse impacts of biofuels on biodiversity and the environment, contractual and regulatory obligations that expose farmers to legal risks, changes in land tenure security, and reduced livelihood opportunities for women, pastoralists and migrant farmers who depend on access to the land resource base (Unruh, 2008; Amigun *et al.*, 2011; German *et al.*, 2011; Schoneveld *et al.*, 2011).

More research is needed to understand fully the socioeconomic and environmental tradeoffs associated with biofuel production in Africa. One critical knowledge gap concerns the effect of biofuel production, particularly large-scale schemes, on land use change and subsequent food and livelihood security. For example, the conversion of marginal lands to biofuel crop production would impact the ability of users of these lands (pastoralists and in some cases women who are allocated marginal land for food and medicinal production) to participate in land use and food production decisions (Amigun *et al.*, 2011; Schoneveld *et al.*, 2011). In addition, biofuel production could potentially lead to the extension of agriculture into forested areas, either directly through conversion of fallow vegetation or the opening of mature woodland, or indirectly through use of these lands to offset food crop displacement (German *et al.*, 2011). Such land use conversion would result in biofuel production reducing terrestrial carbon storage potential (Vang Rasmussen *et al.*, 2012a; Vang Rasmussen *et al.*, 2012b).

Better agronomic characterization of biofuel crops is another key knowledge gap. For example, little information exists with respect to the agronomic characteristics of the oilseed crop Jatropha (*Jatropha curcas*) under conditions of intensive cultivation across differing growing environments, despite the fact that Jatropha has been widely touted as an appropriate feedstock for biofuel production in Africa because of its ability to grow in a wide range of climates and soils. Oilseed yields of Jatropha can be highly variable, and even basic information about yield potential and water and fertilizer requirements for producing economically significant oilseed yields is scanty (Achten *et al.*, 2008; Peters and Thielmann, 2008; Hanff *et al.*, 2011). Such knowledge would not only provide a basis for better crop management but would also help to gain better estimates of the extent of water consumption for biofuel production in the context of non-biofuel water-use needs across landscapes. Assessments of Jatropha's potential as an invasive species and its potential allelopathic effects on native vegetation are also needed, in light of the fact that some countries have designated Jatropha as an invasive species (Achten *et al.*, 2008).

22.6.4. Climate Finance and Management

Recent analyses emphasise the significant financial resources and technological support needed to both address Africa's current adaptation deficit and to protect rural and urban livelihoods, societies and economies from climate change impacts at different local scales, with estimates of adaptation costs between US$20-30 billion per annum over the next couple of decades, up to US$60 billion per annum by 2030 (for example see figure 22.6), although these figures are *likely* to be under-estimates, as studies upon which these estimates are based do not always include the costs of overcoming Africa's current adaptation deficit, may be run for one scenario at a time, and do not factor in a range of uncertainties in the planning environment (Parry et al, 2009b; Fankhauser and Schmidt-Traub, 2010; Watkiss et al, 2010; AfDB, 2011; Dodman and Carmin, 2011; LDC Expert Group, 2011; Smith et al, 2011).

Damages related to climate change may affect economic growth and the ability to trade (Lecocq and Shalizi, 2007; Ruppel and Ruppel-Schlichting, 2012). Costs of adaptation and negative economic impacts of climate change have been referred to in sections 22.3.4.4 and 22.3.6; Warner *et al*. (2012) have highlighted the residual impacts of climate change that would occur after adaptation, for case studies in Kenya and The Gambia. The following examples are illustrative of the move to discuss financial implications in the literature.

Scenarios for Tanzania, where agriculture accounts for about half of gross production and employs about 80% of the labor force (Thurlow and Wobst, 2003), project that changes in the mean and extremes of climate variables, could increase poverty vulnerability (Ahmed *et al*., 2011). Scenarios for Namibia based on a computable general equilibrium model project that annual losses to the economy ascribed to the impacts of climate change on the country's natural resources could range between 1.0% and 4.8% of GDP (Reid *et al.*, 2008). Ghana's agricultural and economic sector with cocoa being the single most important export product is particularly vulnerable, since cocoa is prone to the effects of a changing climate (Black *et al.*, 2011c), which has been central to the country's debates on development and poverty alleviation strategies (WTO Trade Policy Review, 2008).

The potential for adaptation to reduce the risks associated with sea level rise is substantial for cumulative land loss and for numbers of people flooded or forced to migrate, with adaptation costs lower than the economic and social damages expected if nothing is done (Kebede *et al.*, 2010).See Figure 22-6.

[INSERT FIGURE 22-6 HERE
Figure 22-6: Total additional costs of adaptation per year from 2000 to 2100 for Tanzania (including beach nourishment and sea and river dikes). The values do not consider the existing adaptation deficit (values in $US 2005, without discounting Source: Kebede *et al.*, 2010.]

The Dynamic Interactive Vulnerability Assessment (DIVA) model was used to assess the monetary and non-monetary impacts of sea level rise on the entire coast (3,461 km) of Tanzania. Under the B1 low-range sea level rise scenario it was estimated that by 2030, a total area of 3,579 to 7,624 km^2 would be lost, mainly through inundation; with around 234,000 to 1.6 million people per year who could potentially experience flooding. Without adaptation, residual damages have been estimated at between US$ 26 and 55 million per year (Kebede *et al*., 2010). Table 22-7 shows the economic impacts of land inundated in Cape Town based on different sea level rise scenarios.

[INSERT TABLE 22-7 HERE
Table 22-7: Land inundated and economic impacts in Cape Town based on a risk assessment (Cartwright, 2008).]

In line with increasing international impetus for adaptation (Persson *et al.*, 2009) the Parties to the UNFCCC agreed on providing "adequate, predictable and sustainable financial resources" for adaptation in developing countries, and, within this context, paid special attention to Africa which is "particularly vulnerable" to the adverse effects of climate change (UNFCCC, 2009; UNFCCC, 2011; Berenter, 2012). Doubts remain about how private sector financing can be effectively mobilized and channeled toward adaptation in developing countries (Atteridge, 2011; Naidoo *et al.*, 2012). The 2012 Landscape of Climate Finance Report (Buchner *et al.*, 2012) stated that mitigation activities attracted US$ 350 billion, mostly related to renewable energy and energy efficiency, while adaptation activities attracted US$ 14 billion. Approximately 30% of the global distributed adaptation finance went to Africa (Nakhooda *et al.*, 2011) and seems to prioritize the continent (Naidoo *et al.*, 2012). However, it is being questioned, whether the adaptation funding that is currently delivered does fulfill demonstrated needs (Flåm and Skjærseth, 2009; Denton, 2010 for sub-Saharan Africa Nakhooda *et al.*, 2011).

Effective adaptation requires more than sufficient levels of funding. It requires developing country 'readiness,' which includes abilities to plan and access finances; the capacity to deliver adaptation projects and programs, and to monitor, report, and evaluate their effectiveness (Vandeweerd *et al.*, 2012); and also a regulatory framework, which guarantees e.g. property rights (IPCC AR5 WGIII Draft 2 Chapter 16 p.:27; line 30-33). Particularly serious challenges are associated with directing finance to the sectors and people most vulnerable to climate change

(Denton, 2010; Nakhooda *et al.*, 2011; Pauw *et al.*, 2012). The risk of fund mismanagement with regard to climate finance and adaptation funds needs to be borne in mind. Suggestions to address adequately the level of complexity, uncertainty, and novelty that surrounds many climate finance issues *inter alia* include longer-term and integrated programs rather than isolated projects; building capacity and institutions in African countries (Nakhooda *et al.*, 2011; Pauw *et al.*, 2012); identifying priorities, processes, and knowledge needs at the local level (Haites, 2011; Pauw, 2013); and, accordingly, developing grassroots projects (Fankhauser and Burton, 2011).

22.7. Research Gaps

Research has a key role to play in providing information for informed decisionmaking at local to national levels (Fankhauser, 1997; Ziervogel *et al.*, 2008; Arendse and Crane, 2010). While there is significant activity in African research institutions, much African research capacity is spent on foreign-led research that may necessarily prioritize addressing national knowledge gaps about climate change (Madzwamuse, 2010), and African research may lack merited policy uptake or global recognition as it is often not published in peer-reviewed literature (Denton *et al.*, 2011).

The following overarching data and research gaps have been identified also see Table 22.8:

- Data management and monitoring of climate and hydroclimate parameters and development of climate change scenarios as well as monitoring systems to address climate change impacts in the different sectors (for example the impacts of pests and diseases on crops and livestock) and systems;
- Research and improved methodologies to assess and quantify the impact of climate change on different sectors and systems.
- Socio-economic consequences of the loss of ecosystems and also of economic activities as well as of certain choices in terms of mitigation (biofuels and their links with food and livelihood security for example) and adaptation to climate change;
- The links influence of climate change in emerging issues such as migration and urban food security;
- Developing tools allowing decision makers to make their decisions based on the complexity of the world under climate change, taking into consideration gender, age and all regarding the contribution of local communities.

[INSERT TABLE 22-8 HERE

Frequently Asked Questions

FAQ 22.1: How could climate change impact food security in Africa? *[to be inserted in Section 22.3.4.5]*
Food security is comprised of availability (is enough food produced), access (can people get it, and afford it), utilization (how local conditions bear on peoples nutritional uptake from food), and stability (is the supply and access ensured). Strong consensus exists that climate change will have a significantly negative impact on all these aspects of food security in Africa.

Food availability could be threatened through direct climate impacts on crops and livestock from increased flooding, drought, shifts in the timing and amount of rainfall, and high temperatures, or indirectly through increased soil erosion from more frequent heavy storms or through increased pest and disease pressure on crops and livestock caused by warmer temperatures and other changes in climatic conditions. Food access could be threatened by climate change impacts on productivity in important cereal-producing regions of the world which, along with other factors, could raise food prices and erode the ability of the poor in Africa to afford purchased food. Access is also threatened by extreme events that impair food transport and other food system infrastructure. Climate change could impact food utilization through increased disease burden that reduces the ability of the human body to absorb nutrients from food. Warmer and more humid conditions caused by climate change could impact food availability and utilization through increased risk of spoilage of fresh food and pest and pathogen damage to stored foods (cereals, pulses, tubers) that reduces both food availability and quality. Stability could be affected by changes in availability and access that are linked to climatic and other factors.

FAQ 22.2: What role does climate change play with regard to violent conflict in Africa?
[to be inserted in Section 22.6.1.1]
Wide consensus exists that violent conflicts are based on a variety of interconnected causes, of which the environment is considered to be one, but rarely the most decisive factor. Whether the changing climate increases the risk of civil war in Africa remains disputed and little robust research is available to resolve this question. Climate change impacts that intensify competition for increasingly scarce resources like freshwater and arable land, especially in the context of population growth, are areas of concern. The degradation of natural resources as a result of both overexploitation and climate change will contribute to increased conflicts over the distribution of these resources. In addition to these stressors, however, the outbreak of armed conflict depends on many country-specific sociopolitical, economic and cultural factors.

Box CC-GC. Gender and Climate Change

[Jon Barnett (Australia), Marta G. Rivera Ferre (Spain), Petra Tschakert (U.S.A.), Katharine Vincent (South Africa), Alistair Woodward (New Zealand)]

Gender, along with socio-demographic factors of age, wealth and class, is critical to the ways in which climate change is experienced. There are significant gender dimensions to impacts, adaptation and vulnerability. This issue was raised in WGII AR4 and SREX reports (Adger *et al.*, 2007; IPCC, 2012), but for the AR5 there are significant new findings, based on multiple lines of evidence on how climate change is differentiated by gender, and how climate change contributes to perpetuating existing gender inequalities. This new research has been undertaken in every region of the world (e.g. Brouwer *et al.*, 2007; Nightingale, 2009; Buechler, 2009; Nelson and Stathers, 2009; Dankelman, 2010; MacGregor, 2010; Alston, 2011; Arora-Jonsson, 2011; Resureccion, 2011; Omolo, 2011).

Gender dimensions of vulnerability derive from differential access to the social and environmental resources required for adaptation. In many rural economies and resource-based livelihood systems, it is well established that women have poorer access than men to financial resources, land, education, health and other basic rights. Further drivers of gender inequality stem from social exclusion from decision-making processes and labour markets, making women in particular less able to cope with and adapt to climate change impacts (Rijkers and Costa, 2012; Djoudi and Brockhaus, 2011; Paavola, 2008). These gender inequalities manifest themselves in gendered livelihood impacts and feminisation of responsibilities: whilst both men and women experience increases in productive roles, only women experience increased reproductive roles (Resureccion, 2011; 9.3.5.1.5, Box 13-1). A study in Australia, for example, showed how more regular occurrence of drought has put women under increasing pressure to earn off-farm income, and contribute to more on-farm labor (Alston, 2011). Studies in Tanzania and Malawi demonstrate how women experience food and nutrition insecurity since food is preferentially distributed among other family members (Nelson and Stathers, 2009; Kakota *et al.*, 2011).

AR4 assessed a body of literature that focused on women’s relatively higher vulnerability to weather-related disasters in terms of number of deaths (Adger *et al.*, 2007). Additional literature published since that time adds nuances by showing how socially-constructed gender differences affect exposure to extreme events, leading to differential patterns of mortality for both men and women (*high confidence*) [11.3.3, Table 12-3]. Statistical evidence of patterns of male and female mortality from recorded extreme events in 141 countries between 1981-2002 found that disasters kill women at an earlier age than men (Neumayer and Plümper, 2007) [Box 13-1]. Reasons for gendered differences in mortality include various socially- and culturally-determined gender roles. Studies in Bangladesh, for example, show that women do not learn to swim and so are vulnerable when exposed to flooding (Röhr, 2006) and that, in Nicaragua, the construction of gender roles means that middle-class women are expected to stay in the house, even during floods and in risk-prone areas (Bradshaw, 2010). While the differential vulnerability of women to extreme events has long been understood, there is now increasing evidence to show how gender roles for men can affect their vulnerability. In particular, men are often expected to be brave and heroic, and engage in risky life-saving behaviors that increase their likelihood of mortality [Box 13-1]. In Hai Lang district, Vietnam, for example, more men died than women due to their involvement in search and rescue and protection of fields during flooding (Campbell *et al.*, 2009). Women and girls are more likely to become victims of domestic violence after a disaster, particularly when they are living in emergency accommodation, which has been documented in the U.S. and Australia (Jenkins and Phillips, 2008; Anastario *et al.*, 2009; Alston, 2011; Whittenbury, 2013; Box 13-1).

Heat stress exhibits gendered differences, reflecting both physiological and social factors (11.3.3). The majority of studies in European countries show women to be more at risk, but their usually higher physiological vulnerability can be offset in some circumstances by relatively lower social vulnerability (if they are well connected in supportive social networks, for example). During the Paris heat wave, unmarried men were at greater risk than unmarried women, and in Chicago elderly men were at greatest risk, thought to reflect their lack of connectedness in social support networks which led to higher social vulnerability (Kovats and Hajat, 2008). A multi-city study showed geographical variations in the relationship between sex and mortality due to heat stress: in Mexico City, women had a higher risk of mortality than men, although the reverse was true in Santiago and Sao Paulo (Bell *et al.*, 2008).

Recognizing gender differences in vulnerability and adaptation can enable gender-sensitive responses that reduce the vulnerability of women and men (Alston, 2013). Evaluations of adaptation investments demonstrate that those approaches that are not sensitive to gender dimensions and other drivers of social inequalities risk reinforcing existing vulnerabilities (Figueiredo and Perkins, 2012; Arora-Jonsson, 2011; Vincent *et al.*, 2010). Government-supported interventions to improve production through cash-cropping and non-farm enterprises in rural economies, for example, typically advantage men over women since cash generation is seen as a male activity in rural areas (Gladwin *et al.*, 2001;13.3.1). In contrast, rainwater and conservation-based adaptation initiatives may require additional labor which women cannot necessarily afford to provide (Baiphethi *et al.*, 2008). Encouraging gender-equitable access to education and strengthening of social capital are among the best means of improving adaptation of rural women farmers (Below *et al.*, 2012; Goulden *et al.*, 2009; Vincent *et al.*, 2010) and could be used to complement existing initiatives mentioned above that benefit men. Rights-based approaches to development can inform adaptation efforts as they focus on addressing the ways in which institutional practices shape access to resources and control over decision-making processes, including through the social construction of gender and its intersection with other factors that shape inequalities and vulnerabilities (Tschakert, 2013; Bee *et al.*, 2013; Tschakert and Machado, 2012; see also 22.4.3 and Table 22-5).

Box CC-UP. Uncertain Trends in Major Upwelling Ecosystems

[Salvador E. Lluch-Cota (Mexico), Ove Hoegh-Guldberg (Australia), David Karl (USA), Hans O. Pörtner (Germany), Svein Sundby (Norway), Jean-Pierre Gatusso (France)]

Upwelling is the vertical transport of cold, dense, nutrient-rich, relatively low-pH and often oxygen-poor waters to the euphotic zone where light is abundant. These waters trigger high levels of primary production and a high biomass of benthic and pelagic organisms. The driving forces of upwelling include wind stress and the interaction of ocean currents with bottom topography. Upwelling intensity also depends on water column stratification. The major upwelling systems of the Planet, the Equatorial Upwelling System (EUS, 30.5.2, Figure 30.1A) and the Eastern Boundary Upwelling Ecosystems (EBUE, 30.5.5, Figure 30.1A), represent only 10% of the ocean surface but contribute nearly 25 % to global fish production (Figure 30.1B, Table S30.1).

Marine ecosystems associated with upwelling systems can be influenced by a range of 'bottom-up' trophic mechanisms, with upwelling, transport, and chlorophyll concentrations showing strong seasonal and interannual couplings and variability. These, in turn, influence trophic transfer up the food chain, affecting zooplankton, foraging fish, seabirds and marine mammals.

There is considerable speculation as to how upwelling systems might change in a warming and acidifying ocean. Globally, the heat gain of the surface ocean has increased stratification by 4% (WGI 3.2, 3.4.4, 3.8), which means that more wind energy is needed to bring deep waters to the surface. It is as yet unclear to what extent wind stress can offset the increased stratification, due to the uncertainty in wind speed trends (WGI, 3.4.4). In the tropics, observations of reductions in trade winds over several decades contrast more recent evidence indicating their strengthening since the early 1990s (WGI, 9.4.1.3.4). Observations and modelling efforts in fact show diverging trends in coastal upwelling at the eastern boundaries of the Pacific and the Atlantic. Bakun (1990) proposed that the the difference in heat gaining rates between land and ocean causes an increase in the pressure gradient, which results in increased alongshore winds and leads to intensified offshore transport of surface water through Ekman pumping, and the upwelling of nutrient rich, cold waters (Figure CC-UP). Some regional records support this hypothesis, others do not. There is considerable variability in warming and cooling trends over the past decades both within and among systems making it difficult to predict changes in the intensity of all Eastern Boundary Upwelling Ecosystems (30.5.5).

Understanding whether upwelling and climate change will impact resident biota in an additive, synergistic or antagonistic manner is important for projections of how ecological goods and services provided for human society will change. Even though upwellings may prove more resilient to climate change than other ocean ecosystems because of their ability to function under extremely variable conditions (Capone and Hutchins, 2013), consequences of their shifts are highly relevant since these are the most biologically active systems in the ocean. Increased upwelling would enhance fisheries yields. However, the export of organic material from surface to deeper layers of the ocean may increase and stimulate its decomposition by microbial activity, thereby enhancing oxygen depletion and CO_2 enrichment in deeper water layers. Once this water returns to the surface through upwelling benthic and pelagic coastal communities will be exposed to acidified and deoxygenated water which may combine with anthropogenic impact to negatively affect marine biota and ecosystem structure of the upper ocean (high confidence, 6.3.2, 6.3.3; 30.3.2.2, 30.3.2.3). Extreme hypoxia may result in abnormal mortalities of fishes and invertebrates (Keller *et al.*, 2010), reduce the fisheries catch potential and impact aquaculture in coastal areas (5.4.3.3, 6.3.7, 30.5.1.1.2, 30.5.5.1.3, Barton *et al.*, 2012). Shifts in upwelling also coincide with an apparent increase in the frequency of submarine eruptions of methane and hydrogen sulphide gas, caused by enhanced formation and sinking of phytoplankton biomass to the hypoxic or anoxic sea floor . This combination of factors has been implicated in the extensive mortality of coastal fishes and invertebrates (Bakun and Weeks, 2004), resulting in significant reductions in fishing productivity, such as Cape hake (*Merluccius capensis*), Namibia's most valuable fishery (Hamukuaya *et al*., 1998).

Reduced upwelling would also reduce the productivity of important pelagic fisheries, such as for sardines, anchovies and mackerel, with major consequences for the economies of several countries (6.4.1, Chp 7, Figure 30.1A, B, Table S30.1). However, under projected scenarios of reduced upward supply of nutrients due to stratification of the open ocean , upwelling of both nutrients and trace elements may become increasingly important to maintaining upper ocean nutrient and trace metal inventories. It has been suggested that upwelling areas may also increase nutrient content and productivity under enhanced stratification, and that upwelled and partially denitrified waters containing excess phosphate may select for N_2-fixing microorganisms (Deutsch *et al*., 2007; Deutsch and Weber, 2012), but field observations of N2 fixation in these regions have not supported these predictions (Fernandez *et al*., 2011; Franz *et al*., 2012). The role of this process in global primary production thus needs to be validated (*low confidence*).

The central question therefore is whether or not upwelling will intensify, and if so, whether the effects of intensified upwelling on O_2 and CO_2 inventories will outweigh its benefits for primary production and associated fisheries and aquaculture (*low confidence*). In any case increasing atmospheric CO_2 concentrations will equilibrate with upwelling waters that may cause them to become more corrosive, depending upon pCO_2 of the upwelled water, and potentially increasingly impact the biota of Eastern Boundary Upwelling Ecosystems.

[INSERT FIGURE UP-1 HERE
Figure UP-1: Upper panel: Schematic hypothetic mechanism of increasing coastal wind-driven upwelling at eastern boundary systems, where differential warming rates between land and ocean results in increased land-ocean pressure gradients (1) that produce stronger alongshore winds (2) and offshore movement of surface water through Ekman transport (3), and increased upwelling of deep cold nutrient rich waters to replace it (4). Lower panel: potential consequences of climate change in upwelling systems. Increasing stratification and uncertainty in wind stress trends result in uncertain trends in upwelling. Increasing upwelling may result in higher input of nutrients to the euphotic zone, and increased primary production, which in turn may enhance pelagic fisheries, but also decreased coastal fisheries due to an augmented exposure of coastal fauna to hypoxic, low pH waters. Decreased upwelling may result in lower primary production in these systems with direct impacts on pelagic fisheries productivity.]

Box CC-WE: The Water-Energy-Food/Feed/Fiber Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Kenneth M. Strzepek (UNU / USA), Blanca Elena Jimenez Cisneros (Mexico), Andy Reisinger (New Zealand), FerencToth (IAEA / Hungary), Taikan Oki (Japan)]

Water, energy, and food/feed/fiber are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure WE-1. The depth and intensity of those linkages vary enormously between countries, regions and production systems. Energy technologies (e.g. biofuels, hydropower, thermal power plants), transportation fuels and modes, and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops and forages) may require significant amounts of water (Sections 3.7.2, 7.3.2, 10.2, 10.3.4, 22.3.3, 25.7.2; Allan, 2003; King and Weber 2008; McMahon and Price, 2011; Macknick *et al*., 2012a). In irrigated agriculture, climate, irrigating procedure, crop choice and yields determine water requirements per unit of produced crop. In areas where water (and wastewater) must be pumped and/or treated, energy must be provided (Asano et al., 2006; Khan and Hanjra, 2009; USEPA, 2010; Gerten et al., 2011). While food production, refrigeration, transport and processing require large amounts of energy (Pelletier et al., 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (Section 7.3.2, Box 25-10; Diffenbaugh et al., 2012; Skaggs et al., 2012) *(robust evidence, high agreement)*. Food and crop wastes, and wastewater, may be used as sources of energy, saving not only the consumption of conventional non-renewable fuels used in their traditional processes, but also the consumption of the water and energy employed for processing or treatment and disposal (Schievano et al., 2009; Sung et al., 2010; Olson, 2012). Examples of this can be found in several countries across all income ranges. For example, sugar cane by-products are increasingly used to produce electricity or for cogeneration (McKendry, 2002; Kim and Dale 2004) for economic benefits, and increasingly as an option for greenhouse gas mitigation.

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change. The interlinkages of supply/demand, quality and quantity of water, energy and food/feed/fiber with changing climatic conditions have implications for both adaptation and mitigation strategies.]

Most energy production methods require significant amounts of water, either directly (e.g., crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Sections 10.2.2 10.3.4, 25.7.4; van Vliet et al., 2012; Davies et al., 2013) *(robust evidence, high agreement).* Water for biofuels, for example, under the IEA Alternative Policy Scenario, which has biofuels production increasing to 71 EJ in 2030, has been reported by Gerbens-Leenes et al. (2012) to drive global consumptive irrigation water use from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water is also required for mining (Section 25.7.3), processing, and residue disposal of fossil and nuclear fuels or their byproducts. Water for energy currently ranges from a few percent in most developing countries to more than 50% of freshwater withdrawals in some developed countries, depending on the country (Kenny et al., 2009; WEC, 2010). Future water requirements will depend on electricity demand growth, the portfolio of generation technologies and water management options employed (WEC, 2010; Sattler et al., 2012) *(medium evidence, high agreement)*. Future water availability for energy production will change due to climate change (Sections 3.4, 3.5.1, 3.5.2.2) *(robust evidence, high agreement).*

Water may require significant amounts of energy for lifting, transport and distribution and for its treatment either to use it or to depollute it. Wastewater and even excess rainfall in cities requires energy to be treated or disposed. Some non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced potable water from ground/surface water sources vs. desalinated seawater (Box 25-2, Tables 25-6 and 25-7; Macknick et al., 2012b; Plappally and Lienhard, 2012). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user; Döll et al., 2012) is generally more energy intensive than surface water. In India, for example, 19% of total electricity use in 2012 was for agricultural purposes (Central Statistics Office, 2013), with a large share for groundwater pumping. Pumping from greater depth increases energy demand significantly– electricity use (kWhr/m^3 of water) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard, 2012). The reuse of appropriate wastewater for irrigation (reclaiming both water and energy-intense nutrients) may increase agricultural yields, save energy, and prevent soil erosion (Smit and Nasr, 1992; Jimenez, 1996; Wichelns et al., 2007; Raschid-Sally and Jayakody, 2008) *(medium confidence)*. More energy efficient treatment methods enable poor quality ("black") wastewater to be treated to quality levels suitable for discharge into water courses, avoiding additional fresh water and associated energy demands (Keraita et al, 2008). If properly treated to retain nutrients, such treated water may increase soil productivity, contributing to increased crop yields/food security in regions unable to afford high power bills or expensive fertilizer (Oron, 1996; Lazarova and Bahri, 2005; Redwood and Huibers, 2008; Jimenez, 2009) *(high confidence)*.

Linkages among water, energy, food/feed/fiber and climate are also strongly related to land use and management (Section 4.4.4, Box 25-10) *(robust evidence, high agreement)*. Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and compromises food security (Sections 3.7.2, 4.4.4). On the other hand, afforestation activities to sequester carbon have important co-benefits of reducing soil erosion and providing additional (even if only temporary) habitat (see Box 25-10) but may reduce renewable water resources. Water abstraction for energy, food or biofuel production or carbon sequestration can also compete with minimal environmental flows needed to maintain riverine habitats and wetlands, implying a potential conflict between economic and other valuations and uses of water (Sections 25.4.3 and 25.6.2, Box 25-10) *(medium evidence, high agreement)*. Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water and climate (McCornick et al., 2008; Bazilian et al., 2011; Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy and water demand, bioproductivity and other factors (see Figure WE-1 and Wise et al., 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this report.

The interconnectivity of food/fiber, water, land use, energy and climate change, including the perhaps not yet well understood cross-sector impacts, are increasingly important in assessing the implications for adaptation/mitigation policy decisions. Fuel-food-land use-water-GHG mitigation strategy interactions, particularly related to bioresources for food/feed, power, or fuel, suggest that combined assessment of water, land type and use requirements, energy requirements and potential uses and GHG impacts often epitomize the interlinkages. For example, mitigation scenarios described in the IPCC Special Report on Renewable Energy Sources and Climate Change Mitigation (IPCC, 2011) indicate up to 300EJ of biomass primary energy by 2050 under increasingly stringent mitigation scenarios. Such high levels of biomass production, in the absence of technology and process/management/operations change, would have significant implications for land use, water and energy, as well as food production and pricing. Consideration of the interlinkages of energy, food/feed/fiber, water, land use and climate change is increasingly recognized as critical to effective climate resilient pathway decision making *(medium evidence, high agreement)*, although tools to support local- and regional-scale assessments and decision-support remain very limited.

Table 22-1: Major conclusions from previous IPCC assessments.

Report	Major conclusions	Reference
IPCC special report on regional climate change	• Sensitivity of **water resources and coastal zones** to climatic parameters • Identification of climate change as an **additional burden** on an already stressful situation • **Major challenges for Africa**: Lack of data on energy sources; uncertainties linked to climate change scenarios (mainly for precipitation); need for integrated studies; and the necessary links between science and decision makers	Zinyowera *et al.*, 1997
Third Assessment Report (TAR)	• **Impacts of climate change on and vulnerability of six sectors**: water resources; food security; natural resources and biodiversity management; health; human settlements and infrastructure; desertification • **Adaptation strategies** for each of the sectors • Threats of **desertification** and **droughts** to the economy of the continent • **Suggestion of adaptation options**: mainly linked with better resource management • **Identification of research gaps and needs**: capacity building; data needs; development of integrated analysis; consideration of literature in other languages	Desanker *et al.*, 2001
Fourth Assessment Report (AR4)	• Vulnerability of Africa mainly due to its **low adaptive capacity** • **Sources of vulnerability** mainly socioeconomic causes (demographic growth, governance, conflicts, etc.) • **Impacts of climate change on various sectors**: energy, tourism and coastal zones considered separately • Potential impacts of extreme weather events (droughts and floods) • Adaptation costs • Need for mainstreaming climate change adaptation into national development policies • Two case studies: ***1.*** Food security: climate change could affect the three main components of food security ***2.*** Traditional Knowledge: African communities have prior experience with climate variability, although this knowledge will not be sufficient to face climate change impacts. • **Research needs**: better knowledge of climate variability; more studies on the impacts of climate change on water resources, energy, biodiversity, tourism, and health; the links between different sectors (e.g., between agriculture, land availability, and biofuels); developing links with the disaster reduction community; increasing interdisciplinary analysis of climate change; and strengthening institutional capacities	Boko *et al.*, 2007

Table 22-2: Under-nourishment in Africa, by number and % of total population.

Undernourished	1990 – 1992	1999 – 2001	2004 – 2006	2007 – 2009	2010 – 2012
Million	175	205	210	220	239
(%) of total population	27.3%	25.3%	23.1%	22.6%	22.9%

Source: IFAD *et al.*, 2012

Table 22-3: Examples of detected changes in species, natural ecosystems, and managed ecosystems in Africa that are both consistent with a climate change signal and published since the AR4. Confidence in detection of change is based on the length of study, and the type, amount and quality of data in relation to the natural variability in the particular species or system. Confidence in the role of climate being a major driver of the change is based on the extent to which the detected change is consistent with that expected under climate change, and to which other confounding or interacting non-climate factors have been considered and been found insufficient to explain the observed change.

Type of change and nature of evidence	**Examples**	**Time scale of observations**	**Confidence in the detection of change**	**Potential climate change driver(s)**	**Confidence in the role of climate vs. other drivers**
Changes in ecosystem types *Robust evidence*	Across sub-Saharan Africa, 57% increase in agricultural areas and 15% increase in barren (largely desert) areas was accompanied by 16% decrease in total forest cover and 5% decrease in total non-forest cover (Brink and Eva, 2009)	~ 25 years (1975-2000)	**medium**	Increasing CO_2, changing precipitation patterns, increasing temperatures	**low**
	On Mt. Kilimanjaro, increased vulnerability to anthropogenic fires has driven 9% decreases in montane forest and 83% decreases in subalpine forest (Hemp, 2009)	~ 25 years (1976-2000)	**high**	Increasing temperatures, decreasing precipitation	**Low**
	In the Democratic Republic of the Congo, total forest cover declined by 2.3%, with most losses in secondary humid forest (Potapov *et al*., 2012)	~ 10 years (2000-2010)	**high**	None proposed	**low**
	Dieback of seaward edge of mangroves in Cameroon at rates up to 3 m $year^{-1}$ (Ellison and Zhou, 2012)	~ 35 years (1975-2010)	**high**	Sea level rise	**medium**
	Across western Africa, central Africa and Madagascar, net deforestation was 0.28% $year^{-1}$ for 1990-2000 and 0.14% $year^{-1}$ for 2000-2010 (Mayaux *et al*., 2013)	~ 20 years (1990-2010)	**high**	None proposed	**low**

Changes in ecosystem structure *Robust evidence*	Surveys of coral reefs in northern Tanzania indicate relative stability in the abundance and diversity of species, despite climate and non-climate stressors (McClanahan *et al*., 2009)	~ 9 years (1996-2005)	**high**	None proposed	**low**
	Analysis of sediment cores from Lake Victoria indicates current community structure (i.e., dominated by cyanobacteria and invasive fish) was established rapidly, during the 1980s (Hecky *et al*., 2010)	~ 100 years (1900-2000)	**high**	Increasing temperatures	**Low**
	Long-term declines in density of trees and shrubs in the Sahel zone of Senegal (Vincke *et al*., 2010) and Mali (Ruelland *et al*., 2011)	~ 20-50 years (Senegal, 1976-1995; Mali, 1952-2003)	**high**	Drought stress induced by decreasing precipitation	**low**
	Southward shift in the Sahel, Sudan, and Guinean savanna vegetation zones inferred from declines in tree density in Senegal and declines in tree species richness and changes in species composition in Mauritania, Mali, Burkina Faso, Niger, and Chad (Gonzales *et al*., 2012)	~ 40-50 years (density,1954-2002; diversity, 1960-2000)	**medium**	Increasing temperatures, decreasing precipitation	**medium**
	Long-term increase in shrub and tree cover across mesic savanna sites (700-1000 mm MAP) with contrasting land-use histories in South Africa (Wigley *et al*., 2009; Wigley *et al*., 2010)	~67 years (1937-2004)	**high**	Increasing CO_2	**low**
	In long-term field experiments in South Africa where disturbance from fire and herbivory was controlled, density of trees and shrubs increased in mesic savannas (600 and 750 mm MAP) but showed no change in a semi-arid savanna (550 mm MAP) (Buitenwerf *et al*., 2012)	~ 30 – 50 years (1980-2010 for 600 mm MAP site; 1954-2004 for 550 & 750 mm MAP sites)	**high**	In mesic site, increasing CO_2; but lack of response in semiarid site surprising and unexplained	**Medium**
Changes in ecosystem physiology *Moderate evidence*	A reconstruction of drought history in Tunisia and Algeria based on tree ring records from *Cedrus atlantica* and *Pinus halepensis* indicates that a 1999-2002 drought was the most severe since the 15th century (Touchan *et al*., 2008)	~ 550 years (1456–2002)	**high**	Increasing temperatures, decreasing precipitation	**low**
	Across 79 African tropical forest plots, above-ground carbon storage in live trees increased by 0.63 Mg C ha^{-1} yr^{-1} (Lewis *et al*., 2009)	~ 40 years (1968-2007)	**high**	Increasing CO_2	**Medium**
	Increased stratification and reduced nutrient fluxes and primary productivity in Lake Tanganyika (Verburg and Hecky, 2009)	~ 90 years (1913-2000)	**high**	Increasing temperatures	**High**
	Recent increases in surface temperatures and decreases in productivity of Lake Tanganyika exceed the range of natural variability (Tierney *et al*., 2010)	~ 1,500 years (500-2000)	**high**	Increasing temperatures	**High**

Changes in species distributions, physiology, or behavior *Moderate evidence*	The range of *Aloe dichotoma*, a Namib Desert tree, is shifting poleward, but extinction along trailing edge exceeds colonization along leading edge (Foden *et al*., 2007)	~ 100 years (1904-2002)	**high**	Increasing temperatures, decreasing precipitation	**Medium**
	On Tsaratanana Massif, the highest mountain in Madagascar, reptiles and amphibians are moving upslope (Raxworthy *et al.*, 2008)	~ 10 years (1993-2003)	**high**	Increasing temperatures	**Medium**
	Pomacentrus damselfish species vary in avoidance of predation-related mortality under elevated CO_2 (Ferrari *et al*., 2011)	minutes to days (Nov.-Dec. 2009)	**high**	Increasing CO_2	**low**
	In greenhouse experiments, growth of seedlings of woody savanna species (*Acacia karoo* and *Terminalia sericea*) was enhanced at elevated CO_2 (Bond and Midgley, 2012)	~1-2 years	**high**	Increasing CO_2	**medium**

Table 22-4: Projected changes in agro-climatic suitability for perennial crops in Africa by mid-century under an A2 scenario.

Crop	**Suitability change**	**Country**	**Source**
Coffee	Increased suitability at high latitudes; decreased suitability at low latitudes	Kenya	Läderach et al., 2010
Tea	Decreased suitability	Uganda	Eitzinger et al., 2011a,b
	Increased suitability at high latitudes; decreased suitability at low latitudes	Kenya	
Cocoa	Constant or increased suitability at high latitudes; decreased suitability at low latitudes	Ghana, Côte d'Ivoire	Läderach et al., 2011c
Cashew	Increased suitability	Ghana, Côte d'Ivoire	Läderach et al., 2011a
Cotton	Decreased suitability	Ghana, Côte d'Ivoire	Läderach et al., 2011b

Table 22-5: Cross-cutting approaches for equity and social justice in adaptation.

Equitable adaptation approach	Key issues to address for adaptation	Factors that could cause maladaptation	Opportunities	Lessons learned
Gender mainstreamed adaptation in Africa	Lack of empowerment and participation in decision-making (Patt *et al*., 2009) Climate impacts increase women's household roles, with risk of girls missing school to assist (Raworth, 2008; Romero González *et al*., 2011; UNDP, 2011b) Male adaptation strategies e.g. migration risk increasing women's vulnerability (Djoudi and Brockhaus, 2011)	Employment opportunities not sufficiently extended to women in adaptation initiatives (Madzwamuse, 2010) Failure to incorporate power relations in adaptation responses (Djoudi and Brockhaus, 2011; Romero González *et al*., 2011)	Women's aptitude for long-term thinking, trusting and integrating scientific knowledge, and taking decisions under uncertainty (Patt *et al.*, 2009) Potential long-term increase in women's empowerment and social and economic status (Djoudi and Brockhaus, 2011) Women opportunistically using development projects for adaptation (Nielsen, 2010)	Security of tenure over land and resource access is critical for enabling enhanced adaptive capacity of women (ADF, 2010) Research on understanding different adaptive strategies of benefit for women and men is needed
Child-centered approaches to adaptation	Children and youth represent over 60% of Africa's population, yet their issues are largely absent from adaptation policy (ADF, 2010) Children's differential vulnerability to projected climate impacts is high, particularly to hunger, malnutrition and disasters (UNICEF, 2007)	Limits to children's agency related to power imbalances between children and adults, and different cultural contexts (Seballos *et al*., 2011)	Using approaches that stress agency and empowerment, and 'innovative energies' of youth; build on targeted adaptation initiatives, such as child-centred disaster risk reduction and adaptation (ADF, 2010; Seballos *et al*., 2011)	Positive role of children and youth as change agents for climate adaptation, within appropriate enabling environment Child-sensitive programmes and policies can reduce risks children face from disasters (Seballos et al, 2011) Funding for climate resilience programmes will protect children's basic rights (UNICEF, 2010; UNICEF, 2011)
Human rights-based approaches (HRBA)	Common critical rights issues for local communities are land/resource rights, gender equality, and political voice and fair adjudication of grievances for the poor and excluded (Castro *et al.*, 2012)	Lack of recognition and promotion of their human rights blocks indigenous peoples' coping and adaptation capacities (UNPFII, 2008)	Using the HRBA lens to understand climate risk necessitates risk analysis to probe the root causes of differential disaster risk vulnerabilities, to enable structural, sustainable responses (Urquhart, 2014)	Applying HRBA presents a framework for addressing conflicting rights and interests, necessary for building resilience and equitable adaptation responses (Nilsson and Schnell, 2010)

Table 22-6: Key risks from climate change and the potential for risk reduction through mitigation and adaptation in Africa. Key risks are identified based on assessment of the literature and expert judgments made by authors of the various WGII AR5 chapters, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Shifts in biome distribution, and severe impacts on wildlife due to diseases and species extinction (*high confidence*)	Very few adaptation options; migration corridors; protected areas; better management of natural resources		22.3.2.1, 22.3.2.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Stress on water resources currently facing significant strain from overexploitation and degradation, and increased future demand, will be compounded by temperature rise and changes in precipitation (*high confidence*)	Reducing nonclimate stressors on water resources is critical for realizing adaptation co-benefits. Strengthening institutional capacities for demand management, groundwater assessment, integrated water-wastewater planning and integrated land and water governance would advance adaptation planning.		22.3.2.2, 22.3.3, 22.4.2, 22.4.4, 22.4.5	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Degradation of coral reefs results in loss of protective ecosystems and fishery stocks (*medium confidence*)	Few adaptation options; marine protected areas; conservation and protection; better management of natural resources.		22.3.2.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Reduced crop productivity with strong adverse effects on regional, national and household food security, linked to temperature rise and precipitation changes, and secondary (indirect) impacts, such as those linked to increased pest and disease damage and flood risks to food system infrastructure (*high confidence*)	Adaptation can be made more effective where technologic adaptation responses (e.g. stress tolerant crop varieties, irrigation, etc.) are embedded within efforts to enhance smallholder access to credit and other critical production resources, livelihoods diversification, institutional strengthening at local to regional levels to support agriculture and strong gender oriented policy support.		22.3.4.1, 22.4.5.2, 22.4.5.4, 22.4.5.6, 22.4.5.7, 22.4.6	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Adverse effects on livestock linked to temperature rise and precipitation changes that lead to increased heat and water stress, and shifts in the range of pests and diseases, with adverse impacts on pastoral livelihoods and rural poverty (*medium confidence*)	Addressing nonclimate stressors facing pastoralists, including policy and governance features that perpetuate their marginalization, is critical for reducing vulnerability. Natural resource-based strategies such as reducing drought risk to pastoral livelihoods through use of forest goods and services hold potential, provided sufficient attention is paid to forest conservation and sustainable management.		22.3.4.2, 22.4.5.2, 22.4.5.6, 22.4.5.8	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Changes in the incidence and geographic range of vector- and water-borne diseases due to changes in the mean and variability of temperature and precipitation, particularly along the edges of their distribution (*medium confidence*)	Achieving development goals, particularly improvement in access to safe water and improved sanitation, along with enhancement of public health functions, such as surveillance. Specific adaptation options include vulnerability mapping and early warning systems. Coordination activities with other sectors.		22.3.5, 22.3.5.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Undernutrition, with its potential for life-long impacts on health and development and its associated increase in vulnerability to malaria and diarrheal diseases, can result from changing crop yields, migration due to weather and climate extremes, and other factors (*medium confidence*)	Early warning systems and vulnerability mapping (for targeted interventions); diet diversification; coordination with food and Agriculture sectors; improved public health functions to address underlying diseases.		22.3.5.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high

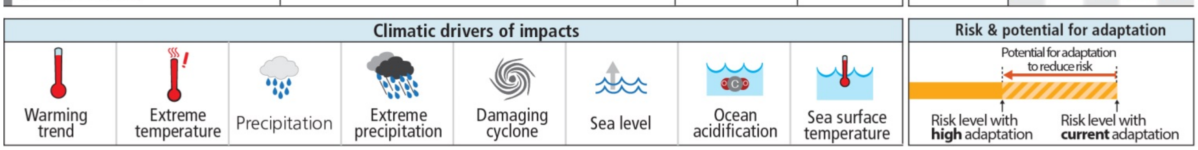

Table 22-7: Land inundated and economic impacts in Cape Town based on a risk assessment (Cartwright, 2008).

Sea level rise scenarios	Land inundated	Economic impacts (for 25 years)
Scenario 1 (+ 2.5 to 6.5 m depending on the exposure) 95%	25.1 km^2 (1% of the total CT area)	5.2 billion R (794 million US$)
Scenario 2 (+ 4.5 m) 85%	60.9 km^2 (2% of the total CT area)	23.7 billion R (30.3 billion US$)
Scenario 3 (+6.5 m) 20%	95 km^2 (4% of the total CT area)	54.8 billion R

Note: The economic impacts are determined based on the value of properties, losses of touristic revenues and the cost of infrastructure replacement. The total geographical gross product for Cape Town in 2008 was 165 billion of Rands.

Table 22-8: Research gaps in different sectors.

Key Sectors	Gaps observed
Climate Science	•Research in climate and climate impacts would be greatly enhanced if data custodians and researchers worked together to use observed station data in scientific studies. Research into regional climate change and climate impacts relies on observed climate and hydrological data as an evaluative base. These data are most often recorded by meteorological institutions in each country and sold to support data collection efforts. However, African researchers are generally excluded from access to these critical data due to the high costs involved which hinders both climate and climate impacts research. •Downscaling GCM data to the regional scale captures the influence of topography on the regional climate. Regional climate information is essential for understanding regional climate processes, regional impacts and potential future changes in these. Additionally, impacts models such as hydrology and crop models generally require input data at a resolution higher than what GCMs can provide. Regional downscaling, either statistically or through using regional climate models, can provide information at these scales and can also change the sign of GCM-projected rainfall change over topographically complex areas [22.2.2.2].
Ecosystems	•Monitoring networks for assessing long-term changes to critical ecosystems such as coastal ecosystems, lakes, mountains, grasslands, forests, wetlands, deserts, and savannas to enhance understanding of long-term ecological dynamics, feedbacks between climate and ecosystems, the effects of natural climate variability on ecosystems, the limits of natural climate variability, and the marginal additional effects of global climate forcing. •Develop the status of protected areas to include climate change effects
Food Systems	•Socioeconomic and environmental tradeoffs of biofuel production, especially the effect on land use change and food and livelihood security; better agronomic characterization of biofuel crops to avoid maladaptive decisions with respect to biofuel production •Vulnerability to and impacts of climate change on food systems (production, transport, processing, storage, marketing and consumption) •Impacts of climate change on urban food security, and dynamic of rural-urban linkages in vulnerability and adaptive capacity •Impacts of climate change on food safety and quality
Water resources	•Characterization of Africa's groundwater resource potential; understanding interactions between non-climate and climate drivers as related to future groundwater resources. •Impacts of climate change on water quality, and how this links to food and health security •Decision making under uncertainty with respect to water resources given limitations of climate models for adequately capturing future rainfall projections

Human security and urban areas	•Research to explore and monitor the links between climate change and migration and its potential negative effects on environmental degradation; the potential positive role of migration in climate change adaptation. •Improved methods and research to analyse the relation between climate change and violent conflict.
Livelihoods and poverty	•Methodologies for cyclical learning and decision-support to enable anticipatory adaptation in contexts of high poverty and vulnerability (Tschakert and Dietrich, 2010) •Frameworks to integrate differentiated views of poverty into adaptation and disaster risk reduction, and to better link these with social protection in different contexts •Ethical and political dimensions of engaging with local and traditional knowledge on climate change
Health	Research and improved methodologies (including longitudinal studies) to assess and quantify the impact of climate change on vector borne, foodborne, waterborne, nutrition, heatstress and indirect impacts on HIV. Research to quantify the direct and indirect health impacts of extreme weather events in Africa; injuries, mental illness; health infrastructure Frameworks and research platforms to be developed with other sectors to determine how underlying risks (for example food security) will be addressed to improve health outcomes.
Adaptation	Research to develop home-grown and to localize global adaptation technologies to build resilience Equitable adaptation frameworks to deal with high uncertainty levels and integrate marginalized groups; and that identify and eliminate multi-level constraints to women's adaptive ability Multi--tiered approach to building institutional and community capacity to respond to climate risk Potential changes in economic and social systems under different climate scenarios, to understand the implications of adaptation and planning choices (Clements *et al.*, 2011) Principles/determining factors for effective adaptation, including community-based adaptation Understanding synergies and trade-offs between different adaptation and mitigation approaches (Chambwera and Anderson, 2011) Additional national and sub-natinal modeling and analysis of the economic costs of impacts and adaptation, including of the 'soft' costs of impacts and adaptation Monitoring adaptation
Other	Methods in vulnerability analysis for capturing the complex interactions in systems across scales Understanding compound impacts from concomitant temperature and precipitation stress, e.g. effect on a particular threshold of a heatwave occurring during a period of below normal precipitation.

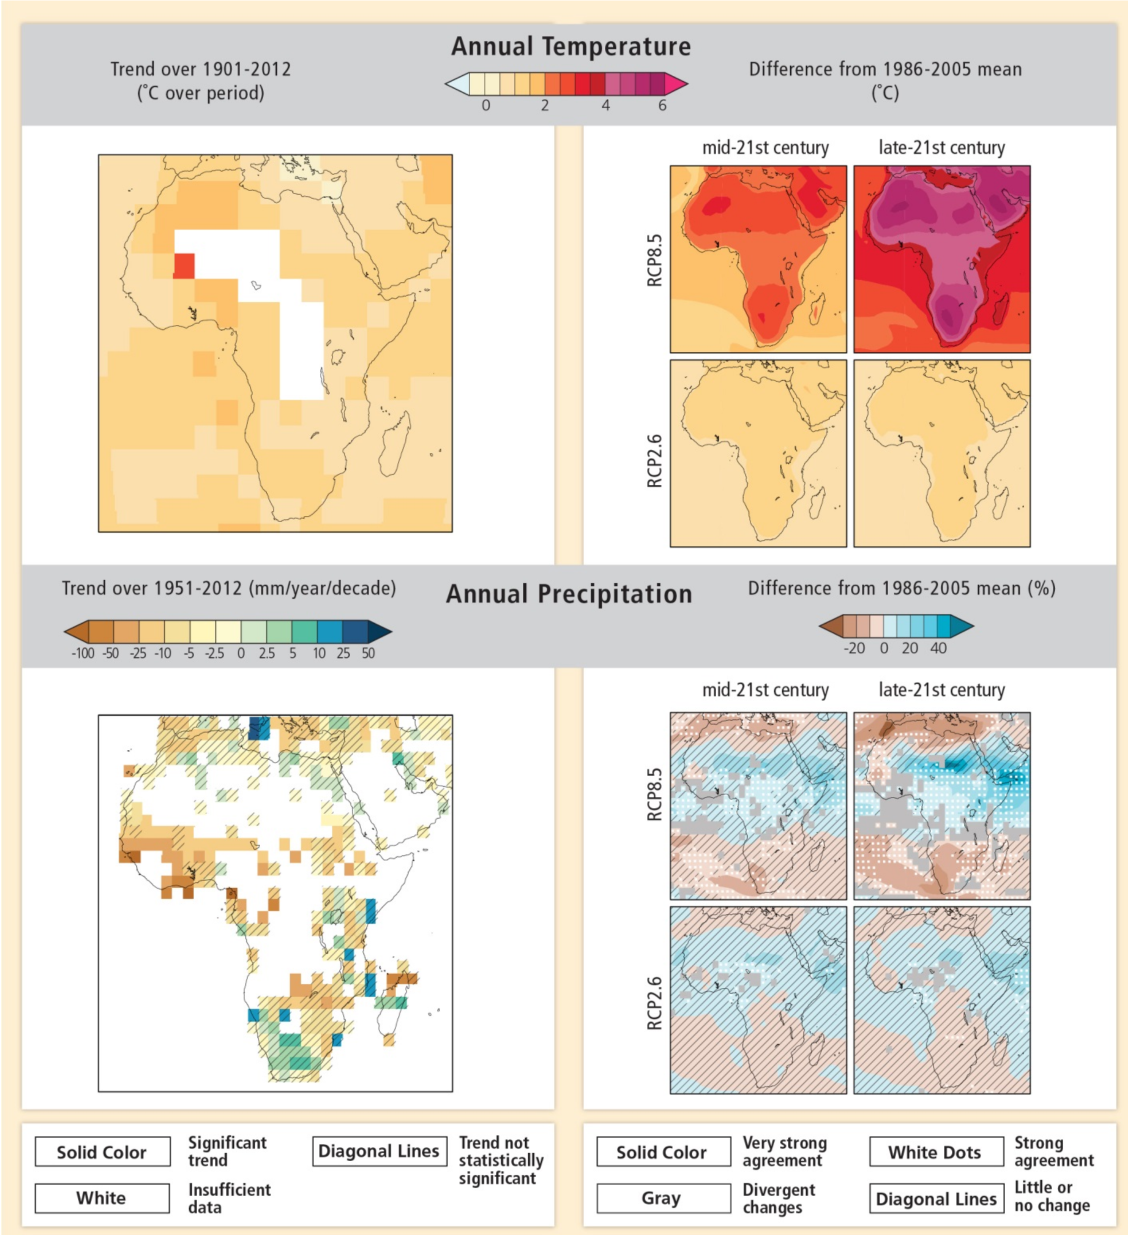

Figure 22-1: Observed and simulated variations in past and projected future annual average precipitation and temperature. Observed differences in the Climate Research Unit, University of East Anglia data (CRU) are shown between the 1986-2005 and 1906-1925 periods, with white indicating areas where the difference between the 1986-2005 and 1906-1925 periods is less than twice the standard deviation of the 20 20-year periods beginning in the years 1906 through 1925. For CMIP5, white indicates areas where <66% of models exhibit a change greater than twice the baseline standard deviation of the respective model's 20 20-year periods ending in years 1986 through 2005. Grey indicates areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation, but <66% of models agree on the sign of change. Colors with circles indicate the ensemble-mean change in areas where >66% of models exhibit a change greater than twice the respective model baseline standard deviation and >66% of models agree on the sign of change. Colors without circles indicate areas where >90% of models exhibit a change greater than twice the respective model baseline standard deviation and >90% of models agree on the sign of change. The realizations from each model are first averaged to create baseline-period and future-period mean and standard deviation for each model, from which the multi-model mean and the individual model signal-to-noise ratios are calculated. The baseline period is 1986-2005. The late-21st Century period is 2081-2100. The mid-21st century period is 2046-2065.

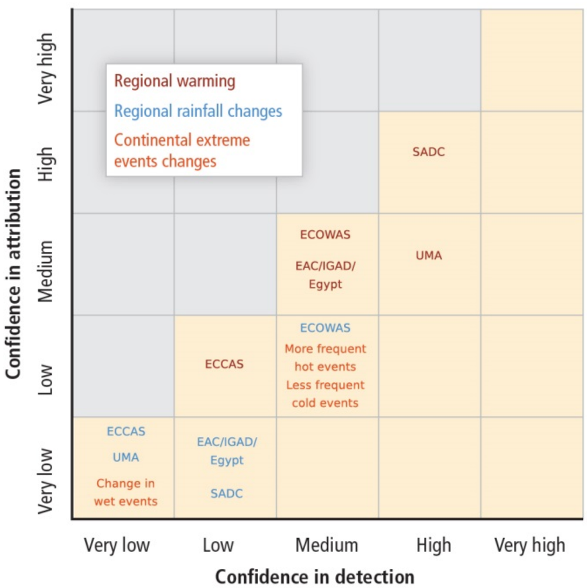
Figure 22-2: Observed and simulated variations in past and projected future annual average temperature over EAC-IGAD-Egypt, ECCAS, ECOWAS, SADC and UMA. Black lines show various estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (63 simulations), historical changes in "natural" drivers only (34), the "RCP2.6" emissions scenario (63), and the "RCP8.5" (63). Data are anomalies from the 1986-2005 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.
[Illustration to be redrawn to conform to IPCC publication specifications.]



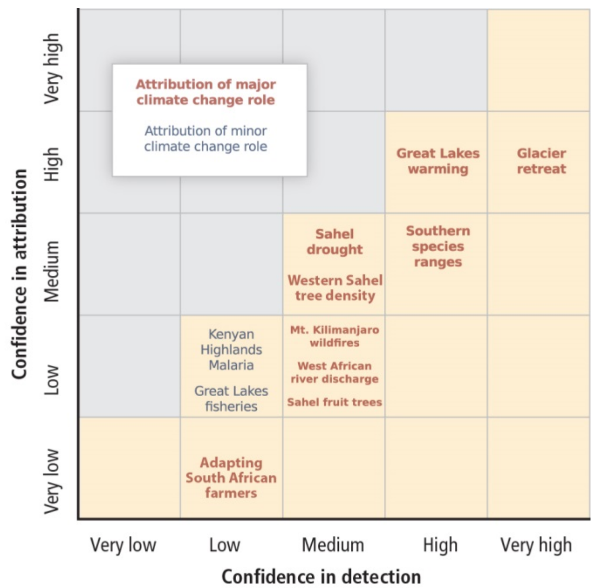


Figure 22-3: Left: Confidence in detection and in attribution of observed climate change over Africa to anthropogenic emissions. All detection assessments are against a reference of no change, while all attribution assessments concern a major role of anthropogenic emissions in the observed changes. See 22.2, and SREX-3, and WGI AR5 10 for details. Right: Confidence in detection and in attribution of the impacts of observed regional climate change on various African systems. All detection assessments are against a reference of no change, except "Kenyan Highlands malaria" (changes due to vaccination, drug resistance, demography, and livelihoods), "Great Lakes fisheries" (changes due to fisheries management and land use) and “Adapting South African farmers” (economic changes). Attribution is to a major role or a minor role of observed climate change, as indicated. See 22.2.2, 22.3.2.1, 22.3.2.2, 2.3.3, 22.4.2, 22.3.4.4, 22.3.5.4, 22.4.5.7 and Tables 18-5, 18-6, 18-7, and 18-9 for details. Assessments follow the methods outlined in 18.2.

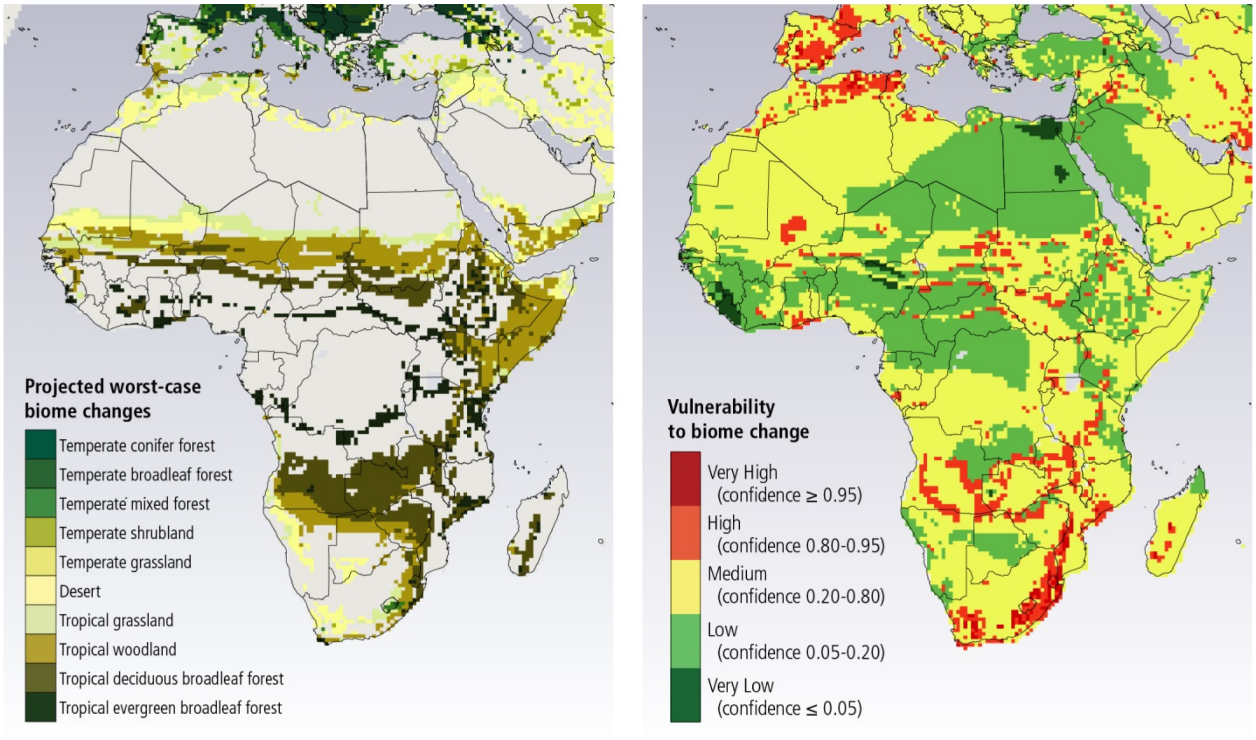

Figure 22-4: Left – Projected biome change from the periods 1961-1990 to 2071-2100 using the MC1 Dynamic Vegetation Model. Change is indicated if any of nine combinations of three GCMs (CSIRO Mk3, HadCM3, MIROC 3.2 medres) and three emissions scenarios (B1, A1B, A2) project change and is thus a worst-case scenario. Colours represent the future biome predicted. Right – Vulnerability of ecosystems to biome shifts based on historical climate (1901-2002) and projected vegetation (2071-2100), where all nine GCM-emissions scenario combinations agree on the projected biome change. Source: Gonzalez et al. (2010).

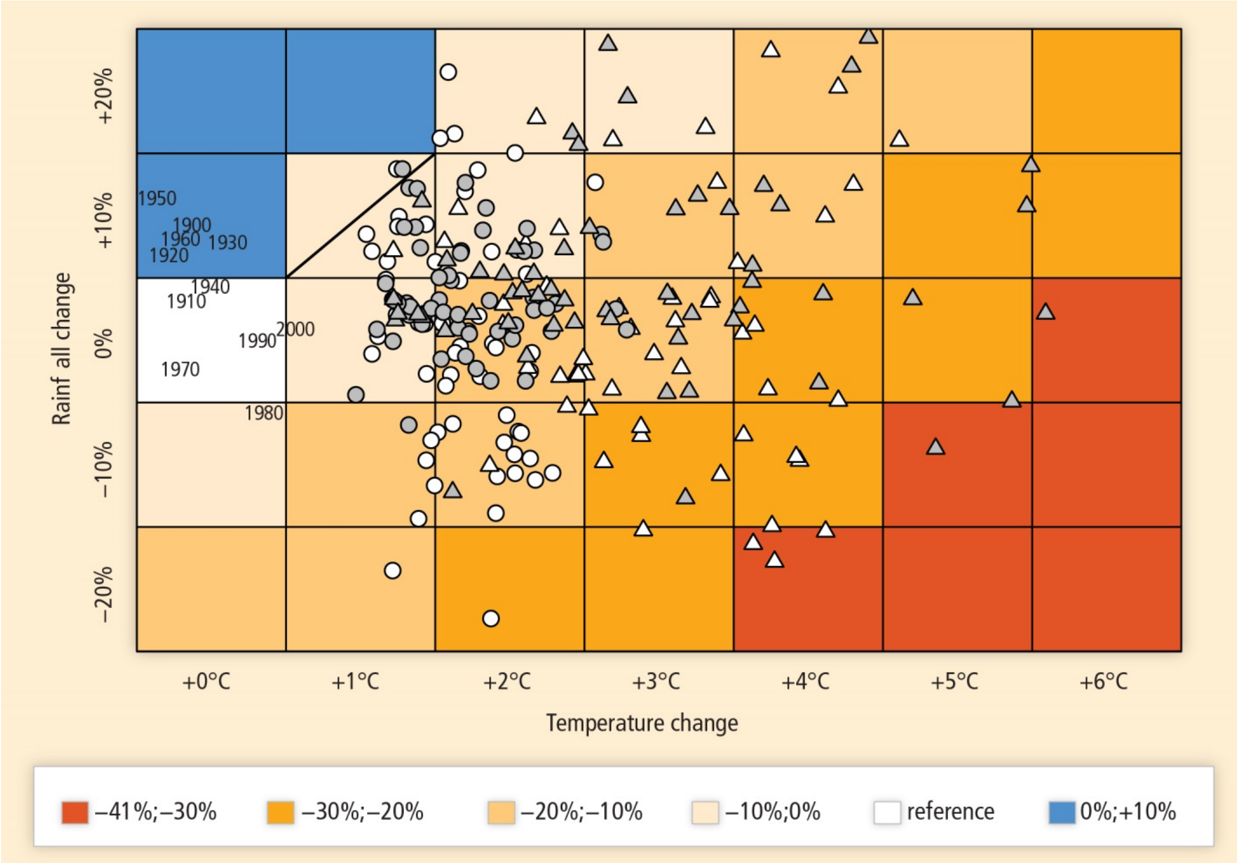

Figure 22-5: The effect of rainfall and temperature changes on mean crop yield. Mean crop yield change (%) relative to the 1961–90 baseline for 7 temperatures (x-axis) and 5 rainfall (y-axis) scenarios. Results are shown as the average over the 35 stations across West Africa and the 6 cultivars of sorghum and millet. White triangles and circles are the projected anomalies computed by several CMIP3 GCMs and three IPCC emission scenarios (B1, A1B, A2) for 2071–90 and 2031–50, respectively. Projections from CMIP5 GCMs and three RCPs (4.5, 6.0 and 8.5) are represented by grey triangles and circles. Models and scenarios names are displayed in figure S2 (available at stacks.iop.org/ERL/8/014040/mmedia). Past observed climate anomalies from CRU data are also projected by computing 10-year averages (e.g. '1940' is for 1941–50). All mean yield changes are significant at a 5% level except boxes with a diagonal line. Source: Sultan et al., 2013.

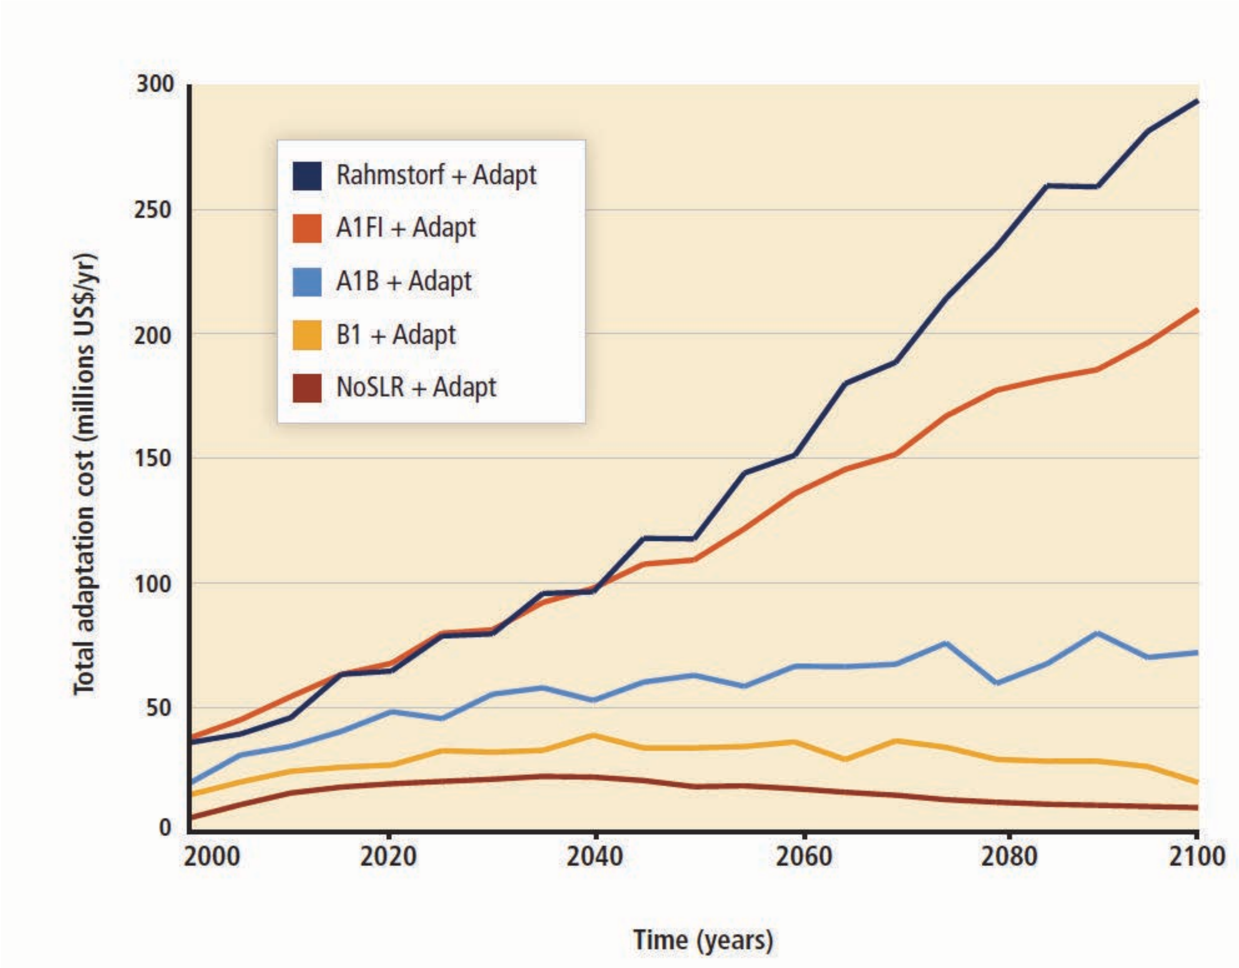

Figure 22-6: Total additional costs of adaptation per year from 2000 to 2100 for Tanzania (including beach nourishment and sea and river dikes). The values do not consider the existing adaptation deficit (values in $US2005), without discounting. Source: Kebede *et al.*, 2010.

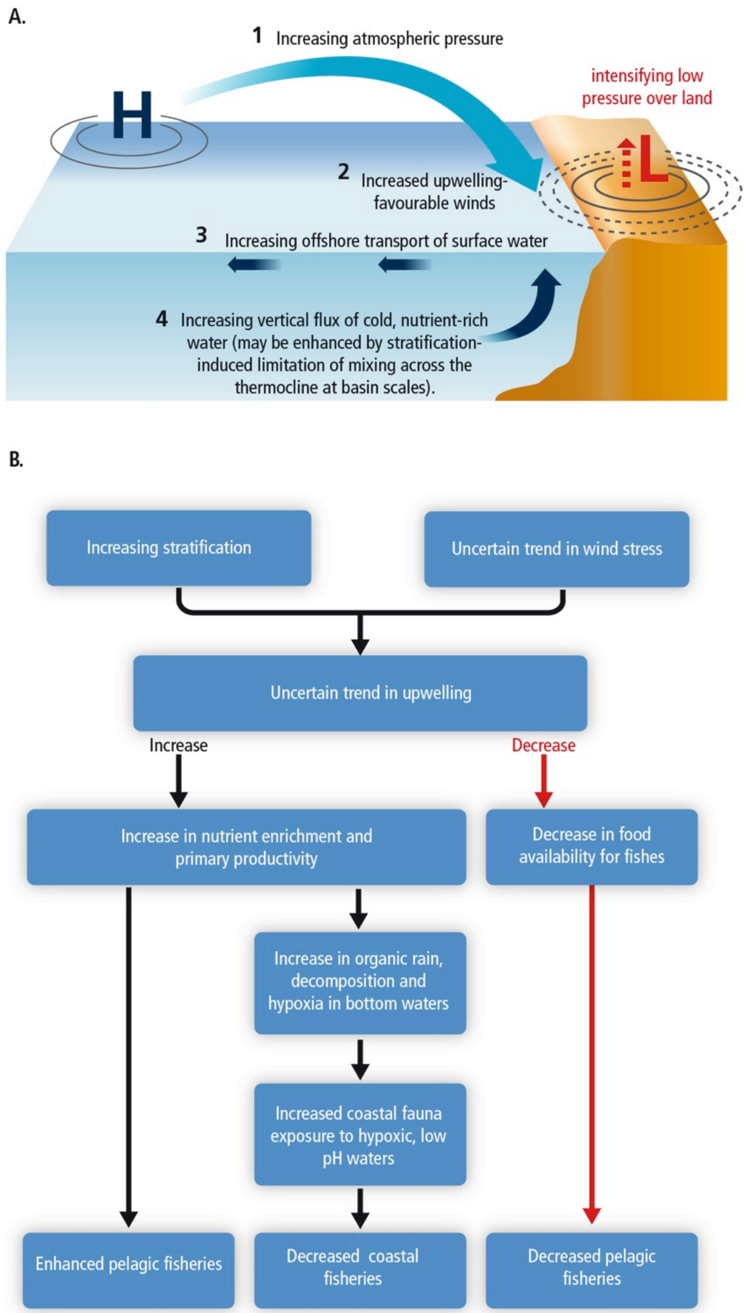

Figure UP-1: Upper panel: Schematic hypothetic mechanism of increasing coastal wind-driven upwelling at eastern boundary systems, where differential warming rates between land and ocean results in increased land-ocean pressure gradients (1) that produce stronger alongshore winds (2) and offshore movement of surface water through Ekman transport (3), and increased upwelling of deep cold nutrient rich waters to replace it (4). Lower panel: potential consequences of climate change in upwelling systems. Increasing stratification and uncertainty in wind stress trends result in uncertain trends in upwelling. Increasing upwelling may result in higher input of nutrients to the euphotic zone, and increased primary production, which in turn may enhance pelagic fisheries, but also decreased coastal fisheries due to an augmented exposure of coastal fauna to hypoxic, low pH waters. Decreased upwelling may result in lower primary production in these systems with direct impacts on pelagic fisheries productivity.

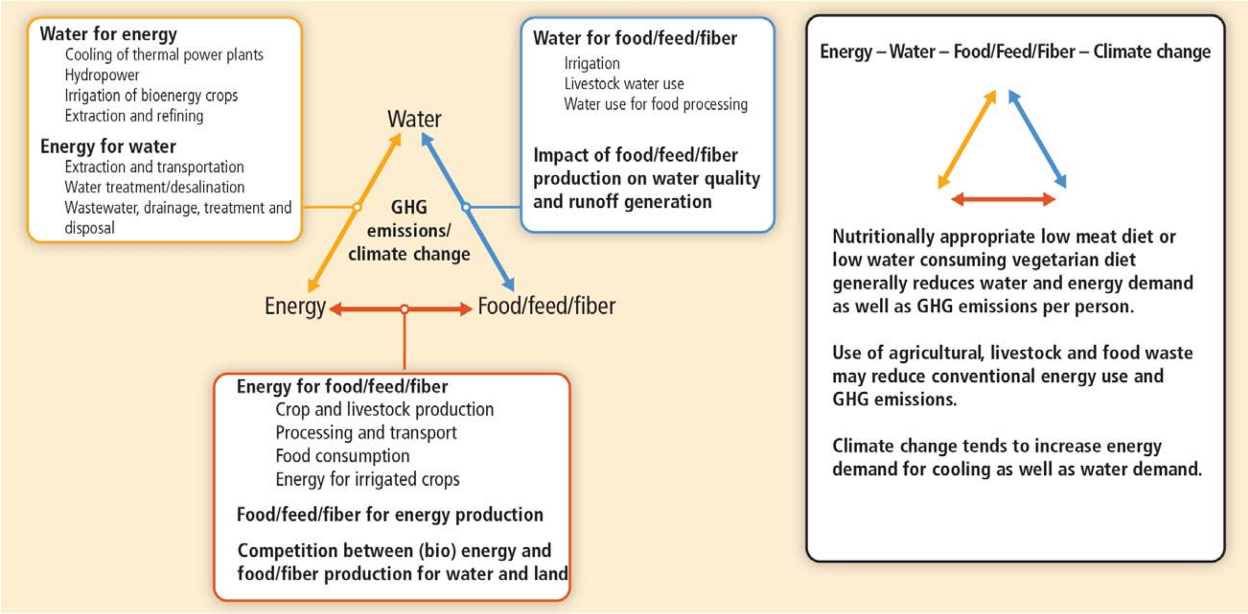

Figure WE-1: The water-energy-food nexus as related to climate change. The interlinkages of supply/demand, quality and quantity of water, energy and food/feed/fiber with changing climatic conditions have implications for both adaptation and mitigation strategies.

Executive Summary

Observed climate trends and future climate projections show regionally varying changes in temperature and rainfall in Europe [***high confidence***] [23.2.2], in agreement with AR4 findings, with projected increases in temperature throughout Europe and increasing precipitation in Northern Europe and decreasing precipitation in Southern Europe [23.2.2.2]. Climate projections show a marked increase in high temperature extremes [*high confidence*], meteorological droughts [*medium confidence*] [23.2.3] and heavy precipitation events [*high confidence*] [23.2.2.3] with variations across Europe, and small or no changes in wind speed extremes [*low confidence*] except increases in winter wind speed extremes over Central and Northern Europe [*medium confidence*] [23.2.2.3].

Observed climate change in Europe has had wide ranging effects throughout the European region including: the distribution, phenology, and abundance of animal, fish and plant species [*high confidence*] [23.6.4, Table 23.6]; stagnating wheat yields in some sub-regions [*medium confidence, limited evidence*] [23.4.1]; and forest decline in some sub-regions [*medium confidence*] [23.4.4]. Climate change has affected both human health (from increased heat waves) [*medium confidence*] [23.5.1] and animal health (changes in infectious diseases) [*high confidence*] 23.4.5]. There is less evidence of impacts on social systems attributable to observed climate change, except in pastoralist populations [*low confidence*].

Climate change will increase the likelihood of systemic failures across European countries caused by extreme climate events affecting multiple sectors [*medium confidence*] [23.2.2.3, 23.2.3, 23.3, 23.4, 23.5, 23.6, 23.9.1]. Extreme weather events currently have significant impacts in Europe in multiple economic sectors as well as adverse social and health effects [*high confidence*] [Table 23.1]. There is limited evidence that resilience to heat waves and fires has improved in Europe [*medium confidence*] [23.9.2, 23.5.], while some countries have improved their flood protection following major flood events [23.9.2, 23.7.3]. Climate change is very likely to increase the frequency and intensity of heat waves, particularly in Southern Europe [*high confidence*] [23.2.2] with mostly adverse implications for health, agriculture, forestry, energy production and use, transport, tourism, labour productivity, and the built environment [Table 23-1, 23.3.2, 23.3.3, 23.3.4, 23.3.6, 23.4.1, 23.4.2, 23.4.3, 23.4.4, 23.5.1].

The provision of ecosystem services is projected to decline across all service categories in response to climate change in Southern Europe and Alpine sub-regions [*high confidence*] [23.9.1, Box 23-1]. Both gains and losses in the provision of ecosystem services are projected for the other European sub-regions [*high confidence*], but the provision of cultural services is projected to decline in the Continental, Northern and Southern sub-regions [*low confidence*] [Box 23-1].

Climate change is expected to impede economic activity in Southern Europe more than in other sub-regions [*medium confidence*] [Table 23.4, 23.9.3], and may increase future intra-regional disparity [*low confidence*] [23.9.3]. There are also important differences in vulnerability within sub-regions, for example, plant species and some economic sectors are most vulnerable in high mountain areas due to lack of adaptation options [*medium confidence]*[23.9.1.]. Southern Europe is particularly vulnerable to climate change [*high confidence*] as multiple sectors will be adversely affected (tourism, agriculture, forestry, infrastructure, energy, population health) [*high confidence*] [23.9] [Box 23-3].

The impacts of sea level rise on populations and infrastructure in coastal regions can be reduced by adaptation [*medium confidence]* [23.3.1, 23.5.3]. Populations in urban areas are particularly vulnerable to climate change impacts due to the high density of people and built infrastructure [*medium confidence*] [23.3, 23.5.1].

Synthesis of evidence across sectors and sub-regions confirm that there are limits to adaptation from physical, social, economic and technological factors [*high confidence*] [23.5]. Adaptation is further impeded because climate change affects multiple sectors [23.10]. The majority of published assessments are based on climate projections in the range 1-4 degrees global mean temperature per century. Limited evidence exists regarding the potential impacts in Europe under high rates of warming (>4 degrees global mean temperature per century) [23.9.1].

Impacts by Sector

Sea level rise and increases in extreme rainfall are projected to further increase coastal and river flood risk in Europe and, without adaptive measures, will substantially increase flood damages (people affected and economic losses) [*high confidence*] [23.3.1, 23.5.1]. Adaptation can prevent most of the projected damages [*high confidence – based on medium evidence, high agreement*] but there may be constraints to building flood defences in some areas [23.3.1, 23.7.1, 23.8.3]. Direct economic river flood damages in Europe have increased over recent decades [*high confidence*] but this increase is due to development in flood zones and not due to observed climate change [23.3.1.2, SREX 4.5]. Some areas in Europe show changes in river flood occurrence related to observed changes in extreme river discharge [*medium confidence*] [23.2.3].

Climate change is projected to affect the impacts of hot and cold weather extremes on transport leading to economic damage and/or adaptation costs, as well as some benefits (e.g. reduction of maintenance costs) during winter [*medium confidence*] [23.3.3]. Climate change is projected to reduce severe accidents in road transport [*medium confidence*] and adversely affect inland water transport in summer in some rivers (e.g. the Rhine) after 2050 [*medium confidence*]. Damages to rail infrastructure from high temperatures may also increase *[medium confidence*]. Adaptation through maintenance and operational measures can reduce adverse impacts to some extent.

Climate change is expected to affect future energy production and transmission [23.3.4]. Hydropower production is likely to decrease in all sub-regions except Scandinavia [*high confidence*] [23.3.4]. Climate change is unlikely to affect wind energy production before 2050 [*medium confidence*] but will have a negative impact in summer and a varied impact in winter after 2050 [*medium confidence*]. Climate change is likely to decrease thermal power production during summer [*high confidence*] [23.3.4]. Climate change will increase the problems associated with overheating in buildings [*medium confidence*] [23.3.2]. Although climate change is very likely to decrease space heating demand [*high confidence*], cooling demand will increase [*very high confidence*] although income growth mostly drives projected cooling demand up to 2050 [*medium confidence*] [23.3.4]. More energy efficient buildings and cooling systems as well as demand-side management will reduce future energy demands [23.3.4].

After 2050, tourism activity is projected to decrease in southern Europe [*low confidence*] and increase in Northern and Continental Europe [*medium confidence*]. No significant impacts on the tourism sector are projected before 2050 in winter or summer tourism except for ski tourism in low altitude sites and under limited adaptation [*medium confidence*] [23.3.6]. Artificial snowmaking may prolong the activity of some ski resorts [*medium confidence*] [23.3.6].

Climate change is likely to increase cereal yields in Northern Europe [*medium confidence, disagreement*] but decrease yields in Southern Europe [*high confidence*] [23.4.1]. In Northern Europe, climate change is very likely to extend the seasonal activity of pests and plant diseases [*high confidence*] [23.4.1]. Yields of some arable crop species like wheat have been negatively affected by observed warming in some European countries since 1980s [*medium confidence, limited evidence*] [23.4.1] Compared to AR4, new evidence regarding future yields in Northern Europe, is less consistent regarding the magnitude and sign of change. Climate change may adversely affect dairy production in Southern Europe because of heat stress in lactating cows [*medium confidence*] [23.4.2]. Climate change has contributed to vector-borne disease in ruminants in Europe [*high confidence*] [23.4.2] and northward expansion of tick disease vectors [*medium confidence*] [23.4.2, 23.5.1].

Climate change will increase irrigation needs [*high confidence*] but future irrigation will be constrained by reduced runoff, demand from other sectors, and by economic costs [23.4.1, 23.4.3]. By 2050s, irrigation will not be sufficient to prevent damage from heat waves to crops in some sub-regions [*medium confidence*]. System costs will increase under all climate scenarios [*high confidence*] [23.4.3]. Integrated management of water, also across countries' boundaries, is needed to address future competing demands between agriculture, energy, conservation and human settlements [23.7.2].

As a result of increased evaporative demand, climate change is likely to significantly reduce water availability from river abstraction and from groundwater resources [*medium confidence*], in the context of increased demand (from agriculture, energy and industry, and domestic use) and cross-sectoral implications which are not fully understood [23.4.3, 23.9.1]. Some adaptation is possible through uptake of more water efficient technologies and water saving strategies [23.4.3, 23.7.2, 23.9.1].

Climate change will change the geographic distribution of wine grape varieties [*high confidence*] and this will reduce the value of wine products and the livelihoods of local wine communities in Southern and Continental Europe [*medium confidence*] and increase production in Northern Europe [*low confidence*] [23.4.1, 23.3.5, 23.5.4, Box 23-2]. Some adaptation is possible through technologies and good practice [Box 23-2].

Climate warming will increase forest productivity in northern Europe [*medium confidence*] [23.4.4], although damage from pests and diseases in all sub-regions will increase due to climate change [*high confidence*] [23.4.4]. Wildfire risk in Southern Europe [*high confidence*] and damages from storms in central Europe [*low confidence*] may also increase due to climate change [23.4.4]. Climate change is likely to cause ecological and socio-economic damages from shifts in forest tree species range (from south-west to north-east) [*medium confidence*], and in pest species distributions [*low confidence*] [23.4.4]. Forest management measures can enhance ecosystem resilience [*medium confidence*] [23.4.4].

Observed warming has shifted marine fish species ranges to higher latitudes [*high confidence*] and reduced body size in species [*medium confidence*] [23.4.6]. There is limited and diverging evidence on climate change impacts on net fisheries economic turnover. Local economic impacts attributable to climate change will depend on the market value of (high temperature tolerant) invasive species [23.4.6]. Climate change is unlikely to entail relocation of fishing fleets [*high confidence*] [23.4.6]. Observed higher water temperatures have adversely affected both wild and farmed freshwater salmon production in the southern part of their distribution [*high confidence*] [23.4.6]. High temperatures may increase the frequency of harmful algal blooms [*low confidence*] [23.4.6].

Climate change will affect bioenergy cultivation patterns in Europe by shifting northward their potential area of production [medium confidence] [23.4.5]. Elevated atmospheric CO_2 can improve drought tolerance of bioenergy crop species due to improved plant water use, maintaining high yields in future climate scenarios in temperate regions [*low confidence*] [23.4.5].

Climate change is likely to affect human health in Europe. Heat-related deaths and injuries are likely to increase, particularly in Southern Europe [*medium confidence*] [23.5.1]. Climate change may change the distribution and seasonal pattern of some human infections, including those transmitted by arthropods [*medium confidence*], and increase the risk of introduction of new infectious diseases [*low confidence*] [23.5.1].

Climate change and sea level rise may damage European cultural heritage, including buildings, local industries, landscapes, archaeological sites, and iconic places [*medium confidence*] and some cultural landscapes may be lost forever [*low confidence*] [23.5.4] [Table 23.3].

Climate change may adversely affect background levels of tropospheric ozone [*low confidence, limited evidence, low agreement*], assuming no change in emissions, but the implications for future particulate pollution (which is more health-damaging) are very uncertain [23.6.1]. Higher temperatures may have affected trends in ground level tropospheric ozone [*low confidence*] [23.6.1.]. Climate change is likely to decrease surface water quality due to higher temperatures and changes in precipitation patterns [*medium confidence*] [23.6.3], and is likely to increase soil salinity in coastal regions *[low confidence]* [23.6.2]. Climate change may also increase soil erosion (from increased extreme events) and reduce soil fertility [*low confidence, limited evidence*] [23.6.2].

Observed climate change is affecting a wide range of flora and fauna, including plant pests and diseases [*high confidence*] [23.4.1, 23.4.4] and the disease vectors and hosts [*medium confidence*] [23.4.3]. Climate change is *very likely* to cause changes in habitats and species, with local extinctions [*high confidence*] and continental scale shifts in species distributions [*medium confidence]* [23.6.4]. The habitat of alpine plants is very likely to be significantly reduced [*high confidence*] [23.6.4]. Phenological mismatch will constrain both terrestrial and marine ecosystem functioning under climate change [*high confidence*] [23.6.4, 23.6.5], with a reduction in some ecosystem services [*low confidence*] [23.6.4, Box 23-1]. The introduction and expansion of invasive species, especially those with high migration rates, from outside Europe is likely to increase with climate change [*medium confidence*]

[23.6.4]. Climate change is likely to entail the loss or displacement of coastal wetlands [*high confidence*] [23.6.5]. Climate change threatens the effectiveness of European conservation areas [*low confidence*] [23.6.4], and stresses the need for habitat connectivity through specific conservation policies [23.6.4].

Adaptation

The capacity to adapt in Europe is high compared to other world regions, but there are important differences in impacts and in the capacity to respond between and within the European sub-regions. In Europe, adaptation policy has been developed at international (European Union), national and local government level [23.7], including the prioritisation of adaptation options. There is limited systematic information on current implementation or effectiveness of adaptation measures or policies [Box 23-3]. Some adaptation planning has been integrated into coastal and water management, as well as disaster risk management [23.7.1, 23.7.2, 23.7.3]. There is limited evidence of adaptation planning in rural development or land-use planning [23.7.4, 23.7.5].

Adaptation will incur a cost, estimated from detailed bottom-up sector-specific studies for coastal defences, energy production, energy use, and agriculture [23.7.6]. The costs of adapting buildings (houses, schools, hospitals) and upgrading flood defences increase under all scenarios relative to no climate change [*high confidence*] [23.3.2]. Some impacts will be unavoidable due to limits (physical, technological, social, economic or political) [Table 23-3, 23.7.7].

There is also emerging evidence regarding opportunities and unintended consequences of policies, strategies and measures that address adaptation and/or mitigation goals [23.8]. Some agricultural practices can reduce GHG emissions and also increase resilience of crops to temperature and rainfall variability [23.8.2]. There is evidence for unintended consequences of mitigation policies in the built environment (especially dwellings) and energy sector [*medium confidence*] [23.8.1]. Low carbon policies in the transport and energy sectors to reduce emissions are associated with large benefits to human health [23.8.3] [*high confidence*].

23.1. Introduction

This chapter reviews the scientific evidence published since AR4 on observed and projected impacts of anthropogenic climate change in Europe and adaptation responses. The geographical scope of this chapter is the same as in AR4 with the inclusion of Turkey. Thus, the European region includes all countries from Iceland in the west to Russia (west of the Urals) and the Caspian Sea in the east, and from the northern shores of the Mediterranean and Black Seas and the Caucasus in the south to the Arctic Ocean in the north. Impacts above the Arctic Circle are addressed in the Polar Regions Chapter 28 and impacts in the Baltic and Mediterranean Seas are addressed in the Open Oceans Chapter 30. Impacts in Malta, Cyprus, and other island states in Europe are discussed in the Small Island Chapter 29.

The European region has been divided into 5 sub-regions (see Figure 23-1): Atlantic, Alpine, Southern, Northern, and Continental. The sub-regions are derived by aggregating the climate zones developed by (Metzger *et al.*, 2005) and therefore represent geographical and ecological zones rather than political boundaries. The scientific evidence has been evaluated to compare impacts across (rather than within) sub-regions, although this is not always possible, depending on the scientific information available.

[INSERT FIGURE 23-1 HERE
Figure 23-1: Sub-regional classification of the IPCC Europe region. Based on Metzger et al., 2005.]

23.1.1. Scope and Route Map of Chapter

The chapter is structured around key policy areas. Sections 23.3 to 23.6 summarise the latest scientific evidence on sensitivity climate, observed impacts and attribution, projected impacts and adaptation options, with respect to four main categories of impacts:

- Production systems and physical infrastructure
- Agriculture, fisheries, forestry and bioenergy production
- Health protection and social welfare
- Protection of environmental quality and biological conservation.

The benefit of assessing evidence in a regional chapter is that impacts across sectors can be described, and interactions between impacts can be identified. Further, the cross-sectoral decision making required to address climate change can be reviewed. The chapter also includes sections that were not in AR4. As adaptation and mitigation policy develops, the evidence for potential co-benefits and unintended consequences of such strategies is reviewed (Section 23.8). The final section synthesise the key findings with respect to: observed impacts of climate change, key vulnerabilities and research and knowledge gaps.

The chapter evaluates the scientific evidence in relation to the five sub-regions discussed above. The majority of the research in the Europe region is for impacts in countries in the European Union due to targeted research funding through the European Commission and national governments which means that countries in eastern Europe and Russia are less well represented in this chapter. Further, regional assessments may be reported for the EU15, EU27 or EEA (32) group of countries [Table SM23-1].

23.1.2. Policy Frameworks

Since AR4, there have been significant changes in Europe in responses to climate change. More countries now have adaptation and mitigation policies in place. An important force for climate policy development in the region is the European Union (EU). EU Member States have mitigation targets, as well as the overall EU target, with both sectoral and regional aspects to the commitments.

Adaptation policies and practices have been developed at the international, national and local levels although research on implementation of such policies is limited. Due to the vast range of policies, strategies and measures it is not possible to describe them extensively here. However, adaptation in related to cross-sectoral decision-making is discussed in section 23.7 (see also Box 23-3 on national adaptation policies). The European Climate Adaptation Platform (Climate-ADAPT) catalogues adaptation actions reported by EU Member States (EC, 2013b). The EU Adaptation Strategy was adopted in 2013 (EC, 2013a). See Chapter 15 for a more extensive discussion of institutions and governance in relation to adaptation planning and implementation.

23.1.3. Conclusions from Previous Assessments

AR4 documented a wide range of impacts of observed climate change in Europe (AR4 WG2 Chapter 12). The SREX confirmed increases in warm days, warm nights and decreases in cold days and cold nights since 1950 (*high confidence*, SREX-3.3.1). Extreme precipitation increased in part of the continent, mainly in winter over western-central Europe and European Russia (*medium confidence*, SREX-3.3.2). Dryness has increased mainly in Southern Europe (*medium confidence*, SREX-3.3.2). Climate change is expected to magnify regional differences within Europe for agriculture and forestry because water stress was projected to increase over central and southern Europe (AR4-12.4.1, SREX-3.3.2, SREX-3.5.1). Many climate-related hazard were projected to increase in frequency and intensity, but with significant variations within the region (AR4-12.4).

The AR4 identified that climate changes would pose challenges to many economic sectors and was expected to alter the distribution of economic activity within Europe (*high confidence*). Adaptation measures were evolving from reactive disaster response to more proactive risk management. A prominent example was the implementation of heat health warning systems following the 2003 heat wave event (AR4 WG2 12.6.1, SREX 9.2.1). National adaptation plans were developed and specific plans were incorporated in European and national policies (AR4 WG2 12.2.3, 12.5) but these were not yet evaluated (AR4 WG2 12.8).

23.2. Current and Future Trends

23.2.1 Non- Climate Trends

European countries are diverse in both demographic and economic trends. Population health and social welfare has improved everywhere in Europe, with reductions in adult and child mortality rates, but social inequalities both within and between countries persist (Marmot *et al.*, 2012). Population has increased in most EU27 countries, primarily due to net immigration (Eurostat, 2011a), although population growth is slow (total and working age population) (Rees *et al.*, 2012). Ageing of the population is a significant trend in Europe, as in all high income populations. This will have both economic and social implications, with many regions experiencing a decline in the labour force (Rees *et al.*, 2012). Since AR4, economic growth has slowed or become negative in many countries, leading to a reduction in social protection measures and increased unemployment (Eurostat, 2011b). The longer term implications of the financial crisis in Europe are unclear, although it may lead to a modification of the economic outlook and affect future social protection policies with implications for adaptation.

Europe is one of the world's largest and most productive suppliers of food and fibre (Easterling *et al.*, 2007) and agriculture is the most important European land use by area (45% of the total area) (Rounsevell *et al.*, 2006). After 1945, an unprecedented increase in agricultural productivity occurred, but also declines in agricultural land use areas. This intensification had several negative impacts on the ecological properties of agricultural systems, such as carbon sequestration, nutrient cycling, soil structure and functioning, water purification and pollination. Pollution from agriculture has led to eutrophication and declines in water quality in some areas (ELME, 2007). Most scenario studies suggest that agricultural land areas will continue to decrease in the future (see also (Busch, 2006) for a discussion). Agriculture accounts for 24 % of total national freshwater abstraction in Europe and more than 80 % in some southern European countries (EEA, 2009). Economic restructuring in some eastern European countries has led to a decrease in water abstraction for irrigation, suggesting the potential for future increases in irrigated agriculture and water use efficiency (EEA, 2009).

Forest in Europe covers approximately 35% of the land area (Eurostat, 2009). The majority of forests now grow faster than in the early 20th century due to advances in forest management practices, genetic improvement and in central Europe, the cessation of site-degrading practices such as litter collection for fuel. Increasing temperatures and CO_2 concentrations, nitrogen deposition, and the reduction of air pollution (SO_2) have also had a positive effect on forest growth. Scenario studies suggest that forested areas will increase in Europe in the future on land formerly used for agriculture (Rounsevell *et al.*, 2006). Soil degradation is already intense in parts of the Mediterranean and central-eastern Europe and, together with prolonged drought periods and fires, is already contributing to an increased risk of desertification. Projected risks for future desertification are the highest in these areas (EEA, 2012).

Urban development is projected to increase all over Europe (Reginster and Rounsevell, 2006), but especially rapidly in Eastern Europe, with the magnitude of these increases depending on population growth, economic growth and land use planning policy. Although changes in urban land use will be relatively small in area terms, urban development has major impacts locally on environmental quality. Outdoor air quality has, however, been improving (ELME, 2007). Peri-urbanisation is an increasing trend in which residents move out of cities to locations with a rural character, but retain a functional link to cities by commuting to work (Reginster and Rounsevell, 2006)(Rounsevell and Reay, 2009).

Several European scenario studies have been undertaken to describe European future trends with respect to: socio-economic development (Mooij de and Tang, 2003), land use change (Letourneau *et al.*, 2012; Verburg *et al.*, 2010)(Haines-Young *et al.*, 2012), land use and biodiversity (Spangenberg *et al.*, 2011), crop production (Hermans *et al.*, 2010), demographic change (Davoudi *et al.*, 2010), economic development (Dammers, 2010) and European policy (Helming *et al.*, 2011)(Lennert and Robert, 2010). Many of these scenarios also account for the effects of future climate change (see (Rounsevell and Metzger, 2010) for a review). Long term projections (to the end of the century) are described under the new Shared Socio-economic Pathway scenarios (SSPs) (Kriegler *et al.*, 2010). Detailed country and regional scale socio-economic scenarios have also been produced for the Netherlands (WLO, 2006), the UK (UK National Ecosystem Assessment, 2011) and Scotland (Harrison *et al.*, 2013). The probabilistic representation of socio-economic futures has also been developed for agricultural land use change (Hardacre *et al.*, 2012). There is little evidence to suggest, however, that probabilistic futures or scenarios more generally are being used in policy making (Bryson *et al.*, 2010).

23.2.2. Observed and Projected Climate Change

23.2.2.1. Observed Climate Change

The average temperature in Europe has continued to increase with regionally and seasonally different rates of warming, being greatest in high latitudes in Northern Europe (AR5 WG2 Chapter 28). Since the 1980s, warming has been strongest over Scandinavia, especially in winter, whereas the Iberian Peninsula warmed mostly in summer (EEA, 2012; Haylock *et al.*, 2008). The decadal average temperature over land area for 2002-2011 is 1.3°C+/-0.11°C above the 1850-1899 average, based on HadCRUT3 (Brohan *et al.*, 2006), MLOST (Smith *et al.*, 2008) and GISS Temp (Hansen *et al.*, 2010). See AR5 WG1 Section 2.4 for a discussion of data and uncertainties and AR5 WG2 Chapter 21for observed regional climate change.

Since 1950, high-temperature extremes (hot days, tropical nights, and heat waves) have become more frequent, while low-temperature extremes (cold spells, frost days) have become less frequent (AR5 WG1 Chapter 2.6, SREX-3)(EEA, 2012). The recent cold winters in Northern and Atlantic Europe reflect the high natural variability in the region (Peterson *et al.*, 2012)(AR5 WG1 section 2.7), and do not contradict the general warming trend. In Eastern Europe, including the European part of Russia, summer 2010 was exceptionally hot, with an amplitude and spatial extent that exceeded the previous 2003 heat wave (Barriopedro *et al.*, 2011). Table 23-1 describes the impacts of major extreme events in Europe in the last decade.

Since 1950, annual precipitation has increased in Northern Europe (up to +70 mm/decade) based on Haylock *et al.* (2008), and decreased in parts of Southern Europe (EEA, 2012). Winter snow cover extent has a high inter-annual variability and a non-significant negative trend over the period 1967-2007 (Henderson and Leathers, 2010). Regional observed changes in temperature and precipitation extremes are also described in Table 3-2 of SREX and in Berg *et al.* (2013). Mean wind speeds have declined over Europe over recent decades (Vautard *et al.*, 2010) with *low confidence* due to problematic anemometer data and climate variability (SREX Section 3.3). Bett *et al* (2013) did not find any trend in windspeed using the Twentieth Century Reanalysis.

Europe is marked by increasing mean sea level with regional variations, except in the northern Baltic Sea where the relative sea level decreased due to vertical crustal motion (Albrecht *et al.*, 2011; EEA, 2012; Haigh *et al.*, 2010; Menendez and WoodWorth, 2010). Extreme sea levels have increased due to mean sea level rise (*medium confidence*, SREX Section 3.5, Haigh *et al.*, 2010; Menendez and WoodWorth, 2010). Variability in waves is related to internal climate variability rather than climate trends (SREX Section 3.5, Charles *et al.*, 2012).

23.2.2.2. Projected Climate Changes

For Europe, sub-regional information from global (AR5 WG1 Chapter 14.8.6; AR5 WG1 Annex 1; AR5 WG2 Chapter 21 supplement) and regional high resolution climate model output (AR5 WG1 Chapter 14.8.6; WG2 Chapter 21, 23) provide more knowledge about the range of possible future climates under the SRES and RCP emission scenarios. Within the recognized limitations of climate projections (AR5 WG1 Chapter 9; WG2 Chapter 21), new research on inter-model comparisons has provided a more robust range of future climates to assess future impacts. Since AR4, climate impact assessments are more likely to use a range for the projected changes in temperature and rainfall. Access to comprehensive and detailed sets of climate projections for decision making exist in Europe (SREX Section 3.2.1, (Mitchell *et al.*, 2004)(Fronzek *et al.*, 2012; Jacob *et al.*, 2013).

Climate models show significant agreement for all emission scenarios in warming (magnitude and rate) all over Europe, with strongest warming projected in Southern Europe in summer, and in Northern Europe in winter (Kjellström *et al.*, 2011)(Goodess *et al.*, 2009). Even under an average global temperature increase limited to 2°C compared to pre-industrial times, the climate of Europe is simulated to depart significantly in the next decades from today's climate (Jacob and Podzun, 2010);(Van der Linden and Mitchell, 2009).

Precipitation signals vary regionally and seasonally. Trends are less clear in Continental Europe, with agreement in increase in Northern Europe and decrease in Southern Europe (*medium confidence*) (Kjellström *et al.*, 2011). Precipitation is projected to decrease in the summer months up to Southern Sweden and increase in winter (Schmidli *et al.*, 2007) with more rain than snow in mountainous regions (Steger *et al.*, 2013). In Northern Europe, a decrease of long term mean snow pack (although snow-rich winters will remain) towards the end of the century (Räisänen and Eklund, 2012) is projected. There is lack of information about past and future changes in hail occurrence in Europe. Changes in future circulation patterns (Kreienkamp *et al.*, 2010; Ulbrich *et al.*, 2009) and mean wind speed trends are uncertain in sign (Kjellström *et al.*, 2011)(McInnes *et al.*, 2011).

Regional coupled simulations over the Mediterranean region provide a more realistic characterization of impact parameters (e.g. snow cover, aridity index, river discharge), which were not revealed by CMIP3 global simulations (Dell'Aquila *et al.*, 2012).

For 2081-2100 compared to 1986-2005, projected global mean sea level rises (metres) are in the range 0.29-0.55 for RCP2.6, 0.36-0.63 for RCP4.5, 0.37-0.64 for RCP6.0 and 0.48-0.82 for RCP8.5 (*medium confidence*, AR5 WG3 Chapter 5). There is a *low confidenc*e on projected regional changes (Slangen *et al.*, 2012)(AR5 WG1 13.6). Low probability/high impact estimates of extreme mean sea-level rise projections derived from the A1FI SRES scenario for the Netherlands (Katsman *et al.*, 2011) indicate that the mean sea-level could rise globally between 0.55 and 1.15 m, and locally (the Netherlands) by 0.40 to 1.05 m, by 2100. Extreme (very unlikely) scenarios for the UK vary from 0.9 to 1.9 m by 2100 (Lowe *et al.*, 2009).

23.2.2.3. Projected Changes in Climate Extremes

There will be a marked increase in extremes in Europe, in particular, in heat waves, droughts and heavy precipitation events (Beniston *et al.*, 2007)(Lenderink and Van Meijgaard, 2008) and AR5 WG2 Chapter 21 Supplement. There is a general *high confidence* concerning changes in temperature extremes (toward increased number of warm days, warm nights and heat waves, SREX Table 3-3). Figure 23-2 (upper panels) shows projected changes in the mean number of heat waves in May to September for 2071-2100 compared to 1971-2000 for RCP4.5 and RCP8.5 with large differences depending on the emission scenario. The increase in likelihood of some individual events due to anthropogenic change has been quantified for the 2003 heat wave (Schär and Jendritzky, 2004), the warm winter of 2006/2007 and warm spring of 2007 (Beniston, 2007).

Changes in extreme precipitation depend on the region, with a *high confidence* of increased extreme precipitation in Northern Europe (all seasons) and Continental Europe (except summer). Future projections are regionally and seasonally different in Southern Europe (SREX Table 3-3). Figure 23-2 (middle panels) shows projected seasonal changes of heavy precipitation events for 2071-2100 compared to 1971-2000 for RCP4.5 and RCP8.5.

[INSERT FIGURE 23-2 HERE
Figure 23-2: First row: Projected changes in the mean number of heat waves occurring in the months May to September for the period 2071-2100 compared to 1971-2000 (number per 30 years). Heat waves are defined as periods of more than 5 consecutive days with daily maximum temperature exceeding the mean maximum temperature of the May to September season of the control period (1971-2000) by at least 5°C. Second and third rows: Projected seasonal changes in heavy precipitation defined as the 95th percentile of daily precipitation (only days with precipitation > 1mm/day are considered) for the period 2071-2100 compared to 1971-2000 (in %) in the months December to January (DJF) and June to August (JJA). Fourth row: Projected changes in the 95th percentile of the length of dry spells for the period 2071-2100 compared to 1971-2000 (in days). Dry spells are defined as

periods of at least 5 consecutive days with daily precipitation below 1mm. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test). For the eastern parts of Black Sea, Eastern Anatolia and Southeast Anatolia (Turkey), no regional climate model projections are available. Changes represent the mean over 8 (RCP4.5, left side) and 9 (RCP8.5, right side) regional model simulations compiled within the EURO-CORDEX initiative. Adapted from Jacob et al. (2013).]

Projected changes of spatially averaged indices over the European sub-regions (Figure 23-1) are described in the supplemental information (Table SM23-2).

In winter, small increases in extreme wind speed are projected for Central and Northern Europe [*medium confidence*] (AR5 WG2 21.3.3.1.6; SREX Figure 3-8) (Beniston *et al.*, 2007; Haugen and Iversen, 2008; Rauthe *et al.*, 2010; Rockel and Woth, 2007; Schwierz *et al.*, 2010), connected to changes in storm tracks [*medium confidence*] (Pinto *et al.*, 2007a; Pinto *et al.*, 2007b)(Donat *et al.*, 2010)(Pinto *et al.*, 2010). Other parts of Europe and seasons are less clear in sign with a small decreasing trend in southern Europe [*low confidence*] (Donat *et al.*, 2011; McInnes *et al.*, 2011).

Extreme sea level events will increase (*high confidence*, AR5 WG1 13.7, SREX 3.5.3), mainly dominated by the global mean sea level increase. Storm surges are expected to vary along the European coasts. Significant increases are projected in the eastern North Sea (increase of 6-8% of the 99th percentile of the storm surge residual, 2071-2100 compared to 1961-1990, based on the B2, A1B and A2 SRES scenarios) (Debernard and Rÿed, 2008) and west of UK and Ireland (Debernard and Rÿed, 2008)(Wang *et al.*, 2008), except South of Ireland (Wang *et al.*, 2008). There is a *medium agreement* for the South of North Sea and Dutch coast where trends vary from increasing (Debernard and Rÿed, 2008) to stable (Sterl *et al.*, 2009). There is a *low agreement* on the trends in storm surge in the Adriatic sea (Jordà *et al.*, 2012; Lionello *et al.*, 2012; Troccoli *et al.*, 2012b)(Planton *et al.*, 2011).

23.2.3. Observed and Projected Trends in the Riverflow and Drought

Streamflows have decreased in the south and east of Europe and increased in Northern Europe (Stahl *et al.*, 2010)(Wilson *et al.*, 2010) (AR5 WG2 3.2.3). In general, few changes in flood trends can be attributed to climate change, partly due to the lack of sufficiently long records (Kundzewicz *et al.*, 2013). European mean and peak discharges are highly variable (Bouwer *et al.*, 2008); for instance in France, upward trends in low flows were observed over 1948-1988 and downward trends over 1968-2008 (Giuntoli *et al.*, 2013). Alpine glacier retreat during the last two decades caused a 13% increase in glacier contribution to August runoff of the four main rivers originating in the Alps, compared to the long-term average (Huss, 2011). Increases in extreme river discharge (peak flows) over the past 30-50 years have been observed in parts of Germany (Petrow *et al.*, 2009)(Petrow *et al.*, 2007), the Meuse river basin (Tu *et al.*, 2005), parts of Central Europe (Villarini *et al.*, 2011), Russia (Semenov, 2011), and Northeastern France (Renard *et al.*, 2008). Decreases in extreme river discharge have been observed in the Czech Republic (Yiou *et al.*, 2006), and no change observed in Switzerland (Schmocker-Fackel and Naef, 2010), Germany (Bormann *et al.*, 2011), and the Nordic countries (Wilson *et al.*, 2010). River regulation possibly partly masks increasing peak flows in the Rhine (Vorogushyn *et al.*, 2012). One study (Pall *et al.*, 2011) suggested that the UK 2000 flood was partly due to anthropogenic forcing, although another showed a weaker effect (Kay *et al.*, 2011).

Climate change is projected to affect the hydrology of river basins (SREX Chapter 3; AR5 WG2 Chapter 4). The occurrence of current 100-year return period discharges is projected to increase in Continental Europe, but decrease in some parts of Northern and Southern Europe by 2100 (Dankers and Feyen, 2008)(Rojas *et al.*, 2012). In contrast, studies for individual catchments indicate increases in extreme discharges, to varying degrees, in Finland (Veijalainen *et al.*, 2010), Denmark (Thodsen, 2007), Ireland (Wang *et al.*, 2006)(Steele-Dunne *et al.*, 2008)(Bastola *et al.*, 2011), the Rhine basin (Görgen *et al.*, 2010; Te Linde *et al.*, 2010a), Meuse basin (Leander *et al.*, 2008)(Ward *et al.*, 2011), the Danube basin (Dankers *et al.*, 2007), and France (Chauveau *et al.*, 2013; Quintana-Segui *et al.*, 2011). Although snowmelt floods may decrease, increased autumn and winter rainfall could lead to higher peak discharges in northern Europe (Lawrence and Hisdal, 2011). Declines in low flows are projected for the UK

(Christierson *et al.*, 2012), Turkey (Fujihara *et al.*, 2008), France (Chauveau *et al.*, 2013), and rivers fed by Alpine glaciers (Huss, 2011).

The analysis of trends in droughts is made complex by the different categories or definitions of drought (meteorological, agricultural, and hydrological) and the lack of long-term observational data (SREX Box 3-3). Southern Europe shows trends towards more intense and longer meteorological droughts, but they are still inconsistent (Sousa *et al.*, 2011). Drought trends in all other sub-regions are not statistically significant (SREX 3.5.1). Regional and global climate simulations project (*medium confidence*) an increase in duration and intensity of droughts in central and southern Europe and the Mediterranean up until the UK for different definitions of drought (Feyen and Dankers, 2009; Gao and Giorgi, 2008; Vidal and Wade, 2009)(Koutroulis *et al.*, 2010; Tsanis *et al.*, 2011) (AR5 WG2 Chapter 21). Even in regions where summer precipitation is expected to increase, soil moisture and hydrological droughts may become more severe due to increasing evapotranspiration (Wong *et al.*, 2011). Projected changes in the length of meteorological dry spells show that the increase is large in Southern Europe (Figure 23-2 fourth row).

23.3. Implications of Climate Change for Production Systems and Physical Infrastructure

23.3.1. Settlements

23.3.1.1. Coastal Flooding

As the risk of extreme sea level events increases with climate change [23.2.3, AR5 WG2 Chapter 5], coastal flood risk will remain a key challenge for several European cities, port facilities and other infrastructure (Nicholls *et al.*, 2008)(Hallegatte *et al.*, 2008)(Hallegatte *et al.*, 2011). With no adaptation, coastal flooding in the 2080s is projected to affect an additional 775,000 and 5.5 million people per year in the EU27 (B2 and A2 scenarios) (Ciscar *et al.*, 2011). The Atlantic, Northern and Southern European regions are projected to be most affected. Direct costs from sea level rise in the EU27 without adaptation could reach 17 billion Euros per year by 2100 (Hinkel *et al.*, 2010), with indirect costs also estimated for land-locked countries (Bosello *et al.*, 2012). Countries with high absolute damage costs include the Netherlands, Germany, France, Belgium, Denmark, Spain and Italy (Hinkel *et al.*, 2010). Upgrading coastal defences would substantially reduce impacts and damage costs (Hinkel *et al.*, 2010). However, the amount of assets and populations that need to protected by coastal defences is increasing, thus, the magnitude of losses when floods do occur will also increase in the futre (Hallegatte et al. 2013), entailing the need to prepare for very large flood disasters in the future.

An increase in future flood losses due to climate change have been estimated for Copenhagen (Hallegatte *et al.*, 2011), the UK coast (Mokrech *et al.*, 2008)(Purvis *et al.*, 2008)(Dawson *et al.*, 2011), the North Sea coast (Gaslikova *et al.*, 2011), cities including Amsterdam and Rotterdam (Hanson *et al.*, 2011), and the Netherlands (Aerts *et al.*, 2008). A 1m sea-level rise in Turkey could affect 3 million additional people and put 12 billion USD capital value at risk, with around 20 billion USD adaptation costs (10% of GNP) (Karaca and Nicholls, 2008). In Poland, up to 240,000 people would be affected by increasing flood risk on the Baltic coast (Pruszak and Zawadzka, 2008). The increasing cost of insurance and unwillingness of investors to place assets in affected areas is a potential growth impediment to coastal and island economies (Day *et al.*, 2008).

23.3.1.2. River and Pluvial Flooding

Recent major flood events in Europe include the 2007 floods in the UK (Table 23-1) (Chatterton *et al.*, 2010) and the 2013 floods in Germany. The observed increase in river flood events and damages in Europe is well documented (see AR5 WG2 18.4.2.1), however, the main cause is increased exposure of persons and property in flood risk areas (Barredo, 2009). Since AR4, new studies provide a wider range of estimates of future economic losses from river flooding attributable to climate change, depending on the modelling approach and climate scenario (Bubeck *et al.*, 2011). Studies now also quantify risk under changes in population and economic growth, generally indicating this contribution to be about equal or larger than climate change per se (Feyen *et al.*, 2009; Maaskant *et al.*, 2009; Rojas *et al.*, 2013)(Bouwer *et al.*, 2010)(Te Linde *et al.*, 2011). Some regions may see increasing risks, but others may see decreases or little to no change (Bubeck *et al.*, 2011)(ABI, 2009)(Feyen *et al.*, 2009)(Lugeri *et al.*, 2010)(Mechler *et al.*, 2010)(Feyen *et al.*, 2012)(Lung *et al.*, 2012). In the EU15, river flooding could affect 250,000-400,000 additional people by the 2080s (SRES A2 and B2 scenarios) and more than doubling annual average damages, with Central and Northern Europe and the UK most affected (Ciscar, 2009)(Ciscar *et al.*, 2011). When economic growth is included, economic flood losses in Europe could increase 17-fold under the A1B climate scenario (Rojas *et al.*, 2013).

Few studies have estimated future damages from inundation in response to an increase in intense rainfall (Hoes, 2006; Willems *et al.*, 2012). Processes that influence flash flood risk include increasing exposure from urban expansion, and forest fires that lead to erosion and increased surface runoff (Lasda *et al.*, 2010). Some studies have costed adaptation measures but these may only partly offset anticipated impacts (Zhou *et al.*, 2012).

[INSERT Table 23-1 HERE
Table 23-1: Impacts of climate extremes in the last decade in Europe.]

23.3.1.3. Windstorms

Several studies project an overall increase storm hazard in northwest Europe [23.2.2.3] and in economic and insured losses [AR5 WG2 Chapter 17.7.3], but natural variations in frequencies are large. There is no evidence that the observed increase in European storm losses is due to anthropogenic climate change (Barredo, 2010). There is a lack of information for other storm types, such as tornadoes and thunderstorms.

23.3.1.4. Mass Movements and Avalanches

In the European Alps, the frequency of rock avalanches and large rock slides has apparently increased over the period 1900-2007 (Fischer *et al.*, 2012). The frequency of landslides may also have increased in some locations (Lopez Saez *et al.*, 2013). Mass movements are projected to become more frequent with climate change (Huggel *et al.*, 2010; Stoffel and Huggel, 2012), although several studies indicate a more complex or stabilising response of mass movements to climate change (Dixon and Brook, 2007; Huggel *et al.*, 2012; Jomelli *et al.*, 2007; Jomelli *et al.*, 2009; Melchiorre and Frattini, 2012). Some land-use practices have led to conditions favourable to increased landslide risk, despite climate trends that would result in a decrease of landslide frequency, as reported in Calabria (Polemio and Petrucci, 2010) and in the Apennines (Wasowski *et al.*, 2010). Snow avalanche frequency changes in Europe are dominated by climate variability; studies based on avalanche observations (Eckert *et al.*, 2010) or favourable meteorological conditions (Castebrunet *et al.*, 2012; Teich *et al.*, 2012) show contrasting variations, depending on the region, elevation, season and orientation.

23.3.2. Built Environment

Built infrastructure in Europe is vulnerable to extreme weather events, including overheating of buildings (houses, hospitals, schools) during hot weather (Crump *et al.*, 2009; DCLG, 2012). Buildings that were originally designed for certain thermal conditions will need to function in warmer climates in the future (WHO, 2008). Climate change in Europe is expected to increase cooling energy demand (23.3.4) (Dolinar *et al.*, 2010), with implications for mitigation and adaptation policies (23.8.1). A range of adaptive strategies for buildings are available, including effective thermal mass and solar shading (ARUP, 2008). Climate change may also increase the frequency and intensity of drought-induced soil subsidence and associated damage to dwellings (Corti *et al.*, 2009).

With respect to the outdoor built environment, there is limited evidence regarding the potential for differential rates of radiatively-forced climate change in urban compared to rural areas (McCarthy *et al.*, 2010). Climate change may exacerbate London's nocturnal urban heat island (UHI) (Wilby, 2008), however, the response of different cities may vary. For example, a study of Paris (Lemonsu *et al.*, 2013) indicated a future reduction in strong urban heat island events when increased soil dryness was taken into effect. Modification of the built environment, via enhanced urban greening, for example, can reduce temperatures in urban areas, with co-benefits for health and wellbeing (23.7.4, 23.8.1).

23.3.3. Transport

Systematic and detailed knowledge on climate change impacts on transport in Europe remains limited (Koetse and Rietveld, 2009).

On *road transport*, in line with AR4, more frequent but less severe collisions due to reduced speed are expected in case of increased precipitation (Brijs *et al.*, 2008)(Kilpeläinen and Summala, 2007). However, lower traffic speed may cause welfare losses due to additional time spent driving (Sabir *et al.*, 2010). Severe snow and ice-related accidents will also decrease, but the effect of fewer frost days on total accidents is unclear (Andersson and Chapman, 2011a)(Andersson and Chapman, 2011b). Severe accidents caused by extreme weather are projected to decrease by 63-70% in 2040-2070 compared to 2007 as a result of modified climate and expected developments in vehicle technology and emergency systems (Nokkala *et al.*, 2012).

For *rail*, consistent with AR4, increased buckling in summer, as occurred in 2003 in the UK, is expected to increase the average annual cost of heat-related delays in some regions, while the opposite is expected for ice and snow-related delays (Dobney *et al.*, 2010; Lindgren *et al.*, 2009; Palin *et al.*, 2013). Effects from extreme precipitation, as well as the net overall regional impact of climate change remain unclear. Efficient adaptation comprises proper maintenance of track and track bed.

Regarding *inland waterways*, the case of Rhine shows that for 1-2 °C increases by 2050 more frequent high water levels are expected in winter, while after 2050 days with low water levels in summer will also increase (Jonkeren *et al.*, 2011)(Te Linde *et al.*, 2011)(Te Linde, 2007)(Hurkmans *et al.*, 2010). Low water levels will reduce the load factor of inland ships and consequently increase transport prices, as in the Rhine and Moselle in 2003 (Jonkeren, 2009)(Jonkeren *et al.*, 2007). Adaptation includes modal shifts, increase navigational hours per day under low water levels, and infrastructure modifications (e.g. canalization of river parts) (Jonkeren *et al.*, 2011; Krekt *et al.*, 2011).

For *long range ocean routes*, the economic attractiveness of the Northwest Passage and the Northern Sea Route depends also on passage fees, bunker prices and cost of alternative sea routes (Verny and Grigentin, 2009)(Liu and Kronbak, 2010)(Lasserre and Pelletier, 2011). Regarding *air transport*, for Heathrow airport in the UK, future temperature and wind changes were estimated to cause a small net annual increase but much larger seasonal changes on the occurrence of delays (Pejovic *et al.*, 2009).

23.3.4. Energy Production, Transmission, and Use

On *wind energy*, no significant changes are expected before 2050, at least in Northern Europe (Pryor and Schoof, 2010)(Pryor and Barthelmie, 2010)(Seljom *et al.*, 2011)(Barstad *et al.*, 2012; Hueging *et al.*, 2013). After 2050, in line with AR4, the wind energy potential in Northern, Continental and most of Atlantic Europe may increase during winter and decrease in summer (Harrison *et al.*, 2008; Hueging *et al.*, 2013)(Nolan *et al.*, 2012; Rockel and Woth, 2007). For Southern Europe, a decrease in both seasons is expected, except for the Aegean Sea and Adriatic coast where a significant increase during summer is possible (Bloom *et al.*, 2008; Hueging *et al.*, 2013; Najac *et al.*, 2011; Pašičko *et al.*, 2012).

For *hydropower*, electricity production in Scandinavia is expected to increase by 5-14% during 2071-2100 compared to historic or present levels (Golombek *et al.*, 2012) (Haddeland *et al.*, 2011); for 2021-2050, increases by 1-20% were estimated (Haddeland *et al.*, 2011)(Hamududu and Killingtveit, 2012; Seljom *et al.*, 2011). In Continental, and part of Alpine Europe, reductions in electricity production by 6-36% were estimated (Schaefli *et al.*, 2007) (Paiva *et al.*, 2011; Pašičko *et al.*, 2012)(Hendrickx and Sauquet, 2013; Stanzel and Nachtnebel, 2010). For Southern Europe, production is expected to decrease by 5-15% in 2050 compared to 2005 (Bangash *et al.*, 2013; Hamududu and

Killingtveit, 2012). Adaptation consists in improved water management, including pump storage if appropriate (Schaefli *et al.*, 2007)(García-Ruiz *et al.*, 2011).

Biofuel production is discussed in section 23.4.5. There are few studies of impacts on solar energy production. Crook et al. (2011) estimated an increase of the energy output from photovoltaic panels and especially from concentrated solar power plants in most of Europe under the A1B scenario.

On *thermal power*, in line with AR4, van Vliet et al. (2012) estimated a 6-19% decrease of the summer average usable capacity of power plants by 2031–2060 compared to 1971-2000, while smaller decreases have been also estimated (Linnerud *et al.*, 2011)(Förster and Lilliestam, 2010). Closed-cooling circuits are efficient adaptation choices for new plants (Koch and Vögele, 2009). In *power transmission*, increasing lightning and decreasing snow-sleet-and blizzard faults for 2050-2080 were estimated for the UK (McColl *et al.*, 2012).

By considering both heating and cooling, under a +3.7 ^{o}C scenario by 2100 a decrease of *total annual energy demand* in Europe as a whole during 2000-2100 was estimated (Isaac and van Vuuren, 2009). Seasonal changes will be prominent, especially for electricity (see Figure 23-3), with summer peaks arising also in countries with moderate summer temperatures (Hekkenberg *et al.*, 2009). Heating degree days are expected to decrease by 11-20% between 2000 and 2050 due solely to climate change (Isaac and van Vuuren, 2009). For cooling, very large percentage increases up to 2050 are estimated by the same authors for most of Europe as the current penetration of cooling devices is low; then, increases by 74-118% in 2100 (depending on the region) from 2050 are expected under the combined effect of climatic and non-climatic drivers. In Southern Europe, cooling degree days by 2060 will increase, while heating degree days will decrease but with substantial spatial variations (Giannakopoulos *et al.*, 2009). Consequently, net annual electricity generation cost will increase in most of the Mediterranean and decrease in the rest of Europe (Eskeland and Mideksa, 2010)(Mirasgedis *et al.*, 2007)(Pilli-Sihlova *et al.*, 2010; Zachariadis, 2010). Future building stock changes and retrofit rates are critical for impact assessment and adaptation (Olonscheck *et al.*, 2011). Energy efficient buildings and cooling systems, and demand-side management are effective adaptation options (Artmann *et al.*, 2008; Breesch and Janssens, 2010; Chow and Levermore, 2010; Day *et al.*, 2009; Jenkins *et al.*, 2008).

[INSERT FIGURE 23-3 HERE
Figure 23-3: Percentage change in electricity demand in Greece attributable to climate change, under a range of climate scenarios and economic assumptions. Source: Mirasgedis et al., 2007.]

23.3.5. Industry and Manufacturing

Research on the potential effects of climate change in industry is limited. Modifications in future consumption of food and beverage products have been estimated on the basis of current sensitivity to seasonal temperature (Mirasgedis *et al.*, 2013). Higher temperatures may favour the growth of food borne pathogens or contaminants (Jacxsens *et al.*, 2010; Popov Janevska *et al.*, 2010) (see also 23.5.1). The quality of some products, such as wine (23.4.1, Box 23-2), is also likely to be affected. In other sectors, the cumulative cost of direct climate change impacts in the Greek mining sector for 2021-2050 has been estimated at 0.245 billion Euros, in 2010 prices (Damigos, 2012). Adaptation to buildings or work practices are likely to be needed in order to maintain labour productivity during hot weather (Kjellstrom *et al.*, 2009)(11.6.2.2).

23.3.6. Tourism

In line with AR4, the climate for general tourist activities especially after 2070 is expected to improve significantly during summer and less during autumn and spring in northern Continental Europe, Finland, southern Scandinavia and southern England (Amelung and Moreno, 2012)(Amelung *et al.*, 2007)(Nicholls and Amelung, 2008). For the Mediterranean, climatic conditions for light outdoor tourist activities are expected to deteriorate in summer mainly after 2050, but improve during spring and autumn (Amelung and Moreno, 2009)(Hein *et al.*, 2009)(Perch-Nielsen *et al.*, 2010)(Amelung *et al.*, 2007)(Giannakopoulos *et al.*, 2011). Others concluded that before 2030 (or even 2060) this region as a whole will not become too hot for beach or urban tourism (Moreno and Amelung, 2009)(Rutty and Scott, 2010), while surveys showed that beach tourists are deterred mostly by rain (De Freitas *et al.*, 2008; Moreno, 2010).

Thus, from 2050, domestic tourism and tourist arrivals at locations in Northern and parts of Continental Europe may be enhanced at the expense of Southern locations (Amelung and Moreno, 2012; Bujosa and Roselló, 2012; Hamilton and Tol, 2007; Hein *et al.*, 2009). The age of tourists, the climate in their home country, local economic and environmental conditions (e.g. water stress, tourist development) are also critical (Hamilton and Tol, 2007)(Moreno and Amelung, 2009; Perch-Nielsen *et al.*, 2010)(Eugenio-Martin and Campos-Soria, 2010; Lyons *et al.*, 2009)(Rico-Amoros *et al.*, 2009).

Tourism in mountainous areas may benefit from improved climatic conditions in summer (Endler *et al.*, 2010; Endler and Matzarakis, 2011b; Perch-Nielsen *et al.*, 2010; Serquet and Rebetez, 2011). However, in agreement with AR4, natural snow reliability and thus ski season length will be adversely affected, especially where artificial snowmaking is limited (OECD, 2007; Steiger, 2011)(Moen and Fredman, 2007). Low-lying areas will be the most vulnerable (Endler *et al.*, 2010; Endler and Matzarakis, 2011a; Serquet and Rebetez, 2011; Steiger, 2011; Uhlmann *et al.*, 2009). Tourist response to marginal snow conditions remains largely unknown, while changes in weather extremes may also be critical (Tervo, 2008). Up to 2050, demographic changes (e.g. population declines in source countries, ageing populations) may have a higher impact than climate change (Steiger, 2012). Artificial snowmaking has physical and economic limitations, especially in small sized and low-altitude ski stations (Sauter *et al.*, 2010; Steiger and Mayer, 2008; Steiger, 2010; Steiger, 2011), and increases water and energy consumption. Shifts to higher altitudes, operational/ technical measures and year-round tourist activities may not fully compensate for adverse impacts.

23.3.7. Insurance and Banking

Insurance and banking face problems related to accurate pricing of risks, shortage of capital after large loss events, and by an increasing burden of losses that can affect markets and insurability, within but also outside the European region (Botzen *et al.*, 2010a; Botzen *et al.*, 2010b; CEA, 2007)(AR5 WG2 Section 10.7). However, risk transfer including insurance also holds potential for adaptation by providing incentives to reduce losses (Botzen and van den Bergh, 2008; CEA, 2009)(Herweijer *et al.*, 2009).

Banking is potentially affected through physical impacts on assets and investments, as well as through regulation and/or mitigation actions by changing demands regarding sustainability of investments and lending portfolios. Few banks have adopted climate strategies that also address adaptation (Furrer *et al.*, 2009)(Cogan, 2008).

Windstorm losses are well covered in Europe by building and motor policies, and thus create a large exposure to the insurance sector. Flood losses in the UK in 2000, 2007 and 2009 have put the insurance market under further pressure, with increasing need for the government to reduce risk (Ward *et al.*, 2008)(Lamond *et al.*, 2009). Other risks of concern to the European insurance industry is building subsidence related to drought (Corti *et al.*, 2009), and hail damage to buildings and agriculture (Kunz *et al.*, 2009; Botzen *et al.*, 2010b; GIA, 2011).

The financial sector can adapt through adjustment of premiums, restricting or reduction of coverage, further risk spreading, and importantly incentivising risk reduction (Botzen *et al.*, 2010a; Clemo, 2008)(Crichton, 2007)(Crichton, 2006)(Wamsler and Lawson, 2011)(Surminski and Philp, 2010). Public attitudes in Scotland and the Netherlands would support insurance of private property and public infrastructure damages in the case of increasing flood risk (Botzen *et al.*, 2009)(Glenk and Fisher, 2010). Government intervention is however often needed to provide compensation and back-stopping in the event of major losses (Aakre and Rübbelke, 2010; Aakre *et al.*, 2010). Hochrainer *et al.* (2010) analysed the performance of the EU Solidarity Fund that supports European governments in large events, and argue there is a need to increase its focus on risk reduction. Current insurance approaches present in Europe are likely to remain, as they are tailored to local situations and preferences (Schwarze *et al.*, 2011).

23.4. Implications of Climate Change for Agriculture, Fisheries, Forestry, and Bioenergy Production

23.4.1. Plant (Food) Production

In AR4, Alcamo et al. (2007) reported that crop suitability is likely to change throughout Europe. During the 2003 and 2010 summer heat waves, grain-harvest losses reached 20 and 30% in affected regions of Europe and Russia, respectively (Barriopedro *et al.*, 2011; Ciais *et al.*, 2005) (Table 23-1). Cereals production fell on average by 40% in the Iberian Peninsula during the intense 2004/2005 drought (EEA, 2010a). Climate-induced variability in wheat production has increased in recent decades in Southern and Central Europe (Brisson *et al.*, 2010)(Hawkins *et al.*, 2013)(Ladanyi, 2008), but no consistent reduction has been recorded in the northernmost areas of Europe (Peltonen-sainio *et al.*, 2010). Country-scale rainfed cereals yields are below agro-climatic potentials (Supit *et al.*, 2010) and wheat yield increases have levelled off in several countries over 1961-2009 (Olesen *et al.*, 2011). High temperatures and droughts during grain filling has contributed to the lack of yield increase of winter wheat in France despite improvements in crop breeding (Brisson *et al.*, 2010; Kristensen *et al.*, 2011). In contrast, in eastern Scotland, warming has favoured an increase in potato yields since 1960 (Gregory and Marshall, 2012). In north-east Spain, grape yield was reduced by an increased water deficit in the reproductive stage since the 1960s (Camps and Ramos, 2012).

Insight into the potential effect of climate change on crops requires the combination of a wide range of emission scenarios, global circulation models (GCM) and impact studies (Trnka *et al.*, 2007)(Soussana *et al.*, 2010). In the EU27, a 2.5 °C regional temperature increase in the 2080s under the B2 scenario could lead to small changes (on average +3%) in crop yields, whereas a 5.4 °C regional warming under the A2 scenario could reduce mean yields by 10% according to a study based on regional climate models (Ciscar *et al.*, 2011). An initial benefit from the increasing CO_2 concentration for rainfed crop yields would contrast by the end of the century with yield declines in most European subregions, although wheat yield could increase under the A2 scenario (Supit *et al.*, 2012, three GCMs, B1, A2 scenarios). Disease-limited yields of rain fed wheat and maize in the 2030s does not show consistent trends across two GCMs (Donatelli *et al.*, 2012). For a global temperature increase of 5° C, agroclimatic indices show an increasing frequency of extremely unfavourable years in European cropping areas (Trnka *et al.*, 2011). Under the A2 and B2 scenarios, crop production shortfalls, defined as years with production below 50% of its average climate normal production would double by 2020 and triple by 2070 as compared to a current frequency of 1-3 years per decade in the currently most productive southern European regions of Russia (Alcamo *et al.*, 2007).

The regional distribution of climate change impacts on agricultural production is likely to vary widely (Iglesias *et al.*, 2012) (Donatelli *et al.*, 2012) (Figure 23-4). Southern Europe would experience the largest yield losses (-25 % by 2080 under a 5.4 °C warming, (Ciscar *et al.*, 2011) with increased risks of rain fed summer crop failure (Bindi and Olesen, 2011)(Ferrara *et al.*, 2010)(Ruiz-Ramos *et al.*, 2011). Warmer and drier conditions by 2050 (Trnka *et al.*, 2010; Trnka *et al.*, 2011) would cause moderate declines in crop yields in Central Europe regions (Ciscar *et al.*, 2011). In Western Europe, increased heat stress around flowering could cause considerable yield losses in wheat (Semenov, 2009). For Northern Europe, there is diverging evidence concerning future impacts. Positive yield changes combined with the expansion of climatically suitable areas could lead to crop production increases (between 2.5 and 5.4°C regional warming) (Bindi and Olesen, 2011)(Bindi and Olesen, 2011). However, increased climatic variability would limit winter crops expansion (Peltonen-Sainio *et al.*, 2010) and cause at high latitudes high risk of marked cereal yield loss (Rötter *et al.*, 2011). Spring crops from tropical origin like maize for silage could become cultivated in Finland by the end of the century (Peltonen-Sainio *et al.*, 2009). Cereal yield reduction from ozone (Fuhrer, 2009) could reach 6 and 10 % in 2030 for the European Union with the B1 and A2 scenarios, respectively (Avnery *et al.*, 2011a; Avnery *et al.*, 2011b). Because of limited land availability and soil fertility outside of Chernozem (black earth) areas, the shift of agriculture to the boreal forest zone would not compensate for crop losses due to increasing aridity in South European regions of Russia with the best soils (Dronin and Kirilenko, 2011).

[INSERT FIGURE 23-4 HERE
Figure 23-4: Percentage change in simulated water-limited yield for winter wheat in 2030 with respect to the 2000 baseline for the A1B scenario using ECHAM5 (left column) and HadCM3 (right) GCMs. Upper maps to do not take adaptation into account. Bottom maps include adaptation. Source: Donatelli et al., 2012.]

With generally warmer and drier conditions, deep rooted weeds (Gilgen *et al.*, 2010b) and weeds with contrasting physiology, such as C_4 species, could pose a more serious threat (Bradley *et al.*, 2010) to crops than shallow rooted C_3 weeds (Stratonovitch, 2012). Arthropod-borne diseases (viruses and phytoplasmas), winter infection root and stem diseases (phoma stem canker of oilseed rape and eyespot of wheat) (Butterworth *et al.*, 2010)(West *et al.*, 2012), *Fusarium* blight (Madgwick *et al.*, 2011), grapevine moth (Caffarra *et al.*, 2012) and a black rot fungus in fruit trees (Weber, 2009) could create increasing damages in Europe under climate change. However, other pathogens like cereal stem rots (e.g. *Puccinia striiformis*) (Luck *et al.*, 2011) and grapevine powdery mildew (Caffarra *et al.*, 2012) could be limited by increasing temperatures. Increased damages from plant pathogens and insect pests are projected by 2050 in Nordic countries which have hitherto been protected by cold winters and geographic isolation (Hakala *et al.*, 2011; Roos *et al.*, 2011). Some pests, like the European corn borer (Trnka *et al.*, 2007), could also extend their climate niche in Central Europe. Pests and disease management will be affected with regard to timing, preference and efficacy of chemical and biological measures of control (Kersebaum *et al.*, 2008).

Autonomous adaptation by farmers, through the advancement of sowing and harvesting dates and the use of longer cycle varieties (Howden *et al.*, 2007; Moriondo *et al.*, 2011; Moriondo *et al.*, 2010; Olesen *et al.*, 2011) could result in a general improvement of European wheat yields in the 2030s compared to the 2000s (Donatelli *et al.*, 2012) (Figure 23-4). However, farmer sowing dates seem to advance slower than crop phenology (Menzel *et al.*, 2006)(Siebert and Ewert, 2012), possibly because earlier sowing is often prevented by lack of soil workability and frost-induced soil crumbling (Oort *et al.*, 2012). Simulation studies which anticipate on earlier sowing in Europe may thus be overly optimistic. Further adaptation options include: changes in crop species, fertilization, irrigation, drainage, land allocation and farming system (Bindi and Olesen, 2011). At the high range of the projected temperature changes, only plant breeding aimed at increasing yield potential jointly with drought resistance and adjusted agronomic practices may reduce risks of yield shortfall (Olesen *et al.*, 2011)(Rötter *et al.*, 2011)(Ventrella *et al.*, 2012). Crop breeding is, however, challenged by temperature and rainfall variability, since: i) breeding has not yet succeeded in altering crop plant development responses to short-term changes in temperature (Parent and Tardieu, 2012) and ii) distinct crop drought tolerance traits are required for mild and severe water deficit scenarios (Tardieu, 2012). Adaptation to increased climatic variability may require an increased use of between and within species genetic diversity in farming systems (Smith and Olesen, 2010) and the development of insurance products against weather-related yield variations (Musshoff *et al.*, 2011). Adaptive capacity and long term economic viability of farming systems may vary given farm structural change induced by climate change (Mandryk *et al.*, 2012); (Moriondo *et al.*, 2010b). In Southern Europe, the regional welfare loss caused by changes in the agriculture sector under a high warming scenario (+5.4°C) was estimated at 1% of GDP. Northern Europe was the single sub-region with welfare gains (+0.7%) from agriculture in this scenario (Ciscar *et al.*, 2011).

23.4.2. Livestock Production

Livestock production is adversely affected by heat (Tubiello *et al.*, 2007)(AR5 WG2 7.2.1.3). With intensive systems, heat stress reduced dairy production and growth performance of large finishing pigs at daily mean air temperatures above 18 and 21°C, respectively (André *et al.*, 2011; Renaudeau *et al.*, 2011). High temperature and air humidity during breeding increased cattle mortality risk by 60% in Italy (Crescio *et al.*, 2010). Adaptation requires changes in diets and in farm buildings (Renaudeau *et al.*, 2012) as well as targeted genetic improvement programmes (Hoffmann, 2010).

With grass based livestock systems, model simulations (A1B scenario, ensemble of downscaled GCMs) show by end of century increases in potential dairy production in Ireland and France, however with higher risks of summer-autumn production failures in Central Europe and at French sites (Graux *et al.*, 2012; Trnka *et al.*, 2009). Climate conditions projected for the 2070s in central France (A2 scenario) reduced significantly grassland production in a four years experiment under elevated CO_2 (Cantarel *et al.*, 2013). At the same site, a single experimental summer drought altered production during the next two years (Zwicke *et al.*, 2013). Resilience of grassland vegetation structure was observed to prolonged experimental heating and water manipulation (Grime *et al.*, 2008). However, weed pressure from tap-rooted forbs was increased after severe experimental summer droughts (Gilgen *et al.*, 2010a). Mediterranean populations could be used to breed more resilient and better adapted forage plant material for livestock production (Poirier *et al.*, 2012).

Climate change has affected animal health in Europe [*high confidence*]. The spread of bluetongue virus in sheep across Europe has been partly attributed to climate change (Arzt *et al.*, 2010)(Guis *et al.*, 2012) through increased seasonal activity of the *Culicoides* vector (Wilson and Mellor, 2009). The distribution of this vector is unlikely to expand but its abundance could increase in Southern Europe (Acevedo *et al.*, 2010). Ticks, the primary arthropod vectors of zoonotic diseases in Europe (e.g. Lyme disease and tick-borne encephalitis), have changed distributions towards higher altitudes and latitudes with climate change (van Dijk *et al.*, 2010)(Petney *et al.*, 2012; Randolph and Rogers, 2010)(AR5 WG2 23.5). Exposure to fly strike could increase in a warmer climate but adaptation in husbandry practices would limit impacts on livestock (Wall and Ellse, 2011). The overall risk of incursion of Crimean-Congo haemorrhagic fever virus in livestock through infected ticks introduced by migratory bird species would not be increased by climate change (Gale *et al.*, 2012). The probability of introduction and large-scale spread of Rift Valley Fever in Europe is also very low (Chevalier *et al.*, 2010). Epidemiological surveillance and increased coordinated regional monitoring and control programmes have the potential to reduce the incidence of vector-borne animal diseases (Chevalier *et al.*, 2010) (Wilson and Mellor, 2009).

23.4.3. Water Resources and Agriculture

Future projected trends confirm the widening of water resource differences between Northern and Southern Europe reported in AR4 (Alcamo *et al.*, 2007). In Southern Europe, soil water content will decline, saturation conditions and drainage will be increasingly rare and restricted to periods in winter and spring, and snow accumulation and melting will change, especially in the mid-mountain areas (García-Ruiz *et al.*, 2011). Across most of Northern and Continental Europe, an increase in flood hazards (Falloon and Betts, 2010)(23.3.1) could increase damages to crops and plant growth, complicate soil workability, and increase yield variability (Olesen *et al.*, 2011). Groundwater recharge and/or water table level would be significantly reduced by the end of the century under A2 scenario for river basins located in Southern Italy, Spain, Northern France and Belgium (Ducharne *et al.*, 2010; Goderniaux *et al.*, 2011; Guardiola-Albert and Jackson, 2011; Senatore *et al.*, 2011). However, non-significant impacts were found for aquifers in Switzerland and in England (Stoll *et al.*, 2011)(Jackson *et al.*, 2011). Less precipitation in summer and higher rainfall during winter could increase nitrate leaching (Kersebaum *et al.*, 2008) with negative impacts on water quality (Bindi and Olesen, 2011). Even with reduced N fertilizer application, groundwater nitrate concentrations would increase by the end of the century in the Seine river basin (Ducharne *et al.*, 2007). More robust water management, pricing and recycling policies, in order to secure adequate future water supply and prevent tensions among users could be required in Southern Europe (García-Ruiz *et al.*, 2011).

Reduced suitability for rainfed agricultural production (Daccache and Lamaddalena, 2010; Daccache *et al.*, 2012; Henriques *et al.*, 2008; Trnka *et al.*, 2011) will increase water demand for crop irrigation (Savé *et al.*, 2012). However, increased irrigation may not be a viable option, especially in the Mediterranean area, because of projected declines in total runoff and groundwater resources (Olesen *et al.*, 2011). In a number of catchments water resources are already over-licensed and/or over-abstracted (Daccache *et al.*, 2012) and their reliability is threatened by climate change induced decline in groundwater recharge and to a lesser extent by the increase in potential demand for irrigation (Ducharne *et al.*, 2010; Majone *et al.*, 2012). To match this demand, irrigation system costs could increase by 20-27% in Southern Italy (Daccache and Lamaddalena, 2010) and new irrigation infrastructures would be required in some regions (van der Velde *et al.*, 2010) However, since the economic benefits are expected to be small, the adoption of irrigation would require changes in institutional and market conditions (Finger *et al.*, 2011). Moreover, since aquatic and terrestrial ecosystems are affected by agricultural water use (Kløve *et al.*, 2011), irrigation demand restrictions are projected in environmentally focussed future regional scenarios (Henriques *et al.*, 2008). Earlier sowing dates, increased soil organic matter content, low-energy systems, deficit irrigation and improved water use efficiency of irrigation systems and crops can be used as adaptation pathways (Daccache and Lamaddalena, 2010; Gonzalez-Camacho *et al.*, 2008; Lee *et al.*, 2008; Schutze and Schmitz, 2010) especially in

Southern and south-eastern regions of Europe (Trnka *et al.*, 2009);(Falloon and Betts, 2010). Improved water management in upstream agricultural areas could mitigate adverse impacts downstream (Kløve *et al.*, 2011) and groundwater recharge could be targeted in areas with poor water-holding soils (Wessolek and Asseng, 2006).

23.4.4. Forestry

Observed and future responses of forests to climate change include changes in growth rates, phenology, composition of animal and plant communities, increased fire and storm damage, and increased insect and pathogen damage. Tree mortality and forest decline due to severe drought events were observed in forest populations in Southern Europe (Affolter *et al.*, 2010; Bigler *et al.*, 2006; Raftoyannis *et al.*, 2008), including Italy (Bertini *et al.*, 2011)(Giuggiola *et al.*, 2010), Cyprus (ECHOES Country report, 2009), and Greece (Raftoyannis *et al.*, 2008) as well as in Belgium (Kint *et al.*, 2012), Switzerland (Rigling *et al.*, 2013) and the pre-Alps in France (Allen *et al.*, 2010; Charru *et al.*, 2010; Rouault *et al.*, 2006). Declines have also been observed in wet forests not normally considered at risk of drought (Choat *et al.*, 2012). An increase in forest productivity has been observed in Russia (Sirotenko and Abashina, 2008).

Future projections show that in Northern and Atlantic Europe the increasing atmospheric CO_2 and higher temperatures are expected to increase forest growth and wood production, at least in the short-medium term (Lindner *et al.*, 2010). On the other hand, in Southern and eastern Europe, increasing drought and disturbance risks will cause adverse effects and productivity is expected to decline (Hlásny *et al.*, 2011; Keenan *et al.*, 2011; Lavalle *et al.*, 2009; Lindner *et al.*, 2010; Silva *et al.*, 2012; Sirotenko and Abashina, 2008). By 2100, climate change is expected to reduce the economic value of European forest land depending on interest rate and climate scenario, which equates to potential damages of several hundred billion Euros (Hanewinkel *et al.*, 2013).

In Southern Europe, fire frequency and wildfire extent significantly increased after the 1970s compared with previous decades (Pausas and Fernández-Muñoz, 2012) due to fuel accumulation (Koutsias *et al.*, 2012), climate change (Lavalle *et al.*, 2009) and extreme weather events (Camia and Amatulli, 2009; Carvalho *et al.*, 2011; Hoinka *et al.*, 2009; Koutsias *et al.*, 2012; Salis *et al.*, 2013) especially in the Mediterranean basin (Marques *et al.*, 2011; Pausas and Fernández-Muñoz, 2012)(Fernandes *et al.*, 2010; Koutsias *et al.*, 2012). The most severe events in France, Greece, Italy, Portugal, Spain, and Turkey in 2010 were associated with strong winds during a hot dry period (EEA, 2010c). However, for the Mediterranean region as a whole, the total burned area has decreased since 1985 and the number of wildfires has decreased from 2000 to 2009, with large inter-annual variability (Marques *et al.*, 2011; San-Miguel-Ayanz *et al.*, 2012; Turco *et al.*, 2013). Megafires, triggered by extreme climate events, had caused record maxima of burnt areas in some Mediterranean countries during last decades (San-Miguel-Ayanz *et al.*, 2013).

Future wildfire risk is projected to increase in Southern Europe (Carvalho *et al.*, 2011; Dury *et al.*, 2011; Lindner *et al.*, 2010; Vilén and Fernandes, 2011), with an increase in the occurrence of high fire danger days (Arca *et al.*, 2012; Lung *et al.*, 2012) and in fire season length (Pellizzaro *et al.*, 2010). The annual burned area is projected to increase by a factor of 3 to 5 in Southern Europe compared to the present under the A2 scenario by 2100 (Dury *et al.*, 2011). In Northern Europe, fires are projected to become less frequent due to increased humidity (Rosan and Hammarlund, 2007). Overall, the projected increase in wildfires is likely to lead to a significant increase in greenhouse gas emissions due to biomass burning (Chiriacò *et al.*, 2013; Pausas *et al.*, 2008; Vilén and Fernandes, 2011), even if often difficult to quantify (Chiriacò *et al.*, 2013).

[INSERT FIGURE 23-5 HERE
Figure 23-5: Changes in forest fire risk in Europe for two time periods: baseline (left) and 2041–2070 (right), based on high-resolution regional climate models and the SRES A1B emission scenario. Source: Lung et al., 2013.]

Wind storm damage to forests in Europe has recently increased (Usbeck *et al.*, 2010). Boreal forests will become more vulnerable to autumn/early spring storm damage due to expected decrease in period of frozen soil (Gardiner *et al.*, 2010). Increased storm losses by 8-19% under A1B and B2 scenarios respectively is projected in Western

Germany for 2060-2100 compared to 1960-2000, with the highest impacts in the mountainous regions (Klaus *et al.*, 2011; Pinto *et al.*, 2010).

An increase in the incidence of diseases has been observed in many European forests (FAO, 2008b; Marcais and Desprez-Loustau, 2007). In Continental Europe, some species of fungi benefit from milder winters and others spread during drought periods from south to north (Drenkhan *et al.*, 2006; Hanso and Drenkhan, 2007). Projected increased late summer warming events will favour diffusion of bark beetle in Scandinavia, in lowland parts of central Europe and Austria (Jönsson *et al.*, 2011; Jönsson *et al.*, 2009)(Seidl *et al.*, 2009).

Possible response approaches to the impacts of climate change on forestry include short-term and long-term strategies that focus on enhancing ecosystem resistance and resilience and responding to potential limits to carbon accumulation (Millar *et al.*, 2007; Nabuurs *et al.*, 2013). Fragmented small-scale forest ownership can constrain adaptive capacity (Lindner *et al.*, 2010). Landscape planning and fuel load management may reduce the risk of wildfires but may be constrained by the higher flammability due to warmer and drier conditions (Moreira *et al.*, 2011). Strategies to reduce forest mortality include preference of species better adapted to relatively warm environmental conditions (Resco *et al.*, 2007). The selection of tolerant or resistant families and clones may also reduce the risk of damage by pests and diseases in pure stands (Jactel *et al.*, 2009).

23.4.5. Bioenergy Production

The potential distribution of temperate oilseeds (e.g. oilseed rape, sunflower), starch crops (e.g. potatoes), cereals (e.g. barley) and solid biofuel crops (e.g. sorghum, Miscanthus) is projected to increase in Northern Europe by the 2080s, due to increasing temperatures, and to decrease in Southern Europe due to increased drought frequency) (Tuck *et al.*, 2006). Mediterranean oil and solid biofuel crops, currently restricted to Southern Europe, are likely to extend further north (Tuck *et al.*, 2006). The physiological responses of bioenergy crops, in particular C3 Salicaceae trees, to rising atmospheric CO_2 concentration may increase drought tolerance due to improved plant water use, consequently yields in temperate environments may remain high in future climate scenarios (Oliver *et al.*, 2009).

A future increase in the northward extension of the area for short rotation coppice (SRC) cultivation leading to greenhouse gas neutral is expected (Liberloo *et al.*, 2010). However, the northward expansion of SRC would erode the European terrestrial carbon sink due to intensive management and high turnover of SRC compared to conventional forest where usually harvesting is less than annual growth (Liberloo *et al.*, 2010).

23.4.6. Fisheries and Aquaculture

In AR4, Easterling *et al*. (2007) reported that the recruitment and production of marine fisheries in the North Atlantic are *likely* to increase. In European seas, warming causes a displacement to the north and/or in depth of fish populations (Daufresne *et al.*, 2009) (AR5 WG2 Chapter 6, 23.6.4) which has a direct impact on fisheries (Cheung *et al.*, 2010; Cheung *et al.*, 2013; Tasker, 2008). For instance, in British waters, the lesser sandeel (*Ammodytes marinus*), which is a key link in the food web, shows declining recruitments since 2002 and is projected to further decline in the future with a warming climate (Heath *et al.*, 2012). In the Baltic Sea, although some new species would be expected to immigrate because of an expected increase in sea temperature, only a few of these species would be able to successfully colonize the Baltic because of its low salinity (Mackenzie *et al.*, 2007). In response to climate change and intensive fishing, widespread reductions in fish body size (Daufresne *et al.*, 2009) and in the mean size of zooplankton (Beaugrand and Reid, 2012) have been observed over time and these trends further affect the sustainability of fisheries (Pitois and Fox, 2006)(Beaugrand and Kirby, 2010) [see also Chapter 6]. Aquaculture can be affected as the areal extent of some habitats that are suitable for aquaculture can be reduced by sea-level rise. Observed higher water temperatures have adversely affected both wild and farmed freshwater salmon production in the southern part of the distribution areas (Jonsson and Jonsson, 2009). In addition, ocean acidification may disrupt the early developmental stages of shellfish (Callaway *et al.*, 2012).

Numerous studies confirm the amplification through fishing of the effects of climate change on population dynamics and consequently on fisheries (Planque *et al.*, 2010). The decline of the North Sea cod during the 1980-2000 period results from the combined effects of overfishing and of an ecosystem regime shift due to climate change (Beaugrand and Kirby, 2010). Over the next decade, this stock was not restored from its previous collapse (Mieszkowska *et al.*, 2009)(ICES, 2010). In North Sea and Celtic Seas, the steep decline in boreal species (Henderson, 2007) was compensated for by the arrival of southern (Lusitanian) species (Engelhard *et al.*, 2011; Lenoir *et al.*, 2011; ter Hofstede *et al.*, 2010).

Climate change may reinforce parasitic diseases and impose severe risks for aquatic animal health [See Chapter 6]. As water temperatures increase, a number of endemic diseases of both wild and farmed salmonid populations are *likely* to become more prevalent and threats associated with exotic pathogens may rise (Marcos-Lopez *et al.*, 2010). In Iberian Atlantic, the permitted harvesting period for the mussel aquaculture industry was reduced because of harmful algal blooms resulting from changes in phytoplankton communities linked to a weakening of the Iberian upwelling (Perez *et al.*, 2010). With freshwater systems, summer heat waves boost the development of harmful cyanobacterial blooms (Johnk *et al.*, 2008). For oysters in France, toxic algae may be linked to both climate warming and direct anthropogenic stressors (Buestel *et al.*, 2009).

Fishery management thresholds will have to be reassessed as the ecological basis on which existing thresholds have been established changes, and new thresholds will have to be developed for immigrant species (Mackenzie *et al.*, 2007)(Beaugrand and Reid, 2012). These changes may lead to loss of productivity, but also the opening of new fishing opportunities, depending on the interactions between climate impacts, fishing grounds and fleet types. They will also affect fishing regulations, the price of fish products and operating costs, which in turn will affect the economic performance of the fleets (Cheung *et al.*, 2012). Climate change impacts on fisheries profits range from negative for sardine fishery in the Iberian Atlantic fishing grounds (Perez *et al.*, 2010)(Garza-Gil *et al.*, 2010), to non-significant for the Bay of Biscay (Le Floc'h *et al.*, 2008) and positive on the Portuguese coast, since most of the immigrant fish species are marketable (Vinagre *et al.*, 2011). Human social fishing systems dealing with high variability upwelling systems with rapidly reproducing fish species may have greater capacities to adjust to the additional stress of climate change than human social fishing systems focused on longer-lived and generally less variable species (Perry *et al.*, 2011; Perry *et al.*, 2010). Climate change adaptation is being considered for integration in European maritime and fisheries operational programs (European Commission, 2013).

_____ START BOX 23-1 HERE _____

Box 23-1. Assessment of Climate Change Impacts on Ecosystem Services by Sub-Region

Ecosystems provide a number of vital provisioning, regulating and cultural services for people and society that flow from the stock of natural capital (Stoate *et al.*, 2009)(Harrison *et al.*, 2010). Provisioning services such as food from agro-ecosystems or timber from forests derive from intensively managed ecosystems; regulating services underpin the functioning of the climate and hydrological systems; and, cultural services such as tourism, recreation and aesthetic value are vital for societal well-being (see section 23.5.4). The table summarises the potential impacts of climate change on ecosystem services in Europe by sub-region based on an assessment of the published literature (2004-2013). The direction of change (increasing, decreasing or neutral) is provided, as well as the number of studies/papers on which the assessment was based (in brackets). Empty cells indicate the absence of appropriate literature. Unless otherwise stated, impacts assume no adaptation and are assessed for the mid-century (2050s). A decrease in natural hazard regulation (e.g. for wildfires) implies an increased risk of the hazard occurring. Biodiversity is included here as a service (for completeness), although it is debated whether biodiversity should be considered as a service or as part of the natural capital from which services flow. What is agreed, however, is that biodiversity losses within an ecosystem will have deleterious effects on service provision (Mouillot *et al.*, 2013).

The provision of ecosystem services in Southern Europe is projected to decline across all service categories in response to climate change [*high confidence*]. Other European sub-regions are projected to have both losses and gains in the provision of ecosystem services [*high confidence*]. The Northern sub-region will have increases in provisioning services arising from climate change [*high confidence*]. Except for the Southern sub-region, the effects of climate change on regulating services are balanced with respect to gains and losses [*high confidence*]. There are fewer studies for cultural services, although these indicate a balance in service provision for the Alpine and Atlantic regions, with decreases in service provision for the Continental, Northern and Southern sub-regions [*low confidence*].

_____ END BOX 23-1 HERE _____

23.5. Implications of Climate Change for Health and Social Welfare

23.5.1. Human Population Health

Climate change is likely to have a range of health effects in Europe. Further studies since AR4 have confirmed the effects of heat on mortality and morbidity in European populations and particularly in older people and those with chronic disease (Corobov *et al.*, 2012; Corobov *et al.*, 2013; Kovats and Hajat, 2008; Åström *et al.*, 2011). With respect to sub-regional vulnerability, populations in southern Europe appear to be most sensitive to hot weather (Baccini *et al.*, 2011; D'Ippoliti *et al.*, 2010; Michelozzi *et al.*, 2009; Michelozzi *et al.*, 2009), and also will experience the highest heat exposures (Figure 23-2). However, populations in Continental (Hertel *et al.*, 2009) and Northern Europe (Rocklöv and Forsberg, 2010)(Armstrong *et al.*, 2011)(Varakina *et al.*, 2011) are also vulnerable to heat wave events. Adaptation measures to reduce heat health effects include heat wave plans (Bittner *et al.*, 2013) which have been shown to reduce heat-related mortality in Italy (Schifano *et al.*, 2012), but evidence of effectiveness is still very limited (Hajat *et al.*, 2010; Lowe *et al.*, 2011). There is little information about how future changes in housing and infrastructure (23.3.2) would reduce the regional or local future burden of heat-related mortality or morbidity. Climate change is likely to increase future heat-related mortality (Baccini *et al.*, 2011; Ballester *et al.*, 2011; Huang *et al.*, 2011) and morbidity (Åström *et al.*, 2013), although most published risk assessments do not include consideration of adaptation (Huang *et al.*, 2011). For most countries in Europe, the current burden of cold-related mortality (Analitis *et al.*, 2008) is greater than the burden of heat mortality. Climate change is likely to reduce future cold-related mortality (Ballester *et al.*, 2011; HPA, 2012)(AR5 WG2 11.4.1).

Mortality and morbidity associated with flooding is becoming better understood although the surveillance of health effects of disasters remains inadequate (WHO, 2013). Additional flood mortality due to sea level rise has been estimated in the Netherlands (Maaskant *et al.*, 2009); and in the UK for river flooding (Hames and Vardoulakis, 2012) but estimates of future mortality due to flooding are highly uncertain. There remains limited evidence regarding the long term mental health impacts of flood events (Paranjothy *et al.*, 2011; WHO, 2013).

Evidence about future risks from climate change with respect to infectious diseases is still limited (Randolph and Rogers, 2010; Semenza and Menne, 2009; Semenza *et al.*, 2012). There have been developments in mapping the current and potential future distribution of important disease vector species in Europe. The Asian tiger mosquito *Aedes albopictus* (a vector of dengue and Chikungunya (Queyriaux *et al.*, 2008) is currently present in Southern Europe (ECDC, 2009) and may extend eastward and northward under climate change (Caminade *et al.*, 2012; Fisher *et al.*, 2011; Roiz *et al.*, 2011). The risk of introduction of dengue remains very low because it would depend upon the introduction and expansion of the *Ae. Aegypti* together with the absence of effective vector control measures (ECDC, 2012).

Climate change is unlikely to affect the distribution of visceral and cutaneous leishmaniasis (currently present in the Mediterranean region) in the near term (Ready, 2010). However, in the long term (15-20 years), there is potential for climate change to facilitate the expansion of either vectors or current parasites northwards (Ready, 2010). The risk of introduction of exotic Leishmania species was considered very low due to the low competence of current vectors (Fischer *et al.*, 2010a). The effect of climate change on the risk of imported or locally-transmitted (autochthonous) malaria in Europe has been assessed in Spain (Sainz-Elipe *et al.*, 2010), France (Linard *et al.*, 2009) and the UK (Lindsay *et al.*, 2010). Disease re-emergence would depend upon many factors including: the introduction of a large population of infectious people or mosquitoes, high levels of people-vector contact, resulting from significant changes in land use, as well as climate change (see chapter 11).

Since AR4, there is more evidence on implications of climate change on food safety at all stages from production to consumption (FAO, 2008a; Jacxsens *et al.*, 2010; Popov Janevska *et al.*, 2010). The sensitive of salmonellosis to temperature has declined in recent years (Lake *et al.*, 2009) and the overall incidence of salmonellosis is declining in most European countries (Semenza *et al.*, 2012). Climate change may also have affects on food consumption patterns. Weather affects pre and post harvest mycotoxin production but the implications of climate change are unclear. Cold regions may become liable to temperate-zone problems concerning contamination ochratoxin *A*, *patulin* and *Fusarium* toxins (Paterson and Lima, 2010). A control of the environment of storage facilities may avoid post-harvest problems but at additional cost (Paterson and Lima, 2010).

Other potential consequences concern marine biotoxins in seafood following production of phycotoxins by harmful algal blooms and the presence of pathogenic bacteria in foods following more frequent extreme weather conditions (Miraglia *et al.*, 2009). There is little evidence that climate change will affect human exposures to contaminants in the soil or water (e.g. persistent organic pollutants). Risk modelling is often developed for single exposure agents (e.g. a pesticide) with known routes of exposure. These are difficult to scale up to the population level. The multiple mechanisms by climate may affect transmission or contamination routes also makes this very complex (Boxall *et al.*, 2009).

Adaptation in the health sector has so far been largely limited to the development of heat health warning systems, but many research gaps regarding effective adaptation options (HPA, 2012). A survey of national infectious disease experts in Europe identified several institutional changes that needed to be addressed to improve future responses to climate change risks: ongoing surveillance programs, collaboration with veterinary sector and management of animal disease outbreaks, national monitoring and control of climate-sensitive infectious diseases, health services during an infectious disease outbreak and diagnostic support during an epidemic (Semenza *et al.*, 2012).

23.5.2. Critical Infrastructure

Critical national infrastructure is defined as the assets (physical or electronic) that are vital to the continued delivery and integrity of the essential services upon which a country relies, the loss or compromise of which would lead to severe economic or social consequences or to loss of life. Extreme weather events, such as floods, heat waves and wild fires are known to damage critical infrastructure. The UK floods in 2007 led to significant damage to power and water utilities, and to communications and transport infrastructure (Chatterton *et al.*, 2010) (Table 23-1). Forest fires can affect transport infrastructure, as well as the destruction of buildings. Major storms in Sweden and Finland have led to loss of trees, with damage to the power distribution network, leading to electricity blackouts lasting weeks, as well as the paralysis of services such as rail transport and other public services that depend on grid electricity.

Health system infrastructure (hospitals, clinics) is vulnerable to extreme events, particularly flooding (Radovic *et al.*, 2012). The heat waves of 2003 and 2006 had adverse effects on patients and staff in hospitals from overheating of buildings. Evidence from France and Italy indicate that death rates in in-patients increased significantly during heat wave events (Ferron *et al.*, 2006; Stafoggia *et al.*, 2008). Further, higher temperatures have had serious implications for the delivery of healthcare, as well drug storage and transport (Carmichael *et al.*, 2013).

23.5.3. Social Impacts

There is little evidence regarding the implications of climate change for employment and/or livelihoods in Europe. However, the evidence so far (as reviewed in this chapter) indicates that there are likely to be changes to some industries (e.g. tourism, agriculture) that may lead to changes in employment opportunities by region and by sector.

Current damages from weather-related disasters (floods and storms) are significant (23.3.1). Disasters have long lasting effects of the affected populations (Schnitzler *et al.*, 2007). Households are often displaced while their homes are repaired (Whittle *et al.*, 2010). Little research has been carried out on the impact of extreme weather events such as heat waves and flooding on temporary or permanent displacement in Europe. Coastal erosion associated with sea level rise, storm surges and coastal flooding will require coastal retreat in some of Europe's low lying areas (Philippart *et al.*, 2011). Managed retreat is also an adaptation option in some coastal areas. Concerns have been raised about equality of access to adaptation within coastal populations at risk from climate change. For example, a study in the UK found that vulnerability to climate change in coastal communities is likely to be increased by social deprivation (Zsamboky *et al.*, 2011).

In the European region, the indigenous populations are present in Arctic regions are considered vulnerable to climate change impacts on livelihoods and food sources (Arctic Climate Impact Assessment, 2005) [12.3.4, 28.2.4]. Research has focussed on indigenous knowledge, impacts on traditional food sources and community responses/adaptation (Mustonen and Mustonen, 2011a; Mustonen and Mustonen, 2011b). However, these communities are also experiencing rapid social, economic and other non-climate-related environmental changes (such as oil and gas exploration) [see 28.2.4]. There is evidence the climate change has altered the seasonal behaviour of pastoralist populations, such as the Nenets reindeer herders in northern Russia (Amstislavski *et al.*, 2013). However, socio-economic factors may be more important than climate change for the future sustainability of Reindeer husbandry (Rees *et al.*, 2008) [28.2.3.5].

23.5.4. Cultural Heritage and Landscapes

Climate change will affect culturally-valued buildings (Storm *et al.*, 2008) through extreme events and chronic damage to materials (Brimblecombe *et al.*, 2006; Brimblecombe and Grossi, 2010; Brimblecombe, 2010a; Brimblecombe, 2010b; Grossi *et al.*, 2011)(Sabbioni *et al.*, 2012). Cultural heritage is a non-renewable resource and impacts from environmental changes are assessed over long timescales (Brimblecombe and Grossi, 2008)(Bonazza *et al.*, 2009a; Bonazza *et al.*, 2009b; Brimblecombe and Grossi, 2009; Brimblecombe and Grossi, 2010; Grossi *et al.*, 2008). Climate change may also affect indoor environments where cultural heritage is preserved (Lankester and Brimblecombe, 2010) as well as visitor behaviour at heritage sites (Grossi *et al.*, 2010). There is also evidence to suggest that climate change and sea level rise will affect maritime heritage in the form of shipwrecks and other submerged archaeology (Björdal, 2012).

Surface recession on marble and compact limestone will be affected by climate change (Bonazza *et al.*, 2009a). Marble monuments in Southern Europe will continue to experience high levels of thermal stress (Bonazza *et al.*, 2009b) but warming is likely to reduce frost damage across Europe, except in Northern and Alpine Europe and permafrost areas (Iceland) (Grossi *et al.*, 2007; Sabbioni *et al.*, 2008). Damage to porous materials due to salt crystallisation may increase all over Europe (Benavente *et al.*, 2008; Grossi *et al.*, 2011). In Northern and Eastern Europe, wood structures will need additional protection against rainwater and high winds (Sabbioni *et al.*, 2012). AR4 concluded that current flood defences would not protect Venice from climate change. Venice now has a flood forecasting system, and is introducing the MOSE system of flood barriers (Keskitalo, 2010). Recent evidence suggests, however, that climate change may lead to a decrease in the frequency of extreme storm surges in this area (Troccoli *et al.*, 2012a).

Europe has many unique rural landscapes, which reflect the cultural heritage that has evolved from centuries of human intervention, e.g. the cork oak based Montado in Portugal, the Garrigue of southern France, Alpine meadows, grouse moors in the UK, machair in Scotland, peatlands in Ireland, the polders of Belgium and the Netherlands and vineyards. Many, if not all, of these cultural landscapes are sensitive to climate change and even small changes in the climate could have significant impacts (Gifford *et al.*, 2011). Alpine meadows, for example, are culturally important within Europe, but although there is analysis of the economics (tourism, farming) and functionality (water run-off, flooding and carbon sequestration) of these landscapes there is very little understanding of how climate change will affect the cultural aspects on which local communities depend. Because of their societal value, cultural landscapes are often protected and managed through rural development and environmental policies. The peat-rich uplands of northern Europe, for example, have begun to consider landscape management as a means of adapting to the effects of climate change (e.g. the moors for the future partnership in the Peak District National Park, UK). For a discussion of the cultural implications of climate change for vineyards see Box 23-2.

_____ START BOX 23-2 HERE _____

Box 23-2. Implications of Climate Change for European Wine and Vineyards

Wine production in Europe accounts for more than 60% of the global total (Goode, 2012) and makes an important contribution to cultural identity. Apart from impacts on grapevine yield, higher temperatures are also expected to affect wine quality in some regions and grape varieties by changing the ratio between sugar and acids (Bock *et al.*, 2011)(Santos *et al.*, 2011)(Duchêne *et al.*, 2010). In western and central Europe, projected future changes could benefit wine quality, but might also demarcate new potential areas for viticulture (Malheiro *et al.*, 2010). Adaptation measures are already occurring in some vineyards (e.g. vine management, technological measures, production control and to a smaller extent relocation) (Battaglini *et al.*, 2009; Duarte Alonso and O'Neill, 2011; Holland and Smit, 2010; Malheiro *et al.*, 2010; Moriondo *et al.*, 2011; Santos *et al.*, 2011).Vineyards may be displaced geographically beyond their traditional boundaries ('terroir' linked to soil, climate and traditions) (Metzger and Rounsevell, 2011), and in principle, wine producers could adapt to this problem by growing grape varieties that are more suited to warmer climates. Such technical solutions, however, do not account for the unique characteristics of wine production cultures and consumer perceptions of wine quality that strongly affect the prices paid for the best wines (Metzger and Rounsevell, 2011)(White *et al.*, 2009). It would become very difficult, for example, to produce fine wines from the cool-climate Pinot Noir grape within its traditional 'terroir' of Burgundy under many future climate scenarios, but consumers may not be willing to pay current day prices for red wines produced from other grape varieties (Metzger and Rounsevell, 2011). An additional barrier to adaptation is that wine is usually produced within rigid, regionally-specific, regulatory frameworks that often prescribe, amongst other things, what grapes can be grown where, e.g., the French AOC or the Italian DOC and DOCG designations. Suggestions have been made to replace these rigid concepts of regional identity with a geographically flexible 'terroir' that ties a historical or constructed sense of culture to the wine maker and not to the region (White *et al.*, 2009).

23.6. Implications of Climate Change for the Protection of Environmental Quality and Biological Conservation

Terrestrial and freshwater ecosystems provide a number of vital services for people and society, such as biodiversity, food, fibre, water resources, carbon sequestration and recreation (Box 23-1).

23.6.1. Air Quality

Climate change will have complex and local effects on pollution chemistry, transport, emissions and deposition. Outdoor air pollutants have adverse effects on human health, biodiversity, crop yields and cultural heritage. The main outcomes of concern are both the average (background) levels and peak events for tropospheric ozone, particulates, sulphur oxides (SO_x) and nitrogen oxides (NO_x). Future pollutant concentrations in Europe have been assessed using atmospheric chemistry models, principally for ozone (Forkel and Knoche, 2006; Forkel and Knoche, 2007). Reviews have concluded that GCM/CTM studies find that climate change per se (assuming no change in future emissions or other factors) is likely to increase summer tropospheric ozone levels (range 1–10 ppb) by 2050s in polluted areas (that is, where concentrations of precursor nitrogen oxides are higher) (AQEG, 2007; Jacob and Winner, 2009)[see also 21.4.1.3.2.]. The effect of future climate change alone on future concentrations of particulates, nitrogen oxides and volatile organic compounds is much more uncertain. Higher temperatures also affect natural emissions volatile organic compounds (VOCs) which are ozone precursors (Hartikainen *et al.*, 2012). One study has projected an increase in fire-related air pollution (O3 and PM10) in Southern Europe (Carvalho *et al.*, 2011).

Overall, the model studies are inconsistent regarding future projections of background level and exceedences. Recent evidence has shown adverse impacts on agriculture from even low concentrations of ozone, however, there is more consistent evidence now regarding the threshold for health (mortality) impacts of ozone. Therefore, it is unclear whether increases in background levels below health-related thresholds would be associated with an increased burden of ill health.

Some studies have attributed an observed increase in European ozone levels to observed warming (Meleux *et al.*, 2007), which appears to be driven by the increase in extreme heat events in 2003, 2006 and 2010 (Solberg *et al.*, 2008). Peak ozone events were observed during the major heat waves in Europe in multiple countries. Wildfire events have had an impact on local and regional on air quality (Hodzic *et al.*, 2007; Liu *et al.*, 2009; Miranda *et al.*, 2009) which have implications for human health (Analitis *et al.*, 2012) (Table 23-1).

23.6.2. Soil Quality and Land Degradation

The current cost of soil erosion, organic matter decline, salinisation, landslides and contamination is estimated to be EUR 38 billion annually for the EU (JRC-EEA, 2010), in the form of damage to infrastructures, treatment of water contaminated through the soil, disposal of sediments, depreciation of land and costs related to the ecosystem functions of soil (JRC-EEA, 2010). Projections show significant reductions in summer soil moisture in the Mediterranean region, and increases in the north-eastern part of Europe (Calanca *et al.*, 2006). Climate change impacts on erosion shows diverging evidence under the A2 scenario. In Tuscany, even with a decline in precipitation volume until 2070, in some month higher erosion rates would occur due to higher rainfall erosivity (Marker *et al.*, 2008). For two Danish river catchments, assuming a steady-state land use, suspended sediment transport would increase by 17-27% by 2071-2100 (Thodsen *et al.*, 2008; Thodsen, 2007). In Upper-Austria, with the regional climate model HadRM3H, a small reduction in average soil losses is projected for croplands in all tillage systems, however with high uncertainty (Scholz *et al.*, 2008). In Northern Ireland, erosion decreases are generally projected with downscaled GCMs for a case study hillslope (Mullan *et al.*, 2012).

Adaptive land-use management can reduce the impact of climate change through soil conservation methods like zero tillage and conversion of arable to grasslands (Klik and Eitzinger, 2010). In central Europe, compared to conventional tillage, conservation tillage systems reduced modelled soil erosion rates under future climate scenarios by between 49 and 87% (Scholz *et al.*, 2008). Preserving upland vegetation reduced both erosion and loss of soil carbon and favoured the delivery of a high quality water resource (House *et al.*, 2011); (McHugh, 2007). Maintaining soil water retention capacity, e.g. through adaptation measures (Post *et al.*, 2008), contributes to reduce risks of flooding as soil organic matter absorbs up to twenty times its weight in water.

23.6.3. Water Quality

Climate change may affect water quality in several ways, with implications for food production and forestry (23.4.3), ecosystem functioning (Box 23-1), human and animal health, and compliance with environmental quality standards, including those of the Water Framework Directive. Shallower waters will witness a more rapid temperature increase than deeper waters, since heat is absorbed mainly in the upper water layers and turbulent mixing is truncated by shallow depth. In parallel, a decrease in saturating oxygen concentrations occurs. Since AR4, there is further evidence of adverse effects caused by extreme weather events: reductions in dissolved oxygen, algal blooms (Mooij *et al.*, 2007; Ulén and Weyhenmeyer, 2007) during hot weather, and contamination of surface and coastal waters with sewage and/or chemicals (pesticides) after rainfall (Boxall *et al.*, 2009). A reduction in rainfall may lead to low flows which increase concentrations of biological and chemical contaminants. Reduced drainage can also enhance sedimentation in drainage systems and hence enhance particle-bound phosphorous retention and reduce phosphorous load to downstream higher order streams (Hellmann and Vermaat, 2012).

Variability in changes in rainfall and run-off, as well as water temperature increases, will lead to differences in water quality impacts by sub-region. Climate change is projected to increase nutrient loadings: in Northern Europe this is caused by increased surface runoff; in Southern Europe this is caused by increased evapotranspiration and increased concentrations due to reduced volumes of receiving lakes (Jeppesen *et al.*, 2011). Local studies generally confirm this pattern: increased nutrient loads are foreseen in Danish watersheds (Andersen *et al.*, 2006), France (Delpla *et al.*, 2011) and the UK (Howden *et al.*, 2010; Macleod *et al.*, 2012; Whitehead *et al.*, 2009); AR5 WG2 Chapter

4.3.2.5). In larger rivers, such as the Meuse, increased summer temperature and drought can lead to more favourable conditions for algal blooms and reduced dilution capacity of effluent from industry and sewage works (van Vliet and Zwolsman, 2008).

23.6.4. Terrestrial and Freshwater Ecosystems

Current and future climate changes including CO_2 increase are determining negative effects of habitat loss on species density and diversity (Mantyka-pringle *et al.*, 2012)(Rickebusch *et al.*, 2008). Projected habitat loss is greater for species at higher elevations (Engler *et al.*, 2011)(Castellari, 2009; Dullinger *et al.*, 2012) and suitable habitats for Europe's breeding birds are projected to shift nearly 550 km northeast by the end of the century (Huntley *et al.*, 2007). Aquatic habitats and habitat connectivity in river networks may become increasingly fragmented (Blaustein *et al.*, 2010; Della Bella *et al.*, 2008; Elzinga *et al.*, 2007; Gómez-Rodríguez *et al.*, 2010; Hartel *et al.*, 2011; Morán-López *et al.*, 2012)(Harrison *et al.*, 2008)(Clark *et al.*, 2010a)(Clark *et al.*, 2010; Fronzek *et al.*, 2006; Fronzek *et al.*, 2010; Fronzek *et al.*, 2011; Gallego-Sala *et al.*, 2010). Despite some local successes and increasing responses, the rate of biodiversity loss does not appear to be slowing (Butchart *et al.*, 2010). The effectiveness of Natura 2000 areas to respond to climate change has been questioned (Araújo *et al.*, 2011). However, when considering connectivity related to the spatial properties of the network, the Natura 2000 network appears rather robust (Mazaris *et al.*, 2013). Several studies now highlight the importance of taking into account climate change projections in the selection of conservation areas (Araújo *et al.*, 2011; Ellwanger *et al.*, 2011; Filz *et al.*, 2013; Virkkala *et al.*, 2013).

Observed changes in plant communities in European mountainous regions show a shift of species ranges to higher altitudes resulting in species richness increase in boreal-temperate mountain regions and decrease in Mediterranean mountain regions (Pauli *et al.*, 2012)(Gottfried *et al.*, 2012). In Southern Europe, a great reduction in phylogenetic diversity of plant, bird and mammal assemblages will occur, and gains are expected in regions of high latitude or altitude for 2020, 2050 and 2080. However, losses will not be offset by gains and a trend towards homogenization across the continent will be observed (Thuiller *et al.*, 2011)(Alkemade *et al.*, 2011). Large range contractions due to climate change are projected for several populations of *Pinus cembra* and *Pinus Sylvestris* (Casalegno et al.,2010)(Giuggiola *et al.*, 2010) while for the dominant Mediterranean tree species, Holm oak, a substantial range expansion is projected under A1B emissions scenario (Cheaib *et al.*, 2012). The human impacts on distribution of tree species landscape may make them more vulnerable to climate change (del Barrio *et al.*, 2006; Hemery *et al.*, 2010).

Observed climate changes are altering breeding seasons, timing of spring migration, breeding habitats, latitudinal distribution and migratory behaviour of birds (Feehan *et al.*, 2009) (Jonzén *et al.*, 2006; Rubolini *et al.*, 2007a; Rubolini *et al.*, 2007b)(Lemoine *et al.*, 2007a; Lemoine *et al.*, 2007b). A northward shift in bird community composition has been observed (Devictor *et al.*, 2008). Common species of European birds with the lowest thermal maxima have showed the sharpest declines between 1980 and 2005 (Jiguet *et al.*, 2010).

Projections for 120 native terrestrial non-volant European mammals suggest that 5-9% are at risk of extinction, assuming no migration, during the 21st century due to climate change, while 70-78% may be severely threatened under A1 and B2 climatic scenarios (Levinsky *et al.*, 2007). Those populations not showing a phenological response to climate change may decline (Moller *et al.*, 2008), such as amphibian and reptile species (Araújo *et al.*, 2006), or experience ecological mismatches (Saino *et al.*, 2011). Climate change can affect trophic interactions, as co-occurring species may not react in a similar manner. Novel emergent ecosystems composed of new species assemblages arising from differential rates of range shifts of species can occur (Keith *et al.*, 2009; Montoya and Raffaelli, 2010; Schweiger *et al.*, 2012).

Since invasive alien species rarely change their original climatic niches (Petitpierre *et al.*, 2012), climate change can exacerbate the threat posed by invasive species to biodiversity in Europe (West *et al.*, 2012) amplifying the effects of introduction of the exotic material such as alien bioenergy crops (EEA, 2012), pest and diseases (Aragòn and Lobo, 2012), tropical planktonic species (Cellamare *et al.*, 2010) and tropical vascular plants (Skeffington and Hall, 2011; Taylor *et al.*, 2012).

23.6.5. Coastal and Marine Ecosystems

Climate change will affect Europe's coastal and marine ecosystems by altering the biodiversity, functional dynamics and ecosystem services of coastal wetlands, dunes, inter-tidal and subtidal habitats, offshore shelves, seamounts and currents (Halpern *et al.*, 2008) through changes in eutrophication, invasive species, species range shifts, changes in fish stocks and habitat loss (Doney *et al.*, 2011)(EEA, 2010d). The relative magnitude of these changes will vary temporally and spatially, requiring a range of adaptation strategies that target different policy measures, audiences and instruments (Philippart *et al.*, 2011)(Airoldi and Bec, 2007).

Europe's northern seas are experiencing greater increases in sea surface temperatures (SSTs) than the southern seas, with the Baltic, North and Black seas warming at 2-4 times the mean global rate (Philippart *et al.*, 2011)(Belkin, 2009). In the Baltic, decreased sea ice will expose coastal areas to more storms, changing the coastal geomorphology (BACC, 2008)(HELCOM, 2007). Warming SSTs will influence biodiversity and drive changes in depth and latitudinal range for intertidal and sub-tidal marine communities, particularly in the North and Celtic seas (Hawkins *et al.*, 2011)(Sorte *et al.*, 2010)(Wethey *et al.*, 2011).

Warming is affecting food chains and changing phenological rates (Durant *et al.*, 2007). For example, changes in the timing and location of phytoplankton and zooplankton are affecting North Sea cod larvae (Beaugrand *et al.*, 2010)(Beaugrand and Kirby, 2010). Temperature changes have affected the distribution of fisheries in all seas over the past 30 years (Beaugrand and Kirby, 2010)(Hermant *et al.*, 2010). Warmer waters also increase the rate of the establishment and spread of invasive species, further altering trophic dynamics and the productivity of coastal marine ecosystems (Molnar *et al.*, 2008)(Rahel and Olden, 2008). Changes in the semi-enclosed seas could be indicative of future conditions in other coastal-marine ecosystems (Lejeusne *et al.*, 2009). In the Mediterranean, invasive species have arrived in recent years at the rate of one introduction every 4 to 5 weeks (Streftaris *et al.*, 2005). While in this case the distribution of endemic species remained stable, most non-native species have spread northward by an average of 300 km since the 1980s, resulting in an area of spatial overlap with invasive species replacing natives by nearly 25% in 20 years.

Dune systems will be lost in some places due to coastal erosion from combined storm surge and sea level rise, requiring restoration (Day *et al.*, 2008)(Ciscar *et al.*, 2011)(Magnan *et al.*, 2009). In the North Sea, the Iberian coast, and Bay of Biscay, a combination of coastal erosion, infrastructure development and sea defences may lead to narrower coastal zones ("coastal squeeze") (EEA, 2010d)(Jackson and McIlvenny, 2011)(OSPAR, 2010).

23.7. Cross-Sectoral Adaptation Decision-making and Risk Management

Studies on impacts and adaptation in Europe generally consider single sectors or outcomes, as described in the previous sections of this chapter. For adaptation decision-making, more comprehensive approaches are required. Considerable progress has been made to advance planning and development of adaptation measures, including the economic analyses (Section 23.7.6) (see Box 23-3), and the developed of climate services (Medri *et al.*, 2012; WMO, 2011). At the international level, the European Union has started adaptation planning, through information sharing (Climate-ADAPT platform) and legislation (EC, 2013a). National and local governments are also beginning to monitor progress on adaptation, including the development of a range of indicators (UK-ASC, 2011).

_____ START BOX 23-3 HERE _____

Box 23-3. National and Local Adaptation Strategies

The increasing number of national (EEA, 2013) and local (Heidrich *et al.*, 2013) adaptation strategies in Europe has led to research on their evaluation and implementation (Biesbroek *et al.*, 2010b). Many adaptation strategies were found to be agendas for further research, awareness raising and/or coordination and communication for implementation (e.g. (Dumollard and Leseur, 2011; Pfenniger *et al.*, 2010). Actual implementation often was limited to disaster risk reduction, environmental protection, spatial planning (23.7.4), and coastal zone and water resources management. The implementation of planned adaptation at the national level was attributed to political will and good financial and information capacity (Westerhoff *et al.*, 2011). Analysis of seven national adaptation strategies (Denmark, Finland, France, Germany, Netherlands, Spain, UK) found that that while there is a high political commitment to adaptation planning and implementation, evaluation of the strategies and actual implementation is yet to be defined (Biesbroek *et al.*, 2010a; Swart *et al.*, 2009b; Westerhoff *et al.*, 2011). One of the earliest national adaptation strategies (Finland) has been evaluated, in order to compare identified adaptation measures with those launched in different sectors. It has found that while good progress has been made on research and identification of options, few measures have been implemented except in the water resources sector (Ministry of Agriculture and Forestry, 2009).

At the local government level, adaptation plans are being developed in several cities (EEA, 2013), including London (GLA, 2010), Madrid, Manchester, Copenhagen, Helsinki, and Rotterdam. Adaptation in general is a low priority for many European cities, and many plans do not have adaptation priority as the main focus (Carter, 2011). Many studies are covering sectors sensitive to climate variability, as well as sectors that are currently under pressure from socioeconomic development. A recent assessment found a lack of cross-sector impact and adaptation linkages as an important weakness in the city plans (Hunt and Watkiss, 2011). Flexibility in adaptation decision making needs to be maintained (Hallegatte *et al.*, 2008)(Biesbroek *et al.*, 2010b).

_____ END BOX 23-3 HERE _____

23.7.1. Coastal Zone Management

Coastal zone management and coastal protection plans that integrate adaptation concerns are now being implemented. Underlying scientific studies increasingly assess effectiveness and costs of specific options (Hilpert *et al.*, 2007)(Kabat *et al.*, 2009)(Dawson *et al.*, 2011) (23.7.6). Early response measures are needed for floods and coastal erosion, to ensure that climate change considerations are incorporated into marine strategies, with mechanisms for regular updating (OSPAR, 2010; UNEP, 2010).

In the Dutch plan for flood protection (Delta Committee, 2008), adaptation to increasing river runoff and sea level rise plays a prominent role. It also includes synergies with nature conservation and fresh water storage (Kabat *et al.*, 2009), and links to urban renovation (cost estimates are included in Section 23.7.6). While that plan mostly relies on large scale measures, new approaches such as small-scale containment of flood risks through compartmentalisation are also studied (Klijn *et al.*, 2009). The UK government has developed extensive adaptation plans (TE2100) to adjust and improve flood defences for the protection of London from future storm surges and flooding (Environmental Agency, 2009). An elaborate analysis has provided insight in the pathways for different adaptation options and decision-pointss that will depend on the eventual sea-level rise.

23.7.2. Integrated Water Resource Management

Water resources management in Europe has experienced a general shift from “hard” to “soft” measures that allow more flexible responses to environmental change (Pahl-Wostl, 2007). Integrated water resource management explicitly includes the consideration of environmental and social impacts (Wiering and Arts, 2006). Climate change has been incorporated into water resources planning in England and Wales (Arnell, 2011)(Charlton and Arnell, 2011)(Wade *et al.*, 2013) and in the Netherlands (de Graaff *et al.*, 2009). The robustness of adaptation strategies for water management in Europe has been tested in England (Dessai and Hulme, 2007) and Denmark (Haasnoot *et al.*, 2012; Refsgaard *et al.*, 2013). Other studies have emphasised the search for robust pathways, for instance in the Netherlands (Haasnoot *et al.*, 2012; Kwadijk *et al.*, 2010). Public participation has also increased in decision making, e.g. river basin management planning (Huntjens *et al.*, 2010), flood defence plans (e.g. TE2100), and drought contingency plans (Iglesias *et al.*, 2007). Guidance has been developed on the inclusion of adaptation in water management (UNECE, 2009) and river basin management plans (EC, 2009b). Adaptation in the water sector could also be achieved through the EU Water Framework and Flood Directives (Quevauviller, 2011), but a study of decision makers, including local basin managers, identified several important barriers to this (Brouwer *et al.*, 2013). Water allocation between upstream and downstream countries is challenging in regions exposed to prolonged droughts such as the Euphrates-Tigris river basin, where Turkey plans to more than double water abstraction by 2023(EEA, 2010a).

23.7.3. Disaster Risk Reduction and Risk Management

A series of approaches to disaster risk management are employed in Europe, in response to national and European policy developments to assess and reduce natural hazard risks. New developments since the AR4 include assessment and protection efforts in accordance with the EU Floods Directive (European Parliament and Council, 2007), the mapping of flood risks, improve civil protection response and early warning systems (Ciavola *et al.*, 2011). Most national policies address hazard assessment and do not include analyses of possible impacts (de Moel *et al.*, 2009). The effectiveness has been assessed of flood protection (Bouwer *et al.*, 2010) and also non-structural or household level measures to reduce losses from river flooding (Botzen *et al.*, 2010a)(Dawson *et al.*, 2011). Some studies show that current plans may be insufficient to cope with increasing risks from climate change, as shown for instance for the Rhine river basin (Te Linde *et al.*, 2010a; Te Linde *et al.*, 2010b).

Other options that are being explored are the reduction of consequences, response measures, and increasing social capital (Kuhlicke *et al.*, 2011), as well as options for insuring and transferring losses (Section 23.3.7). The Netherlands carried out a large-scale analysis and simulation exercise to study the possible emergency and evacuation response for a worst-case flood event (ten Brinke *et al.*, 2010). Increasing attention is also being paid in Europe to non-government actions that can reduce possible impacts from extreme events. Terpstra and Gutteling (2008) found through a survey that individual citizens are willing to assume some responsibility for managing flood risk, and they are willing to contribute to preparations in order to reduce impacts. Survey evidence is available for Germany and the Netherlands that, under certain conditions, individuals can be encouraged to adopt loss prevention measures (Thieken *et al.*, 2006)(Botzen *et al.*, 2009). Small businesses can reduce risks when informed about possibilities immediately after an event (Wedawatta and Ingirige, 2012).

23.7.4. Land Use Planning

Spatial planning policies can build resilience to the impacts of climate change (Bulkeley, 2010). However, the integration of adaptation into spatial planning is often limited to a general level of policy formulation that can sometimes lack concrete instruments and measures for implementation in practice (Mickwitz *et al.*, 2009)(Swart *et al.*, 2009a). There is evidence to suggest the widespread failure of planning policy to account for future climate change (Branquart *et al.*, 2008). Furthermore, a lack of institutional frameworks to support adaptation is, potentially, a major barrier to the governance of adaptation through spatial planning (ESPACE, 2007)[chapter 16]. Climate change adaptation is often treated as a water management or flooding issue, which omits other important aspects of the contribution of land use planning to adaptation (Mickwitz *et al.*, 2009)(Wilson, 2006)(Van Nieuwaal *et al.*, 2009). For example, in the UK, houses were still being built in flood risk areas (2001-2011) due to competing needs to increase the housing stock (ARUP, 2011).

City governance is also dominated by the issues of climate mitigation and energy consumption rather than in adapting to climate change (Bulkeley, 2010; Heidrich *et al.*, 2013). Some cities, e.g. Rotterdam, have started to create climate adaptation plans and this process tends to be driven by the strong political leadership of mayors (Sanchez-Rodriguez, 2009). The Helsinki Metropolitan Area's Climate Change Adaptation Strategy (HSY, 2010) is a regional approach focusing on the built environment in the cities of Helsinki, Espoo, Vantaa and Kauniainen, and their surroundings. It includes approaches for dealing with increasing heat waves, more droughts, milder winters, increasing (winter) precipitation, heavy rainfall events, river floods, storm surges, drainage water floods and sea level rise.

Green infrastructure provides both climate adaptation and mitigation benefits as well as offering a range of other benefits to urban areas, including health improvements, amenity value, inward investment, and the reduction of noise and outdoor air pollution. Green infrastructure is an attractive climate adaptation option since it also contributes to the sustainable development of urban areas (Gill *et al.*, 2007; James *et al.*, 2009). Urban green space and green roofs can moderate temperature and decrease surface rainwater run-off (Gill *et al.*, 2007). Despite the benefits however of urban green space, conflict can occur between the use of land for green space and building developments (Hamin and Gurran, 2009).

European policies for biodiversity (e.g. the European Biodiversity Strategy (EC, 2011)) look to spatial planning to help protect and safeguard internationally and nationally designated sites, networks and species, as well as locally valued sites in urban and non-urban areas, and to create new opportunities for biodiversity through the development process (Wilson, 2008). Conservation planning in response to climate change impacts on species aims to involve several strategies to better manage isolated habitats, increase colonisation capacity of new climate zones and optimise conservation networks to establish climate refugia (Vos *et al.*, 2008).

23.7.5. Rural Development

Rural development is one of the key policy areas for Europe, yet there is little or no discussion about the role of climate change in affecting future rural development. The EU White Paper on adapting to climate change (EC, 2009a) encourages Member States to embed climate change adaptation into the three strands of rural development aimed at improving competitiveness, the environment, and the quality of life in rural areas. It appears however that little progress has been made in achieving these objectives.

For example, the EUs Leader programme was designed to help rural actors improve the long-term potential of their local areas by encouraging the implementation of sustainable development strategies. Many Leader projects address climate change adaptation, but only as a secondary or in many cases a non-intentional by-product of the primary rural development goals. The World Bank’s community adaptation project has seen a preponderance of proposals from rural areas in Eastern Europe and Central Asia (Heltberg *et al.*, 2012) suggesting that adaptation based development needs in Eastern Europe are currently not being met by policy.

23.7.6. Economic Assessments of Adaptation

Compared to studies assessed in AR4 (AR4 WG2 Chapter 17.2.3), costs estimates for Europe are increasingly derived from bottom-up and sector-specific studies, aimed at costing response measures (Watkiss and Hunt, 2010), in addition to the economy-wide assessments (Aaheim *et al.*, 2012). The evidence base, however, is still fragmented and incomplete. The coverage of adaptation costs and benefit estimates is dominated by structural (physical) protection measures, where effectiveness and cost components can be more easily identified. For energy, agriculture, infrastructure there is medium coverage of cost and benefit categories. There is a lack of information regarding adaptation costs in the health and social care sector. Table 23-2 summarises some of the more comprehensive cost estimates for Europe for sectors at regional and national level. It is stressed that the costing studies use a range of methods and metrics and relate to different time periods and sectors, which renders robust comparison difficult. As an example, there are large differences between the cost estimates for coastal and river protection in the Netherlands and other parts of Europe (Table 23-2), this is due to the objectives for adaptation and the large differences in the level of acceptable risk. For example, Rojas *et al.* (2013) assess a 1 in 100 year level of protection for Europe, while the Netherlands has set standards up to 1 in 4,000 and 10,000 year level return periods. More detailed treatment of the economics of adaptation is provided in AR5 WG2 Chapter 17.

[INSERT TABLE 23-2 HERE
Table 23-2: Selected published cost estimates for planned adaptation in European countries.]

23.7.7. Barriers and Limits to Adaptation

The implementation of adaptation options presents a range of opportunities, constraints and limits. Constrains (barriers) to implementation are financial, technical and political (see discussion in AR5 WG2 16). Some impacts will be unavoidable due to limits (physical, technological, social, economic or political). Examples of limits in the European context are described by sector in Table 23-3. For example, the contraints on building or extending flood defences would include pressure for land, conservation needs, and amenity value of coastal areas (AR5 WG2 5.5.5).

Towards the end of the century, it is likely that adaptation limits are expected to be reached earlier under higher rates of warming. Opportunities and co-benefits of adaptation are also discussed in section 23.8 below.

[INSERT TABLE 23-3 HERE
Table 23-3: Limits to adaptation to climate change.]

23.8. Co-Benefits and Unintended Consequences of Adaptation and Mitigation

Scientific evidence for decision making is more useful if impacts are considered in the context of impacts on other sectors and in relation to adaptation, mitigation and other important policy goals. The benefits of adaptation and mitigation policies can be felt in the near term and in the local population, although benefits relating to greenhouse gas emissions reduction may not be apparent until the longer term. The benefits of adaptation measures are often assessed using conventional economic analyses, some of which include non-markets costs and benefits (externalities)(Watkiss and Hunt, 2010). This section will describe policies, strategies and measures where there is good evidence regarding mitigation/adaptation costs and benefits. Few studies have quantified directly the trade-offs/synergies for a given policy.

23.8.1. Production and Infrastructure

Mitigation policies (decarbonisation strategies) are likely to have important implications for dwellings across Europe. The unintended consequences of mitigation in the housing sector include: changes to household energy prices and adverse effects from decreased ventilation in dwellings (Mavrogianni *et al.*, 2012)(Davies and Oreszczyn, 2012)(Jenkins *et al.*, 2008; Jenkins, 2009). The location, type and dominant energy use of the building will determine its overall energy gain or loss to maintain comfort levels. Adaptation measures such as the use of cooling devices will probably increase a building's energy consumption if no other mitigation measures are applied. The potential for cooling dwellings without increased energy consumption, and with health benefits is large (Wilkinson *et al.*, 2009).

When looking at the broader context of urban infrastructures, despite existing efforts to include both adaptation, and mitigation into sustainable development strategies at city level (e.g. Hague, Rotterdam, Hamburg, Madrid, London, Manchester), priority on adaptation still remains low (Carter, 2011). There is potential to develop strategies that can address both mitigation and adaptation solutions, as well as have health and environmental benefits (Milner *et al.*, 2012). In energy supply, the adverse effect of climate change on water resources in some coastal regions in southern Europe may further enhance the development of desalination plants as an adaptation measure, possibly increasing energy consumption and thus greenhouse gases emissions. Coastal flood defence measures may alter vector habits and have implications for local vector-borne disease transmission (Medlock and Vaux, 2013).

In tourism, adaptation and mitigation may be antagonistic, as in the case of artificial snowmaking in European ski resorts which requires significant amounts of energy and water (OECD, 2007; Rixen *et al.*, 2011) and the case of desalination for potable water production which also requires energy. However, depending on the location and size of the resort, implications are expected to differ and thus need to be investigated on a case-by-case basis. A similar relationship between adaptation and mitigation may hold for tourist settlements in southern Europe, where expected temperature increases during the summer may require increased cooling in order to maintain tourist comfort and thus increase greenhouse gas emissions and operating costs. Furthermore, a change of tourist flows as a result of tourists adapting to climate change may affect transport emissions, while mitigation in transport could also lead to a change in transport prices and thus possibly affect tourist flows.

23.8.2. Agriculture, Forestry, and Bioenergy

Agriculture and forestry face two challenges under climate change, both to reduce emissions and to adapt to a changing and more variable climate (Smith and Olesen, 2010)(Lavalle *et al.*, 2009). The agriculture sector contributes to about 10% of the total anthropogenic greenhouse gas (GHG) emissions in the EU27 (EEA, 2010b). Estimates of European carbon dioxide, methane and nitrous oxide fluxes between 2000 and 2005 suggest that methane emissions from livestock and nitrous oxide emissions from agriculture are fully compensated for by the carbon dioxide sink provided by forests and by grassland soils (Schulze *et al.*, 2010). However, projections following a baseline scenario suggest a significant decline (-25 to -40%) of the forest carbon sink of the EU until 2030 compared to 2010. Using wood for bioenergy results initially in a carbon debt due to reduced storage in forests, which affects the net GHG balance depending on the energy type that is replaced and the time span considered (McKechnie et al., 2011). Including additional bioenergy targets of EU member states has an effect on the development of the European forest carbon sink (and on the carbon stock), which is not accounted for in the EU emission reduction target (Bottcher *et al.*, 2012).

In arable production systems, adapting to climate change by increasing the resilience of crop yields to heat and to rainfall variability would have positive impacts on mitigation by reducing soil erosion, as well as soil organic carbon and nitrogen losses. Improving soil water holding capacity through the addition of crop residues and manure to arable soils, or by adding diversity to the crop rotations, may contribute both to adaptation and to mitigation (Smith and Olesen, 2010). There are also synergies and trade-offs between mitigation and adaptation options for soil tillage, irrigation and livestock breeding (Smith and Olesen, 2010). Reduced tillage (and no-till) may contribute to both adaptation and mitigation as it tends to reduce soil erosion and run-off (Soane *et al.*, 2012) and fossil-fuel use (Khaledian *et al.*, 2010), while increasing in some situations soil organic carbon stock (Powlson *et al.*, 2011). However, increased N_2O emission may negate the mitigation effect of reduced tillage (Powlson *et al.*, 2011). Irrigation may enhance soil carbon sequestration in arable systems (Rosenzweig *et al.*, 2008)(Rosenzweig and Tubiello, 2007), but increased irrigation under climate change would increase energy use and may reduce water availability for hydro-power (reduced mitigation potential) (Wreford *et al.*, 2010). In intensive livestock systems, warmer conditions in the coming decades might trigger the implementation of enhanced cooling and ventilation in farm buildings (Rosenzweig and Tubiello, 2007), thereby increasing energy use and associated GHG emissions. In grass-based livestock systems, adaptation by adjusting the mean annual animal stocking density to the herbage growth potential (Graux *et al.*, 2012) is *likely* to create a positive feedback on GHG emissions per unit area (Soussana and Luscher, 2007; Soussana *et al.*, 2010).

Land management options may also create synergies and trade-offs between mitigation and adaptation. Careful adaptation of forestry and soil management practices will be required to preserve a continental ecosystem carbon sink in Europe (Schulze *et al.*, 2010) despite the vulnerability of this sink to climatic extremes (Ciais *et al.*, 2005) and first signs of carbon sink saturation in European forest biomass (Nabuurs *et al.*, 2013). In areas that are vulnerable to extreme events (e.g. fires, storms, droughts) or with high water demand, the development of bioenergy production from energy crops and from agricultural residues (De Wit *et al.*, 2011) (Fischer *et al.*, 2010b) could further increase demands on adaptation (Wreford *et al.*, 2010). Conversely, increased demands on mitigation could be induced by the potential expansion of agriculture at high latitudes which may release large amounts of carbon and nitrogen from organic soils (Rosenzweig and Tubiello, 2007).

23.8.3. Social and Health Impacts

Significant research has been undertaken since AR4 on the health co-benefits of mitigation policies (see WGIII chapters on Housing, Transport and Energy, and WGII chapter 11). Several assessment have quantified benefits in terms of lives saved by reducing particulate air pollution, and trying to coherent policy objectives for emissions reductions in local and global pollution. Policies that improve health from changes in transport and energy can be said to have a general benefit to population health and resilience (Haines *et al.*, 2009a; Haines *et al.*, 2009b).

Changes to housing and energy policies also have indirect implications for human health. Researches on the benefits of various housing options (including retrofitting) have been intensively addressed in the context of low energy, healthy and sustainable housing (see WGIII).

23.8.4. Environmental Quality and Biological Conservation

There are several conservation management approaches that can address both mitigation, adaptation and biodiversity objectives (Lal *et al.*, 2011). Some infrastructure adaptation strategies, such as desalinisation, sea defences and flood control infrastructure may have negative effects on both mitigation and biodiversity. However, approaches, such as forest conservation and urban green space (23.7.4) have multiple benefits and potentially significant effects. There has been relatively little research about the impacts of future land use demand for bioenergy production, food production and urbanisation on nature conservation.

Figure 23-6 (Paterson *et al.*, 2008) summarizes the evidence regarding mitigation and adaptation options on biodiversity assessed from the literature. The figure shows that the options that come closest to being win-win-win are green rooftops, urban tree planting, forest conservation and low-till cultivation. Other options with clear benefits are afforestation, forest pest control, increased farmland irrigation and species translocation.

[INSERT FIGURE 23-6 HERE
Figure 23-6: Adaptation and mitigation options and their effects on biodiversity. The horizontal axis ranges from positive effects on biodiversity (left-hand side) to negative effects (right-hand side). Each mitigation/adaptation option is located on the biodiversity effect axis (solid bars), including an estimate of the uncertainties associated with the assessment (error bars). The various options are given vertically with mitigation at the top and adaptation at the bottom. Options located toward the centre of the vertical axis have benefits for both mitigation and adaptation. Thus, options located at the centre left of the figure have benefits for mitigation, adaptation and biodiversity and hence are labelled as 'win-win-win'. Other combinations of benefits and dis-benefits are labelled accordingly, e.g. win-lose-win, lose-win-lose, etc. Based on Paterson et al., 2009.]

23.9. Synthesis of Key Findings

23.9.1. Key Vulnerabilities

Climate change will have adverse impacts in nearly all sectors and across all sub-regions. Table 23-4 describes the range of impacts projected in 2050 on infrastructure, settlements, environmental quality and the health and welfare of the European population. The projected impacts of climate change on ecosystem services (including food production) are described in Box 23-1. A key finding is that all sub-regions are vulnerable to some impacts from climate change but that these impacts differ significantly in type between the sub-regions. Impacts in neighbouring regions (inter-regional) may also redistribute economic activities across the European landscape. The sectors most likely to be affected by climate change, and therefore with implications for economic activity and population movement (changes in employment opportunities) include: tourism (23.3.6), agriculture (23.4.1), and forestry (23.4.4).

[INSERT TABLE 23-4 HERE
Table 23-4: Assessment of climate change impacts by sub-region by 2050, assuming a medium emissions scenario, and no planned adaptation. Impacts assume economic development, including land use change. Impacts are assessed for the whole sub-region, although differences in impact within sub-regions are estimated for some impacts.]

The majority of published assessments are based on climate projections in the range 1-4 degrees global mean temperature per century. Under these scenarios, regions in Europe may experience higher rates of warming (in the range 4-6 degrees per century), due to climate variability (Jacob et al. 2013). Limited evidence exists on the potential impacts in Europe under very high rates of warming (>4 degrees above pre-industrial levels) but these would lead to large increase in coastal flood risk as well as impacts on global cereal yields and other effects on the global economy (AR5 WG2 19.5.1).

Many key vulnerabilities are already well known since the AR4, but some new vulnerabilities are emerging based on the evidence reviewed in this report. The policy/governance context in Europe is extremely important in determining key vulnerabilities (either reducing or exacerbating vulnerability) since Europe is a highly regulated region. Further, vulnerability will be strongly affected by changes in the non-climate drivers of change (e.g. economic, social protection measures, governance, technological drivers).

Extreme events affect multiple sectors and have the potential to cause a systemic impacts from secondary effects (chapter 19). Past events indicate the vulnerability of transport, energy, agriculture, water resources and health systems. Resilience to very extreme events varies by sector, and by country (Ludwig *et al.*, 2011; Pitt, 2008; Ulbrich *et al.*, 2012). Extreme events (heat waves and droughts) have had significant impacts on populations as well impacts on multiple economic sectors (Table 23-1), and resilience to future heat waves has only been addressed within some sectors. However, there is surprisingly little evidence regarding the impacts of major extreme events (e.g. Russian heat wave of 2010) and on responses implemented post-event to increase resilience. Future vulnerability will also be strongly affected by cross-sectoral (indirect) interactions, e.g. flooding-ecosystems, agriculture-species, agriculture-cultural landscapes, and so on.

Climate change is likely to have significant impacts on future water availability, and the increased risks of water restrictions in Southern, Central and Atlantic sub-regions. Studies indicate a significant reduction in water availability from river abstraction and from groundwater resources, combined to increased demands from a range of sectors (irrigation, energy and industry, domestic use) and to reduced water drainage and run-off (as a result of increased evaporative demand) (Ludwig *et al.*, 2011).

Climate change will affect rural landscapes by modifying relative land values, and hence competition, between different land-uses (Smith *et al.*, 2010). This will occur directly, e.g. through changes in the productivity of crops and trees [23.4], and indirectly through climate change impacts on the global supply of land-based commodities and their movement through international trade [23.9.2].

Climate change will have a range of impacts in different European sub-regions. The adaptive capacity of populations is likely to vary significantly within Europe. Adaptive capacity indicators have been developed based on future changes in socio-economic indicators and projections (Lung *et al.*, 2012; Metzger *et al.*, 2008)(Acosta *et al.*, 2013). These studies concluded that the Nordic countries have higher adaptive capacity than most of the Southern European countries, with countries around the Mediterranean having a lower capacity than the countries around the Baltic Sea region. Some regions or areas are particularly vulnerable to climate change:

- Populations and infrastructure in coastal regions are likely to be adversely affected by sea level rise, particularly after mid-century [23.3.1, 23.5.3].
- Urban areas are also vulnerable due to high density of people and built infrastructure from weather extremes [23.3, 23.5.1].
- High mountains. Due to high impact of climate change on natural hazard, water and snow resources and lack of migration possibilities for plant species, mountain regions concentrate vulnerabilities in infrastructure for transport and energy sectors, as well as for tourism, agriculture and biodiversity
- Mediterranean region will suffer multiple stresses and systemic failures due to climate changes. Changes in species composition, increase of alien species, habitat losses and degradation both in land and sea together with agricultural and forests production losses due to increasing heat waves and droughts exacerbated also by the competition for water will increase the sub-region vulnerability (Ulbrich *et al.*, 2012).

The following risks have emerged from observations of climate sensitivity and observed adaptation:

- Arable crop yields. There is new evidence to suggest that crop yields and production may be more vulnerable as a result of increasing climate variability. This will limit the potential poleward expansion of agricultural production. Limits to genetic progress to adapt are increasingly reported.

- New evidence regarding implications during summer on inland waterways (decreased access) and long range ocean transport (increased access).
- Terrestrial and freshwater species are vulnerable from climate-change shifts in habitats. There is new evidence that species cannot populate new habitat due to habitat fragmentation (urbanization). Observed migration rates are less than that assumed in modelling studies. There are legal barriers to introducing new species (e.g. forest species in France). New evidence that phenological mismatch will cause additional adverse effects on some species.
- A positive (and emerging) effect that may reduce vulnerability is that many European governments (and individual cities) have become aware of the need to adapt to climate change and so are developing and/or implementing adaptation strategies and measures.

Additional risks have emerged from the assessed literature:

- Increased summer energy demand, especially in southern Europe, requires additional power generation capacity, which will be under-utilised during the rest of the year, entailing higher supply costs.
- Housing will be affected, with increased overheating under no adaptation and damage from subsidence and flooding. Passive cooling measures alone are unlikely to be sufficient to address adaptation in all regions and types of buildings. Retrofitting current housing stock will be expensive.
- An emerging concern is the vulnerability of cultural heritage, including monuments/buildings and cultural landscapes. Some cultural landscapes will disappear. Grape production is highly sensitive to climate, but production (of grape varieties) is strongly culturally-dependent and adaptation is potentially limited by the regulatory context.
- Good evidence that climate change will increase distribution and seasonal activity of pests and diseases. Limited evidence that such effects already occurring. Increased threats to plant and animal health. Public policies are in place to reduce pesticide use in agriculture use and antibiotics in livestock, and this will increase vulnerability to the impact of climate change on agriculture and livestock production.
- Lack of institutional frameworks is a major barrier to adaptation governance. In particularly, the systematic failure in land use planning policy to account for climate change.

[INSERT TABLE 23-5 HERE
Table 23-5: Key risks from climate change in Europe and the potential for reducing risk through mitigation and adaptation. Risk levels are presented in three timeframes: the present, near-term (2030-2040), and longer-term (2080-2100). For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state. For a given key risk, change in risk level through time and across magnitudes of climate change is illustrated, but because the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks, sectors, or regions. Key risks were identified based on assessment of the literature and expert judgment.]

23.9.2. Climate Change Impacts Outside Europe and Inter-Regional Implications
